As you have taken your seat within it
So, today you are everywhere
In the blueness of sky
In the greeness of earth

—Rabindra Nath Tagore

Foreword

Textbook of Anaesthesia for Postgraduates is a very comprehensive textbook for all postgraduate students, as well as for fresh anaesthesiologists who have just stepped into the vast world of clinical practice of anaesthesia. This book includes many basic facts of the subject which are often omitted or considered unimportant in other books. In every chapter the reference to the historical aspect makes this book even more interesting. The language of this book is very subtle, smooth and easy for all readers. The author, a young and eminent anaesthetist with tremendous clinical experience has tried his best to explain the subject by putting himself in the shoes of the fellow students. He has also tried to conglomerate the aspect of anatomy, physiology, pathology, pharmacology, medicine and surgery related to the text in each chapter to make this book a thorough and complete one and I am sure it will help all the concerned greatly.

Foreword

This book is written by a young anaesthetist who works hard in different super specialist hospital in Kolkata and in 200 beds Disha Eye Hospitals which is a super specialist ophthalmic institution, serving the whole Eastern Zone of India. I have gone through all the pages of this book and think it will be a very helpful to all the postgraduate students and even the budding anaesthesiologist who have just completed the postgraduate course. This is because it contents many necessary chapters which are written very elaborately and in much lucid language. Each chapter of this book covers the preclinical and clinical aspect of it. So, it will cause the students to avoid the reading of many preclinical and clinical books to pass the examination and to face the viva. It will help the students to participate in quiz competition also.

Still I think there are many lacks in this book which will be removed in subsequent edition by adding more chapters.

Foreword

When Dr Agasti asked me to write the foreword for his book on *Textbook of Anaesthesia for Postgraduates*, I was definitely taken aback. I did see him obsessively writing notes between intervals in the hospital and even at home. But that it would cumulate into a book of anaesthesiology is something, I could not conceive. I am an Ophthalmic Surgeon for the last 25 years who enjoys ophthalmology without knowing a word of ophthalmic anaesthesia and that is courtesy Dr TK Agasti. He is our anaesthetist from my very initial days of practice. I tried to understand why he picked a novice like me to write the foreword for his book but when I went through the book, I assimilated the fundamentals and also the core of the subject, anaesthesia. As colleagues, we always shared that anaesthesia was not to eliminate pain for the patient during a surgery. It was about taking their fear away and reassuring them of the procedure they were undergoing.

In ophthalmic surgery you can loose or fight to save an eye but you cannot loose a patient. Dr TK Agasti has been doing this for us over years. His meticulous pre-operative assessment and his wonderful inclination towards safety during and after surgery has made us so relaxed as surgeons. I understand it has aptly reflected in his writing. He would work with a patient pre-operatively then struggle during anaesthesia.

He hails from a small town in East Midnapore where he has been groomed by his affluent family to serve patients rather than to take medicine as a career. The book reflects this. It is not aimed to dish out student popular stuff and get a good sale but brings out the flavour of anaesthesia which is safety and relaxation of the patient and their family to the procedure through meticulous service towards them.

I wish him and his book the very best.

Preface

The anaesthesiology is a subject which is mainly studied at the postgraduate level, after passing MBBS, without giving much emphasis during the undergraduate course. But, this interesting branch of medical science involves the knowledge of all preclinical and clinical subjects just like the branch of medicine of medical science. When this knowledge is incorporated with some special knowledge of patient's condition during trauma, pain, severe medical illness, surgery and anaesthesia, then a new subject called anaesthesiology is evolved.

Just like specialising on the subject of medicine, the specialisation in this subject of anaesthesiology also does not involve a single organ such as skin, eye, heart, etc. or a single system such as gastrointestinal system, nervous system, etc. Moreover, this subject of anaesthesiology links many disease processes with surgery and handles many cardiotoxic drugs which are not used by the specialists of other disciplines of medical science. It also involves multiple sophisticated and complicated machines and equipments for the delivery of anaesthesia, monitoring of patients during surgery and also during recovery of already very sick patients which cannot be imagined in other subject of medicines.

Moreover, this subject of anaesthesiology is very vast. It is linked with all the disciplines of medical science and also infiltrates the other specialities like critical care, trauma, pain management, intensive care, etc. This branch of medical science has also changed drastically during the last few years in terms of technology, for maximum safety of patients. All these lead to extreme work load, necessity of advanced knowledge and intense responsibilities of anaesthesiologist.

There are many books which helps the students during the study of postgraduate course in anaesthesiology. But still the students are required to take the help of many preclinical and clinical books of anatomy, physiology, pharmacology, medicine, etc. for meticulous understanding. So referring to too many books confuses the students causing irritation and even helplessness. Hence, in this book an earnest attempt has been made to fill all the gaps so that students do not have to go through other preclinical and clinical books.

There is no end to knowledge. So as the provider of knowledge, no book can be complete. If an author shift towards the more completeness of a book, then its volume increase tremendously which may also be irritating and troublesome to many students. So, there should be a compromise between the information provided and the volume of book. Every new book gives some new information and I have tried my level best to collect all these information in my book which helps the students without going through many books, I think.

Many chapters are also lacking in this edition of my book which I commit to provide in the subsequent editions. So, I am regretful to my readers. I think there are many mistakes in this first edition of my book which is very obvious. For this I also apologise to my readers. I make an earnest appeal to all my readers to communicate with me regarding any mistake in my book and/or suggestions, if they have any.

At the end there is nothing more to write. So, thanking all, I start my first voyage towards the deep and vast ocean of knowledge of all readers of my book.

TK Agasti

Acknowledgements

I am extremely grateful to all my colleagues who consistently inspired me to write a book which will cover the anatomy, physiology, pharmacology, medicine and historical aspects of all the chapters which are lacking in most of the commonly read books. I am greatly indebted to by wife Dr B Agasti who consistently inspired me to write a book which is get rid of complex scientific experiments and their inferences that make the students very tired and confused. I am paying my sincere and boundless thank to Dr Debasish Bhattacharya, Director of Disha Eye Hospitals at Barrackpore, Kolkata, West Bengal, India for being my friend, philosopher and guide. I will also take the opportunity to thank to Dr S Basak a world famous ophthalmologist for being my inspiration.

Dr SM Basu and Dr Anupam Goswami has taken the pains of thoroughly reading this book and have given the foreword. So, I extend my sincere gratitude to them. Finally, I am grateful to all my patients who had submitted themselves for anaesthesia and permitted me to learn the subject of anaesthesiology. At last, I am also very grateful to M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi for publishing this book in a very presentable manner in a very short time.

Contents

1 Anaesthetic Machine

INTRODUCTION

The Boyle's anaesthetic machine is a continuous flow type of equipment which is used for administration of inhalational anaesthesia and artificial ventilation. It receives gas supply from gas supply unit consisting of cylinders or pipelines, controls this flow of gas to the flow metre, reduces their pressure to the desired safe level, vapourises the volatile anaesthetic agents and finally delivers the gas mixture to a breathing circuit.It was introduced first by HEG Boyle in 1917. After that it was modified at different times which is discussed in 'Inhalational anaesthesia' chapter. Now, it has become more modernised and sophisticated by attaching ventilators, O_2 failure alarm, hypoxic guard, gas analysing component, different monitors measuring vital parameters of body, electronic sophisticated vapouriser, etc. Now the Boyel's anaesthetic machine have become made extremely sophisticated by incorporating many built in safety features and devices and one or more microprocessors that can integrate, enhance and monitor all the components of the machine. These microprocessors now also provide option for sophisticated ventilator modes, automated record keeping and net working with local or remote computer monitors and as well as with hospital information system. So, it is now called as the anaesthetic work station. Due to this extreme sophistication lots of adverse outcome are now coming infront related to the malfunction of machine. This mainly because of the nonfamiliarity of an anaesthetic machine or work station with the anaesthetist. So this preventable adverse outcome resulting many mishaps can easily be avoided by increasing the familiarity of machine with the anaesthetist through proper education and proper checking the function of machine previously (Fact file-I).

A modern anaestheic machine consists of the following basic components. There are: (i) gas supplying unit such as pipeline or cylinders, (ii) pressure gauges, (iii) reducing valves or pressure regulators, (iv) flow meters, (v) vapouriser, (vi) ventilators, (vii) circle breathing system, (viii) common gas outlet, (ix) monitors, and (x) miscellaneous such as emergency O_2 flush, nonreturn pressure relief valve, O_2 supply failure alarm, hypoxic guard, suction apparatus, etc. (Fact file-II).

GAS SUPPLY UNIT

Pipeline

Now, in a big hospital or nursing home the supply of gases such as O_2, N_2O, compressed air, etc, through pipelines to the anaesthetic machine situated at different OT, or ventilators in ICU, ward, etc, from a central source is a common feautre. The advantages of sypplying gases through these pipelines from a central source are that it is easy, convenience, economic

FACT FILE- I

Safety features of modern anaesthetic machine

The safety features of modern anaesthetic machine are:

1. Noninterchangeable screw thread (NIST) system for connection of colour coded hose to machine from pipeline for central gas supply system and pin index system for cylinders.
2. Colour coded pressure gauge.
3. When O_2 pressure will be low, the supply of N_2O to patient will be cut off.
4. O_2 and N_2O ratio monitor and controller, called hypoxic guard.
5. Colour coded flow meters.
6. O_2 will be the last gas to be added to the mixture, i.e the flow metre for O_2 should be at the right most position.
7. Inspired O_2 concentration (FiO_2) monitor or analyser.
8. Oxygen supply failure alarm.
9. Alarm during disconnection of ventilator.
10. The anaesthetic machine using central gas pipeline should have atleast one O_2 cylinder in reserve.

FACT FILE - II

The components of an anaesthetic work station are:

1. Provision of secondary source for supply of gases in the event of failure of primary source.
2. Provosion of safe delivery of anaesthetic gases and vapours.
3. Provision for inbuilt breathing system with circle circuit.
4. Provision for any respiratory support of patient by sophisticated automatic ventilators with full range of patient's need.
5. Provision for monitoring the full range of patient's physiological parameters with display.
6. Provision for monitoring the full range of function and settings of all the components of machine with audio and visual alarm.
7. Provision for automatic record keeping.
8. Provision for online access to information for expert decision.
9. Provision for appropriate connection to an anaesthetic gas scavenging system.
10. Provision for suction vacum system with regulator.
11. Provision for auxilliary O_2 flow metre with suplemental O_2 supply.
12. Storage facility for items of everyday use.

and avoid frequent changing of cylinders. There is also less chance of explosion and increased patient's safety. But the high initial cost is the only disadvantages of it. The pipeline system for delivery of gases consist of (i) a central supplying unit using tank, or concentrator or cylinders for O_2, only cylinders for N_2O and cylinders or compressor for compressed air, and (ii) distributing pipelines with their outlet located at the point of use. The supplying pipeline is made up of high quality copper alloy which prevents the decomposition of gases and has bacteriostatic property. The usual pressure of gases kept in pipeline is about 400KPa. The size of the pipeline differs according to the demand. The pipes of 42 mm of diameter are usually used for leaving the central supply unit and the smaller diameter tubes of 15 mm are used after repeated branching. They also have specific colour code according to the gas they carry (Fig. 1.1).

The network of central pipelines ultimately terminate in the OT, ICV and/or ward at their outlet which is mounted on the wall or suspended from the ceiling. These outlets of pipeline at the point of use is easily identified by their specific colour code, shape and the name of gas stamped on them. They accept the matched and quick connect / disconnect 'Schrader' probe of a flexible colour coded hoses which ultimately connect the outlet of central pipeline to the anaesthetic machine. The anaesthetic machine end of these hoses may be connected with the machine permanently by screw and thread system where the thread is gas specific and not interchangeable, known as non-interchangeable screw threat (NIST) system, or through the ususal yoke assembly with pin index system located on the metal yoke bar of anaesthetic machine where the cylinders are usually attached. The previously described non interchangeable screw and thread system of connection which attaches the hosepipe with the pipeline outlet and the anaesthetic machine is also known as the diameter index safety system (DISS) where a hose of a particular diameter can only be connected to the machine. But the disadvantage in this system is that there is delay in connection with this system. So, the quick connect / disconnect 'Schrader' couplers are preferred. Where its other end is connected to the machine through pin index system (Fig. 1.2).

At the central gas suppling room from where the pipelines are distributed there should have a low pressure alarm which will detect the failure of supply of gas through pipeline. A reserve bank of cylinders should be available if primary supply through pipeline fails. An anaesthetist is only responsible for the supply of gas from the terminal outlet of pipeline to the anaesthetic machine, while only engineering department will be responsible for gas pipelines behind the wall. There is also risk of rupture or fire in pipeline carrying O_2 gas under high pressure from central source to machine due to worm out or damage of it. So for maintenance and to avoid any mishap the pipelines should be tested from time to time according to the guidelines laid by the international or national committee such as tug test to detect wrong connection, single hose test to detect cross connection, etc. (Fig. 1.3).

The central sources of gases which are distributed by the pipeline may be a storaged tank or cylinder manifold or O_2 concentrator for O_2, only cylinder manifold for N_2O and cylinder manifold or compressor machine for compressed air. In the oxygen storage tank the O_2 is stored as liquid between –160° and –170°C temperature at pressure of 5 to 10 atmosphere. Actually, the O_2 storage tank acts as huge thermo flask which is made up of double layer steel with vacuum between them. The innersides of these two steel layers is lined by a chemical, named perlite. The vacuum between these two steel layers acts as an insulator and maintain the temperature of inside of the tank. During the use of tank the evaporation of liquid O_2 requires heat which is known as the latent heat of evaporation and it is taken from the remaining liquid O_2. Thus it helps to maintain such low temperature of the remaining liquid portion of O_2 inside the tank. By a coiled copper tubing the cold O_2 gas which comes out from tank is warmed for use.

Fig. 1.1: Wall mounted outlet of the central oxygen pipeline

Fig. 1.2: Flexible colour coded Schrader probe

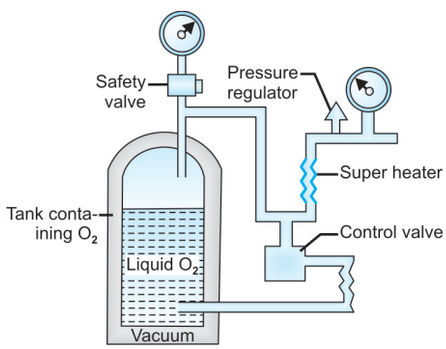

Fig. 1.3: The schematic diagram of O_2 tank

Then a pressure regulator allows the gas to enter the pipelines with pressure at 400 KPa. There is a safety valve on the tank which allows the gas to escape in emergency when excessive pressure builds up inside the tank during no use or under demand use of O_2. During excessive use of O_2 the control valve which is usually kept closed is opened and it allows the liquid O_2 to pass through an uninsulated coils of copper tube. During passage of liquid O_2 through this uninsulated copper tube, it evaporates within the tube and can supply more gas. The storaged O_2 tank usually rests on a weighing balance. It measures the mass of liquid O_2 in tank and thus gives an idea of the total contents of it. A differential pressure gauge is also used which measures the difference of pressure between the liquid O_2 at the bottom and the gaseous O_2 at the top of the tank and gives an idea of the total contents of a tank. This is because as the liquid O_2 evaporates, its mass and pressure at bottom decreases, so by measuring this difference in pressure between the bottom and the top the actual contents of the tank is calculated. At one atmospheric pressure and 15°C temperature 1 litre liquid O_2 gives 842 litres of gaseous O_2. When the supplying tanks of hospital become empty then liquid O_2 is pumped in the tank from an outside O_2 tanker by a cryogenic hose assembly. During this process of filling the spillage of cryogenic liquid O_2 on the handling person can cause frost bite, cold burns, and hypothermia. Reserve bank of cylinders should always be kept ready when O_2 is used from a storage tank particularly in case of sudden accidental failure. The O_2 tank should always be housed away from the main hospital building due to fire hazard (Fig. 1.4).

Other than storaged tank, manifold system is also used in a small hospital or nursing home as a central source of supply of O_2, N_2O, and compressed air. In this system large bulk cylinders (Type E) are used and divided into two groups which

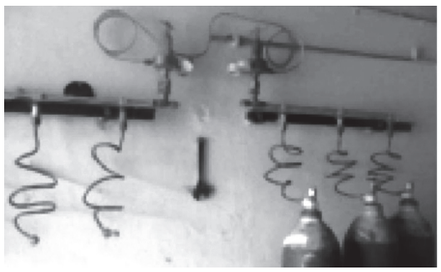

Fig. 1.4: Cylinder manifold

alternately supply gases in the pipe line. The number and size of cylinders in each group depends on the expected demand of gas used by the hospital. All the cylinders of each group are connected to a common pipe line through a nonreturn valve and a pressure gauge. This common pipeline from each group then in turn is connected with the distributing pipeline system through a check valve and a pressure regulator. In each group all the cylinders are opend at the same time and allows them to empty simultaneously. When all the cylinders of one group become empty, then the manifold system allows the supply to change over automatically to another group of cylinders. This change over is achieved through a pressure sensitive automatic device that also activates an electric audio signal to alert staff. At the same time the exhausted group of cylinders are turned off automatically. All the exhausted cylinders of previous group are then replaced by fresh full cylinders immediately. The manifold system for the supply of N_2O gas may cool to very low temperature due to the latent heat of vapourisation. So, the water vapour of atmosphere may condense or even freeze on the outer surface of the pipeline. This can block also the pipeline and the flow of N_2O if it contains some water vapour which is freezed inside the pipe line at this very low temperature. So, a thermostatically controlled heater may be needed at the outlet of N_2O manifold system to warm the gas at 47°C which prevents the condensation of water vapour within the gas of pipeline and allow uninterrupted flow of it. Like the O_2 tank this manifold system for central supply of O_2, N_2O and compressed air should also be housed in a well spaced and ventilated room which is constructed by fire proof tiles. This room should be located away from the main hospital building and on the ground floor for the easy access of transport trucks. This room which is used to store tank or manifold system of cylinders should not be used as the general store room for the other empty and full cylinders which are not in use. So, all the empty cylinders should be removed immediately after exhausted. The motor driven compressor for the central supply of air and the O_2 concentrator for the central supply of O_2 and the central vacuum plant should also be located there. The central vacuum pipeline should be provided with colour code, separate pressure gauge and high and low pressure signal device.

The compressed, oil free medical air which is cleaned by filters is also supplied in hospital through pipelines to run many power driven tools in ICU and OT and for other clinical use at pressure of 400 KPa. They may be supplied from manifold system consisting of large cylinders containing compressed air or more economically by a motor dirven compressor. The anaesthetic machines and the blender of most intensive care ventilators accept the connection from the 400 KPa outlet of compressed air pipeline.

The O_2 concentrator is a device which extract O_2 from air by differential absorption method and supply it. They become a small one which is designed to supply O_2 only for a single anaesthetic machine or a single ventilator. Otherwise it can be large enough to supply adequate O_2 through pipeline system. The small O_2 concentrators are of light weight, portable and can be used at remote location or for domestic purpose. In this O_2 concentrator machine there is a compressor which first filter air from atmosphere and then compressed it. After that this compressed air is exposed to multiple columns of zeolite (hydrated

aluminium silicate of alkaline earth metal) molecular sieve at a certain pressure which retain N_2 and other unwanted components of air except the O_2 and argon. Hence the argon cannot be separated from the concentrated O_2 produced by this type of machine. Thus maximum concentration of O_2 by 95% in volume is achieved. The columns of zeolite molecular sieve in O_2 concentrator which absorb N_2 and other gases releases them again in atmosphere when it is heated and vacuum is applied. This O_2 concentrator can be used in vast majority of cases, but not in circle system. This is because in this system its use leads to gradual accumulation of argon. However this can be avoided only by high gas flow. The main disadvantage of O_2 concentrator is its high initial cost which can be recovered easily later by free O_2 supply. The other disadvantages of it are risk of fire, contamination of zeolite sieve and sometimes malfunction.

Cylinder

Boyle's anaesthetic machine is equipped with O_2 and N_2O gas cylinder which are used when there is no provision for pipeline supply of gases or during emergency when the pipeline supply of gases have failed. These gas cylinders are made up of light weight seamless molybdenum steel designed to withstand intense internal pressure when gases are stored in gaseous (O_2) or liquid form (N_2O) under high pressure. The cylinders which are used in MRI suit are made up of aluminium, However the very large bulk cylinders are made of manganese steel. Very light weight cylinders of O_2 also can be made from aluminium alloy with fibre glass covering by epoxy resin matrix. These are used for domestic or transport purposes in ambulance or mountaineering purposes (Fig. 1.5).

The cylinders supplying gases are identified by their specific colour code, labelling stamped on their shoulder and plastic or paper collar. In the past different countries use different colour for their cylinders

Fig. 1.5: Shoulder of cylinder with engraved marking

containing different gases and there was no pin index system. So, with time when this colour is lost and the level is indistinguishable, then any interchange of N_2O and O_2 cylinder during attachment to the anaesthetic machine can lead to mortality. So an international standard which is given in table was laid out regarding the colour code and pin index (discussed later) by which the cylinders can easily be identified and cannot be interchanged when they are attached to the anaesthetic machine (i.e. it is practically impossible to attach any cylinder to wrong yokes). There are two international standard of colour code according to the school of UK and USA. However, in India UK standard is followed (Table 1.1).

The cylinders are also manufactured in different sizes which are usually named by alphabet from A to L. Among these the size A is the smallest and size L is the largest. The smallest sized A cylinder can hold 1.2 L of water and the largest sized L cylinder can hold 50L of water. Among these the A and H size cylinders are not used for medical purposes. The cylinders which are attached with the anaesthetic machine are usually of D and E size and the cylinders of size J are commonly used for cylinder manifold system for central supply. The O_2 and N_2O cylinder of size D contains 400 L of O_2 and 940 L of N_2O respectively. Whereas the O_2 and N_2O cylinder of size E contain 680 L and 1800 L of O_2 and N_2O respectively. A full O_2 cylinder of any size at atmospheric pressure can deliver O_2 which is 130 times of its original capacity.

The O_2 is stored in a cylinder as a gas at a pressure of 1900 psi and N_2O is stored in a cylinder as a liquid at a pressure of 750 psi. So, the cylinder which contain a gas in the form of liquid such as in N_2O and CO_2 is partially filled. Hence, this amount of partial filling of cylinder is described as the filling ratio and is defined as the weight of fluid in a cylinder divided by the weight of water required to fill the cylinder. The cylinders containing gases in liquid form are not filled up fully. This is because the partial filling of cylinders with liquid such as in the case of N_2O and CO_2 reduces the risk of explosion due to the sudden dangerous increase in pressure within the cylinder sudden increase in evaporation of liquid gas during sudden increase in temperature of atmosphere. So, in cold country such as in UK the filling ratio in N_2O and CO_2 cylinder is kept at 0.75, whereas in hot countries the filling ratio of these two types of cylinders is kept at 0.67.

Only a gas containing cylinder during its emptying at constant temperature shows a linear and proportional decrease in cylinder pressure. But this does not happen in case of cylinder which are filled with gas as liquid such as N_2O and CO_2. Here, initially the pressure in side the cylinder remains constant, because more gas is produced by

Table 1.1: Colour coding of medical gas cylinders

Name of gas	*Colour of body*	*Colour of shoulder*	*Physical state in cylinder*
N_2O	Blue	Blue	Liquid / gas
O_2	Black (UK) Green (USA)	White (UK) Green (USA)	Gas
CO_2	Gray	Gray	Liquid / gas
Air	Gray (UK), Yellow (USA)	White (UK) Black quarter (UK) Yellow (USA)	Gas

evaporation from liquid to replace the gas that is used. After that once when all the liquid has been evaporated to gaseous state, then the pressure in the cylinder starts to decrease with the process of emptying. So, the O_2 pressure gauge shows continuously the contents of a cylinder which is proportional to the gauge pressure and the N_2O pressure gauge does not show the actual content of the cylinder. The N_2O pressure gauge shows a constant pressure of N_2O gas which is present above the liquid and till the later is completely depleted. Then the pressure in the gauge starts to drop. So, the N_2O pressure gauge does not show the actual contents of its cylinder till the whole liquid is completely evaporated to gas. During the emptying of such cylinder containing gas as liquid, the temperature of it also decreases. This is because of the withdrawn of latent heat for vapourisation of liquid within the cylinder from the outside atmosphere, leading to the formation of ice on the outside of the cylinder. As the pressure gauge of N_2O cylinder can not tell the total content of it, so a full N_2O cylinder can only be identified by comparing the weight of it with that of an empty one, or in other way a full cylinder will give a ringing sound when tap by a metal while a empty will give a dull thud sound.

The cylinders are tested following manufacture at regular intervals, usually 5 years, by:

i. visual inspection from outside or inside (endoscopic),
ii. tensile test where strips of a cylinder are cut longitudinally and stretched till they elongate with yield point not being less than 15 tons/sq inch,
iii. flattening test where one cylinder is kept in between two compression blocks and pressure is applied to flatten it till the distance of these two blocks becomes 6 times of the thickness of the cylinder wall without crack,
iv. bend test where a strip of 25 mm width is cut from the cylinder wall and equally divided into 4 strips which are then bend inwards till the inner edge is apart proving cylinder wall will not develop any crack,
v. impact test where three longitudinal and three transverse strips are cut from a cylinder wall and struck by mechanical hammer with mean energy needed to produce a crack it should not be less than 5 ft lb for transverse strip and 10 ft lb for longitudinal strip,
vi. pressure or hydraulic or water jacket test where the cylinder is subjected to high pressure which is more than 50% of their normal working pressure without damage. All these test are usually done for at least one out of every 100 cylinders. The gases and vapours should be free of water vapour when stored in cylinders. Becasue water vapour may freeze and block the exit port of cylinder when the temperature of cylinder valve decreases tremendously on opening. All the cylinder after filled with gas should be stored in a dry, well ventilated, fire proof room and not subjected to extremes of heat. They should not be stored near flammable materials like grease or oil, etc., or near any source of direct heat or fire (Fig. 1.6).

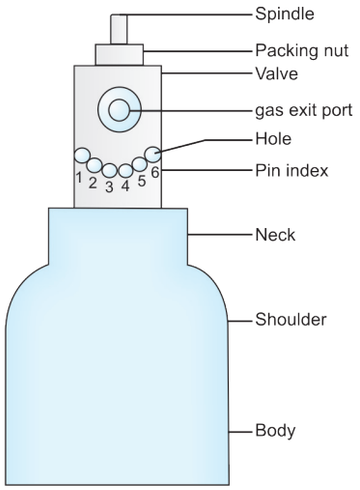

Fig. 1.6: The different parts of a cylinder and different combination of pin index.Gas exit port accommodates the yoke nipple and the hole accommodate the pine of pin index system

A cylinder has four parts such as body, shoulder, neck and valve. The size of the body of a cylinder varies according to the designations which are named as A to L and is painted according to the colour code. The upper part of the cylinder which is called as the shoulder suddenly becomes narrow. This is called as the neck. The shoulder and the neck of a cylinder is also painted according to the colour code which may be the same with the body or not. The neck ends in a tapered screw thread into which the valve of a cylinder is fitted. This thread between the neck and the valve of a cylinder is sealed by a special material which melts if the cylinder is exposed to excessive heat suddenly, and allows the contents of a cylinder to escape avoiding the risk of explosion. There is a plastic disc around the neck whose colour and shape indicates the year when the cylinder was last examined. The marks engraved on the shoulder of a cylinder are: date of last test performed, test pressure, chemical formula of the contents of this cylinder and tare weight (weight of empty cylinder). Every cylinder should also have a paper lebel which is sticked on the body or will hang from the neck. This will show: cylinder size code, specification of contents (which include name, chemical symbol, pharmaceutical form, proportion of gases in a gas mixture), batch number, maximum cylinder pressure in bars, nominal cylinder contents in litre, filling and expiry date, direction of use, hazard and safety instruction, storage and handling precaution, etc. (Fig. 1.7).

At the top every cylinder is fitted with a valve which is known as the cylinder valve. Several types of cylinder valves like flush type, bull nosed, straight type, angle type, etc., are available. But the noninterchangeable flush type of valve with pin index system which is commonly used to attach a cylinder at the yoke bar of anaesthetic machine will be discussed here. It is screwed into the neck of a cylinder via a threaded connection which is sealed by a special material with

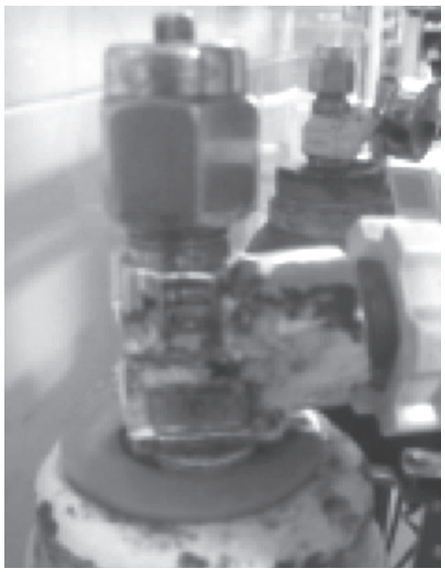

Fig. 1.7: Bull nose type of cylinder valve.

low melting point. This cylinder valve is made of brass and plated with chromium or nickel which allow the rapid dissipation of heat, if generated due to compression during filling (Fig. 1.8A).

The chemical formula of gas by which the cylinder is filled up is engraved on its valve. The valve seals the contents of a cylinder and is used to start, regulate and stop the flow of gas from the cylinder by a spindle which is described below. On the top of the cylinder valve there is an on/off stem or spindle with packing nut. When this stem is turned with a spanner, then it allows the gas to flow through its outlet situated on the valve. In modern modification the top of the valve is so designed that the on and off of the cylinder can be done by manual turning of the stem or spindle with the packing nut without the need of a spanner. There is an outlet hole and another two holes below the previous one at one side of the cylinder valve which fits with the yoke assembly of Boyle's machine through a specific noninterchangeable pin index system consisting of a nipple and two pins. A compressible yoke sealing washer named Bodok seal should be placed between the anaesthetic machine and the cylinder valve to make a gas tight joint when the cylinder is connected to the machine at the yoke assembly. Corresponding to the two pins of the pin index system, there is also two holes on the same side of cylinder value below the outlet port. If the yoke nipple is damaged or the pins of yoke assembly and the holes of cylinder valve are not aligned properly (i.e. pin index of a particular cylinder valve does not match with the yoke assembly), then the gas exit port of the cylinder valve will not seal tightly against the Bodok washer and the gas will leak. The Bodok washer is made of carbon impregnated rubber with a metal ring around it. It is 2.4 mm thick and only one seal is allowed inbetween the cylinder valve and the yoke assembly to fit the cylinder without leak. The excessive tightening of the screw of yoke assembly to press the cylinder valve against this seal may also damage it (Fig. 1.8B).

Fig. 1.8A: CO_2 cylinder with flush type cylinder valve

The cylinder valves are usually wrapped by a plastic covering after filling to protect it from anything which can enter the exit port and block it. The valve should be slightly opened and then closed before connecting the cylinder with the anaesthetic machine. This procedure usually cleans dust, oil, and grease from the exit port which would otherwise enter the anaesthetic machine and may damage it.

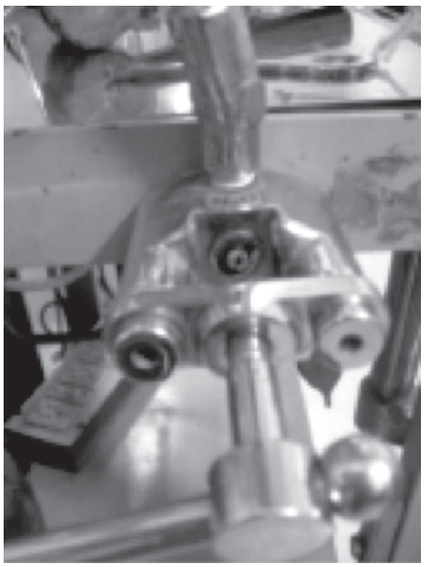

Fig. 1.8B: Pin index system (Yoke assemble)

The cylinder valve should be turned on slowly during use when attached to the anaesthetic machine. Because it prevents the sudden rise in pressure and temperature of gas while flowing through in the machine's pipe line. During closure of cylinder, overtightening of valve should also be avoided. Because it may damage the seal between the valve and the neck of a cylinder (Fact file- III).

Bourdon Pressure Gauge (Fig. 1.9)

It is attached with the anaesthetic machine to measure the pressure of gas with in the cylinder such as O_2, N_2O, and compressed air, or pipe lines after connecting with the anaesthetic machine. However, one which is designed to measure the pressure of cylinder should not be used for pipeline and vice versa. Because it may lead to inaccurate result and can cause damage to the pressure gauge. Inside this type of pressure gauge there is a robust, but flexible coiled tube made of copper alloy. It is closed at its inner end and is connected through a lever to a needle pointer which moves over a dial indicating pressure. The other end of this coiled tube is opened to a gas supply line coming from cylinder or pipeline (Fig. 1.10A).

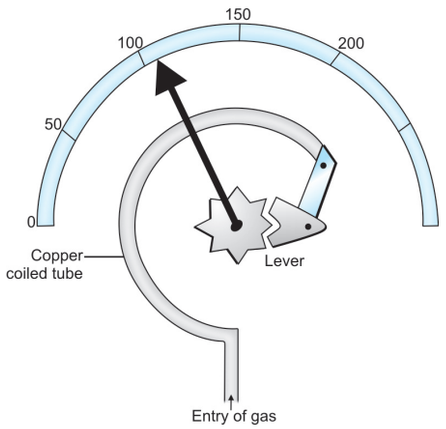

Fig. 1.10B: The mechanism of action of Bourdon pressure gauge

FACT FILE- III

Machine inlets

Most anaesthetic machines have three separate inlets each for O_2, N_2O and air. Some machines also have a 4th inlet for CO_2, helium or Heliox. However, the compact models of machine lack the air inlet. These inlets of machine which are connected with the pipelines are separated from the inlet of machine which are connected with the cylinder. So the machines have separate pressure gauges at pipelines inlet and cylinder inlet to measure their respective pressure. However, there are many machines which (we commonly use in our country) have no separate inlets for the pipeline and cylinder and the pipeline supply is attached at the inlet of machine where the cylinders are attached. In the machines where there is separate inlet for pipeline (and cylinder), a colour coded hose pipe is used to connect the outlet of pipeline to the anaesthetic machine through a noninterchangeable DISS that prevents incorrect hose attachment. At this connection a filter is attached which helps to filter the gas and a one way check valve is attached which prevents the retrograde flow of gas in the pipeline. At the cylinder inlet of machine the cylindrs are attached to the machine through a yoke assembly that utilises PISS (pin index safety system)to prevent wrong connection of cylinders. The yoke assembly includes PISS, a washer, a gas filter and a check valve that prevents retrograde gas flow. In some machines there have an extra O_2 or air inlet which is used to drive the ventilator.

After turning on the valve and opening the cylinder the gas under high pressure first starts to flow into this colied copper tube of pressure gauge and causes it to uncoil or straight out. Then this movement of the tube during uncoiling causes the needle pointer to move on dial and indicates pressure of gas inside the cylinder or pipeline. Each pressure gauge is calibrated for a particular gas, colour coded and bears the name and symbol of gas for which types of gas cylinder or pipeline it is used. At the front, every pressure gauge is protected by a cover of heavy fibre glass. So, in case of any breakage of coiled copper tube, the gas escape from behind, rather than the front. The measured pressure in the pressure gauge is depicted in unit such as KPa or lbs/sq.inch or Kg/sq.cm. When the central pipeline for O_2 supply is connected to the anaesthetic machine, then the pressure gauge at the connection shows 4 bars or 60 psi pressure (Fig. 1.10B).

Reducing Valve or Pressure Regulator

The gases are usually presented to anaesthetic machine under different high pressure from different types of cylinders or pipelines. So, they are passed through a single or multiple reducing valves which are placed between the cylinder or pipelines and the rest of the components of anaesthetic machine to decrease their high variable pressure to a safe constant operating pressure before reaching the gas to flow metre. Otherwise in the absence of these valves when the pressure of a cylinder decreases with use, then in order to maintain the supply of gas to patient at a constant flow and pressure, continuous adjustment of flow metre is required. These reducing valves also allow a delicate control of gas flow through flowmetre and protect the different sophisticated component of anaesthetic machine against the sudden surges of high pressure of gases (Fig. 1.11).

In this type of pressure regulator or reducing valve there are two chambers such as a high pressure chamber and a low pressure chamber, connected through a gap which is guarded by a valve. The high pressure chamber gets its gas flow through its inlet directly from cylinder. The small valve intervening between the high and low pressure chamber is attached to a diaphragm

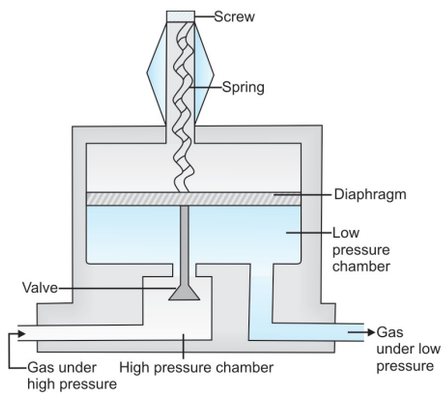

Fig. 1.11: The mechanism of action of reducing valve

which is again attached to a spring through which the pressure regulator can be adjusted to get the supply of gas flow at a constant low pressure. After entering the gas into the high pressure chamber directly from cylinder the force exerted by the gas under high pressure tries to close the gap by the small valve and decrease the gas flow to low pressure chamber from high pressure chamber. On the other hand, the opposite opening force exerted by the spring and diaphragm tries to open the valve. Then a balance is reached between these to forces leading to a constant fixed opening or gap which leads to a constant flow of gas under fixed desired pressure to low pressure chamber from high pressure chamber and ultimately passes out (Fig. 1.12).

If the gas in cylinder contains water vapour, then when the gas with water vapour enter the low pressure chamber from high pressure chamber, then due to loss of heat due to expansion of gas in low pressure chamber, there is chance of ice formation inside the regulator causing malfunctioning of it. There is also the chance of rupture of diaphragm leading to mulfunctioning of it. So, these regulators should be serviced at regular intervals and the rubber diaphragm is checked and renewed. The control of high pressure in pipeline is also achieved by a flow restrictor (a separate type of device which control the flow of gas) and a second stage pressure regulator. If there is only flow restrictor and no pressure regulator for pipeline, then when there is some change in pipeline pressure, the flow metre should be adjusted accordingly. A one way valve is also placed within the cylinder supply line within the anaesthetic machine next to the inlet of yoke. Their function is to prevent the back flow and loss or leakage of gas through an empty yoke (if a cylinder is not connected there) from working cylinder. They also prevent the transfilling of gas when one cylinder is full and working and the other cylinder is empty. Recently this one way valve is incorporated with in the design of a pressure regulating or reducing valve.

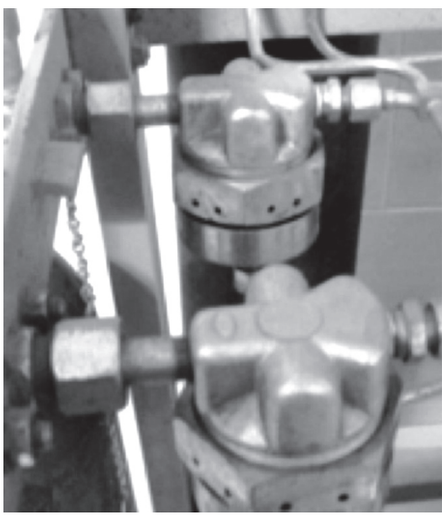

Fig. 1.12: Reducing valve

This type of reducing valve is also called the preset pressure regulator, because by adjusting the screw before hand during manufacturing we can adjust the diaphragm and subsequently the valve which is situated between the high and low pressure chamber. Thus we will be able to keep a fixed low pressure in low pressure chamber from which the gas will be delivered continuously at low pressure to the flow meter. In India BOC uses the preset regulator or reducing valve which are set to deliver gases at constant low pressure of 60 lbs/sq.inch by adjusting the screw and thus subsequently adjusting the inside diaphragm and valve of regulator. There is another type of preset pressure regulator which is called the Adam's valve. These are used in many anaesthetic machines (Fact file - IV).

Pressure regulators are so adjusted that the anaesthetic machine uses both the gas from pipelines when the pipeline pressure is 50 psi or greater and cylinder valve is also simultaneously open. So, when the gases from pipeline are being used, the cylinder valve should be closed. This is because the machine will always use gas from the source that has higher pressure. But, sometimes if the pipeline pressure drops below that supplied by cylinder and its valve is open, then some gas will be withdrawn from the cylinder. Thus gradually the cylinder will be exhausted without the knowledge of anaesthetist and then it will not help during emergency.

FACT FILE- IV

After passing through the Bourdon pressure gauge and check valve the gases from pipeline and cylinder passes through a common pathway to the flowmetre. The pressure regulator situated on the cylinder supply line are so adjusted that in this common pathway the gas pressure coming from the cylinder is always lower than the gas pressure coming from the pipeline. So, it allows the machine to use preferentially the gas from pipeline, still if the cylinder is left open (unless the pipeline pressure drops below the gas line pressure coming from cylinder attached with machine). A high pressure relief valve is also sometimes provided in some machines distal to pressure regulator. It sets open when the supply pressure from cylinder or pipeline exceeds the machine's maximum safety limit in case of failure of pressure regulator. Some machines also use a second pressure regulator instead of this relief to drop both the pipeline and cylinder pressure in case of the failure of first one. This is known as two stage pressure regulation. This two stage pressure regulation is also needed for an auxiliary O_2 flowmetre, to drive gas to power the pneumatic ventilators, or for the O_2 flush mechanism. The pressure in the supply of O_2 is reduced more than that of N_2O. This differential reduction of pressure between these two gases is important for the proper functioning of N_2O/O_2 flow linkage safety device, i.e. in the failure of the supply of O_2, the N_2O will not also flow. This safety device sense the pressure of O_2 through a small piloting pressure line that is derived directly from gas inlet or second regulator. If the pressure in this pilot line falls below a threshold level, it shuts off the valve preventing the flow of N_2O. Modern machines also uses some proportioning safety devices (discusses in text) with the pressure of this threshold shutt off valve which proportionately reduces the flow of N_2O gas when the flow of O_2 reduces below 25% in total gas mixture. All machines also have an O_2 supply low pressure sensor that activates an electric alarm or a gas whistle when the inlet gas pressure of O_2 goes below the threshold value. The gas lines proximal to the controlling knob of flow valve of rotameter is considered as the high pressure circuit and the gas lines distal to it upto the common gas outlet is considered as the low pressure circuit of machine.

Flow Metre (Fig. 1.13)

It is incorporated into the Boyle's anaesthetic apparatus to measure the flow rate

Fig. 1.13: Flow metre (Rotameter)

of gases such as O_2, N_2O and air passing through them. The flow metre used in anaesthetic machine is also known as the rotameter. The other type of flow metre used in industry are: Waterside, Heidbrink, Connell, Foreggar, etc. The flowmetre consists of a series of specially designed glass tube (Thrope tube) with rotating bobbin inside it to measure the flow of individual gases in the flow metre. The tubes are placed within a chromium plated metal casing and in front there is a transparent plastic window which helps in clear reading and protection of flow metre tube from damage and dust. A detachable radiolucent plate is also provided at the back of the metal casing of flowmeter to facilitate the observation of a working and rotating bobbin within the tube during use in a darkened operation theatre. A flow metre basically has two components such as flow control valve and flow metre tubes with rotating bobbin inside it (Fig. 1.14).

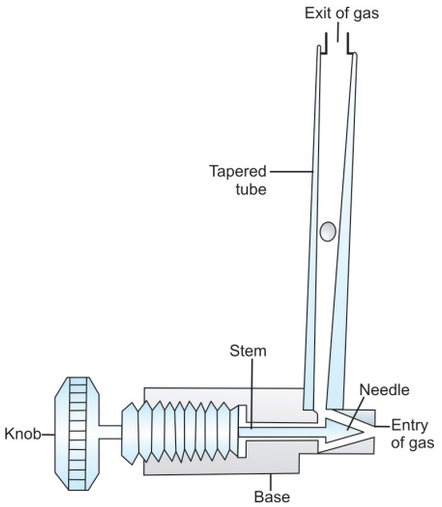

Fig. 1.14: The flow control valve and the tubes of flow metre

The flow control valves control the flow of gas through the tubes of flow metre by manual adjustment of its knobs. It is situated at the base of the flow metre and its body is made of brass. The stem of the adjusting knob screws into the body of flow control valves and ends as a needle which is placed at the site of inflow of gas to the tube of flow metre. The flow control knobs which are attached to the stems of flow control valve are labelled and colour coded for their respective gases. In some design the O_2 control knob is larger and has a longer stem than the other stems and knobs used for other gases. So, this makes it easily recognisable and acts as a safety measure. In some designs a flow control knob guard is attached to protect against the accidental adjustment of flow metres (Fig. 1.15).

The tubes of flow metre are especially made of tapered glass tube with a rotating bobbin inside it. They are set strictly in vertical position on the body of flow control valve. Because inclined position of tube gives incorrect reading by causing friction of bobbin on the wall of the tube and thus producing resistance during the flow of gas. Each tube is individually calibrated at room temperature and one atmospheric pressure for that gas which

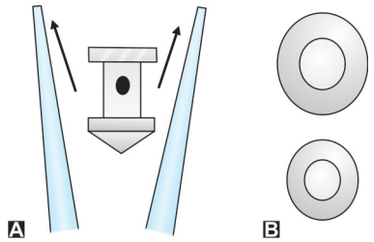

Fig. 1.15A: The route of flow of gases through the tubes of flow metre. **B** shows that the gap between the bobbin and tube wall increases as bobbin goes up

flows through it giving accuracy of about ±2% in measuring the rate of flow of gases. For flows below 2 L/min the measuring units are 100 ml/min and for flows above it the measuring units are L/min. The rotating bobbin or ball in the flow metre tubes which shows us the rate of gas flow through it are made of light aluminium. They are held floating within the tube by the gas flowing around it through the gap between the tube's wall and bobbin. During floating the effect of gravity on the bobbin is counteracted by the flow of gas. When the bobbin is lifted by the flow of gas, then the upward pressure caused by the gas and the weight of the bobbin is in equilibrium at that height of bobbin showing the rate of flow of gas. The flow metre tubes are tapered in such a fashion that the clearance or gap between the bobbin and the tube wall gradually widens from the bottom to the top. So, at low flow rate the clearance between the bobbin and the wall of the tube is longer and narrower acting as a tube and at these circumstances the flow is laminar, governed by the viscosity of gas. On the other hand, at high flow rate the clearance between the bobbin and the wall of the tube is wider and shorter acting as a orifice. Thus, under these circumstances the flow is turbulent and governed by the density of gas. So, each flow metre is calibrated for its specific gas, according to its density and viscosity (Fig. 1.16).

The flow metre can give inaccurate result if the bobbin sticks to the wall of the

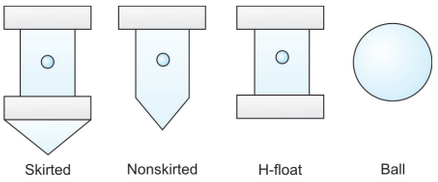

Fig. 1.16: Different types of bobbin used in rotameter

tube due to dirt from contaminated gas supply and / or due to static electricity caused by the continuous friction arising from rotating bobbin during floating. The problem of dirt can be eliminated by using filter at the gas inlet site of anaesthetic machine and the problem of static electricity can be solved by making the bobbin of antistatic material or applying some antistatic spray over it or coating the tube's interior with a conductive substance which grounds the system and reduces the effect of static electricity. At the upper margin of the bobbin there are many cuts or slits (flutes) at the sides. So, when the gas flows by the side of it, the flutes cause the bobbin to rotate. There is radiolucent dot on the bobbin and it indicates that the bobbin is rotating and is not stuck to the wall of the tube. There are two bobbin stops which are made of spring and is situated at the extreme either end (top and bottom) of the tube. It always ensures the visibility of bobbin during operation at the extremes of flow. According to the shape and size different types of bobbins are also used in the flow metre such as ball, nonrotating H float, skirted and nonskirted. But usually the ball and the skirted varities are commonly used in anaesthetic machine. The reading of the flow metre is taken from the top of the bobbin. But when a ball is used then the reading is generally taken from the midpoint of the ball. When very low flow is required such as in circle breathing system, then an arrangement of two flow metre tube for each gas which are attached in series in rotameter are used for the fine adjustment of flow. But these two tubes are controlled by single flow control valve and knob (Fig. 1.17).

The O_2 tube of a flow metre is kept at extreme right of all the gas tubes. Because when it is placed at extreme left of all the tubes, then if any crack develops in a flow metre distal to it, O_2 may leak through this distal crack and may deliver hypoxic mixture to the patient. So, to avoid this problem O_2 is the last to be added to the gas mixture and is finally delivered to the back bar of anaesthetic machine. During mechanical ventilation pressure rises at the common gas outlet when the bag is compressed by ventilator or manually. This is transmitted back to the gas in the tube of flow metre above the bobbin which results in the drop of it during inspiration and inaccurate reading. This can be prevented by attaching a flow restrictor at the down stream of flow metre (Fact file - V).

Antihypoxic Devices

There are many devices which are incorporated in the modern anaesthetic machine to stop the flow of N_2O in the absence of flow of O_2 or there should be a minimum 25% concentration of O_2 in the gas mixture or the machine will give audible alarm when O_2 pressure drops in the pipeline of machine. These antihypoxic devices are consists of hypoxic guard and O_2 failure alarm. This hypoxic guard device maintain minimum 25% flow of O_2 in the gas mixture or when O_2 flow is reduced below 25% of total flow then the N_2O flow will be automatically reduced. It works by mechanical, pneumatic or electronic principle. In mechanical method the N_2O and O_2 flow control valves are linked together by a chain. This chain relays the movement of O_2 knob to the N_2O knob. So, when the O_2 flow control knob is turned to reduce the flow of this gas, then the chain link will also move and reduce the flow of N_2O as if always a minimum 25% of O_2 mixture can reach to the patients or without the flow of O_2, the N_2O will not flow alone. The O_2 flow control knob can be independently opened further. But it cannot be closed below a setting that will produce less than 25% O_2 in the gas mixture if N_2O is used. In pneumatic method there is special type of valve known as the ratio mixer valve where O_2 is exerting pressure on one side of the diaphragm and

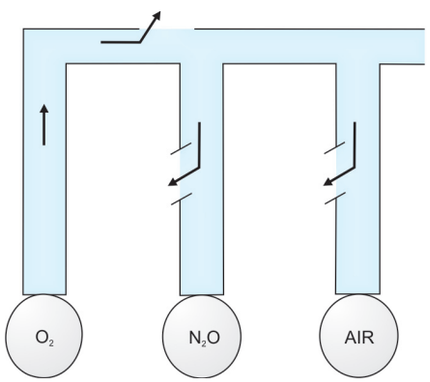

Fig. 1.17: How the O_2 will leak from cracks at different sites if its tube is placed at extreme left

FACT FILE - V

The flow metres of anaesthetic machines are classified either as a constant pressure variable orifice flow metre which are commonly used (and is already described in text) or a electronic flow metre. In electronic flow metre the amount of pressure drop caused by a flow restrictor is the principle for the measurement of gas flow and the amount of flow is displayed digitally and/or graphically. In such circumstances a backup conventional auxiliary O_2 flow metre is also provided for emergency. In anaesthetic machine where electronic flow metre is used, there separate flow metre each for O_2, N_2O and air is used in the flow control section before the gases are mixed together.

In the constant pressure variable orifice flow metre when the gas starts to flow, it gives pressure at the under surface of the bobbin and raise it in the tube. As the bobbin raises the gas flows around it and the bobbin will stop at that position when its weight is equivalent to the difference in pressure above and below it. This pressure difference is constant whatever may be the rate of flow and the position of bobbin in tube. However, it depends on the cross sectional area of tube and the weight of bobbin. At the bottom of the tube where the diameter is small, a low flow of gas will create higher pressure at the under surface of the bobbin and raises it more than the top of the tube where the tube widens and high flow of gas will create less pressure under the bobbin and raises it less, though the pressure difference between below and above of the bobbin is constant.

N_2O on the other side. Thus when there is increased flow of N_2O, then it will also cause increased flow of O_2 maintaining a minimum 25% concentration of it. But when O_2 flow is only increased, the flow of N_2O will not increase. In electronic device a paramagnetic O_2 analyser is used to analyze the mixture of gases which are sampled continuously. Then if due to any reason the O_2 concentration falls below 25% in the inspired gas mixture, then the flow of N_2O will also be stopped and give an alarm (Fig. 1.18).

In O_2 supply failure alarm when the pressure in the pipeline of machine carring only O_2 drops below a certain fixed lavel then the O_2 is directed through a whistle to produce a sound causing alarm. This alarm is activated only when the pressure of O_2 in the machine gas pipeline falls below 200 KPa. This alarm cannot be switched off unless the O_2 supply is restored.

Vapourisers

A vapourisers is a device by which a controlled amount of volatile anaesthetic agent is added to the fresh gas flow mixture after vapourising it from liquid. Initially all the types of vapourisers are divided under two broad headings: variable bypass vapourisers and measured flow vapourisers (Fig. 1.19).

In variable bypass vapourisers the fresh gas flow is first splitted into two so that only a small portion of it passes through the vapourisers and when it passes over the liquid volatile anaesthetic agent in the vapourising chamber it becomes saturated with the vapour of this anaesthetic agent. Then, it leaves the vapouriser to mix with the remaining fresh gas flow that has gone through the bypass. The final desired concentration is achieved by varying the splitting ratio between the bypass gas and the gas that enters the vapourising chamber of a vapouriser using an adjustable valve (regulating dial). On the otherhand, vapouriser can be designed so that it heats the anaesthetic liquid to a temperature above its boiling point and make it a gaseous state which is then allowed to leave the vapouriser in calculated amount (measured) controlled by regulating dial to mix with the fresh gas flow in achieving desired concentration of it. These are known as the measured flow vapourisers. The example of this measured flow vapouriser are TEC-6, TEC-6 plus, D-TEC, where desflurane is only used.

The variable bypass vapourisers are again divided into two types such as draw over vapourisers and plenum vapourisers. In draw over vapourisers a portion of fresh gas flow regulated by controlled knob is allowed to simply flow over the liquid volatile anaesthetic agent and to pick up the vapour of this agent. They are of low resistance and the anaesthetic vapour leaving the vapouriser is not saturated with the vapour of liquid anaesthetic agent. The splitting valve which divides the gas flow to the vapourisers and to the by pass channel is of wide bore and works over a wide range of flow rates. This type of vapouriser is also known as the 'inside the circuit' vapouriser, because being of low resistance and having no unidirectional valve, it acts as a continuous component of the circuit of the anaesthetic machine. On the otherhand, in plenum (which means high resistance, and unidirectional) vapouriser the carrier gas which enters the vapourising chamber of vapouriser is made to be saturated by the vapour of volatile anaesthetic agent present in the vapouriser and pressurised (cause is described later) so that it is rather forced to mix with the bypass fresh gas flow than it simply blows over the surface of the volatile liquid anaesthetic agent in vapourising chamber taking the unsaturated vapour of it like draw over vapouriser. The vapourising chambers of plenum vapourisers act as pressurised chamber containing saturated vapour of volatile anaesthetic agent at all times from where continuous flow of gas saturated with anaesthetic agent comes out. This is made possible by increasing the capacity of vapourisation of liquid volatile anaesthetic agensts to very high level by adding wicks and baffles inside the vapourising chamber, and restricting the exit of gas from the chamber by control valve than the vapourising capacity.

These plenum vapourisers are also called the 'outside the circuit' vapourisers, because they do not acts as the part of anaesthetic circuit due to high resistance and spilitting valve is of narrow bore. They do not act over the wide range of flow rate like draw over vapourisers and so it allow the vapouriser to calibrated very accurately. The examples of the draw over vapourisers are: Boyel's ether bottle vapouriser, Goldman vapouriser, Oxford miniature vapouriser (OMV), EMO vapouriser and TEC-3 vapouriser. The TEC-3 vapouriser is a draw over vapouriser but temperature compensated.

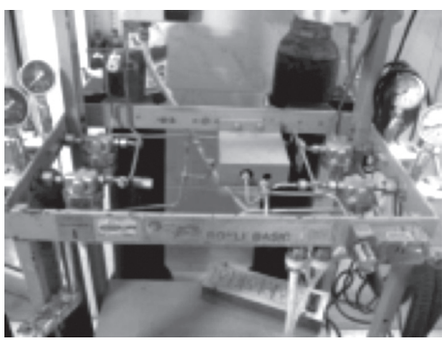

Fig. 1.18: Oxygen failure alarm

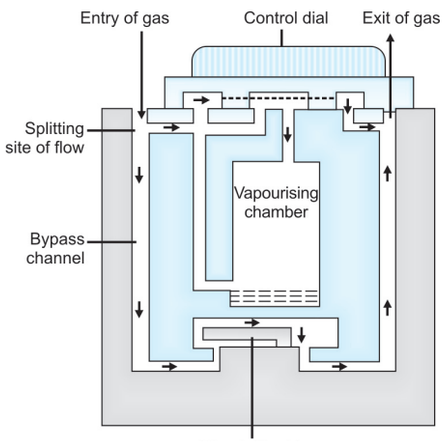

Fig. 1.19: This is a schematic diagram of TEC-5 plenum vapouriser

The examples of plenum vapourisers are: all the temperature compensated (TEC) vapourisers of Datex ohmeda series such as TEC-4, TEC-5, TEC-7 and Drager vapouriser 19 and 2000 series. These different models or types of plenum vapourisers differ among them only in their interior design regarding the arrangement of baffles and wicks to increase the capacity of vaporization made by different companies to remove some technical disadvantages of previous one, but their basic mechanism of action is same. The old model plenum TEC-3 vapouriser is out of market now. At present the commonly used model of plenum vapourisers are TEC-5 and TEC-7 of Datex ohmeda series and Drager vapouriser of 19 and 2000 series. The Aladdin vapouriser which is discussed in more details in chapter is another example of plenum vapouriser with electronic control for vapourisation. The TEC-6 vapouriser which is developed to use only desflurane is the example of measured flow vapouriser (Fig. 1.20).

All the plenum vapourisers are temperature compensated. It means with cooling of volatile anaesthetic agent during vapourisation, the delivered vapour concentration of it after vaporization of anaesthetic agent does not reduce. This is achieved by controlling the splitting ratio of fresh gas flow which enter the vapouriser by a temperature sensitive bimetallic strip which is made of two strips of metal with different coefficients of thermal expansion bonded together. It allows more flow into the vapourising chamber by bending as the temperature decreases and vice versa. This bimetallic strip or temperature sensitive valve is located in the vapourisation chamber in TEC-2 model. Whereas in the TEC-3, 4 and 5 model it is situated outside the vapourisation chamber (Fact file -VI).

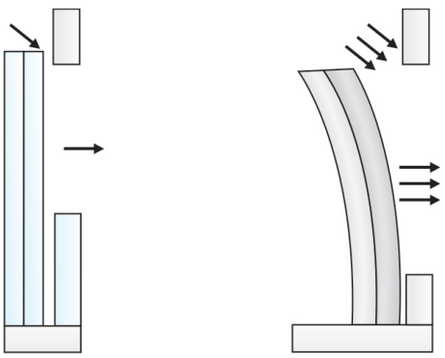

Fig. 1.20: The mechanism of action of bimetallic strip causing thermocompensation of vapouriser

All the variable bypass plenum vapourisers are flow compensated and its explanation is described below. On entering the vapouriser the fresh gas flow is splitted into two streams. The main larger stream of gas flows through the bypass channel and the smaller narrow stream of gas flows through the vapourising chamber of vapouriser. After vapourisation these two gas streams again reunite when they leave the vapouriser together. This is controlled by a regulating dial which dictate how much gas will enter the vapourising chamber, then after being completely saturated with anaesthetic agent, will be reunited with the fresh gas flow coming through bypass channel. The vapourising chamber of a plenum vapouriser is such designed that the gas leaving it is always fully saturated with vapour of volatile liquid anaesthetic agent before it joins with the gas of bypass stream whatever may be the amount of fresh gas flow into the vaporising chamber. This is achieved by increasing the surface area of contact between the gas entering the vapourising chamber and the volatile liquid anaesthetic agent by adding wicks soaked by the agent and a series of baffles. Thus whatever may be the rate of fresh gas flow through vaporising chamber the delivered concentration of anaesthetic agent can be controlled by both controlling the flow of gas entering the vapourising chamber and thus controlling the rejoining of gas saturated with anaesthetic agent with the main gas flow by controlling the dial. Thus it will not be influenced by the rate of fresh gas flow through vaporizer like the draw over vapriser such as goldman, ether vaporiser, etc. In modern designs the anaesthetic concentration of volatile anaesthetic agent supplied by vapouriser is independent

FACT FILE -VI

Electronic vapourisers

The vapourisers where the volatile anaesthetic agents are vaporized by heating it electrically such as TEC-6 desflurane vapourisers or where there is a elctronically regulated flow control valve located at the outlet of vapourising chamber but vapourisation is done by conventional blowing the gas over the volatile liquid anaesthetic agent like other variable bypass vapourisers such as Aladin Cassette vapourisers are called the electronic vapourisers.

The boiling point of desflurane is 22°C. Thus it boils almost at room temperature. So, its vapopur pressure is very high which is near about 681 mm of Hg at 20°C (Halothane = 243°C, Isoflurane = 240°C, Sevoflurane = 160°C). Again the potency of it is near about 1/5th than that of other volatile anaesthetic agent. Hence all these characteristic of desflurane presents a unique delivery problem of it and is solved by the development of TEC-6 vapouriser where only desflurane is used. In this vapouriser there is a reservoir containing desflurane which is heated electrically to 39°C to vaporize it. So, this reservoir always contains the dense vapour of desflurane at the pressure of 2 atmosphere. On the other hand, no fresh gas from flow metre is allowed to flow over the desflurane for vapourisation of it through by pass channel like other variable by pass vapourisers. Rather the measured amount of pure vapour of desflurane is allowed to flow from the reservoir which is regulated by a control dial and to mix with the fresh gas flow coming from flow metre to make the desired delivered concentration of it. Thus, it maintains a desired constant concentration of desflurane over a wide range of fresh gas flow rates.

In Aladin Cassette vapouriser the volatile liquid anaesthetic agent is not vaporized by heating electically like TEC-6 vapouriser. Here like other conventional plenum vapouriser the fresh gas flow from flow metre is divided regulated by control dial and a portion is allowed to flow through vapourising chamber to vaporize the anaesthetic liquid. However, this vapourisation is conducted into a agent specific colour coded cassette (Aladin cassette). The anaesthetic machine accept one casette at a time and recognise this cassette through magnetic lebelling. Unlike the traditional vapourisers, here the liquid anaesthetic agents can not escape from it during handling and so it can be carried in any position.

of gas flow through vaporising chamber between 0.5 to 15 L/min. Hence, they are flow compensated. But the changing of composition of gas from 70% N_2O to 100% O_2 may increase the concentration of anaesthetic agent due to the greater solubility of N_2O in volatile liquid anaesthetic agents. In comparison to the flow compensated vaporisers the draw over vapourisers are not flow compensated, because under certain dial setting the portion of gas entering the vapourising chamber varies with the rate of fresh gas flow, and the gas coming out from the vapourising chamber is not fully saturated. Thus the rejoining of gas mixed with variable concentration of anaesthetic agent to the main gas flow is not controlled. During vapourisation due to the loss of latent heat of vapourisation the cooling of anaesthetic agent occurs and makes it less volatile, reducing vapourisation. So, in order to compensate this heat loss two measures are taken. One, the vapouriser is made up of such material which has high density, high specific heat and high thermal conductivity such as copper. So it acts as heat reservoir and readily gives heat to the cooled anaesthetic agent, maintaining its temperature and vapourisation nearly constant. Two, a temperature sensitive valve made of bimetallic strip allows more flow into the vapourising chamber by bending as the temperature decreases and vice versa.

All the modern vapourisers are agent specific. So, filling of them with wrong agents should be avoided. For example filling of an halothane specific vapouriser by sevoflurane would lead to anaesthetic concentration in under doses and vice versa. This is because the vapour pressure of halothane at one atmospheric pressure and 20°C is 243 mm of Hg, whereas the same of sevoflurane is 160 mm of Hg. So, if sevoflurane is used in halothane TEC-7 or TEC-5 vapouriser, it will cause near about 40% lesser amount of anaesthetic concentration to be released and vice versa. So, the modern TEC-5 and TEC-7 vapourisers (TEC-4 is also obsolete now) are equipped with agent specific filling ports and colour coded agent specific filling devices to prevent the use of wrong agent in wrong vapourizer. In older vapourisers during IPPV there may be transient reversal of flow of fresh gas and pressure into the vapouriser through the by pass channel and it will lead to the delivery of unpredictable concentration of anaesthetic agent. This is known as the pumping effect which is more pronounced with low gas flow. Hence in modern vapourisers some change in design and placement of a one way check valve limit the occurance of this problem. During transport or due to any reason if vapourisers are tilted excessively then the anaesthetic agent may spill over and flood the by pass channel of vapouriser which may lead to sudden delivery of dangerously high concentration of anaesthetic agent when first used. So, during handling of it when not attached to machine, excessive tilting of vapouriser should be avoided.

Ventilator

All the modern anaesthetic machines are equipped with ventilator for IPPV during anaesthesia which are of bag in bottle type in most of the cases. They have mainly the CMV mode for ventilation, but some have the facilities to provide other few more mode for ventilation modes such as SIMV, CPAP and PEEP. These bag in bottle type of anaesthetic ventilators have mainly two basic components: a driving unit and a control unit. The driving unit consists of a chamber with tidal volume ranging from 0 to 1500 ml and an ascending or descending type of bellow receiving fresh gas flow within it. In paediatric version the tidal volume in chamber ranges from 0 to 400 ml, whereas in adult version the tidal volume in chamber ranges from 100 to 1500 ml. The controll unit of the ventilator contains variety of controlling knobs, display system and alarms. The controlling knobs include the respiratory rate, tidal volume, airway pressure, I/E ratio, power supply, etc., to regulate the IPPV of patient during anaesthesia (Fig.. 1.21).

In these types of bag in bottle ventilator compressed air or O_2 is used as the driving pressure. On entering the driving chamber of ventilator this driving gas forces the bellows down in case of ascending type of bag in bottle ventilator and delivers the fresh anaesthetic gas mixture to the patient which was accommodated in side the bellow during the previous expiratory phase of respiratory cycle. The volume of driving gas entering the chamber is always equal to the tidal volume and remains completely separated from the fresh gas flow which remarks in side the bellow. Then during expiration the bellow again ascends due to the flow of fresh gas mixed with expired gas within it and the driving gas comes out (Fig. 1.22).

There are another type of bellow known as the descending bellow. Here, during expiration the gas sucked from patient into the bellow by a weight placed at the base of it. So, the probable advantage of this type of descending bellow is the absence of expiratory resistance. This advantage is not available in ascending bellow as it is claimed that the pressure required to fill the bellow both by fresh gas from machine and expired gas from patient adds some expiratory resistance to patient and may

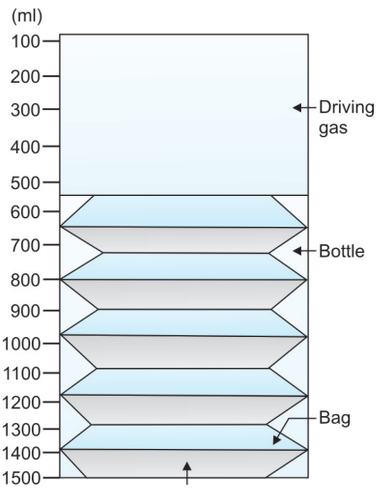

Fig. 1.21: The mechanism of action of a bag in bottle type of ventilator

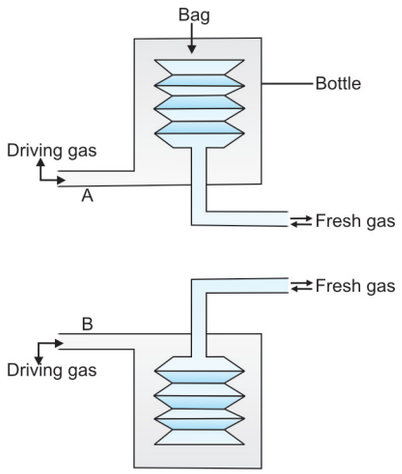

Fig. 1.22: Ascending (A) and descending (B) type of bag in bottle ventilator

prevent complete exhalation. Therefore, it is claimed that ascending bellow provides a degree of PEEP (2 to 4 cm of H_2O) which may otherwise be beneficial.

The another advantage of ascending bellow is that it collapses to an empty position and remains stationary at that empty position if there is any leak in bag or disconnection of circuit. Whereas in descending design of bellow it automatically hangs down to fully expanded position, even if there is any leak or disconnection of circuit and may continue to move almost normally. In such condition the driving gas would also be able to enter the bellow through the leak and dilute the anaesthetic gas mixture within it which is not possible in ascending variety.

The arrangement in descending bellow also allows the driving control unit to be placed above the bellow in the free standing version. So the bellow of it could be placed on the lower shelf of an anaesthetic machine with the controls panel easily at hand. However the descending bellow is now no longer popular (Fact file- VII to IX).

Miscellaneous

Non return pressure relief valve

It is situated on the back bar of anaesthestic machine after the vapouriser or at the common gas outlet. Here it acts as nonreturn valve and helps to prevent the effect of back pressure on the vapourisers or flow metre during positive pressure ventilation by ventilator or manual. It also opens when the back bar pressure exceeds 30 KPa and acts as pressure relief safety valve.

Emergency O_2 flush

It is presented in the machine as nonlocking button and when is activated by manual

FACT FILE - VII

Other than the bellows in bottle which is squeezed pneumatically it may be inflated or deflated without bottle by a piston that is powered by gas and is attached to the bellow by a lever. The advantage of this principle is that it removes the potential danger of mixing between the driving gas which is situated outside the bellow and the patient's gas which is situated inside the bellow. The another advantage of this principle is that the piston may be driven by a smaller quantity of gas from cylinder. So, it is very valuable where there is scarcity of gas. The Manley Servovent and Oxford Mark 2 ventilators work on this principle. The bellows may also be moved mechanically by motor and suitable levers and gears. The speed of motor can be changed to produce the varieties of flows both during inspiration and expiration. This principle is used in the Drager E series of ventilatos. In some ventilators, the bellows are not used, instead a long wide bore hose pipe is substituted. In this method the driving gas is directly pushed into the breathing system with the fresh gas by ventilator, but it does not mixed with the fresh gas due to long length of hose pipe. The example of ventilator working on this principle is Penlon Nuffied 200 series.

FACT FILE - VIII

There are now many major advances in the working principles of ventilator which are used in intensive care unit and also anaesthetic ventilator. Among these the two most important parts are electronic flow valve and microprocessor. In an electronic flow valve first current is allowed to pass through an wire coil (solenoid) to produce a magnetic field which moves the ferromagnetic piston and closes and open the valve with the help of a spring. The movement of the valve depends on the flow of current and thus control the movement of driving gas by corresponding amount of closing and opening of it. As this valve is used in high pressure gas pathways, so the little movement of valve is enough to control the flow of driving gas very quickly varying between 1 to 120 litre/min. The response time of this type of solenoid valve is only 5 milliseconds and is very compact to be fitted easily in a small equipment.

The microprocessor part of a ventilator controls the electrical signal to the electronic flow valve of it. They are usually programmed to provide a wide variety of ventilatory modes and response. Most of the ventilators now work on this principle but they only differ according the user display, variable programming and the quality of components.

FACT FILE - IX

Description of function of a commonly used bag in bottle type of anaesthetic ventilator attached with anaesthetic machine.

This represents a model of a pneumatically driven bag in bottle type of ventilator with an arrangement of ascending bellows. There the driving gas is controlled by electronic flow valve which is again under the control of microprocessor to provide a wide range of ventilatory function.

Inspiratory

In this phase, the pressurised driving gas is first passed through a filter and a regulator to enter the electronic flow valve which is held shut when not in use. Then the gas passes to the bottle that contains an arrangement of ascending bellow and compresses the bellow forcing the fresh gas to flow through a wide bore hose into a breathing system for inspiration of patient. This driving gas also supplies a small pneumatic valve which closes the expiratory port and prevents the fresh gas destined for inspiration from escaping.

The passing of driving gas through electronic flow valve is controlled by a microprocessor which receives information from the ventilator setting of front panel by anaesthetist, fresh gas flow through the anaesthetic machine and inspiratory flow to the patient. Thus the changes in these flows will also change the flow of driving gas through the electronic flow valve and consecutively control the tidal volume which depends on the force on the bag caused by driving gas.

Expiratory valve

At the end of the time cycled inspiratory phase the microprocessor instructs the electronic flow valve to close and a second valve to open. Thus, the driving gas passes away to the atmosphere from bottle through second valve and causes its pressure to fall to zero. This allows the exhaled gas from patient mainly from dead space and fresh gas to enter the bellow. If Bain circuit is used then this exhaled gas comes from the patient through the wider external tube which is attached to the input of ventilator. When the bellow becomes full and its pressure is raised above the atmosphere then the expiratory port opens and expired gas from alvesli containing CO_2 escapes to the atmosphere through output channel. At the same time the driving gas leaving the bellow also passes out through the output channel.

pressure then pure O_2 at the flow rate of 30 to 70 L/min is supplied to the patient from the common outlet of anaesthetic machine bypassing the flow metre and vapourisers. It also is used to flush the breathing circuit or to rapidly refill the breathing bag. It should not be activated when the minute volume divider ventilator is in use. Injudicious use of this emergency O_2 flush may dilute the anesthetic gases and will cause the inadequate depth of anaesthesia and awareness. It may cause barotrauma also when the patient is connected to a completely closed breathing circuit.

Common gas outlet and O_2 analyzer

All the anaesthetic machine has only one common outlet supplying fresh anaesthetic gases mixed with O_2 to breathing circuit in contrast to multiple inlets which supply different gases to the machine. Modern machines are equipped with devices which measure the flow of gases through this common outlet and gives signal during detachment of this outlet from the breathing circuit.

It is fundamental to monitor the inspired O_2 concentration (FiO_2) or partial pressure of it in the gas mixture delivered to the patient. Without an O_2 analyser which measures the inspired O_2 concentration an anaesthetic machine is always incomplete and general anaesthesia should never be administered. It is placed in the inspiratory or expiratory limb if close circuit is used. Otherwise, if the circuit has one limb, then it should be placed at the patient's end of it. But it should not be placed at the fresh gas line. Due to O_2 consumption by patient the partial pressure of O_2 in expiratory limb is slightly lower than that of the inspiratory limb. An audible alarm can be set for high and low concentration of O_2 such as 40% and 28% respectively.

Three types of O_2 analyzers which measures FiO_2 are used in modern anaesthetic machine. These are: paramagnetic, fuel cell (or galvanic), or Clark electrode (polarographic). The paramagnetic sensor works on the principle that only O_2 is attracted by the magnetic field whereas the other gases are repelled. This attraction and repulsion of individual gas depends on their concentration and partial pressure in the sample gas. It is costly than the others and has no consumable parts without requiring frequent replacement. Its response time is very fast than the galvanic and Clark electrode O_2 analyzers and can differentiate the partial pressure of O_2 between the inspired and expired air as it measures the inspired and expired O_2 concentration simultaneously on breath by breath basis. However, this analyzer is affected by water vapour in sample gas. Therefore a water tap is incorporated in the design. The another advantage of this paramagnetic sensor is, it is self calibrating. The galvanic and polarographic sensor is also called the electrochemical sensor, because both of them contain the anode and cathode electrodes embedded in an electrolyte gel which is separated from the gas sample by an O_2 permeable membrane. After diffusing through the membrane, O_2 reacts with the electrode in the gel and produces a current which is proportional to the concentration and partial pressure of it in the sample gas. Thus they measure the partial pressure of O_2 as a percentage. These galvanic and polarographic O_2 analyzer have slow response time (20 to 30 seconds), because they are dependent on membrane diffusion of O_2. These sensors have limited life span to about 1 year, because of the exhaustion of material of it due to continuous exposure to O_2. It needs regular service and calibration is achieved by using 100% O_2 and room air (21% O_2). It reads only inspiratory or expiratory O_2 concentration and water vapour does not affect its performance.

N_2O and other inhalation anaesthetic agent concentration analyzer

The measurement of inspired and end tidal concentration of N_2O and other inhalational anaesthetic agents are very important, mainly when the circle system is used. This is because the expired inhalational anaesthetic agents are recirculated and are added to the fresh gas flows which is also carrying the volatile anaesthetic agents. So, the ultimate inspired concentration of inhalational anaesthetic agents is different from the setting of vapouriser, especially during low flow. Hence, the modern analyzers can assure the inspired concentration of all the inhalational anaesthetic agents such as N_2O, halothane, isoflurane, sevoflurane, desflurane, etc. The principles by which the concentration of inhalational anaesthetic agents are measured are: infrared technique, ultraviolet ray absorption technique, mass spectrometry, Raman spectroscopy, Piezoelectric quartz crystal oscillation technique, etc.

In infrared technique a light of wavelength of 4.6 nm is used for N_2O. On the otherhand an infrared light of wavelength of 8 to 9 nm is used for other volatile anaesthetic agents. This is to avoid interference from the methane and alcohol that happens at the lower 3.5 nm wavelength. Some infrared analyzers are not agent specific. These must be programmed by the user for specific agent being administered. Incorrect programming result in incorrect result. In Piezoelectric oscillation technique a lipophilic coated Piezoelectric quartz crystal is used which undergoes continuous changes in its frequency of oscillation when lipid soluble inhalational anaesthetic agent is exposed to it. This changes in oscillation is directly proportional to the concentration of agent. Mass spectrometer is used to analyze the inhalational anaesthetic agents on breath to breath basis. In this technique the principle of action is to change the particles of sample gas by bombardment of them with electron beam and then to separate the components arising from this bombardment by a magnet into different spectrum according to their specific mass: charge ratio. The relative concentration of ion in a spectrum of a specific mass: charge ratio is

Table 1.2: Various methods used to analyse gases

Methods	*O_2*	*CO_2*	*N_2O*	*Volatile agents*
Infrared	-	+	+	+

Raman spectroscopy	+	+	+	+
Mass spectrometry	+	+	+	+
Piezoelectric oscillation	-	-	-	+

determined by the concentration of a particular agent in gas mixture (Table 1.2).

Measurement of tidal and minute volume

During GA the measurement of tidal volume and from it the measurement of minute volume is very critical which the anaesthetic machine performs by Wright spirometer (respirometer), hot-wire anemometer, ultrasonic flow sensor and pneumotochograph etc. These are used in all the modern sophisticated anaesthetic machine to measure the exhaled tidal volume by attaching them in breathing circuit near the exhalation valve. Some machines measure the inspiratory tidal volume by attaching these just distal to the inspiratory valve. However, in the latest model of Datex-Ohmeda machine these are attached near the Y-connection of patient to measure the actual delivered and exhaled tidal volume.

In Wright respirometer there is a rotating vane which is surrounded by multiple slits and this vane is attached to a pointer on a dial. When the gas passes through it then the slits which surround the vane create a circular flow and rotate the vane with pointer on front dial. The vane does 150 revolutions for each litre of gas passing through it. In clinical use the respirometer reads accurately the tidal volume within the range of 4 to 24 L/min. A minimum flow of 2 L/min is required for the respirometer to function accurately. A paediatric version of spirometer is also now available which can measure the tidal volume in the range of 15 to 200 ml per breath. A sophisticated version of this Wright spirometer uses the reflection of light technique to measure the tidal volume more accurately. Other modification of this Wright spirometer is the use of semiconductive device where the tidal volume is measured from the changes in magnetic field and converting it electronically.

The hot-wire anemometer is used in Drager-Fabius anaesthetic machine to measure the tidal volume. Here, electrically heated fine platinum wires are used. The cooling effect of these wires by increasing gas flow through it causes a change in electrical resistance which is proportion to the gas flow and is determined by the current needed to maintain a constant wire temperature. In ultrasonic flow sensors an upstream and downstream ultrasonic beams are passed at an angle from where the shift of doppler frequency is measure which is proportional to the flow of gas or tidal volume. In pneumotachograph the parallel bundles of tubes of small diameter in a chamber or a mesh screen is used which provide resistance to air flow and drop of pressure. This drop of pressure across the resistance is sensed by a differential pressure transducer and is proportional to the flow rate. Thus calculation of flow rate over time measures the tidal volume. Moreover analysis of this volume, pressure and time relationship will give us the potential valuable information about lungs and airway mechanics.

2 Anatomy and Physiology of Respiratory System

INTRODUCTION

An anaesthesiologist must acquires an extensive knowledge, regarding the anatomy and physiology of respiratory system before taking any care of his patients in the operating room, ITU and the intensive care unit. This is because mastery on the anatomy and physiology of respiratory system is the principal prerequisite to understand the mechanism of gas exchange that occurs during anaesthesia, surgery and in different disease processes of patients in OT and in intensive care unit.

From anaesthetic point of view the anatomy of respiratory system is divided into two main heading such as (i) the conducting part including trachea, bronchus and its multiple divisions up to alveolus, and (ii) the actual lung parenchyma.

TRACHEA

The trachea or wind pipe is a membrano-cartilaginous structure. It extends downwards as a continuation of larynx from the lower margin of cricoid cartilage.

Course and Measurement

The trachea as a continuation of larynx begins at the level which lies opposite to the C_6 vertebra or at the lower border of cricoid cartilage. It then passes downwards to end opposite to the sternal angle by dividing into the right and left bronchus (plural-bronchi). This bifurcation of the trachea or begining of the bronchus corresponds with the lower border of T_4 vertebra in supine position or T_6 vertebra in standing position. But, in the newborn the trachea bifurcates at the higher level, opposite to the T3 vertebra.

The length of an adult trachea is about 10 to 11 cm. The external diameter of trachea is about 2 cm in adult male and 1.5 cm in adult female. The internal diameter of trachea is approximately 12 mm in adult. In new born, the internal diameter of trachea is only 3 mm, which persists upto 3rd year of life. Thereafter, the lumen increases by about 1 mm for each year upto the 12th year, after which it remains fairly constant. So, this knowledge is fairly important for an anaesthetist in selecting the size of an ET-tube during the intubation in children. In children, the trachea is deeply placed and more movable, whereas in adult it is superficial and more fixed. Moreover, in children the left brachio-cephalic vein and the summit of the arch of aorta crosses the trachea at higher level than adult near supra-sternal notch. So, low tracheostomy is risky in children than adult.

The trachea moves with flexion and extension of head and with respiration. With deep inspiration, the trachea moves 2.5 cm downward and during expiration this same length is moved upwards. The extension of head and neck which is an ideal position to maintain an unobstructed airway in an anaesthetized patient usually increase the length of trachea by about 20 to 30%. In some clinical situation, where a patient is intubated with head in a flexed position and the ET-Tube just passes beyond the vocal cords, then the subsequent extension or hyperextension of head and neck may withdraw the tube above the cords.

Structure

The trachea consists of a number of incomplete C-shaped cartilagenous rings. On the posterior surface, the two free ends of these incomplete cartilagenous ring are connected by strong fibroelastic membrane and involuntary trachialis muscles.

The C-shaped cartilagenous rings are made up of hyaline cartilage. The total number of cartilagenous rings varies between 16 to 20 in an adult male. Among all the rings the first is broadest and the last is triangular in shape which is called carnia. It hooks upwards from the lower margin of trachea and then surrounds the commencement of two bronchi. The carnia represents a ridge in the interior of tracheal bifurcation and acts as a guide for the surgeon during bronchoscopic or other endoscopic examination of trachea or bronchi.

The mucous membrane of upper respiratory tract at the level of carnia is most sensitive area and is associated with the cough reflex. So, the carnia is often considered to act as the last line of defense, causing expulsion of the aspirated foregin body by violent cough. As the cartilagenous ring of trachea is absent posteriorly, so it allows the expansion of oesophagus during the deglutition of food. The air pressure in the trachea is negative in relation to the atmosphere during inspiration.

Therefore, the positive pressure from outside might collapse the trachea. In order to avoid this, the tracheal wall is composed of elastic and rigid cartilagenous rings to maintain the potency of lumen. For this purpose the cartilage cells are nature's best choice than bone cells. Because the cartilage requires no separate blood supply and they get nutrition only by diffusion from the nearest capillary plexus.

The interior of the trachea is lined by pseudo-stratified ciliated columnar epithelium, resting on a basement membrane with numerous serous and mucous glands. The epithelial cells are single layered with different heights and different nuclear positions. Hence, this layer shows apparent stratification under light microscope and is called pseudo-stratified. The taller cells in this pseudo-stratified epithelium present cilia and each cell supports about 270 cilia. The electron microscope shows that each cilia contains 11 microtubules. Among these, 2 microtubles are in the centre and other 9 are at the periphery. The mucous secreted by the goblet cells of mucous glands entrap dust, other foreign particles and bacteria. Then these entrapped particles are swayed by the ciliary beats towards the upper part of the trachea and the larynx. Then, they are expelled by the cough reflexes. Thus, the mucuous membrane helps in the defensive mechanism of respiratory passage by acting as a muco-ciliary barrier. The cilia in the epithelium is present as far as up to the terminal bronchiole where they give way to the squamous cells without cilia (Figs 2.1A and B).

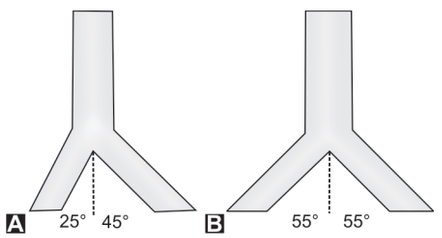
The glands and cartilages are present up to the begining of the preterminal or terminal bronchioles. The bronchioles less than 1 mm in diameter do not have cartilage in their walls. As the bronchiole is traced distally, it is found that the cartilaginous rings recede gradually and is replaced by irregular plates which occur sporadically until the diameter of the bronchhiole comes down to 0.6 mm and then they disapear completely. If it is progressed more downwards continuously along the bronchial tree then it is also found that the tubular outline of bronchial wall start to change. Gradually small projections appear from all the directions in increasing numbers. This area is now termed as the respiratory bronchiole and the small projections are known as the alveolar ducts, leading to the air sacs. The walls of the bronchioles contain more smooth muscle. Of which the largest amount of muscle relative to the thickness of the wall is present in the terminal bronchioles. Smooth muscles are found in the walls of all the airways down up to the level of alveolar duct and most abundant in the terminal bronchiole. On the contrary, the trachea and bronchi have cartilages in their walls, but relatively little smooth muscle.

Bronchus

The trachea bifurcates into two main bronchous — right and left. Then, each main bronchus enters the corresponding lung through their hilum. After that each bronchus divides and subdivides into successive smaller bronchi and finally produce terminal respiratory bronchioles which merge with the alveolar sacs and ultimately terminate into the alveoli which constitute the lung parenchyma.

Right Bronchus

The right bronchus passes downwards and to the right from the bifurcation of trachea and makes an angle of 25° with the midline. It enters the hilum of right lung at the level of 5th thoracic vertebra.



Figs 2.1A and B: Angle of the main bronchi, A. in the adult, B. in the children

In children under the age of 3 years, the angulation of two main bronchi at the carina is equal on both sides. The right bronchus is wider, shorter and more vertical than the left bronchus. The length of the extra-pulmonary part of the right bronchous is about 2.5 cm. It is more wider becasue it supplies the more voluminous right lung. It is more vertical because the trachea at its bifurcation deviates more towards the right side. So, a foreign body in the trachea is usually aspirated into the right lung. However, the short length of right bronchus makes the approach to the lumen of it difficult when it is required during thoracic anaesthesia (Fig. 2.2).

Within the lung, first the right principal or primary bronchus divides into three secondary or lobar bronchus to supply the each lobe of right lung (right lung has three

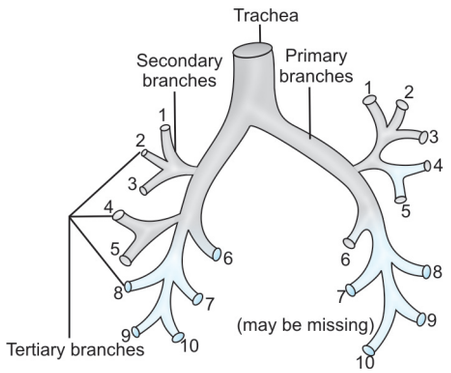


Fig. 2.2: Distribution of tertiary bronchi in right and left lungs

Upper lobe
1. Apical bronchus
2. Posterior bronchus
3. Anterior bronchus

Right middle lobe	Left middle lobe
4. Lateral bronchus	4. Superior lingular bronchus
5. Medial bronchus	5. Inferior lingular bronchus

Lower lobe

6. Apical bronchus	6. Apical bronchus
7. Medial basal (cardiac)	7. Medial basal (sometimes missed)
8. Anterior basal bronchus	8. Anterior basal bronchus
9. Lateral basal bronchus	9. Lateral basal bronchus
10. Posterior basal bronchus	10. Postrior basal bronchus

lobes). Then each secondary or lobar bronchus subdivides into segmental or tertiary bronchus. Thus, there are ten segmental or tertiary bronchus in right lung. The area of the lung supplied by tertiary or segmental bronchus is known as the broncho-pulmonary segment which acts as an independent respiratory district or unit. So, there are ten broncho pulmonary segments in right lung.

This ten broncho-pulmonary segments supplied by ten tertiary or segmental bronchus in right lung are:

a. *Upper lobe:* apical, anterior, posterior
b. *Middle lobe:* medial, lateral
c. *Lower lobe:* apical, anterior basal, posterior basal, medial basal, lateral basal.

Each broncho-pulmonary segment is wedge in shape with there base directed towards the surface of the lung. These segments are separated from one another by intersegment areolar septa which prevent the spread of infection from one segment to another. The branches of the pulmonary artery follow the segmental or tertiary bronchi and are segmental in distribution. Whereas, the tributaries of pulmonary vein run through the intersegmental septa and are intersegmental in drainage. Thus, the area of the lung drained by an intersegmental tributary of pulmonary vein is known as the broncho-vascular unit which includes a number of broncho pulmonary segments. Hence, the surgical resection of a broncho-pulmonary segment produces obvious haemorrhage (Fig. 2.3).

Now, the tertiary or segmental bronchus divides and subdivides and then finally end into smaller branches which enter the lung lobules through their apices. These smaller divisions of bronchus which enter the lung lobules are called the preterminal bronchioles. Thus, a preterminal bronchiole is the part of a conducting system which supply a lung lobule. A preterminal bronchiole is intralobular and is devoid of cartilages and glands. The lung lobules are self-contained and bounded by connective tissue septa which has no anastomotic connections with other adjacent lobules. In every lung lobules each preterminal bronchioles then divides into 3 to 7 terminal bronchioles. After that each terminal bronchiole again subdivides dichotomously by 3 successive orders into respiratory and then into terminal respiratory bronchioles. Each terminal respiratory bronchioles then terminate by branching into 2 to 11 alveolar ducts. The alveolar ducts are cone shaped and thin walled tubes with squamous epithelial lining. The number of alveolar ducts in each lung is about 2 million. Each alveolar duct then further divides or end by branching into 2 to 4 atria. Numerous air saccule open off from the atria. The total number of air saccule in each lung is about 4 million. Ultimately each air saccule gives rise to 30 alveoli (Fig. 2.4).

About 16 orders of division of respiratory passage takes place from the principal bronchus to the terminal bronchioles.

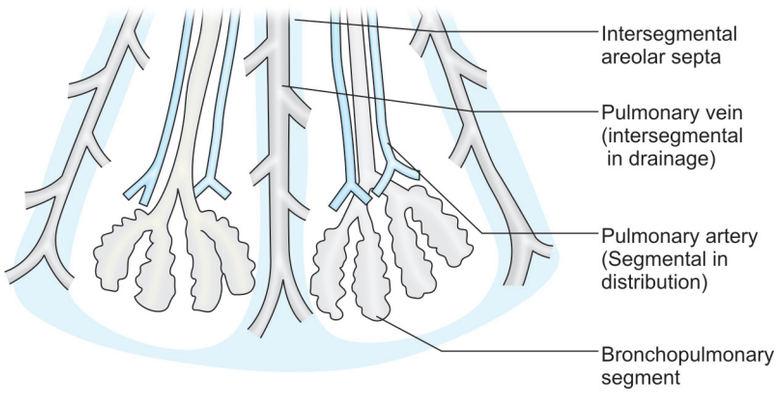

Fig. 2.3: Bronchopulmonary segments and their relations with pulmonary blood flow

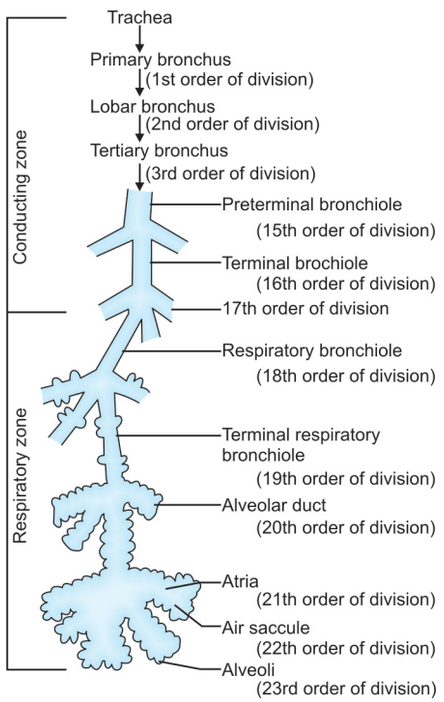

Fig. 2.4: Acinus (or primary lobule) is a subunit of pulmonary tissue consisting of respiratory bronchiole, alveolar ducts, atria and alveoli. Intercommunications exist between acini. Thus disease can spread from acinus to acinus. But functional deficiency in any part of one acinus can be compensated by by-pass mechanisms via these anastomotic channels. Secondary or lung lobule is the unit of pulmonary tissue served by a preterminal bronchiole. They are self-contained and bounded by connective tissue septa. It has no anastomotic connections with other lobules

The next 7 orders of division occur from the terminal bronchiole to the alveoli. The total number of terminal bronchioles in each human lung is about 33,000. Each terminal bronchiole subdivide into respiratory bronchiole. Respiratory bronchiole exibit alveolar outpockets from the side walls. Respiratory bronchiole divides into terminal respiratory bronchiole. The total number of terminal respiratory bronchioles in each human lung is about 2,60,000.

Therefore, 23 orders of division are encountered from the principal bronchus to the alveoli. The total number of alveoli in each lung is estimated to be about 150 million. Hence, the total number of alveoli

in both the lungs of an adult is about 300 million. All these alveoli of both the lungs together represent the total surface area of about 70 to 100 sq metres. The total number of alveoli in both the lungs of a new born is about 20 million and by about 8 years after birth the adult number is reached (Fig. 2.5).

The area of lung supplied by one terminal respiratory bronchiole is known to take part in gaseous exchange. So, from the functional point of view the area supplied by one terminal respiratory bronchiole is known as the functional pulmonary unit or lung unit. Thus, one lung unit consists of one terminal respiratory bronchiole, 3 successive orders of dichotomous subdivision of terminal respiratory bronchioles into alveolar duct and from alveolar duct to atria, air saccules and alveoli. Each lung unit or pulmonary unit is also called acinus. Intercommunication exist between two acinus or lung unit and also between acinus and respiratory bronchioles. Thus, the disease can spread from one acinus to another acinus and functional deficiency in any part of an acinus can be compensated by by-pass mechanism via these anastomotic channels to another acinus. The total number of alveoli in each lung is about 150 million (including those alveoli connected to the respiratory bronchioles).

Respiratory bronchioles and air passages distal to it are lined by simple squamous epithelium resting on a basement membrane and surrounded externally by intense pulmonary capillary plexus. But, lyumphatic plexus is absent from the terminal respiratory bronchioles and distal to it. The part of the bronchial tree extending from trachea up to the terminal bronchiole i.e. the first 16 generations of air passages is called the conducting zone and does not take part in gas exchange. This is lined by ciliated columnar epithelium. The Part of the respiratory passage extending from respiratory bronchioles to the alveoli, i.e. the distal 7 generations of air passage is called the respiratory zone and take part in gas exchange, because it is lined by squamous epithelium. Glands and cartilages are present up to the beginning of the preterminal bronchioles. These multiple divisions of respiratory passages greatly increase the total cross sectional area of the airways from 2.5 cm^2 in the trachea to 11,800 cm^2 in the alveoli. So the velocity of air flow in the small airways declines from very rapidly to a small value (Fig. 2.6).

Thus, the divisions and subdivisions of respiratory passage from trachea to alveoli may be summarised as follows:

- Principal bronchus (1st order)
- Secondary or lobar bronchi (2nd order)
- Tertiary or segmental bronchi (3rd order)
- Preterminal bronchioles (15th order)
- Terminal bronchioles (up to that 16 order of division)
- Respiratory bronchioles (18th order)
- Terminal respiratory bronchioles (19th order)
- Alveolar duct (20th order)
- Atria (21st order)
- Air saccules (22nd order)
- Alveoli (total 23 order of division)

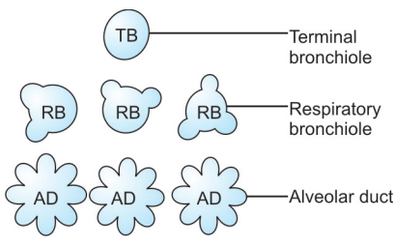

Fig. 2.5: A definitive flow of air is maintained up to the terminal bronchiole. Beyond this point the actual flow of air stops and air movement is effected by diffusion. One terminal bronchiole (TB) gives rise to 3-5 respiratory bronchiole (RB), and diameter of each RB = diameter of TB. Each RB gives rise to several alveolar duct (AD) of similar diameter to RB

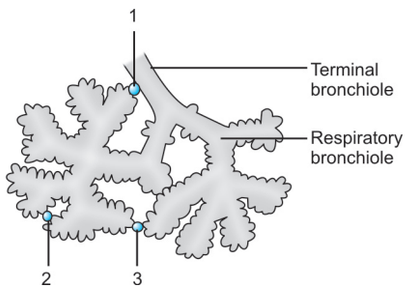

Fig. 2.6: Anatomical intercomunicating channels in acinus. These exist at three levels. 1. between one or more atria and the related terminal bronchiole. 2. between the alveoli of atria of same respiratory bronchiole. 3. between the alveoli of adjacent respiratory bronchioles. These alveolar connections are known as the pores of Kohn

Left Bronchus

The left principal or primary bronchus is longer, narrower and more oblique than the right one. The length of the extra pulmonary part of it is about 5 cm. It makes an angle of 45° with the trachea at the midline and passes downwards and to the left below the arch of the aorta. It then enters the left lung through its hilum at the level of the 6th thoracic vertebra.

Then, the left principal or primary bronchus divides only into upper and lower secondary or lobar bronchus to supply the respective lobe of the left lung, because the left lung is divided only into two lobes (whereas the right principal on primary bronchus divides into three secondary or lobar bronchus). After that the left upper secondary lobar bronchus again divides into 5 tertiary or segmental bronchi: apical, anterior, posterior, upper lingular, and lower lingular. The lower secondary lobar bronchus divide into 4 or 5 tertiary or segmental bronchi: apical, medial basal (may be missing), lateral basal, anterior basal and posterior basal (Fig. 2.7).

So, the nine or ten broncho-pulmonary segments of the left lung, supplied by the tertiary or segmental bronchi are:

- Upper lobe: apical, anterior, posterior, upper lingular, lower lingular.
- Lower lobe: apical, medial basal (may be missing), lateral basal, anterior basal and posterior basal.

Structure of Bronchus

As discussed before, within the lung a principal bronchus divides successively

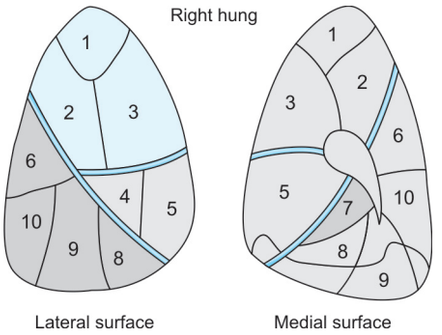

Fig. 2.7: Bronchopulmonary segments of right lung:

Apical segment of lower lobe, 7. Medial basal segment of lower lobe, 8. Anterior basal segment of lower lobe, 9. Lateral basal segment of lower lobe,10 .Posterior basal segment of lower lobe

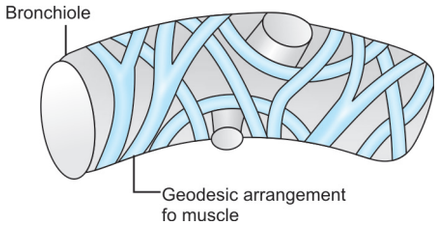

Fig. 2.8: The arrangement of muscle fibres on a bronchiole. The principal aim of this arrangement of muscles fibres in bronchiole is to permit the alterations of the length and width of the airway tube, during various phases of respiration. So, this type of arrangement of muscle fibres on airway is of great importance. This arrangement of muscle fibre on airway is known as the 'geodesic network' . A geodesic line in defined as the shortest distance between two points on a curved surface. Therefore, a geodesic pattern is the ideal method of withstanding or producing maximum pressures in a tubular structure without any tendency of being slipped of fibres along the surface of the tube

into secondary (lobar), tertiary (segmental) and numerous subtertiary branches up to alveoli. All these branches of bronchi run in the interlobular septa accompanied by the corresponding branches of the pulmonary arteries, pulmonary veins and bronchial vessels, till the preterminal bronchioles is reached when it leaves the interlobular septa and enter into the pulmonary or lung lobule at its apex. Actually the smaller branches of bronchi which leave the interlobular septa and enter the lung lobule are generally known as the bronchioles. A bronchiole is intralobular (not interlobular) and is devoid of cartilages and glands (Fig. 2.8).

Structurally, a bronchus is consist of from outside inwards are:

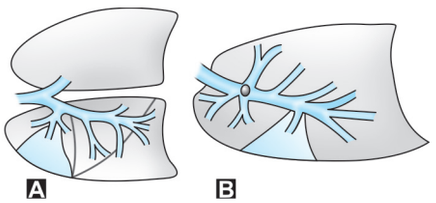
i. Fibro-elastic coat,
ii. Irregular plates of hyaline cartilages,
iii. Involuntary bronchial muscles which are helical in arrangements, and run in opposite directions, winding like a shoe - lace pattern,
iv. Mucous membrane which is ciliated columnar in nature and provided with goblet cells, mucous glands and numerous serous glands. Ultrastructurally, ten types of epithelial cells are present in the epithelial layer of tracheo bronchial air passage. Among them, the important cells are: ciliated, serous, goblet, brush, intermediate, clara and argentaffin cells.

In the bronchial mucous membrane the ciliated columnar cells are abundant in number and the ciliae are wrapped by low viscous or more serous fluid with their tip projected into it. This serous fluid is secreted by the serous cells and the mucous is secreted by the goblet cells. The brush cells are absorptive in functions. The intermediate cells are somewhat undifferentiated and probably help in regeneration of ciliated or secretory cells. The clara cells are nonciliated and are concerned with the secretion of some amount of surfactant. The argentaffin cells belong to the diffuse endocrine system of APUD cells series and secrete serotonin or histamine in response to the chemical or nervous stimuli.

Applied Anatomy

i. The breath sound over the right lung is more and distinctly audible than the left, because the trachea comes in more close contact with the right lung than the left one.
ii. Since the right principal bronchus is shorter, wider and more vertical than the left bronchus, so a foreign body is more likely to be aspirated in the right lung.
iii. The apical tertiary segment of the lower lobe (in supine position) and posterior tertiary segment of the upper lobe (lying on side) are the more common sites for lung abscess, becasue these segments are the most dependent part of lung in recumbent position. In such condition, the patient is advised to lie in the prone position which allows the infected material from these segments to accumulate in the principal bronchi and in the carina and subsequently the purulent material is expectorated out by stimulating the cough reflex (Fig. 2.9A and B).

Such natural drainage by adopting different postures may have some drawbacks. For example, pus from the apical segment of lower lobe may trickle in prone position through the opening of the middle lobe bronchus, because the mouths of the two bronchi are facing each other. In order to avoid such incidence, segmental resection of the apical segment of the lower lobe should be done. The apical segment of the lower lobe is most frequently involved in aspiration pneumonia (Memdelson's syndrome).



Figs 2.9A and B: Materials relationship between the posture and the common site of lung abscess. A. When a patient lies on his side, the common site of lung abscess is the posterior segment of the right upper lobe. Because inhaled mateirals easily collect in this broncho pulmonary segment. B. When a patient lies on his back, the common site of lung abscess is the apical segment of the right lower lobe

iv. The posterior segment of the right upper lobe is the most frequent site of tuberculosis.
v. The patency of middle lobe bronchus of both the lungs are particularly vulnerable to glandular swelling. Because they are closely related to the tracheobronchial group of glands (Fig. 2. 10).

LUNG

Actually the lungs are more a space than an organ. It is composed of serous coat, subserous coat and pulmonary substance or parechyma itself (from outside inwards). The serous coat invests the entire lung except the hilum and is derived from the pulmonary pleura. The subserous coat consists of thin elastic fibro-aleolar tissue and invests the whole lung under the serous coat. It again projects into the interior of the lung through the hilum as numerous fibro elastic septa and divide and subdivide the lungs. The smallest spaces between these septa are called the lung lobules. Each lung lobule is provided with one preterminal bronchiole and about 20,000 lobules are present in each lung.

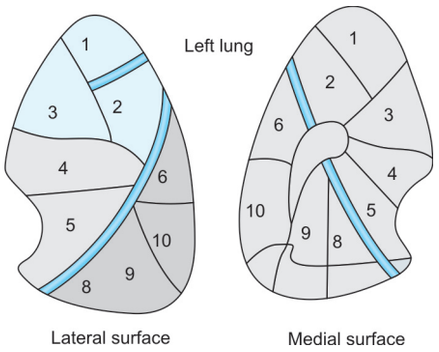


Fig. 2.10: Bronchopulmonary segments of left lung:

1. Apical segment of upper lobe, 2. Posterior segment of upper lobe, 3. Anterior segment of upper lobe, 4. Superior lingular segment, 5. Inferior lingular segment, 6. Apical segment of lower lobe, 7. Medial basal segment of lower lobe (may be missing), 8. Anterior - basal segment of lower lobe, 9. Lateral - basal segment of lower lobe, 10. Posterior - basal segment of lower lobe

Though the lung lobule is the anatomical pulmonary unit, but the alveoli is the functional or physiological unit of lungs. However, on the otherhand gas exchange occurs not only at the alveolar level but also in the respiratory bronchioles, alveolar ducts, atria and air saccules level. So, the area of lung supplied by the terminal respiratory bronchiole is actually the functional pulmonary unit. Hence, from the functional aspects the exact anatomical differences between these structures such as alveoli, air saccules, atria, alveolar ducts, etc. are not of great importance. The pulmonary alveoli are polygonal or polyhedral in shapes and are packed very tightly within the lung lobule. On an average, each alveolus is about 200 to 300 µm in diameter at functional residual capacity level and is sorrounded– by about 1800 capillary segment. The total length of the pulmonary capillary bed of both the lungs measures about 1500 miles and contains about 150 ml of blood. Each alveolus is lined by thin squamous epithelial cells with an insoluble thin film of lipoprotein, called surfactant spreading over it. The average thickness of this thin film of surfactant is 50Å in human being (Fig. 2. 11).

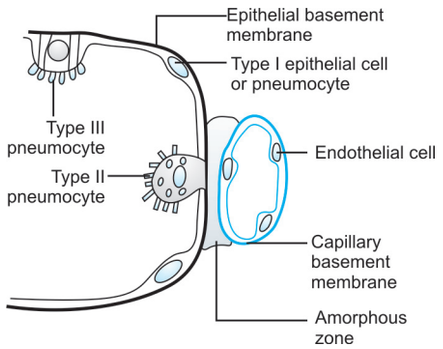

Fig. 2.11: Histology of the alveolus. In type I pneumocyte, the nucleus is situated at the angle of alveolus and its thin cytoplasmic extensions line most of the alveolar surface. Type II granular pneumocyte projects into the alveoli and are covered by microvilli. They produce surfactant and are essentially reserved cells which undergo hyperplasia when the type I pneumocytes are injured. Type III pneumocytes are pyramidal in shape with thick microvilli and contain filaments extending through the cell body. It resembles the chemoreceptor cells and have phagocytic property

Many structures interven between the air in the alveoli and the blood in the pulmonary capillaries and constitutes the pulmonary air-blood barrier through which gaseous exchange takes place. These structures are:

a. The flattened epithelial cells of alveoli which is about 0.05 µm thick,
b. The basement membrane upon which the alveolar epithelial cells rest,
c. The basement membrane of capillary endothelium on which the capillary endothelial cells rest. At some places these two basement membranes are fused, while in other places these are separated by an interval which is occupied by some undifferentiated mesenchyme or leucocytes,
d. the flattened endothelial cells of the capillaries. The total thickness of this air-blood barrier is about 0.2 to 0.5 µm.

The air surface of the alveoli is corrugated. This is due to the presence of capillaries and various subcellular structures. The alveoli share walls with the neighbouring alveoli and constitute a interalveolar septum between the two. Sometimes, there are some gaps in this septum which are called the alveolar pores. Thus, there is direct connection between the two alveoli through these pores.

There are three types of cells that line the alveoli and form the alveolar wall. These are: type I alveolar cells or membranous pneumocyte, type II alveolar cells or granular pneumocyte and type III alveolar cells or alveolar phagocytes. The type I alveolar cells are simple squamous epithelial cells and are connected with each other by tight junctions. They make up to 97% of the alveolar surface area and take part in gaseous exchange. The nucleus of these cells are situated at any one angle of it and a thin cytoplasmic extension lines most of the alveolar surface. The type II alveolar cells project into the alveoli and are covered by microvilli. They secret surfactant which by reducing the surface tension of alveolar living fluid helps to prevent the

collapse of alveoli during expiration. The surfactant fluid is rich in phospholipids, the principle constituent of which is dipalmitoyl phosphatidyl choline. The type II alveolar cells posses proliferative power and may replace the type I cells when they are injured. Alveolar phagocyte or type III alveolar cells are derived from the monocytes of blood. They appear within the alveoli by active migration through the air blood barrier. These cells phagocyte the bacteria, dust particles and other debris materials which enter the alveoli. Then, they move towards the bronchioles where the phagocytosed materials are eliminated by coughing. In congestive heart failure, alveolar phagocytes engulf the extravasated red blood cells and produce brick red or pinky sputum. So, these cells are sometimes also called the heart failure cells.

Pulmonary Vessels

Pulmonary Arteries

Each lung is provided with one pulmonary artery which is derived from the pulmonary trunk arising from right ventricle and conveys deoxygenated blood to the lung. Within each lung the branches of the pulmonary artery follow the division and subdivision of the bronchial tree and supply the corresponding bronchopulmonary segments by forming capillary plexus around the alveoli. So the pulmonary arteries are segmental in distribution. Usually, they supplies the deoxygenated blood to the alveolar capillary plexus and nutrition to the respiratory part (not conducting part) of the lung. The branches of the pulmonary and bronchial arteries anastomose with each other around the intrapulmonary part of bronchi and bronchioles, but they have different vascular pressure. In stenosis or embolism of pulmonary artery the bronchial artery supply the nutrition to the respiratory part of the lungs.

Pulmonary Veins

Each lung presents two pulmonary veins–upper and lower and so there are total four pulmonary veins. Upper pulmonary vein of right lung drains the blood from the upper and the middle lobes. While the upper pulmonary vein of the left lung drains the blood only from the upper lobe. Lower pulmonary vein drains the blood from the lower lobe of the respective lung. The pulmonary vein begins from the capillary plexus around the alveoli and terminates directly into the left atrium. In the peripheral part of the lung the pulmonary veins are intersegmental in position (whereas pulmonary arteries are segmental in distribution) and receive the blood from a number of broncho-pulmonary segments. Pulmonary vein does not convey 100% oxygenated blood from the alveoli to the left atrium. Because it receives some deoxygenated blood from the deep bronchial veins.

Bronchial Arteries

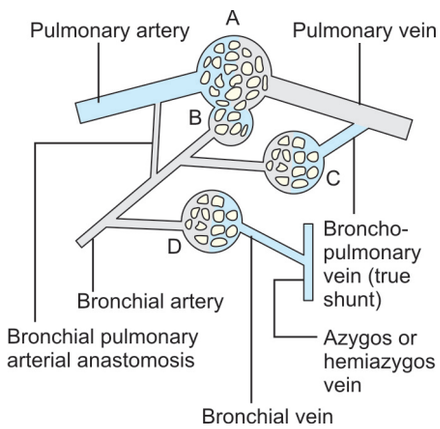
Usually they are three in number — two on the left side and one on the right side. The two left bronchial arteries, supplying the left lung arise from the thoracic aorta, and the single right bronchial artery, supplying the right lung arises either from an intercostal artery or from the upper left bronchial artery. In addition to these three main bronchial arteries, there are other many smaller bronchial arteries.

On entering the lung through hilum, the bronchial arteries make themselves embeded in the connective tissue layer around the bronchus and then run along the divisions and subdivisions of the bronchial tree, until the distal end of the terminal bronchiole is reached. Up to this level the bronchial arteries supply the O_2 and nutrition to the conducting part of the airways and then ultimately drain through bronchial vein into the azygos, hemiazygos, or intercostal vein.

After reaching the terminal bronchiole, the bronchial arteries start to break into multiple branches and produce a distinct set of capillary plexus. Gradually this capillary plexus fuses with the plexuses that is formed around the alveoli by the branches of pulmonary artery and ultimately drain through the pulmonary veins. Some branches of bronchial artery form plexuses around the airways below the level of terminal bronchiole and ultimately drain directly into the plumonary vein through broncho-pulmonary vein. They constitute the true shunt (Figs 2.12A to D).

Bronchial Veins

These veins consist of two systems—superficial and deep. The superficial bronchial veins drain blood from the pleura and the conducting part of bronchi. From the right lung the superficial veins drain into the azygos vein, whereas from the left lung it drains into the hemiazygos and left superior intercostal vein. The deep bronchial vein receive blood from the respiratory part of bronchi and terminate into one



Figs 2.12A to D: Relationship between the bronchial and pulmonary circulation.

A. Represents the pulmonary capillary network around the alveoli, atrium, alveolar duct and respiratory bronchiole (gas exchanging part). It is supplied by the pulmonary artery and drained by the pulmonary vein.

B. Represents the bronchial capillary network which joins with pulmonary capillary network (A) and drains through the pulmonary vein.

C. Represents the capillary network around the bronchi which does not communicate with pulmonary capillary. These vessels form the bronchopulmonary veins and empty into the pulmonary veins (true shunt).

D. Represents the bronchial capillary network around the lobar and segmental bronchi (conducting airway). These networks form true bronchial veins which drain into the azygos, hemiazygos or intercostal veins.

of the pulmonary veins. Thus, the superficial bronchial veins drain into the right heart and the deep bronchial veins drain into the left heart (true shunt).

Therefore, the lungs get its nutrition from two sources: (i) the conducting part of the respiratory passage upto the beginning of respiratory bronchiole or the distal end of terminal bronchiole is supplied by the bronchial arteries, and (ii) the respiratory part is supplied by pulmonary arteries via the pulmonary capillary plexus.

Innervation of Lungs

The lungs are innervated by both the sympathetic and parasympathetic nerves. The post-ganglionic sympathetic fibres are derived from the 1st to 4th thoracic ganglia, inferior cervical ganglion and sometimes from the middle cervical ganglion of sympathetic chain. The parasympathetic supply to the lungs is derived from the vagus and joins with the sympathetic fibres to from the posterior pulmonary plexus behind the roots of the lungs. The fibres from these posterior plexus also pass in front of the root of the lungs and again form the anterior pulmonary plexus.

The pulmonary plexuses (posterior and anterior) divides into two—periarterial and peribronchial plexus. The peribronchial plexus again divides into two—extra chondrial and intra-chondrial plexus, in relation to the cartilagenous ring. On reaching the non-cartilagenous part of the bronchial tree these two plexuses again reunite and continue distally as one. For parasympatheitc system, the peripheral ganglia are found at the level of the bronchial tree. The short postganglionic fibres arise from this peripheral parasympathetic ganglia and reach the bronchial smooth muscle, gland, and other structures.

In all the probability, the glands of bronchial tree are innervated by only vagus. Regarding the vessels, vagus carries the cholinergic vasodilator fibres and sympatheitc carries the adrenergic vasoconstrictor fibres.

MECHANISM OF RESPIRATION

Introduction

The respiration is divided into two processes: Inspiration and expiration. Among these, the inspiration is defined as active and the expiration is defined as passive process. In quiet resting state of breathing, the inspiration persists for about 1 second and the expiration persists for about 2 to 3 seconds. So, in adult the normal respiratory rate varies between 16 to 20 per minute. In infant, this respiratory rate ranges between 30 to 40 and in children it ranges between 25 to 30 per minute. The inspiration involves the expansion of chest cavity by (i) the downward movement of diaphragm, so as to increase longitudinal length and (ii) the elevation of the ribs by contraction of the intercostal muscle so as to cause the increase in antero-posterior and transverse diameter of chest. As expiration is passive process, so it involves all the reverse movement which occurs in inspiration. Thus, respiration is accompanied by respiratory muscles which again is controlled by the respiratory centre.

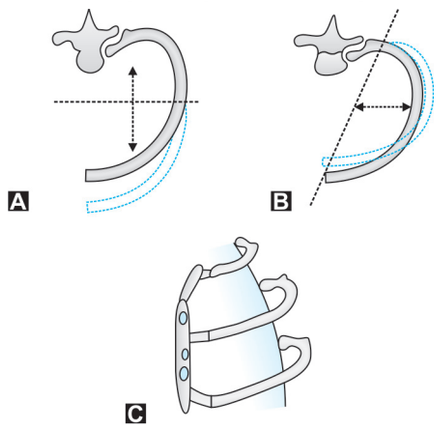
Respiratory Muscles

The respiratory muscles have got no inherent rhythmicity for constraction. But, they contract at a certain intervals by the motor impulses, originating from respiratory centre situated at the cortex (voluntary), midbrain, medulla and pons in brain. Diaphragm is a large, dome shaped sheet of muscle and separates the thoracic cavity from the abdominal cavity. It is the only principal muscle of inspiration that take part in quiet breathing. But, it is not absolutely essential for breathing. Because in absence of it other muscles also can take the responsibility of it. Contraction of diaphragm increases all the three diameters (vertical, anteroposterior, transverse) of thorax and helps in inspiration (Figs 2.13A to C).

On the otherhand, it (diaphragm) is the only inspiratory muscle in neonates and infants. Because all the ribs at this age are horizontal and movements of the ribs by contraction of the intercostal muscles can not increase the diameters of the thorax. The oblique direction of the ribs appears after the age of second year. Hence, the respiration below the second year is predominantly abdominal in type, depending only on diaphragm. Again the diaphragm becomes essential for maintenance of respiration during anaesthesia, because the intercostal muscles become early paralysed and become inactive during anaesthesia than the diaphragm. Besides these, in condition of paralysis of the intercostal muscle due to disease or spinal and epidural anaesthesia, only the diaphragm can maintain the basic respiration. This diaphragmatic respiration is known as the abdominal type of respiration.

The diaphragm is supplied by the phrenic nerve which takes origin from the spinal cord by the anterior roots of 3rd, 4th and 5th cervical spinal nerve. So, during high central neuroaxial block such as thoracic epidural where the level of anaesthesia extends below the level of the cervical segments, the respiration also can be maintained only by the diaphragm. This is because maximum intercostal muscles become paralysed in such condition.

The intercostal muscles move the ribs and thus help in inspiration and expiration



Figs 2.13A to C: A. Pump - handle type of movement, B. Bucket–handle type of movement, C. Ribs and their movements at manubrio - sternal joint

with the diaphragm. Among them the external intercostal muscles elevate the ribs and cause active inspiration. While the internal intercostal muscles depress the ribs and cause active expiration. But, we will have to keep in mind that the internal intercostal muscle does not take part in normal passive expiration. External intercostal muscles run obliquely downward and forward from the upper ribs to the lower ribs. So, when they contract they elevate the lower ribs. This pushes the sternum outward and increases the antero-posterior diameter of the chest. In this movement the transverse diameter of thoracic cavity also increases along with the AP diameter, but to a lesser extent. On the other hand, the internal intercostal muscles run obliquely downward and posteriorly from upper ribs to lower ribs. Therefore, contraction of these muscles cause downward pull on the rib cage which is opposite to the movement of inspiration and thus produce expiration. The movements of the upper six ribs increase mostly the antero-posterior diameter of the thorax. Whereas the movements of the lower ribs widen mainly the transverse diameter of the thorax. The electromyographic studies suggest that the lower intercostal muscles are active in quiet breathing and upper intercostal muscles are only involved progressively during deep respiration. Increase in 1 cm of circumference of thorax during inspiration allows about 200 ml of flow of air into the lungs.

The scalene group of muscles and the sternomastoid muscles are active only during deep and active inspiration. The scalene group of muscles elevate the first and second ribs, while the sternomastoid muscle elevates the clavicle. In quiet respiration the first and second ribs and the clavicle remain fixed and does not take part in respiration. The pectoral group of muscles and serratus also help in only forced inspiration. It works only when the bones of upper limbs are fixed. The erector spinal muscles make the thoracic part of the vertebral column straight and helps it to act as a pivot against which other muscles can act and bones can move. Thus, it also facilitates the spreading of the lower ribs with widening of the infra-sternal angle and so help in deep inspiration. The quadratus lumborum muscle fixes the last rib and helps in the action of diaphragm during deep inspiration. The other accessory muscles that take part in decreasing the resistance of air flow and help in respiration are the mylohyoid, digastric, alae nasai, platysma, cheeck muscles, lavator palati, laryngeal muscles, tongue muscles, the posterior neck muscles, etc. During muscular exercise when the ventilation increases manifold, then all the accessory muscles of respiraton including the trapezius and back muscles also take part in the action.

As previously said that the expiration is a passive process and it is due to the elastic recoil property of lungs and thoracic cage, so during inspiration the potential energy is gained due to the contraction of the inspiratory muscle and during expiration this stored energy is released by the elastic recoil property. But, only the few muscles come into action during forced expiration. These are the flat muscles of anterior abdominal wall (external and internal oblique, transversus abdominis, rectus abdominis), lattissimus dorsi and internal intercostal muscles. The contraction of the muscles of the anterior abdominal wall aid in expiration by pulling the rib cage downward. Muscles of the anterior abdominal wall also compress the abdomen and increases the intra-abdominal pressure. Thus, it displaces the diaphragm upwards and the volume of thoracic cavity is diminished, causing expiration. In normal breathing they are practically inactive, but during coughing, sneezing, etc, they become highly active. Latissimus dorsi also reduces the thoracic volume by compressing the thorax from behind.

The anteor-posterior diameter of thorax is increased by the elevation of the ribs, mainly from 2nd to 6th. An oblique axis passes through the costovertebral and costotransverse joints of the neck of the ribs of one side and the costochondral junction of the opposite site. When the ribs move around this axis, then the antero-posterior diameter of thorax is increased. This is caused by the contraction of external intercostal muscles of one side and the internal intercostal muscles of the opposite side due to their same fibre direction. This movement of ribs is called the pump-handle type of movement. In this type of movement, the body of sternum moves forward during elevation of the ribs (at the sterno-manubrial joint) during inspiration and swings backward during expiration. The first rib and the manubrium sterni form a rigid unit and do not move in quiet breathing, except during forced inspiration. The 2nd to 6th ribs sloped downwards and forwards with their cartilages. So, their elevation cause forward and upward movement of the body of the sternum and increases the antero-posterior diameter.

The 7th to 10th ribs is sloped downward and forward, but their cartilages are directed upwards and medially to join the body of the sternum. So, the movement of these ribs around this oblique axis causes backward movement of the sternal body at the sterno-manubrial joint and diminishes the antero-posterior diameter. Therefore, two opposite forces work together at the sterno-manubrial joint. Movement of upper ribs produces forward movement and movement of lower ribs produces backward movement. Thus, this explain the formation of sternal angle at the junction between the manubrium and the body of the sternum.

The transverse diameter of thoracic cavity is increased by two methods—active and passive. Active process is observed between 7th to 10th ribs. Here, the movement takes places around an axis which passes through the costovertebral and the costosternal joint of the same side. Movement of these ribs around this axis

causes elevation of the middle portion of the ribs, resembling bucket handle type of movement and increase the transverse diameter of thorax. Movement of 2nd to 6th ribs around the oblique axis which increases the antero-posterior diameter also increases the transeverse diameter of thorax passively. This passive increase of transverse diameter is facilitated by the curved nature of the articular surfaces of the costotransverse joint.

The vertical diameter of thorax increases due to up and down piston like movement of diaphragm. It also helps to increase the transverse diameter. Initially during inspiration when the diaphragm contracts, the lower ribs become fixed and the central tendon or vault of the diaphragm descents. This central descent of diaphragm causes downward displacement of the upper abdominal viscera and bulging forward of the anterior abdominal wall. When a limit of the forward bulging of the anterior abdominal wall is reached then the descent of diaphragm ceases and the central tendon becomes fixed. After that, during further contraction of diaphragm, i.e. when the central tendon is fixed, the lower ribs are elevated by the bucket handle type of movement and the volume of thorax is further increased by widening of the transverse diameter. In quiet breathing the range of this piston like diaphragmatic movements is about 1.5 cm which can be increased between 6 to 10 cm in forced respiration. In normal respiration, when the diaphragm descends about 1.5 cm, the thoracic volume is increased by about 400 cc. Normally out of 500 cc of tidal air, 400 cc is due to this 1.5 cm movement of diaphragm.

SUMMARY

The lungs can be inflated or deflated by two ways:

i. By downward and upward movement of the diaphragm which increases or decreases the volume of chest cavity and subsequently the volume of lungs.
ii. By elevation and depression of the ribs which increases and decreases the antero posterior and transverse diameter of the chest cavity and subsequently the volume of lungs.

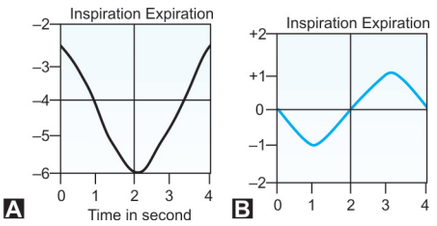
The normal quiet breathing is almost entirely accomplished by the movement of diaphragm. During inspiration diaphragm contracts and increases the volume of lungs, the mechanism of which is described before and air is rushed in. During expiration the diaphragm simply relaxes. Thus due to the elastic recoil property of the lungs, chest wall and abdominal structures all compress the lungs and air is rushed out.

But, during heavy or active breathing the second method of expansion of lungs by the rib cage comes into play. In natural resting position, the ribs are slanted downwards. But, when the rib cage is elevated by the muscular contraction, then the ribs project forward and upward directly. Thus, the sternum also moves upward and forward away from the spine, increasing the antero-posterior diameter of thoracic cavity. With the forward elevation of the ribs, there is also buckle handle type of movement of ribs which increase the transverse diameter of the rib cage. Therefore, the muscles that elevate the chest cage are called the muscles of inspiration and the muscles that depress the chest cage are called the muscles of expiration. So, the muscles of inspiration are: the external intercostal (main inspiratory muscles), the sternocleidomastoid (by lifting the sternum upward), anterior serratus (by lifting many of the ribs where it is attached), scaleni (by lifting the first two ribs). The last three muscles are called the helping inspiratory muscles. The muscles of expiration are : abdominal recti (by pulling downward the lower ribs and at the same time with other abdominal muscles by compressing the abdominal contents upward against the diaphragm) and internal intercostal (by pulling the ribs downward due to the downward and backward direction of their attachment).

Intrathoracic and Intrapulmonary Pressure

Under normal resting condition when there is no inspiration or expiration, then the intra-thoracic pressure, more precisely called the intrapleural pressure is sub atmospheric and measures about –2 mm of Hg. In similar condition the intra-alveolar or intra-pulmonary pressure is zero i.e equal to the atmospheric pressure.

The chest wall and the lung is covered by a thin layer of membrane which is known as the parietal and visceral pleura, respectively. This two layers of pleura are separated by a thin layer of fluid, called the pleural fluid which lubricates the movement of lungs within the chest cavity. The pressure within the space, between these two pleura, is called the intrapleural pressure. Theoretically, this intra pleural pressure is -8 to -10 mm of Hg. This negative intra pleural pressure is caused by the more rapid absorption of pleural fluid by the lymphatics and by the capillaries of the visceral pleura, since such lymphatics and capillaries are belonged to the low pressure pulmonary circulatory system. On the other hand, the value of pressure on the pleural surface due to the contact between the visceral and parietal pleura is about + 6 mm of Hg. So, the resultant practical intra pleural pressure which we measure is the theoretical intra pleural pressure due to absorption of fluid plus the intra pleural contact pressure i.e –8 + 6 or –2 mm of Hg. But, this value is an average one. Actually, the intrapleural pressure at the base of the lungs which is normally about –2 mm of Hg at the start of the inspiration, decreases to about –6 mm of Hg at the end of inspiration in quite breathing. Strong inspiratory efforts increase this negative intrapleural pressure to values as low as –30 mm of Hg or more, producing corresponding greater degrees of lung inflation (Figs 2.14A and B).



Figs 2.14A and B: A. It is the graphical representation of changes in intrathoracic or intrapleural pressure during respiration. B. is the graphical representation of changes in intra-pulmonary or intraalveolar pressure during respiration

Such negative intrapleural pressure which helps the lungs to inflate allows the visceral and parietal pleura to come in close contact with each other as if they are glued together. But, the presence of thin intraplural fluid allow the free movement of these two pluras when the chest contracts and expands. The lungs tissues possess an inherent elastic property to recoil from the chest wall, but this negative intrapleural pressure prevents this. Thus, the intrapleural pressure being subatmospheric keeps the lungs in apposition with the chest wall and make it partially inflated. But, if the chest wall is opend to atmosphere, the lungs will collapse due to its inward recoling elastic property and due to the absence of subatmospheric intraplural pressure. On the otherhand, if the lungs lose their recoil property or elasticity, it remains in inflated or expanded condition and becomes barrel shaped. It is estimated that one-third of the inward recoiling elastic force of the lungs is derived from the stretched elastic fibres within it such as elastin, collagen, etc. and two thirds from the surface tension of the fluid, lining the alveoli.

At rest, when there is no inspiration or expiration the intrapulmonary or intra-alveolar pressure is maintained at 0 mm of Hg (i.e. same as the atmospheric pressure or 760 mm of Hg). So, at this condition no air enters in or comes out of the lungs. During inspiration, as lungs expand due to more and more subatmospheric intrapleural pressure which is again due to expansion of chest wall, then the intra-alveolar or intra pulmonary pressure gradually falls and air rushes into the lungs. Thus, during inspiration the intra-alveolar pressure gradually falls from 0 mm of Hg to about –2 or –6 mm of Hg (at that time intrapleural pressure also falls from –2 mm of Hg to –6 or –10 mm of Hg or more). During deep inspiration this intrapleural pressure becomes more sub-atmospheric and this is due to the active contraction of respiratory muscles. That active contraction of respiratory muscles try to create more negative intrapleural pressure and subsequently more negative intra-alveolar pressure to overcome the different resistances such as elastic recoil of lung, frictional resistance due to deformation of tissues of the lungs and thorax, and frictional airway resistance which prevents the expansion of thorax and lungs from the entry of air into it. At the end of the inspiration maximum sub atmospheric intra pleural pressure is maintained. During forced inspiration, intra-alveolar and intra-pleural pressure may be as low as -40 mm of Hg and -50 mm of Hg respectively. At the end of inspiration, intra-alveolar pressure gradually comes back from sub atmospheric to 0 or atmospheric level, like at the begining of inspiration, due to filling of lungs by air and thus air flow ceases (Fig. 2.15).

During normal expiration, the volume of thoracic cage and the volume of lung decreases passively due to the inward elastic recoiling property of lung parenchyma and chestwall tissues. Thus, the intra-alveolar or intrapulmonary pressure rises above the atmospheric level. It generally goes up to + 3 or + 4 mm of Hg and permits exit of air from the lungs. At that time the intrapleural pressure also comes back from -6 mm of Hg to –2 mm of Hg, but always remains –ve. When forced expiratory efforts are made with closed glottis, such as during muscular exercise, defaecation or micturition. etc, then the intrapulmoanry pressure may go up from +10 mm of Hg to +40 mm of Hg. In coughing and

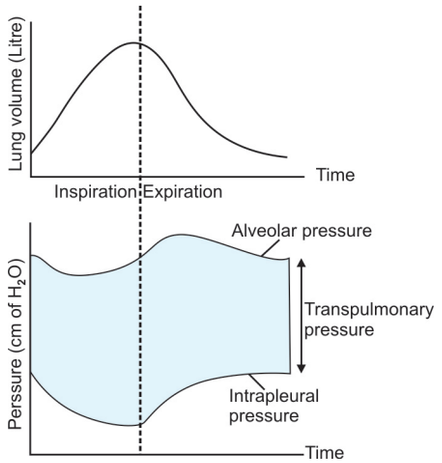


Fig. 2.15: Changes in alveolar pressure, intrapleural pressure, transpulmonary pressure and lung volumes during normal inspiration and expiration

sneezing, the intrapulmonary pressure may also go far above the normal level and may be +100 mm of Hg with glottis closed. At the end of the expiration, when air stops to exit then the intra-alveolar pressure again gradually comes down to atmospheric or zero level.

Thus, it is to be noted that during normal inspiration and expiration the changes of pressure within the lungs (or the intra-alveolar pressure) go both above and below the '0' line or the atmospheric pressure. But, pressure changes in the pleura (i.e intra-pleural pressure) always remain below the '0' line or sub atmospheric level (i.e negative) and pressure level in the abdomen always remain above the '0' line (i.e positive). The difference between the intra-alveolar pressure and the intra-pleural pressure is called the transpulmonary pressure. Actually it is the pressure difference between the inside and outside of the lungs and is equivalent to the elastic forces of the lungs that tends to collapse it at the each moment of respiration.

The physical principles that determine the respiration are the production of pressure gradient between the interior of the lungs and the atmosphere. According to the physical laws, the air will flow from the higher pressure head to the lower one.

During inspiration, the intra-alveolar pressure falls below the atmospheric one and so air rushes in. But during expiration, the intra-alveolar pressure goes above the atmospheric pressure level and air goes out. Thus, the normal breathing is called the negative pressure breathing. But, if the atmospheric pressure is raised above the intra-alveolar pressure to push the air into the lungs during inspiration, then this type of respiration is called the positive pressure beathing which is used in general anaesthesia with complete muscle paralysis.

Compliance of the Lungs

The compliance is a stretching force which is opposite to the elastic force that tries to collapse the lungs. It is measured as the change of volume of lungs during expansion of it for each unit increase of transpulmonary pressure. The average total compliance of both the lungs together in an adult human being is 200 ml per cm of H_2O (or 0.2 L/cm of H_2O) transpulmonary pressure. It means that for increase in every cm of H_2O of transpulmonary pressure, the total volume of both the lungs will expand to 200 ml. Therefore, the compliance of single lung is 100 ml per cm of H_2O (or 0.1 L/cm of H_2O).

Usually, the compliance of lungs is represented diagrammatically by two curves. Among these, one is called as the inspiratory complaince curve and the other is called as the expiratory compliance curve. While the entire diagram represents the total compliance of the lungs.

It is previously told that compliance which is defined as the stretching force is opposite to the elastic forces (or elasticity). So, compliance of lungs is best understood and calculated from it (elasticity). On the other hand, elasticity has two components: (i) elasticity caused by the lung tissue or parenchyma itself, and (ii) elasticity, caused by the surface tensin of fluid lining the inside of alveoli. The elastic forces (elasticity) of the lung parenchyma is caused by the interwoven elastin and collagen fibres, situated in the parenchyma of lungs. In completely collapsed lungs these fibres are in completely contracted state. Thus, when the lungs expand these fibres become stretched and thereby exerts an elastic forces which prevents the expansion and reduce the compliance (Fig. 2.16).

The elasticity caused by the surface tension of alveoli is more interesting. On the inner side of the alveolar wall there is always some thin layer of fluid. So, when the lungs are filled with air, there is always an interface between the fluid and the air in the alveoli. This fluid and air interface in the alveoli is responsible for the surface tension which try to collapse the alveoli and subsequently the lungs. This is because, when a fluid have a surface with air, then the fluid molecules on the interface with air have a force of strong attraction for one another. This is called the surface tension. As a result, the fluid surface towards the air always tries to contract and takes the smallest spherical shape. Thus, the alveoli with their fluid surface try to collapse, forcing the air out of the lungs. This elastic force caused by the fluid-air surface tension in the alveoli is two-third of the total lung elasticity. On the other hand, the tissue elasticity due to stretching of elastin and collagen fibres represents only about one third of the total lung elasticity.

The surfactant is a chemical surface active agent which greatly reduces the surface tension of liquid. This chemical agent or surfactant is present in the fluid lining the alveoli and subsequently reduce the contractile elastic force of the lungs due to surface tension (not due to elastin and collagen fibres of lung parenchyma). In the absence of this surfactant, the surface tension in the alveoli and subsequently the contractile elastic forces due to this surface tension will increase tremendously and then, it is not possible to inflate the lungs. This chemical agent or surfactant is the complex mixture of many phospholipid, proteins and ions. Among these components the most important components are: Dipalmitoyl phosphatidylcholine (DPPC), apoproteins and calcium ions. They act by not completely dissolving in the fluid, lining the alveoli, but remain spread over the surface of the fluid that lines the inner side of the alveoli.

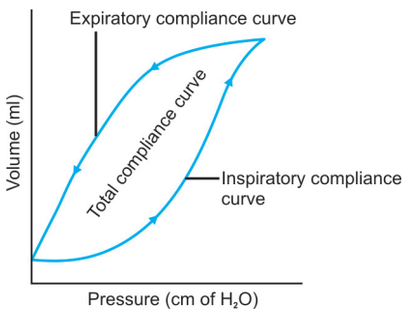

Fig. 2.16: Two compliance curves of lung

Due to surface tension alveoli tends to collapse. Thus a increased pressure is generated within the alveoli. This pressure or contractile force can be calculated from the following formula of Laplace law :

$$\text{Pressure (P)} = \frac{\text{2 wall tension (T)}}{\text{Radius of alveolus (r)}}$$

From the above formula, it is noted that the pressure which is generated in the alveoli from its contraction due to surface tension is inversely proportional to the radius of that alveolus. It means that the smaller the radius of the alveolus will be, the greater will be the alveolar pressure generated by the increased collapsing force due to increased surface tension. Therefore, when the alveoli decrease in size during expiration, then the pressure tending to collapse or collapsing force will increase and thus a vicious cycle will be established. But, in practical this does not occur, because as the alveoli are coated with surfactant which reduces the surface tension and as the alveoli decrease in size during expiration, so the amount of surfactant per unit area of alveolar surface will also increase and reduces the surface tension more than the expected. Thus, the action of surfactant will be more efficient when the alveoli will decrease in size. Therefore, contrary

to Laplace's law, the smaller alveoli can be inflated more easily than a larger one in the presence of surfactant. If there was no surfactant, the larger alveoli would tend to inflate further at the expense of smaller ones which would collapse.

The radius of a normal adult alveoli is 100 micrometers. The normal value of surface tension in such alveoli created by the lining fluid with normal amount of surfactant varies between 5 to 30 dynes/cm. Then, the intra-alveolar pressure is calculated to 4 cm of H_2O. In newborn the radius of the alveoli is 50 micrometers which is half than that of the adult. In such situation pressure generated by collapsing alveoli due to the surface tension will be doubled, with normal amount of surfactant. This is more significant in premature newborn where the radius of alveoli is more or less one quarter than that of an adult person. Here, pressure inside the alveoli due to collapse increases to four fold. Further, many premature newborn has little or no surfactant in their alveoli. So, their lungs have extreme tendency to collapse which is sometimes as great as eight times than that of a normal adult person. This explains why such patients need high positive pressure ventilation.

RESPIRATORY CENTRE AND ITS REGULATION

The normal rate of respiration in an adult healthy individual is about 14 to 18 per minute, with a tidal volume of about 500 ml. But the rate and depth of respiration i.e. the total pulmonary ventilation per minute varies according to the requirements of the body.

The important functions of respiration are:

i. To supply the adequate amount of O_2 and to eliminate CO_2,
ii. To regulate H^+ ion concentration of blood,
iii. To maintain the temperature balance of the body
iv. To excrete volatile substances like ammonia, ketone bodies, alcohol, water vapour, etc.
v. To help in circulation. During inspiration the intrathoracic pressure falls and intra-abdominal pressure rises. This is one of the most important factors that help in the return of venous blood to heart and lymph in the circulation.

Whenever these requirements increase, then the respiration is stimulated. For example, when the metabolic rate increases due to any cause, then the necessity for supplying more oxygen and the necessity for eliminating more CO_2 will also rise. In this condition, blood will tend to become more acid and heat production will be more. So, to maintain these factors at the normal level, respiration will also have to be stimulated. This is also found in muscular exercise, when the pulmonary ventilation rises enormously. On the other hand, during sleep the metabolic requirements are low, hence the respiration is also depressed. As a whole, it can be stated that the total pulmonary ventilation is directly proportional to the metabolic need of the body. Since, as the rate and depth of respiration can be accurately adjusted according to the body needs, so it is necessary that there must be an efficient mechanism for its regulation.

The spontaneous respiration is produced by the rhythmic discharge of impulses from some motor neurons of higher respiratory centre which are situated in the brain and that innervate the respiratory muscles through the cervical and thoracic segment of spinal cord. This rhythmic discharges of impulses from the respiratory centre that produce spontaneous repiration are regulated by the alternations of the arterial PO_2, PCO_2 and H^+ concentration (chemical regulation). Again this chemical control of breathing is supplemented by a number of other nonchemical stimuli (nervous regulations) that also have influences on it (Fig. 2. 17).

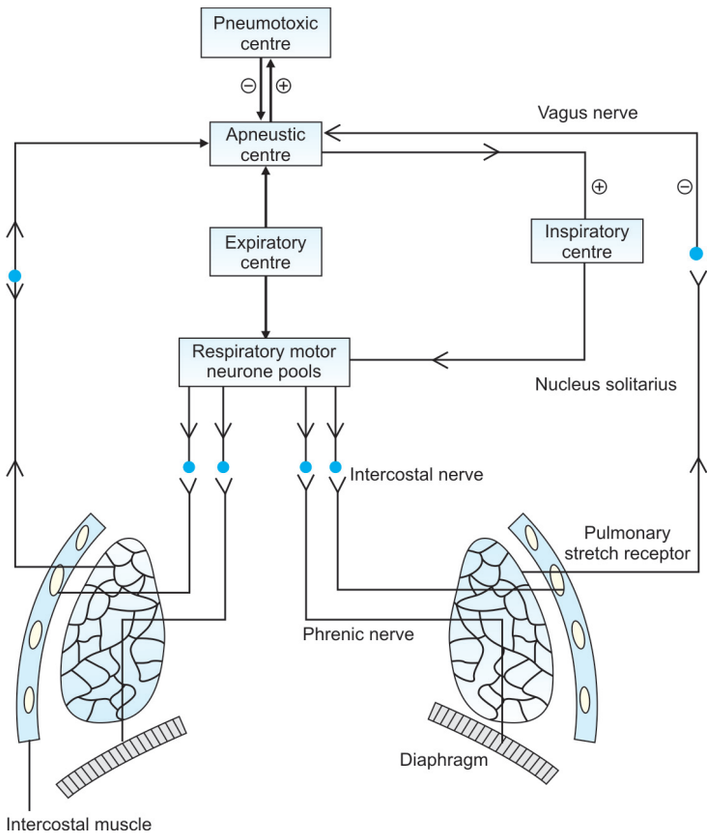

Fig. 2.17: Diagrammatic representation of central respiratory mechanism

Usually, two separate neural mechanisms regulate the respiration. Among these one is responsible for the voluntary control and the other is responsible for the automatic rhythmical control. The centre for voluntary control of respiration is located in the cerebral cortex and sends impulses directly to the respiratory motor neurons (not the respiratory centre) supplying the diaphragm and the intercostal muscles, situated in the spinal cord (cervical and thoracic segment) via the corticospinal tracts. On the otherhand, the automatic rhythmical control of respiration is driven by a group pacemaker cells situated in the brainstem, medulla and pons which are called together the respiratory centre (RC). Impulses from these cells activate rhythmicaly the motor neurons in the cervical and thoracic segment of the spinal cord that innervate the inspiratory muscles. Those in the cervical segment of spinal cord activate the diaphragm via the phrenic nerves and those in the thoracic segment of spinal cord activate the external and internal intercostal muscles.

The motor neurons to the expiratory muscles are inhibited when those supplying the inspiratory muscles are activated and vice versa. This is called the reciprocal innervation of RC. Thus, the mechanism of regulating the respiration has been arbitarily divided into three parts: Respiratory centre, nervous regulation and chemical regulation.

Respiratory Centre

It has been suggested that there are certain collection of nerve cells in the brainstem, medulla and pons (although they does not form a descrete structure) that control the respiratoy movements of chest wall and diaphragm. These collection of nerve cells together is called the respiratory centre which under normal circumstances generate the rhythm of breathing and organize respiration. However, this organisation of the respiratory centre is very complex and include several subcentres. These subcentres on each side consists of inspiratory centre, pneumotoxic center, apneustic centre and expiratory centre which are located at various level of the brainstem, medulla and pons.

These respiratory subcentres are bilateral with the same and contralateral sided control. They also freely communicate with each other. Connections exist within the similary acting centres of the opposite sides and within the oppositely acting centres of the same side. For example an impulse that stimulates one centre, will inhibit the other and vice versa. But the center of one side controls the respiratory muscles of the same side. Thus, the respiratory centre of right side is connected to the spinal motor neurons of the phrenic and intercostal nerves, supplying the muscles of respiration of the right side.

Though, there is much uncertainty regarding the actual site of the origin of respiratory rhythmicity, but still it is generally thought that there is an inherent rhythmicity in the certain groups of respiratory neurons in the brainstem which is modified by other affarent inputs. At present the established theory is that the first primary inspiratory drive comes from the apneustic centre to the inspiratory centre. Then, the inspiration starts with the increasing activity of the inspiratory centre. During inspiration, the tonic impulses from the apneustic centre also excite the pneumotoxic centre to sent in turn the inhibitory impulses from pneumotoxic centre to the apneustic centre. At the height of inspiration, the inhibitory impulses from the pneumotoxic centre, as well as inhibitory impulses from the pulmonary stretch receptors through vagus depress the apneustic centre. Thus, inspiration is ceased and the expiration starts passively. Expiration is normally a passive process during quiet breathing. But, it becomes active during exercise. During expiration the same inhibitory effects on the apneustic centre are no longer present and so inspiration starts again. Thus, this process is repeated again and again. It is probable that the medullary inspiratory centre is not under direct control of pneumotoxic centre, but under the direct control of pontine apneustic centre. With the inhibition of the inspiratory centre, the expiratory centre starts functioning, keeping in mind that in quiet breathing expiration is passive. The expiratory centre functions actively only during active expiration, but not during quite breathing.

SUMMARY

i. The activity of two feedback mechanism such as the inhibitory vagal affarent impulses from pulmonary stretch receptors and the negative impulses from pneumotoxic centres have got probably no direct inhibitory control upon the inspiratory centre or direct stimulating effect upon the expiratory centre.
ii. The apneustic centre probably sends tonic discharges simultaneously to the inspiratory centre and to the pneumotoxic centre.
iii. The inspiratory centre discharges impulses to the spinal motor neurons supplying the respiratory muscles for normal inspiratory efforts.
iv. The pneumotoxic centre in its turn discharges inhibitory impulses to apneustic centre.
v. The apneustic centre being inhibited by the inhibitory impulses from the vagi and also from the pneumotoxic centre ceases to stimulate the inspiratory centre.
vi. The inspiratory centre ceases its activity and expiration follows passively.

Nervous Regulation

In nervous regulation of respiration, the respiratory centres are regulated by few reflexes conducted through different nerves and centres. These are as follows:

Vagus Nerve

The rhythm and the depth of respiration are controlled by reflexes from the lungs itself which pass through the vagus. This

reflex is called the Hering-Breuer reflex. This is an inflation reflex and the pulmonary stretch receptors are responsible for this. These receptors are unencapsulated and are found in the smooth muscle of the airway without an end organ. They are generally believed to be responsible for signalling the changes of mechanical state of the lungs to the brain. During inspiration the stretching of pulmonary tissue send inhibitory impulses to the apneustic centre which subsequently for this inhibitory effect fails to send stimulatory impulses to inspiratory centre. When inspiration is going on, then due to the gradual increase of the volume of lungs more and more inhibitory impulses pass to the apneustic centre and at the maximum inhibition of apneustic centre inspiration stops. Then, passive expiration starts and the inhibitory impulses to the inspiratory centre gradually wane. When this inhibitory impulses over the inspiratory centre completely wane or totally withdrawn during expiration, then inspiration again starts.

The afferent nerve endings responding to both the mechanical and chemical factors regulating the respiration also have been described. They are situated in the epithelium of the airways and extend from the trachea to the respiratory bronchioles. They are concentrated mainly at the carina and at the points of branching of the bronchial tree. There affarent pathway is the vagus. They are activated by some chemical irritants such as ether, smoke, dust, etc., and mechanical stimuli such as foreign body, secretion, etc. Stimulation of these receptors results in hyperpnoea and laryngeal or bronchial spasm. All these are also vagal reflexes.

J-receptors (juxta-pulmonary capillary receptors) are situated on the walls of the alveoli and also possibly on the smaller airways. Like the other lung receptors, their afferent pathway is also vagas. They can respond to numerous different stimuli, but they are chiefly stimulated by the increase in insterstitial fluid between the capillary endothelium and alveolar epithelium which may be caused by pulmonary oedema, microembolism, pneumonia or irritant gases. There is evidence to suggest that stimulation of these J-receptors cause tachypnoea, bronchoconstriction and contraction of the adductor muscles of the larynx. But since the causes of their stimulation often have other effects, so it is difficult to think that these effects are due to the J-receptor stimulation alone.

Sinus and Aortic Nerve

This sino-aortic nerve consists of sinus and aortic nerve. The sinus nerve (affarent) arises from the carotid sinus (baroreceptor) and carotid body (chemoreceptor) and passes along the glossopharyngeal nerve to end in the medulla in close relation with the respiratory, cardiac and vasomotor centre. On the otherhand, the aortic nerve (afferent) arises from aortic arch (baroreceptor) and aortic body (chemoreceptor) and passes along the vagus nerve to end in the medulla in close relation with the respiratory, cardiac and vasomotor centre. So, they regulate the respiration during the changes of blood pressure, arterial CO_2 and O_2 tension, and H^+ concentration.

CO_2 excess will stimulate the respiration by reflexly acting through the carotid and aortic bodies. Alteration of H^+ concentration due to any other causes such as in metabolic acidosis or alkalosis other than changes in CO_2 concentration will also act in the same way as CO_2. Oxygen lack will also stimulate the respiration by reflexly acting through the carotid and aortic bodies. But its direct action on the respiratory centre is depression of respiration. Rise of blood pressure will also depress the respiration, but fall of blood pressure will stimulate the respiration. They act through the baroreceptors such as the carotid sinus and the aortic arch.

Impulses from Higher Centres

Certain and several parts of the cerebral cortex, hypothalamus, limbic systems, vasomotor centre and other parts of the brain also reflexly alter and regulate the respiration through respiratory centre.

Other Factors

There are certain other factors which also affect the respiratory centres reflexly. These are: cough, yawning, hiccough, sneezing and other reflexes arising from the body surface and viscera (such as thermoreceptor, pain receptor, touch receptors etc. also affect respiration). Reflexes arising from the muscles and joints increases pulmonary ventilation during exercise and is partly due to the impulses originating from the active muscles and joints.

Chemical Regulation

The respiratory centres are highly sensitive to the alterations of chemical composition of the blood. Changes in the CO_2 tension, O_2 tension and H^+ ion concentration of blood alter the pulmonary ventilation profoundly. In any case, the main purpose is to adjust the respiration in such way that it may be able to meet the demands of the body adequately during emergency. The effects of these changes are briefly summarised below.

The chemical regulatory mechanism adjust ventilation in such a way that the alveolar PCO_2 is normally held constant, the excess H^+ in the blood are combated, and arterial PO_2 is raised, when it falls to a potentially dangerous level. The respiratory minute volume is proportionate to the metaboic rate, but the link between the metabolism and the ventilation is CO_2, but not O_2. The link between metabolism and ventilation is established by the receptors in the carotid and aortic bodies which are stimulated by the rise in arterial PCO_2 or H^+ concentration or decline in PO_2.

Effects of Alteration in CO_2 Tension

The arterial PCO_2 is normally maintained at 40 mm of Hg (between 35 to 45 mm of Hg) because the respiratory centre is extremely sensitive to the slight alteration

in arterial CO_2 tension. A slight rise of CO_2 concentration in the inspired air increases respiration enormously. Respiration increases at first in depth and then in rate and last by both. Thus, the total pulmonary ventilation is raised. The degree of stimulation of respiration shows a quantitative relationship with the increase of CO_2 tension. The total pulmonary ventilation is so nicely adjusted that the alveolar CO_2 tension which is proportional to the arterial CO_2 tension (if there is no abnormality in diffusion at alveoli) remains more or less constant. This reflex works maximally up to the inspired CO_2 concentration of 5%. But, if the percentage of CO_2 concentration in the inspired air goes above 5%, then this adjustment fails and consequently the alveolar CO_2 content rises. So, breathing of air containg up to 5% CO_2 will not do any harm, although respiration will be stimulated. But, if the inspired CO_2 content is raised further, the alveolar CO_2 tension will rises in spite of hyperventilation. This will lead to the accumulation of CO_2 in the blood and thereby cause the toxic effects of CO_2 narcosis (headache, confusion and coma).

CO_2 acts on the respiratory centre both by directly (centrogenic) acting on it and by reflexly acting through the carotid and aortic bodies (reflexogenic). During anaesthesia the threshold level of arterial CO_2 tension which stimulate the respiratory centre increases. Thus, in anaesthetized condition respiratory centre becomes insensitive to CO_2 or threshold level for stimulation becomes high.

Effect of Changes in H^+ Concentration

The changes of H^+ ion concentration in blood also alter the pulmonary ventilation. Duing metabolic acidosis respiration rises and during metabollic alkalosis it falls. The purpose of it is briefly stated as follows:

During acidosis due to only metabolic causes, respiration increases and more CO_2 is eliminated from the alveoli. This lowers the alveolar CO_2 tension below the normal. Consequently more and more CO_2 comes out of the blood stream into the alveoli which is formed by the reaction between H^+ and HCO_3^-. Thus, the H^+ ion concentration of blood is lowered and metabolic acidosis is compensated. On the other hand, during metabolic alkalosis respiration is depressed $\rightarrow$ less and less CO_2 is washed out $\rightarrow$ alveolar CO_2 tension increases $\rightarrow$ less CO_2 diffuses out of the blood $\rightarrow$ more CO_2 accumulates in the blood stream $\rightarrow$ increase in H^+ ion concentration of blood $\rightarrow$ combat alkalosis. Thus, blood reaction is maintained by adjustment of the pulmonary ventilation during metabolic acidosis and alkalosis. But, this is applicable to metabolic causes only. In respiratory acidosis and alkalosis this is not applicable, because here lungs or respiratory system does not act as compensatory organ. Because they them selves are the cause of respiratory acidosis and alkalosis.

The mode of action of H^+ ion in regulating respiration is same as CO_2. So, as the action of CO_2 and H^+ ion is same, it is thought that the action of CO_2 is not due to its own effect, but due to the associated change in H^+ ion concentration. There is controversy that whether it is the intracellular H^+ or CO_2 which regulates the activity of the respiratory centre. CO_2 is more easily diffusible through the cell membrane than H+ ion. So, it is probable that CO_2 diffuses inside the respiratory neurons which is carried here by blood from the different body tissues and inside the cell with the help of carbonic anhydrase this CO_2 is changed to H_2CO_3.

Then, intracellular H_2CO_3 is ionized and H^+ ions are liberated. Now the intracellular H^+ ions are supposed to be the sole factor, regulating the rhythmical activity of the respiratory centre.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \ D \ H^+ + HCO_3^-$$

Effect of Changes of Oxygen Tension

The effect of changes of O_2 tension on respiratory centre can be described under two headings: the effects of oxygen lack and the effect of oxygen excess.

Oxygen lack act on the respiratory centre reflexly through the carotid and aortic chemoreceptors and it is stimulating in effect. But, the direct effect of O_2 lack on the respiratory centre is depression. The effects of oxygen lack on the respiratory centre will vary according to the severity and the rapidity with which the lack is produced. If severe oxygen lack is produced very rapidly, then the results will be disastrous. Here, we will discuss only the effects of the gradual reduction of oxygen concentration or tension (perssure). It is seen that O_2 tension in the inspired air can be reduced to13% without any appreciable change of respiration and any discomfort on the part of the subject. But, with the further reduction (more than 13%) of O_2 concentration, respiration starts rising with a feeling of uneasiness. This shows that the respiratory apparatus is much less sensitive to oxygen lack (hypoxia) than to CO_2 excess (hypercapnoea). On the other hand, we can say that the CO_2 tension is the strongest stimulus in adjusting respiration. Oxygen lack or hypoxia will be stimulus, only when it is sufficiently reduced. In many circumstances, hypoxia and hypercapnoea exist together and they act synergistically. When they act separately in different circumstances, then the effect, including the blood pH, is also different. If the O_2 lack is gradual as in high altitude, it stimulates the breathing. Thus the alveolar and the arterial CO_2 tension fall and alkalosis is produced which got depressing effect on the respiration. But, the excess of alkalis are excreted by the kidney and alkalosis is combated.

It is previously stated that the reflex effect of hypoxia, acting through the carotid and aortic chemoreceptors, is to stimulate the respiratory centre. But the direct effect of it on respiratory centre is depression. However, as the reflex effect is dominant, so respiration is found to increase. 60% oxygen mixture can be

breathed continuously for any length of time without any distress. 75% O_2 mixture can be tolerated for several days, after which ill effects appear. Pure oxygen (100%) at 1 atmospheric pressure can be breathed for few hours without any ill effects. But when the oxygen pressure is raised to several atmospheres, the patient develops convulsions and die rapidly. Human beings develop bad effects in less than one hour (fainting, fall of BP etc), if they are exposed to oxygen at 4 atmospheric pressure.

Breath Holding

Respiration can be voluntarily inhibited for some time but eventually this voluntary control is overridden. The point at which the breathing can no longer be voluntarily inhibited is called the 'breaking point'. Breaking is due to the rise in arterial PCO_2 and the fall in PO_2. Individuals can hold their breath longer after removal of the carotid bodies. Breathing 100% O_2 before breath holding raises arterial PO_2 initially, so that the breaking point is delayed. The same is true for hyperventilation with room air, because CO_2 is blown off and arterial PCO_2 is lower at the start. Reflex and mechanical factors also appear to influence the breaking point. Psychological factors also play an important role and subjects can hold their breath longer when they are told that their performance is very good than when they are not.

METABOLIC FUNCTIONS OF LUNG

Except the gas exchange and chemical control of blood, the lungs have also many metabolic functions. For example, lung is the major site of inactivation of 5 HT, bradykinis and noradrenaline. Near about 30% of these compounds are metabolised during their single passage through the lungs. But, this is not applicable for adrenaline. This metabolic function of lungs is very selective. This is because, more than 90% of PGE1, PGE2, PGF2 are metabolised during single passage of these compounds through lungs. Whereas PGA1, PGA2 and prostacyclin are not metabolised by lungs.

There are different converting enzymes in the endothelial cells of the pulmonary capillary wall. They catalyses the angiotensin I (A-1) to angiotensin II (A-II) which is a very potent vasoconstrictor. Lungs also secrete certain substances like SRS-A (slow reacting substance of anaphylaxis) and histamine during anaphylaxis. Prostacyclin, a potent vasodilator and inhibitor of platelet aggregation are also secreted by lungs. Its generation at the lungs is sitmulated by A-II, hyperventilation and their peptides. Hyperventilation acts by streteching of the lung tissues.

3 Pulmonary Physiology Related to Anaesthesia

PULMONARY CIRCULATION

Physiological Anatomy

Lungs gets its blood supply from two sources: pulmonary arteries, arising from the pulmonary trunk and bronchial arteries, arising from the aorta. The pulmonary trunk arises from the right ventricle and is only 5 cm in length. It divides into right and left main branches (right and left pulmonary artery) that supply the right and left lungs, respectively. The wall of the pulmonary artery is thin, elastic and distensible. But, the cross section of it is like that of the aorta. Through the pulmonary trunk the total output of right ventricle which is same as that of the left ventricle passes to both the lungs. The right and left main branches of pulmonary trunk i.e. right and left pulmonary arteries then breaks up into multiple branches such as the smaller pulmonary arteries, arterioles and capillaries which form a very rich network around the alveoli.

The branches of pulmonary arteries are short and all the branches of it even the arterioles and capillaries have larger diameters than their systemic counterpart. Thus, the three properties of it such as wide diameter, thin wall and distensibility give the pulmonary arterial system a large compliance which is near about 7 ml/mm of Hg. This total compliance of the whole pulmonary arterial system is similar to that of the entire systemic arterial system, though the former is of much lower volume than the later. Thus, it allows the pulmonary arterial system to accommodate the total output of right ventricle which is similar to that of left ventricle or systemic circulation, though of low volume. Like the pulmonary arteries, pulmonary veins are also short and the main pulmonary veins are four in number. They drain into the left atrium.

Pulmonary arteries carry the nutrition and deoxygenated blood to the alveoli. Alternatively, bronchial arteries carry the oxygenated blood and nutrition to the bronchial tree and the supporting tissues of the lungs (parenchyma). Bronchial arteries arise from the aorta. Then, it breaks up into capillaries around the alveoli and the bronchial trees. These capillaries which formed from the bronchial artery around the alveoli ultimately join with the capillaries a round the alveoli which is formed from the pulmonary artery and subsequently drain into the pulmonary vein. On the otherhand, the capillaries formed around the bronchial tree from bronchial arteries drain into the systemic venous system through the azygous vein. Bronchial artery carries about 1 to 2% of cardiac output. So, the deoxygenated blood of the bronchial veins which drain in the oxygenated blood of pulmonary vein also carry 1 to 2% of CO. Thus, the left ventricular output is 1 to 2% greater than the right ventricle and contains 1 to 2% deoxygenated blood. This is called the intrapulmonary true shunt. Thus, the nutrition and O_2 supply to the pulmonary tissues comes from the deoxygenated blood through pulmonary artery and as well as from the oxygenated blood through the bronchial artery.

Total Blood Volume in Pulmonary Circulation

At any moment, both the lungs together contain approximately 450 to 500 ml of blood. It is about 9% of the total blood volume of the body. Of this total pulmonary blood volume, only about 70 ml of blood remains in the pulmonary capillary of each lung at any moment. The remainder is divided equally to fill the pulmonary arteries and veins. On the otherhand, the total blood flow in a minute through both the lungs together is about 4 to 5 litres. This is sum of the right ventricular output plus the blood flow through the bronchial arteries.

The total amount of blood volume, flowing through the pulmonary circulation varies under different physiological and pathological conditions. This variation of quantity of pulmonary blood flow may change from as little as half of the normal value to twice of it. During inspiration, the intrapleural and the intra alveolar pressure falls. Therefore, more blood flows into the lungs. This is also facilitated by the elongation of capillaries due to stretching and their dilatation due to negative pressure. Thus, during inspiration lungs hold 10% more of the total pulmonary blood volume. During expiration the reverse occurs. If high pressure builts up in the lungs during expiration, such as in coughing, playing trumpet, applying IPPV with high pressure, etc, then as much as 250 ml of blood can be expelled out from the pulmonary circulation to the systemic circulation. On the otherhand, during haemorrhage the loss of blood from the systemic circulation

can be compensated by the shift of blood from the lungs to the previous system.

If there is any pathology on the left side of the heart causing obstruction to the blood flow, then it also causes to dam up the huge amount of blood in the pulmonary circulation. Sometimes, it may increases up to 100%, causing large increase in pulmonary vascular pressure. But, as the volume of systemic circulatory bed is 9 times greater than that of the pulmonary circulation, so a small amount of shift of blood from the systemic circulation to pulmonary circulation has greater effect on it, with mild or no effect on previous one.

Pressure in the Pulmonary Circulatory System

The right side of the heart and the pulmonary circulatory system is a low pressure system than the left side of the heart and the systemic circulatory system. In human being, the systolic pressure of right ventricle averages to about 25 mm of Hg. So, subsequently the systolic pressure in the pulmonary artery is also about 25 mm of Hg. But, the diastolic pressure in the right ventricle suddenly comes down to 0 or 1 mm of Hg, whereas the diastolic pressure in pulmonary artery does not fall precipitously to this value. The diastolic pressure in PA falls slowly to around 8 mm of Hg as blood flows away from the pulmonary artery to the capillaries of the lungs. Thus, the mean pulmonary arterial pressure results in 15 mm of Hg, whereas the mean pressure in RV remains at 25 mm of Hg (Fig. 3.1).

The mean hydrostatic pressure in the pulmonary capillary is about 8 mm of Hg. Whereas, the mean hydrostatic pressure in the major pulmonary veins and the left atrium varies between as low as 1 mm of Hg to as high as 5 mm of Hg, according to the position of the body. So, the average pressure in pulmonary veins and LA is 2 mm of Hg in the recumbence position.

Clinically, it is not feasible to measure the pulmonary venous and LA pressure directly in the human being. This is because it is not possible to pass a catheter directly through the right side of the heart into the pulmonary veins and LA (i.e. left side of the heart) through pulmonary capillary. So, we try to measure the pressure of the left side of the heart indirectly with moderate accuracy by wedging a balloon situated at the tip of a catheter which is introduced into the pulmonary capillary (but actually this is not the pulmonary capillary, it is the smallest branch of the pulmonary artery) by passing it through the large systemic veins, RA, RV and PA. After wedging of balloon in the smallest branch of the pulmonary artery, the blood flow is stopped in this vessel and then the tip of the catheter directly communicates with the venous side of the pulmonary circulatory system and LA beyond the balloon. Thus, the tip of the catheter senses the pressure in this smallest branch of PA which is proportional to the pulmonary venous system and LA. This is called the pulmonary capillary wedge pressure (PCWP), which is clinically taken as the pulmonary venous and LA pressure and is about 5 mm of Hg. This PCWP is usually 2 to 3 mm of Hg greater than the actual LA pressure.

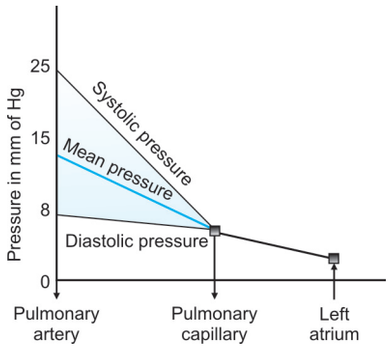

Fig. 3.1: The pressure of pulmonary artery, pulmonary capillary and left atrium

Distribution of Pulmonary Blood Flow

The distribution of pulmonary blood flow in the lungs is not uniform. It is different at different areas. This is because lung tries to accomplish adequate oxygenation of blood which is the most important function of it. So, to achieve this blood has to be more distributed to those areas of lungs where the alveoli are better ventilated. Thus, the distribution of pulmonary circulation is governed by the following mechanisms or principles. These principles are :

(i) Effect of alveolar O_2 tension on local pulmonary blood flow

This is a very unique feature of lungs. When the O_2 concentration in the alveoli decreases below 70% (or alveolar O_2 tension is < 70 mm of Hg), then the local blood vessels in the pulmonary tissue constrict and PVR increases locally. This causes shifting of blood to the other parts of lungs where it is well ventilated and try to compensate the hypoxia. This increase in PVR may be 6 fold in extreme hypoxia. This is opposite to the effect, found in the systemic circulation where hypoxia causes vasodilatation and increases circulation. But, the mechanism of pulmonary vasoconstriction in response to hypoxia is not clearly known. The probable theory is that the local pulmonary vasoconstriction is accomplished by some chemical substances secreted by the hypoxic epithelial cells.

(ii) Effect of hydrostatic pressure gradient on pulmonary blood flow

Another important factor which causes different amount of blood flow through the different areas of lungs is the hydrostatic pressure gradient. The hydrostatic pressure is nothing but the weight of blood column in a blood vessel. The difference between the highest (top) and the lowest point (bottom) of the lung is 30 cm in upright position. This height of lung causes difference in the hydrostatic pressure in pulmonary artery of the apex and the base of the lungs and is about 23 mm of Hg, however taking into account that pressure in pulmonary artery at the level of the heart is zero. This can be explained in

another way that in a standing person the pulmonary arterial pressure at the top of the lung is 15 mm of Hg less (–15 mm of Hg) than the pulmonary arterial pressure at the level of the heart and the pulmonary arterial pressure at the base of the lung is 8 mm of Hg higher (+8 mm of Hg) than that at the level of the heart. Thus, the difference of hydrostatic pressure in pulmonary artery at the apex and the base of lung is 8 – (–15) or 23 mm of Hg. This also can be calculated in another way that the pulmonary arterial pressure increases or decreases by about 1 cm of H_2O per centimeter of change of vertical distance of the lung. This change of hydrostatic pressure in pulmonary artery is due to the influence of gravity on the distribution of pulmonary circulation and is important because this is of a low pressure system.

(iii) Effect of cardiac output (CO) and exercise on pulmonary blood flow

Actually, the CO and exercise effect the total amount of pulmonary blood flow, but not the local distribution of it in lungs. Heavy exercise and increased CO increase the pulmonary blood flow near about five to seven times, but with very little increase in pulmonary arterial hydrostatic pressure. This increased blood flow in the lungs is accomplished by: increasing the number of opened capillaries and distending it. These two changes in pulmonary vasculature decrease the PVR. So, there is little increase in pulmonary arterial pressure (Fig. 3.2).

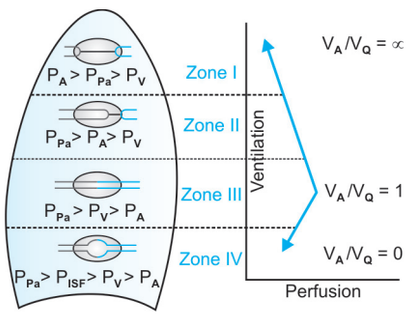

Fig. 3.2: The difference of distribution between ventilation and perfusion and VA / VQ ratio at different parts of the lung

(iv) Effect of alveolar pressure and pulmonary venous pressure on pulmonary blood flow

The Increased alveolar pressure and pulmonary venous pressure decreases the pulmonary blood flow. On the other hand, the distribution of pulmonary blood flow in the lungs not only depends on the pulmonary alveolar pressure and pulmonary venous pressure, but also on the interaction between the pulmonary arterial pressure (P_{Pa}), alveolar pressure (P_A) and pulmonary venous pressure (P_{Pv}). Thus, lungs can be divided into three zones:

Zone I

In this region $P_A > P_{Pa} > P_{Pv}$ and this region is situated at the apex of the lungs. Thus, at this area as the alveolar pressure outside the vessels is greater than the capillary pressure, so no blood flow will occur through the wall of these alveoli and no gaseous exchange will take place. Hence, this region (zone 1) acts as alveolar dead space. Normally, no or little area of zone 1 exists. But, it greatly exists or increases in oligemic shock (where P_{Pa} is further reduced) or IPPV (where PA is further increased).

Zone II

It exists below the zone 1 and here $P_{Pa} > P_A > P_{Pv}$. So, in this region blood starts to flow through pulmonary capillary. Since P_{Pa} gradually increases downwards along this region of the lung, and P_A remains constant, so the mean driving pressure (P_{Pa} - P_A) for blood flow increases linearly downward in this area, causing more and more blood to flow from upper to lower limit of this zone. On the otherhand, as P_A, P_{Pa}, P_{Pv} changes continuously with respiration and cardiac cycles, so at a given time a particular point in zone 2 may shift to either zone 1 or zone 3 making it (zone 2) a dynamic area.

Zone III

It lies in lower portion of the lung below the zone 2, where $P_{Pa} > P_{Pv} > P_A$. So, here the blood flow depends on the pulmonary arteriovenous pressure difference (P_{Pa} - P_{Pv}), but not on the P_{Pa} - P_A difference. As in this region the pulmonary vascular pressure (P_{Pa} - P_{Pv}) always exceeds the alveolar pressure (P_A), so the vessels remain permanently open and blood flows continuously. If we go downwards along the zone 3 then we will see that gravity will cause the increase in both the P_{Pa} and P_{Pv} but at the same rate, so that the driving pressure (P_{Pa} - P_{Pv}) remains unchanged. On the otherhand, the pressure outside the vessels i.e. pleural pressure (P_{Pl}) increases from above downwards, but at a rate lesser than that of P_{Pa} and P_{Pv}. So, the transpulmonary distending pressure (i.e P_{Pa} - P_{Pl} and P_{Pv} - P_{Pl}) increases gradually downwards along the zone 3. Hence, the radii of vessels increase, vascular resistance decreases and blood flow further increases from upper to lower limit of this zone.

Zone IV

Normally, a small amount of fluid flows into the pulmonary interstitial space from pulmonary intravascular space and is cleared immediately and adequately by the lymphatics. But when the pulmonary vascular pressure is very high such as in volume overload, pulmonary hypertension, pulmonary embolism, mitral stenosis etc, then the excessive amount of fluid transduates in the interstitial compartment which cannot be cleared by lymphatics. Thus, the expansion of the pulmonary interstitial space by fluid causes increased pulmonary interstitial pressure (P_{ISF}) and exceeds P_{Pv}. Thus, at the base of the lung a zone is created where $P_{Pa} > P_{ISF} > P_{Pv} > P_A$. This is called zone 4. In this zone the flow of blood through pulmonary capillaries is governed by the $P_{Pa} - P_{ISF}$ value, which is less than the $P_{Pa} - P_{Pv}$ value. Therefore, in zone 4 blood flow is less than zone 3. Again as P_{ISF} increase in zone 4, it causes vascular compression and increased vascular resistance which further decreases the blood flow in this region.

Throughout the whole lung when P_{Pa} and P_{Pv} increases gradually, then three things happen:

i. If both increases from low to moderate range, then recruitment of more alveoli is the principle. So zone 1 will become zone 2, zone 2 will become zone 3 and so on.
ii. If P_{Pa} and P_{Pv} increases from moderate to high range, then distension of the vessels is the principle. So, vessels of zone 3 dilates and blood flow increases. Thus the area of zone 3 increases.
iii. If P_{Pa} and P_{Pv} increases from high to very high ranges, then the zone 3 vessels will become so dilated that they leak fluid and transudation occurs. Thus, zone 3 vessels converted to zone 4 vessels.

Dynamics of Pulmonary Capillary Circulation

After entering into the lung parenchyma pulmonary arteries are ultimately divided and subdivided into pulmonary capillaries which lined the alveolar walls. So, finally the alveolar walls are covered by so many capillaries that they lie side by side touching with one another, as if the alveolar wall is bathed by a sheet of blood flow. Therefore, the alveolar gas is separated from the capillary blood by a number of anatomical layers. From capillary side these layers are: capillary endothelium, basement membrane of this endothelium, interstitial space (IS), epithelial basement membrane and alveolar epithelium (type I pneumocyte). The interstitial space (IS) lying between the basement membrane of endothelial (capillary) and epithelial (alveolus) cell layers contains some connective tissues which make the lung parenchyma. These connective tissues are made of elastic fibres, tissue fibrils, fibroblasts and macrophages, and is continuous with the connective tissues around the airways and blood vessels of the lungs. Thus, the perialveolar or perivascular space is continuous with the interstitial tissues space which surrounds the terminal bronchioles, other airways and its associated vessels, because both the spaces contain the same connective tissues of the lungs. Lymphatics start in the interstitial space at the level of terminal bronchiole and flow upwards towards the bronchi and trachea. But it is absent beyond it towards the alveoli (Fig. 3.3).

The endothelial and the epithelial cells are not tightly attached with one another. There are multiple holes at their (cells) junctions which provide potential path for the fluid to move from capillaries to IS and finally from IS to alveoli and vice versa. The holes between the endothelial cells of pulmonary capillary are relatively larger than that of the epithelial cells of alveoli and is therefore termed as loose. On the otherhand, the holes between the epithelial cells are smaller and therefore is termed as tight. The pulmonary capillary permeability (K) is thus the expression of the sizes of these holes and its subsequent function.

During the development of lungs, the bronchi and the arteries as a tissue of bud invaginate into the pleural cavity at the level of hilum with the connective tissues sheath (lung parenchyma) around them which ends at the level of the terminal bronchiole and become continuous with the connective tissues of the IS between the alveolar epithelium and capillary endothelium. Thus, the potential space around the bronchi and arteries containing the connective tissues is continuous with the IS between the alveolar epithelium and capillary endothelium, containing the same connective tissues. The pressure in this interstitial space is negative and progressively increases from distal to proximal i.e from alveoli to bronchi. This negative interstitial pressure in the connective tissues surrounding the vessels, bronchi and bronchioles exerts a radial outward force of traction which tends to hold them open and increases their diameter.

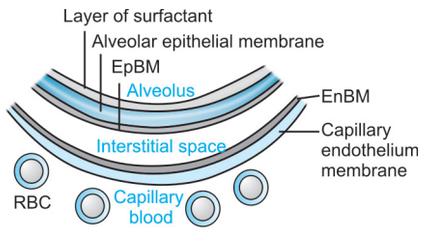

Fig. 3.3: This is a schematic diagram of structures intervening between the alveolar air and capillary blood.
EpBM = Epithelial basement membrane,
EnBM = Endothelial basement membrane.

When the CO is normal, the time taken by the blood to pass through pulmonary capillaries is 0·8 sec. But when the heart rate and CO increases, then this capillary circulation time is shortened to 0.3 sec. But this shortening of time has no pronounced effect on the gaseous exchange. This is because more and more capillaries are opened up with increased CO and within only a fraction of a second blood can take up O_2 and excretes its CO_2.

The dynamics of pulmonary capillary circulation and the exchange of gas and fluid between the pulmonary capillaries and alveoli are qualitatively same as that of the systemic capillary circulaion. But, they differ only quantitatively.

The difference between the dynamics of pulmonary and systemic capillary circulation are:

i. The mean pulmonary capillary hydrostatic pressure is 7 mm of Hg (the mean left atrial pressure is 2 mm of Hg and the mean pulmonary arterial pressure is 15 mm of Hg), whereas the mean systemic capillary hydrostatic pressure is 17 mm of Hg.
ii. The interstitial fluid pressure (or hydrostatic pressure in IS) in the lungs is negative and is about −8 mm of Hg. Whereas the interstitial fluid pressure in the peripheral tissues is not so negative, rather positive.
iii. The colloidal oncotic pressure of pulmonary capillary due to the presence of plasma protein is about 28 mm of Hg and this is equal to that of systemic capillary. The pulmonary capillaries are loose. So, protein molecules

continuously come out in the IS from capillary. Therefore, a colloidal oncotic pressure is formed in this space which is about 14 mm of Hg. This is approximately ½ of the colloidal oncotic pressure of interstital space of peripheral tissues.

Thus, the net forces governing the transcapillary fluid movement in the interstitial space of lung tissue can be calculated as follows. This net force (F) is equal to the difference between the pulmonary capillary hydrostatic pressure (P_{in}) and the hydrostatic pressure in the IS (P_{out}) and between the capillary colloidal oncotic pressure (O_{in}) and the interstitial colloidal oncotic pressure (O_{out}). P_{in} pushed the fluid out of the capillary in the IS, but P_{out} opposes this force. On the otherhand, O_{out} draws the fluid in the capillary from IS, but O_{out} opposes this force.

So, $F = K \{(P_{in} - P_{out}) - \sigma(O_{in} - O_{out})\}$; K is the filtration coefficient and is related to the total capillary surface area per mass of tissues, and σ is the permeability coefficient of capillary endothelium to albumin. when the value of σ is one, it indicates endothelium is completely impermeable to albumin and zero value of σ indicates free passage of albumin and other particles. The pulmonary endothelium is partially permeable to albumin. So the interstitial albumin concentration is one half of that of plasma. Therefore, the O_{out} must be about 14 mm of Hg (one half of that of plasma).

Therefore, $F = \{7 - (-8)\} - (28-14) = 15 - 14 = +1$

This net forces (F) which governed the movement of fluid from pulmonary capillary to IS and subsequently in the alveoli can also be calculated from another angle.

i. The forces which tries to move or push the fluid from pulmonary capillary into IS are :
   Capillary hydrostatic pressure = 7 mm of Hg
   IS oncotic pressure = 14 mm of Hg
   Negative IS hydrostatic pressure = 8 mm of Hg
   So, the total outward force which pushes the fluid from capillary to IS = 7 + 14 + 8 = 29 mm of Hg
ii. The forces which try to draw the fluid from IS to capillary [i.e the opposite force of (i)] are :
   Plasma colloidal oncotic pressure = 28 mm of Hg
   Thus, the total outward filtration pressure from capillary to IS is :

Total outward driving force (29 mm of Hg) − Total inward driving force (28 mm of Hg) = 1 mm of Hg.

Therefore, the net outward driving force (F) = + 1 mm of Hg

So, this slight positive outward filtration pressure continuously causes the movement of small amount of fluid from the pulmonary capillaries into the IS and subsequently from IS to alveoli. Then, part of this fluid evaporate through the alveoli and the remaining part is pumped back into the circulation through the pulmonary lymphatic system. This also explains why the alveolar surface remains always dry and there is constant lymphatic flow which is about approximately 500 ml/day (10 to 20 ml/hour). Again, when the extra fluid appears in the alveoli from exogenous source then it will simply be sucked into the IS of lung, mechanically through the openings between the alveolar epithelial cells. This excess fluid is then further carried out through the pulmonary lymphatics into the circulation. Thus, under normal situations, the alveoli are kept constantly dry except that a small amount of fluid which sips from the epithelial cells on their alveolar surface to keep them moist.

Pulmonary Oedema

The pulmonary oedema may be regarded as an exaggeration of this pulmonary capillary dynamics. It occurs when the transudation of fluid is more than its reabsorption capacity through the lymph and gradually accumulates in the IS i.e when the safety and the reserve factors which are described later fail. The alveolar epithelial membrane is usually impermeable to albumin, but permeable to water and gases. Thus, when the fluid accumulates in IS, then it also moves from IS to the inside of the alveoli and produces the full picture of pulmonary oedema. So, the mechanism of formation of pulmonary oedema is same as that of the formation of systemic oedema, elsewhere in the body. The most commonly factors which play the important roles in the formation of pulmonary oedema are:

(i) Increased pulmonary capillary hydrostatic pressure

It may be due to any cause such as pulmonary hypertension, LVF, fluid overload, disease of mitral valve, etc. All these factors will cause the rapid increase in pulmonary venous pressure and subsequently the pulmonary capillary hydrostatic pressure, producing blood of IS and alveoli with fluid.

When the pulmonary artery pressure rises above 30 mm of Hg, then it is called the pulmonary hypertension. It again can be due to four mechanisms.

(a) Increase in pulmonary blood flow

It occurs when the left (L) to right (R) shunt is present e.g VSD, ASD etc, In these conditions blood flow through the lungs increases 3 times more than that of the left ventricular output. If these states persist for few years, then pulmonary vascular resistance begins to rise due to some structural changes in pulmonary vessels. Thus, the pulmonary artery pressure rises further. Eventually, if the pressure on the right side of the heart exceed than that on the left side, then the left to right shunt is reversed and subsequently the right to left shunt with central cyanosis appears.

(b) Increase in left atrial pressure

It is due to the aortic or mitral valve disease or left ventricular failure which increases the left atrial pressure with dilatation and/or hypertrophy. Thus, subsequently the

back pressure from left atrium causes the pulmonary arterial hypertension.

(c) Rise in pulmonary vascular resistance

It occurs in massive pulmonary embolism and in some lung diseases (such as chronic bronchitis, COPD, emphysema, etc). In chronic lung diseases pulmonary hypertension is due to the combination of chronic hypoxia and obliteration of pulmonary vascular bed by disease process itself.

(d) Over transfusion

Excessive IV transfusion of any fluid may lead to increased pulmonary capillary hydrostatic pressure and pulmonary oedema.

(ii) Increased pulmonary capillary permeability

It is due to some chemical injury of the pulmonary capillary membrane, caused by bacterial endotoxin (septicaemia), breathing toxic gases, ARDS, ALI etc. In each of these cases, there is rapid leakage of both the plasma protein and fluid out of the capillaries into both the IS and alveoli. This further increases O_{out} and subsequently the effective or net filtration pressure (F). Thus, a vicious cycle sets up to produce pulmonary oedema.

(iii) Dimished pulmonary capillary colloidal osmotic pressure

It is very unlikely that it can be the cause of pulmonary oedema in clinical situations, but can intensify the process, initiated by other causes.

(iv) Pulmonary lymphatic obstruction

It is unlikely to be the primary cause of pulmonary oedema, but might be an important secondary factor.

(v) Extremely negative pleural pressure

Normally, the negative intrapleural pressure is subsequently transmitted to the peribronchial, perivascular and IS space. So, this negative (or subatmospheric) IS hydrostatic pressure (P_{out}) promotes the slow loss of fluid into this space across the capillary endothelial holes by suction. But if due to any cause, sudden extremely negative intrapleural and subsequently sudden excessive negative IS hydrostatic pressure is developed, then there is excessive accumulation fluid in IS across the endothelium (exceeding absorption by lymph) and will cause pulmonary oedema. Causes of excessive negative intrapleural pressure are: vigorous spontaneous respiration against an obstructed airway. This may be due to upper airway mass, severe laryngospasm, severe inflammation and oedema of the upper airway, vocal cord paralysis, strangulation, vigorous pleural suctioning (e.g thoracocentesis), etc.

(vi) Neurogenic pulmonary oedema

It occurs in patients with head injury or other intracranial pathology. It is thought to be due to intense centrally mediated pulmonary vasoconstriction by sympathetic stimulation due to CNS injury. Hypoxia has no role as an aetiological factor in this type of pulmonary oedema and administration of O_2 does not help to restore the permeability of this type of injured and leaky capillary membrane.

Thus, the causes of pulmonary oedema are divided under two broad headings: (i) haemodynamic or cardiogenic pulmonary oedema and (ii) noncardiogenic pulmonary oedema. In the former, there is increase in the pulmonary capillary hydrostatic pressure due to cardiac problems causing increase in net filtration pressure across the capillary membrane. But, in the later there is increase in permeability of the capillary membrane without any increase in pulmonary hydrostatic pressure due to cardiogenic causes. The difference between these two etiologies can often be diagnosed by measuring the pulmonary artery occlusion pressure (PAOP) and the protein content of oedema fluid. If the PAOP is >18 mm of Hg, then it indicates that increased hydrostatic pressure is the cause of pulmonary oedema and vice versa. And if the protein content in the fluid of pulmonary oedema is high, then increased permeability without any increase in the hydrostatic pressrue of pulmonary capillary is the cause of pulmonary oedema.

The normal value of left atrial pressure is 1 to 5 mm of Hg. In healthy individual, it never rises above +6 mm of Hg, even during heavy exercise. This small change in left atrial pressure, even during strenous exercise has virtually no effect on pulmonary circulation. This is because, it merely expands the existing capillaries and opens up more and more capillaries, so that the blood flows easily and causes better oxygenation without increasing the hydrostatic pressure. But, when the left heart fails, then blood begins to accumulate in the left atrium. As a result, the left atrial pressure may rise from its normal value to 30 to 40 mm of Hg. The initial rise of pressure up to 7 mm of Hg in left atrium has very little effect on pulmonary circulation. But, when this pressure rises above 7 or 8 mm of Hg, then there is equal and parallel increase in the pulmonary arterial pressure. When the left atrial pressure rises above 30 mm of Hg, then pulmonary oedema is likely to develop.

Pulmonary Reserve and Safety Factors

There are some pulmonary reserve and safety factors which prevents the formation of pulmonary oedema, when there is moderate, but not severe change in pulmonary capillary hydrostatic pressure (PCHP) occurs. It is found experimentally that PCHP must rise to a value which is at least equal to the colloidal oncotic pressure of plasma, before significant pulmonary oedema occurs. In human being the normal plasma colloid oncotic pressure is 28 mm of Hg. Therefore, one can expect that PCHP must increases from the normal level of 7 mm of Hg to more than 28 mm

of Hg to cause pulmonary oedema. This is called the reserve factor for the development of pulmonary oedema. Thus, the reserve factor against the development of pulmonary oedema is 28 − 7 = 21 mm of Hg increase of PCHP.

On the other hand, if the PCHP gradually elevated over prolonged period, at least > 2 weeks, then the lungs become more resistant to pulmonary oedema due to starting of compensatory mechanism. This is because the lymph vessels increase their capability of carrying more fluid away from the IS as much as 10 fold. Therefore, in chronic MS, PCHP is frequently measured to 40 to 50 mm of Hg without any development of pulmonary oedema. This is the maximum safety factor of pulmonary oedema.

If the PCHP rises rapidly slightly above the safety factors level, then the pulmonary oedema ensures within an hour. The rapidity of development of pulmonary oedema depends on the speed of increase of PCHP above the safety level (Table 3.1).

Stages of pulmonary oedema

Pulmonary oedema is regarded as an exaggeration of the pulmonary capillary dynamics of fluid exchange which continuously operates under the normal physiological condition within reserve. So, pulmonary oedema develops in stages when the reserve is gradually burnt out. These stages are:

Table 3.1: Mechanism of hypoxia

A.	Increased alveolar-arterial PO_2 difference
	a. Right to left shunt
	b. Increased areas of low V_a / V_a ratio
	c. Low mixed venous PO_2 ↓CO ↑O_2 consumption iHb concentration
B.	Low alveolar PO_2
	a. Low inspired O_2 tension FiO_2
	b. High altitude
	c. Alveolar hypoventilation
	d. Increased O_2 consumption
	e. Third gas effect (diffusion hypoxia)

Stage I

In this first phase, excessive accumulation of fluid in the IS is not totally countered or compensated by increased lymph flow which may go up to 10 times. Thus, fluid gradually accumulate in IS and lungs become stiff. So, at this initial phase, patient only becomes tachypnoeic due to gradual decrease of the pulmonary compliance. Thus, this phase is only called as the interstitial pulmonary oedema and is only diagnosed by chest X-ray which shows the increased interstitial markings and peribronchial cuffing.

Stage II

In this phase, the fluid begins to reach and fill the alveoli in addition to IS, but being only confined to the angles between the adjacent septa.

Stage III

In this phase, the flooding of alveoli with the capillary fluid occurs and many alveoli are compeletly filled with fluid containing no air. Initially, this is most prominent in the dependent portion of the lungs and later spreads through out the whole lungs. So, this phase is called the alveolar flooding phase. Blood flows through this wall of fluid filled alveoli without any gas exchange and causes large increase in the intrapulmonary shunt (these are not true shunt). So, hypocapnia (due to hyperventlation of the non affected part of the lung) and hypoxia (due to shunting of blood) is the characteristic of this stage.

Stage IV

Finally the flooding of alveoli with oedema fluid is of sufficient magnitude, spreading all over the lungs and spills over into the airway as froth. This is frequently pink in colour, because of the rupture of many capillaries and increased diapedesis of erythrocytes. In this stage gas exchange is severely compromised. So, progressive hypercapnia and severe hypoxaemia will follow due to the both airway obstruction and massive intrapulmonary shunting.

ALVEOLAR VENTILATION (V_A)

Alveolar ventilation is the pulmonary factor which control the oxygenation of blood and excretion of CO_2 through lungs. It is a part of minute volume and is so calculated as L/min. We know that the minute volume is the total inspired volume of gas in one minute. So,

Minute volume = Tidal volume (V_T) × Respiratory rate (f) (Table 3.2).

All the inspired gases do not reach the alveoli and does not take part in the process of gaseous echange. Some remain in the airway and later exhaled with the alveolar gas. So, that part of the ventilation which remains in the airway without taking part in gaseous exchange is known as the dead space (V_D) ventilation. Therefore, the alveolar ventilation is defined as the volume of inspired gases in one minute which only take part in gaseous exchange. Thus,

Alveolar ventilation (V_A) = {Tidal volume (V_T) − Dead space (V_D)} × Respiratory rate (f)

or $V_A = (V_T - V_D) \times f$

The normal value of alveolar ventilation is 3·5 to 4·5 L/minute or 2 to 2·4 L/minute/metre^2 of body surface area in adult. From the above equation we can easily say that alveolar ventilation depends on three factors such as tidal volume, dead space and respiratory rate. When the tidal volume decreases or dead space increases or

Table 3.2: Effect of variations of respiratory rate and depth (tidal volume) on alveolar ventilation

	A	*B*
Tidal volume (ml)	400	200
Dead space (ml)	150	150
Respiratory rate (per min)	20	40
Minute volume (in litre)	8	8
Alveolar ventilation (in litre)	(400-150) × 20 = 5	(200-150) × 40 = 2

respiratory rate decreases, then the alveolar ventilation dramatically falls. But fortunately in healthy adult, the dead space decreases with decrease of tidal volume, so that the effect on the alveolar ventilation is lessened. Hyperventilation is not a very effective way of increasing the alveolar PO_2 (or preventing hypoxia) as washing out the CO_2 (or preventing hypercarbia). But, hypoventilation is potentially a disastrous cause of hypoxia than hypercarbia. On the otherhand a rise of small alveolar CO_2 concentration due to hypo ventilation will further produce a fall in alveolar O_2 tension, unless extra O_2 is added to the inspired air. So, in a patient under anaesthesia with spontaneous respiration, any reduction of V_A due to any changes in respiratory rate, tidal volume, and dead space, or any anaesthesia induced changes such as V_D/V_T ratio, compliance, FRC/CC relationship, work of breathing, etc, cause arterial hypoxaemia. Thus, it is always advisable to administer (Fig. 3.4) a minimum 33% of O_2, with all the anaesthetic gas mixtures to prevent hypoxia during anaesthesia. We know that V_A is not distributed evenly through out the whole lungs. The right lung

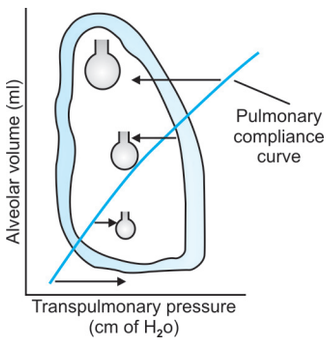

Fig. 3.4: As the intrapleural pressure relatively increases from top to the bottom of lung, so the alveolar volume decreases from apex to base of the lung. The calibre of air passages also decreases from apex to the base of the lung. The red line represents the transpulmonary pressure and alveolar volume curve. The less compliant, large alveoli in apex of the lung is situated at the flat upper portion of the curve. Whereas the more compliant, small alveoli in the base of the lung is situated at the steep lower portion of the curve and receive the largest share of tidal volume

is better ventilated than the left and the lower dependent area gets more ventilation than the upper apical area. This is due to the gravity induced gradient of transpulmonary distending pressure which decreases from above downwards allowing the more potentiality of distension of alveoli if necessary which are now less distended and smaller in lower dependent area of lung.

Truly, the lung is a viscoelastic structure. Within the visceral plural sac it is just like a plastic bag, containing gel. When it is not within the chest wall, gravity cause the bag to bulge outward at the bottom and inward at the top. But within the chest wall the present shape of the lung is maintained by relatively more negative intrapleural pressure at the top than the bottom of the pleural cavity. So, the intra pleural pressure (P_{Pl}) at the bottom is relatively more positive (i.e. less negative) than the top. The intrapleural pressure increases from top to bottom at the rate of 0·25 cm of H_2O / cm. The height of an upright lung is 30 cm. Thus the pleural pressure (P_{Pl}) increases by 30 cm × 0·25 cm of H_2O / cm = 7·5 cm of H_2O from top to the bottom of the lung. But intraalveolar pressure (P_A) is same throughout the whole lung. Thus the transpulmonary distending pressure ($P_A - P_{Pl}$) is greater at the top than the bottom.

This difference in transpulmonary pressure which helps to distend the alveoli have placed the different sized alveoli of different areas of lungs at different points on the pulmonary compliance curve. So, alveoli in the upper part of the lung remain maximally inflated and this is due to the higher trans pulmonary distending pressure at the top. Thus, they are relatively less compliant and undergo little further expansion during inspiration. On the otherhand, the alveoli at the base of the lung remain little inflated due to the lower transpulmonary distending pressure. So, they are more compliant and later may undergo more expansion during inspiration. The alveolar ventilation is also affected by the airway resistance and inspiratory time. A short inspiratory time and increased resistance will prevent the alveoli from reaching the expected change in volume during inspiration. This is described further below.

Time Constant and Alveolar Ventilation

The inflation of alveoli or alveolar ventilation depends on the time constant (T). It is defined as the time which the alveoli would, take to reach its final volume, if adequate gas flow rate is maintained throughout the inflation. The time constant again depends on the resistance and the compliance of the lung. This is calculated as:

Time constant = Resistance × Compliance

In normal lung, the compliance is 0.1 L/cm of H_2O and resistance is 2 cm H_2O/L/S. So, the time constant is 0.2 second. Increase in resistance and decrease in compliance give rise to longer time constant. It means alveoli will take a long time for a given volume of inflation. In such condition short inspiratory time during tachypnoea will result in poor ventilation of those zones of lung which have long time constant due to the increase in resistance and decrease in compliance. As a result there will be increase in V_A/Q mismatch.

Normally, the resistance and compliance is not uniform through out the whole lung. The compliance of normal functioning individual alveoli differs from top of the lung to its bottom. Again, normally the resistance of individual airway differs widely depending on their length and its caliber. Therefore, a variety of time constant for inflation of alveoli will exist throughout the whole lung. Thus, regional variations in resistance and compliance not only impair the alveolar filling, but also asynchrony. So, during inspiration as some alveoli may continue to fill, while others are empty.

VENTILATION (V_A) / PERFUSION (Q) RATIO OR V_A/Q RATIO

V_A/Q ratio express the amount of ventilation against the amount of perfusion at any

given regions of lungs at any certain time. Therefore, the lungs are usually divided into 4 zones in reference to V_A/Q ratio, as the ventilation and perfusion is not the same at different areas of the lungs. We know from the previous discussions regarding the distribution of perfusion and ventilation that both of them increase linearly from above downwards in normal upright position of lung, but not in same proportion. Perfusion increases more rapidly than ventilation while the distance is going down from top to the bottom of lungs. Thus, the V_A/Q ratio also decreases gradually from top to the bottom of the lungs. Normally the alveolar ventilation is approximately 4 L/min and pulmonary perfusion is about 5 L/min. So, the overall on average V_A/Q ratio of lung is about 0.8. But, it can range from zero (no ventilation, only perfusion at the bottom) to infinity (only ventilation, no perfusion at the top where ventilation is going wasted). Thus, the zero V_A/Q ratio refers to the true pulmonary shunt and infinity V_A/Q ratio refers to the alveolar dead space. Usually, in a normal healthy lung V_A/Q ratio ranges between 3·3 and 0·63 with major area remaining close to the value of 1. Apex of the lung is less perfused in relation to their ventilation ($V_A/Q > 1$ and near about 3·3), whereas the base of the lung is somewhat over perfused in relation to their ventilation ($V_A/Q < 1$ and near about 0·63). Thus, the bottom of the lungs is relatively hypoxic and hypercarbic compared with the top of the lung, where ventilation is going wasted. (Fig. 3.5).

The importance of V_A/Q ratio is that it tells us the efficiency with which the lung unit works, i.e. absorb O_2 and eliminate CO_2. Low V_A/Q ratio of one part of lung is compensated by the high V_A/Q ratio of another part of lung. But practically this does not happen, because less oxygenation of one part of a lung is not compensated by better oxygenation of other part of lung like excretion of CO_2. This is explained in further details below. Thus an inequal V_A/Q ratio have different effect on the arterial

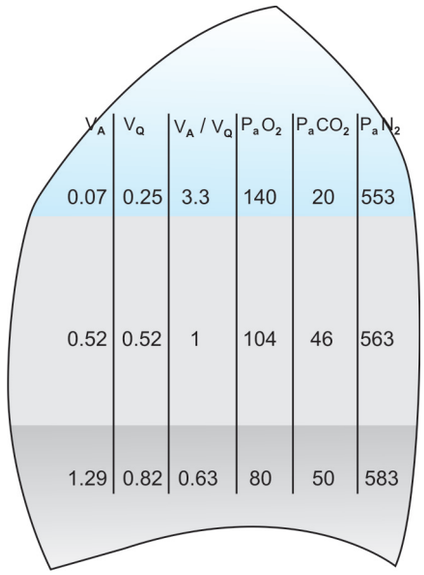

Fig. 3.5: The regional difference of alveolar ventilation (V_A), perfusion (V_Q) and V_A/V_Q ratio. This figure also compares the top with the bottom of the lungs which has low ventilation (iV_a), high perfusion (^hVq) and low V_a/V_q ratio. This bottom area is relatively more hypxoic and more hypercarbic

O_2 and CO_2 tension (P_aO_2 and P_aCO_2). The blood passing through the underventilated alveoli tends to retain CO_2 and can not take up adequate O_2. So, blood passing through this area is hypoxic and hypercarbic. On the otherhand, the blood passing through the over ventilated alveoli, at the top of the lung gives up excess CO_2 as a compensatory of under ventilated alveoli, but cannot take up increased amount of O_2 as a compensatory for under ventilated alveoli. This is due to flatness of the upper part of O_2 dissociation curve and less solubility of O_2 than CO_2 in blood (CO_2 is 20 times more soluble than O_2). Thus, due to uneven V_A/Q ratio the gradient between P_ACO_2 and P_aCO_2 remains small (so, the P_ACO_2 or $ETCO_2$ can be considered as equivalent to P_aCO_2), but the gradient between P_AO_2 and P_aO_2 remains high.

The concept of alveoli of zero and infinity V_A/Q ratio with the concept of physiological shunt and physiological dead space.

The alveoli of zero V_A/Q ratio means, there is no ventilation, but presence of adequate perfusion. So, the air which is already present within this type of alveoli will come in equilibrium with the PO_2 and PCO_2 of venous blood without getting further O_2 from air and excreting CO_2. Normally the PO_2 and PCO_2 of venous blood is 40 and 46 mm of Hg respectively. Therefore, the PO_2 and PCO_2 of air of these type of alveoli with zero V_A/Q ratio will be 40 and 46 mm of Hg, respectively.

The alveoli of infinity V_A/Q ratio means, there is only presence of ventilation but no perfusion. Therefore, the PO_2 and PCO_2 of these alveolar air becomes equal to the humidified inspired air, because inspired air loses no O_2 and gains no CO_2. Normally, the PO_2 and PCO_2 of humidified inspired air is 149 and 0 mm of Hg, respectively. So, the PO_2 and PCO_2 of these type of alveolar air will be 149 and 0 mm of Hg, respectively.

Now, when there is optimal alveolar ventilation and perfusion, then there is optimal exchange of O_2 and CO_2 through the alveolar membrane. Therefore, the alveolar air PO_2 remains at 104 mm of Hg which lies between that of the inspired air (149 mm of Hg) and that of the venous blood (40 mm of Hg). Similarly, the alveolar air PCO_2 remains at 40 mm of Hg which lies between 46 mm of Hg in venous blood and 0 mm of Hg in inspired air (Fig. 3.6).

So, under normal healthy condition the average alveolar air PO_2 and PCO_2 is 104 and 40 mm of Hg, respectively.

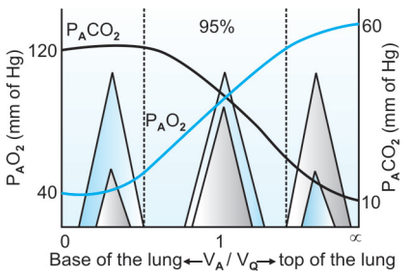

Fig. 3.6: Distribution of V_A/V_a ratio at different parts of lungs. Blue triangle is the perfusion and red triangle is the ventilation. 95% of the lung volume has matched ventilation and perfusion ratio

When the V_A/Q ratio is below normal, then the blood flowing through these alveolar capillaries is not properly oxygenated. Therefore, a portion of venous blood that does not undergo any gasseous exchange through the alveolar capillaries due to less ventilation returns back to systemic circulation. This is called the shunted blood and the total quantity of shunted blood per minute in normal conditions is called the physiological shunt. The greater the physiological shunt, the greater the amount of blood fails to be oxygenated, while passing through the lungs. This physiological shunt is measured by analyzing the concentration of O_2 in both the mixed venous blood and arterial blood and calculating the cardiac output. From these values, the physiological shunt is obtained by the formula below:

$$\frac{\text{Physiological shunt}}{\text{Cardiac output}} = \frac{(\text{Normal concentration of } O_2 \text{ in arterial blood}) - (\text{Measured concentration } O_2 \text{ in arterial blood})}{(\text{Normal concentration of } O_2 \text{ in arterial blood}) - (\text{Measured concentration } O_2 \text{ in mixed venous blood})}$$

This physiological shunt is also called the venous admixture. The venous admixture in normal individuals is typically less than 5%. This physiological shunt or venous admixture is usually expressed as a fraction of total cardiac output and is calculated clinically by obtaining a sample of mixed venous blood from pulmonary artery catheter and by arterial blood gas measurement (Fig. 3.7).

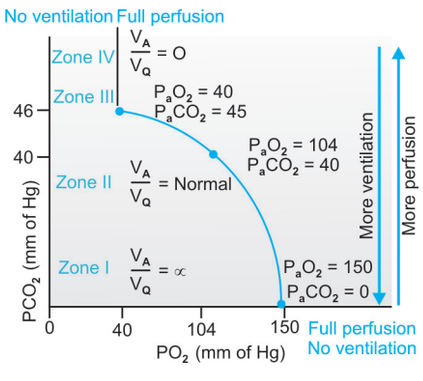

Fig. 3.7: V_a/V_q curve

When the V_A/Q ratio is above normal, then there is far more available O_2 in alveoli than can be transported away by the flowing blood. Thus some of the alveolar ventilation is wasted. When this wasted alveolar ventilation is summed up with the wasted ventilation of the anatomical dead space, then we will get the physiological dead space. This physiological dead space can be measured by analyzing the tidal volume and PO_2 and PCO_2 in the arterial blood and expired air, respectively. From these values, physiological dead space is obtained by the formula below:

$$\frac{\text{Physiological dead space (VD)}}{\text{Tidal volume (VT)}} = \frac{(\text{Arterial } CO_2 \text{ tension } (P_aCO_2)) - (CO_2 \text{ tension in expired air } (P_ECO_2))}{(\text{Arterial } CO_2 \text{ tension } (PaCO_2))}$$

This above equation is also called the Bohr equation. In this equation we can place P_ACO_2 instead of P_aCO_2 because in normal healthy adult P_ACO_2 is usually equivalent to P_aCO_2. In chronic obstructive lung disease, there is both the features of obstruction of small air ways and emphysema. The alveoli beyond the obstruction are not ventilated with uncompromised perfusion. So, the V_A/Q ratio approaches to zero. On the other hand, in emphysematous part of the lung, most of the ventilation is wasted because of inadequate blood flow. So, the V_A/Q ratio approaches to infinity. Thus in COPD, some area of lungs show excessive physiologic shunt and some areas show excessive physiologic dead space. So, both of these conditions produce severe V_A/Q mismatch and seriously impair the effectiveness of lung's function.

ALVEOLAR OXYGEN TENSION, PULMONARY END CAPILLARY OXYGEN TENSION, ARTERIAL OXYGEN TENSION, MIXED VENOUS OXYGEN TENSION

Alveolar oxygen tension (P_AO_2) (Table 3.3)

When a gas is kept in a container, it gives pressure on the surface of its walls. Thus, the pressure or tension of a gas in the container is due to the multiple impacts or bombardment of its moving molecules against the surface of the container. In case of a mixture of gases, the total pressure exerted by this gas mixture on container's wall is the summed up forces of impact of all the molecules of different gases against the container's surface at any given moment. This means the pressure exerted by a single gas component of a mixture is directly proportional to the concentration of this gas in the total mixture. This is called the partial pressure of that gas in mixture. In the atmospheric air there are mainly two gases N_2 and O_2 and their respective proportion or concentration is 79% and 21% respectively. (The actual composition of air is 78.62% N_2, 20.84% O_2, 0.04% CO_2 and 0.5% H_2O). The total pressure of atmospheric air at sea level is about 760 mm of Hg. Thus, it is clear from the previous discussion on the molecular basis that pressure (which for the individual gase of a mixture is called the partial pressure) contributing by each gas in a mixture is directly proportional to their concentration in it. So, 79% pressure of 760 mm of Hg i.e 600 mm of Hg is exerted by N_2 and 21% pressure of 760 mm of Hg i.e. 160 mm of Hg is contributed by O_2. Thus, the partial pressure of N_2 in the air is 600 mm of Hg, the partial pressure O_2 in the air is 160 mm of Hg and the total pressure of air at sea level is 760 mm of Hg (as other gases which are present in the air are in vary minimal concentration, so here they are deliberately omitted from this calculation). The partial pressure of

Table 3.3: Diffusion coefficient of different gases

He	0.95
CO	0.81

individual gases in a gas mixture is designated as PO_2, PN_2, PH_2O, etc.

When air, containing little or no water vapour is breathed in, it is immediately humidified in the respiratory passage by water vapour, evaporating from the surfaces of the airway. Then, the partial pressure exerted by these water molecules in the inspired air is called the partial pressure of water vapour (PH_2O). The quantity of evaporation of water from the surfaces of respiratory passages and its concentration in the inspired air depends on the temperature. At normal body temperature of 37°C, the concentration of water vapour in the inhaled air is 6.2%. Therefore, the water vapour pressure at 37°C in inspired air is 6.2% of 760 mm of Hg or 47 mm of Hg. The greater will be the temperature, the greater will be the water vapour concentration and its pressure in the inspired air. Alternativley, the lower will be the temperature, the lesser will be the water vapour concentration and its pressure in the inspired air. Thus, water vapour pressure at 0°C is 5 mm of Hg and at 100°C is 760 mm of Hg. So, the partial pressure of N_2 and O_2 in the inspired air after full humidification at 37°C will come down to 564 and 149 mm of Hg respectively (564 mm of Hg N_2 + 149 mm of Hg O_2 + 47 mm of Hg H_2O = 760 mm of Hg humidified inspired air).

O_2 is continuously absorbed from alveoli into the blood and then new O_2 is continuously breathed in into the alveoli from atmosphere. When more and more O_2 is absorbed into the blood from alveoli (e.g. exercise) or less new O_2 enters in the alveoli (e.g. respiratory depression, high altitude etc) then the lower will be the concentration and partial pressure of O_2 in the alveoli (P_AO_2). Alternatively, when less O_2 is absorbed into the blood from alveoli (e.g. rest) or higher its concentration is in inspired air (e.g. O_2 therapy), then the higher will be its concentration and partial pressure in the alveoli (P_AO_2). Therefore, the concentration and subsequent partial pressure of O_2 in the alveoli is controlled by: (i) the rate of absorption of O_2 in the blood, (ii) the rate of entry of new O_2 in the alveoli, and (iii) the presence of CO_2 or other gases in the alveoli. Therefore, the alveolar O_2 tension (P_AO_2) can be calculated by the following formula:

$$P_AO_2 = P_IO_2 - P_aCO_2 / RQ$$

RQ = respiratory quotient, P_IO_2 = inspired O_2 tension and P_aCO_2 = arterial CO_2 tension which is equivalent to the alveolar CO_2 tension (P_ACO_2).

When the air enters the body from atmosphere, it rapidly becomes saturated at 37°C (i.e body temperature) with water vapour and reaches the alveoli where it mixed with CO_2. The partial pressure of water vapour and CO_2 in alveoli at 37°C are 47 mm of Hg and 40 mm of Hg, respectively. So, the next 673 mm of Hg (760 − 47 − 40 = 673 mm of Hg) accounts for the combined partial pressure of N_2 and O_2. The partial pressure of N_2 in air or alveoli is 569 mm of Hg.

Therefore, P_AO_2 = 673 − 569 = 104 mm of Hg.

Thus, the P_AO_2 is 104 mm of Hg when a normal healthy adult person breaths atmospheric air at sea level. But if the patient breaths only 100% O_2, then the alveolar gas contains only O_2, CO_2 and water vapour, and no N_2.

In such situations,

$$P_AO_2 = P_IO_2 - P_aCO_2 - PH_{2O}$$
$$= 760 - 40 - 47$$
$$= 673 \text{ mm of Hg}$$

(RQ is usually not measured).

Another simple method of estimating P_AO_2 (in mm of Hg) is to multiply the percentage of inspired O_2 concentration by 6·7. Thus at 40% of F_IO_2, the P_AO_2 is 6·7 × 40 = 268 mm of Hg and at 100% F_IO_2, the P_AO_2 is 6·7 × 100 = 670 mm of Hg at normal atmospheric pressure.

Pulmonary End Capillary O_2 Tension

Oxygen passes from alveoli to pulmonary capillaries by passive diffusion and thus oxygenates the blood. At the end of diffusion, the pulmonary end capillary O_2 tension (P_CO_2) is more or less equal to the P_AO_2. Therefore, P_AO_2 - P_CO_2 gradient is normally insignificant. But, if there is any impairment of diffusion of O_2 across the alveolar capillary membrane, then the P_AO_2 - P_CO_2 gradient will increase. The diffusion of O_2 from alveoli through the pulmonary capillary depends in many factors. These factors are:

A. The rate of diffusion of O_2 across the alveolar capillary membrane.
B. The pulmonary capillary blood volume or flow.
C. The transit time.
D. The capacity of binding of O_2 with Hb.

A. The rate of diffusion of O_2 across the alveolar capillary membrane

This again depends on the following factors:

i. the thickness of the respiratory membrane
ii. the surface area of the respiratory membrane
iii. the diffusion coefficient of gases (here O_2)
iv. the difference of partial pressure of the gases (here O_2) between alveoli and capillary.

(i) Thickness of respiratory membrane

The O_2 diffuses from alveoli into the RBC through different layers or membrane which constitute the respiratory or alveolar capillary membrane. These layers are: layer of fluid lining the alveolus containing surfactant, alveolar epithelium composed of thin epithelial cells, an epithelial basement membrane, a thin interstitial space between alveolar epithelial basement membrane and capillary endothelial basement membrane, capillary endothelial basement membrane and capillary endothelial membrane. The average thickness of this respiratory membrane is 0.4 to 0.6 µm. Sometimes, it is as thin as 0.2 µm. This extreme thinness of respiratory

membrane facilitates the diffusion of O_2 from alveoli to blood, because the rate of diffusion of gases through the membrane is inversely proportional to the thickness of it. Any factor that increases the thickness of respiratory membrane, such as oedema, fibrosis, deposition of substances, etc, significantly interfere the diffusion of gases (O_2) across the respiratory membrane.

(ii) Total surface area of respiratory membrane

The large capillary surface area of alveoli also greatly facilitate the diffusion of O_2. The total surface area of respiratory membrane is about 70 square meter in a normal healthy adult male. The total quantity of blood present in the alveolar capillaries at a given moment is 60 to 140 ml and this small amount of blood is spread over such a big surface area. So, it is easily understood how O_2 is easily diffused from the alveolar air to the pulmonary capillary blood through this such huge surface area. When the surface area for diffusion is reduced such as in emphysema, then the diffusion is significantly impaired. In emphysema, the alveoli are coalesced due to the rupture of their wall and new alveoli are formed. This new alveoli are larger than the original one, but the total surface area of respiratory membrane is greatly reduced.

(iii) Diffusion coefficient of gases (Table 3.4).

The diffusion capacity of gases through respiratory membrane is expressed as the diffusion coefficient, because diffusion of gases from alveoli to capillary blood is dictated by the diffusion coefficient of that gases. It depends directly on the solubility of the gases in water and inversely on the square root of their molecular weight (mW). Thus, diffusion of gases from alveoli to pulmonary capillary blood through the respiratory membrane first depends on their solubility characteristic in water. Further, the solubility of individual gas in water depends on their partial pressure in their gaseous phase at the one side of the membrane and their concentration (expressed in volume of gas dissolved in each volume of water) on the other side of the membrane. This relation is expressed as the solubility coefficient in water at body temperature for individual gases. On the other hand, the solubility determines the partial pressure of gas in its liquid phase which again dictates the net diffusion of it between its gaseous and liquid phase. Thus the solubility coefficient can be calculated from the Henry's law, which is expressed as:

Solubility coefficient = Concentration of dissolved gas ÷ partial pressure.

From the solubility coefficient table, it is found that CO_2 is 20 times more soluble in water than O_2 and O_2 is 2 times more soluble in water than N_2. So, for a given partial pressure CO_2 diffuses 20 times more rapidly from capillary blood to alveoli than O_2 from alveoli to capillary blood and O_2 diffuses 2 times more rapidly than N_2.

(iv) The difference of partial pressure of the gases between the alveoli and capillary (Table 3.5)

There are some types of molecules which are physically or chemically attracted to the water molecules, while others are repelled. This is called the solubility. The more solubility means the more gas molecules are attracted to water molecules and dissolved within it without building up excess pressure within the solution which is expressed by the free gas molecules in water but not dissolved within it. Alternatively, in the case of those that are not readily attached to water molecules, are repelled and make an impact or force on the surface or the membrane. Thus, they develop a pressure on the surface with fewer dissolved molecules. So, the solubility of a gas is inversely proportional with the development of partial pressure which means increased solubility decreases the partial pressure, exerted by the gas.

Now, it is clear from the previous discussion that after dissolving in water or body tissues every gas exerts a pressure on the surface or the membrane according to their solubility (in the same way as a gas in liquid phase or a gas in gaseous phase). This is because every dissolved gas molecule moves randomly and have kinetic energy. When a mixture of gases exerts a pressure then the individual pressure exerted by individual gases are called the partial pressure. Again this partial pressure of a gas in a liquid phase depends on their concentration in the liquid and the solubility coefficient of that gas (Henry's law) in this liquid.

The pressure difference across the alveolar membrane represents the difference between the partial pressure of gas in alveoli and the partial pressure of gas in the capillary blood. The partial pressure

Table 3.4: Solubility coefficient of different gases

Gases	*Solubility coefficient*
O_2	0.024
N_2	0.012

CO	0.018

Table 3.5: Partial pressure of gases (mm of Hg) in the different inspired and expired air

Gases	*Atmospheric air*	*Humidified air*	*Alveolar air*	*Expired air*
N_2	597 (80%)	563	563	566
O_2	159 (20%)	150	150	120
H_2O	4	47	40	27
CO_2	-	-	47	47
Total pressure (mm of Hg)	760	760	760	760

means the total number of molecule of a particular gas striking on a unit area of surface in a unit time either as gas in gaseous phase (in alveoli) or as gas in liquid phase (in capillary blood). Therefore, the partial pressure difference represents the net tendency for the gas molecules to move through the membrane to any of their phase. So, when the partial pressure of any gas (as for example O_2) in the alveoli is greater than the partial pressure of gas in the blood, then the net diffusion from the alveoli into the blood occurs. Similarly, when the partial pressure of any gas (as for example CO_2) in the blood is greater than the partial pressure of it in the alveoli, then net diffusion from the blood into the alveoli occurs (Fig. 3.8).

B. Pulmonary capillary blood volume or flow

The pulmonary capillary blood volume, especially the volume of red cells which are able to take up the O_2 is also a very important factor for diffusion of O_2 and CO_2 between the alveoli and capillary. Thus, anaemic patients tend to have low diffusion factor and a polycythemic patients have a higher one.

C. The transit time

The capillary transit time which also have an impact on the diffusion of O_2 from the alveoli to capillary can be estimated by dividing the pulmonary capillary blood volume by cardiac output. Thus the normal capillary transit time is 70 ml ÷ 5000 ml/min = 0.8 sec. But the majority of diffusion of O_2 occurs within the first third (0.3 sec) of this transit time. Thus, virtually a complete equilibrium of O_2 tension between the alveolus and the blood has been established at the venous end of capillary within this small time, providing a large safety of margin. So, during exercise almost complete equilibrium of O_2 still occurs, though the transit time may be reduced to 2/3 of the normal, i.e. 0.1 sec.

D. Capacity of binding of O_2 with Hb

The rate of binding of O_2 with Hb also appears to be the rate limiting factor for diffusion of O_2 from alveolus to the capillary. This is further discussed else where.

Arterial O_2 Tension (PaO_2)

When breathing air, the tension of O_2 (PO_2) in the air of the alveoli averages to about 104 mm of Hg. Whereas, the PO_2 in the venous blood entering the pulmonary capillary at its arterial end averages only about 40 mm of Hg. Therefore, the initial pressure difference which cause the O_2 to diffuse into the pulmonary capillary from alveoli is 104 − 40 = 64 mm of Hg (Fig. 3.9).

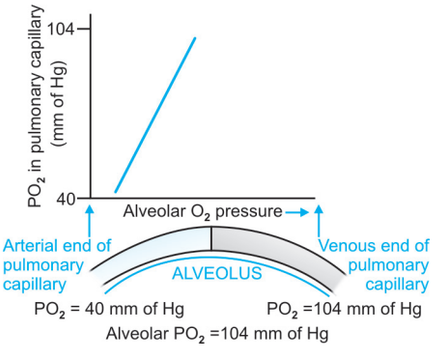

Fig. 3.9: Diffusion of O_2 from alveolar air into the pulmonary capillary blood

After diffusion from alveoli in the capillary blood, the O_2 build up a tension in it and reaches an equilibrium. Thus, the PO_2 of blood that enter the left atrium is also like that of alveolar PO_2 and averages about 104 mm of Hg. But, the blood coming from lungs to the heart with PO_2 of 104 mm of Hg constitute 98% of the cardiac output. (Fig. 3.10).

Another 2% of the cardiac output comes from the bronchial veins which is

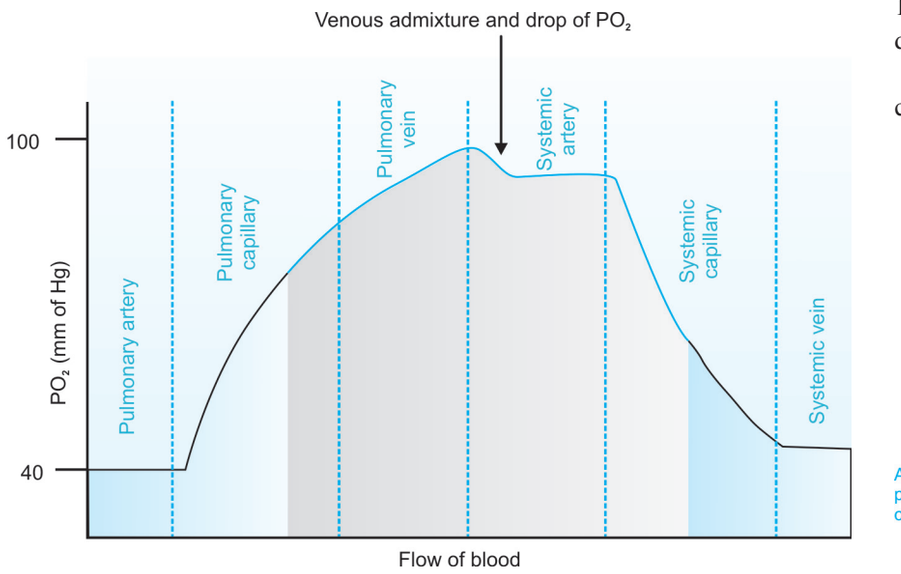

Fig. 3.8: The changes in PO_2 while blood is flowing through systemic vein, to right ventricle, to pulmonary artery, to pulmonary capillary, to left ventricle, to systemic artery, to systemic capillary, and again to systemic vein

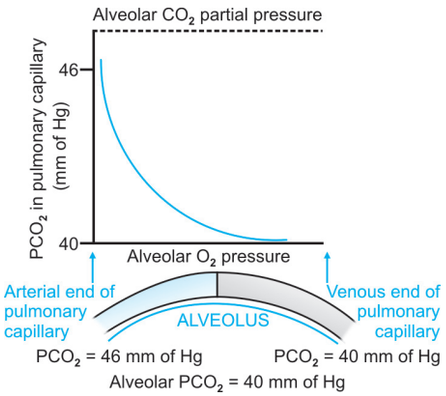

Fig. 3.10: Diffusion of CO_2 from pulmonary capillary blood into the alveolar air

not oxygenated. Normally 2% of the cardiac output passes from aorta through the bronchial circulation and supplies mainly the deep tissues of the lungs. This blood is not exposed to lung air for ventilation and comes back to left atrium with PO_2 about 40 mm of Hg which is similar to that of systemic venous system. This blood flow is called the shunt (true) flow. When this deoxygenated shunted blood (PO_2 = 40 mm of Hg) combines with the oxygenated blood of pulmonary vein (PO_2 = 104 mm of Hg) then this is called venous admixture of blood and PO_2 in left ventricular blood comes down to 97 mm of Hg from 104 mm of Hg. Then, this venous admixtured blood enters the heart and pumped into the aorta with PO_2 of it about 97 mm of Hg. This is the actual systemic arterial O_2 tension (P_aO_2). When this oxygenated arterial blood passes through different tissues, the PO_2 comes down in stages at different site which is shown in figure of O_2 cascade in the chapter of 'O_2 and CO_2'.

Alveolar and arterial O_2 tension difference ($P_AO_2 - P_AO_2$)

When a patient is breathing air at sea level in 37°C temperature, then normal P_AO_2 is 104 mm of Hg and P_aO_2 is 97 mm of Hg. So, the normal alveolar to arterial O_2 tension difference (P_AO_2-P_aO_2 or A–a gradient) is 104 − 97 = 7 mm of Hg, and normally it lies below 15 mm of Hg. But it may vary between 5 and 25 mm of Hg, and gradient increases progressively with increase of age up to 20 to 30 mm of Hg. This is due to the progressive increase in closing capacity (cc) in relation to FRC with increased age. From age, the P_aO_2 can be calculated by the following formula:

$$P_aO_2 = 102 - Age/3$$

The $P_AO_2 - P_aO_2$ is the most common mechanism of hypoxaemia. The A − a gradient for O_2 depends on V_A/Q ratio, shunt and mixed venous O_2 tension. It is directly proportional to V_A/Q mismatch and shunt and inversely proportional to the mixed venous O_2 tension. Thus, $P_AO_2 - P_aO_2$ difference is influenced by the following factors.

(i) V/Q ratio

From the aspect of ideal V_A/Q ratio, no alveoli are ideal. Some are overventilated or some are overperfused. So, the blood from different parts of the lungs after passing through the alveolar capillaries and after taking part in gaseous exchange with different PO_2 mixes at the venous end of pulmonary capillary and flows through the pulmonary vein to the left atrium. There final PO_2 i.e P_aO_2 is definitely lower than P_AO_2. Therefore, more V_A/Q mismatch results in more $P_AO_2 - P_aO_2$ difference.

(ii) Shunt (Fig. 3.11)

The blood which passes without any gaseous exchange is called shunted blood. As more and more blood passes through the shunt and mixes with the oxygenated blood, coming from different alveoli with different V_A/Q ratio at the left side of the heart, then $P_AO_2 - P_aO_2$ difference will increase. Shunt can be classified into two: true and false. True shunts are those that do not pass through the alveolar capillary or not through the lungs at all. They are also called the anatomical shunt. The examples of anatomical or true shunts are bronchial circulatory system, reverse ASD, reverse VSD, reverse PDA, etc. False shunts are those that pass through the alveolar capillary, but due to different pathological condition they can not take part in gaseous exchange. They are also called the physiological shunt and indicate mainly the zero V_A/Q zones of the lung.

The venous admixture or shunt causes reduction in arterial O_2 content and increase in arterial CO_2 content. Further due to the shape of the O_2 and CO_2 dissociation curve, this small reduction of O_2 content is reflected as a large reduction in arterial PO_2 (about 7 mm of Hg), whereas this small increase in CO_2 content is reflected by only a small increase in arterial PCO_2 (less than 1 mm of Hg). The arterial PO_2 is, therefore, the best indication of the amount of venous admixture or shunt than the arterial PCO_2. So, the high $P_AO_2 - P_aO_2$ difference is due to V_A/Q mismatch or true shunt and can be detected only by giving the subject 100% O_2 to breath. If there is small increase in arterial PO_2, then the $P_AO_2 - P_aO_2$ difference or hypoxemia is due to true shunt. Up to the presence of 50% shunt, changes is FiO_2 have virtually no effect on P_aO_2 (Table 3.6).

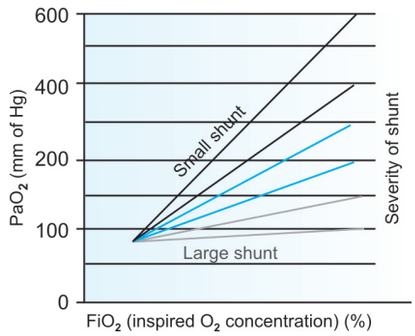

Fig. 3.11: The effect of various concentration of inspired O_2 concentration on arterial O_2 tension (PaO_2) with various amount of shunt. In case of very large shunt there is very little benefit with increasing inspired O_2 concentration

(iii) Venous admixture and O_2 tension in mixed venous blood (Fig. 3.12).

When the blood passes through different organs or tissues of body then the

extraction of O_2 from blood by these different organs or tissues depends on the rate of metabolism of that tissues and the fraction of cardiac output supplied to these tissues. So, the partial pressure of O_2 in venous blood coming from different tissues are different. When these venous blood coming from different organs or tissues with different PO_2 reach at the right side of the heart, they mix and produce the venous admixture with given O_2 tension in mixed venous blood. The causes which reduce the mixed venous blood O_2 tension (PVO_2) such as increased metabolism and low cardiac output increases the $P_AO_2 - P_aO_2$ difference. Low cardiac output tends to increase the effect of V_A/Q mismatch and subsequently its effect on shunt and ultimately their effects on PO_2 and PVO_2. On the otherhand, low cardiac output reduces the venous admixture secondary to the increased pulmonary vasoconstriction due to lower mixed venous O_2 tension (compensatory phenomenon) (Table 3.7).

Concentration of Hb also has an effect on O_2 tension of mixed venous blood and subsequently on A-a oxygen gradient. Low Hb concentration can depress mixed venous PO_2 and increase the A-a oxygen gradient.

Mixed Venous O_2 Tension (PVO_2)

Mixed venous O_2 tension represents the overall balance between the delivery and the consumption of O_2. The normal value of it in a healthy adult is 40 mm of Hg. A true mixed venous blood sample for measurement of O_2 tension should must be obtained from SVC, IVC and right heart. So, it should be obtained by pulmonary artery catheter. Other details regarding PVO_2 is described in previous paragraph.

DEAD SPACE

When a person breaths, then all the air taking during inspiration does not take part in the gaseous exchange. Some of the air reach the alveoli and take part in gaseous exchange, but some simply fill the respiratory passages such as nose, nasopharynx, trachea, etc, where gas exchange does not occur. Thus, the part of the inspired air which does not take part in gaseous exchange is called the dead space air. During expiration the dead space air is expired first, followed by the exit of air from alveoli that takes part in gaseous exchange. Therefore, the dead space is very disadvantageous for gaseous exchange i.e oxygenation of blood and elimination of CO_2 and for removing the expiratory gases from lungs. Normally 2/3 of each breath takes part in gaseous exchange and this portion or volume of breath is called the alveolar ventilation. Whereas, the remaining 1/3 of each breath does not take part in gaseous exchange and this portion or volume of breath is called the dead space or dead space ventilation (Table 3.8).

The dead space is actually composed of two components: anatomical dead space and alveolar dead space. The sum of the two is referred to as the total or physiological dead space. Normally, in healthy adult the anatomical and physiological dead space is nearly equal and is about 150 ml each. This is because in a given healthy subject the anatomical dead space remains fixed and all the alveoli are functional, with no alveolar dead space. But, in some persons this physiological dead space may be as high as 10 times of the anatomical dead space and it is due to the presence of some partial functioning or completely nonfunctioning alveoli in some parts of the lungs which increases alveolar dead space.

Anatomical Dead Space

It is that portion of the total or physiological dead space which occupy only the conducting path of the respiratory passage. It varies with the age, sex and size of the lung. Normally, in a healthy adult the approximate value of it is 2 ml/Kg or 150 ml. But in young women, it is as

low as 100 ml and in old man it can rise as much as up to 200 ml. The anatomical dead space is reduced when the neck is flexed and tongue falls back (30 ml reduction). It also can be reduced by pneumonectomy, tracheostomy, etc. On the otherhand, antomical dead space is increaed by protrusion of jaw and extension of neck (40 ml increase). In supine position, the antomical dead space is equal to the total or physiological dead space as alveolar dead space becomes zero or negligible due to the obliteration of zone 1. But in erect posture the alveolar dead space increases from zero to 60 or 80 ml due to the creation of Zone 1. So, physiological dead space also increases.

Alveolar Dead Space

It is that portion of the total or physiological dead space that occupy or ventilate the nonperfused alveoli. So, in that portion of the lung, ventilation goes wasted. It increases when the zone 1 area increases such as in upright position, hypotension, low cardiac output state, etc.

Total or Physiological Dead Space

As the total or physiological dead space is the sum of the anatomical and alveolar dead space, so when any of the above two dead space increases, then the physiological or total dead space also increases. The examples are: old age, upright position, high respiratory rate (inspiratory time < 0.5 sec), administration of atropine, COPD, asthma, pulmonary embolism, hemorrhage, hypotension, etc.

Apparatus Dead Space

It is the volume of gas that is present in any anaesthetic apparatus between the patient and the point in the system where rebreathing of exhaled gases ceases to occur, for example the expiratory valve in Magill system, the side arm in Ayre's T-piece, etc. The volume of apparatus dead space in Magill system is 125 ml. So it is very important for an anaesthetised small children.

Dead space and alveolar ventilation

Alveolar ventilation (V_A) is the major determining factor of the alveolar O_2 and CO_2 tension which later subsequently determine the O_2 and CO_2 tension of blood. On the otherhand, dead space is the major determining factor of alveolar ventilation. So, it is easily understood how the dead space (V_D) controls the alveolar and arterial O_2 and CO_2 tension through alveolar ventilation from the formula below:

$$V_A = (V_T - V_D) \times F$$

V_A = Alveolar ventilation, V_T = Tidal volume, V_D = Dead space, F = Respiratory rate.

For a healthy adult person, if V_T = 450 ml (6 ml/Kg), V_D = 150 ml and F = 12/min,

then, $V_A = (450-150) \times 12 = 3600$ ml/min.

The dead space (total or physiological) to tidal volume ratio (V_D/V_T) also provides a useful expression of the efficiency of ventilation. Normal V_D/V_T ratio is 0·25 to 0.4. It averages to 0.3 which means dead space is 30% and ventilation is 70% of tidal volume. In patient with obstructive airway disease V_D/V_T ratio may increase to 0.6 or 0.7 (60 or 70%). It means dead space is increased to 60 to 70% and ventilation is reduced to 40 to 30% of total tidal volume, or ventilation which is grossly inefficient. V_D/V_T ratio also increases with age which can be roughly estimated from formula:

$$V_D/V_T = 33 + \text{Age}/3 \text{ percent.}$$

This is due to the more vascular obliteration with age. The V_D/V_T ratio also can be derived by the Bohr equation :

$$\frac{V_D}{V_T} = \frac{P_ACO_2 - P_ECO_2}{P_ACO_2}$$

P_ACO_2 = alveolar CO_2 tension, P_ECO_2 = expired CO_2 tension. In normal healthy adult P_ACO_2 is equivalent to P_aCO_2 and P_ECO_2 is the average measured over several minutes. So, this equation is useful clinically, because we can measure the V_D from this equation.

For example, P_ACO_2 = 40 mm of Hg, P_ECO_2 = 28 mm of Hg and V_T = 500 ml.

So, $V_D/V_T = (40-28)/40 = 12/40$

or $V_D = 12/40 \times 500 = 150$ ml.

Table 3.9: Components and its percentage that constitute the resistance of breathing Elastic resistance 65%

Nonelastic resistance
Airway resistance 28%
Viscous nonelastic resistance such as bones, muscles, etc, 7%

RESISTANCE (TABLE 3.9)

During respiration i.e. inspiration and expiration, the chestwall and lungs move out and in and the air flows in and out through the airways and lungs. But, the movement of chestwall with lungs and the flow of air through it is always associated with some impedence. This impedence is called the resistance. This is due to the friction during movement between the tissues of chestwall and lungs, and during the flow of air between the air and its passage. Generally, this resistance is overcomed by creating a pressure gradient between the atmosphere and alveoli which is accomplished by work of breathing. Thus, the resistance is defined as the unit change of pressure gradient causing unit volume of air to flow.

The resistance is divided under two broad headings: elastic resistance and nonelastic resistance. The elastic resistance is imparted by the elastic recoil property of the lungs and chestwall, and also by the surface tension acting at the air fluid interface in the alveoli. Elastic resistance is measured in terms of compliance as the later is opposite to the elastic recoil property of the lungs and chestwall which contributes to the elastic resistance. On the otherhand, the nonelastic resistance is imparted by the friction of air in the air passage during its flow through it and by the friction among the tissues during movement of the non elastic part of the lungs and chestwall, such as bones, muscles, etc.

The work of breathing necessary to develop the pressure gradient to overcome the elastic resistance is stored as potential energy which is subsequently used during

passive expirations. Whereas, the work of breathing necessary to overcome the non-elastic resistance is expressed as heat.

Elastic Resistance

From the previous discussion, it is now clear that the elastic resistance is due to the elastic recoiling property of the lung tissues, the soft chestwall tissues and the surface tension in the alveoli. Again the elastic recoiling property of the lungs and the chestwall is due to their high content of elastin and collagen fibres. Clinically, the resistance offered by these elastin and collagen fibres cannot be measured directly and isolatedly. Similarly, the only measurement of elastic resistance offered by the surface tension is not so helpful clinically. Therefore, the whole elastic resistance is measured indirectly by the compliance (Fig. 3.13).

Elastic Resistance Due to the Elastic Recoiling Property of Lungs and Chestwall

The elastic recoiling property of the lungs and chestwall greatly determine the elastic resistance and is calculated indirectly by the compliance. Because compliance is opposite to resistance i.e compliance = 1/resistance (or vice versa) and it is also reproduced like resistance by the pressure volume curve. If the lungs are affected by fibrosis (e.g interstitial pulmonary fibrosis) where the elastin and collagen fibres are replaced by the fibrous tissue, then the elastic resistance will increase and the compliance will decrease. Thus, the lungs become stiff and the pressure - volume curve will shift downwards and to the right. On the otherhand, in emphysema the total mass of elastin and collagen fibres are reduced and the recoiling property of the lungs are lost. Thus, it becomes voluminus and the elastic resistance will decrease with increase of compliance. So, the pressure - volume curve is shift upwards and to the left (Table 3.10).

Elastic resistance due to surface tension

Another important factor affecting the elastic resistance of lung is the surface tension which is due to the gas-fluid interface, present in the alveoli. This surface tension or force tries to reduce the gas-fluid interfacing area and favours the alveolar collapse. Thus, it increases the pressure gradient required for per unit of air to flow to increase the volume of lungs or to prevent the collapse of alveoli. This is known as the elastic resistance due to surface tension. If the lung is filled with saline, then surface tension will become zero due to the absence of air-fluid interface. In such condition, the elastic resistance will measure only the tissue elastic resistance. Whereas, the resistance obtained from the alveoli filled with air measures both the tissue elastic resistance and elastic resistance due to surface tension.(Fig. 3.14).

Normally, the elastic resistance due to surface tension is reduced by the presence of surfactant. In the absence of surfactant, the alveoli will collapse due to increased surface tension or the inward retraction force, especially during expiration when the alveoli gradually become smaller. This is because when the alveoli gradually become more and more smaller, then the surface tension gradually increases following the Laplace law. This is because as the fluid molecules come more and more closer, then the attraction force between these molecules increase. This has theoretically two disadvantages:

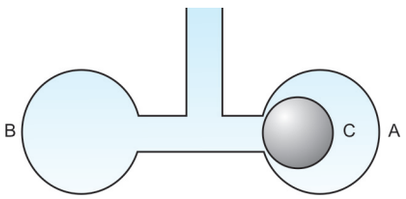

Fig. 3.14: According to Laplace law P = 2T/R

Story 1: The two alveoli A and B are of same size, but alveoli A has no surfactant. The radius of alveoli A is 0.5 cm and surface tension is 10 dynes/cm, whereas the radius of alveoli B is 0.5 cm and surface tension is 5 dynes/cm, due to the presence of surfactant. Then, the intraalveolar pressure of alveoli A will be P = 2 ´10/0.5 = 40 dynes/sq cm. The intra-alveolar pressure of alveoli B with surfactant of same radius will be P = 2 ´ 5/0.5 = 20 dynes/sq cm. So, due to high pressure in alveoli A, the air will flow from it to alveoli B and gradually the alveoli A will reduce in size. On the otherhand, alveoli B will increase in size. Hence, in this story alveoli A needs surfactant to reduce the intraalveolar pressure.

Story 2: The two alveoli C and B of different radius, but of same surface tension. The radius of alveoli C is 0.2 cm and surface tension is 5 dynes/cm, whereas the radius of alveoli B is 0.5 cm and surface tension is 5 dynes/cm. Then the pressure within alveoli C will be P = 2 × 5/0.2 = 50 dynes/sq cm. While the pressure within the alveoli B will be P = 2 × 5/0.5 = 20 dynes/sq cm. So the smaller alveoli C will drain in alveoli B and will reduce in size. Hence, in this story alveoli C needs more surfactant than B, though surface tension is same, because its radius is small.

Story 3: In the presence of surfactant the smaller alveoli will have less surface tension due to crowding of the surfactant molecule in a small space. For example, there are two alveoli C and B. The radius of alveoli C is 0.2 cm and surface tension is 1 dynes/cm. Whereas the radius of alveoli B is 0.5 cm and surface tension is 5 dynes/cm. Then, the pressure within alveoli C will be P = 2 × 1/0.2 = 10 dynes/sq cm. Whereas the pressure within the alveoli B is 20 dynes/sq cm. Thus, the gas will flow from alveoli B to alveoli C, untill the two alveoli reach to equal size and volume become stable

i. Smaller alveoli have greater surface tension and have more tendency to collapse than a larger alveoli. So, each small alveolus will progressively discharge into a large one and ultimately a gigantic alveolus would be left.
ii. Retractive forces of the lung due to increased surface tension should increase as the lung volume decreases. So, the lung volume will decrease in vicious manner and ultimately it will completely collapse.

This above phenomenon can be explained by the Laplace law. According to the Laplace law: P = 2 T/r. Here, P is the pressure at inside of the alveolus which increases or decreases according to the size of the alveolus and again depends on the surface tension. T is the surface tension and r is the radius of the alveoli. From the Laplace law, it is easily understood that smaller alveoli with smaller radius (r) have increased intraalveolar pressure which indicates its collapsing nature due to increased inward retraction force or increased surface tension. On the other-hand, we can say that the collapse of alveoli is more likely when the surface tension increases or alveolar size decreases. Thus, the alveolar collapse is directly proportional to surface tension and inversely proportional to the radius of the alveolus.

Moreover, within the alveolus the ability of surfactant to reduce the surface tension is directly proportional to its concentration. So, when the alveoli become smaller during expiration or due to any cause, the concentration of surfactant on the lining fluid of alveoli will be increased and the surface tension will be more effectively reduced, offsetting the increased surface tension due to the reduction of the size of alveoli. Alternatively, when the alveoli are over distended, the concentration of the surfactant on the lining fluid is reduced and the surface tension is less effectively reduced. Thus, a balance is reached when larger alveoli are prevented from over distension and smaller alveoli are prevented from collapse.

Compliance

Compliance is also termed as stretchability. In character it is opposite to the elasticity which is described before. Elasticity tries to squeeze the lungs and chestwall, and offers resistance for air to flow in the lungs. Whereas, it is countered by the stretchability of both the lungs and chestwall which is called the compliance. Thus, the elasticity or the resistance which prevents the air to flow in the lungs is measured indirectly in the form of stretchability or compliance which facilitates the air to flow in the lungs (Fig 3.15).

For air to flow in the lungs, a pressure gradient must have to be developed which will help to overcome the elastic and the nonelastic resistance of the lungs and chestwall. So, the compliance (C) is defined as the unit change in volume of lung for unit change in developed pressure and is calculated by dividing the total change in volume (ΔV) of lung by the total distending pressure (ΔP) which causes this change. Whereas, the resistance is defined as changes in distending pressure divided by changes in volume.

Thus, C (L/cm of H_2O) = ΔV (in L) / ΔP (cm of H_2O)

Compliance may be calculated isolatedly taking only the chestwall (Cw) or the lung (CL) component or both together (CT). So, the equation of compliance of individual component can be represented as:

i. C_L litre/cm of H_2O = ΔV litre/transpulmonary pressure gradient or ($P_A - P_{Pl}$) cm of H_2O
ii. C_W litre/cm of H_2O = ΔV litre/transmural pressure gradient or ($P_{Pl} - P_{atmos}$) cm of H_2O. (Fig. 3.16).

Thus C_T litre/cm of H_2O = ΔV litre/transthoracic pressure gradient or ($P_A - P_{atmos}$) cm of H_2O. [C_T is the total compliance]

The normal C_L value is 200 ml/cm of H_2O or 0.2 L/cm of H_2O. Any pathological condition of lungs such as pulmonary oedema, atelectasis, emphysema, etc, can affect the C_L. The normal C_W value is also 200 ml/cm of H_2O or 0.2 L/cm of H_2O. Any pathological condition of chestwall such as pain, injury, trauma, paralysis, osteoarthritis, etc., can also affect the C_W. Thus, the normal total compliance (lung and

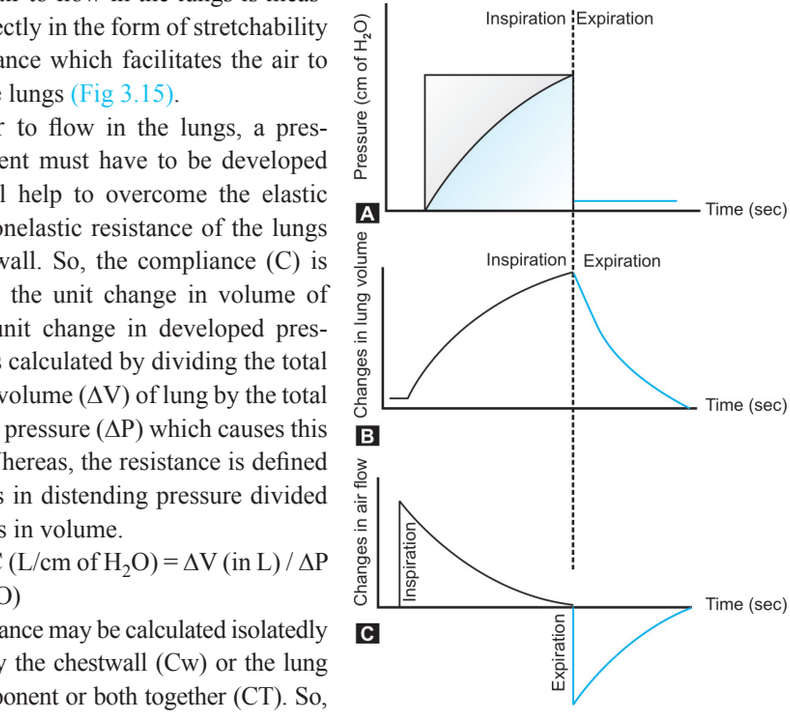

Fig. 3.15: Compliance

Figs 3.16A to C: Picture A represents the graphic changes in intrapulmonary pressure during IPPV when a constant pressure is applied (square wave). Line x represents the sudden rise of intrapulmonary pressure produced by a pressure gradient to overcome the both elastic and nonelastic airway resistance. Among these the red area represents the nonelastic airway resistance and the blue area represents the elastic resistance. The pressure gradient to overcome the nonelastic resistance is maximum initially and then decreases exponentially. Whereas, the pressure gradient require to overcome the elastic resistance is minimum initially and then increases exponentially. Alveolar filling ceases when the pressure from elastic forces balance the applied pressure. Expiration is passive and intrapulmonary pressure suddenly comes down to zero level with the ending of inspiration and initiation of expiration. Fig. B and C show the changes in lung volume and air flow respectively which correspond to the Fig. A

chestwall together) is 100 ml/cm of H_2O or 0.1 L/cm of H_2O. This is expressed by the following equation:

$1/C_T = 1/C_L + 1/C_W$

The transthoracic pressure gradient which helps to flow air inside the lungs first increases to peak value to overcome the nonelastic airway resistance and to inflate the stiff alveoli. Then, it decreases to somewhat lower plateau value to inflate the more compliant alveoli. Alternatively the pressure gradient required to overcome the elastic resistance is minimum initially, but then increases exponentially. If patient is on PEEP, this must be substracted from this peak or plateau value of transthoracic pressure before calculating the compliance.

Nonelastic Resistance

This is due to the friction created between the air and the wall of its passage, during the flow of it through the trachea and the bronchial tree (in case of anaesthetized person the anatomical dead space portion in the breathing system should also be included) and due to the friction among the tissues (such as bones muscles, etc.) during the movement of lungs and chestwall. The nonelastic resistance due to the movement of tissues are not considered clinically, as it is very minimal. So, we will take into account here only the frictional resistance due to the flow of air through the trachea- bronctrial tree. Usually, there are three patterns of airflow: laminar flow, turbulent flow and orifice flow.

The laminar flow occurs in tubes where its sides are parallel and when the velocity of flow is below the critical level. In the centre of the laminar flow the velocity is highest and it decreases gradually towards the periphery.

For an air to flow, a pressure gradient has to be developed. So, the relationship between the developed pressure gradient (P) and the rate of flow of air or the change in volume of lung is known as the airway resistance (Raw). Thus the equation of airway resistance is:

$$\text{Raw (cm of } H_2O\text{/L/S)} = \frac{\text{P (cm of } H_2O)V}{(L/S)}$$

According to Poiseuille's law:
Pressure gradient (P) = Flow (v) × 8 length of tube (L) × viscosity (μ) / π radius4 (r). Therefore,

$$R_{aw} = \frac{8L \times \mu \times V}{\pi r^4 \times V} = \frac{8L \times \mu}{\pi r^4}$$

The value or normal airway resistance is 0.5 to 2 cm of H_2O/L/S.

When the flow of air exceeds the critical velocity, then the laminar flow becomes turbulent. The important feature of this turbulent flow is that the drop of pressure during flow of air along the airway is not directly proportional to the flow rate, but is proportional to the square of it. Therefore, the pressure increases much more than the increase in flow. So, the resistance in turbulent flow will also increase much more than the laminar flow and is proportional to the gas flow which is opposite to the laminar flow. Therefore, in the turbulent flow the equation is:

$$\text{Pressure gradient} = \frac{V^2 \times \text{Gas density}}{r^5}$$

Therefore, during turbulent flow the resistance (R_w) = P/V

$$\text{or, } R_{aw} = \frac{V^2 \times \text{Gas density}}{r^5 \times V}$$

$$\frac{V \times \text{Gas density}}{r^5}$$

So, the nonelastic airway resistance in turbulent flow is directly proportional to the amount of flow (V) and the density of gas and is inversely proportional to the fifth power of the radius (r^5). Therefore, the turbulent flow is extremely sensitive to the airway caliber (Table 3.11).

Hence, the turbulence generally occurs during the high gas flow, at sharp angles and during certain change of airway diameter. Whether the flow will be turbulent or laminar usually depends on the Reynolds number. The equation of Reynolds number is:

$$\text{Reynolds number} = \frac{\text{Linear velocity} \times \text{Diameter} \times \text{Gas density}}{\text{Gas viscosity}}$$

If the Reynold number is below 1000, then the flow of gas will be laminar. Whereas Reynold number above 1500 produces turbulent flow. The gases with low density/viscosity ratio have less Reynold number and produces the laminar flow. Thus, they reduces the airway resistance. For example, helium (He) and O_2 mixture has least density/viscosity ratio and less likely to cause turbulent flow with reducing the airway resistance. So, it is useful clinically during severe turbulent flow caused by the upper airway obstruction.

The orifice flow occurs when it meets a severe constriction. The equation for orifice flow is equal to the turbulent flow. So, here the drop of pressure or the gradient is proportional to the square of flow rate and gas density replaces its viscosity. As density is used as a numerator in the equation of resistance of gas flow, so it is easily understood why the low density gas such as helium dimishes the resistance to flow. It diminishes the flow of resistance three fold as compared to air in severe obstruction.

The orifice flow occurs in larynx. Whereas the turbulent flow is mainly confined to trachea and main bronchi during most of the respiratory cycle. On the otherhand, laminar flow is found in the airway below the main bronchi. This is because though the division and subdivision of airway below the main bronchi reduce the individual diameter, but the total cross sectional area of airway increases due to this branching. Thus, the resistance in large bronchi is low because of their large diameter and also the resistance in small bronchi is low because of their large total cross sectional area. So, the velocity of air flow also decreases causing laminar flow. But during bronchoconstriction the diameters

Table 3.11: Density/viscosity ratio of O_2, N_2O and He

Gases	*Density*	*Viscosity*	*Den/Vis*
O_2	1.11	1.11	1
N_2O and O_2 (60:40)	1.41	0.89	1.49
He and O_2 (80:20)	0.33	1.08	0.31

of smaller bronchi and bronchioles reach such a critical level that the laminar flow is converted to the turbulent flow with increase of resistance.

WORK OF BREATHING

Ventilation is the main function of lungs. So, for ventilation air has to enter into it. But three resistance factors has to be overcomed for entry of air into the lungs. These are: (i) elastic recoiling resistance of the chest wall and lungs (elastic resistance), (ii) frictional resistance due to the flow of air in the airways (nonelastic resistance) and (iii) the tissue frictional resistance (nonelastic resistance). So, work has to be performed by the respiratory muscles to overcome all these three resistance by stretching the elastic tissues of the lungs and chestwall (elastic work) and by moving the nonelastic tissues (viscous resistance work) and thus by creating a pressure gradient which helps to move the air through the airways (airway resistance work). Thus, the total work of breathing done against all these resistance during inspiration is stored as potential energy in the inspiratory muscles. Later, it is used passively during expiration to expel the gases. So, the overcoming of expiratory resistance in normal individual is nonactive (used from stored energy) as the entire expiratory cycle is passive. But this not applicable in obstructive airway diseases, where expiration is also active.

The increased inspiratory resistance is overcomed by the increased effort of inspiratory muscles. But when the expiratory resistance increases then the lung volume also increases as a compensatory phenomenon such that tidal volume (V_T) reaches to FRC level. Thus, the greater energy stored at a higher lung volume tries to overcome the added expiratory resistance. Except that excess expiratory resistance also stimulate the expiratory muscles to work more (Fig. 3.17).

We know :

Work = Force × Distance

But, Force = Pressure × Area

and, Distance = Volume /Area

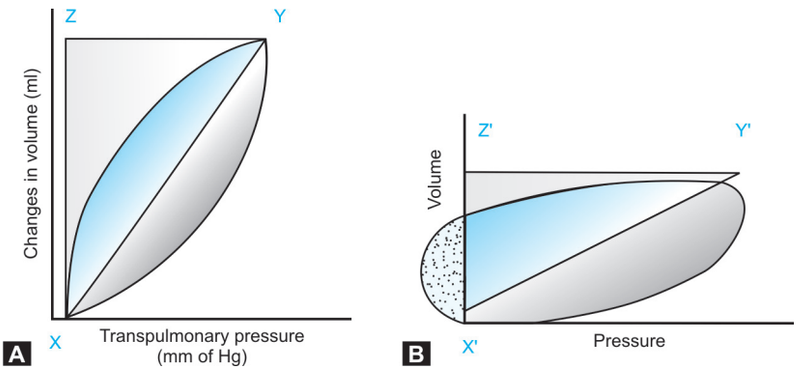
Thus, Work = Pressure × Volume

So, the respiratory work (gm × cm) can be expressed as the product of pressure (gm / cm^2) and volume (cm^3).

During optimum conditions, in a normal healthy adult the respiratory muscles work only with 10% efficiency and 90% energy is dissipated as heat due to the elastic and airway resistance. For that, only 2 to 3% of total O_2 consumption of body is used. But it can raise up to 50%, if the patient suffers from pulmonary diseases. The estimated total work for quite breathing in a healthy adult ranges from 0.3 to 0.8 Kg-meter/minute.

When the work of breathing is increased by increasing the depth of respiration but not in rate, then the work done only against the nonelastic airway resistance will increase. On the otherhand, when the work of breathing is increased by increasing the respiratory rate, then only the work done against the airway resistance will increase.

Thus, when these two phenomenons are summed up, then there is optimal increase in the depth and frequency of respiration where the total increase in work of breathing is minimal. This phenomenon can be explained by another way. The increased work required to overcome the increased elastic resistance is accomplished by not increasing the tidal volume (V_T) or the depth of respiration, but by increasing the rate of respiration. Whereas the increased work required to overcome the increased airway resistance is accomplished by not increasing the respiratory rate, but by increasing the depth of respiration. So, patients suffering from pulmonary oedema, interstitial fibrosis, etc, where elastic resistance increases favour rapid shallow breathing. Whereas patients suffering from asthma, COPD, etc, where the only airway resistance increases favour deep and slow breathing. Again, when there is both the increase in elastic and airway resistance, then the patient tries to minimize the work of breathing by altering the tidal volume and respiratory rate in optimal.



Figs 3.17A and B: Pressure and volume curve or the compliance of lung. Fig. A is for the normal patient and Fig. B is for the anaesthetised patient. In Fig. A, the XY line indicates compliance which is about 100 ml/cm of H_2O. In Fig. B the X 'Y' line indicates compliance which is about 50 ml/cm of H_2O. Fig. A is the picture of highly compliant, small, dependent alveoli situated at the base of the lung. Whereas Fig. B is the picture of less compliant, medium sized alveoli situated normally in the middle of the lung. The dimensions of pressure multiplied by volume is the work of breathing. In the picture, the total area shown by red, blue and grey colour represent the total work of breathing. The red area represents the inspiratory work necessary to overcome the airflow resistance during inspiration. The triangle XYZ represents the fraction of total inspiratory work which is necessary to overcome the elastic resistance. The blue area represents the passive expiratory work. In Fig. B, the dotted area represents the active expiratory work necessary to overcome the airflow resistance during forced expiration

Lung Volumes and Capacities

For clinical anaesthesia practice the different lung volumes and lung capacities are very important parameters to an anaesthetist. The difference between the lung volumes and lung capacities are that when the two or more lung volumes are combined together then we get the lung capacities. There are four basic lung volumes which are usually measured. Then, from these lung volumes the different lung capacities are computed. As for examples, the sum of the 4 basic lung volumes which are described below is equal to the maximum capacity of lung i.e. the total lung capacity (TLC) to which the lung can be maximally inflated. A simple method of studying the different lung volumes is called the spirometry and the instrument is called the spirometer (Fig. 3.18).

Lung Volumes

(i) Tidal volume (V_T)

It is the volume of air which is inspired or expired during each normal breath. The normal value of V_T in an adult male is 500 ml.

(ii) Inspiratory reserve volume (IRV)

It is the maximum extra volume of air that can be inspired with full force after the normal inspired tidal volume. The normal value of IRV in an adult male is about 3000 ml.

(iii) Expiratory reserve volume (ERV)

Similar to IRV, it is the extra volume of air that can be expired maximally with full force after the normal expired tidal volume. The normal value of ERV in an adult male is about 1000 ml.

(iv) Residual volume (RV)

It is the volume of air that still remains in the lung after the most forceful expiration (i.e after the expiration of normal tidal volume and ERV). The normal value of residual volume in an adult male is about 1200 ml (Fig. 3.19).

Lung Capacities

(i) Inspiratory capacity (IC)

It is the inspiratory tidal volume plus the inspiratory reserve volume (i.e. IC = V_T + IRV) after a normal expiration. So, it is the amount of air that a person can maximally breath in after a normal expiration. The normal value of IC in an adult male is about 3500 ml.

(ii) Functional residual capacity (FRC)

It is the volume of air which is equal to the ERV plus RV (i.e FRC = ERV + RV). So, FRC is the amount of air that remains in the lungs after a normal tidal expiration. The normal value of FRC in an adult male is about 2300 ml. It is a very important parameter for lung function test in the clinical anaesthesia practice, because its value markedly changes in different types of pulmonary diseases. So, it is often desirable to measure this parameter. FRC can not be measured directly from spirometer, because RV can never be expired on the spirometer for its measurement, but this volume constitutes near about half of the FRC. So, to measure the FRC spirometer is used indirectly by applying the N_2 washout method or helium wash out (or dilution) method or body plethysmograph. The beauty of FRC parameter is that it indicates a volume of lung where the inward elastic recoil property of lung becomes equivalent to or is balanced by the outward stretching force on lung which is called compliance. The FRC also defines a volume of lung from where the normal breathing of tidal volume takes place. There are multiple factors which affect the FRC. These are:

i. Sex and age: Female has 10% less FRC value than male. The relation between

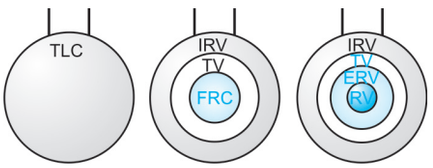


Fig. 3.18: Different lung volumes
TLC = Total lung capacity,
TV = Tidal volume
IRV = Inspiratory reserve volume,
RV = Residual volume,
ERV = Expiratory reserve volume.

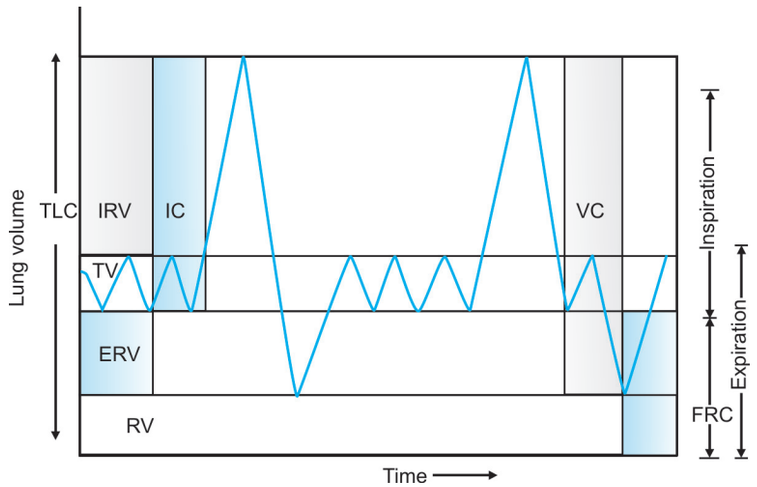

Fig. 3.19: The graphical representation of different lung volumes
TV = Tidal volume, IR V = Inspiratory reserve volume,
RV = Residual Volume,ERV = Expiratory reserve volume,
IC = Inspiratory capacity, TLC = Total lung capacity,
FRC = Functional residual capacity, VC = Vital capacity.

age and FRC is discussed later under the heading of closing capacity (cc).

ii. Posture: FRC is reduced in supine or prone from upright position. This is due to the reduction of chest compliance in lying down condition, as diaphragm is pushed upward by the abdominal viscera. Up to the 30 degree change in inclination, there is no change in FRC. But, it occurs maximally between 60° and 90° inclination from upright position.

iii. Obesity: Obesity is inversely proportional to FRC. This is because it directly reduces the lung compliance. Height is also an important determining factor of FRC and is also directly proportional.

iv. Lung diseases: Any pulmonary disease which affect the compliance of lung or chestwall or both (characteristic of restrictive pulmonary disorder) are associated with low FRC.

v. Anaesthesia: Induction of anaesthesia also reduces the FRC. It is due to both the decrease in compliance and increase in elastic recoil property of lung in anaesthesia during both spontaneous respiration and IPPV.

vi. Post operative period: FRC is also reduced in the postoperative period due to the abdominal distension, pneumoperitoneum, spasm of abdominal and thoracic muscles due to pain etc.

vii. PEEP: Positive end expiratory pressure (PEEP) always increases FRC and is an important mode of management in different lung diseases where FRC < CC.

During expiration the lung is reduced in volume and there comes a point at which some small airways begin to close. This volume of lung when the small airways begin to close during expiration is called the closing capacity (CC). On the other-hand, the closing volume (CV) is the volume of lung which represents from the starting to the end of closing of all the small airways during expiration. Then, the remaining volume of the lung is the residual volume (RV). So CC = CV + RV (Fig. 3. 20).

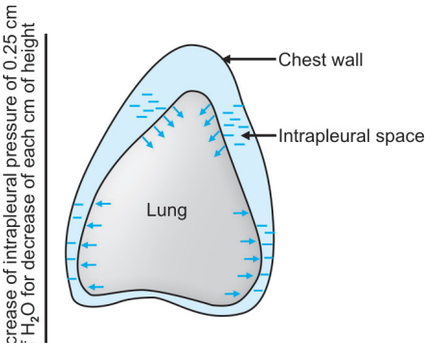

Fig. 3.20: Lung is a viscoelastic structure. So, it tends to collapse from the chest wall and tries to take a globular shape. The top of the lung collapses inward and the base of the lung tries to spread outward.Thus, a relatively more negative pressure is created at the top of the intrapleural space and a relatively less negative pressure is created at the base of the intrapleural space. So the intrapleural pressure increases from top to bottom of the lung by 0.25 cm of H2O per cm of decrease of height

(iii) Vital capacity (VC)

VC is a frequently measured clinical index of pulmonary function test. It is the largest amount of air that can be expired after a maximal inspiratory effort. It equals to the IRV plus V_T plus ERV. The normal value of VC in an adult male is about 4500 ml/ or 60 to 70 ml/Kg. The fraction of VC which is expired in the first one second during forced expiration is also an important parameter for lung function test and gives additional information. This is designated as FEV_I and is called as the timed vital capacity. For example, in some disease where airway resistance is increased such as in asthma, COPD etc, VC may be normal, but the FEV_I is reduced. It gives a useful information about the strength of respiratory muscles. In addition to the body height, weight, posture, etc., VC is also dependent on the chest and the lung compliance.

(iv) Total lung capacity (TLC)

It is defined as the maximum volume of lungs which can be inflated with the greatest possible effort. It equals to the VC + RV. The normal value of TLC in an adult male is about 6000 ml. (Fig. 3.21).

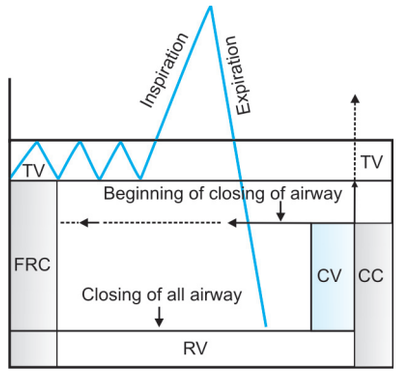

Fig. 3.21: The relationship between the functional residual capacity (FRC), closing capacity (CC) and closing volume (CV)

(v) Airway closure and closing capacity (CC)

During expiration when the lung volume is gradually reduced, then at certain volume of lung the small airways begin to close and therefore prevent any further expulsion of gas from the related alveoli. This causes the trapping of air in the concerned alveoli beyond the closed airways. The lung volumes at which this phenomenon begins to occur is called the closing capacity. This phenomenon of closing of airways first occure at the small airways in the dependent parts of the lungs. Then, with more and more forceful expiration larger airways are also gradually involved in closing. The mechanism of this airway closure is discussed in more details below.

The lung is made of a viscoelastic tissue. So, it tries to take the globular shape within the chest wall. Thus, the top of the lung collapses inward and the bottom of the lung spreads outward. So, a negative intrapleural pressure is created at the apex of the lung and a relatively positive intrapleural pressure (less negative than the apex) is created at the base of the lung. Hence the intraplural pressure increases from above downwards by 0·25 cm of H_2O for each centimeter of change in the height of lung. This intraplural pressure determines the regional alveolar size and the regional difference in compliance and ventilation of alveoli.

At normal resting end expiratory volume of the lung (or FRC), the gradient between the distending transpulmonary pressure and the transmural pressure is −5 cm of H_2O. This gradient of pressure make the airway patent. During inspiration this pressure gradient increases to –7 cm of H_2O which causes the patency of airway and the entry of air into alveoli. Then after inspiration, expiration starts and it is passive. During expiration the intra alveolar pressure is increased and this is due to the elastic recoil property of lungs and chestwall. So,air comes out and the gradient between the trans pulmonary and transmural pressure increases to –3 cm of H_2O. As this pressure gradient is still negative it favours the patency of small non cartilagenous airway. During forced expiration in a normal lung, this pressure gradient increases far above the atmospheric pressure and is transferred to the alveoli and the airways which causes expulsion of air and closer of airway. Actually during expiration the intra alveolar pressure is 2 cm of H_2O higher than this pressure gradient due to the addition of elastic recoil property of alveolar septa. During exhalation of air through airways intra luminal pressure gradually comes down along the length of the airways from the alveoli to the bronchi. Along the airway from alveoli to bronchi at a point where this pressure gradient becomes greater than the intraluminal pressure, the airway closes. This point is called the equal pressure point (EPP). When the EPP falls on the airways which are distal to the 11th generation and have no cartilages, then they close during expiration at certain lung volume. But, when this EPP falls on airways which are proximal to the 11th generation and have cartilages, then they are held open by these cartilages. The progressive movement of EPP from larger to smaller airways depends on the lung volumes and the force of expiration. When the lung volume decreases more and more or the expiration becomes more powerful, then the EPP moves progressively from smaller to larger airways and more and more airways close.

The closing capacity (CC) is measured by the single breath N_2-washout technique. In this process during breathing of normal air, the individual will slowly expire up to RV. Then, he will slowly takes a single breath of 100% O_2 up to maximum inhalation which will be held for few seconds and after that it will be expired slowly. During expiration the N_2 concentration and the volume of expired air is measured and recorded serially. Thus, a characteristics curve is obtained. This curve has four phases: Phase (I) dead space gas, Phase (II) mixed dead space and alveolar gas, Phase (III) mixed alveolar gas from all the alveoli and a phase (IV) at which there is sudden increase in concentration of N_2. The CC is the volume at which phase IV begins (Fig. 3.22).

The explanation is as follows. During inspiration the oxygen is preferentially distributed to the smaller alveoli at the dependent part of the lungs. This is due to the shape of the alveolar compliance curve which causes a larger change in the volume of smaller alveoli at the bottom of the lungs than the larger one at the apex of it. Therefore, N_2 will be more diluted by O_2 in the smaller alveoli at the bottom of the lung. During expiration, the initial exhaled gas (phase I) is the gas that filled the anatomical dead space and consequently contains no N_2. This is followed by a mixture of dead space and alveolar gas (phase II) which contains N_2. So, N_2 concentration will suddenly increase in this phase. Then in next phase the gas other than in dead space which has already been expelled in previous phase is expelled, containing gases coming from all the alveoli of lungs. This indicate phase III. Here, the N_2 concentration remains costant and maintains a plateau level, as the expired air is coming from all the alveoli without any closer of the airway. This phase will continue untill the point at which airway closure begins. At this moment the N_2 concentration suddenly again increases and the phase IV begins. The volume of lung at the begining of phase IV is the CC. This is because the expulsion of gases from the smaller airways ceases and exhalation is continued from those areas of lungs (i.e apex of lung) where the nitrogen concentration is higher due to the less dilution by O_2. Instead of N_2, other tracer gases such as

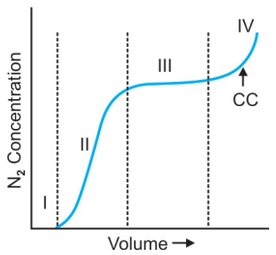

Fig. 3.22: Nitrogen washout technique for measuring the closing capacity (CC), FRC and dead space. First patient will take a deep breath of pure O_2 (100%). Then he will exhale steadily while the N_2 concentration in the expired air is continuously measured and a graph is prepared. Initially in phase I, the expired gas does not contain any N_2 as it comes from the anatomical dead space. This is followed by phase II which contain the mixture of dead space gas and alveolar gas. Here the concentration of N_2 in expired gas rises steadily as more and more alveolar gas containing N_2 is expired. Then comes the phase III where the concentration of N_2 in expired air takes a plateau level. This is because the expired gas in this phase contains only the alveolar gas which comes from all shorts of alveoli from top to the bottom of lungs and contain a average fixed concentration of N_2. Phase III terminates at closing capacity (cc) and is followed by phase IV, during which the N_2 content of the expired gas increases suddenly. CC is the lung volume (above RV) when the airways in the lower dependent parts of the lungs begin to close. The gas in the upper portion of lung is richer in N_2 than the gas in the lower dependent portion. This is because the alveoli in the upper portion of lung are more distend and less compliant at the start of the inspiration of O_2. So, they undergoes less ventilated and subsequently, the N_2 in them is less diluted by O_2. Therefore, the expired gas in phase IV comes mainly from upper part of the lungs containing more N_2 as the airways in the lower part of the lung closes. Phase III has a slight positive slope even before phase IV. This indicates that even during phase III, there is gradual increase in the portion of the expired gas which comes from the relatively N_2 rich upper part of the lung. The volume of the dead space is the volume of gas expired from begining of expiration to the mid portion of phase II

argon, helium, ^{133}xenon etc, also may be used in a similar way.

Thus, the lung volume above the residual volume (RV) at which these small airways begin to close is called the closing capacity (CC). It usually starts at the dependent part of the lungs, because the distending trans pulmonary and transmural pressure gradient is less at the base than the apex of the lung. So, it causes the four fold decrease in alveolar volume at the base than the apex of the lung. The caliber of the airways also decreases as the lung volume decreases from above downwards and make it prone to early closure.

The alveoli after closing of the airways continue to be perfused, but are no longer ventilated. Thus, it causes V_A/Q mismatch and intrapulmonary shunting.

In patients with normal lung during expiration the airways, small or large, do not close as FRC > CC, and all the airways remain open. But during forceful expiration the smaller airways (0·5 to 0·9 mm in diameter) shows a tendency to close. But the larger airways still remains open. However, it does not produce any impact on P_aO_2 or P_aCO_2. Now, if due to any reason CC increases or FRC goes much below the CC level, then more and more airways close and causes hypoxia and hypercarbia.

In patients with emphysema, bronchitis, asthma, pulmonary oedema, etc, the early airway closer occurs with mild active expiration, and at higher lung volumes. In all these conditions the airway resistance also increases. This, causes larger pressure decrease from the alveoli to the larger bronchi. Thus it creates a potential for positive intra-pulmonary and intra-airway pressure gradient which causes early closing of airways and traping of air in alveoli. Moreover, the structural integrity of airways are lost due to imflammation and scaring during the disease process. Therefore, these airways are easily collapsed or closed at higher lung volumes and low pressure gradient (Fig. 3.23).

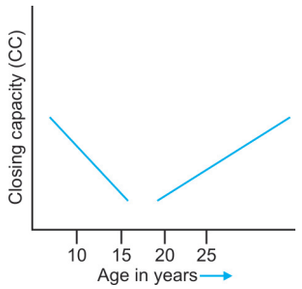

Fig. 3.23: The relationship between the age in years and the closing capacity in normal subject

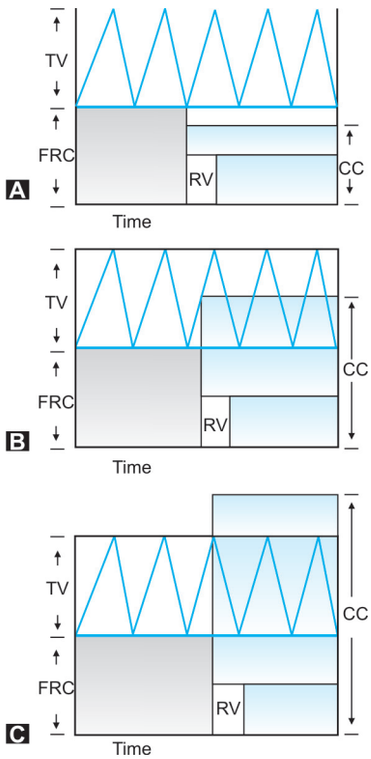
In emphysema, the airways are poorly supported or stretched due to the loss of lung parenchyma and the intraluminal pressure becomes quickly negative. So, the EPP shifts close to the alveolus. Therefore, with only a mild forced expiration the airway closes early. Thus, the use of PEEP or CPAP in an emphysematous patient maintain the intraluminal pressure and prevent the airway collapse. In asthma, due to bronchospasm the middle sized airways are narrowed. During forced expiration they are further narrowed by positive intrapulmonary intraluminal pressure gradient. Thus PEEP or CPAP is also important to maintain the airway in asthma patient.

Closing capacity (CC) is also expressed as the percentage of total lung capacity (TLC). It is obtained by adding closing volume (CV) with the residual volume (RV). In healthy individual, CC is normally well below FRC. But it rises steadily with age and is the probable explanation for the normal age related decline in P_aO_2. At the age of 60, CC = FRC in upright position, but CC > FRC in supine position. On the otherhand, at the age of 40 CC < FRC in upright position but CC = FRC in supine position. Thus, in subject with normal lung CC becomes equal to FRC in age of 60 years in upright position and in the age of 40 years in supine position. CC is minimum at teenage between 15 to 20 years. Before 15 years and after 20 years CC continues to increase and tries to touch the FRC. Except age and position, smoking and obesity also affect CC. They decrease FRC and increase CC.

The Relationship between FRC and CC

The FRC and CC relationship is very important than the consideration of FRC and CC isolatedly. Becaue this relationship determines whether a given lung unit will remain in normal, atelectic or low V_A/Q ratio state. FRC is the normal resting end expiratory lung volume. Whereas CC is the expiratory lung volume when airways begin to close. In normal situation FRC > CC. It means during normal expiration when lung volume is gradually



Figs 3.24A to C: The relationship between the FRC and CC, which result in normal to low V_A/V_Q ratio (ventilation perfusion ratio) causing atelectasis. FRC is the percentage of total lung capacity (TLC) that exists at the end of expiration. Normally (Fig. A) the closing capacity remains below the FRC level and the alveoli open and empty fully before the airway closes. Increase in CC above FRC means airway closes before full exhalation during normal inspiration and expiration. When CC rises up to the mid level of tidal volume (in Fig. B) then alveoli open and closes partially and tidal volume is reduced to half. When CC level rises above the level of tidal volume (in Fig. C) then alveoli never open and atelectasis results

decreasing then FRC does not reduced to CC level where airways start to close. But this may happen even in normal lungs when the patient tries to expire forcefully and FRC goes below the CC level. So, in normal healthy patient with expiration of tidal volume small airways and alveoli remain open during both inspiratory and expiratory phase and helps in adequate gas exchange with normal V_A/Q ratio (Fig. 3.24).

In pathological condition FRC can decrease relative to CC or CC can increase relative to FRC, thus making the equation CC = FRC or CC > FRC. So, in such condition before completion of expiration upto tidal level or before reaching the FRC volume, airways start to close i.e CC volume reaches. Thus during entire period of inspiration airways open and air enter the alveoli. But during mid of the expiration when FRC goes below CC level or before reaching the full tidal volume airways start to close. This causes stoppage of ventilation and gas exchange and make these areas of lungs of low V_A/Q ratio. If the value of CC lies in between the upper and lower limit of tidal volume, then as the lung volume increases during inspiration, some previously closed airways (which occur during previous expiration) will open for a short time. Then, when during expiration lung volume recedes and FRC once again goes below the CC, the airways closes. Thus, during closing and opening of airways at expiration and inspiration, they will open for short period with less time in praticipating for fresh gas exchange, causing low V_A/Q ratio with hypoxaemia.

In severe pathological condition when the value of CC rises above the upper limit of inspiratory tidal volume then the equation will be CC >> FRC. In such situation as the CC always lies above the upper limit of tidal inspiratory volume, so no airway will open even during inspiration. Thus, all the alveoli will remain close both during inspiration and expiration. This condition is called atelectasis and will cause severe V_A/Q mismatch with severe hypoxaemia.

In condition when CC > FRC and if PEEP is applied to IPPV, then PEEP increases the FRC above the CC value and restore the normal FRC and CC relationship. Thus, no airway will close during respiration with normal tidal volume and no ventilation perfusion mismatch with hypoxaemia will occur.

4 Oxygen and Carbon Dioxide

HISTORY

William Harvey of London (1538-1657) had first described the circulation of blood in his book, named 'deMotu Cordis'. He was the pupil of Galileo. He had first observed the difference of colour between the arterial and venous blood. But he was not able to give any reason regarding this difference in colour and drew no firm conclusion about the function of the lungs. Then, between 1665 and 1675, Robert Hooke, Robert Boyle, Richard Lower and John Mayow of Oxford had made a understanding that certain components of the air was absorbed by the lungs and this process was necessary for both the maintenance of life and the burning of substances. At that time 'Phlogiston theory' was in voke for nearly 100 years. According to this theory 'phlogiston' was supposed to be a part of all the combustible substances and was liberated during their combustion or during an animal's respiration. When it is accumulated in excess as a result of combustion or by respiration in a closed containers, then it prevents further chemical activity, causing stopage of combustion or respiration resulting death.

After that, Joseph Priestly had first prepared oxygen from potassium nitrate in1771 and was first given the credit for discovering oxygen. But, instead of oxygen he called this gas as 'dephylogisticated air'. Because, he observed that this new gas was better than air for supporting respiration and combustion. He also supposed this, because it contained less phlogiston. So, he called it as 'dephylogisticated air'.

Then, Lavoisier had first clarified the use of oxygen in the process of respiration and combustion. Simultaneously, he also clarified the production of carbon-dioxide during combustion of substance and respiration. He, subsequently, demonstrated that oxygen was absorbed by the lungs and after metabolism in the body, it was eliminated as CO_2 and water. Later, he and Laplace coined the term oxygen (Oxy – acid, gene – producer) in 1779. They were also the first to compare the heat produced during respiration in animal with that produced during the combustion of carbon and showed the relationship between the oxygen used and carbon-dioxide produced. But, later Lavoisier was executed by gillotine during French revolution.

Then, Von Liebig had showed, in 1851, that carbohydrates and fats were the substrates of metabolism in cell and not carbon itself. In 1850, French chemist, Boussinggault also had first discovered that at a temperature of about 1000°C bariummonooxide absorb oxygen from air forming barium-dioxide and again release it at a more higher temperature. Then this process made charmed and was patented by his pupils, named the Brin brother, in 1880. After that they had formed a company and their company eventually then became the British Oxygen.

PROPERTIES

Oxygen is a tasteless, colourless and odourless gas. The concentration of O_2 in the atmospheric dry air at 760 mm of Hg pressure is 20.95%. The molecular weight of oxygen is 32. In atmosphere mainly O^{16} isotope of oxygen is present, but a small amount of O^{17} and O^{18} isotopes of it are also found. In one atmospheric pressure (760 mm of Hg) and at −183°C temperature, the oxygen becomes liquid (boiling point) and in same atmospheric pressure at −218°C temperature, it becomes solide (melting point). The critical temperature of oxygen is −118°C. So, at temperature greater than this, oxygen exists as gas and can not be liquified by raising the pressure. The relative density (air = 1) of oxygen is 1.105. The solubility of O_2 in plasma at 37°C temperature is 0.003 ml/100 ml of blood.

The O_2 cannot be ignited itself, but it aids combustion. So, substances often burn more vigorously or even explode in the presence of oxygen. Thus, the explosion can occur due to the presence of grease on the valves of oxygen cylinder. Due to some unpaired electrons, the oxygen molecule is attracted to the region of high flux in magnetic field and is so said the paramagnetic gas. Hence, this property of O_2 is utilized in some oxygen analysers to measure the concentration of it in a mixture of gases.

PREPARATION

Commercially, in large scale the oxygen is prepared or manufactured by the fractional distillation of liquid air. When this liquid air is gradually heated, then the more volatile nitrogen gas (boiling point at 760 mm of Hg pressure is –196°C) is separated

first followed by oxygen (boiling point is −183°C of 760 mm of Hg pressure). After that other components of air are also separated as required one after another.

STORAGE

Oxygen is usually stored at high pressure as a gas in cylinder or as a liquid in an insulated tank. For large hospitals, the storage of O_2 as liquid form in an insulated tank is much more economical. Tank with huge capacity of liquid oxygen is usually insulated by a high vacuum shell to maintain the inside temperature between −175°C to −150°C. But, still there is continuous evaporation of some liquid O_2 present within the tank. This is due to the continuous absorption of small amount of heat from the sorrounding, inspite of this vacuum insulation. So, if no oxygen is drawn off for long time from the tank, then this accumulated gas within the tank should be vented out to the atmosphere. All the O_2 tanks or cylinders are guarded with a pressure regulator valve maintaining a constant supply of oxygen at constant pressure from the tank or the cylinder into the hospital pipe line system.

The medical grade of O_2 contains 99 to 99·5% pure form of it. In most of the small hospitals, the O_2 is stored in more than two separate banks of H type of cylinders. They are connected by manifolds and valves. The number of cylinders in one bank and the number of banks depends on the anticipated daily demand of O_2 by this hospital. Only one bank is utilised at one time. The valves in the manifold connection reduces the cylinder pressure to the given pressure of the pipe line and supply gases. A bank automatically switches to another bank when one group of cylinders are emptied. In large hospitals where the liquid O_2 is used in tanks, should have a additional smaller O_2 supply system of compressed O_2 cylinders that can be used as reserve in emergency. Most of the anaesthetic machines accomodate one or two E type of O_2 cylinder in addition to pipe line connection to guard against the hospital pipe line failure. Anaesthesiologists must ensure the supply of O_2 from these cylinders before starting of any operation.

OXYGEN TRANSPORT IN BODY

The anaesthetists are mainly concerned about the transport and delivery of O_2 from the air to tissue at cellular level. The delivery of O_2 from the air to the cell at mitochondrial level is a continuous process and is occured in four phases. These are: (i) the mechanical act of breathing by which O_2 with air reaches the alveoli, (ii) the exchange of gas in alveoli by which O_2 passes from the air to the blood, (iii) the oxygenated blood, then, is transported to the tissues by circulation and finally, (iv) at the level of tissue capillaries O_2 enters into the cell and mitochondria.

Transport of Oxygen from Air to Alveoli

The mechanical act of breathing which transport O_2 from air to alveoli is fully discussed in separate chapter. But, here we will discuss only, how the PO_2 falls gradually during its transport from air to alveoli. So, when the O_2 reaches from atmosphere to the mitochondria in cell through alveoli, then the tension of O_2 (PO_2) drops in steps. This is called the oxygen cascade. The PO_2 drops in stages from 159 mm of Hg in dry air of atmosphere to the very low levels of 2 mm of Hg in the mitochondria. When the level of PO_2 in mitochondria falls below about 1 to 2 mm of Hg, which is called the Pasteur point, then the aerobic metabolism inside the cells stops. The partial pressure or tension of O_2 in the inspired air (P_1O_2) is about 159 mm of Hg (20 kpa). It is influenced by the baromatric or atmospheric pressure (P_B) and the fractional concentration of oxygen (FiO_2) in air. The normal barometric pressure at sea level is known as the one atmospheric pressure and is equivalent to 760 mm of Hg and in this condition the normal FiO_2 in air is 21% or 0.21.

So, the equation of P_1O_2 is:

$$P_1O_2 = P_B \times FiO_2$$
$$= 760 \times 21/100$$
$$= 159 \text{ mm of Hg.}$$

Then, the inspired air is saturated and diluted by water vapour, while it is passing through the air passages to reach the alveoli. It causes the reduction of PO_2, when it reaches the alveoli. The partial pressure of water vapour at 1 atmospheric pressure and body temperature (37°C) is 47 mm of Hg (Fig. 4.1).

So, when the inspired air saturated with water vapour reaches the alveoli, then the P_IO_2 comes down to 149 mm of Hg which is calculated by the following way :

$$P_1O_2 \text{ (Sat)} = (P_B - P_{H2O})\, FiO_2$$
$$= (760 - 47) \times 21/100$$
$$= 149{\cdot}73 \text{ mm of Hg}$$
$$\approx 149 \text{ mm of Hg}$$

Then, the inspired gas is further diluted by the addition of CO_2 and the removal of O_2 in the alveolus.

So, the final alveolar oxygen tension (P_AO_2) can be estimated by the 'alveolar gas equation'.

The equation is:

$$P_AO_2 = [F_IO_2\,(P_b - 47) - P_aCO_2] \times F$$
$$= [21/100\,(760 - 47) - 46] \times F$$
$$= 103{\cdot}73\ F$$
$$\approx 103 \text{ (while it is taken as 103 mm of Hg and F is ignored)}$$

Here P_AO_2 = alveolar O_2 tension, F_1O_2 = fractional inspired O_2 concentration. P_b = barometric pressure, 47 is the vapour pressure of water at body temperature (37°C), P_aCO_2 is the arterial CO_2 tension and F is the respiratory exchange ratio.

From the above equation, it is estimated that the normal value for P_AO_2 is

PO_2 in dry atmospheric air	159 (mm of Hg)
PO_2 in humidified air in airway	149 (mm of Hg)
PO_2 in alveolar air	104 (mm of Hg)
PO_2 in arterial blood	100 (mm of Hg)
PO_2 in tissue	40 (mm of Hg)
PO_2 in mitochondria	2 (mm of Hg)

Fig. 4.1: Oxygen cascade

103 mm of Hg at sea level. The normal P_AO_2 will decrease with (i) increasing altitude or decreasing P_b, (ii) increasing P_ACO_2 or (iii) with decreasing F_IO_2. So, a hypercapnic patient at high altitude would have a substantially lowered P_AO_2 .

Exchange of Gases in Alveoli

The oxygen tension of blood, entering at the arterial end of the pulmonary capillaries is 40 mm of Hg (SPO_2 75%). Whereas the PO_2 in alveolar air is 103 mm of Hg. Thus, this pressure gradient helps the O_2 to enter the blood from alveolar air across the alveolar membrane. In the blood O_2 first dissolved in plasma and then finally unite with Hb for its carriage to the tissues. Thus, at the venous end of pulmonary capillaries the PO_2 in blood is 103 mm of Hg. In the tissues, the tension of O_2 in the arterial side of the capillary blood is about 100 mm of Hg. The O_2 tension (Table 4.1)in the tissue is near about 40 mm of Hg. When the arterial blood passes through the tissues, it carries about 20 ml of O_2 as oxyhaemoglobin and about 0·3 ml of O_2 as physical solution per 100 ml of blood. As the O_2 tension in the tissue level is much lower, so the oxygen present as physical solution in plasma first passes from plasma to the tissues by diffusion. As a result the O_2 tension in the arterial plasma falls. So, the oxyhaemoglobin in the RBC being exposed to the low O_2 tension in plasma, dissociates and releases O_2 form the Hb. Then, this O_2 from RBC enters in the plasma and is carried as physically dissolved solution. Again this physically dissolved O_2 leaves the blood stream and enters the tissues. Thus, the portion of O_2 dissolved as physical solution in plasma remains always constant and this is measured as PO_2 of blood. About 30% of O_2 is liberated from blood to supply the tissues, when the tissue cells are in the resting phase. This dissociation of oxygen from oxyhaemoglobin in the RBC depends upon : the plasma O_2 tension, the plasma CO_2 tension, H^+ concentration, electrolyte content and the temperature of blood and tissues (Fig. 4.2).

The CO_2 tension and its content in the tissues are much higher than that of the capillary blood. Due to this difference of pressure, CO_2 diffuses from the tissues in the blood of capillaries. Thus, CO_2 tension in the capillary blood rises which also subsequently favours the dissociation of O_2 from oxyhaemoglobin and enters in the tissues. As the increase in PCO_2 in capillary blood favours the dissociation of O_2 from Hb, similarly the increase in PO_2 in tissues favours the dissociation of CO_2 from tissues. Hence, as a result of supply of O_2 to the tissues, the O_2 tension and O_2 content of the capillary blood fall. Thus, at the venous end of tissue capillaries O_2 tension of the blood is about 40 mm of Hg and O_2 content is about 14 to 15 ml as oxyhaemoglobin and about 0.15 ml as physical solution per 100 ml of blood. Subsequently, when this systemic venous blood with PO_2 of about 40 mm of Hg passes through the pulmonary capillaries into the lungs where in the alveoli PO_2 is about 103 mm of Hg, then O_2 again enter from alveoli into the systemic venous blood during passing through the pulmonary artery and capillaries. Therefore, O_2 tension (PO_2) rises and more oxy-Hb is formed in the red cells. Simultaneously, CO_2 diffuses out from the systemic venous blood of pulmonary artery into the alveolar air. CO_2 tension and H^+ concentration in the venous blood fall which also favour the entry of O_2 in the pulmonary capillary. The entry of O_2 in pulmonary capillary blood from alveoli also favours the exit of CO_2 from pulmonary capillary blood to alveoli.

CO_2 is much more soluble in plasma than O_2. So, hypercapnia is rarely a problem in pulmonary fibrosis which is discussed in Chapter- 3. It does occur only when the alveolar ventilation is severely inadequate and there is much V_A/Q inequality. If due to any cause the arterial PCO_2 increases other than ventilation, then by increasing the ventilation the extra CO_2 can easily be expired. But it accumulates when the ventilation is severely compromised. It is to be noted that in normal condition the difference between P_ACO_2 and P_aCO_2 is very small and alveolar ventilation (V_A) has a great impact on P_aCO_2 and P_aO_2. Doubling the alveolar ventilation (V_A) results in half of P_aCO_2 and half of V_A results in a doubling of P_aCO_2. The relationship between V_A and P_aCO_2 is exponential. If this change is entered into the 'alveolar gas equation', then we will get the relationship between the V_A and P_aO_2. It can also be seen that hypoxaemia develops rapidly than hypercarbia as V_A decreases. But, it can readily be corrected by a small increase in FiO_2 from 0.21 to 0.3.

Table 4.1: Partial pressure of gases in alveoli during normal ventilation and hypoventilation with breathing air

	Normal ventilation $PaCO_2$ = 40 mm of Hg	*Hypoventilation $PaCO_2$ =100 mm of Hg*
O_2	103 mm of Hg	43 mm of Hg
N_2	570 "	570 "
CO_2	40 "	100 "
H_2O	47 "	47 "
Total	760 mm of Hg	760 mm of Hg

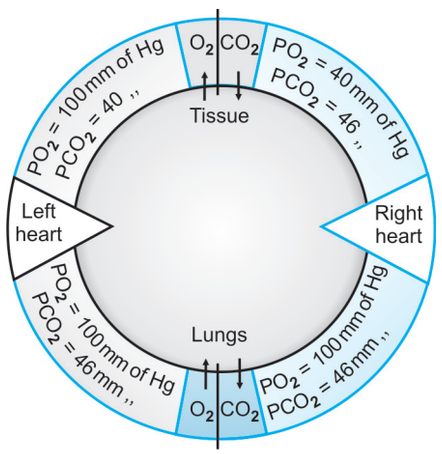


Fig. 4.2: Transport of O_2 in blood

Transport of Oxygen by Blood

The amount of O_2 transported or delivered to the tissues by blood depends on: (i) blood flow (cardiac output) and (ii) quantity of O_2 carried by blood (O_2 content). Again the O_2 content carried by blood depends on: (i) the rate of diffusion

of O_2 or oxygenation of blood in lungs (P_aO_2 and S_aO_2) and (ii) Hb content. On the otherhand, oxygenation of blood or diffusion of O_2 in blood depends on: the inspired and subsequently alveolar O_2 tension. The alveolar O_2 tension (P_AO_2), on the other hand, determines the arterial O_2 tension (P_aO_2). The alveolar and arterial O_2 tension difference (A-a) or gradient is the simplest way of quantifying the pulmonary diffusion. Other determining factors of P_aO_2: R-L shunt and pulmonary diffusion barriers. We should consider these two factors during determination of P_aO_2, only in pathological condition.

Oxygen is transported by blood: (i) by simple physical solution dissolved in plasma, and (ii) by combining with Hb.

Carriage of O_2 by simple physical solution dissolved in plasma

Very small proportion of total O_2 is carried in blood as physically dissolved solution i.e 0.3 ml/100 ml of blood/100 mm of Hg pressure (0.003 ml/100 ml of blood / 1 mm of Hg pressure). But this small quantity of O_2 is very important, because it alone reflects the tension of O_2 in blood (PO_2). First, when O_2 enters into the blood stream, it dissolves as physical solution in plasma. Then, from plasma the O_2 enter into the RBC to attach with Hb. At tissue level this plasma part of O_2 is first transferred to tissue cells and its position is rapidly taken over by O_2 liberated from Hb.

Carriage of O_2 by Hb

Except as physical solution, O_2 is also carried by combined with Hb, present in the red cells. This combination of O_2 with Hb is called oxyhaemoglobin which is loose and reversible compound. O_2 is quickly combined with Hb in the capillary of alveoli where its tension is high and then is equally quickly dissociated from Hb in the capillary of tissues where its tension is low.

Hb is a chromoprotein and has four subunits. Each sub unit (Table 4.2) contains one structure of haeme with one iron atom and is attached with the polypeptide chain of globin. So, a haemoglobin molecule contains 4 atoms of iron in ferrous form and its molecular weight is 68000. Each atom of iron can reversibly combine with one molecule of O_2. As one Hb molecule contains four haeme units and 4 iron atoms, so it reacts with 4 molecules of O_2 with formation of oxy-Hb (Hb_4O_8). Under physiological conditions, the reaction of Hb with O_2 takes place in 4 separates but simultaneous reactions, which are given below.

$Hb_4 + O_2 \rightarrow Hb_4O_2 + O_2 \rightarrow Hb_4O_4 + O_2 \rightarrow Hb_4O_6 + O_2 \rightarrow Hb_4O_8$

Table 4.2: Gradient of CO_2 and O_2 at tissue and pulmonary level

At Lungs		
A.	Venous PCO_2 = 46 mm of Hg	
	Alveolar PCO_2 = 40 mm of Hg	
	Gradient of PCO_2 = 6 mm of Hg	
B.	Venous PO_2 = 40 mm of Hg	
	Alveolar PO_2 = 103 mm of Hg	
	Gradient of PO_2 = 63 mm of Hg	
At tissue		
C.	Arterial PO_2 = 100 mm of Hg	
	Tissue PO_2 = 40 mm of Hg	
	Gradient of PO_2 = 60 mm of Hg	
D.	Arterial PCO_2 = 40 mm of Hg	
	Tissue PCO_2 = 46 mm of Hg	
	Gradient of PCO_2 = 6 mm of Hg	

Oxygen content

The oxygen content of blood is defined as the total quantity of oxygen (in millilitre) carried by 100 ml (1 dl) of blood. It is the total quantity of O_2 contained in the red cell plus the total quantity of O_2 dissolved in the plasma. 1 gm of fully oxygenated Hb contain only 1.39 ml of O_2 at 100 mm of Hg pressure. Average Hb level in an adult male is about 15 gm/100 ml. At an arterial PO_2 of 100 mm of Hg, Hb is 100% saturated.

So, the total O_2 content (CO_2) in 100 ml of arterial blood at 100 mm of Hg pressure.

$= 1.39 \times Hb \times \%$ of saturation $+ 0.003 \times P_aO_2$

$= 1.39 \times 15 \times 1 + 0.003 \times 100$

$= 20.85 + 0.3$

$= 21.15$ ml / 100 ml

Sometimes, this value is taken as average 20 ml/100 ml of arterial blood.

In the venous blood PO_2 is 40 mm of Hg and Hb is 75% saturated.

So, O_2 content (CO_2) in 100 ml of venous blood at 100 mm of Hg pressure.

$= 1.39 \times 15 \times 0.75 + 0.003 \times 40$

$= 15.63 + 0.12$

$= 15.75$ ml / 100 ml

Therefore, tissue extracts only 21.15 − 15.75 = 5.4 ml (average 5 ml) of O_2 from every 100 ml of arterial blood, while it is passing through the tissue capillaries. Thus, alternately every 100 ml of blood while passing through the lungs takes about 5 ml of O_2 (Table 4.3).

Oxygen Flux

The total amount of O_2 leaving the left ventricle per minute, when breathing air at sea level, has been termed as the oxygen flux. The normal oxygen content (CO_2) of arterial blood is 21.15 ml / 100 ml or 211.5 ml/litre. The normal cardiac output is 5 L/min.

So, oxygen flux = 5×211.5 ml/min = 1057.5 ml/min

The O_2 content of venous blood is 15.75 ml / 100 ml or 157.5 ml/L

Therefore, the total amount of O_2 leaving the right ventricle $= 5 \times 157.5 = 787.5$ ml/min

Hence, 1057.5 − 787.5 = 270 ml of O_2 is used up by the whole body during cellular metabolism in every minute and this amount of O_2 is taken up from alveolar air in every minute.

Table 4.3: Distribution of the amount of O_2 in arterial and venous blood

Oxygen	*Arterial blood*	*Venous blood*
Amount of O_2 as physical solution in plasma	0.3 ml / 100 ml	0.13 ml / 100 ml
Tension of O_2	100 mm of Hg	40 mm of Hg
Amount of O_2 combined with Hb	21 ml / 100 ml	15 ml / 100 ml
Saturation of O_2	100%	75%

Oxygen flux when Hb drops to 4 gm / 100 ml in anaemia

This can be calculated by the following way:

The O_2 content of 100 ml arterial blood with 4 gm of Hb

$= 1.39 \times 4 \times 1 + 0.003 \times 100$

$= 5.56 + 0.3$

$= 5.86$ ml / 100 ml

$= 58.6$ ml/litre

Therefore, O_2 flux = 5×58.6 ml/min = 293 ml/min. It indicates there will be no O_2 reserve.

Oxygen Delivery at Tissues

The mechanism of delivery of O_2 at the tissue level has been discussed in this chapter before. But, here we will discuss only some extra points. Previously, it was stated that the amount of O_2 delivered to the tissues depends on the cardiac output and the total oxygen content in blood. This overall flow rate of O_2 to the tissues is called the O_2 delivery. With a normal cardiac output of 5 L/min and with normal O_2 content (20 ml/100 ml of blood), the normal O_2 delivery to the tissues is 1000 ml/min.

Cardiac output varies with the size of the patient. So, cardiac output is commonly indexed to body surface area (BSA). This is called the cardiac index (CI) and can be represented as:

$CI = CO / BSA$ (L/min/m^2)

or $CO = CI \times BSA$

So, O_2 delivery can be expressed as index:

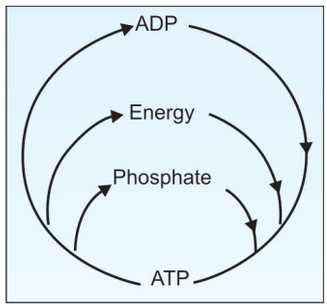
Therefore O_2 delivery (index) = $CO_2 \times CO$ (ml/min)

$= CO_2 \times CI \times BSA$ (ml/min/m^2)

In normal adult patient, the O_2 content (CO_2) = 20 ml/100 ml of blood the CI = 3 L/min/m^2 and BSA = 10 m^2. So the O_2 delivery index is 600 ml/min/m^2.

LACK OF OXYGEN OR HYPOXIA

The failure to receive adequate quantities of O_2 by the tissues is called hypoxia. Whereas, the total lack of O_2 is called anoxia and it is used in more restricted sense. In concious patient there are certain regulatory mechanism which prevents the tissue to suffer from the lack of oxygen. But, during the course of anaesthesia due to the lack of this regulatory mechanism the hypoxia has a deleterious effect (Fig. 4.3).



Light energy

$6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6 + 6O_2$

Fig. 4.3: Mechanism of formation of ATP

We get energy from the sun. Earth's atmosphere originally contain no O_2. But, during photosynthesis with the help of CO_2, plant absorbed this light energy in the form of glucose and release O_2 in the atmosphere.

Light energy

$$6CO_2 + 6H_2O \rightarrow C_6H_{12}O_6 + 6O_2$$

But, within our cell this reaction is reverse. The solar energy which is incorporated in the glucose is released by oxidation with the help of oxygen and is used for cellular acitvity.

$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$ + Energy (Heat)

So, O_2 is very essential to maintain life. Some energy also can be obtained in absence of O_2 (anaerobic metabolism), but in terms of ATP production the anaerobic process is 1/19 as less efficient as aerobic process of metabolism. Because, during aerobic metabolism one glucose molecule produces 38 ATP, whereas in anaerobic process only 2 ATP is produced from one glucose molecule. Again lactic acid accumulation as a result of anaerobic metabolism will lead to metabolic acidosis. Then when O_2 becomes available, this lactate can further be metabolised to CO_2 and H_2O with further ATP formation.

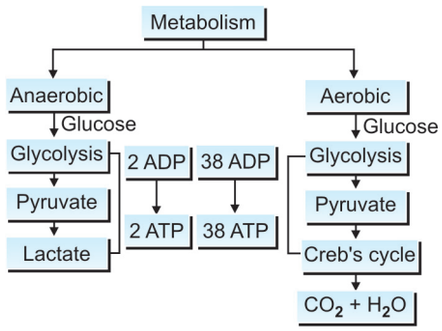


Fig. 4.4: Difference between aerobic and anaerobic metabolism

The hypoxia may result from various causes and according to the cause of hypoxia it can be classified into five types such as hypoxic hypoxia, anaemic hypoxia, stagnant hypoxia, histoxic hypoxia and conditions where P_{50} is low (Fig. 4.4).

Types of Hypoxia

Hypoxic hyopoxia

Here, the cause of hypoxia is defective oxygentation of blood or Hb in the alveoli of lungs. This results in incomplete saturation of haemoglobin by oxygen and less amount of O_2 is available in physically dissolved form, causing low oxygen tension in the arterial blood. Hypoxic hypoxia is produced in the following conditions.

(a) Decreased partial pressure of O_2 in inspired gas or air ($PIO_2\downarrow$)

This is due to:

i Fall in fractional concentration of O_2 in the inspired gas (FiO_2). This occurs during rebreathing or when the supplied gas is hypoxic in mixture,

ii Fall in barometric pressure, for example, at high altitude. At sea level, with 1 atmospheric pressure (760 mm of Hg) the air contains 20 to 21% O_2 and alveolar air contains 14% O_2. The remaining part of alveolar air is filled up by CO_2, N_2 and H_2O vapour. The total pressure exerted by these gases in alveoli is same

as the barometric pressure. So, the partial pressure of O_2 in alveoli is 14% of 760 mm of Hg or about 106 mm of Hg. At an altitude of 5500 meters or 18000 feet, the barometric pressure is only 380 mm of Hg. So, the partial pressure of O_2 in alveoli at this altitude will be 14% of 380 mm of Hg i.e. only about 50 mm of Hg. At mount Everest, where barometric pressure is only 236 mm of Hg, there alveolar PO_2 is only 40 mm of Hg (after saturated with water vapour at nasopharynx). Thus, due to diminution of partial pressure of O_2 in the alveoli which is due to the reduction of barometirc pressure at high altitude, less amount of O_2 will diffuse from the alveoli into the blood and as a result there will be reduced tension of oxygen in the blood.

(b) Fink effect or diffusion hypoxia

At the end of anaesthesia which is carried out by N_2O and O_2, when the patient breaths room air, then N_2O will diffuse out from the body tissues via venous blood into the alveoli. Subsequently the N_2 now being breathed with room air will fill the alveoli and diffuse back from the alveolar air into the tissue. Due to the higher solubility of N_2O than N_2, relatively small amount of N_2 will diffuse in from the alveolar air into the blood and restore tissue PN_2. But, much larger amount of N_2O than N_2 will diffuse out from the tissue in the alveoli and dilutes the alveolar O_2 concentration. Thus, it reduces the alveolar PO_2 and produces hypoxia which is opposite to the phenomenon occuring during the induction of anaesthesia with $N_2O : O_2$ mixture. This is called the diffusion hypoxia which is opposite to the second gas effect (Fig. 4.5).

Second gas effect

N_2O is more soluble in blood than N_2. So, during induction with N_2O, the volume of N_2O taken up by the blood is much higher than the volume of N_2 entering the alveoli from the tissue via blood. Therefore, the alveoli becomes gradually smaller and the

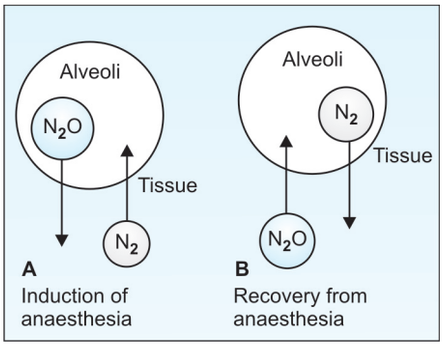

Fig. 4.5: The comparison between N_2O and N_2 regarding their speed and amount of entry and exit during induction and recovery from anaesthesia

partial concentration of the remaining gases in the alveoli increases. Now, if another inhalation anaesthetic agent (e.g. halothane) is also given with N_2O, then the fractional concentration of this anaesthetic gaseous agent will also increase. This phenomenon is called the second gas effect and increases the speed of induction by this agent. In the early part of induction, the volume of N_2O absorbed from alveoli is in the order of 1 litre/min. Although, the volume of N_2O in alveoli has decreased due to high absorbtion, the concentration of it does not reduce to the same extent, because the volume of alveoli is also decreased.

(c) Reduced alveolar ventilation

Arterial O_2 tension (PaO_2) depends on the alveolar O_2 tension (P_AO_2) which again depends on the alveolar ventilation. The relation between the alveolar ventilation (V_A) and the alveolar PO_2 (P_AO_2) is hyperbolic. It indicates (Fig. 4.6) that a reduction in ventilation of 2 litre/minute i.e. from 6 to 4 litre/minute has little effect on P_AO_2. Whereas, the reduction of ventilation from 4 to 2 litres/minute has very marked effect on P_AO_2 . Again, raising the inspired PO_2 by 64 mm of Hg (achieved by increasing the F_IO_2 from 0·21 to 0·3) results in a rise in P_AO_2 of the same amount like the reduction of ventilation from 4 litre to 2 litre/min. Raising the O_2 consumption also shifts the V_A and P_AO_2 relationship downwards and to the right. It means that what

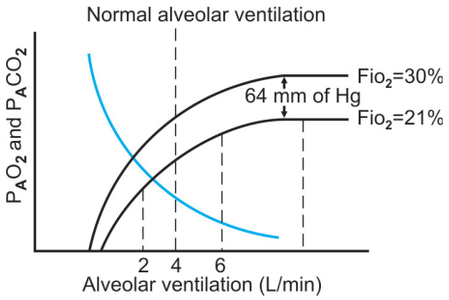

Fig. 4.6: The effect of change of alveolar ventilation on alveolar O_2 tension (P_AO_2) drawn in red line and alveolar CO_2 tension (P_ACO_2) drawn in blue line. It also shows the effect of change of FiO_2 from 21% to 30% on P_AO_2.Doubling of V_A results in halving of P_aCO_2 and vice versa. The relationship between V_A and P_aO_2 also shows that hypoxaemia develops rapidly as V_A decreases. But, it can be readily corrected by a small increase in FiO_2. On the otherhand, hyperventilation results in little increase in P_aO_2

was previously a perfect adequate alveolar ventilation may be grossly inadequate now, if the oxygen consumption increases. For example, 'halothane shake' is a common cause of increase O_2 consumption and hypoxic hypoxia which occurs in the early part of the postoperative period.

(d) Reduced diffusing capacity of O_2 across alveoli

Due to thickening of alveolar capillary membrane for any cause, there is also impairment of diffusion of O_2 from alveolar gas across the alveolar and pulmonary capillary membrane into pulmonary capillary blood, causing hypoxia. The examples of such type of hypoxia are : emphysema, pulmonary oedema, pneumonia, interstitial fibrosis, etc.

(e) Abnormalities of pulmonary mechanics

Many abnormalities in pulmonary mechanics such as asthma, emphysema, pneumothorax, collapse, obstruction in the air passages, etc, also produce hypoxic hypoxia by reducing the ventilation or decreasing the FiO_2 or changing the V_A/Q ratio.

(f) Venous admixture and shunt

This refers to some conditions when blood passes directly from the venous side of

circulation i.e. right side of the heart to the left side of heart without picking up any oxygen from lungs or passing through the zones of lung with low V_A/Q ratio, so that it is less oxygenated than normal. The examples of such direct communication between the right and left side of the heart are true shunt which is responsible for not picking up any oxygen from lungs. This takes place in PDA, patent foramen ovale or VSD etc, with pulmonary hypertension where blood flow from right to left side of the heart (true shunt).

Anaemic hypoxia

Here, the problem lies in the carrying of O_2 by blood to the tissues, but not in the oxygenation or uptake of O_2 by Hb in alveoli. The characteristic of this anaemic hypoxia is that the total O_2 content of arterial blood is reduced, but the partial pressure and the saturation of Hb by O_2 is normal. Therefore, the haemoglobin is fully saturated with O_2, but as the quantity of O_2 carrying Hb is low, so the total amount of O_2 carried by it is below normal. This is called the anaemic hypoxia. Anaemic hypoxia will result from:

(a) Anaemia

When the Hb concentration in blood becomes half, then the O_2 content of blood is also reduced to half. But the partial pressure of O_2 in blood remain the same. Thus, O_2 dissociation curve shifts to the left. But, for compensatory mechanism, anaemia causes increase in 2,3-DPG level, therefore shifting again the oxygen dissociation curve to the right at its normal position and favour the unloading of O_2 to the tissue. Shifting of the O_2 dissociation cure to the left prevents the unloading of O_2 to the tissues.

(b) Carbon monoxide (CO) poisoning or carboxyhaemoglobinaemia (Fig. 4.7)

As affinity of CO to haemoglobin is 250 times greater than that of the O_2, so a small amount of CO will replace the substantial amount of O_2 from Hb and will produce large amount of carboxyhaemoglobin. Therefore, little free haemoglobin will be available for carrying O_2. The other changes produced by carboxy-Hb is the shifting of O_2 dissociation curve to the left. The significance of this shifting of O_2 dissociation curve to the left is that it also unfavours the unloading of remaining O_2 to the tissues. Shift in the oxygen dissociation curve of Hb are usually presented mathemetically as changes in the P_{50} value. The P_{50} value is defined as the PO_2 at which Hb is 50% saturated. The normal value of P_{50} is 27 mm of Hg. It means that at 27 mm of Hg in O_2 tension Hb is only 50% saturated. A shift to the left lowers the P_{50} value i.e. it indicates that at 50% saturation of Hb the O_2 tension is less than 27 mm of Hg. Similarly a shift to the right raises the P_{50} value which indicates that at 50% saturation of Hb the O_2 tension is more than 27 mm of Hg. But the changes in P_{50} have only a modest effect on the uptake of O_2 in the lungs. The main consequence of alterations of P_{50} is on the release of O_2 in the tissues. A low P_{50} or shifting of O_2-dissociation curve to the left decreases the O_2 availability to the tissues and may therefore lead to cellular hypoxia. Similarly, a high P_{50} value or shifting of O_2 dissociation curve to the right increases the O_2 availability to the tissues. As the upper part of the O_2 dissociation curve is flat, so the changes in PO_2 at this portion have relatively little effect on the Hb saturation and therefore the blood O_2 content. Whereas, over the lower more vertical part of the curve, the changes in PO_2 have a very marked effect on the percentage of saturation of oxy-Hb, so the transfer of O_2 from Hb to the tissues. This changes in O_2 dissociation curve is also very crucial to the survival of patient, following a massive blood transfusion. Another significance of the shifting of the point P_{50} or O_2 dissociation curve is that in order to offload the same amount of O_2 to the tissues, the venous PO_2 is also reduced to a much lower level. When the Hb level is 14.4 gm/dl, the venous point is 40 mm of Hg. In anaemia (Hb = 7·2 gm/dl) the venous point is 27 mm of Hg. In 50% HbCO (Hb = 14.4 gm/dl) the venous point is 14 mm of Hg. So, although this shift of the oxyhaemoglobin dissociation curve has little effect on the arterial O_2 content, but its effect on venous PO_2 is very significant. At a cerebral venous PO_2 of 14 mm of Hg, the subject will be unconscious.

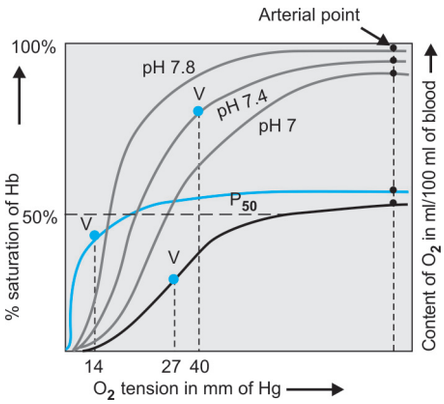

Fig. 4.7: Different O_2-Hb dissociation curves in different conditions, such as normal, acidosis and alkalosis (black curves), CO poisoning (green curve) and anaemia (red curve)

Coal gas has 10% CO as its content. Natural gas also contains trace amount of CO but does not cause CO poisoning. So, coal gas has been replaced by natural gas which contain about 90% methane, with only trace amounts of carbon monoxide. Carbonmonoxyhaemoglobin level also goes upto 10% in cigarette smoking. Car exhaust and commercial paint removal, containing methylene chloride causes also severe CO poisoning.

The treatment of CO poisoning consists of hyperbaric O_2 mixed with 5% CO_2, in order to shift the oxyhaemoglobin dissociation curve to the right towards its normal position (Table 4.4).

(c) Methaemoglobin and sulphaemoglobin

Methaemoglobinaemia is an another important, but uncommon etiology for development of cyanosis and anaemic hypoxia which demands prompt diagnosis and treatment. So, for quick evaluation the history, physical examination, bedside diagnostic

Table 4.4: Classification and causes of hypoxia

Hypoxic hypoxia	↓FiO_2, ↓Barometric pressure ↓V_A, Diffusion hypoxia, V/Q mismatch, Pulmonary diffusion defect, R → L shunt
Anaemic hypoxia	Anaemia, co-poisioning, methaemoglobinaemia, Sulphaemoglobinaemia.
Stagnant hypoxia	↓Cardiac output, MI, heart failure, dehydration
Histotoxic hypoxia	Cyanide poisoning
Low P_{50}	↓pH, ↓2,3-DPG

techniques and laboratory confirmation are all important. But, in the absence of significant history, mild cyanosis can easily be missed in dark skinned individuals during the preanaesthetic check up.

Actually methaemoglobinaemia is a condition where ferrous iron (Fe^{2+}) of the haemoglobin complex is oxidized to ferric iron (Fe^{3+}). Usually, under normal conditions methaemoglobin ($HbFe^{3+}OH$) is continuously being formed in the red blood cells of a normal individual by the process of autooxidation. But, a continuous reduction mechanism maintain the methaemoglobin levels in blood less than 1% of the total haemoglobin. The most important mechanism for converting the methaemoglobin back into the normal haemoglobin is the enzymatic reduction by NADH cytochrome-b5 reductase enzyme. Other minor alternative pathways of mathaemoglobin reduction utilizes the reduced form of NADPH which is generated by glucose-6-phosphate dehydrogenase in the pentose phosphate pathway. Glutathione and ascorbic acid also can reduce the methaemoglobin to normal haemoglobin directly, but quantitatively are not very important.

The accumulation of large amounts of the chocolate - brown, reversibly oxidised methaemoglobin in the red blood cells may be either inherited or acquired. The inherited condition producing methaemoglobinaemia is also due to two reasons: (i) a dominantly inherited abnormality in the synthesis of a special type of haemoglobin, called the haemoglobin M, in which the structural lesion prevents the reduction of methaemoglobin to haemoglobin and (ii) a recessively inherited deficiency in the synthesises of enzyme methaemoglobin reductase.

Thus in summary, the congenital causes of methemoglobin anemia include: haemoglobin M disease in which there is globin chain mutation defect (autosomal dominant) and deficiency of enzyme such as NADH cytochrome-b5 reductase (autosomal recessive). Hereditary methaemoglobinaemia, once regarded as a homogeneous clinical entity is now known that it is the result of at least 10 different mutations at three distinct gene loci : two at the locus coding for the α chain of haemoglobin, three at the locus that encodes the β chain of haemoglobin and at least five at the NADH dehydrogenase locus. The acquired methaemoglobinemia also can be caused by the exposure of haemoglobin to the coal gas, car exhaust, smoking and other oxidizing chemicals or drugs such as nitrites, xylocaine, prilocaine, phenacetin, acetanilide, sulphanilamide, etc.

The irreversible formation of another haemoglobin, causing anaemic hypoxia is sulphaemoglobin. It has distinct abnormal spectral properties and results from the administration of drugs, particularly sulphonamides. This condition is called the sulphaemoglobinaemia. The sulphaemo globinaemia also can be produced by other compounds that cause methaemoglobinaemia and these two conditions frequently coexist. Sulphaemoglobinaemia produces marked cyanosis, but disappears spontaneously as the cells containing the abnormal pigment are gradually removed from the circulation with the passing of time and further production is prevented.

As the methaemoglobinaemia results due the oxidation of iron from its ferrous (Fe^{2+}) to its ferric (Fe^{3+}) state, so the concomitant oxidation of haemoglobin protein may cause its precipitation as Heinz bodies and resulted in haemolytic anaemia. The methaemoglobin (ferric haemoglobin) can not carry oxygen and when present in excess, results in a functional anaemia. It also shifts the oxygen dissociation curve to the left and thus limits the release of oxygen to the tissues. So, the symptoms of methaemoglobinaemia are due to hypoxia and anaerobic metabolism. In many cases, there are no clinical features, other than cyanosis. But when the concentration of methaemoglobin rises to 20 to 45%, then anoxic symptoms like headache, fatigue, dysponea and lethargy may develop. There may also be alteration in the level of consciousness when methaemoglobin level rises to 44 to 55%. Cardiac arrhythmias, circulatory collapse, seizures and even death may occur at the methaemoglobin level of 70% or more.

The diagnosis of methaemoglobinaemia is based upon the presence of central cyanosis, unresponsive to oxygen therapy and decreased oxygen saturation in presence of still normal P_aO_2. Since, methaemoglobin has an absorption characteristic similar to that of deoxy haemoglobin, so its presence in the blood falsely lowers the saturation of Hb as read on the pulse oximeter. On the otherhand, oxygen saturation measured by pulse oximetry may be falsely normal. If co-oximetry is not available, methaemoglobin levels can also be estimated by the difference between the oxygen saturation calculated from the P_aO_2 and that measured directly by blood gas analysis. The saturation reported on the arterial blood gas analysis is based on the partial pressure of dissolved oxygen and assumes no abnormal haemoglobin is present. Therefore, the reported oxygen saturation from arterial blood gas analysis is higher than that measured by the pulse oximeter.

Methaemoglobinaemia induced by drugs or chemicals is spontaneously reversed when the agent is withdrawn. Most of the oxidising agents are eliminated by metabolism directly from the body, making diuresis ineffective. Supplemental O_2 should be administered.

Dialysis may be useful, depending on the specific compounds. Higher levels of pigment amounting to more than 30 to 40% of the total pigment can be life threatening and are best treated by the infusion of 1% methylene blue in the dose of 1 to 2 mg per Kg of body weight over 5 minutes. Cyanosis alone is not an indication for methylene blue therapy in methaemoglobinaemia. In patients with anaemia or cardiovascular disease where the manifestations of hypoxia are present, then methylene blue treatment may be indicated at a lower levels of methaemoglobin. After methylene blue, if clinical response is not observed within 1 hour, then the dose may be repeated. A methaemoglobin level of 40 g/L can be expected to decrease by half in 1 to 2 hour after beginning of treatment with methylene blue. However, as long as the oxidizing agent remains in the body, the methaemoglobin will be generated and additional doses of methelene blue may be necessary. This methylene blue dye helps to combine the highly efficient NADP linked methaemoglobin reducing system to methaemoglobin and thus will result in rapid reduction of methaemoglobin to haemoglobin in all patients, but not in G6PD deficient patients.

The side effects of methylene blue that occur during the treatment of methaemoglobinaemia include precordial pain, dyspnoea, restlessness, tremor, apprehension, and transiet blue colour of skin and urine. Methylene blue is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, because it can cause hemolysis. Exchange transfusion for treatment of methaemoglobinaemia is indicated when: methaemoglobin level is very high, the patient is refractory to the treatment by methylene blue and the patient is deficient in glucose-6-phosphate dehydrogenase. Although methaemoglobinaemia due to methaemoglobin reductase deficiency also responds to methylene blue treatment, but this chronic disorder is best treated by the daily oral administration of 1 to 2 gm of ascorbic acid. Cyanosis due to haemoglobin M does not respond to any treatment, but is ordinarily a benign condition.

To conclude, low SPO_2 reading in the presence of normal P_aO_2 suggest the possible presence of dyshaemoglobin (methaemoglobin or other abnormal Hb) which may affect the accuracy of the pulse oximeter. This is because only two wavelengths of light are used in this device, one for oxy-Hb and another is for deoxy-Hb or reduced Hb. The role of laboratory co-oximeter which uses light of several wave lengths can identify and quantify the different types of dyshaemoglobins. Thus its role in such situations can not be overemphasized.

Stagnant hypoxia

This type of hypoxia occurs when there is decreased circulation in tissues or when the demand of O_2 at tissues level increases than the supply of it. Hence, it causes increased difference between the supply and demand of O_2 at tissue level. This hypocirculation of tissue is due to the reduced cardiac output, peripheral vasoconstriction, trauma, arterial occulation due to embolism or atheroma, etc.

Histotoxic hypoxia

Here, the diffusion of O_2 at the level of alveoli and transport of it through the blood to the tissues is alright. But the defect lies at the cellular mitochondrial level which impair the utilisation of O_2 by the cell and produce hypoxia. In mitochondria when glucose is oxidised, H^+ is removed by NAD and become NADH. Then this H^+ is passed down through the cytochrom enzymatic systems with formation of ATP and at the last react with O_2 to form H_2O. Thus poisoning of this cytochrome enzyme system by cyanide, nitropruside, etc, causes stoppage of this machine and make unable the use of O_2, delivered to the tissues causing the stoppage of aerobic metabolism and hypoxia. So, as the metabolism is stopped, CO_2 is not produced and O_2 is not utilised. Thus, reduced production of CO_2 by tissues causes fall in venous PCO_2 and subsequently reduced O_2 consumption rises mixed venous PO_2.

Condition where P_{50} is low i.e. oxygen dissociation curve is shifted to the left

P_{50} is the partial pressure of O_2 at which Hb is 50% saturated. The normal value of P_{50} is 27 mm of Hg, which means at PO_2 of 27 mm of Hg haemoglobin is 50% saturated. Low P_{50} means oxygen dissociation curve of Hb is shifted to the left which means at low partial O_2 pressure (< 27 mm of Hg) Hb is 50% saturated or in otherwords at 50% saturation of Hb it has low O_2 tension. For diffusion of O_2 at tissues, the partial pressure of O_2 at tissue level must be lower than that of the blood. But if partial pressure of O_2 at capillary level remains less, then O_2 will not flow from blood to the tissue, leading to cellular hypoxia. The example of low P_{50} value causing hypoxia are: acidosis, hypothermia, electrolyte imbalance, etc. (Table 4.5).

Effects of Hypoxia

The effects of hypoxia or anoxia vary according to the severity and the rate of occuring of it. When the supply of oxygen is cut off very rapidly, then sudden loss of consciousness will occur. But, if the hypoxia develops gradually such as in mountaineering, then the effects on the different systems of it are as follows:

Table 4.5: Effects of chronic hypoxia

1. CVS	:	↑Cardiac output, ↑BP, ↑HR, ↑sympathetic activity, Ferebral vasodilatation, ↑SVR
2. RS	:	↑Ventilation, ↑PVR
3. Metabolism	:	↓Aerobic metabolism, ↓ATP formation, ↑Anaerobic metabolism, ↑Metabolic acidosis
4. Haemoglobin	:	Polycythemia, ↑Viscosity of blood, cyanosis, reduced Hb is a better buffer
5. Organ failure	:	Depressed myocardium, unconsciousness

CVS

The hypoxia has profound effect on cardiovascular system. By direct effect it causes the systemic vasodilatation and fall of BP. This hypotension and hypoxia is compensated by ↑ sympathetic activity by peripheral baroreceptor and chemoreceptor stimulation. In the preliminary compensatory stage due to the stimulating effect of hypoxia and hypotension on vasomotor and cardioaccelerator centre, there is rise in heart rate, minute output and blood pressure. Therefore, the splanchnic and cutaneous blood vessels constrict. Thus, a large amount of blood is shifted from the non vital organs to the vital organs such as the heart and brain, so that they may be supplied by adequate amount of oxygen. In non-anaesthetized person if hypoxia continue, then hypotension will no longer be compensated and heart rate will increase further. But the force of cardiac contraction becomes gradually weaker due to the weakness of cardiac muscles caused by hypoxia and heart starts to fail. Then, CO and BP gradually goes to zero and cardiac arrest will result. In anaesthetised person, where there is no compensatory mechanism, this fall of BP and cardiac arrest will occur early. The prognosis of hypoxic cardiac arrest is extremely poor, because by the time the heart is stopped as a result of hypoxia, there is always nearly irreversible brain damage, though hypoxia increase the blood flow to most organs, especially the brain.

Respiratory system (RS)

It is seen that no alteration of respiration or breathing takes place, till the O_2 content in the inspired air is reduced to about 13 to 14%, when a slight increase of respiratory rate is seen. Later if the O_2 content in inspired air is more and more reduced, then respiration gradually more and more is stimulated. Thus, this increased ventilation try to keep the arterial O_2 tension normal, but washes out excessive amount of CO_2. This excess excretion of CO_2 also favours the better oxygenation. So, O_2 content of blood remains proportionately high, but the CO_2 tension falls. Then, gradually due to the low CO_2 tension the reflex respiration is not further stimulated and dies down, causing again less ventilation and reduced oxygenaton of blood with raised CO_2 tension. Consequently, respiration is again stimulated. In this way, respiration becomes alternately stimulated and depressed, resulting in what is known as the periodic breathing. The sequence of these events may be summarised as follows: O_2 lack stimulates breathing – washes out more CO_2 – arterial CO_2 tension is lowered – respiration is depressed – CO_2 tension in blood is again raised – breathing stimulated and so on. In this way, respiration goes on alternately waxing and waning during gradual increase in severity of hypoxia.

Thus, when the inspired O_2 concentration is reduced more and more and goes down below 15%, then cyanosis develops. The consciousness becomes dull and soon after this, the subject becomes unconscious due to the effects of hypoxia on higher centres.

But, when the lack of oxygen or hypoxia is very gradual then the results are different, because the compensatory changes are brought into play. It is best studied in subject ascending slowly to the higher altitudes. At higher altitude, the percentage of composition of air is same as over the plane. But, due to the less barometric pressure the air is more rarified or much less condensed, so that each ml of such air will contain less number of molecules of oxygen and other gases which causes less partial pressure of them than over the plane. The symptoms first appear at about 3657 metres or 12000 feet height where the barometric pressure is two third of 1 atmospheric pressure (760 mm of Hg) i.e. about 500 mm of Hg. At that height slight breathlessness and tendency to periodic breathing, especially during sleep, will appear. Nervous symptoms which closely resemble of alcohol poisoning will also appear. Gradually all the other systems will be affected and the subject will get what is called the 'altitude sickness' or 'mountain sickness'. The altitude sickness with mental depression, nausea, vomitting, etc, usually start 8 to 12 hours after the exposure to that height and may even present for few days after descent from this high altitude. But, generally these effects pass off quickly. If the oxygen lack is severe and the exposure is prolonged, then grave after effects may occur. For example, in hypoxia due to CO poisoning even when the composition of blood has been restored to normal, still the subject may not regain consciousness for many hours. He may pass into coma and may die. Even if the patient becomes conscious and apparently be normal, till there may be bouts of convulsions at intervals, owing to the irritation of nervous systems. Even the paralysis of various parts of the body may follow as a result of damage of the nerve cells. There may be complete dementia or just a temporary impairment of mind.

All these features point out that the hypoxia or anoxia devitalises and injures the whole body. From such observations Haldane has remarked that 'hypoxia or anoxia not only stops the machine, but also wrecks the machinery'. Hypoxia causes pulmonary arteriolar vasoconstriction and as a compensatory phenomenon shifts the blood from the hypoxic to the well ventilated area of lungs, keeping the P_aO_2 at normal. This is a beneficial effect for one lung intubation, lobar consolidation, etc. Chronic hypoxia due to intracardiac shunt such as ASD, VSD, PDA, etc, cause total pulmonary arteriolar vasoconstriction and increases the right sided pressure of the heart with reversal of shunt and arteriolar desaturation. This is because chronic hypoxia causes irreversible increase in PVR with pulmonary hypertension.

Metabolism

In hypoxia, anaerobic metabolic path is switched on with formation of less ATP and accumulation of lactic acid

(metabolic acidosis). The total mechanism is described below.

There is requirement of glucose for energy in all the tissues. But, in some tissues like brain and erythrocytes the requirement of glucose is substantial. Glycolysis is the (Fig. 4.8) major pathway of metabolism of glucose for energy and is found in all the cells. It is a unique pathway, because it can utilise oxygen if available (aerobic) and it can also function in the absence of O_2 (anaerobic) if it is not available. Glycolysis is the principal route of glucose metabolism leading to the production of pyruvate which undergoes further oxidation in the citric acid cycle through acetyl - CoA in the presence of O_2. Glycolysis also provides the main dependable pathway for the metabolism of fructose, galactose and other substrates derived from the diet. The crucial biological significance of glycolysis is its ability to provide ATP, still in the absence of O_2. So, it allows the skeletal muscle to perform glycolysis at very high levels when the aerobic oxidation becomes insufficient to survive anoxic episodes. Conversely, the heart muscle which is adapted only for the aerobic performance, has both the relatively poor glycolytic ability and poor survival rate under conditions of ischaemia.

Though, it has been customary to separate carbohydrate metabolism into anaerobic and aerobic phases, but this distinction is arbitrary. Because, the steps of reactions in glycolysis are the same as in the presence of oxygen or in its absence, except in extent and the end products. When the O_2 is not in supply, then reoxidation of NADH formed from NAD during glycolysis is impaired. Under these circumstances, NADH is only reoxidised during the reduction of pyruvate to lactate and the NAD so formed is used again at the step 5 of glycolytic pathway and allows further glycolysis to proceed. This reaction from pyruvate to lactate is catalysed by the lactate dehydrogenase. Thus, glycolysis also can take place under anaerobic condition. But, this has to given price for its limited action, regarding the low amount of energy liberated per mole of glucose oxidised. Consequently, to provide a given amount of energy, more glucose must undergo glycolysis under anaerobic condition as compared with aerobic conditions.

$$\text{Pyruvate} + \text{NADH} + H^+ \longleftrightarrow \text{Lactate} + NAD^+$$

The reoxidation of NADH to NAD during lactate formation allows glycolysis to continue even in the absence of oxygen by regenerating sufficient NAD^+. Thus, tissues that function under hypoxic circumstances continue the glycolysis to produce lactate. This is particularly true for skeletal muscle, where the rate at which the organs perform work is not limited by its capacity for

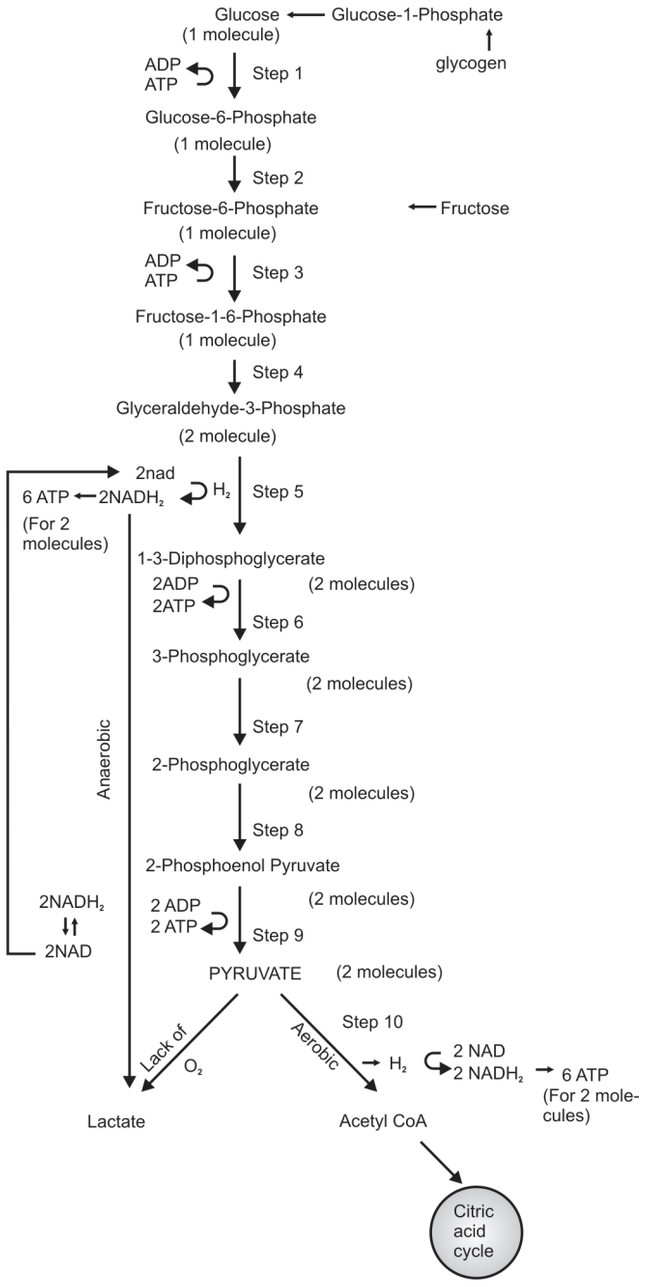

Fig. 4.8: Schematic representation of glycolysis

oxygenation. So the additional quantities of lactate thus produced may be detected in the tissues and in the blood and urine. Glycolysis which occur in erythrocytes, even under aerobic conditions always terminates in lactate. Because the mitochondrias that contain enzymatic machinery for aerobic oxidation of pyruvate through citric acid cycle are absent in RBC. The mammalian erythrocyte is unique in that about 90% of its total energy requirement is provided by only the glycolysis. Besides skeletal muscle and erythrocytes, other tissues that normally derive most of their energy from glycolysis and produce lactate include brain, GI tract, renal medulla, retina and skin. The liver, kidneys and heart usually take up this lactate and oxidise it, but will produce it only under hypoxic conditions. The overall equation for glycolysis to lactate is Glucose + 2 ADP + $2P_1 \rightarrow 2\ _L(+)$ Lactate +2 ATP + 2 H_2O All the enzymes for the glycolytic pathway are found in the extramitochondrial cytoplasm. They catalyse all the reactions involved during the glycolysis from glucose to pyruvate (in the presence of O_2) or lactate (in the absence of O_2) (Table 4.6).

In erythrocytes, the step six in glycolytic pathway from 1,3-diphosphoglycerate to 3-phosphoglycerate is bypassed. An additional enzyme, diphosphoglycerate mutase, catalyses the conversion of 1,3-diphosphoglycerate to 2,3-diphosphoglycerate (2,3-DPG). The latter is then converted to 3-phosphoglycerate. Thus, the loss of high energy phosphate as there is no net production of ATP when glycolysis takes this by pass route, may be an advantage to the function of red cell. The advantage is 2,3-diphosphoglycerate (2,3-DPG), which is present in high concentration in RBC combines with Hb and causes the decrease in affinity of Hb for O_2 with displacement of the oxyhaemoglobin dissociation curve to the right. Thus, its presence in the red cells helps oxyhaemoglobin to unload oxygen in the tissues while it is flowing through tissue capillaries.

Before the pyruvate can enter the citric acid cycle, it must be transported into the mitochondria. Within the mitochondria the pyruvate is first decarboxylated to acetyl CoA.

Pyruvate + NAD + CoA $\rightarrow$ Acetyl-CoA + NADH + H^+ + CO_2

The citric acid cycle which is also known as the Krebs cycle or tricarboxylic acid (TCA) cycle is a series of reactions in mitochondria. It brings about the catabolism of acetyl residues of acetyl-CoA liberating hydrogen ions which after oxidation while passing through cytochrome system lead to the release of most of the free energy in the form of ATP for tissue fuels. Thus the major function of this citric acid cycle is to act as the final common pathway for the oxidation of substrates including carbohydrates, lipids and proteins. This is because glucose, fatty acids and many aminoacids are all metabolised to acetyl CoA which can enter the citric acid cycle. It also plays a major role in gluconeogenesis, transamination, deamination and lipogenesis. Several of these process are carried out in many tissues, but the liver is the only tissue in which all the reactions occur to a significant extent (Table 4.7).

Essentially, the citric acid cycle starts with the combination of a molecule of acetyl-CoA with a molecule of oxaloacetate of 4 carbon atoms, resulting in the formation of a citrate with 6 carbon atoms. Then, this follows a series of reactions, in the course of which 2 molecule of CO_2 are released and again oxaloacetate is regenerated. The citric acid cycle is an integral part of the metabolic process by which huge amount of free energy in the form of ATP is liberated. During the course of oxidation of acetyl CoA in the citric acid cycle, reducing equivalents in the form of hydrogen or electrons are formed which are taken by NAD

Table 4.7: Total formation of ATP during catabolism of one molecule of glucose in anaerobic condition

Pathway	*Step*	*Method of production*	*No of ATP formed*
Glycolysis	Step 6	Substrate level	+2
	Step 9	Substrate level	+2
	Step 1	ATP consumed	−1
	Step 3	ATP consumed	−1
		Formation of net ATP	2

Formation of 2 molecules of NADH at step 5 is used for further metabolism of pyruvate to lactate in anaerobic condition.

Table 4.6: Total formation of ATP during catabolism of one molecule of glucose in aerobic condition

Pathway	*Step*	*Method of production*	*No. of ATP formed*
Glycolysis	S-5	Respiratory chain oxidation of 2 NADH	6
	S-6	Substrate level	2
	S-9	Substrate level	2
			10
	S-1	ATP consumed	−1
	S-3	ATP consumed	−1
		Formation of net ATP	8
Kreb cycle	S-11	Oxidation of 2NADH	6
or	S-15	Oxidation of 2 NADH	6
Citric acid	S-17	Oxidation of 2NADH	6
cycle	S-18	Substrate level	2
	S-19	Oxidation of FADH2	4
	S-21	Oxidation of 2NADH	6
		Formation of net ATP	30

Total formation of ATP molecules in aerobic condition from each molecules of glucose is 30 + 8 = 38

or FAD, forming NADH or FADH. These reducing equivalents then enter the respiratory chain, where large amounts of ATP are generated by the process of oxidative phosphorylation. This process is aerobic, requiring O_2 as the final oxidant of the reducing equivalents. Therefore, absence (anoxia) or partial deficiency (hypoxia) of O_2 causes total or partial inhibition of the cycle.

The enzymes of this citric acid cycle are located in the mitochondrial matrix, either free or attached to the inner surface of the mitochondrial membane. These enzymes facilitate also the transfer of reducing equivalents to the adjacent enzymes of the respiratory chain, situated also in the inner mitochondrial membrane.

When 1 mol of glucose is combusted in a calorimeter to CO_2 and H_2O, then approximately 2780 kJ are liberated as heat. But when this oxidation occurs in the tissues, then some of this energy is not lost immediately as heat, but is 'captured' as high energy phosphate in ATP. Usually 38 mol of ATP are generated per molecule of glucose when it is oxidized both by the glycolysis and citric acid cycle to CO_2 and H_2O. Assumming each high energy bond in ATP to be equivalent to 30·5 kJ, then the total energy captured as ATP per mole of glucose oxidised is 1159 kJ which is approximately 41·7% of the energy of combustion or metabolism. Most of the ATP is formed as a consequence of oxidative phosphorylation through cytochrome system, resulting from the reoxidation of reduced coenzymes such as NADH and FADH by the respiratory chain. The remainder is generated by phosphorylation directly at the substrate level.

Organ

Brain and retina is most sensitive to hypoxia. Due to the lack of O_2, the cerebral function gradually deteriorates like changes of mood to confusion to unconsciousness. If circulation stops, then the time taken for brain from stop of functioning to the extent of loss of consciouness is called the 'survival time'. Usually the survival time is 0·5 minute. Whereas the 'revival time' is defined as the time beyond which the recovery of function of brain is not possible. Usually the revival time of brain is 3 minute. Spinal cord is also very sensitive to hypoxia, for example, clamping of aorta, occlusion of anterior spinal artery, etc. Kidney has survival times of 10 minutes. More prolonged hypoxia than this causes renal tubular necrosis, renal cortial necrosis, etc. Chronic renal hypoxia causes increased synthesis of erythropoietin which subsequently causes ↑synthesis of erythrocytes from bone marrow and polycythaemia. In liver, the centrilobular cells being far remote from the systemic blood supply exhibit the first necrotic changes in response to hypoxia. In acute hypoxia the centrilobular necrosis of liver is seen.

Changes in blood (in chronic hypoxia)

In chronic hypoxia blood volume and haemoglobin concentration increases as a compensatory mechanism. Therefore, as haemoglobin content of blood rises, so the O_2 content in it is also raised. This is brought about in two ways: (i) The immediate effect is believed to be due to the contraction of spleen and the consequent pumping out of the stored red blood cells into the circulation. (ii) In the delayed effect, as the rate of multiplication of the erythrogenic tissues in the red bone marrow is stimulated by erythropoietin released from kidney in response to chronic hypoxia, so the red cell count is further raised. Therefore, many immature types of red cells (such as reticulocytes) are present in the blood during chronic hypoxia, indicating rapid erythrogenesis. This increased quantity of Hb is very helpful to carry adequate amount of O_2 in the lack of it. As for example at high altitude though Hb is not fully saturated with O_2, but as the total amount of Hb is being more, so the ultimate total O_2 supply to the tissues can be maintained. Due to chronic hypoxia as respiration is stimulated to maintain adequate oxygenation, so there is also tendency towards respiratory alkalosis due to washing out of excess CO_2. This is again combated by excretion of alkaline urine.

Changes in urine

Chronic hypoxia is associated with compensatory respiratory stimulation leading to respiratory alkalosis. Hence, in chronic hypoxia due to respiratory alkalosis kidney excretes alkaline urine as a compensatory mechanism. So, in urine the urea content is increased and ammonium salt is decreased. In other words, the ammonia coefficient of urine falls. Therefore, there is less excretion of acid in urine. All these are attempts to combat respiratory alkalosis (Fig. 4.9).

Delayed changes

The red marrow proliferates as a result of hypoxia. The yellow marrow may be transformed into red marrow. This is due to an attempt to increase the O2 carrying capacity by increasing the red cell production as a compensatory phenomenon. Vital capacity of lungs also increases in those people who live at higher altitude for long periods.

CAUSES OF POSTOPERATIVE HYPOXIA

Three types of hypoxia can occur post operatively. These are : hypoxic hypoxia, stagnant hypoxia (↓CO) and anaemic hypoxia (blood loss). The hypoxic hypoxia again may be due to diffusion problem, increased V/Q mismatch, and hypoventilation. But, whatever may be the cause of hypoxia, the O_2 flux and O_2 requirement should be matched. Otherwise, it will lead to hypoxia. The O_2 requirement also tremendously increases postoperatively due to shivering and pyrexia.

Some examples or causes of postoperative hypoxia are:

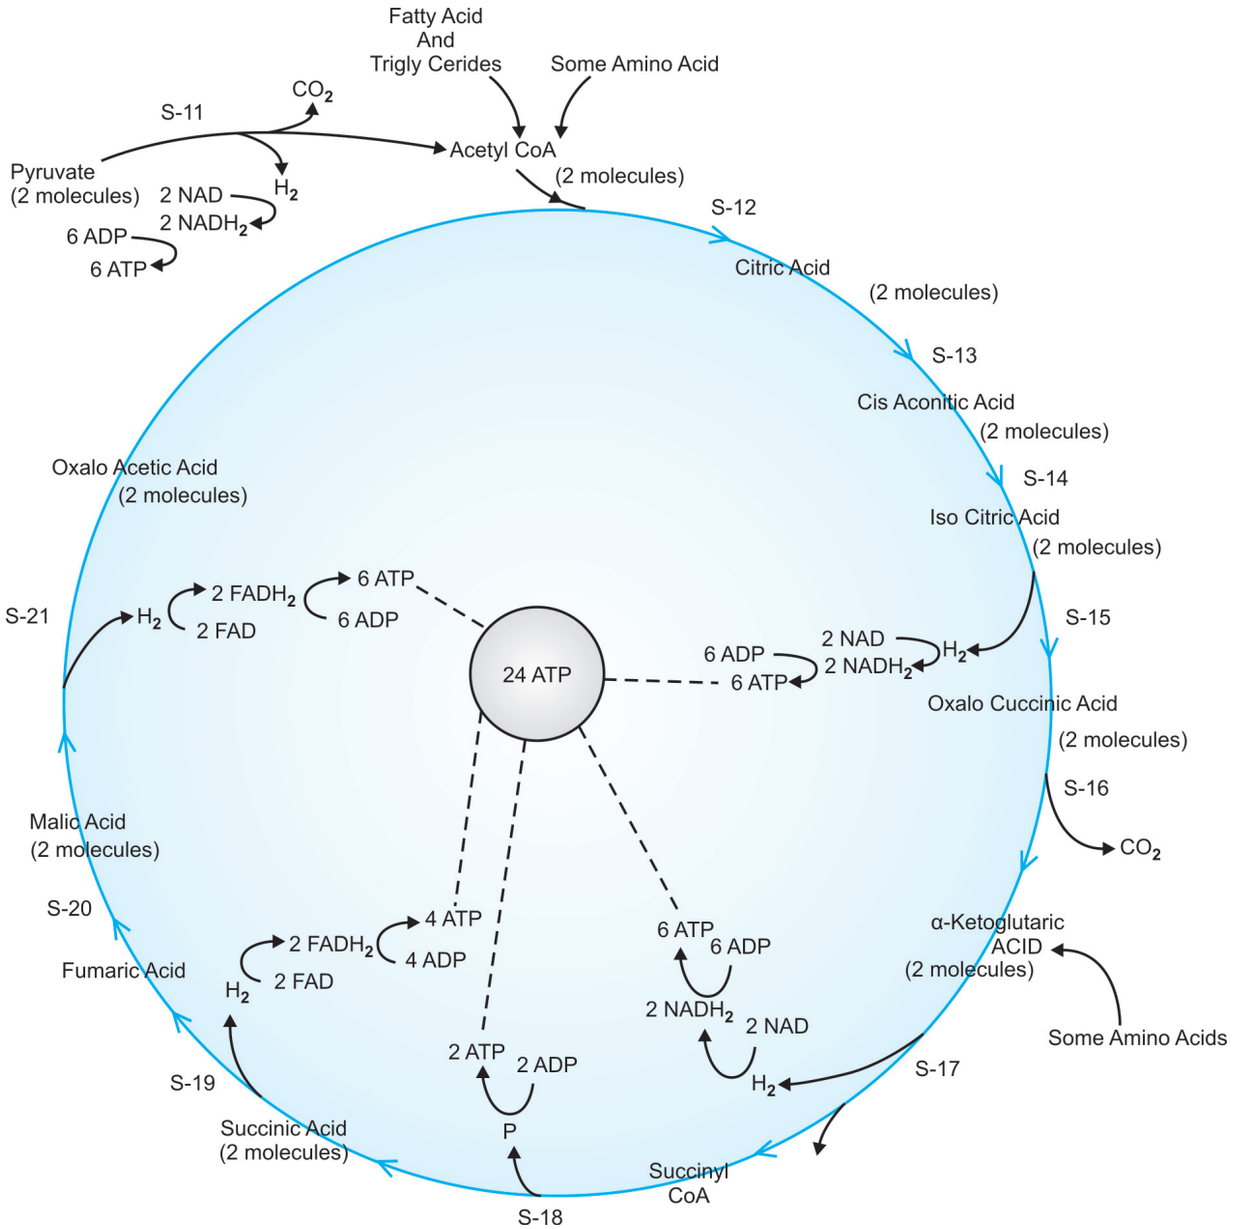

Fig. 4.9 : Schematic representation of citric acid cycle (tricarboxylic acid)

(i) Diffusion hypoxia or Fink effect

This is an example of hypoxic hypoxia.

(ii) Postoperative increased V/Q mismatch

It is also an example of hypoxic hypoxia. It is due to anaesthesia induced reduction of FRC below CC. Upper abdominal surgery causes 30% ↓FRC and increases V/Q mismatch. Elderly people, obese patients, COPD, smoking history, etc, also are more vulnerable to increased V/Q mismatch (hypoxic hypoxia).

(iii) Hypoventilation is due to:

a. drugs such as anaesthesia inducing agents, opiates, muscle relaxants, etc.
b. Obstruction of air passage by mucous plug, vomiting, blood, secretions, etc.
c. Pain preventing the free movement of thoracic and abdominal muscles.
d. Abdominal distention. It causes elevation of diaphram which contributes to hypoventilation.
e. Intra-operative hyperventilation. It causes deficit of body CO_2 reserve. So, to compensate this deficit after anaesthesia, spontaneous ventilation is reduced producing hypoxia.

(iv) Reduction of cardiac output due to any cause

It is an example of stagnant hypoxia.

So prolonged operation, thoracic and upper abdominal surgery, old age, previous lung diseases, heart diseases, huge blood loss, sickle cell disease, heavy sedation, inadequate recovery, hypotension, shivering, pyrexia, etc, where there is every possibility of hypoxia, needs post-operative O_2 therapy by masks at the rate of 3 to 4 lit/min to prevent this hypoxia. Increase in PVR by hypoxia may initiate R-L shunt through VSD, ASD or PDA, if they are patent.

HYPOXIA AND ALTITUDE

As the altitude increases, subsequently then the atmospheric pressure and then the partial pressure of O_2 in the inspired air is reduced. A list, depicted in the table, will show how the atmospheric pressure and subsequently the PO_2 in air will decrease with the increase of altitude (Table 4.8).

Normally, when a person breaths air, he becomes unconscious if SPO_2 falls to 50% or below. Usually this happens at the 23,000 feet height. But, when this person breaths only O_2 instead of air, then this height goes up to 47,000 feet at which or above unconciousness ensures inspite of inhalation of 100% O_2. The height at which the symptoms of altitude sickness actually starts or the physiological changes manifest are not common to all. Generally, within 10,000 feet height there is no necessity for additional O_2 to breathe. It has however been noticed that in most cases breathing becomes laboured at about 12,000 feet height. At about 18,000 feet heights, there is definite panting and other symptoms of altitude sickness appear. Addtional O_2 is necessary from 10,000 feet to 34,000 feet height. It has been generally observed that beyond 22,000 feet acclimatisation sometimes fails and there is a steady deterioration of condition advising to use O_2 supplementation. Pure O_2 is required from 34,000 feet to 42,000 feet height and pressure suit or pressure cabin becomes essential beyond 42,000 feet height.

Table 4.8: Partial pressure of O_2 in atmosphere at different height from sea level

Height	*Partial pressure of O_2 (PO_2)*	*Atmospheric pressure*
At sea level =	159 mm of Hg	760 mm of Hg
5,000 feet height =	130 "	–
10,000 " " =	110 "	522 "
15,000 " " =	90 "	–
20,000 " " =	73 "	346 "
30,000 " " =	48 "	–
50,000 " " =	18 "	85 "

Physiological Changes at High Altitude

At the high altitude the physiological changes occur in the following manner : High altitude − hypoxia − stimulation of periphral chemoreceptor − hyperventilation − washout of CO_2 − ↓ $PaCO_2$ − pH of CSF ↑ (alkaline) − induces renal excretion of bicarbonate − ↓ CSF bicarbonate (compensation) − normalisation of pH of CSF − allowing peripheral chemoreceptor to drive ventilation unopposed. Ventilation reaches maximum at 4th days and reaches to equilibrium over year if stays at high altitude for long time. When he again comes down to sea level, reverse reaction occurs which can be summarised as : ↑P_AO_2 − ↓peripheral chemoreceptor drive − ↓ventilation − ↑ P_aCO_2 −↑ brain PCO_2. As the pH of CSF and extracellular fluid of brain are now lower than normal (since the bicarbonate concentration is still lower than normal), so ventilation is driven by an increased central drive which gradually declines as CSF bicarbonate reaccumulates and brings back the pH of brain to normal. Other physiological changes have been described previously in hypoxia.

Sudden ascend to 10,000 feet height by an unacclimatised man leads to mountain sickness which ranges from weakness and shortness of breath to pulmonary and cerebral oedema. Prophylaxis of this can be taken by slow ascend or acetazolamide. Highest permanent habitation in the world is at about 16,000 feet height where P_AO_2 is only 45 mm of Hg, requiring 40% inspired O_2 concentration to restore the sea level condition. There are many major cities at 6,000 feet height, where PO_2 in inspired air is only 118 mm of Hg which is equivalent to 16% O_2 in air at sea level and P_AO_2 to 75 mm of Hg. At sea level, concentration and tension of O_2 in inspired air is 21% and 159 mm of Hg respectively. Alveolar O_2 tension (P_AO_2) with breathing air at sea level is 103 mm of Hg.

OXYGEN EXCESS OR TOXICITY

The oxygen toxicity is a complex phenomenon. So, inspite of much investigations over many years, still it remains an enigma. Although, it is possible that high O_2 tension could affect many, but not all the organ systems. It would also appear that certain organ systems are more susceptible than others. It is thought that the organs in body which are more susceptible to oxygen toxicity are lungs, retina, brain and cardiovascular system. Oxygen toxicity is a potential complication when FiO_2 of 0.6 or greater is given for more than 72 hours. The condition can be prevented in some cases by the use of PEEP, which allow FiO_2 values to keep below 0.6 for maintaining adequate P_aO_2 instead of higher FiO_2 while primary therapy for the underlying pathological condition is instituted. There is at present no evidence that pulmonary oxygen toxicity develops in man at an inspired O_2 concentration below 0.5, even with prolonged exposure. At inspired O_2 concentration of 0.5 (FiO_2 = 0.5), the damage occurs very slowly if it at all happens and at O_2 pressure greater than 3 ATA the pulmonary problem is overshadowed by the signs of central nervous system toxicity such as convulsions. The rate of development and the degree of damage to the lungs appears to be proportional

both to the concentration of oxygen and to the duration of exposure. Thus, O_2 is safe within a narrow spectrum of partial pressure to maintain life. It is lethal to life at partial pressure outside that ranges.

Pulmonary Effect

Prolonged inhalation of high concentration of O_2 is known to damage mainly the lungs. For the development of pulmonary O_2 toxicity, local alveolar than arterial O_2 tension is more important. Breathing 100% O_2 at 1 atmospheric pressure can cause discomfort and reduction in vital capacity after as little as 10 hours. But, recovery of this decreased vital capacity may take several days after resumption of breathing of air. So, administration of 100% O_2 for up to 10 hours at sea level with normal atmospheric pressure (760 mm of Hg) can be considered safe. But, administration of greater than 50 to 60% O_2 at sea level or 1 atmospheric pressure for more than 24 hours may lead to toxicity and is undesirable.

O_2 is irritant to the lungs and produces inflammation and congestion. This pulmonary O_2 toxicity is thought to be due to the generation of highly reactive metabolites of O_2 such as superoxide, activated hydroxyl ions, hydrogen peroxide, etc, in the cells. These metabolites of oxygen are cytotoxic and cause damage to the cellular DNA, sulfhydryl proteins and lipids of the alveolar epithelial cells. The O_2 mediated pulmonary injury produces a syndrome that is clinically and pathologically indistinguishable from ARDS. In mild cases the bronchopulmonary dysplasia and tracheobronchitis may also result.

The pulmonary oxygentoxicity shows: (i) increased capillary endothelial permeability causing accumulation of fluid in the interstitial space, (ii) depression of mucociliary transport function of airway, (iii) inhibition of phagocytosis of alveolar macrophages, (iv) changes in surfactant activity and its production. The exact highest concentration of O_2 which causes the lung damage is still not known and it varies with individual sensitivity, presence of concomitant previous lung diseases and the concentration and duration of exposure to O_2. In ICCU the FiO_2 should be kept as lower level as possible with optimum P_aO_2.

If only O_2 remains in alveoli, it is quickly absorbed by pulmonary capillary and subsequently alveoli collapses. At sea level in healthy subject, the normal ventilation is maintained by small hypoxic drive. But, in severe COPD patient the main ventilatory drive is severe hypoxia or low P_aO_2. So, therapy by high concentration of O_2 in such pathological situations remove this respiratory drive causing ↓ ventilation –↑ PCO_2 – ↓PaO_2 resulting respiratory arrest, arrhythmia and cardiac arrest. In such patient appropriate inspired O_2 concentration and ventilation is ensured by repeated blood gas analysis.

CVS Effect

The effects of increased arterial O_2 concentration or tension causing O_2 toxicity of CVS is as like as administering peripheral vasoconstrictor, producing ↑ peripheral vascular resistance, ↑BP and ↑HR.

Effect on Body N_2 Store

Inhalation of 100% O_2 causes rapid fall of arterial and body N_2 content. Blood is cleared of N_2 in few minutes, but brain tissue take 20 minutes to clear N_2 store. Whereas, the other tissues like fat, muscle, bone, etc, take few hours to clear their N_2 store. Thus, inhalation of 100% O_2 is used to remove the air and N_2 from body cavities and to prevent the air embolism. When a normal subject breath 100% O_2 the different values of tension of different gases in blood in comparison to when breath air are given in the table (Table 4.9).

From the above table we can see that PvO_2 during breathing of 100% O_2 is slightly higher than that of when breathing air. This is because of the shape of O_2-Hb dissociation curve characterised by the top part which is virtually horizontal. The amount of O_2 carried in physical solution is negligible compared with that in combination with Hb. So, the O_2 content of arterial blood during breathing of 100% O_2 is only slightly greater than that during breathing air. Therefore, there is very little difference between the mixed venous O_2 content and arterial O_2 content. This is because as we are now operating on the steep part of the curve where this small O_2 content difference is reflected by only a small PO_2 difference.

Table 4.9: Partial pressure of different gases in arterial and venous blood when breathing 100% O_2 and air

Tension of gases in arterial and venous blood	*Breathing 100% O_2 (mm of Hg)*	*Breathing of air (mm of Hg)*
$P_a O_2$	600	100
$P_a CO_2$	40	40
$P_a N_2$	0	569
PvO_2	50	40
$PvCO_2$	46	46
PvN_2	0	569

As the gases diffuse down along the gradient of their partial pressure at the level of alveoli and tissue, so the breathing of 100% O_2 containing no N_2 will enormously increase the rate of elimination of N_2 and other gases from a gas loculus within the body, such as penumothorax, emphysematous bullae, air embolism, etc.

Central Nervous System

In CNS convulsions, similar to those of grand mal epilepsy occur during oxygen toxicity.

Retrolental Fibroplasia (RLF)

The retrolental fibroplasia (RLF) is the result of O_2 toxicity in retina and is caused by retinal vasoconstriction. Due to high P_aO_2 the obliteration of most of the immature retinal vessels and subsequent new vessel formation at the site of damage is the principal pathology of this disease. So, the RLF is also called as a proliferative retinopathy. Leakage of extravascular fluid from

this new proliferation of blood vessels in retina also leads to vitreoretinal fibrosis, adhesions and subsequent retinal detachment. RLF usually occurs in infants exposed to hyperoxia in the NICU. It is related not to the FiO_2, but to an elevated retinal arterial PO_2. This is because, high FiO_2 is not always related to high P_aO_2 due to different lung pathology in neonates or prematurity which prevents the diffusion of O_2 through alveoli. It is not known the actual threshold level of P_aO_2 which is responsible for the development of this retinal damage. An umbilical arterial PO_2 of 60 to 90 mm of Hg is associated with a very low incidence of RLF. It should be noted, however, that there are also many factors which are involved in the development of RLF in addition to retinal arterial hyperoxia.

RLF is recently termed as ROP (Retinopathy of prematurity). It develops in 84% of premature infants born at ± 28 weeks of gestational period. But, fortunately it resolves in 80% of cases without any visual loss form retinal detachment and scarring. Risk of ROP increases not only with delivery at early gestational period (severity of prematurity), but also with the other comorbidities such as sepsis, ARDS, etc, which need management by ventilators with high FiO_2. In contrast to pulmonary toxicity, ROP correlates better with P_aO_2 than P_AO_2. Between 1940 to 1950s ROP had reached an epidemic lebel. This was due to the administration of high O_2 concentration ($FiO_2 > 0.5$) in incubators. So, the recommended P_aO_2 for premature infants receiving O_2 is 50 to 80 mm of Hg. But, if due to any cardiopulmonary reasons a premature infant needs arterial O_2 saturation of 96 to 99%, then it should not be withheld in the fear of ROP.

O_2 DELIVERY SYSTEM

The O_2 can be delivered at different concentration and at different atmospheric pressure by the different techniques such as nasal catheters, simple mask and pipe from oxygen cylinder, complicated anaesthetic machine, heart lung machine, O_2 pressure suit, etc. But, here only the few bed side methods of O_2 delivery system has been discussed.

Nasal Catheters or Cannulas

This is the most simplest bedside device for delivery of O_2 to the patients. It is available in all the sizes for adults, children, infants and neonates. Two types of nasal cannulas are used : one is soft, plastic, blind ended with an over the ear head -elastic adjustment and the second is dual flow with under the chin variable adjustment. The FiO_2 during the use of these cannulas is unpredictable. It is determined by: the total O_2 flow, tidal volume, respiratory rate and the nasopharyngeal volume of the patient which act as the O_2 reservoir during inspiration or during mouth breathing. Since, as the O_2 flows continuously through these catheter so 80% of the delivered O_2 is wasted during expiration which again depend on the rate of respiration. The FiO_2 increases by approximately 1 to 2% for each litre of O_2 flow during quite breathing. By the flow of 3 to 4 L/min, the FiO_2 can be increased up to 30 to 35%. Again by the flow of 5 L/min, the FiO_2 can be increased up to 40%. But the higher flow rate than 5 L/min is poorly tolerated by patient. This is due to the discomfort as the gas jets into the nasal cavity and causes dry crusting of the nasal mucosa (Table 4.10).

The advantages of nasal cannula are that it is comfortable, well tolerated and allows the patient to speak, eat, drink, etc during O_2 therapy. It is also nonclaustrophobic and allows long term use. It also can be used by cannula fixed with spectacles frame for more convenince or cosmetic purpose. To avoid the wastage of O_2 during expiration, the cannulas fitted with inlet reservoir are also used by the patients who are receiving long term O_2 therapy. This concept has resulted the development of valved reservoir device which stores the incoming O_2 during expiration till the inspiration occurs.

Table 4.10: Different O_2 delivery system, O_2 flow rate and FiO_2

Delivery system	*Flow rate (L/min)*	*FiO_2 (%)*
Nasal canula	2	25
	4	30
	6	40
Mask without reservoir	6	40
	8	50
Mask with reservoir	4	40
	6	50
Venturi mask	4	24
	6	28
	8	35
	10	40
	12	50

Cannulas providing O_2 to the patient are connected to the flow meter and cylinders or pipeline through a humidifier and a small bore tubing. Now a days, the paediatric sized nasal cannulas are also available for paediatric patient and this use has become increasingly common. During reduced minute ventilation due to any cause, the flow of O_2 through the cannulas should also be proportionately reduced. This generally requires a pressure compensated flow meter which accurately delivers the O_2 flow less than 1 to 3 L/min and will reduce the wastage. With the paediatric sized cannulas when the O_2 flows at the rate of 0.25, 0.5, 0.75 or 1 L/min, then the FiO_2 reaches 35%, 45%, 60% and 70% respectively.

Oxygen Mask with or without Reservoir

It is a simple, disposable and transparent plastic device which is placed over the face, covering both the nose and mouth. When it covers only the nose, it is called the nasal mask. The lower edge of the nasal mask rests on the upper lip surrounding the external nose only. The advantage of nasal mask over the cannula for delivery of O_2 is that it is not jetted into the nasal cavity like cannula and allows patient's comfort.

Both the nasal and the face mask are fastened to the patient's face by adjustable elastic headband. Some manufacturers provide a maleable metal nose bridge adjustment device for proper fitting of mask at the root of the nose. When the O_2 masks are used, then the patients receive the mixture of O_2 and entrained room air which enters through the leak between the mask and face. In some masks there have some small room air entrainment holes near the connection between the mask and the tubing which lead to the flow meter.

The body of the face mask actually acts as a reservoir for both the inspired O_2 and expired CO_2. So, a minimum O_2 flow of approximately 5 L/min is needed to avoid rebreathing during the use of face mask. The level of desired FiO_2 during the management of hypoxia with mask depends on the O_2 flow, mask volume, tidal volume and the respiratory rate (pattern of ventilation) of the patient. Usually, during normal breathing the FiO_2 reaches 30 to 60%, when the O_2 flow varies between 5 to 10 L/min. The FiO_2 can be higher with low respiratory rate or increased tidal volume. Masks are used for patients who need high level of FiO_2 than nasal cannula and for short period of time such as during patient transport, in the post anaesthetic care unit and in emergency department, etc. But, it is not the device of choice for delivery of O_2 in patient who is suffering from severe hypoxaemia, tachypnoea or unable to protect their airway from aspiration.

Sometimes a plastic bag is attached to the face mask, which acts as a reservoir of O_2 during inspiration. These are called the reservoir face mask. These are more scientific than the usual cannula or only face mask without reservoir. The reservoir masks are again of two types: the rebreathing reservoir mask and the nonrebreathing reservoir mask. In rebreathing reservoir mask the patient's expired air enters the bag and refill it. But usually this expired gas comes from the patient's dead space and does not cause any significant rebreathing of CO_2. In non rebreathing reservoir mask, a valve is used between the bag and the mask which prevent rebreathing. The successful use of reservoir face mask needs sufficient flow of O_2, so that the bag is atleast partially full during inspiration. Typically with O_2 flow of 5 to 10 L/min the FiO_2 reaches between 40 to 60%. With flow of 15 L/min, the FiO_2 may approach 100%. So this type of mask is indicated for severe hypoxaemia, MI or carbon monoxide poisoning, etc.

Venturi Mask

These masks are also called the air entrainment mask or high air flow with oxygen entrainment (HAFOE) system. In this system O_2 is directed by a small bore tube in jet. Then, a large amount of air is entrained through the ports which are present by the side of the small tube and mixes with the O_2. The final O_2 concentration depends on the ratio of air drawn in through the entrainment ports and the principal O_2 flow. The manufacturers have developed both the fixed and adjustable type of venturi mask, where the amount of air entrained in the mask can be adjusted or fixed. The venturi mask is used for patients whose hypoxaemia can not be controlled by nasal canula or face mask. But, it is always advised to use the minimum flow of O_2 in the ventimask. As a large amount of air entrains in the mask, so the patients get adequate amount of flow for inspiration. Hence, patients with COPD who tend to hypoventilate with moderate FiO_2 are the best condidates for the venturi mask. As low flow of O_2 is used in venti mask, so slight interruption of O_2 flow may cause serious problem resulting hypoxaemia and hypercarbia. On the otherhand, if the entrainment ports are accidentally obstructed by any means such as by bed sheet, patient's hands etc; then FiO_2 will suddenly increase due to getting pure O_2 without mixing with air.

Oxygen Hood

Many young infants and neonates do not tolerate appliances like nasal cannulas and masks over their faces, though different paediatric sizes of its are available. So, for them the oxygen hood is the best alternative for short terms O_2 therapy. Actually hood is ideal for newborns and inactive infants. While the nasal canula, face mask or ventimask provide greater acceptability for mobile paediatric group of patients. Hoods can be of different sizes for different age group of paediatric patients. Some are simple Plexiglass box. But, others have definite system for sealing the neck opening. There should be no attempt to completely seal the system which can cause the accumulation of CO_2. So, to remove CO_2 the hood needs minimum flow of O_2 greater than 7 L/min, but flows of 10 to 15 L/min are adequate for majority of patients.

HYPERBARIC OXYGEN

Hyperbaric condition is defined as the circumstances where the total enviornmental or atmospheric pressure is increased. Thus the O_2 therapy at this hyperbaric condition is known as the hyperbaric oxygen. The higher will be the atmospheric pressure, the higher will be the PO_2 in air for a fixed concentration of it in air. This is because in higher atmospheric pressure there will be increased concentration of O_2 molecule in a given volume of air which will increase the partial pressure of O_2. The higher will be the PO_2 in the inspired gas or air, the higher will be the alveolar PO_2 and arterial PO_2, provided the diffusion of O_2 through the alveolar membrane is normal. The relationship between the alveolar PO_2 and arterial PO_2 is almost linear. The higher will be the arterial PO_2, the higher will be the amount of oxygen carried as physical solution in arterial blood. This is because the amount of O_2 carried as physical solution in blood only determines the PO_2. But the amount of O_2 carried by Hb which determines the oxygen saturation will not increase.

At the sea level the fresh air contains 21% O_2, the rest being mainly nitrogen.

At the sea level the barometric pressure is of 760 mm of Hg and the partial pressure of O_2 in inspired air is thus 159 mm of Hg, which is 21% of 760 mm of Hg. When air is inspired then during its passage through respiratory tract it rapidly becomes saturated with water vapour at body temperature in the airway and on entering the alveoli it mixes with alveolar gases which contains expired CO_2. The partial pressure of water vapour and CO_2 accounts for about 47 mm of Hg and 40 mm of Hg respectively of the total alveolar gaseous pressure which is 760 mm of Hg and thus leaving pressure of 673 mm of Hg as only for the combined pressures of nitrogen and oxygen in the inspired air. At 1 atmospheric pressure air contains 78% N_2 and it comes down to 75% when reaches the alveoli. So, the partial pressure of N_2 in alveolar air is 75% of 760 mm of Hg or 569 mm of Hg. Thus, the partial pressure of O_2 in alveolar air or alveolar O_2 tension (P_AO_2) is 673 − 569 = 104 mm of Hg. Thus when 100% O_2 alone is inspired, then nitrogen is displaced from the alveoli, leaving the whole 673 mm of Hg partial pressure for only O_2. Thus, the alveolar O_2 pressure or tension can readily be calculated when breathing 100% O_2 at various ambient pressure from the following formula.

$$P_AO_2 = P_IO_2 - P_{H_2O} - PCO_2$$
$$= 760 - 47 - 40$$
$$= 673 \text{ mm of Hg}$$

P_IO_2 = Inspired partial pressure of O_2 at different atmospheric pressure.

P_ACO_2 = Alveolar partial pressure of CO_2 (usually 40 mm of Hg)

PH_2O = Alveolar pressure of water vapour (47 mm of Hg at 37°C).

Table 4.11 shows the alveolar O_2 tension or pressure at different atmospheric pressure when pure or 100% O_2 is administered.

The alveolar PO_2 is the principal determining factor of arterial PO_2. Normally the difference between the two is small (2 to 4 mm of Hg) and is mainly due to the venous admixture.

Table 4.11: Different alveolar O_2 tension in relation to different atmospheric pressure

Atmospheric pressure ATA	*Alveolar PO_2 tension (P_AO_2 in mm of Hg)*
1	673
2	1438
3	2193
4	2953
5	3713
6	4473

Oxygen is carried in blood by chemical combination with Hb and as dissolved physical solution in plasma. One gram of Hb combines with 1.34 ml of O_2 at one atmospheric pressure. Assuming haemoglobin concentration is of 14.6 grams per 100 ml of blood, the amount of O_2 which can be carried as the chemical combination with Hb will be 19.6 ml per 100 ml of blood. When breathing air at one atmospheric pressure, Hb is only 97% saturated with O_2. So only 19 ml of O_2 which is 97% of 19.6 ml is carried per 100 ml of blood. In a healthy individual when 100% O_2 is breathed at one atmospheric pressure, the Hb becomes fully saturated and carries maximum up to 19.6 ml of O_2. By increasing the atmospheric pressure this amount of O_2 carried by Hb can not be increased.

In equilibrium the amount of physically dissolved oxygen in plasma is proportional to the partial pressure of O_2 in alveolus and which again depends on the atmospheric pressure. Normally the plasma contains 0.003 ml O_2 /100 ml blood/mm of Hg arterial O_2 pressure. When breathing room air at an alveolar PO_2 of 104 mm of Hg which corresponds to the arterial O_2 tension (P_aO_2) of 100 mm of Hg at equilibrium, then the amount of dissolved O_2 as physical solution mounts to 0.3 ml O_2 per 100 ml of blood. If the P_AO_2 rose to 673 mm of Hg (when the patient breathed pure 100% oxygen at 1 atmospheric pressure) then the P_aO_2 rises to 600 mm of Hg and the amount of physically dissolved O_2 in plasma would be 1·8 ml per 100 ml of blood. If a subject breathes O_2 at 3 ATA, then the P_AO_2 will be 2193 mm of Hg and arterial PO_2 will be 2000 mm of Hg. In this situation the amount of physically dissolved O_2 would be 6 ml / 100 ml of blood. Here the dissolved O_2 would be sufficient to supply all the O_2 required for a resting man and venous blood would return to the lungs with the Hb still fully saturated.

Thus, at normal atmospheric pressure, the O_2 content of arterial blood is largely dependent on the Hb content. But when hyperbaric O_2 is given then the Hb cannot increase its O_2 load, because it is already fully saturated and in such circumstances as the P_AO_2 rises so the O_2 content of plasma carried only by the physical solution increases.

When an individual is breathing room air, his O_2 stores as the physically dissolved part in plasma are extremely limited and confined mainly to O_2 carried by Hb. However, O_2 stores in the dissolved form in plasma are considerably increased when the hyperboric O_2 is given. At 3 ATA, O_2 is physically dissolved in body water including plasma to the extent of about 6 ml / 100 ml. In a 70 Kg adult, with 50 litres body water, this would create a potential O_2 reservoir of $6 \times 500 = 3000$ ml of O_2. So, such increase in O_2 store will theoretically allow the tissues to survive temporary anoxia for much longer periods which is not possible without hyperbaric O_2 .

It was also stressed before that the tissue O_2 levels depend not only on the arterial O_2 tension, but also upon other factors which are responsible for delivery of O_2 to tissues. These include haemoglobin, cardiac output, its distribution in different tissue and some transfer factors. The hyperbaric O_2 may also cause some physiological adjustments which tend to offset the increase in tissue O_2 levels. For example, cerebral blood vessels may constrict in response to changes in CO_2 transport and thus limits the increase in cerebral tissue O_2 tension.

Today, the clinical applications of hyperbaric O_2 are only confined to some unusual

disease processes which include: carbon monoxide poisoning, gas gangrene, congenital cardiac anomalies, peripheral vascular insufficiencies and cancer therapy.

Carbonmonoxide has considerably greater affinity for Hb than O_2. So, exposure of even low concentration of carbonmonoxide (CO) to Hb rapidly leads to 'anaemic hypoxia', because this gas interfare with the ability of Hb to combine with O_2 and its transport. So, prompt institution of hyperbaric O_2 therapy has an important part to play in the management of carbon monoxide poisoning. O_2 therapy between 2 to 3 atmospheric pressure alleviates this situation in three ways: (i) it provides enough amount of physically dissolved O_2 in the plasma to keep the patient alive. (ii) It causes the shift of the O_2 dissociation curve to the right – thus enabling the remaining oxyhaemoglobin to give up more O_2 at tissue level. (iii) It accelerates the rate of dissociation of carboxyhaemoglobin twice than that achieved by conventional treatment with 5% CO_2 in 100% O_2 at normal (one) atmospheric pressure. The treatment by hyperbaric O_2 should be continued until the carboxy haemoglobin is no longer detectable in the blood by which time the consciousness will return, provided there has been no brain damage.

OXYGEN HAEMOGLOBIN DISSOCIATION CURVE

The haemoglobin is a complex molecule of haeme and globin. Again the haeme part of haemoglobin is formed by a divalent iron (Fe^{2+}, +2 charges) atom and 4 porphyrin rings. In a haemoglobin molecule there is four heme subunits. So, there is four divalent iron atom in each Hb-molecule. Only divalent Fe^{+} atom can combine with O_2 and each iron atom takes only one molecule of O_2. So, one Hb molecule can carry four O_2 molecules. The globin part of Hb consists of two α and two β subunits and these four subunits of globin are held together by weak bonds.

Each gram of Hb interacts and combines chemically with 1.39 ml of O_2. This interaction between Hb and O_2 to form oxy-Hb occurs in 4 steps. However, every step brings some conformational changes in Hb and acclerates the next step. Thus, binding of first 3 molecules of O_2 with Hb greatly accelerates the binding of last 4th molecule of O_2 and is responsible for last 75 to 100% saturation of Hb which is again responsible for the peculiar S-shaped line of oxy-Hb dissociation curve. After 90% saturation of Hb by O_2, the availiability of receptors on Hb for binding of O_2 suddenly declines. Then, O_2 combines with Hb very slowly and saturation rises gradually up to 100%. After that the oxygen saturation of Hb does not rise further as all the haemoglobin are combined with O_2 and nothing left. But, only O_2 tension of blood can be raised indefinitely without any limit as the physically dissolved amount of it in plasma which depends on atmospheric pressure and is responsible for the O_2 tension (PO_2) in blood is increased (Fig. 4.10).

The saturation of Hb by O_2 is defined as the percentage of the presence of oxy-Hb against the total amount of Hb to be oxygenated. On the otherhand, haemoglobin saturation by O_2 is the amount of O_2 expressed as percentage out of its total O_2 binding capacity. After the initial entry of O_2 in the blood stream it first partially physically dissolves in plasma and produces an O_2 tension in blood. Then, this O_2 enters in the RBC to combine with Hb producing oxyhaemoglobin. But this part of O_2 does not produce any oxygen tension in blood. Thus, Hb gradually becomes saturated by O_2 and in this phase percentage of oxy-Hb rises sharply with less increase in O_2 tension in plasma (this less increase of O_2 tension is due to the gradual mixing of O_2 in plasma from where it passes to Hb). After 100% saturation of Hb, O_2 further begins to dissolve rapidly in plasma. In that phase, the percentage of saturated oxy-Hb does not rise, but only the O_2 tension in blood increases (Fig. 4.11).

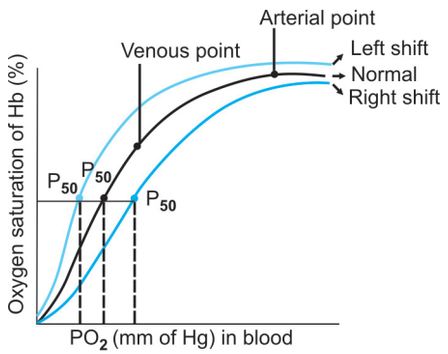

Fig. 4.10: O_2-Hb dissociation curve

Thus, the graphical representation of this whole event of relationship between the percentage of saturated oxy-Hb and the gradually developed tension of O_2 in blood forms the oxygen haemoglobin dissociation curve. Actually, the O_2-Hb dissociation curve tells us the percentage of saturation of Hb by O_2, the tension of O_2 in blood, the total content of O_2 in blood and the availability of O_2 to the tissues. The O_2-Hb dissociation curve is an elongated S-shaped line and has mainly two parts: the upper flat or near horizontal slope and the lower straight or near vertical slope. The vertical downward slope starts when the O_2 saturation of Hb or SPO_2 level comes down to 90% from 100% which corresponds to arterial O_2 tension of 60 mm of Hg. After that any slight fall of P_aO_2 causes steep fall of O_2 saturation of Hb. This is due to the large amount of O_2 uncombined from Hb for delivery to

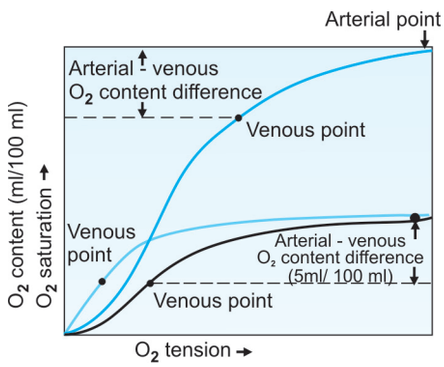

Fig. 4.11: Oxy-Hb dissociation curve of normal Hb in normal patient (red line), in anaemic patient (black line) and carbon monoxide poisoning (carboxy-Hb) (green line). The patient who has half his Hb with carbon monoixide poisoning is in much worse state than the anaemic patient who has just half Hb than normal individual

tissues which increases greatly for a given slight decrease in arterial PO_2.

There are many factors which can influence the O_2 -Hb dissociation curve. But, among them the important factors are : CO_2 tension, H^+ concentration, type of Hb, temperature and the concentration of 2,3-DPG (diphospho glycerate) level. The influences of these above factors can be expressed by P_{50}. The P_{50} is defined as the O_2 tension at which Hb is 50% saturated. Normally P_{50} value is 27 mm of Hg. It means that at 50% saturation of Hb by oxygen, the O_2 tension in blood reaches to 27 mm of Hg. Increase or decrease of P_{50} value indicats shifting of O_2-Hb dissociation curve to the right or left. The P_{50} value lower than 27 mm of Hg describes left ward shifting of the curve which means that at 50% O_2 saturation of Hb there is less tension of O_2 (< 27 mm of Hg) in blood. It also means that at this given O_2 tension Hb is more saturated than normal which also means Hb has a higher affinity for O_2, leading to less release or unloading of O_2 at the tissues, causing cellular hypoxia. The principal causes of left ward shifting of oxy-Hb dissociation curve are: alkalosis (metabolic or respiratory), hypothermia, abnormal forms of Hb (e.g foetal-Hb, methaemoglobin, carbomonoxy-Hb etc) and decrease of 2,3-DPG level.

P_{50} value higher than 27 mm of Hg describes the shifting of O_2-Hb curve to the right. It means for the same saturation of Hb, blood has higher O_2 tension (> 27 mm of Hg) or at any given PO_2, Hb is less saturated. It indicates Hb has low affinity for O_2 or more readily gives up O_2 to the tissues. The principal causes of the right wards shifting of O_2-Hb dissociation curve are : acidosis (metabolic or respiratory), hyperthermia, other haemoglobinopathies or the presence of abnormal Hb and increased 2,3-DPG level (Fig. 4.12).

Acidosis and alkalosis controls the O_2-Hb dissociation curve by controlling the CO_2 tension or H^+ concentration in blood. An increase in plasma H^+ concentration or

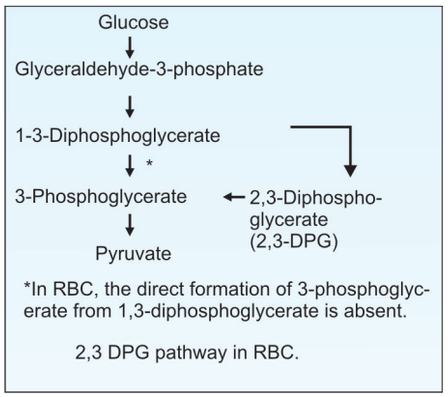

Fig. 4.12: The steps of synthesis of 2, 3-DPG in RBC

CO_2 tension decreases the affinity of O_2 to Hb and vice versa. This is called the Bohr effect. When blood flows through the tissue capillaries then the gradual increase of CO_2 tension in plasma shift the O_2-Hb dissociation curve to the right and affinity of Hb for O_2 is reduced which facilitates the release of O_2 at the tissues. Reversely, in pulmonary capillaries the lowering of CO_2 tension due to its gradual release in alveoli shifts the O_2-Hb dissociation curve to the left. Thus, the affinity of Hb for O_2 increases and facilitates the uptake of O_2 in alveoli.

Increased 2,3-DPG level in plasma shifts the O_2-Hb dissociation curve to the right and reduce the affinity of Hb for O_2 causing increased unloading of O_2 at the tissues. This plays an important compensatory role in patients with chronic hypoxia, anaemia and in blood transfusion. The 2,3-DPG is a by-product of glycolytic pathway in RBC and accumulates within it only during anaerobic metabolism. Thus, it helps in hypoxic condition by increasing the supply of O_2 to tissues through its effects on oxy-Hb dissociation curve. Under physiological condition the glycolytic pathway in RBC runs in normal pathway and less formation of 2,3-DPG through alternate pathway. So the effect of 2,3-DPG on this curve is minimum.

The use of ACD as anticoagulant during collection of blood for transfusion, there is an immediate fall of 2,3-DPG level in RBC after it is taken from the human body and dissociation curve shifts to the left. So the recently transfused blood is reluctant to give up O_2 to the tissues. Then, 2-3 days is required to recover the level of 2,3-DPG level in RBC after transfusion. Whereas the use of CPD as anticoagulant in stored blood delays the fall of 2,3-DPG level for 10 days, at which time the level is still near to normal in CPD blood (Fact file-1).

The abnormal haemoglobins which have influences on the O_2-Hb dissociation curve are methaemoglobin, suphaemoglobin, fetal haemoglobin, sickle cell haemoglobin, haemoglobin C, haemoglobin E, etc. They prevent the carrying of O_2 by Hb and have their own O_2 saturation

FACT FILE -1

2,3 DPG is very plentiful in RBC. It is formed from 3-phosphoglyceraldehyde which is a product of glycolysis via the Embden Meyerhof pathway. It is a highly charged anion that binds to the β-chain of deoxyhaemoglobin. One mole of deoxyhaemoglobin binds to one mole of 2,3 DPG.

$HbO_2 + 2,3\ DPG \longleftrightarrow Hb\text{-}2,3\ DPG + O_2$

In this equation, an increase in the concentration of 2,3 DPG shifts the reaction to the right, causing more O_2 to be liberated. Factors affecting the concentration of 2,3 DPG in RBC include pH. This is because acidosis inhibits red cell glycolysis and the formation of 2,3 DPG and vice versa. Exercise causes an increase in 2,3 DPG within 60 minutes. Therefore, much more O_2 is removed from each unit of blood flowing through active tissues which have low PO_2. Finally at low PO_2 the O_2-Hb dissociation curve is steep, and large amount of O_2 is liberated per unit drop of PO_2. Ascent to high altitude also causes a rise in 2,3 DPG level, with consequent increase in P_{50} and increase in availability of O_2 to tissues.

The affinity of foetal - Hb (Hb-F) for O_2 increase is greater than adult Hb. This facilitates the movement of O_2 from the mother to the foetus. This is due to the poor binding of 2-3 DPG by the g-polypeptide chain which is the characteristic of Hb-F. Some abnormal Hb in adults have low P_{50} values and the resulting high O_2 affinity of these Hb causes enough tissue hypoxia to stimulate increased RBC formation, with resulting polycythemia. It is because these Hb do not bind to 2,3 DPG.

The 2,3 DPG concentration in RBC is increased in anaemia and in variety of diseases where there is chronic hypoxia. This facilitates the delivery of O_2 to the tissues by raising the PO_2 at which O_2 is released in peripheral capillaries.

characteristics. The foetal - Hb has greater affinity for O_2 than the adult Hb and shifts the dissociation curve towards the left. Some chemicals like carbon monoxide, cyanide, nitric acid, etc, also combine with Hb at it O_2 binding site and prevent the O_2 to combine with Hb. Thus, they all shift the O_2 saturation curve to the left. Carbon monoxide has 200 to 300 times more affinity for Hb than O_2 and combine with it forming carboxyhaemoglobin. Thus, it decreases the O_2 carrying capacity of Hb by shifting the saturation curve to the left and impairs the release of O_2 to the tissues.

The O_2 dissociation curve is also shifted towards the right during the rise of temperature like the fall of plasma pH, showing decreased afinity of Hb for O_2 and increased unloading of it at the tissue level. Reverse effect is seen when the temperature is decreased.

Myoglobin is another iron containing pigment which resembles haemoglobin. It is present in the muscle and its affinity for O_2 is much higher than Hb. So, the O_2-Hb dissociation curve of myoglobin shifts to the left and looks like rectangular hyperbola. O_2 from myoglobin is released only when it is exposed to very low PO_2.

Coefficient of O_2 Utilisation

It indicates what percentage of arterial O_2 is used up from its total contents by a tissue. It is expressed by the following formula :

$$\text{Coefficient of } O_2 \text{ utilisation} = \frac{O_2 \text{ taken up by the tissue}}{O_2 \text{ content of arterial blood}} \times 100$$

Normally, the arterial blood contains 19 ml and venous blood contains 14 ml of O_2 per 100 ml of blood. So, usually the arteriovenous difference of O_2 content is about 5 ml. Thus the coefficient of O_2 utilisation is 5 × 100/19 or 26%. The arteriovenous O_2 difference or the utilisation coefficient of O_2 is directly proportional to the rate of tissue activity. In heavy exercise, this coefficient may increase upto 80%. Normally, in heart tissue the arteriovenous O_2 difference or O_2 taken up by myocardium is 12 ml. So, the O_2 utilisation coefficient of heart is 12 × 100/19 or 63%. During exercise it further rises. Hence, the O_2 utilisation coefficient is a true index of degree of tissue activity.

Effect of O_2-Hb saturation curve on CO_2 content and its transport

The deoxygentaed Hb has 3·5 times greater affinity for CO_2 than the O_2-Hb. So, when the blood passes through tissue capillaries, and Hb gives up O_2 becoming deoxygenated, then it helps it to carry more CO_2. As a result, venous blood contains more CO_2 than the arterial blood. Similarly, O_2-Hb has 3.5 times less affinity for CO_2 which helps it to give up CO_2 at pulmonary level. As a result, the arterial blood has less CO_2 than the venous blood. Hence, the combination of CO_2 with Hb depends on the O_2 status of it and vice versa. It is called the Haldane effect. Thus, the deoxygenation at tissue level and oxygenation at pulmonary level helps the Hb to combine with CO_2, transport of it and release of CO_2 at lung. This is indicated by that the O_2-Hb dissociation curve shifts to the right at tissue level and shifts to the left at pulmonary level.

The Haldane effect can be explained by the following way. It also explains the acid-base behaviour of Hb. At physiological pH, Hb acts as buffer due to its high content of histidine. Moreover, at tissue capillary level the removal of O_2 from Hb causes it to behave more like a base, $HbO_2 \longleftrightarrow Hb + O_2$. So, it takes up hydrogen ion which is formed from carbonic acid : $CO_2 + H_2O = H_2CO_3$. $H_2CO_3 = H^+ + HCO_3^-$, $Hb + H^+ = HbH^+$. Thus, by taking up H^+ the Hb shifts the CO_2 and bicarbonate equilibrium in favour of more bicarbonate formation.

$HbO_2 + CO_2 + H_2O \longleftrightarrow HbH^+ + HCO_3^- + O_2$.

This indicates that the deoxygenation of Hb increases the content and transport of CO_2 in venous blood as bicarbonate. Hence, the CO_2 content in venous blood increases which is reflected as an increase in bicarbonate. In the lungs the reverse occurs. Here, the combination of O_2 with Hb causes it to behave more like an acid and gives up hydrogen ion and shifts the CO_2-bicarbonate equilibrium in favour of more formation of CO_2 which is excreted through lungs.

$HbH^+ + O_2 = HbO_2 + H^+$

$H^+ + HCO_3^- = H_2CO_3$

$H_2CO_3 = CO_2 + H_2O$

$HbO_2 + CO_2 + H_2O \longleftrightarrow HbH^+ + HCO_3^- + O_2$

Hence, the total CO_2 content in blood decreases which is reflected by decrease in HCO_3^- level.

CO_2 DISSOCIATION CURVE

Under different physiological and pathological conditions the CO_2 content and its tension in blood varies. When these variations and the relationship between them is plotted in a graph, then it is called the CO_2 dissociation curve (Fig. 4.13).

Usually, the facts which can be expressed from this CO_2-dissociation curve are:

i. At any given CO_2 tension, reduced Hb takes up larger amount of CO_2 than oxygenated Hb. So, in the body the reduction of Hb in the tissue capillaries increases the degree of CO_2 uptake from the tissues.
ii. Oxygenation of Hb causes evolution of CO_2. This happens in lungs.
iii. As the CO_2 tension is increased, the total amount of CO_2 taken up by blood also rises. As the CO_2 tension falls, CO_2 content also diminishes.

The factors which influences the O_2 dissociation curve also influence the CO_2 dissociation curve, but in opposite direction. That is the factors which decrease the affinity of Hb for O_2 and shift the O_2 dissociation curve to the right also shift the CO_2 dissociation curve to the left and increases the affinity of Hb for CO_2.

CO_2 STORES

In the body always there is production, store and elimination of CO_2 which establishes

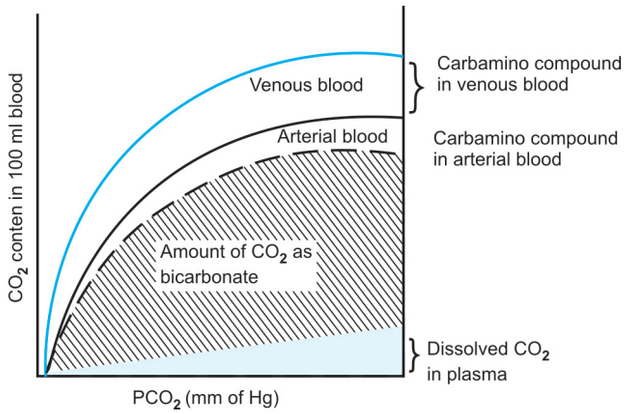

Fig. 4.13: CO_2 dissociation curve of arterial and venous blood

an equilibrium. Usually CO_2 is stored in the body in the form of dissolved CO_2 in plasma, bicarbonate and CO_2-Hb. The amount of total stored CO_2 in an adult is about 120 litres. It is stored in the body in three compartment: rapid, intermediate and slow. Rapid compartment is consist of highly vascular structures such as brain, heart, liver, kidney, etc. Intermediate compartment is mainly consist of muscle tisues and slow compartment is consist of fat and bones. When there is imbalance between the production and elimination of CO_2, then there is also change in the total amount of CO_2 stored in the body and a new equilibrium is established. This usually takes long time, near about 20 to 30 minutes (compared with O_2 which takes less than 3 to 5 minutes) and it is due to the large capacity of intermediate and slow compartment. During equilibrium, the rate of rise of CO_2 tension in arterial blood is generally slow than its fall following acute change in ventilation.

HYPERCAPNIA AND HYPOCAPNIA

Definition

Hypercapnia refers to the accumulation of CO_2 in blood. This is indicated by an arterial CO_2 tension greater than 6 kPa or end - tidal CO_2 tension greater than 60 mm of Hg. On the otherhand, hypocapnia refers to the deficit of CO_2 in blood and is indicated by an arterial CO_2 tension less than 4 kPa or end - tidal CO_2 tension less than 40 mm of Hg.

Causes of Hypercapnia

Common causes of hypercapnia during anaesthesia are inadequate CO_2 removal or excessive CO_2 production. Inadequate CO_2 removal is most commonly caused by hypoventilation or increased alveolar dead space. But it may also result from inadequate fresh gas flow or exhausted sodalime.

Hypoventilation

It is due to abnormal position of patient during surgery, increased airway resistance, decreased compliance of thorax and lungs, decreased respiratory drive due to anaesthetic agents and sedatives, and mechanical hypoventilation during IPPV. The equipmental or technical causes of hypo ventilation are obstruction, kinking, leak or disconnection, etc, at any part of the breathing circuit.

Increased Dead Space Ventilation

i. It occurs when the pulmonary artery pressure drops due to hypotension. It increases the area of pulmonary zone I. Thus, subsequently it increases the ventilation - perfusion mismatch and alveolar dead space ventilation.
ii. It also occurs when the airway pressure increases which subsequently increases the area of pulmonary zone I. Thus, subsequently it increases the ventilation - perfusion mismatch and alveolar dead space ventilation.
iii. Pulmonary embolism, thrombosis, vascular obliteration, etc, also increases the amount of lung that is ventilated, but under perfused. This also increases the dead-space ventilation by increasing the ventilation - perfusion mismatch.
iv. Rapid short inspiration may be distributed preferentially to the more compliant alveoli, causing the less compliant alveoli under ventilated. This is due to the short time constant of the less compliant alveoli. This also increases the dead space ventilation.
v. Anaesthesia apparatus also increases the total dead space by increasing the length of airway and by increasing the rebreathing of expired gas which is equivalent to dead space ventilation. The during order of increasing the rebreathing with spontaneous ventilation with Mapleson circuit is A, D, C, B and during controlled ventilation is D, B, C, A. There will be no rebreathing in circuit E (Ayre T-piece) if the patient's duration of expiration is long enough permitting the complete washout of the expired gases for a given fresh gas flow, however only if the fresh gas flow is greater than the peak inspiratory flow rate.

The effect of increased dead space can be countered by increasing the respiratory rate. Example, let minute volume of a patient is 10 L/min and V_D / V_T is 30%. Then alveolar ventilation is 7 lit/min. If due to any reason V_D / V_T is increased to 50%, then minute ventilation should be increased to 14 lit/min to maintain the alveolar ventilation at 7 lit/min.

Increased CO_2 Production

Fever, malignant hyperthermia, sepsis, shivering, hypertension, thyroid storm, increase release of catecholamines, etc, are the few of many causes of increased CO_2 production during anaesthesia. In febrile patient there is 13% increase in CO_2 production for each 1°C rise in temperature. Inadvertent or excessive CO_2 delivery from the anaesthetic machine due to exhausted sodalime and the excessive apsorption of CO_2 during laparoscopic procedure are also

other causes of hypercapnia. They indirectly increase the CO_2 production.

Causes of Hypocapnia

Causes of hypocapnia are opposite to hypercapnia. These are hyperventilation, decreased dead space ventilation (change from mask to ETT, decreased PEEP, increased pulmonary artery pressure, decreased rebreathing), decreased CO_2 production (hypothermia, deep anaesthesia) etc. Among these the mechanical passive hyperventilation is the commonest cause of hypocapnia.

Effect of Hypercapnia

In awake normal patient the progressive hypercapnia stimulates the sympathetic nervous system. It results in ↑BP, tachycardia, sweating, arrhythmias and increased cerebral blood flow. This increased cerebral blood flow is dangerous for patients with ↑ICP such as brain tumour. As anaesthesia suppresses the autonomic responses, so these signs may not occur and are masked until CO_2 tension is markedly increased. Mechanism of effect of hypercapnia on CVS is same as hypoxia. So, like hypoxia it acts both through direct effect on the myocardium which is depression and through indirect reflex (through sympathetic neural and humoral) mechanism which is stimulation. But the direct depression effect of myocardium by CO_2 is overshadowed by the indirect activation of myocardium by sympathetic nervous system. Hypercapnia, like hypoxaemia, also increase the myocardial O_2 demand (due to tachycardia, early hypertension) and decrease the myocardial O_2 supply (due to late hypotension). With moderate to severe hypercapnia hyperkinetic circulation also results. This is due to increased cardiac output and decreased SVR.

Arrhythmias due to acute hypercapnia in unanaesthetised patient have seldom been of serious problem. But, high P_aCO_2 level is more dangerous in anaesthetised patient. With halothane anaesthesia, arrhythmias will frequently occur, if P_aCO_2 goes above the arrhythmic threshold level which is often constant for a particular patient.

CO_2 is a powerful respiratory stimulant and for each mm of Hg rise of P_aCO_2 normal awake subjects increase their minute ventilation by about 2 to 3 L/minute. Maximal stimulatory respiratory effect is attained by P_aCO_2 up to about 100 mm of Hg. With higher P_aCO_2 than this, stimulation is reduced and at very high level, respiration is depressed. Later it ceases altogether. Patient with ventilatory failure, CO_2 narcosis occure when P_aCO_2 rises between 90 to 120 mm of Hg. This unconsciousness is due to the fall in CSF pH at high P_aCO_2 level. Chronic hypercapnia or respiratory acidosis results in compensatory increased resorption of bicarbonate by kidney, constituting secondary metabolic alkalosis. On the otherhand, the chronic hypocapnia causes the reverse. In each case blood pH returns to normal value, but bicarbonate concentration departs further from normal and may exceed 40 mEq/L. Hypercapnia cause leakage of Ca^{2+} and K^+ from the cells in plasma. So, it is also associated with hypercalcaemia and hyperkalaemia.

Effect of Hypocapnia

Unintentional hyperventilation in association with decreased arterial CO_2 tension is the usual cause of hypocapnia during anaesthesia. Hypocapnia produces respiratory alkalosis with decrease in serum potassium concentration. There are reductions in cerebral blood flow, cardiac output and tissue O_2 delivery. There may also be delay in onset of spontaneous ventilation at the end of anaesthesia.

Hypocapnia causes decrease in CO_2 by three mechanisms

First: Increase in intrathoracic pressure by increasing ventilation causes hypocapnia and decreased CO_2.

Second: Hypocapnia withdraws the sympathetic nervous system activity and thus decrease the ionotropic state of heart.

Third: Hypocapnia can increase pH and thus decrease the ionized Ca^{2+} and inturn the ionotropic state of heart. Hypocapnia with respiratory alkalosis shift the oxy-Hb dissociation curve to the left which increases Hb affinity for O_2 and thus impairing O_2 unloading at tissue level. Hypocapnia also increases the whole body O_2 consumption by increasing the pH mediated uncoupling of oxidation from phosphorylation. P_aCO_2 of 20 mm of Hg will increase tissue O_2 consumption by 30%. Hypocapnia cause V_A/Q abnormalities by inhibiting the compensatory HPV (hypoxic pulmonary vasoconstriction).

TRANSPORT OF CO_2

CO_2 is produced in the tissues by metabolism. Then, it enters the blood stream at tissue capillary level and is carried to the lungs where it is liberated in the alveolar air. 100 ml of venous blood carries about 52 ml of CO_2, whereas 100 ml of arterial blood carries about 48 ml of CO_2. Therefore, the average normal arteriovenous difference of CO_2 content is about 4 ml per 100 ml of blood. In other wards, each 100 ml of arterial blood, while passing through the tissues collects about 4 ml of CO_2. Similarly, each 100 ml of venous blood, while passing through lungs also releases 4 ml of CO_2. So, the blood always carries a constant amount of CO_2 which is about 48 ml per 100 ml. This constitutes the alkali reserve (as bicarbonates).

Although much CO_2 is carried in the blood, yet blood reaction does not become acid. This proves that during CO_2 transport some buffers system in blood play a very important role to maintain the acid-base balance. CO_2 is carried in the blood in following forms (Fig. 4.14).

(i) As Physical Solution

Under normal conditions of temperature and pressure only about 2.7 ml of CO_2 is carried as physical solution in plasma (i.e. as H_2CO_3) per 100 ml of venous blood. Since, this represents a very small portion of total CO_2 carried in blood, so it is evident

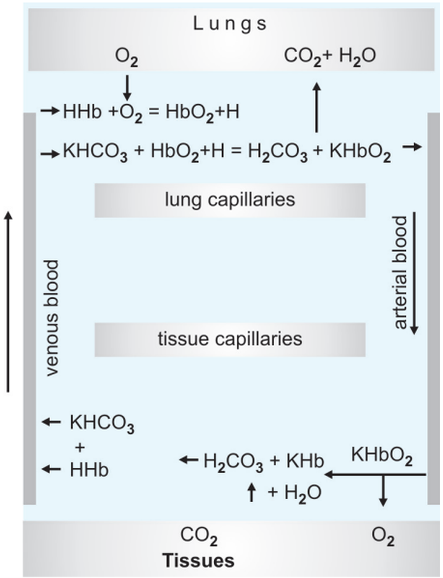

Fig. 4.14: Mechanism of entry and exit of O_2 and CO_2 at lung and tissue level

that the major portion of CO_2 is transported in some another form of chemical compounds other than the physical solution.

(ii) As Chemical Compounds

Two types of chemical compounds are formed by CO_2 in blood. These are :

1. Bicarbonates:
   a. $NaHCO_3$ in plasma: arterial blood - 33.1%,
   venous blood - 35·2%
   b. $KHCO_3$ in red cells: arterial blood - 9·8%, venous blood - 10·5%
2. Carbamino compounds:
   a. Carbamino – haemoglobin in red cells (arterial blood- 2%, venous blood - 2·6%)
   b. Carbamino – proteins (with plasma proteins) in the plasma (arterial blood- 1%, venous blood - 1·1%).

Carriage of CO_2 as Bicarbonate

A. In corpuscles

Haemoglobin remains combined with K and forms potassium bicarbonates with CO_2 in the following way:

$CO_2 + H_2O \longleftrightarrow H_2CO_3$

$KHb + H_2CO_3 = HHb + KHCO_3$

This reaction takes place at the tissue level. At the pulmonary level, the reverse reaction takes place and CO_2 is evolved out. Carbonic anhydrase which is present in the RBC helps this process as catalyst.

Carbonic anhydrase: The rate of formation and breakdown of bicarbonates depend upon the rate of this primary reversible reaction: $CO_2 + H_2O \longleftrightarrow H_2CO_3$. This reaction is catalyst by carbonic anhydrase. In absence of carbonic anhydrate when water is exposed to CO_2, a period of about 15 to 30 minutes is required for a this reaction to take place. Similarly about the same time is required for the complete dissociation of CO_2 from its water solution. But in our body, blood in the tissue capillaries becomes saturated with CO_2 in about 1 to 2 seconds only and the same time is required for the evolution of CO_2 from blood in the lungs. This is due to the existance of enzyme, called carbonic anhydrase. It is protein in nature containing Zn and its action is inhibited by cyanide and acetazolamide. In the blood, it is almost exclusively present in the red cells. So, this reaction mainly takes place in RBC. All other tissues contain it in traces. But kidney, pancreas and stomach contain considerable amounts.

B. In plasma

1. By the phosphate buffer:
   Alkaline phosphates combine with carbonic acid and form sodium bicarbonate.
   $Na_2HPO_4 + H_2CO_3 \longleftrightarrow NaH_2PO_4 + NaHCO_3$
2. By plasma proteins :
   The plasma proteins, mostly remain combined with sodium (to be represented as NaPr) and form bicarbonates in the following way.
   $NaPr + H_2CO_3 \longleftrightarrow HPr + NaHCO_3$
3. Chloride shift or Humburger Phenomenon:
   When the whole blood is saturated with CO_2, the following changes are seen:
   – The bicarbonate contents of plasma and corpuscles increase.
   – The chloride content of plasma is diminshed and that of the red cell is increased.
   – The total base (cations) of both plasma and corpuscles remain unchanged.
   – The water content and the volume of corpuscles increase (Table 4.12).

When CO_2 is removed from blood at the alveoli, reverse changes take place. From these observations it is evident that when CO_2 enters the blood, then chlorine of NaCl from plasma enters the red cells, while the base (Na^+) is left behind in plasma. When CO_2 escapes from blood, chlorine again leaves the cells, enters the plasma and combines with the base (Na^+). Due to this alternate movement of chloride ion, this phenomenon is called chloride shift or Humburger phenomenon. This can be explained by the following way.

The membrane of red cells is not permeable to basic ions (K^+, Na^+ etc), but is permeable to anions (HCO_3^-, Cl^- etc). When CO_2 enters the blood stream from the tissues, then H_2CO_3 is formed. But it is very little in amount in plasma and largely in the corpuscles, because red cells are rich in carbonic anhydrase and permeable to CO_2. The red cells contain 4 to 5 times more carbonic anhydrase than the plasma. In the RBC H_2CO_3 reacts with KHb producing $KHCO_3$ and HHB. Thus, the bicarbonate content of red cells increases and, thereby, the reaction of the cells tends to become alkaline.

So, to maintain a constant pH, either the alkali ion (K^+) is to get out of the cell or an acid ion from the plasma should enter the cell. Since, the red cell membrane is not

Table 4.12: CO_2 content in arterial and venous blood

	Venous blood (ml/100 ml)	*Arterial blood (ml/100 ml)*
Dissolved CO_2	2.7	2.4
As bicarbonate	45.7	42.9
As carbamino compound	3.7	3
Total CO_2 content	**52.1**	**48.3**

permeable to alkali ion, K^+ can not come out. So consequently, the acid ion Cl^- of NaCl from plasma, enters the red cells and combines with $KHCO_3$ forming KCl and HCO_3^- ion. The free HCO_3^- ion now tends to make the cell reaction alkali. This is prevented by the migration of HCO_3^- from the cell into the plasma. In plasma it combines with free Na^+ of NaCl which was left free by the shift of chlorine ion and forms $NaHCO_3$. All these changes takes place in the tissue capillaries. Owing to this reaction, a large amount of free Na^+ of NaCl in plasma should be made available for carriage of CO_2.

In the lungs, these changes are reversed. Chlorine comes out of the cells, reacts with $NaHCO_3$ of plasma forming NaCl and carbonic acid. Carbonic acid, thus formed is broken down into CO_2 and passes out through the lungs. In the tissue capillaries, chlorine shifts from the plasma into the cells. Thereby, the osmotic pressure of the cell will rise, water will be drawn in and the cell volume will increase. In the pulmonary capillaries, it shifts from the red cells back into the plasma. This will reudce the osmotic pressure of the red cell and the cell volume will shrink.

Carriage of CO_2 as Carbamino Compounds

CO_2 is also carried as carbamino compounds in blood. In this process, the NH_2 radicle of the globin part of haemoglobin and that of the other plasma proteins combines with one molecule of CO_2 (as free gas but not as H_2CO_3). It does not require the help of carbonic anhydrase. This reaction may be presented as: CO_2 + Pr. $NH_2 \longleftrightarrow$ Pr. NH. COOH. About 3.7 ml of CO_2 is carried in this form per 100 ml of venous blood, viz, 2.6 ml in red cells and 1.1 ml in plasma.

SUMMARY

Thus, it will be seen that CO_2 is carried in blood in three forms. 100 ml of venous blood carries about 52 ml of CO_2 as follows:

i. In physical solution (2.7 ml).
ii. As bicarbonates (45.7 ml). Bicarbonates are formed in four ways; (a) with NaPr, (b) with Na_2HPO_4, (c) with Na of NaCl helped by 'chloride shift', (d) with KHb. These are the chief forms in which CO_2 is carried in blood. It can explain about 90% of the total CO_2 transport of which the major part is carried in plasma as $NaHCO_3$. A large part of this bicarbonate remains permanently in the plasma and constitutes the so called alkali reserve of blood.
iii. As carbamino compounds (3.7). These are chiefly formed in the red cells (2.6) and only in traces in the plasma (1.1). It constitutes about 5-10% of the total CO_2 carriage and is responsible for a large part of the normal arteriovenous difference.

Interrelation between the carriage of oxygen and carriage of carbon dioxide

It has been found that reduced blood can take up more CO_2 than oxygenated blood. Also blood containing less CO_2 (Fig. 4.15) will take up relatively more O_2. In other words, these two gases tend to displace each other. This is explained by the fact that oxyhaemoglobin acts as a stronger acid (than H_2CO_3) and unites with more base. Reduced haemoglobin, on the other hand is a weaker acid (than carbonic acid) and can unite with less base. Hence, oxygenation of Hb in the lungs makes it a stronger acid and unites with more base. The latter being taken from the bicarbonates and (thus carbonic acid is formed from where CO_2 is liberated through lungs). On the otherhand, reduced haemoglobin as in the tissues being weaker acid can not hold its base and taken away by $-HCO_3$ to form bicarbonate. This $-HCO_3$ comes from carbonic acid which is formed in the red blood cells. In the RBC carbonic acid is formed from CO_2 which comes from tissues with the help of carbonic anhydrase.

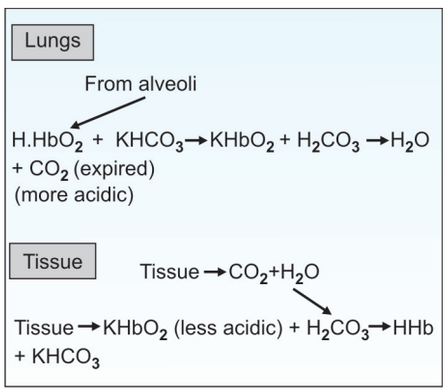

Fig. 4.15: The basic mechanism of transport of O_2 and CO_2 from lungs to tissues and tissues to lungs respectively

Factors that Determine Intake of CO_2 from the Tissues

The following factors are responsible for entry of CO_2 from the tissues into the blood stream.

1. Pressure gradient

In the tissue capillaries the CO_2 tension in arterial blood is 40 mm of Hg. The CO_2 tension in the resting tissues is about 46 mm of Hg. In the active tissues, it may be much higher (about 63 mm of Hg). Due to difference of partial pressure, CO_2 diffuses out of the tissues and enters the capillaries.

2. Reduction of Haemoglobin

Oxyhaemoglobin is reduced in the tissues, so that the base freed from the reduced haemoglobin is made available for fixing H_2CO_3. Thus more and more amount of H_2CO_3 is formed from CO_2 which diffuses from the tissues in the blood.

3. With the help of Humburger phenomenon

This is described before.

4. Carbamino compounds are formed

This is helped by increased CO_2 tension, as well as reduction of oxyhaemoglobin in the tissue capillaries.

Factors Concerned in the Liberation of CO_2 in Lungs

Since CO_2 is liberated in the lungs, it is obvious that in the pulmonary bed the factors responsible for releasing the CO_2 must be the reverse of those that are operating in the tissues.

5 Cardiovascular System (Anatomy and Physiology)

BRIEF ANATOMY OF HEART

The Greek name of heart is 'Card', from where we get the word 'cardiac' and the Latin name of heart is 'Cor', from where we get the word 'Coronary'. Heart is a hollow muscular and somewhat conical structure. It is situated in the middle of the mediastinum and covered by pericardium. It is about the size of a clenched fist of a normal adult individual. In a healthy adult individual the heart measures about 12 cm in longitudinal diameter extending from apex to base, 6 cm in antero-posterior diameter and 9 cm in widest transverse diameter. The transverse diameter of a heart should not be more than one-half of the transverse diameter of the thorax. The weight of a heart varies from 250 gm in a healthy adult female to 300 gm in a healthy adult male.

The human heart is considered as two parallel pumps and is composed of 4 chambers − right atrium, right ventricles, left atrium and left ventricles. The atria lie above and behind the ventricles. The two atria are separated from each other by inter atrial septum. Similarly, the two ventricles are separated from each other by interventricular septum. The atrium and ventricles are separated externally by coronary sulcus or atrio ventricular groove. On the otherhand, the two ventricles are also separated on the external surface by two grooves which are called as the anterior and posterior interventricular groove. The anterior interventricular groove is situated on the sternocostal surface and the posterior interventricular group is situated on the diaphragmatic or inferior surface of the heart. They meet at the apex.

The heart presents: apex, base, three surfaces and three borders. The three surfaces are: sternocostal, diaphragmatic and left surfaces. The three borders are: right, inferior and left borders.

Apex

It is a conical area of the heart and is formed only by the left ventricle. It is directed downwards, forward and to the left towards the 5th intercostal space, which is situated about 9 cm laterally from the midline and slightly below and medial to the left nipple (male). The apex is separated from the anterior thoracic wall by the anterior part of left lung and pleura. The apex beat is a forward thrust which is felt at the left 5th intercostal space, just medial to the midclavicular line or 9 cm lateral from the midsternal line, during the ventricular systole. It is due to the twisting of the heart by vortex like disposition of the ventricular muscles close to the apex. In the new born, the apex beat is usually felt at the left fourth intercostal space, just lateral to the midclavicular line. But, after about 2 years it reaches the adult position.

Base

The base or posterior surface of the heart is somewhat quadrilateral in outline and is the most fixed part of the heart. It is directed backwards and to the right. It is formed by two atria, of which 2/3 is formed by the left atrium and 1/3 is formed by the right atrium. At the base, the superior vena cava (SVC) and inferior vena cava (IVC) open in the right atrium and the four pulmonary veins, two from each lung, open in the left atrium. Between the base of the heart and the vertebral column there lies: the right and left bronchi, oesophagus and descending thoracic aorta. The distended left atrium in mitral stenosis may produce difficulty in swallowing due to the oesophageal compression. This is called the Ortner's syndrome (Fig. 5.1).

Right Border

It is rounded and convex in shape and is formed only by the right atrium. It extends from the right side of the opening of superior vena cava to that of the inferior vena cava. The right border of the heart separates the base from the sternocostal surface of it. A shallow vertical groove known as the sulcus terminals accompanies the right border of the heart. It corresponds with an internal ridge named crista terminalis in the interior of the right atrium.

Inferior Border

It is a sharp border and separates the sternocostal surface of the heart from the diaphragmatic surface of it. It extends from the opening of IVC to the apex of the heart. This border is accompanied by the right marginal branch of right coronary artery and its corresponding vein. Close to the apex, it presents a notch known as the incisura apicis cordis which gives passage to the anterior interventricular branch of the left coronary artery.

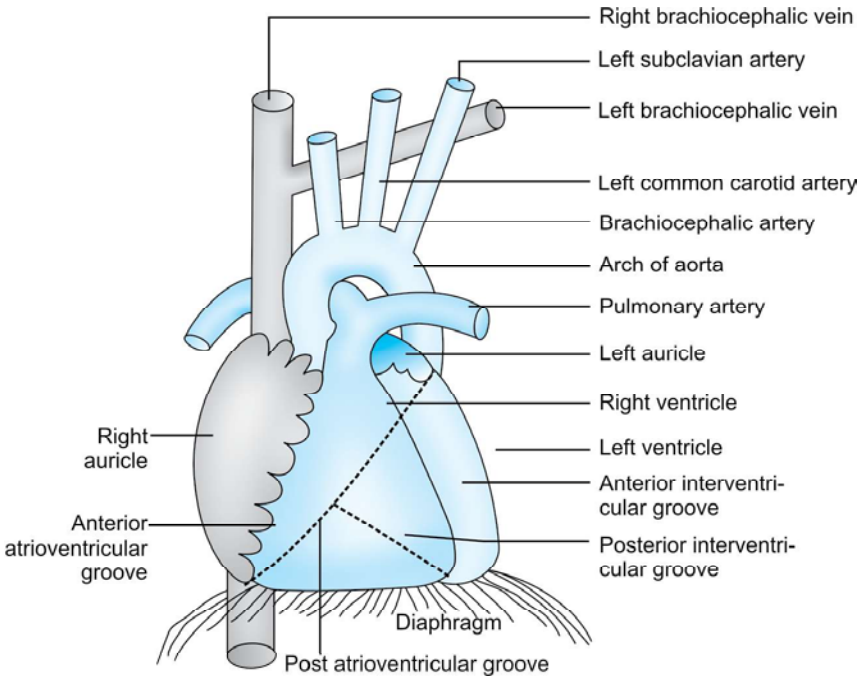

Fig. 5.1: The anterior surface of the heart

Left Border

It is an ill defined, convex border which separates the sternocostal surface of the heart from the left one. It extends from the left auricle to the apex of the heart with convexity directed upwards and to the left. This border is accompanied by the left marginal branch of left coronary artery and its corresponding vein.

Sternocostal surface

It is directed forwards, upwards and laterally towards left. It is separated from the base of the heart by the right border, from the diaphragmatic surface of the heart by the inferior border and from the left surface of the heart by the left border. It lies against the posterior surface of the body of the sternum and 3rd to 6th costal cartilages of both sides. This sternocostal surface is formed by the following parts of the heart such as:

i. The anterior surface of the right atrium and its auricle,
ii. The anterior surface of the right ventricle (2/3),
iii. A part of the anterior surface of the left auricle,
iv. The anterior surface of the left ventricle (1/3).

This sternocostal surface presents:

i. The anterior part of the atrio ventricular groove which passes downwards and to the right between the right atrium and the right ventricle. The groove holds the trunk of right coronary artery and the anterior cardiac vein.
ii. The anterior interventricular groove which passes downwards and parallel to the left border of the heart. It meets the inferior border at the apex. The groove holds the anterior interventricular branch of the left coronary artery and great cardiac vein.

Diaphragmatic or Inferior Surface

It is a flat surface and rests on the central tendon and the left part of the musculature of diaphragm. It is formed by two ventricles, of which 2/3 is formed by the left and 1/3 is formed by the right. It is separated from sternocostal surface by inferior border, from the base by the posterior part of the atrioventricular groove and from the left surface by a less defined unnamed border which is the backward continuation of the inferior border of heart. The posterior interventricular groove runs forwards along this surface and meets with the antrior interventricular groove at the apex. This posterior interventricular groove lodges the posterior interventricular branch of the right coronary artery and the middle cardiac vein (Fig. 5.2).

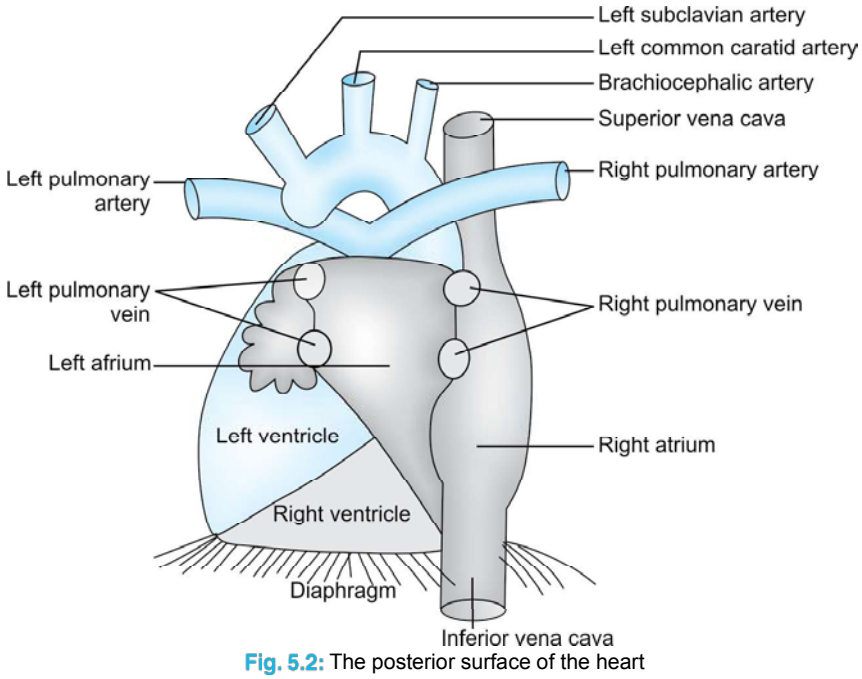

Fig. 5.2: The posterior surface of the heart

Left Surface

It is directed backwards, upwards and to the left. It is formed mainly by the left ventricle and partly by the left atrium and its auricle. This lateral surface of the heart lies against the cardiac impression of the left lung. The left part of the atrioventricular groove lies in this surface and lodges the following structures:

i. Trunk and the circumflex branch of left coronary artery,
ii. Termination of the great cardiac vein,
iii. Commencement of the coronary sinus.

Atrioventricular Groove

It is a C shaped curve and is deficient in front due to the presence of the root of pulmonary trunk and aorta. It is divided into anterior and posterior part. The anterior part is again subdivided into right and left halves. The right part of the anterior atrioventricular groove runs downwards and to the right between the right atrium and the right ventricle. It contains the trunk of right coronary artery. The left part of the anterior atrioventricular groove intervenes between the left auricle and the left ventricle. It lodges the trunk and the circumflex branch of the left coronary artery, the termination of the great cardiac vein and the commencement of the coronary sinus.

The posterior part of the atrioventricular groove intervenes between the base and the diaphragmatic surface of the heart. It contains coronary sinus and the anastonomoses between the right and left coronary arteries. The meeting point of the posterior interatrial groove, posterior interventricular groove and posterior part of the right and left atrioventricular groove from opposite direction is known as the 'crux' of the heart.

Some points to remember

1. The apex of heart is formed only by the left ventricle,
2. The base of heart is formed only by the two atria,
3. The right border of heart is formed only by the right atrium,
4. The diaphragmatic surface of heart is formed by the two ventricles.

1/3 and 2/3 features of heart

i. Base − 1/3 of the base is formed by the right atrium and 2/3 by the left atrium,
ii. Diaphragmatic surface − 1/3 of the diaphragmatic surface is formed by the right ventricle and 2/3 by the left ventricle,
iii. Sternocostal surface − 1/3 of the sternocostal surface is formed by the left ventricle and 2/3 by the right ventricle,
iv. Entire heart − 1/3 of the entire heart is right to the midline and 2/3 is left to the midline.

Right Atrium

The atria are thin walled, low pressure chambers and served as conduits of ventricle. The right atrium receives venous blood from the whole body through the SVC and IVC and pumps it out through the right atrioventricular or tricuspid opening into the right ventricle. Right atrium forms the right border, base and part of the anterior surface (or sternocostal surface) of the heart. On the outer surface along the right border of the right atrium there is a shallow vertical groove which passes from the SVC to the IVC. This groove is called the sulcus terminalis and it corresponds to an internal muscular ridge called the cristaterminalis. Cristaterminalis divides the interior of the right atrium into two parts. The posterior part is smooth and is called the sinus venaram. Whereas the anterior part is rough and is called the atrium proper which also includes the right auricle. The right auricle is a conical muscular projection which arises from the antero superior part of the atrium and extends upwards and to the left towards the ascending aorta. Multiple smooth muscular ridges arise from the crista terminalis and pass forwards, towards the right atrioventricular orifice. Some of these ridges form a network in the interior of the right auricle. These muscular ridges are called the musculi pectinati. Thus, the right auricular appendage is a potential site for the formation of thrombi, which if dislodged, can result in pulmonary embolism. Opening of the coronary sinus is situated between the opening of IVC and right atrioventricular orific, in the lower part of the interatrial septum. Just above the opening of coronary sinus lies the AV node. The SA node is situated at the upper part of the sulcus terminalis. On the external surface the right atrium is separated from the right ventricle by the right atrioventricular groove which contains the right coronary artery.

The right and left atrium is separated by a septum, called the interatrial septum. It is placed obliquely, so that the right atrium lies in front and to the right side of the left atrium. The upper part of this septum is thicker than its lower part. The right side of the interatrial septum is characterised by the presence of fossa ovalis, annulus ovalis and the AV node. The fossa ovalis is an oval depression in the lower part of the septum and the floor of the fossa is formed by the septum primum. It represents the foramen ovale during intrauterine life. The annulus ovalis is a sickle shaped fold which surrounds the upper, anterior and posterior margins of the fossa ovalis. It represents the lower free margin of the septum secundum. The AV node is situated in the lower part of the interatrial septum above the opening of the coronary sinus (Fig. 5.3).

The interatrial septum is developed from the septum primum, septum intermedium and septum seccundum. The septum primum grows as a septum from the roof and the dorsal wall of the primitive single chamber of atrium. Then like a curtain it passes downwards. During that period, another septum, named septum intermedium also grows from the below and passes upward. They do not unite and keep a gap between them. Thus, a foramen known as 'ostium primum' is formed between the upper border of the septum

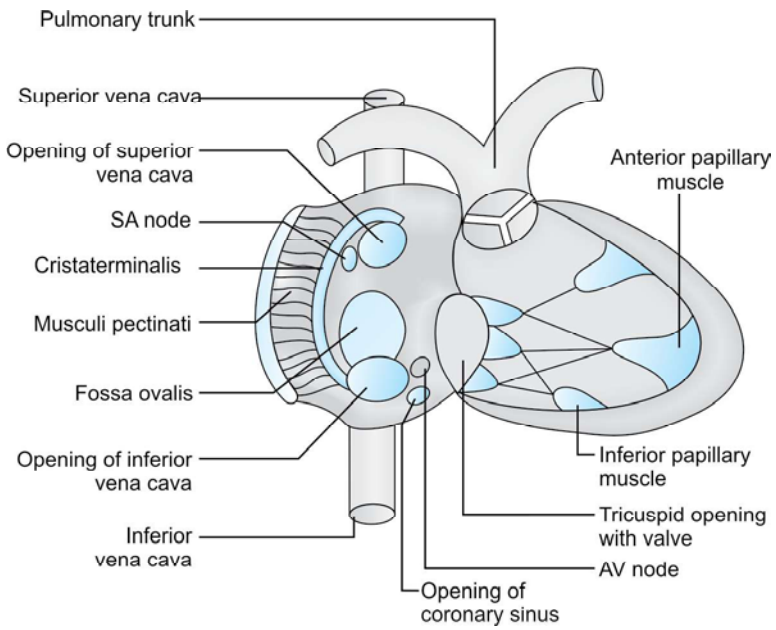

Fig. 5.3: The interior of right atrium and right ventricle

intermedium and the lower border of the septum primum. Later, ostium primum is closed by the fusion of these two septaes. Again with the closure of ostium primum, the upper part of septum primum disintegrates forming a foramen known as the 'ostium secundum'. Then another septum, called the septum secundum also grows from above and passes downwards with a sickle shaped lower free margin. The lower margin of the septum secundum grows sufficiently to overlap the ostium secondum situated on the septum primum. Thus the flap like valvular opening formed between the lower margin of the septum secundum and the upper margin of the ostium secundum of the septum primum is known as the 'foramen ovale'. The purpose of the development of septum secundum is to convert ostium secundum into a valvular foramen ovale, so as it can regulate the flow of blood from the right to the left atrium, but not in opposite direction.

After birth, the intraatrial pressure of both the sides of the atrium becomes equal and the foramen ovale is closed at first functionally and later anatomically by the fusion of the margins of septum primum and septum secundum. In about 20% of human heart, the foramen ovale is closed functionally, but anatomically it may remain patent which can be proved by passing a probe from the right to the left side of the heart.

Congenital atrial septal defect (ASD) are of the following types:

i. Probe patency of foramen ovale
   It occurs when the foramen is closed functionally, but remains patent anatomically. These subjects are considered as normal.
ii. Persistant ostium secundum:
   This is due to the incomplete development of septum secundum or extensive disintigration of the septum primum forming large ostium secundum.
iii. Persistant ostium primum:
   This may appear as single defect or associated with the patent interventricular foramen.
iv. Biventricular monoatrial heart:
   The is due to complete failure of the septation of primitive single chamber of atrium.
v. Prenatal closure of foramen ovale:
This is a rare anomaly.

The opening of IVC in the right atrium is guarded by a rudimentary valve. During intrauterine life this valve guides the inferior vena caval blood, which is oxygenated and comes from the placenta and the lower half of the body, to the left atrium through the foramen ovale. The 'intervenous tubercle of Lower' is a very small projection on the posterior wall of the atrium and situated just below the opening of SVC. During embryonic life it directs the superior vena caval blood to the right ventricle which is deoxygenated and comes from the head and neck and upper extremities.

The right atrium proper communicates with the right ventricle through the right atrioventricular orifice. This opening is oval in shape. It permits usually the tips of three fingers and is guarded by tricuspid valve. This area of right atrium proper is also known as the vestibule of the tricuspid valve. The plane of the atrioventricular orifice is almost vertical, so that blood flows almost horizontally from the right atrium to the right ventricle.

Right Ventricle

It forms the whole inferior border, larger part (2/3) of the anterior surface and a smaller part (1/3) of the inferior surface of the heart. The wall of the right ventricle is thinner than that of the left ventricle and the ratio of thickness is 1:3. But, in utero the ratio of RV : LV wall thickness is approximately 1:1. This is because the right ventricular pressure or the pressure of the right side of the heart is greater or equal to the left side of the heart. After delivery, the pulmonary vascular resistance rapidly decreases with the expantion of lungs and the SVR increases with the loss of placenta. So, the right side of the heart becomes of low pressure system than that of the left side of the heart and undergoes less muscular hyppertrophy than the left ventricle after birth. Therefore, over the 1st month of extrauterine life the RV: LV wall thickness ratio become 1:3 which is similar to that of the adult.

On cross section, the interior of the right ventricle is semilunar. Whereas, that of the left ventricle is circular. This is because the interventricular septum bulges with the convexity towards the right ventricle due to increased LV pressure than that of RV pressure. The thickness of the muscular wall of the right ventricle is 3 to 5 mm and that of the left ventricle is 8 to 12 mm.

The interior of the right ventricle consists of two parts: the inflowing rough part or inflow tract or the ventricle proper and the outflowing smooth part or outflow tract. This outflow tract is also known as the conus arteriosus or infundibulum. The inflow tract receives blood from the right atrium and the outflow tract ejects the blood from the right ventricle into the pulmonary trunk. The conus arteriosus of the right ventricle with its outflow orifice is situated in front, above and to the left side of the inflow tract. Therefore, the blood of inflow tract during ejection through the outflow tract bends roughly at an obtuse angle. The supra ventricular crest intervens between this inflow and outflow tract of the right ventricle.

The right ventricle receives blood from the right atrium through the tricuspid orifice which is guarded by tricuspid valve. Then, it ejects this blood into the pulmonary trunk or artery through the pulmonary orifice which is guarded by the pulmonary valve. The right atrioventricular or tricuspid orifice is oval in shape. It is oriented almost vertically making an angle of 40° with the sagittal plane. The orifice is directed forwards, downwards and to the left towards the apex. The tricuspid valve has three cusps − anterior, medial and pasterior and admits the tips of three fingers (8 to 11 cm^2). The chordae tendinae connect the free margins of the 3 valve cusps of the tricuspid orifice with the 3 papillary muscles and prevent the eversion of cusps to the atrium during ventricular contraction. There are three papillary muscles and each papillay muscle is connected to the contiguous halves of two cusps. Of the three papillary muscles, anterior is the largest. The tricuspid valve is closed during ventricular systole by the apposition of the atrial surfaces of the cusps near their serrated margins.

The pulmonary valve which guards the pulmonary orifice is also called the semilunar valve, because their cusps are semilunar in shape. It comprises of 3 cusps such as anterior, right and left. Normally the pulmonic valve area is 4 cm^2. Usually, the right ventricular pressure varies in the ranges between 15 to 30 mm of Hg during systole and 0 to10 mm of Hg during diastole. Whereas the pulmonary artery pressure varies in the ranges between 15 to 30 during systole and 3 to 12 mm of Hg during diastole, respectively.

Left Atrium

It forms 2/3 of the base, the greater part of the upper border, part of the anterior and lateral surfaces, and a part of the left border of the heart. The muscular wall of the left atrium is thicker than that of the right atrium and the thickness is being about 3 mm. Antero superiorly the left atrium presents a conical projection which is called the left auricle. It projects upwards and medially, towards the root of the pulmonary trunk. The most of the interior wall of the left atrium is smooth. But in certain portion a network of musculi pectinati is found within the cavity of left auricle. It receives only oxygenated blood from the lungs through 4 pulmonary veins, where orifices are not guarded by any valve and pumps it out to the left ventricle through the bicuspid or mitral orifice which is guarded by bicuspid or mitral valve. The area of mitral valve is only 6 to 8 cm^2 and admits the tip of two fingers. The mitral valve has two cusps, a larger anterior and a smaller posterior, hence it is called the bicuspid valve. The cusps of mitral valve are smaller and thicker than those of the tricuspid valve. There are two papillary muscles in the left ventricle − anterior and posterior. Chordae tendinae from both these papillary muscles are attached to both the cusps of the mitral valve. The right and left atrial pressure vary anywhere between 0 to 10 mm of Hg. The clinical importance of left auricle are:

i. It is a potential site for formation of thrombi which may dislodge at any time and can result in cerebral, renal or any systemic embolism,
ii. During mitral valvotomy operation, amputation of the left auricle may injure the circumflex branch of left coronary artery.

Left Ventricle

It forms the apex, left border, left surface and 2/3 of the inferior surface of the heart. It is conical in shape, and circular on cross section. Its musculature is three times thicker than that of the right ventricle. The muscular thickness of left ventricle is about 8 to 12 mm. The muscle of the left ventricle is thin at the apex and at the aortic vestibule the muscles of left ventricle are mostly replaced by fibrous tissue. The interior of the left ventricle is similar to that of the right ventricle. Thus, it consists of an inflow tract or ventricle proper and an outflow tract or aortic vestibule. The inflow tract of left ventricle consists of mitral valve complex and conducts blood from the left atrium to the apex of the left ventricule. The outflow tract is also called the aortic vestibule. It is smooth walled and ejects the blood into the aorta through the aortic orifice. The area of the aortic opening is only 3 to 4 cm^2 and is guarded by the aortic valve with three semilunar cusps. These are named as posterior, right and left. Opposite to the each cusp the aortic wall is dilated and form the aortic sinuses. The right and left coronary arteries arise from these right and left aortic sinuses, respectively. The opening of the coronary arteries in aortic sinuses are called coronary ostia. These aortic sinuses are significant because they prevent occlusion of the coronary ostia.

The right and left ventricles are separated by the interventricular septum. It consists of a thinner upper membranous part and a thicker lower muscular part which forms the major portion of the septum. It

is placed obliquely backwards and to the right and presents a convexity towards the right ventricle. Hence, on cross section the right ventricular cavity is semilunar and left ventricular cavity is circular in outline. The attachment of the intraventricular septum within the ventricle is indicated on the outer surface of the heart by anterior and posterior interventricular grooves. The left branch of the AV bundle first passes through the right side of the membranous part of the interventricular septum and then appear on the left side by piercing it. On the right side of the interventricular septum, the base of the septal leaflet of the tricuspid valve extends from the muscular part of the interventricular septum to the central region of the membranous part of it. As a result the part of the interventricular septum which is situated in front of the septal leaflet intervens between the two ventricles. But the portions behind the septal leaflet separates the right atrium from the aortic vestibule of the left ventricle. This portion of the interventricular septum is known as the atrio ventricular septum.

The interventricular septum develops from three sources : ventricular septum proper (septum inferior), proximal bulbar septum and septum intermedium. The primitive ventricle develops as a single cavity. It lies between the common atrium on the dorsal side and the bulbus cordis on the ventral side. From the single cavity of common atrium develops two atriums. Whereas, the bulbus cordis develop the outflow tract of the two ventricles and the root of the pulmonary and aortic trunk. Therefore, for complete separation of the ventricle, it must be done in harmony with the septation of atrium, ventricle and the proximal part of the bulbus cordis. The ventricular septum proper or septum inferior grows from below from the floor of the primitive ventricle and passed upwards. It presents a sickle shaped margin with the concavity directed upwards and backwards. Again a septum develops which divides the bulbus cordis into right and left chambers. This is called the bulbar septum which grows downwards and fuses with the upper margin of the ventricular septum proper. But still a small gap remains between these two septums. Right part of the bulbus cordis incorporates with the right ventricle and forms the infundibulum part of it. Similarly, the left part of the bulbus cordis forms the aortic vestibule of the left ventricles. The small gap which still remains after the fusion of the previous two septum is closed later by septum inter medium. Sometimes, this small gap is not closed and remains as VSD. The part of the septum formed from septum intermedium persists in adults as the membranous part of the interventricular septum.

When the intermedium septum is not developed, then it affects the membranous part of the interventricular septum and may appear as single defect (VSD). Thus it also complicates the Fallot's Tetralogy. The tetralogy of Fallot includes the pulmonary stenosis, the displacement of aortic orifice to the right to over ride the ventricular septum, the patent interventricular foramen and the hypertrophy of the right ventricle. The primary defect in fallod is tetralogy lies in the pulmonary stenosis which is due to the unequal division of the bulbus cordis, so that bulbur septum fails to fuse with the ventricular septum. Sometimes, there is complete absence of the interventricular septum. Then this condition is known as the biatrial monoventricular heart. Normally, the left ventricular pressure varies in the ranges between 100 to 140 mm of Hg during systole and 3 to 12 mm of Hg during diastole. The normal aortic pressure also varies between 100 to 140 and 60 to 40 mm of Hg during systole and diastole, respectively.

CONDUCTING SYSTEM OF THE HEART

Normally the atria and ventricles are separated by an eight shaped fibrous ring. But the fibrous tisue is not able to conduct impulses, so this ring acts as an insulator between the atrium and ventricles. Hence, a conducting system is needed for conduction of impulses from the atrium to the ventricles after its initiation in the atrium. This conducting system is actually made up of specialised fine myocardial cells. These specialised fine myocardial cells which form the conducting system of heart are completely striated and include the : SA node, AV node, junctional tissues, bundle of HIS (or AV bundle), right and left divisions of the bundle, their arborizatious under the endocardium (Purkinje fibres), and finally the terminal fibres which penetrate the ventricular musculature. Thus, this conducting system of the heart connect certain pace maker regions of heart with the ordinary working cardiac myocytes and speed up the wave of excitation to travel for synchronous action of different chamber. The intrinsic rhythmic excitation of cardiac muscle fibres are regulated by some pace maker cells in heart and the rhythmicity of these pacemaker cells in turn is regulated by the nerve impulses from the vaso motor centres of the brain stem which supply the heart (Fig. 5.4).

The conducting tissue of heart is composed of three types of specialised myocardial cells : nodal, transitional and Purkinje myocytes. The nodal and transitional myocytes posses high rates of rhythmical excitability, but their conduction velocity is slow. On the contrary, the Purkinje myocytes are blessed with maximal conduction velocity, but are less excitable. The Purkinje myocytes posses a conduction velocity of 2 to 3 meters/sec. Whereas, the nodal and transitional myocytes conduct the impulses only at the rate of 0·6 metre/sec. The SA node of the conducting system is mainly composed of highly rhythmic nodal myocyte cells, but few transitional and Purkinje myocytes are present within it. On the otherhand, the AV node is mainly composed of transitional myocytes or cell and the Purkinje fibres are mainly composed of Purkinje cells or myocytes.

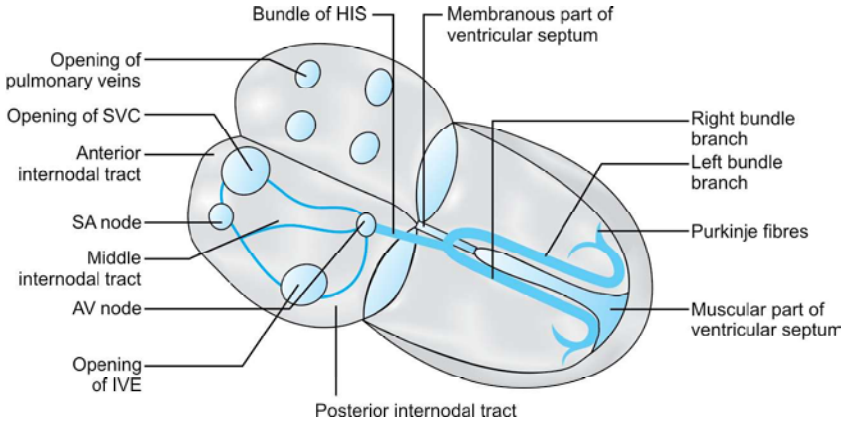

Fig. 5.4: The conducting system of the heart

SA Node

The SA node was first discovered in 1907 by Keith and Flack. It is a horse shoe shaped structure and is situated at the atriocaval juncton on the upper part of the sulcus terminalis. It extends downwards along the sulcus terminalis for a distance of about 2 cm and measures approximately 20 mm × 5 mm × 2 mm in dimensions. It is developed from the right sided embryological structure. So, there is a preponderance of the right vagal innervation on it. The parasympathetic terminal neurons of vagus are only numerous at the periphery of the SA node, whereas the excitatory postganglionic sympathetic fibres are present in the centre of it.

The discharge of impulses from the SA node passes to the AV node through atrial muscular wall via three bundles of fibres. These are the anterior internodal tract of Bachmann, the middle internodal tract of Wenckebach and the posterior internodal tract of Thorec. Of these, probably the most important is the anterior internodal pathway which also conducts impulses directly to the left atrium.

The central axis of the SA node is traversed by a nodal artery. In the majority of human population, it is derived from the right coronary artery. Possibly the thickend adventitia of this nodal artery acts as baro receptors. It monitors the aortic pressure and regulates the sinus rhythm by means of feed back. The SA node is composed of nodal myocytes (maximum quantity), transitional myocytes (less quantity) and Purkinje myocytes (least quantity). They are arranged circularly around the nodal artery from within outwards.

AV Node

Before the discovery of SA node, this node was discovered in 1906 by Tawara. It is a button shaped structure, but smaller than SA node and measures about 20 mm × 10 mm × 2 mm in three dimensions. It is situated on the lower and dorsal part of the interatrial septum, just above the opening of the coronary sinus. The AV node is embryologically originated from the left sided structure of heart and is innervated, therefore, mainly by the left vagus nerve. Impulses from the SA node converge on the AV node through three internodal tracts which are described before. Microscopically the AV node is divided into three discrete functional regions or zones. These are : (i) the AN region which joins the atrial musculature to the node; (ii) the nodal (N) or central region or the AV node proper and (iii) the NH region which joins the node to the bundle of HIS. The AN and to a lesser extent the N region is responsible for the delay that occurs during transmission of impulses from the atrium to the ventricle and allow for adequate time for filling of the later. This delay in transmission of impulse is responsible for the PR interval in ECG (Fig. 5.5).

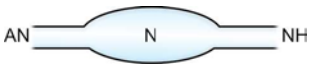

Fig. 5.5: The microscopic structure of AV node

In 80 to 90% of subjects, the AV node is supplied by the right coronary artery. In contrast to SA node, the AV node is essentially or mainly composed of slow conducting transitional myocytes, occasional nodal myocytes and covered by Perkinje myocytes which are in continuity with the AV bundle. Due to the rich population of the transitional myocytes, there is a conduction delay in the AV node.

AV Bundle (Bundle of His)

It is the only muscular (myocytes) connection between the atrium and the ventricles which are separated by 8 shaped nonconducting fibrous ring. The bundle of HIS begins at the AV node. It is enveloped by a vascular connective tissue sheath and crosses the right fibrous ring. Then, it descends along the posterior-inferior border and the right side of the membranous part of the interventricular septum (subendocardially) and reach the upper medial part of the muscular interventricular septum. At the upper border of the muscular part of the interventricular septum it divides into right and left branches. Then the left branch pierses the interventricular septum and reach the left side of it.

Right branch of the AV bundle

It passes along the right side of the interventricular septum and reaches the anterior wall of the right ventricle where it brakes into Purkinje fibres.

Left Branch of the AV bundle

It consists of two to three fascicules and passes sub endocardially along the left side of the interventricular septum in an envelope of connective tissue sheath. Then, after traversing a course of 2 to 3 cm, it splits into anterior and posterior sheets to reach the base of the corresponding

papillary muscles. Finally, it breakes into Purkinje fibres.

Sometimes the few fibres of conducting myocytes of the internodal tracts between the SA and AV node bypass the AV node and join straight with the common AV bundle. Much speculations appear about the existence of this accessory AV bundle in close proximity to the common AV bundle or around the mitral and tricuspid annuli. The presence of such accessroy conducting tissue might explain the causes of certain form of cardiac arrhythmias.

Purkinje Fibres

The purkinje fibres are composed of somewhat specialised larger cells of myocytes and forms a subendocardial plexus. The cellular outlines of these myocytes are indistinct. The central cytoplasm of these myocytes is granular and contains several nuclei. The peripheral cytoplasm of there myocytes contains myofibrillae, but these are separated by more sarcoplasm. The glycogen content of Purkinje cell is very high.

THE ARTERIES SUPPLYING THE HEART

The heart is supplied mostly by two coronary arteries such as the right and left. They arise from the root of the ascending aorta and run in the corresponding atrioventricular groove or coronary sulcus. Only the inner 100 µm of the endocardial surface of the myocardium of heart gets nutrition directly from the blood of the cardiac chambers. Anatomically, the coronary arteries are not the end arteries. Because, they anastomose with each other by their trunks, branches and subbranches, mostly at the precapillary level. But, functionally, however, they behave like end arteries, since most of the anastomoses remain impervious. Each coronary artery is actually a vasavasorum of the ascending aorta. Because the heart is developed from the fusion of two primitive endothelial tubes, from where the great vessels are developed.

Right Coronary Artery

It is smaller than the left coronary artery. It arises from the right aortic sinus of ascending aorta behind the right aortic cusp. It then passes forward and to the right and emerges on the surface of the heart between the root of the pulmonary trunk and the right auricle. It then runs downward along the right anterior atrioventricular groove or coronary sulcus up to the junction of the right and inferior border of the heart. Then, it winds round the inferior border to reach the diaphragmatic surface of the heart. After that, it runs backwards and to the left through the right posterior coronary sulcus to reach the post interventricular group where it gives a branch, named the post descending artery (in 60% population) and terminate by anastomising with the left coronary artery. In 60% subjects, the terminal part of the right coronary artery anastomoses with the circumflex branch of the left coronary artery at the 'crux of the heart' which is the meeting point of the posterior interatrial, posterior interventricular and posterior part of the atrioventricular grooves. In 20% cases, the right coronary artery traverses the entire posterior atrioventricular groove and reach the left border of the heart where it makes anastomosis with the left coronary artery. In 10% cases, it directly reaches the apex of the heart through posterior interventricular groove instead of the giving posterior descending artery and makes anastomosis with the anterior descending artery. In remaining 10% subjects, it is very short and reaches only up to the junction of the right and inferior border of the heart (Fig. 5.6).

The branches of the right coronary artery are: right conus artery, right marginal artery, posterior descending or interventricular artery and multiple muscular branches to the atrium and ventricle. The right conus artery is usually the first branch of the right coronary artery and supplies the infundibulum of the right ventricle. Sometimes, it arises directly from the anterior aortic

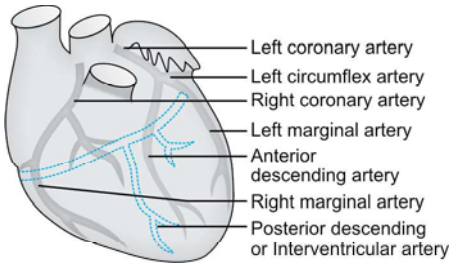

Fig. 5.6: Coronary arteries and their branches

sinus and then it is called the third coronary artery. The right conous artery sometimes anastomoses infront of the aortic root with the same type of left conus artery, derived from the circumflex branch of the left coronary artery. This anastomotic necklace, thus formed around the infundibulum, is known as the annulus of Vieussens.

The right marginal artery arises from the right coronary artery at the junction of the right border and inferior border of the heart. Then, it runs along the inferior border of the heart towards the apex and supplies the adjoining surfaces of the right ventricle. The atrial and ventricular branches or rami are the small arteries which arise from the right coronary artery at the right angles of it at fixed interval while it passes through the right half of the anterior and posterior atrioventricular group. The anterior ventricular rami or branches supply the sternocostal surface and the posterior ventricular rami or branches supply the diaphragmatic surface of the right ventricle. Atrial rami are also grouped in anterior and posterior and supply the anterior and posterior wall of the right atrium. Among the atrial rami one large artery suply the SA node which is called the 'sinoatrial nodal artery'. In 65% cases this sinoatrial nodal artery arises from the right coronary artery and in 35% subjects it arises from the circumflex branch of the left coronary aretery (Fig. 5.7).

In 60% cases the posterior descending artery or the posterior interventricular branch arises from the right coronary artery near the crux and passes downwards along the posterior interventricular

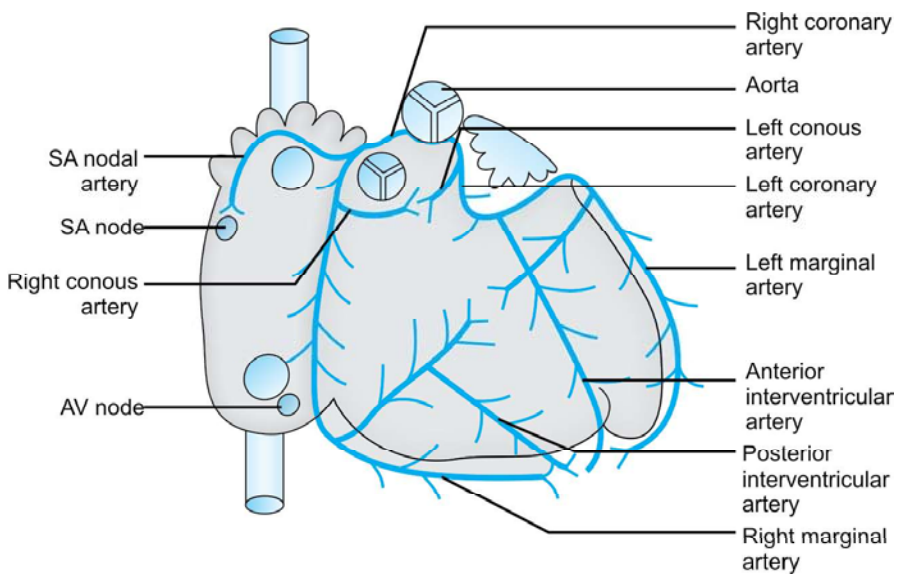

Fig. 5.7: Right and left coronary arteries with their branches

groove towards the apex. At the apex, it anastomoses with the anterior descending or anterior interventricular branch of left coronary artery. In 10% individuals, the posterior interventricular branch is derived as a continuation of the left coronary artery. So, on the basis of the origin of the posterior interventricular branch from the right or left coronary artery, the right coronary predominance' or 'the left coronary predominance of heart' is described. It supplies the diaphragmatic surface of both the right and left ventricle and postero inferior part (½) of the interventricular septum. The first septal branch of the posterior descending or posterior interventricular artery supplies the AV node. In 80 to 90% subjects the AV nodal artery is derived from right coronary artery and in 10 to 20% cases from the it is derived left coronary artery.

Left Coronary Artery

It is larger than the right coronary artery and arises from the left aortic sinus, behind the left cusp of the aortic valve. After arising from the aorta, it first runs forward and to the left between the pulmonary trunk and the left auricle. Here it gives off the anterior interventricular branch or anterior descending artery which runs downward through the anterior-interventricular groove. While passing through the anterior interventricular groove, the anterior descending artery gives off multiple branches at right angle which supplies the sternocostal surface of both the ventricles and the anterior portion of interventricular septum. One such branch of the anterior descending artery, supplying the left ventricle is large and is called the diagonal artery which arises from the junction of the anterior descending artery and the circumflex branch. In such condition the trunk of the left coronary artery actually trifurcates. The septal branches of the anterior descending artery supply the anterior 2/3 of the interventricular septum. The rest posterior 1/3 of the interventricular septum is supplied by the posterior descending artery which is the branch of the right coronary artery.

The further continuation of the left coronary artery is sometimes called as the left circumflex artery. After giving off the anterior interventricular branch, this left circumflex artery runs to the left in the left anterior ventricular groove or left coronary sulcus. Then, it winds round the left border of the heart and continues in the left coronary sulcus posteriorly. Near the posterior interventricular groove this circumflex artery terminates by anastomosing with the right coronary artery. The circumflex artery lies close to the mitral valve and may be damaged during mitral valve replacement surgery. While passing through the anterior and posterior atrio ventricular groove, the circumflex artery gives of branches supplying the adjoining surfaces of the left atrium and left ventricle. During winding round the left border of the heart, it gives a prominent branch which follows the left border of the heart towards the apex. It is called the left marginal artery. In coronary artery bypass surgery (CABG) a vascular autograft is usually anastomosed to the left marginal artery distal to the site of obstruction.Thus, the main branches of left coronary artery are: anterior interventricular (ant. descending) artery, left marginal (or obtuse marginal) artery and multiple atrial and ventricular branches or rami.

Summary of Coronary Circulation

i. The left coronary artery supplies: (a) whole of the left atrium, (b) most of the left ventricle, except a strip along the posterior and inferior surface and (c) anterior 2/3 of the interventricular septum.
ii. The right coronary artery supplies: (a) the whole of the right atrium, (b) most of the right ventricle, except a strip along the anterior interventricular groove, (c) posterior 1/3 of the interventricular septum, (d) SA node and AV node in the majority of subjects.
iii. Sometimes left coronary artery arises from the pulmonary trunk and produce left ventricular failure. Occasionally, it arises from the anterior aortic sinus and undergoes a longer course behind the pulmonary trunk, before dividing into branches. In this anomaly, the main artery may be compressed between the aorta and pulmonary trunk after severe

exercise and results in sudden cardiac death.

iv. The parasympathetic stimulation has negligible direct effect on the coronary vessels. Sympathetic α-receptors (constrictor effect) are predominant over the epicardial segment of the coronary vessels. But sympathetic β-receptors (dilatation effect) are predominant over the intramuscular segment of the coronary arteries. Therefore, sympathetic stimulation constricts the epicardial arteries and dilates the intramuscular arteries.

v. The coronary arteries are the only vessels in the body where the blood flows maximally during the diastole of cardiac cycle.

vi. Majority of people possesses 'right coronary artery predominance' where the posterior interventricular or posterior descending artery is derived from the right coronary aretery. Minority of population has 'left coronary artery predominance' where posterior descending artery extends as a continuation of the left coronary artery. These people are likely to be affected by coronary disease. This is because the entire left ventricle and the interventricular septum are under the nutritional control of left cornary artery. So, obstruction of the latter may produce output failure for systemic circulation. Sometimes, on rare occasions the posterior descending artery is derived from both the right and left coronary arteries. Individuals with such balanced type of coronary distribution are least affected by coronary disease.

vii. In the subepicardial fat, potential communication exists between the branches of the coronary arteries, the branches of the internal thoracic artery and the branches of the descending aorta such as pericardial, bronchial, phrenic and oesophageal artery. In slow obstruction of coronary arteries, these collateral channels dilate and maintain the nutrition of heart.

viii. Clinically, occlusion of the main coronary arteries and their major branches may be located within the first 2 cm of the anterior descending and/or circumflex artery or proximal distal third of right coronary artery. Average frequencies of critical narrowing of the three major arterial trunk are as follows: anterior descending branch of left coronary artery (LAD) 40 to 50%, right coronary artery (RA) 30 to 40%, (left coronary) circumflex artery 15 to 20%. Other infrequent locations of the coronary artery occlusion are : diagonal branches of the anterior descending artery, left marginal branch of the circumflex artery, trunk of left coronary artery.

ix. The total coronary circulation time is about 8 sec. The volume of coronary blood flow is about 225 ml/minute. It is about 5% of the total cardiac output in resting condition. The flow of blood through coronary capillary falls during systole and rises during diastole. Blood flow through the subendocardial arterial plexuses falls almost to zero during systole. But, in diastole blood flow through the subendocardial arteries is greater than that of the epicardial arteries. This explains why myocardial infarction in coronary occlusion involves first the subendocardial regions.

x. The incomplete and spasmodic obstruction of coronary arteries are expressed as angina pectoris where the subject complains of intense precordial pain which is occasionally referred along the left upper arm. In cardiac ischaemia due to vascular occlusion CABG operation is advocated with promising results. It is now possible to dilate the obstructed coronary arteries with a balloon, introduced percutaneously (percutaneous transluminal angioplasty - PCTA) (Fig. 5.8).

Venous Drainage of the Heart

Most of the venous blood from myocardium returns to the heart through the great (anterior) cardiac vein and the coronary sinus. Both of them drain into the right arium. The coronary sinus conveys the blood mainly from the left coronary artery

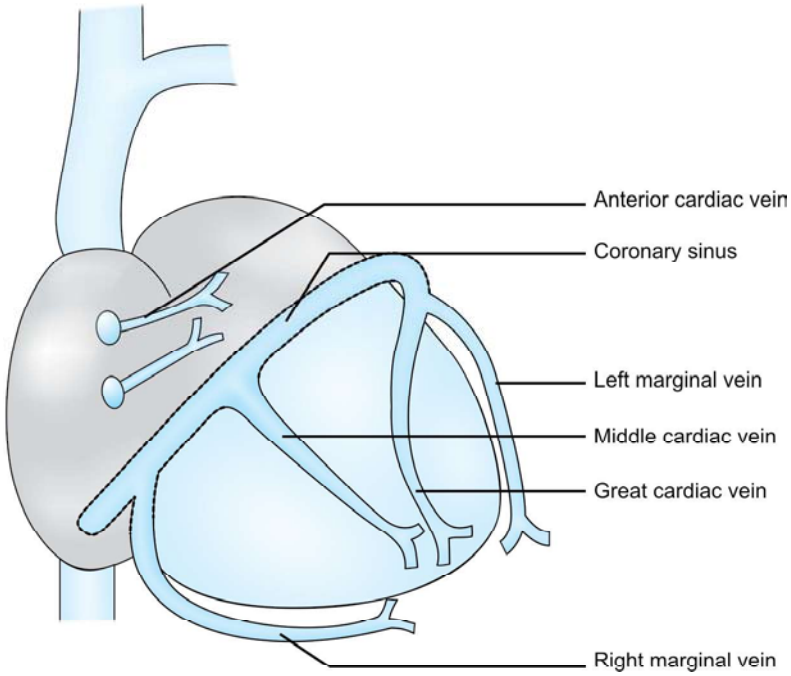

Fig. 5.8: The venous drainage of myocardium

and the anterior cardiac vein conveys the blood from the right coronary artery. The coronary sinus is a wide channel which is 2 to 3 cm long and is situated in the posterior atrioventricular groove. It receives 60% of venous blood from the myocardium. It begins in the left part of the post atrioventricular groove where it receives the great cardiac vein. Then, the sinus runs to the right and drains in the right atrium between the opening of IVC and right atrio ventricular orifice. Its main tributaries are: great cardiac vein, middle cardiac vein, right marginal vein and left marginal vein. The great cardiac vein begins at the apex of the heart and passes upwards along the anterior interventricular groove. Then, it winds with coronary sinus. The middle cardiac vein starts at the apex and runs upwards along the posterior interventricular groove to join the coronary sinus. There are also other vessels which drain directly into any of the cardiac chamber. These vessesls are: arteriosinusoidal, thebesian and arterioluminal vessels. Arteriosinusoidal vessels are capillary like sinusoidal channels which connect arterioles with the cardiac chambers. Thebesian veins are vessels that connect capilaries with the cardiac chambers. Arterioluminal vessels are small arteries which directly empty into the cardiac chambers. In addition, multiple anastomoses occur between the coronary arterioles and the extracoronary arterioles, especially around the mouth of great veins (Fig. 5.9).

CARDIAC CELLULAR ANATOMY

The cardiac muscle cells or fibres are unique in that it incoporates the characteristic features of both the skeletal and smooth muscle cells in it. They are separated from each other by the cell membrane and the connective tissues called endomysium, along with the blood vessel and lympahtics. Each cardiac muscle fibre or cell is not one straight simple cylinder, but has got short cylindrical branches in all directions. These branches are coming in contact with that of the adjacent cardiac muscle cells or fibres and ultimately forms a three dimensional network structure. Under light microscope these network of cardiac muscle cells appear as syncytium (cytoplasmic continuation in between neighbouring cells) which is also supported by the property of cardiac muscle that if one myocardial cell contracts, then all the muscle cells and the heart will contract as a whole. But, Electron Microscope reveals that the cytoplasm of each cardiac muscle cell is separated from other by intercalated disc. So, heart muscle is not a structural, but functional syncytium, because the electrical resistance offered by the intercalated disc is very low and impulse passes easily as if there is no barrier between the cytoplasm of two myocardial cells. Thus, when one cell is excited then the excitation process spreads easily and quickly across the intercalated disc to its neighbouring cells and ultimately to all the cardiac muscle cells (Fig. 5.10).

Impulse propagation in the heart depends on two factors, such as, the magnitude of the depolarizing current (usually Na^+current) and the geometry of the cell to cell electrical connection. Cardiac cells are long, thin branched and are well attached at their longitudinal end or at their branched end with the next cell through a specialised gap junction protein, called the intercalated disc. Whereas, the lateral (transverse) gap junction protein are sparser. As a result, impulses which spread along

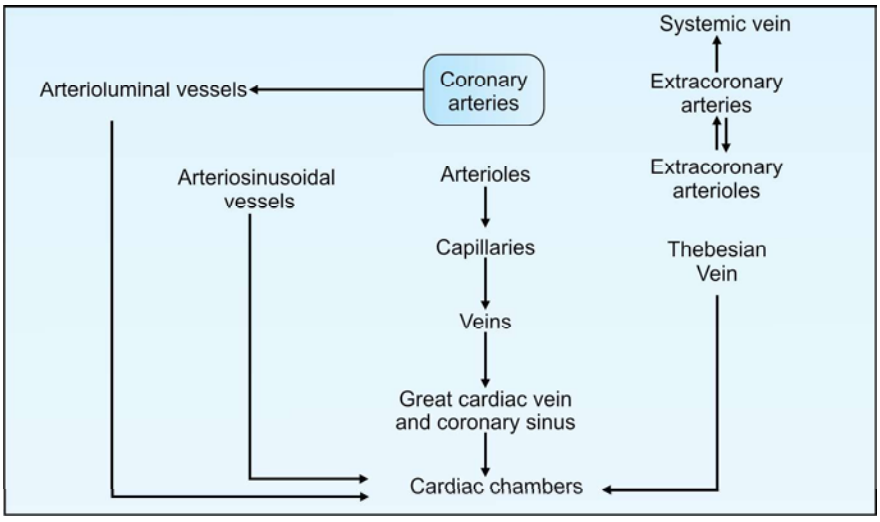

Fig. 5.9: Schematic diagram of venous drainage of heart

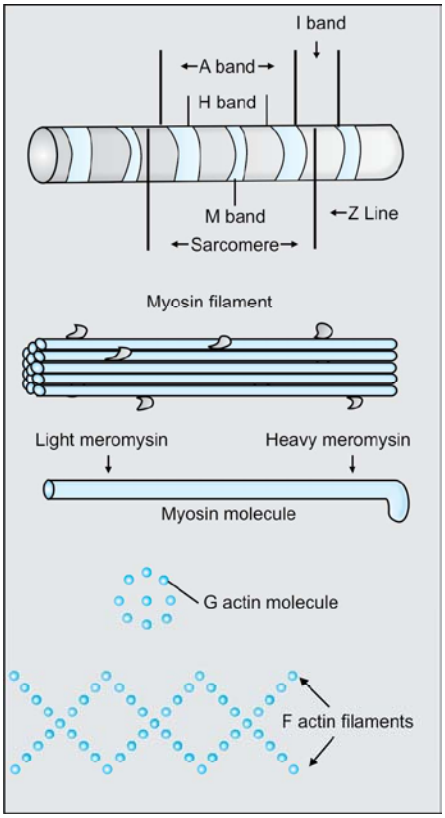

Fig. 5.10: Schematic diagram of a muscle fibre shown under polarised light, structure of myosin and actin myofilament

the longitudinal axis of the cells is 2 to 3 times faster than that of the transverse axis of the cells. This 'anisotropic' (direction-dependent) conduction may be a factor in the generation of certain arrhythmias.

Each myocardial cell or fibre is 100 µm in length and 15 µm in breadth. They are covered by an outer cell membrane, called the sarcolemma. It surrounds the numerous striated myofibrils or myofilaments which are present longitudinally in the cytoplasm of the myocardial cell. Each myofibril consists of two contractile proteins − actin and myosin. They are interrupted at intervals of 1·2 to 2·5 µm by dark lines, known as Z-lines. The portion enclosed by two adjacent Z-lines of a myofibril is considered as the contractile unit and is named as the sarcomere. It extends about 2 to 3 µm in length. During each cardiac contraction the myosin and actin filaments combine reversibly to form the actomyosin complex. This interaction is the fundamental basis of muscular contraction.

Each cardiac muscle cell or fibre consists of alternate light and dark bands. This dark band is shown as the doubly refractive (anisotropic) area when studied under polarised light. Hence, this dark band is named as the A-band. The light band is shown as monorefractive (isotropic) area under the polarised microscope. Hence it is called as the I-band. This I-band is bisected at the midpoint by the so called Z-line. At the Z-line one cardiac muscle cell or fibre ends anatomically. Here, the cell membrane (sarcolemma) contains extensive networks of interdigitating folds, and give attachment to the ends of individual actin myofibrils of two adjacent cells. These intercellular junction is called the intercalated disc and indicated by the Z-line. These intercalated discs form the tight connection with lowest resistance between the two adjacent myocardial cells and give attachment to the longitudinally arranged actin myofibrills. This also allow for tension to be transferred uniformly between the cells on that particular longitudinal axis. The Electron Microscope (EM) reveals that intercalated disc or Z-line is made up of the cell membranes of two adjacent cells. A complex pattern of ridges and papillary projection of the cell membrane at each end of the cell fit into the corresponding grooves and pits of the other cell membrane which form an elaborately interdigited junction or specialised cell to cell cohesion, with intercellular space obliteration. These areas of the intercellular space obliteration are of low electrical resistance which helps in the rapid propagation of electrical impulses from cell to cell and through out the whole mass of the heart through their branching and thus assisting the myocardium to behave as syncytium (Fig. 5.11).

The light areas adjacent to the Z-line are made up of only thin actin filaments which are anchored to the Z-line. The actin filaments, before approaching the Z-line, appear to be branched into four fine diverging filaments, called the Z-filaments which ultimately anchored with Z-line.

The dark central A-band of each cardiac muscle cell is due to the interdigitation or overlapping of thick myosin and thin actin filaments. Again the central portion of this A-band is pale in colour and called H-band. This is due only to the presence of myosin filaments and absence of actin filaments. At the mid-point of the H-band there is also a narrow dark line which is called the M-band, where the each myosin filaments are thickened maximally. This myosin and actin filaments are over lapped at the peripheral dark portion of the A-band which is named as the O-band. Transverse section of the myofibrils at different levels of the A-band and I-band will give different representations (Fig. 5.12).

Transection through the I-band will show the thin actin filaments only. Transverse section through the O-band will present both the thin actin and thick myosin filament and that at the H-band and M-band only myosin filament will be presented. In cross-section at the O-band the arrangements of the thin actin filaments appears in hexagonal shape with one myosin filament at the centre. But again when the thick myosin filaments are considered then the myosin filaments are appeared forming triangles with one central actin filaments. But in the longitudinal section, each myosin filament is followed by two actin filaments. The thin actin filaments are also connected with each other longitudinally by means of still more thinner S-filaments.

Under EM, within the myocardial cell the myofibrils or the myofilaments are seen to have surrounded by another longitudinal network of membranous-tubular structure, called the sarcoplasmic

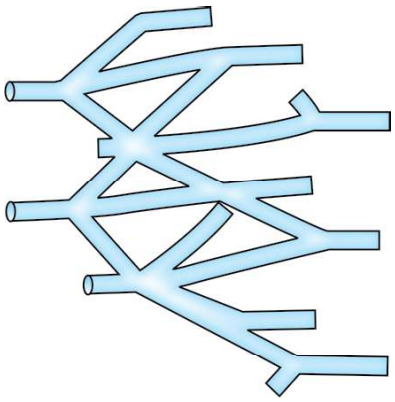

Fig. 5.11: Branched actin filaments or Z filaments at Z-line

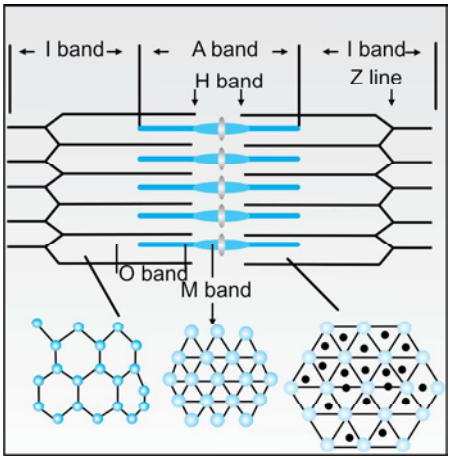

Fig. 5.12: Schematic diagram showing disposition of actin and myosin filament

reticulum (SR). This SR is identical with the endoplasmic reticulum of other cells, but with the difference that its membrane does not possess ribosomes. These longitudinal tubules of SR is dilated at their terminal end and called the 'terminal cistern'. In each myocardial cell, at the level of Z-line, a transverse invagination of the sarcolemma (plasma membrane) occurs. Thus, this results in extension of the extracellular space into the more central portion of the myocardial cells at the level of the Z-lines. These transverse invagination or tubules of sarcolemma are called T-tubules. Thus, at the level of each Z-line these T-tubules approximate with the longitudinal tubules of SR, but do not anastomose with each other. So, the term 'triad' is used to describe this arrangement of the terminal dilatation of two longitudinal tubules (terminal cisterns) from opposite direction on each side of the transverse tubule (Fig. 5.13).

The depolarization of sarcolemma causes the development of an action potential which is conducted through the transverse tubules (T-tubules) into the central portion of the cells and causes a small intracellular influx of Ca^{2+} from it. This small release of Ca^{+} from the T-tubules occurs through the L-type of calcium channel which is situated in it. Then the impulse which passes down the T-tubules causes depolarization of the adjacent cisternae of longitudinal tubule of SR. SR is the main storage site for Ca^{2+} within the cell. A large protein complex termed the Calcium Release Channel (CRC) is present within these terminal cisternae of longitudinal tubules of SR. These respond to small influx of Ca^{2+} from the T-tubules due to depolarization of cell membrane and then subsequently release the large amounts of Ca^{2+} from the stored SR into myoplasm or sarcoplasm. This results in an sudden large increase in the intracellular Ca^{2+} concentrations from 10^{-7} M to 10^{-5} M. The short distance between the L-type Ca^{2+} channel in T-tubule and the foot process of the CRC in terminal cisternae of SR allows the Ca^{2+} entry from L channel to CRC channel and immediate release of huge amount of Ca^{2+} in cytoplasm from the later.

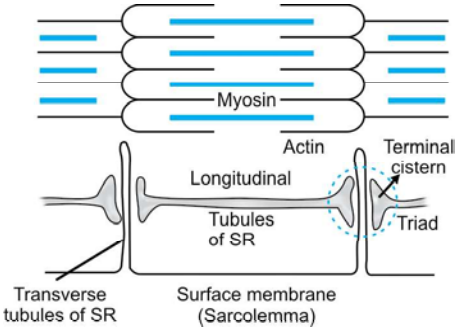

Fig. 5.13: Two dimensional diagram showing connection between the surface of muscle fibre and the endoplasmic reticulum

Ca^{2+} then diffuses from cytoplasm into the myofibrils or filaments and activates myosin. Myosin then splits ATP, yielding the necessary energy for the formation of the actomyosin complex for the contracton of muscle. After contraction, the Ca^{2+} again actively transported back into the cistern of longitudinal tubules of SR and relaxation occurs. This occurs through Ca/Mg ATPase pump which is embeded in the whole membrane of the longitudinal SR. After removal of Ca^{2+} from cytoplasm, the intracellular concentration of it is again restored to 10^{-7} M at diastole.

Like other cells, cardiac muscle cells or fibres also contain numerous mitochondria surrounded by myofibril, single nucleus, small Golgi apparatuses and abundant cytoplasm.

Mechanism of Myocardial Contraction

Myofilaments or myofibrils are the contractile units of the cardiac muscle cells. They are of two types such as the thinner ones (50 ^{o}A in diameter) are called the actin filaments and the thicker ones (100^{o}A in diameter) are called the myosin filaments.

The molecular weight of actin myofibril is 43,000. With very high magnification under electron microscope, it is found that each actin filament is consist of two strands, arranged spirally. Each strand of actin filaments which are called fibrous actin or F-actin appears as beaded and seem to consist of globular subunits, called G-actin. The two strands or F-actin are entwined in a helix. Two complex proteins such as tropomysin and troponin are interoposed between this two thin strands (F-actin) of actin filaments. Molecular weight of tropomysin is 70,000 and lies within the sulcus of two thin strands of actin filaments (F-actin). Troponin is also consists of three distinct polypeptides - Troponin T, Troponin I and Troponin C and lies within the groove of two thin strands of actin filaments (F-actin) at regular interval. Each polypeptide of troponin fulfills different functions in the regulations of muscular contractions. Troponin T binds with the tropomysin and forms a complex. Troponin I inhibits the reactions of actin with myosin filament. Troponin C binds Ca^{2+} and activates contractions by inhibiting troponin I. The binding of Ca^{2+} to Troponin C is the triggering factor that initiates the chain of reaction causing conformational changes of actin and leads to the development of mechanical activity. (Like Troponin C, calmodulin which is present in other nonmyocardial cells in place of Troponin C also binds with Ca^{2+} and initiates the different enzymatic reactions in these cells) (Fig. 5.14).

The thicker contractile element of myofibrils or myofilaments is called myosin. It consists of large asymetrical molecules, consisting of two heavy chains and four light chains. The molecular weight of heavy chain and light chain is 2,20,000 and 20,000, respectively. Each myosin molecule consists of : (i) one globular head containing the activity of enzyme ATP-ase which hydrolyses ATP to provide energy and interacts with actin to form cross - bridges, (ii) one neck area, appears to be involved in the development of tension and (iii) one tail which helps to

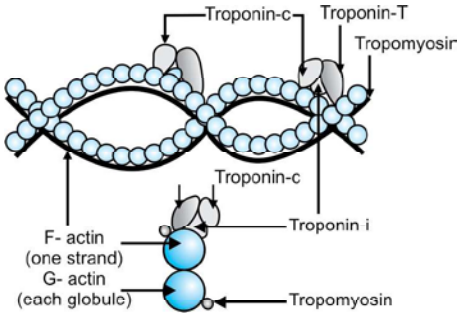

Fig. 5.14: The structure of actin filament. The backbone of each actin filament is two strands which are made up of actin monomers (G-actin). Each strand is called F-actin. Troponin complex which is made up of one molecule each of troponin-C, troponin-I and troponin-T are distributed at regular intervals along the actin filaments. Elongated tropomysin molecules, which is another protein structure and is attached to the actin filaments, lie in the grooves between the two actin strands. A cross-section of actin filaments at the level where troponin complexes are located shows the probable relationship between the actin, tropomyosin and the three components of the troponin complex. The strength of the bond linking troponin I and actin varies. It depends on whether Ca^{2+} is bound to troponin C or not

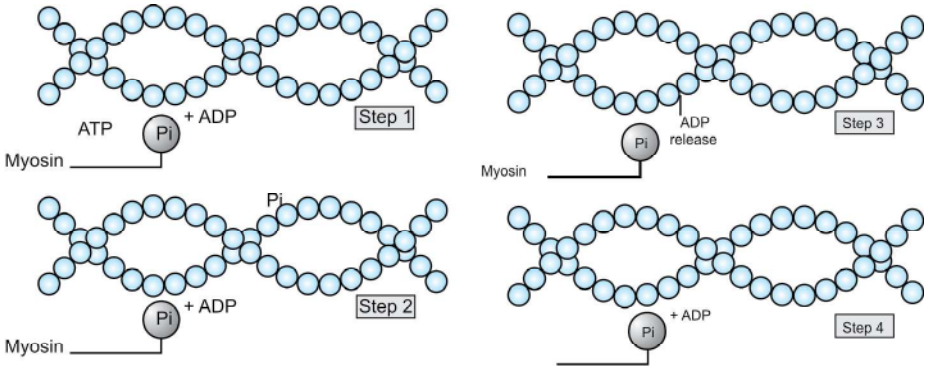

Fig. 5.15: The reaction mechanism between the actin and myosin filament is described in simplified form in four steps:
Step 1: On the head of the myosin filaments there is an ATP hydrolyzing site. After hydrolysis of myosin bound ATP at this site, energy is released. This is transferred to the myosin head and it is activated and energised. In a relaxed muscle the intracellular Ca^{2+} concentration is low and in this low Ca^{2+} concentration troponin and tropomysin complex on the actin filaments do not allow the actin filaments to intereact with the energised activted myosin head. Therefore, even though the myosin heads are energised, they can not interact with actin filament.
Step 2: After depolarization there is increased concentration of intracellular Ca^{2+}. Then, increased Ca^{2+} is attached with troponin C and make some conformational changes of actin filaments. This conformational changes of actin filament causes binding of actin with the already energised mysin filaments and formation of cross bridges.
Step 3: After the attachment of head of the mysin with the actin filament energy is released from the head which causes changes in the angle of the attachment of the head of myosin filament and the rowing motion of cross bridges. This is called the power stroke which produce muscle contraction.
Step 4: Then the muscle returns to its resting state and the cycle ends when a new molecule of ATP binds with the myosin head and dissociats the cross bidges from the actin filaments. The contraction continues until Ca^{2+} is dissociated from the troponin C of the actin filament which causes the contractile proteins to return to the resting state. Thus, (i) binding of another ATP molecule which leads to the detachment of cross bidge, (ii) the cycle of hydrolysis of ATP and (iii) reattachment of myosin head with formation of cross bridge with actin filament begin again

anchor one myosin molecule to another forming thick myosin filament. The head and neck portion of each myosin molecule is called the heavy meromysin and tail or rod like portion of it is called the light meromysin. The thickness of the myosin filament is believed to be due to the parallel arrangement of myosin molecules in such a fashion that the globular heads project outward near the surface of the myosin filaments and the rod like tail part takes its position in the smooth central portion of the myosin filament. The heads of myosin molecules are arranged in a radial pattern and each set of six head complete one revolution around the myosin filament within one 400°A segment. Each head of the myosin molecule is pointed towards a separate actin filament and make a cross bridges during actin myosin complex formation and muscular contraction.

The impulse or the wave of depolarisation is propagated from the sarcolemma (cell membrane) through the T-tubules into the interior of the cell. Then, the depolarisation of the T-tubules cause the entry of small amount of Ca^{2+} from the extracellular space into the sarcoplasm. This small entry of Ca^{2+} occurs through the L-type of Ca^{2+} channel situated on the T-tubules and acts solely as a trigger to initiate the huge release of Ca^{2+} from the longitudinal tubules of SR. The Ca^{2+} release channel on the 'terminal cisterns' of the longitudinal tubules of SR is a huge protein molecule of molecular weight of 5,65,000 with foot process which lies in close proximity to the L-type of Ca^{2+} channel. The short distance between the L-type of Ca^{2+} channel in the T-tubular membrane and the foot process of Ca^{2+} channel on terminal cistern (CRC or calcium release channel) allows the immediate entry of this small amount of Ca^{2+} in the SR and subsequent huge release of Ca^{2+} from the 'terminal cistern' of it (Fig. 5.15).

After release of Ca^{2+} and contraction of muscle, it again reaccumulates back in the longitudinal tubules of SR. This is accomplished by Ca / Mg-ATP ase pump, embedded on the membrane of the longitudinal tubule of SR. So, the removal of free intracellular Ca^{2+} from the sarcoplasm back into longitudinal tubule of SR is an active, energy consuming process. Thus, the low sarcoplasmic Ca^{2+} concentration i.e. 10^{-7} M from the high Ca^{2+} concentration i.e 10^{-5} M is restored by the tubule of the SR during diastole.

The activity of Ca^{2+} channel on the sarcoplasmic reticulum (SR) can be augmented by the cAMP dependent phosphorylation of an another SR protein called phospholamban. The β-adrenergic stimulation leads to the increase in phosphorylation of this phospholamban, causing increased Ca^{2+} channel activity and

increase in concentration of Ca^{2+} in sarcoplasm and increased force of contraction.

In the resting state, the Troponin-I exerts an inhibitory effect on the actin filaments via tropomysin and Troponin-T. But Troponin-C has an afinity for Ca^{2+} and binds calcium to its saturation point when the sarcoplasmic Ca^{2+} concentration rises to 10^{-5} M. Thus when Troponin-C is activated, it inhibits Troponin-I. As a result the inhibitory influence of the troponin-tropomysin complex on actin is removed. Simultaneously, the rise in the Ca^{2+} concentration in the sarcoplasm activates the ATP-ase enzyme situated on the myosin head. This activated ATP-ase breaks the ATP to ADP with the release of energy which energizes the myosin head and forms cross bridges with actin causing muscular contraction.

In summary, the mechanism of myocardial contraction and relaxation may be expressed as the follwoing order.

i. *Contraction:* membrane depolarization → Ca^{2+} released from the sacroplasmic reticulum (SR) → myosin ATP-ase is activated → cross bridges formed → actin slides along the myosin filaments → tension is developed.

ii. *Relaxation:* Ca^{2+} pumped back into sacroplasmic reticulum → myosin ATP-ase is depressed → cross bridges broken → actin is pulled back to its resting state → tension disappears.

CARDIAC ELECTROPHYSIOLOGY

The flow of different charged ions across the cell membrane results in the appearance of different ionic currents such as the Na^+ current, K^+ current, Ca^+ current, etc, and these make up the cardiac action potential. The action potential of a cell is a highly integrated event. Changes in the flow of one ionic current almost inevitably produces stimulatory or inhibitory secondary changes on the flow of other ionic currents. Movements of ions across the cell membrane occurs not only passively through the lipid bilayer of it, but also actively through the different specific ion channels and transporter systems, situated on it. These occur in response to either electrical or concentration gradient or both.

The contraction and relaxation of cardiac muscle are due to the event of action potential (like skeletal muscle and nerve fibres) which originates from the SA node and passes to the AV node through the atrial muscle. This initiates the atrial contraction and relaxation. It then passes through the bundle of HIS and Perkinje fibres to the ventricular muscle and initiates the ventricular contraction and relaxation. The rapid alteration of electrical potential during depolarization of cardiac muscle cell differs little from that of the nerve fibres and skeletal muscle cells which is discussed later. But, the repolarisation in cardiac muscle cell requires 400 ms. This is entirely different from the situation found in the skeletal muscle cells and nerve fibres in which the total action potential including the depolarization and repolarization is completed within few miliseconds. Because of this long duration of action potential due to the prolonged repolarisation, the cardiac muscle cells can not be further reexcited for few fraction of a second, even when the previous mechanical contraction is almost complete. Thus the heart muscle can not be tetanized like the skeletal muscle. This property of long refractory period ensues enough time for recovery of the cardiac muscle cells.

Action potential of heart is of two types. One is 'the fast response action potential' which occurs in the cells of the atrial muscle, ventricular muscle and Purkinje fibres. And second is 'the slow response action potential' which occurs in the SA and AV node and is responsible for the automaticity or pace maker activity. The myocardial cells which have the characteristic of 'fast response action potential' also posses the pace maker activity. But, it is usually suppressed by the activity of the myocardial cells which have the characteristic of 'slow response action potential'.

The differences between these two type of action potentials is discussed under different headings below:

(i) In the Resting Membrane Potential

In slow response action potential, the resting membrane potential attains rarely more negative than −60 mV. Whereas, in fast response action potential which is found in other cardiac muscle cells except the SA and AV node, the resting membrane potential approximately goes down to −80 or −90 mV. In the type of slow response action potential, during the period of phase 4, the resting membrane potential spontaneously and progressively changes from −60 mV to approximately −40 mV which is the threshold value for excitation, and thereafter a fulminant upstroke of a full action potential or depolarization occurs. This slow ascent of membrane potential to a more positive value i.e from −60 mV to −40 mV during the phase 4 of AP characterises the 'pace maker' activity of the SA or AV node. This is due to the slow inward flow of sodium current in phase 4. Initially this inward Na^+ current only slightly exceeds the outward K^+ current. But gradually the outward K^+ current stops allowing continuous inward Na^+ current to produce a progressively more positive or less negative membrane potential (Fig. 5.16).

Once the resting membrane potential achieves a threshold level of −40 mV, then there occurs a very rapid rise of inward flow of Na^+ current and the depolarisation

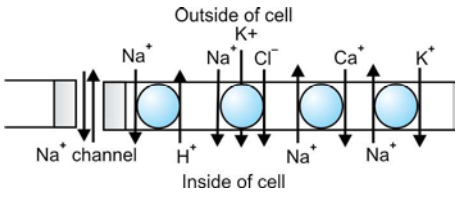

Fig. 5.16: Different types of Na+ transport systems which act during different phase of action potential. From left to right these include: The Na^+ channel, Na^+-H^+ antiport exchange. Na^+-K^+ contransport, Na^+-Ca^{2+} exchanger and the Na^+-K^+ ATPase pump

part of action potential takes off. It indicates that the threshold level for excitation is achieved earliest in the SA nodal cell and the action potential, generated there, is conducted to the other cardiac cells. As other cardiac cells are latent pace maker and the depolarisation, arising from the SA node, arrives there before their own diastolic depolarisation in phase 4 is reached to threshold level, so their automaticity is supressed.

(ii) In the Rate of Rise of Upstroke in Action Potential

In the slow response action potential of SA and AV nodal cell, there is slow depolarisation phase, slow repolarisation phase and also the slow slope of diastolic depolarisation phase (phase 4 of action potential). The peak of the action potential in case of slow response is rounded, but uninterrupted. In atrial, ventricular and Purkinje cells where the fast response action potential occurs the depolarisation phase is very sharp, the peak is mostly pointed. Besides these, there is interrupted fall of repolarisation and the upward slope of diastolic depolarisation phase is absent (actually not absent but depressed). Thus, in SA node dominated heart, the pace maker activity of the cells of atrial muscle, ventriculsr muscle and Purkinje fibres are depressed due to the higher rhythmical activity of the SA node. This is evident from the absence of the slope of slow diastolic depolarisation phase in these group of muscle fibres. But if the transmembrane potential is recorded from isolated fibres of these group of muscle cells, then the slope of slow diastolic depolarisation (phase IV) is observed (Fig. 5.17).

(iii) In the Propagation Velocity of AP

It is important to note that the conduction velocity of impulses through the AV node is slow (0·2 m/Sec). Thus, it ensures an appreciable delay between the atrial and ventricular depolarisation or contraction.

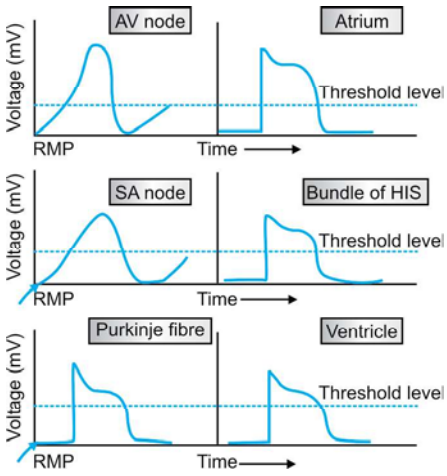

Fig. 5.17: Different configurations of action potential of different tissues of heart. The SA node has the steepest phase 4 showing rapid spontaneous depolarisation in diastole. So, it undergoes fast self excitation and acts as pacemaker. Other tissues also undergo the phase 4 slow depolarisation, but at a slower rate. So, they receive a propagated impulses from SA node, before their phase 4 of action potential reach the threshold level and remain as latent pacemakers. Two types of action potential are found in different cardiac tissues. These are slow and fast action potential. The slow action potential is characterised by: (i) shorter duration, (ii) phases 1, 2 and 3 are not clearly demarked, (iii) low amplitude, rounded overshot, initiation of action potential at lower threshold (less negative) level

This slow conduction of AV node is partly due to the small size (radius 7 µm) of the AV nodal cells compared to the Purkinje cells or fibres (radius 50 µm) which conduct the impulses at the rate of 4 m/sec. It is also partly due to the fact that the amplitude of ionic currents generated by the nodal fibres are far less than those developed by the Purkinje fibres.

There is direct relationship between the transmembrane action potential recorded from the individual cardiac muscle cells (SA node, atrium, AV node, ventricular muscle, Purkinje fibre) and ECG. But the total action potential of atrial (not SA or AV nodal) and ventricular muscles due to their increased amount of musculature dominate over the action potential of other myocardial cell present in heart and is usually recorded in clinical 12 lead ECG. The individual recording of action potential from the cells of SA node, AV node, bundle of HIS, Purkinje fibres, etc, needs special technique. The normal ECG is composed of a P wave, a QRS complex and a T wave. The QRS complex has often, but not always, three separate components : the Q wave, the R wave and the S wave. The P wave is caused by the electrical potentials when the atria depolarizes and its contraction begins. The QRS complex is also caused by the generated electrical potentials when the ventricles depolarizes and its contraction begins. Therefore both the P wave and the components of the QRS complex are deploarisation waves. The T wave is caused by the electrical potentials when the ventricles recover from the state of depolarisation. This process normally occurs in ventricular muscle 0·25 to 0·35 seconds after the depolarization. So, the T wave is known as the repolarisation wave of ventricles. The repolarisation of atrium falls within the duration of QRS complex. So, it can not be seen in usual ECG.

The cellular electrical properties of myocardium which can be assumed from the ECG are:

(a) Heart rate

It reflects the pace maker activity of the sinus node and the P wave reflects the whole atrial depolarisation and the initiation of contraction. The only depolarisation of the cells of SA node can not be recorded by the clinical ECG. The atria repolarise which lasts for about 0·15 to 0·2 second after the termination of the atrial depolarisation or P wave. This also occurs approximately when the QRS complex is being recorded in the ECG. Therefore, the atrial repolarisation wave, known as the atrial T wave, is usually obscured by the much larger QRS cmplex in ECG. For this reason, an atrial T wave seldom is observed in the ECG. Atrial depolarisation and repolarisation make atrial systole. This atrial systole is followed by atrial diastole which extend from the end of its repolarisation (it can not be seen in ECG

as it is overshadower by QRS complex) to the beginning of next P wave.

(b) PR interval

It reflects the AV nodal conduction time i.e the time taken for the wave of atrial depolarization to cross the AV node from the atrium to the ventricle. This period is also called the P-Q interval, if Q wave is present. But Q wave is likely to be absent and so it is termed as the PR interval.

(c) QRS duration

It reflects the time taken for the conduction of impulses to travel through the ventricle and the depolarisation period of the whole ventircle.

(d) QT interval (Fig. 5.18)

It is the total duration of ventricular depolarisation plus repolarisation, i.e. full period of ventricular action potential or contraction. Among this the QRS duration only implies the time taken for the initiation of depolarisation of different parts of the ventricle to full ventricular depolarisation. The ST segment implies the duration in which the whole ventricle stays in full depolarization state and T-wave implies the full repolarisation period of ventricle. Thus, the contraction of ventricle lasts almost entirely from the beginning of the Q wave (or R wave, if Q wave is absent) to the end of the T wave. The time interval in the ECG between the end of one T wave and the beginning of next QRS wave corresponds with the phase 4 of action potential and ventricular diastole.

If we corresponds the action potential graph of ventricle and ECG, then we will find that the QRS waves appear at the beginning of the action potential of ventricle (or phase 0) and T waves appear at the end of phase 3. In between these waves and also after the T waves no electrical potential difference is recorded. Thus, no movement of impulse and its corresponding graph is recorded in the ECG or oscillometer (ECG is a type of oscillometer), when the whole ventricular muscle is either completely depolarised or completely repolarised. Hence, only when the muscle is partly polarized (i.e partly depolarised or partly repolarised) then does the current flow from one part of the atrium or ventricle to another part. Therefore, current also flows on the surface of the body to produce a graph in ECG Beginning of QRS complex indicates starts of ventricular depolarisation. The QRS complex and ST segment indicates the whole duration of ventricular depolarisation. The beginning of T wafe indicates end of depolarisation and the start of ventricular repolarisation. The end of T wave indicates the end of repolarisation.

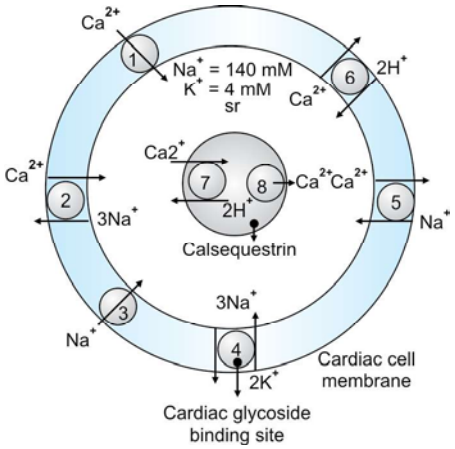
(e) Twave

It represents the ventricular repolarisation. Some ventricular muscle fibres begin to repolarise about 0.20 seconds after the begining of the depolarisation (QRS complex). But in many other fibres, it takes as long as 0.35 sec. Thus, the whole process of ventricular repolarisation extends over a long period. For this reason, the T-wave in the normal ECG is a prolonged wave. But, the voltage of the T-wave is considerably less than the voltage of the QRS complex, partly because of its prolonged length.

ECG actually represents the electrical activity of multiple cells, but not of a single cell. For this reason, the amplitude and shape of the P, R and T waves of an ECG mostly dependent upon the amount of electircal activities offered together by the group of these cells and also upon the different configuration of action potential of these cells than that of an individual one.

Cardiac Action Potential

The whole action potential of cardiac tissue is divided into two stages: depolarisation and repolarisation or more (Fig. 5.19) scientifically into stages, numbered as 0, 1, 2, 3 and 4. Among these stages 0 represents depolarisation and stages 1, 2, 3



1 = Ca^{2+} channel, 2 = Na^{+}-Ca^{2+} exchange, 3 = Na^{+} channel, 4 = Na^{+}-K^{+} ATPase pump, 5 = Na^{+}-Ca^{2+} exchanger, 6 = Ca^{2+} ATPase pump, 7 = Ca^{2+} ATPase pump, 8 = Ca^{2+} release channel

Fig. 5.18: The sarcolemmal exchange of Na^{+} and Ca^{2+} during action potential of cardiac muscle cells. Na^{+} and Ca^{2+} enter the cells during each cycle of depolarization. It triggers the release of larger amount of Ca^{2+} through Ca^{2+} release channel (8), in the sarcoplasmic reticulum (SR). The resulting tremendous increase in concentration of intracellular Ca^{2+} interacts with troponic C. This interactions is responsible for activation of the cross bridge reactions between the actin and myosin filament. Thus they form the cross bridges that result in sarcomere shortening. The electrochemical gradient for Na^{+} and K^{+} across the cell membrane is maintained by active ATP consuming Na^{+}, K^{+}ATPase pump (4). It extrudes Na^{+} out of the cell. While the Na^{+} is actively extruded by Na^{+}, K^{+}ATPase pump, the bulk of cytosolic Ca^{2+} is pumped back by Ca^{2+} ATPase pump (7) in the SR. In the SR, Ca^{2+} is bound with the protein calsequestrin. The remaining portion of intracellular Ca^{2+} is removed from the cell by either a plasma membrane bound Ca^{2+}ATPase pump (6) or by a Na^{+}-Ca^{2+} cation exchange protein (2 and 5). This cation protein exchanger (2 and 5) exchanges $3Na^{+}$ ions in for every single Ca^{2+} ion out. This direction of cation exchange is reversed briefly during depolarization. This is because when the electrical gradient across the cell membrane is transiently reversed. β-adrenergic receptor agonists and phosphodiesterase inhibitors activate the protein kinase (1) by increaseing the intracellular cAMP levels. This activated pk enhances the contractile state by phosphorylating the target proteins including phospholamban and the α-subunit of the L-type Ca^{2+} channel

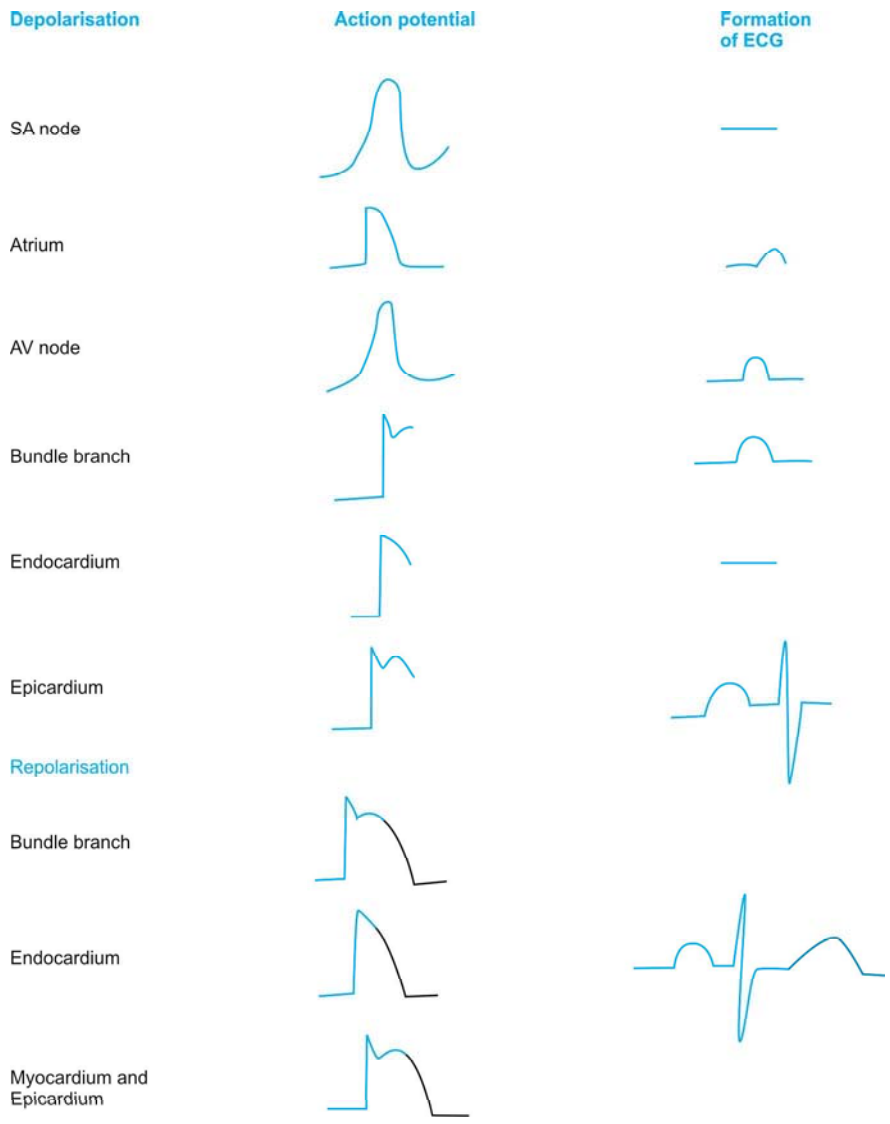


Fig. 5.19: The action potential and its subsequent ECG formation of different tissues of heart are shown. Red line indicated depolarisation and blue line repolarisation

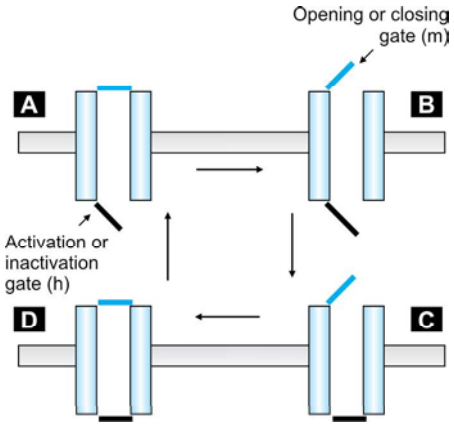
represent repolarisation. The heart remains in systole both at the stage of depolarization and repolarisation i.e from stage 0 to stage 3. But it remains in diastole only during stage 4. After repolarisation i.e. after stage 3, in phase 4 the membrane potential comes down to the resting level. But, the ionic distribution of Na^+ and K^+ across the cell membrane remains in opposite state to that which is found in the resting state. So, in phase 4 of non pacemaking cells, the opposite ionic distribution of Na^+ and K^+ comes back to normal state without any change of the resting membrane potential which is achieved at the end of the phase 3. But this stage 4 is called the 'slow diastolic depolarisation' for the pace making cells. Because in this stage of pace making cells, the inside of the cell again starts to become slowly positive (i.e. depolarisation) from normal resting membrane potential which is achieved at the end of the stage 3, though the ionic concentration of Na^+ and K^+ is opposite to the resting condition. This slow process of depolarisation during diastole of heart is the characteristic of pacemaker activity of the SA or AV nodal cells and is absent in other cells than pace maker cells.

At rest, in the non pace making myocardial cells the membrane potential (resting membrane potential Vm) is maintained at the level of −60 mV to −70 mV, with negativity inside and positivity outside of the cell like the resting nerve and muscle cells. This resting membrane potential or the electrical gradient is established by pumps, especially the Na^+, K^+ ATPase pump which extrudes Na^+ and pushes K^+ inside the cell and some fixed anionic charges which are present within the cells. Other Na^+ channel remains closed at this negative transmembrane potential and so no Na^+ does enter inside the normal resting myocardial cell through this channel. Whereas the other specific K^+ channel (inward rectifier K^+ channel) remains in an open conformation at this negative resting membrane potential and allows the normal cardiac cells to become permeable to K^+ from outside to inside at rest. This inward rectifier K^+ channel along with the Na^+, K^+ ATPase pump maintains the intracellular K^+ concentration which is higher than the extracellular concentration. So, the concentration of K^+ in the extra cellular space is the major determinant factor for the resting membrane potential.

For each individual ion there is an equilibrium potential (Ex) after which there is no movement of ion across the cell membrane, still if the channels are open. For K^+ this value of equilibrium potential is −94 mV i.e. at this voltage there is no net force which drives the K^+ ions into or out of the cells. The Na^+ channels which allow Na^+ to move along the gradient are closed at negative transmembrane potential. So, Na^+ does not enter into the normal resting cardiac cells (Fig. 5.20).

The resting membrane potential will be maintained until the resting state is not disturbed by the propagated impulse or the slow diastolic depolarisation in phase 4. If there is any propagated impulse or the



Figs 5.20A to D: A. Closed and activated channel but no current flows. B. Open and activated channel with current flows. C. Open but inactivated channel and no current flows. D. Closed and inactivated channel − no current flows. Schematic diagram of dynamics of a voltage dependent double gated fast Na+ channel that occur during action potential of a cardiac cycle. At resting stage the channel is initially closed, but activated where upper m-gate is closed but lower h-gate is opened. Then, depolarisation causes activation of channel which opens the upper m-gate and allows the entry of Na+ ions into the cell. Subsequently the time dependent h-gate closes and inactivate the channel and prevent the ion flow where m-gate still remains open. Then, both the m-gate and h-gate is closed. This is followed by removal of inactivation, which causes opening of the h-gate and priming of the channel for voltage sensitive activation

slow diastolic depolarisation reaches the threshold level, then the resting membrane potential is changed fulminantly from −90 mV of nonpace making cells to the value of +30 mV, making the inside of the cell positive in respect to outside. This initial stage of action potential is called the depolarisation or phase 0 and this is due to the sudden influx of Na^+ into the cell from outside after the threshold level is reached and also due to some influx of Ca^{2+} into the cell. The entry of Na^+ into the cell is operated through the voltage dependent double gated fast Na^+ channel. In this channel, the outer m-gate (activation gate) remains closed and the inner h-gate remains open during resting state at the end of the repolarisation and be ready for depolarisaton (A). When the stimulus is reached, outer m-gate then opens and Na^+ is allowed to flow in the cell along its concentration and electrostatic gradient (B). As the membrane potential reaches +30 mV, then the inner h-gate (inactivation gate) closes preventing further influx of Na+ and marks the end of depolarisation or phase 0 (C).

Then when repolarisation starts, the upper m-gate closes. In this state both the m and h gate is closed and is known as the closed and inactivated state (D). During repolarisation of the cell membrane, Na^+ channel also changes its conformation from closed and inactivated state to close and activated state when the outer m-gate remains close, but the inner h-gate opens and make the Na^+ channel ready for further depolarisation. During depolarisation both the gates are again opened and Na^+ enters through this 'open and activated' sodium channel. Thus this cycle of closed and inactivated (D) → close and activated (A) → open and activated (B) → open and inactivated (C) form of Na^+ channel repeats.

After depolarisation, repolarisation occurs in several steps. These are :

i. There is an initial partial rapid repolarisation or phase I where membrane potential falls from +30 mV to +10 mV,
ii. It is followed by plateau or phase 2, in which the membrane potential falls slowly from +10 mV to −20 mV,
iii. Then it is followed by a last stage or phase 3 where a relatively more rapid drop of membranes potential to the resting value of −90 mV (for nonpace making cells) or −60 mV(for pace making cells) is achieved from −20 mV (Fig. 5.21).

After the cells are depolarised by inward Na^+ currents, the K^+ channels transiently change their conformation to open state. This results in an outward movement of K^+ or repolarisation current which contributes to phase I. The small notch of phase I is also associated with the flow of inward Ca^{2+} current which opposes the outward repolarizing K^+ current and is

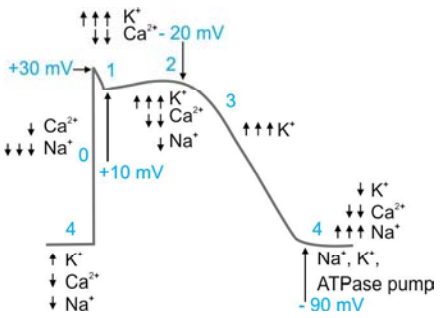


Fig. 5.21: The four phases of action potential and the movement of various ions that occur by electrostatic and / or electrochemical gradient with membrane depolarization. Na^+ current is 50 fold larger than any other current. Multiple types of Ca^{2+} current have been identified. It is likely that each represents a different channel protein and is responsible for haemostasis of Ca^{2+}. Downward arrow indicates influx of ions into the cell and upward arrow indicates eflux of ions out of the cell

responsible for the shortness of the notch. Transient outward K^+ channels, like Na^+ channels, then rapidly is inactivated. After that phase 2 starts and is dominated by the increased influx of Ca^{2+} through the L-type voltage dependent Ca^{2+} channel and to lesser extent influx of Na^+ through its slow channel (not fast channel) and balance the still outward repolarising K^+ current through the 'delayed rectifier' K^+ channel (not the previous K^+ channel). In this stage repolarising (outward) K^+ current balance the depolarising (inward) Ca^{2+} and Na^+ current and thus maintain a plateau. The entry of Ca^{2+} into the cell trigger further releases of Ca^{2+} from the intracellular SR and initiates contractile process. Catecholamines such as epinephrine and nor epinephrine increase this inward Ca^{2+} current and increase the contractile forces which is inhibited by Mg^{2+} and calcium channel blockers (dihydropyridines). After the phase 2, the phase 3 occurs as with the passing of time outward K^+ current through 'delayed rectifier K^+' channel increases, while inward Ca^{2+} current inactivated. This result in a relatively rapid repolarisation of cardiac cells (several hundred milliseconds after the initial Na^+ channel opens). Thus, the repolarising

outward K^+ current through the 'delayed rectifier' channel gradually lower the transmembrane potential to the resting state with the closure and inactivation of slow Ca^{2+} and Na^+ channels. During this period no further depolarization of cell take place and is known as the absolute refractory period. Thus, at the end of repolarisation, i.e. after phase 3 though the resting membrane potential is achieved, but the Na^+ and K^+ concentration in the intra and extracellular fluid is opposite to the normal resting condition of the cell. Thus, the restoration of concentration of Na^+ and K^+ to their pre-excitation level inside and outside of the cell occurs via an active transport system, called the Na^+/K^+ ATPase pump at a ratio of 6 Na^+ ions out for every 3 K^+ ions in. As a result the act of pumping itself generates a net outward (repolarising) current. There are also other channels through which K^+ enters the cells and maintains the pre excitational intracellular concentration of K^+, balancing the excess extrusion of Na^+ by Na^+, K^+ ATPase pump. But other Na^+ channels remain closed during the phase 4, except in the cell with the character of automaticity where few Na^+ channels open and gradually Na^+ enters the cells causing slow diastolic depolarisation.

The homeostasis of intracellular Ca^{2+} which enters the cell during phase 2 is maintained by (i) Ca/Mg ATPase pump on SR, (ii) sarcolemmal Ca-ATPase pump and (iii) Na^+ - Ca^{2+} exchange mechanism on the cell surface, which exchange three Na^+ ions in for each Ca^{2+} ion out from the cell. In phase 0, Na^+ enters and Ca^{2+} exits the cell and in phase 2 vice versa. This Na^+-Ca^{2+} exchange is not shown in the figure of action potential.

Finally, the phase 4 represents the period between the completion of repolarisation and the initiation of depolarisation of next action potential. During this period, K^+ continues to leak slowly from the cell along its concentration gradient. On reaching its most negative value after repoalrisation the membrane potential again gradually ascent to more positive value due to gradual entry of Na^+ in the cell and droping of K^+ efflux from cell. When K^+ efflux stops and due to gradual entry of Na^+, the threshold transmembrane potential of approximately −40 mV is achieved, then spike action potential again takes off and a new cycle starts.

This phase 4 or slow progressive depolarisation which occurs during diastole is called the slow diastolic depolarisation. This phase is very important for generating automaticity or pace making activity and is the characteristic of cells of nodal tissue. Normally the rate of rise of diastolic depolarisation is 15 to 20 mV/sec in SA node, whereas that of AV node and other cells are appreciably slower. In some cardiac cells this phase is flat with maintaining the resting membrane potential fixed, at −90 mV.

Acetylcholine causes a three fold inerease in the rate of loss of the positively charged K^+ from the cell with resulting more negativity of inside of the cell and thereby hyperpolarises the cell. Atropine prevents this membrane action of ACh even though it is present. Vagus stimulation, like ACh, also abolishes the slow diastolic depolarisation and indeed hyperpolarize the cell and abolishes the spontaneous rhythm. Sympathetic stimulation increases the rate of diastolic depolarisation and thus the rate of heart rate.

Different Types of Action Potential of Different Types of Cardiac Cells

In heart, there are different types of cardiac cells and therefore, there are different types of action potentials. This is due to variability in the number of different ion channel (genes expressed) in individual cells. The cells of His-Purkinje system have action potential of very long duration. The atrial cells have action potential of short duration than that of His-Purkinje system. The cells of the sinus and AV node display the phenomenon of spontaneous slow diastolic depolarisation in phase 4 and thus the RMP spontaneously reach the threshold value for regeneration of new action potentials. The cells of AV node, bundle of HIS and Purkinje system has also the slow diastolic depolarization phase in action potential and pace making activity. But the rate of spontaneous firing is usually fastest in the SA nodal cells and serves as the natural pacemaker of the heart suppressing the pace making activity of others.

Modern technique helps us to study the electrophysiological behaviour of single ion channel protein and identify the channels that may be particularly responsible for the particular pathological condition. For example, mutation in the genes which is responsible for encoding the repolarizing K^+ channel (both 'transient outward' and 'delayed rectifier' channels) is responsible for congenital long QT syndrome. Some K^+ channels remains quiescent when intracellular ATP store is normal and they become active when ATP store is depleted. Such ATP - inhibited K^+ channel also sometimes is important to produce arrhythmia in myocardial ischaemia. Most antiarrhythmic drugs affect more than one ion channels and thus usually exert multiple action which can be beneficial or harmful in individual patient (Fig. 5.22).

NERVE SUPPLY OF HEART

The heart is supplied by both the parasympathetic and sympathetic nerve with their afferent and efferent fibres and control the different cardiac functions. Both these nerves are also responsible for cardiac pain and different cardiac reflexes. To supply the heart both the afferent and efferent fibres of the sympathetic and parasympathetic nerves form the cardiac plexus from where the heart derives its nerve supply. This cardiac plexus is formed by the interlacement of nerve fibres and nerve cells and is situated at the base of the heart. This plexus is consists of

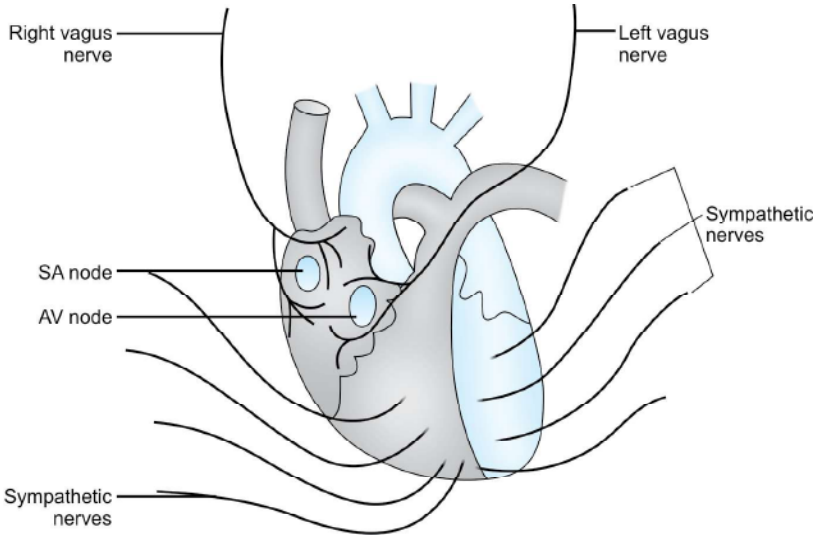

Fig. 5.22: Sympathetic and parasympathetic nerves supplying heart

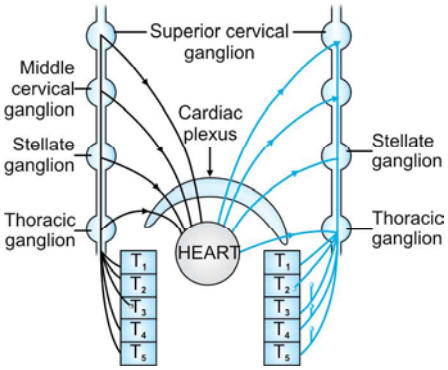

Fig. 5.23: Schematic diagram of sympathetic supply of heart. Red line indicates sympathetic motors (efferent) and green line indicates sympathetic sensory (afferent)

two parts − superficial and deep. The atria and the conducting system of the heart are innervated by both the sympathetic and parasympathetic nerves. On the otherhand, ventricular muscle is supplied only by the sympathetic nerves.

The afferent nerves from the heart passes both through the parasympathetic and sympathetic nerves as follows:

i. From the heart → through vagus, and from the aortic arch→ through aortic nerve. Both are parasympathetic.
ii. From the heart → through superior, middle, stellate and first four thoracic sympathetic ganglion → through white rami communicants → posterior nerve root and posterior dorsal ganglion → to the posterior horn cells.
iii. From the carotid sinus → through the sinus nerve, a branch of glosso pharyngeal nerve (parasympathetic). The efferent nerves supplying the heart also run through both the parasympathetic (vagus) and sympathetic nerves, as follows.

The efferent preganglionic fibres of parasympathetic nerve arise from the nucleus ambiguous and from the dorsal nuclei of vagus in the brain. They are situated on the floor of the 4th ventricle in the medulla. After their origin they descend downward as the vagus nerve. Then the cardiac fibres separate from the main trunk of vagus nerve in the neck and proceed towards the heart to from the deep and superficial cardiac plexuses with the fibres from the sympathetic nerve. After that the parasympathetic fibres finally reach the atrial muscle where they make the synaptic connections with the cells in the peripheral parasympathetic ganglion, which are situated near the SA and AV node. From the ganglion, postganglionic parasympathetic fibres arise and supply the SA and AV node and also extend between the atrial muscle fibres (Fig. 5.23).

The efferent preganglionic sympathetic fibres start from the lateral horn cells of T_1 to T_5 or T_6 thoracic segments of spinal cord. These are called the spinal sympathetic cardiac centres. Preganglionic sympathetic fibres then enter the sympathetic chain after coming out via the ventral root of the T_1 to T_5 spinal nerve and the white rami communicants. After that these preganglionic fibres make synapses with the ganglionic cells situated in the superior, middle and inferior cervical ganglia and the upper thoracic ganglia from where the postganglionic sympathetic fibres arise. In human beings the last cervical ganglion and the first thoracic ganglion fuses together to form the stellate ganglion. Then the postganglionic fibres, arising from the superior cervical, middle cervical, and stellate ganglion pass directly to the heart and form the cardiac plexus.

Cardiac branches from the superior cervical sympathetic ganglion does not contain any afferent fibres. It contains only the efferent postganglionic sympathetic fibres. Otherwise, all the cardiac branches of vagus and sympathetic nerve contain both the afferent and efferent fibres. In contrast to vagus, the exact location of the higher cardiac sympathetic centre in the brain is not yet fully known. Usually, the spinal sympathetic cardiac centres are controlled by the higher centres of brain like the cortex, thalamus, hypothalamus, etc.

The dorsal motor nucleus of vagus in the medulla is the cardioinhibitory centre and it continuously transmits tonic inhibitory vagal impulses to the heart. It is because this higher parasympathetic centre gets direct connection from the afferent fibres, coming from the peripheral baroreceptors and chemoreceptors through the sinoaortic nerves. Reflex bradycardia during the rise of systemic blood pressure is due to the stimulation of this cardioinhibitory vagus centre by the affarent impulses from baroreceptors. On the other hand, tachycardia during the fall of BP is due to

the inhibition of this cardioinhibitory centre i.e. withdrawal of vagal tone from this cardioinhibitory centre. Under such condition sympathetic cardiac centre also take the upper hand secondarily (Fig. 5.24).

As mentioned earlier, the SA node develops from the right sided embryological structure. So, it receives innervation from the right vagus nerve (parasympathetic) and the right stellate ganglion (sympathetic). Similarly also as the AV node is developed from the left sided embryological structure, so it is supplied by the left vagus nerve (which produce variable degree of nodal conduction block) and the left stellate ganglion which have a greater effect on the contractility of heart. Thus in general, the sympathetic and the parasympathetic supply via the left stellate ganglion and the left vagus nerve have a greater effect on the contractility of heart and the sympathetic and parasympathetic supply via the right stellate ganglion and the right vagus nerve have a greater effect on the heart rate.

The pain of angina pectoris or myocardial infarction is commonly felt at the retrosternal region and radiates along the inner side of the left arm. Sometimes, this pain is referred to the right arm or the both arms. Some patients experience pain of myocardial ischaemia in the neck or epigastric region. This is because the impulses of these pain are conveyed by the sensory sympathetic cardiac fibres and reach the T_1 to T_5 segment of the spinal cord, usually through the dorsal root ganglia of the left side. Hence, the pain is referred to the left arm. Sometimes, the connector neurons of the spinal cord conduct the impulses to the right side of the corresponding segments of the spinal cord. This may explain why the pain is occasionally referred to the right side or both the sides. Since, the embryonic heart is initially located in the neck and later descends in the thorax, so it is not unlikely that the pain fibres for the heart reach from the upper cervical spinal segment via the sympathetic nerve. So, sometimes the pain is also felt in the neck region.

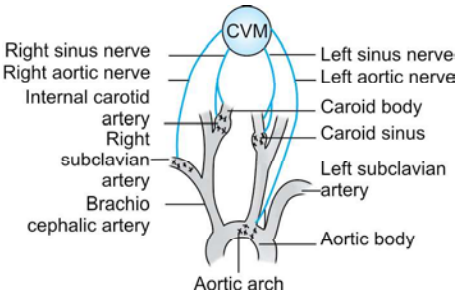

Fig. 5.24: The baroreceptors and chemoreceptors in the aorta and internal carotid artery with aortic and sinus nerves. CVM = Cardiovascular medullary centre

The parasympathetic efferent fibres work through the muscarinic (M_2) receptors and the sympathetic efferent fibres work through the β-receptors on the myocardial cells. The action of both the parasympathetic and sympathetic nerve balances each other. But, under normal resting condition in the adult, the parasympathetic tone predominates over the sympathetic tone. The efferent parasympathetic diminishes the heart rate and coronary blood flow (secondary effect). Larger branches of coronary arteries are predominantly supplied by sympathetic nerves. Whereas the smaller branches are supplied by the vagus nerves. Sympathetic efferent increases the heart rate and cardiac output. It produces vasodilatation of the intramuscular branches of the coronary artery and vasoconstriction of the epicardial arteries.

There are three types of affarent receptors through which parasympathetic reflexes work. Type A receptor is supplied by the myelinated vagal affarent fibres and is responsible for the control of heart rate. Type B receptor is also supplied by the myelinated affarent vagal fibres and is responsive to atrial stretches and changes in volume than heart rate. Type C receptors are also responsive to the changes in pressure. All the above mentioned receptors are located in the atrium. There are also receptors in the ventricle which are supplied by the myelinated vagal affarent fibres and is responsive to the changes in the rate of rise of ventricular pressure and send impulses at the onset of ventricular ejection.

The sympathetic fibres form an extensive plexus or network over the epicardium of the heart and penetrate the myocardium along the various branches of the coronary vessels. Sympathetic innervation on ventricle is more dense than atrium, where as the parasympathetic innervation is more dense on atrium than ventricle.

Sympathetic neurotransmitter or agonist work through the β-adrenergic receptors which are located on the myocardial cell surface. The attachment of sympathetic agonist with the β-receptor induces a conformational changes of this receptor and permits interaction of this receptor with the stimulatory G-proteins (Gs) at the inner site of the cell membrane. The G-protein are in the family of heterotrimeric structure, and composed of α, β, γ subunit. Binding of Gs protein with the receptor causes dissociation of the α-subunit from the remaining β − γ complex of G-protein, with the concomitant expenditure of guanosine triphosphate (GTP) to GDP. This broken α-subunit then stimulates the adenylcylase located on the cytosolic side of the membrane which hydrolysed ATP to cAMP. Thus the increase in cAMP, in turn act on certain Protein Kinases (PK_A) which phosphorylates the various intracellular proteins, especially those are related to SR and ultimately raise the intracellular Ca^{2+} concentration. The phosphorylation of many other functional proteins, including troponin and phospholamban also help to interact with Ca^{2+}, resulting in increased force of contraction (Fig. 5.25A).

The parasympathetic stimulation works through the neurotransmitter named acetylcholine (ACh) which binds with muscarinic M_2 receptor, located on the myocardial cell membrane. The binding of ACh with M_2 receptor causes conformational changes of this receptor and in turn allow the binding of receptor

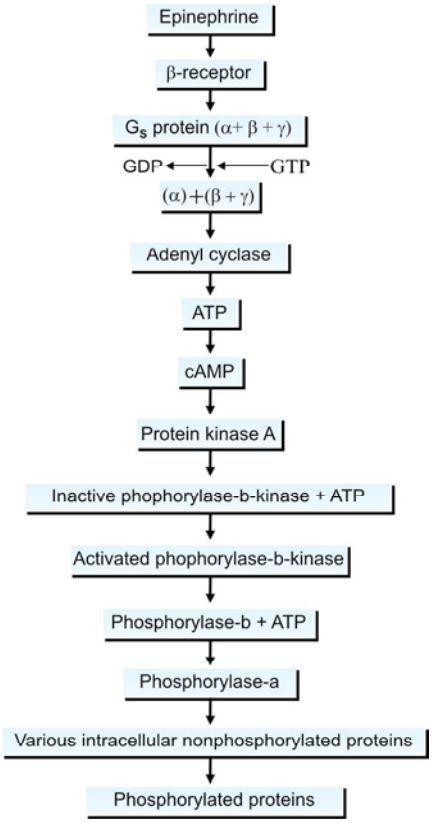

Fig. 5.25A: Schematic diagram showing the mechanism of action of sympathetic agonist through beta-receptor

with the inhibitory Gi protein. This activates the Gi protein by dissociating the α-subunit from it. The activated Gi protein inhibits adenyl cyclase leading to decrease in cAMP synthesis and in turn inhibition of PK_A and its sequelae described above.

Finally, the ACh released from the parasympathetic postganglionic nerve terminals that lie in close proximity to sympathetic postganglionic nerve terminals may also inhibit the release of norepinephrine and this in turn decrease the β-receptor stimulation and ultimately cAMP levels.

CORONARY BLOOD FLOW AND VARIATIONS OF IT DURING DIFFERENT PHASES OF CARDIAC CYCLE

The heart muscle is rich in blood supply. The predominance of supply of heart by right coronary artery is seen in about 50% of cases. Whereas, in about 20% of human heart the predominance is by the left coronary artery. But, in about 30% of cases both the coronary arteries predominate. The last group in which the nature of supply is not made predominantly by either right or left coronary artery is least vulnerable to the cardiovascular disorder.

Anatomically the coronary arteries are not the end arteries. But functionally the coronary arteries are the end arteries, though anatomical anastomoses are present and become active under the pathological state. In adult human heart each cardiac muscle fibre receives one capillary twig, whereas in foetal life one capillary twig supplies 4 to 6 muscle fibres. During rest, for each 100 gm of left ventricular musculature the left coronary inflow is 65 to 85 ml/min and the total coronary blood flow is 250 ml/min. This is about 5% of the total cardiac output. While during heavy exercise this coronary inflow rises to 5 folds than that of the rest, i.e. 300 to 400 ml/100 gm/min or 800 to 1000 ml/min. The myocardial arteriovenous differences of O_2 content at rest is also very high and is about 10 to 15 ml per 100 ml of blood (desaturation is 70%). This signifies that the extraction of O_2 from arterial blood by the cardiac muscle is very high. Normally, the myocardial tissue extracts about 65 to 70% of O_2 supplied by the myocardial arterial blood. Thus, if the arterial O_2 content is 20 ml per 100 ml, then the blood in the coronary sinus which drains the left ventricle contains only 6 to 7 ml of O_2 per 100 ml, even when the individual is at rest. The ratio of systolic coronary blood flow to diastolic coronary blood flow is approximately 0.22 at rest which is increased to 0·9 during exercise (Fig. 5.25B).

Cardiac Cycle

The two atriums of the heart contract and relax simultaneously in a cyclical fashion like the two ventricles. But when the atria contract, the ventricles dialate and vice versa. The duration of systole

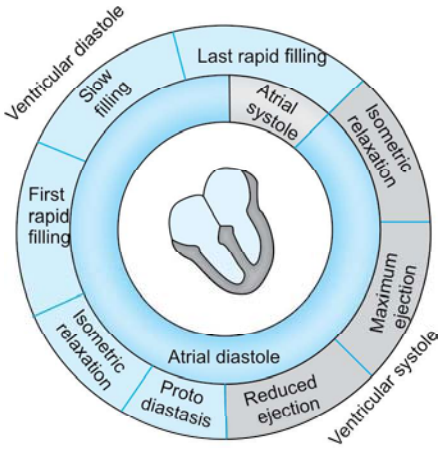

Fig. 5.25B: The cardiac (atrial and ventricular) cycle

and diastole of atrium is 0.1 sec and 0.7 sec, respectively. Whereas, the duration of systole and diastole of ventricle is 0·3 sec and 0.5 sec, respectively. However, though the atrium and ventricle have the separate cycle of function, but mainly the ventricular cycle will be considered here as the cardiac cycle and will determine the variations of coronary blood flow during the different phases of it. It starts at point A and signifies the later half of ventricualr diastole with filling of blood from atrium. This blood comes to the atrium at its phase of diastole during the time of previous ventricular systole. In the middle of ventricular diastole when the ventricular pressure goes below the atrium or atrial pressure exceeds than that of the ventricle then the atrioventricular valves (tricuspid and mitral) open (point A) and blood enters the ventricular chamber. At this stage both the atrium and the ventricle is in diastole and blood flows passively to ventricle from atrium which accounts for roughly 75% of the total ventricular filling. The rest of the ventricular filling is contributed by the active atrial contraction or atrial systole (point A′) which begins with the depolarisation of the SA node and corresponds to the P wave of ECG. Thus, the curve of the ventricular filling, shown in figure by the AB segment, depends on the compliance of ventricle and the venous

return to atrium. Passive ventricular filling will be hampered if the ventricle and its wall becomes less compliant (such as muscular hypertrophy, fibrosis and many other causes) and if there is hypovolaemia. In these circumstances atrial systole is very important to maintain the adequate ventricular filling (Fig. 5.26).

After the ventricular filling at its diastole, ventricular systole starts with the closure of the tricuspid and mitral valve and corresponds to the R-wave on ECG and point B on the picture. The first part of the ventricular systole is called isovolumic or isometric contraction (shown in figure by BC segment), where all the valves are closed and the intraventricular pressure rises sharply without any change in the intraventricular volume. In the 2nd part of the ventricular systole at the point when the developed pressure within the two ventricles exceed than that of the pulmonary artery and aorta (point C), then the pulmonic and aortic valves open and allow the blood to flow into their respective circulations. This second portion of the ventricular systole is called the ventricular ejection phase (shown in figure as CE segment). It has an initial rapid phase (point C to D) or maximum ejection phase, characterised by maximal forward flow of blood. Then, it gradually tapers, because as the systole progresses (point D to E) the ejection phase is slowly reduces.

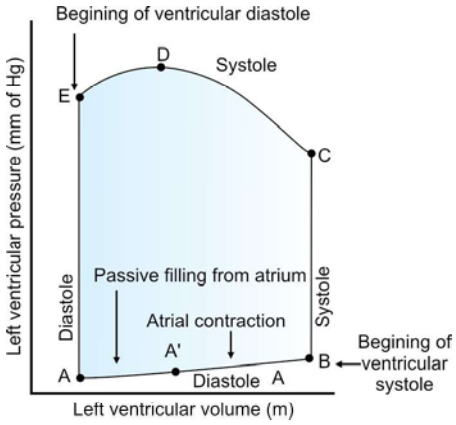

Fig. 5.26: The changes of left ventricular volume and pressure during different phases of cardiac cycle. AB = Ventricular diastole, AA′ = Atrial diastole, A′B = Atrial systole

After systole, the ventricular diastole begins at the point E with the closure of the pulmonic and aortic valve. This is due to the fall of intraventricular pressure below that of the aorta and pulmonary artery. The EA segment of ventricular diastole is called the isovolumetric or isometric relaxation phase, because during this period the pulmonary and aortic valve closes, but the atrioventricular valve does not open and no flow of blood occurs into the ventricle from atrium. After beginning of ventricular diastole as point E. The ventricular pressure continues to drop until they fall below that of the right or left atria. At the point A during ventricular diastolic period the atrioventricular valve (tricuspid and mitral) opens and blood starts to flow from the atrium to the ventricle. Thus, the ventricular filling commences and the cycles repeat themself. This point E corresponds to the end of the T wave on the ECG.

During systole the peak left ventricular pressure is about 120 mm of Hg and the peak right ventricular pressure is about 25 mm of Hg. At the end of the diastole the volume of the ventricles is 130 ml and it is called the 'end diastolic ventricular volume' (EDVV). About 50 ml of blood always remains in each ventricle after ejection at the end of the systole. This is called the 'end systolic ventricular volume' (ESVV). The percent of end diastolic ventricular volume which is ejected with each stroke is called the ejection fraction and is about 65 to 85% in a normal healthy individual.

The cardiac muscle has unique property of depolarisation and repolarisation which is faster than that of any other muscles of the body. This is more prominent when the heart rate increases. The duration of ventricular systole decreases from 0·3 sec at the heart rate of 75/ minute to 0·2 sec at the heart rate of 200/ min. This shortening is mainly due to the decrease in duration of systolic ejection period. However, the duration of systole is much more fixed than that of diastole. So, when the heart rate is increased then the duration of diastole is shortened to a much greater extend than that of the systole. For example, at a heart rate of 75/min, the duration of diastole is 0·5 sec. Whereas at a heart rate of 200/min, it is only 0·1 sec. This fact has important physiologic and clinical implications. This is because it is only during diastole that the heart muscle rests and coronary blood flow to the subendocardial portions (which is most vulnerable to infarction) occur. Furthermore, most of the ventricular filling occurs in diastole. Thus up to the heart rates of about 180 per minute, the ventricular filling and (Fig. 5.27) cardiac output is adequate, but as long as there is ample venous return. However, at very high heart rates (>180) ventricular filling may be compromised to such a degree even with adequate venous return that CO falls and symptoms of heart failure develop.

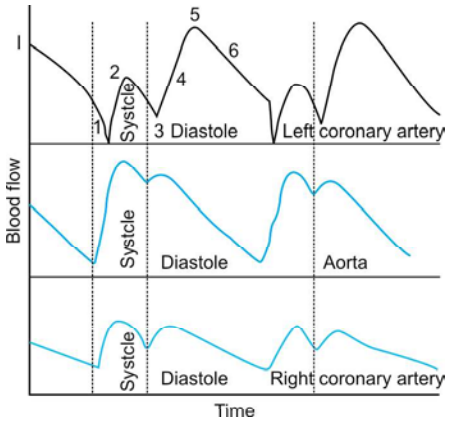

Fig. 5.27: The blood flow in the aorta, left coronary artery and right coronary artery during various phases of the cardiac cycle
1 = Isometric ventricular contraction (BC segment),
2 = Maximum ejection phase (CD segment),
3 = Reduced ejection phase (DE segment),
4 = Isometric relaxation phase (EA segment),

6 = Later part of diastole (2nd part of AB segment)

Variation of Coronary Inflow with Cardiac Cycle

The ventricular contraction affects the coronary circulation in two ways: (a) by altering the aortic pressure which produces the pressure head for coronary circulation and (b) by exerting a variable degree of compression on the coronary vessels by myocardium. Thus, the following variations of coronary inflow are seen during the ventricular contraction and relaxation.

i. During the phase of isometric ventricular contraction (BC segment), the coronary flow sharply falls and reaches minimum or even falls below the level of zero due to the back flow. This is because at this stage the aortic pressure is minimum and this is due to no flow of blood in the aorta and the subsequent compression on the coronary vessels by myocardium is maximum.

ii. During the maximum ejection phase (CD segment) coronary inflow rises sharply due to the sudden rise of aortic pressure. This is again due to the high aortic inflow which reaches its maximum.

iii. During the reduced ejection phase (DE segment) the coronary inflow again falls below the previous level. This is because gradually the aortic pressure is falling, but the compression on coronary vessel by myocardium is still continued.

iv. During the phase of isometric relaxation (EA segment) the coronary inflow again sharply rises. This is because the aortic pressure in this phase is still fairly high, though no extra blood flows into the aorta or pulmonary artery from ventricle but the compression of myocardium on coronary vessel is minimum. Maximum coronary filling takes place during this phase due to the maximum fall of coronary vascular resistance or compression in this period.

v. During the rapid ventricular filling phase (1st part of AB segment or the AA′ segment) the coronary inflow again continues to rise, but slowly. This is because the relaxation of the myocardium continues and the vessels begin to open.

vi. During the later part of diastole (i.e. later part of AB segment or the A′B segment) the coronary inflow again slowly diminishes. This is because the aortic pressure is failing and the coronary vessels are stretched due to the gradual filling of heart and the consequent elongation of the cardiac muscles (Fact file-I).

Neverthless, from the above discussion the conclusion can be drawn that about 80% of the total coronay blood flow occurs in diastole and this is because though during this period the mean aortic pressure head is low, than systole, but the true coronary vascular resistance caused by the myocardial compression on the vessels is still even lower.

During the ventricular isometric contraction phase the blood flow through the right coronary artery sharply falls and then rapidly rises again in the maximum ejection phase. Then, it again falls during the reduced ejection phase. During the isometric relaxation phase the right coronary inflow rises again, but not so steeply high like the left coronary inflow.

In conclusion, it is said that the coronary blood flow is dependent on the pressure gradient which is principally guided by the difference between the mean aortic pressure and the resistance of coronary arteries due to the compression by the ventricular musculature. The coronary blood flow through the left ventricle is maximal during the early diastole, corresponding to the period of isovolumic relaxation which accompanied by the minimal coronary vascular compresson by the myocardium. However, the coronary blood flow through the right coronary artery is maximal during the period of peak systole. This is because the developed right intramyocardial pressure and consequently the vascular compression by the right ventricle are considerably less than the pulmonary arterial pressure and thus allowes for anterograde flow through right coronary artery during both systole and diastole of right ventricle (Table 5.1).

Although the blood flow through the left coronary arteries supplying the subendocardial portion of the left ventricle occurs only during diastole, but as the contractile force during systole is sufficiently dissipated in the more superficial portions of the left ventricular myocardium, i.e. epicardium, so some blood flow

FACT FILE - I

So, greater coronary inflow takes place in diastole than systole due to less compression of the coronary vessels during relaxation of the cardiac muscle and diminution of the intramural tension. The left coronary inflow during systole is affected much as the pressure difference between the aorta and the left ventricle becomes −2 mm of Hg. But the right coronary inflow during systole is not so much affected as the pressure difference between the aorta and the right ventricle is 95 mm of Hg.

Table 5.1: Pressure in aorta, left coronary artery (LCA) and right coronary artery (RCA)

	Pressure in aorta (mm of Hg)	*Pressure in LV and LCA (mm of Hg)*	*Pressure difference between aorta and LCA (mm of Hg)*
Systole	120	122	−2
Diastole	80	0	80
	Pressure in aorta (mm of Hg)	*Pressure in RV and RCA (mm of Hg)*	*Pressure difference between aorta and RCA (mm of Hg)*
Systole	120	25	95
Diastole	80	0	80

LV = Left ventricle, LCA = Left coronary artery, RCA = Right coronary artery

in this region also occurs during systole through out the cardiac cycle. Since the ventricular diastole is more shorter, when the heart rate is high, so the left ventricular coronary flow is further reduced during tachycardia. Thus, as during both the systole and diastole no blood flow occurs through the myocardium and the subendocardial portion of the left ventricle during tachycardia, so this region is maximally prone to ischaemic damage and is the most common site of myocardial infarction. Blood flow to the left ventricular musculature is further decreased in patients with stenotic aortic valves. This is because in aortic stenosis the pressure in the cavity of left ventricle must be much higher than that of the aorta to eject the blood. Consequently, the coronary vessels are severly compressed during systole and there is less development of pressure (Fact file- II) head in the aorta for coronary flow due to less ejection of blood in the aorta. So, patients with this disease are particularly prone to develop symptoms of myocardial ischaemic, in part because of the compression of the coronary arteries, in part because of the myocardium requires more O_2 to expel blood through the stenotic aortic valve and in part because of the less coronary flow due to less ejection of blood in the aorta. Coronary flow is also reduced when the aortic diastolic pressure is low. The rise in venous pressure in condition such as congestive heart failure also reduces the coronary flow because it decreases the effective coronary perfusion pressure.

The difference between the minimum (resting) and the maximal coronary blood flow is termed as the 'coronary flow reserve'. Under normal circumstances the myocardial wall pressure is highest near the endocardium and lowest near the epicardium. Thus, a gradual negative gradient of coronary blood flow was seen to exist during the ventricular systole from epicardium to endocardium. So, the outer layers of ventricular wall receives a larger share of blood flow and innermost wall presumbly receives no flow of blood at the peak of systole and thus make the endocardium relatively more sensitive to ischaemia. Thus, the endocardial blood flow is greatly influenced by ventricular relaxation during diastole which decreases the myocardial wall pressure and enhances the coronary flow from epicardium to endocardiaum. So, the endocardium is more sensitive to pathological changes like hypotension, coronary occlusion, hypertrophy, aortic stenosis, etc. (Fig. 5.28).

Regulation of Coronary Blood Flow

Like renal and cerebral arteries, coronary arteries also have the autoregulation. This autoregulation maintains constant coronary blood flow within perfusion pressure ranging between 50 to 120 mm of Hg and is independent of myocardial O_2 demand. Coronary perfusion pressure is defined as

FACT FILE - II

Factors influencing the coronary circulation

1. Mean aortic pressure:
   It is the chief motive force for driving blood into the coronary vessels. Any alteration of aortic pressure will, therefore, cause parallel changes in coronary circulation.
2. Cardiac output :
   Obviously, the coronary inflow is directly proportional to the cardiac output. Increased output raises the coronary flow in two ways : (a) raising the aortic pressure, (b) by reflex inhibition of the vagal vasoconstrictor tone.
3. Metabolic factors:
   With increased metabolism of the heart, the O_2 requirement and subsequently the coronary circulation is also increased. There is a casual relationship between the myocardial metabolic activity, O_2 consumption and coronary blood flow.
4. CO_2 and O_2:
   If O_2 supply to the heart muscle is decreased, then the coronary flow is increased. But, if the supply of O_2 is more than requirement, then the coronary circulation is decreased. Similarly, CO_2 stimulates the coronary flow. When the CO_2 concentration in the blood is increased, then coronary flow is also increased in first stage in order to maintain the total O_2 requirement of the cardiac muscle. If this state prevails further, the coronary flow is decreased abruptly and the heart stops in diastole.
5. Effects of ions :
   K+ in low concentration dilates the coronary vessels, whereas K+ in higher concentration constricts. Ca^{2+} in therapeutic doses increases the flow and O_2 consumption of the cardiac muscle.
6. Polypeptides :
   Angiotensin II is an active octapeptide which causes arteriolar constrction of the skin, kidney, brain and also in coronary vessels. Bradykinin is claimed to cause coronary vasodilatation but still its physiogical role is not proved.
7. Adenine neucleotides :
   It is discussed in the test.
8. Cardiac sympathetic and parasympathetic nerves :
   Stimulation of the cardiac sympathetic fibres from the stellate ganglion produces increased coronary flow. This is mainly due to the release of norepinephrine which causes coronary dilatation and increased coronary flow.
9. Heart rate :
   When the heart rate is increased minute cardiac output and aortic blood pressure is increased, but the stroke volume decreases. The phasic coronary blood flow and O_2 consumption per beat decrease, but the minute coronary flow and O_2 consumption per minute are increased. With the increase of heart rate, O_2 consumption of the heart muscle is increased and is maintained normally through increase of minute flow.
10. Pitressin or vasopressin :
    It causes increased coronary resistance and diminution of coronary flow.
11. Temperature :
    With rise of body temperature, body metabolism and O_2 requirement is increased. Therefore, to meet this O_2 demand coronary flow also increases.
12. Viscerocardiac reflex :
    The coronary flow is markedly decreased during visceral distension and it is often encountered in a patient with ischaemic heart disease.
13. Anaemia :
    In anaemia, the coronary flow is increased sharply in order to maintain the normal O_2 need of the cardiac muscle.

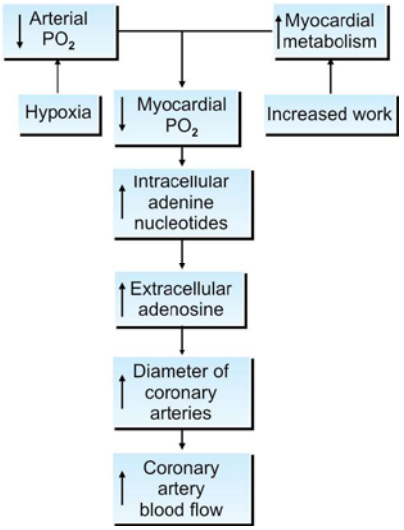

Fig. 5.28: The local mechanism of control of myocardial blood flow

the difference between the diastolic aortic pressure and the LV end diastolic pressure. Sympathetic adrenergic stimulation causes the coronary artery dilation. This can be explained by the following way. Unopposed α_1-adrenergic stimulation produce coronary vasoconstriction and unopposed β-adrenergic stimulation cause coronary vasodilation. But, when the both act at the same time, then the β-receptor's vasodilating properties predominates over the α-receptor's vasoconstricting properties.

Sympathetic stimulation also increases the coronary blood flow due to their stimulant effect on the both cardiac contractile force and metabolism. But the increase in coronary blood flow secondary to metabollic changes in heart is of far less quantitative significance than that caused by the increased discharge of impulse from the sympathetic nerves and receptor stimulation which occur simultaneously.

The stimulation of parasympathetic muscarinic receptor also produce coronary vasodilation. Though vagi are not proven to supply the coronary vessels, but vagal stimulation, sufficient to cause cardiac arrest, does increase coronary flow. This effect is probably due to the lessened intramural tissue pressure and lessened extravascular resistance, caused by the reduction of force of contraction. There are other various chemical mediators which control the coronary vascular tone. These are O_2, CO_2, K^+, histamine, prostagladins and adenosine. Among these adenosine is the most important chemical mediator which couples the coronary blood flow to the O_2 consumption and demand.

Adenosine arises from the adenine nucleotides (ATP, ADP) of myocardial cells which are disrupted by hypoxia. This nucleoside, adenosine, does traverse the myocardial cell membrane and gain access to the resistance vessels including the precapillary sphineters of the coronary vascular system and causes dilation. Like adenosine the ATP, ADP are equally potent vasodilator, but is not permeable to cell membrane. In the blood, adenosine is destructed by adenosine deaminase to inosine and hypoxanthine which have no vasodilating properties. Like cerebral circulation coronary circulation (like brain) is also conspicuous in manifesting self control on vascular resistance which is effected by chemical rather than by nervous influences. Thus with increase metabolism of heart the O_2 requirement is increased and the circulation is greatly increased. Similarly, CO_2 also stimualtes the coronary blood flow. For the increased coronary blood flow this increased O_2 requirement acts through hypoxia and adenosine mechanism (Fig. 5.29).

Study of Coronary Blood Flow

The coronary blood flow has been viewed by angiography. It also can be measured by inserting a catheter into the coronary sinus, and by taking sample and applying the Kety method on the heart. A number of techniques, utilising radionuclides, radioactive tracers, etc, that can be detected with radiation detectors over the chest, also have been used to study the regional blood flow in the heart. It detect the areas of ischaemia and infarction as well as evaluate the ventricular function.

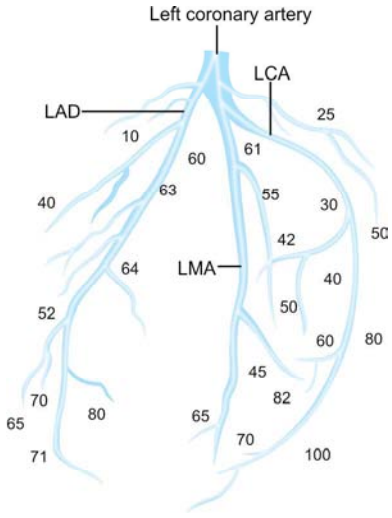

Fig. 5.29: The myocardial perfusion pattern following injection of 133Xe into the left main coronary artery. The numbers indicates the flow values in ml/100 gm/minute, measured by scintillation detector.
LAD = Left anterior descending artery,
LCA = Left circumflex artery,
LMA = Left marginal artery.

When radio nuclides such as thallium 201 (^{201}TI) is used, it is forced into the cardiac muscle cells by Na^+-K^+ ATPase pump and equilibrate with the intracellular K^+ pool. For the first 10 to 15 minutes after IV injection, thallium 201 distribution is directly proportional to the myocardial blood flow. Then, the areas of ischaemia can be detected by their low uptake of thalium 201 in the myocardial tissues by special instrument. The uptake of this isotope by heart is often determined soon after exercise and again several hours later to bring out areas in which exertion leads to compromised flow. Conversely, radiopharmaceutical agent such as technetium 99 m pyrophosphate (^{99m}Tc - PyP) also can be used which is selectively taken up by the infarcted tissue by an incompletely understood mechanism and make the infarct area to stand out as 'hot spots'on CT scans of the chest. The coronary angiography also can be combined with measurement of ^{133}Xe washout technique to provide the detailed analysis of the coronary blood

flow. Radiopaque contrast medium is first injected into the coronary arteries and X-rays are used to outline their distribution. The angiographic camera is then replaced with a multiple crystal scintillation camera and ^{133}Xe washout is measured. An example of normal flow distribution after injection in a left coronary artery is shown in figure.

Myocardial Metabolism

To maintain the cell integrity by controlling the Na^+, K^+ ionic gradients across the cell membrane and for contraction of myocardium, energy is needed. Heart uses ATP and creatine phosphate as the source of this energy to perform this mechanical and chemical work such as contraction and ion transport. Substrates like glucose, lactate, fatty acids are usually used by the heart muscle to get its metabolic energy source of ATP. During fasting, the free fatty acids are the main substrate for the energy source of heart. When carbohydrates is used as energy source the myocardial respiratory quotient (RQ) exceeds 0·9. But, fasting lowers the RQ to 0·7. This characterises that fat is metabolised during fasting.

When cardiac muscles contract, the ATP is broken down to ADP and inorganic phosphate (Pin) is produced. But, ATP is again rapidly synthesized by the Lohmann reaction from creatine phosphate.

Lohman reaction

$$ATP \xrightarrow{\text{Actomycin}} ADP + Pin \text{ (energy)}$$

$$ADP + CP \xrightarrow{\text{Creatine phosphotransferase}} ATP + C \text{ (creatine)}$$

When the heart is subjected to hypoxia, then the creatine phosphate concentration drops strikingly and the ATP/ADP (Fig. 5.30) ratio of the myocardium falls precipitously. The myocardial cells contain phosphorylase in an inactive form, i.e. phosphorylase-b. This inactive form can be activated by the cAMP to phosphorylase-a. The cAMP is formed from ATP by the enzyme adenyl cyclase which is again activated by adrenaline. Phosphorylase-a breaks down the glycogen to yield glucose-1-phosphate which is converted to glucose-6-phosphate. This compound is then broken down in myocardium by glycolysis to give pyruvic acid (in aerobic metabolism) which again enter the citric acid cycle to yield further energy by the synthesis of ATP (aerobic metabolism).

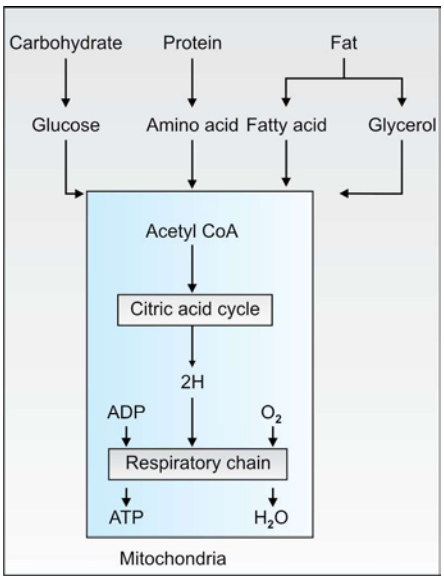

Fig. 5.30: The myocardial metabolism

The inner membrane of mitochondria consists of multiple folds and contain multiple enzymes which are needed for the aerobic metabolism or the citric acid cycle. The mitochondria also contains cytochrome system which are involved in the electron transport and ATP formation. Thus, mitochondria and O_2 become the sources of continuous supply of energy in the form of ATP for continuous cardiac function (Fact file - III).

Glucose is metabolised by the glycolytic pathway to yield pyruvate. Then pyruvate is metabolized to lactate when O_2 supply is inadequate. But if the supply of O_2 is adequate then pyruvate enter into the mitochondria for citric acid cycle. In the first step of citric acid cycle pyruvate is enzymatically transformed to acetyl-co-A and NADH. The enzyme responsible for this transformation of pyruvate to acetyl-coA is pyruvate dehyogenase which is a highly step limiting regulated

FACT FILE - III

The net production of ATP during the metabolism of glucose or glycogen to pyruvate depends on whether the metabolism occurs aerobically or anaerobically. During oxidation of glucose through Embden-Meyerhof pathway, the conversion of 1 mol of phosphoglyceraldehyde (PGD) to phosphoglycerate (PG) generates 1 mol of ATP, and the conversion of 1 mol of phosphoenolpyruvate to pyruvate generates another 1 mol of ATP. Therefore, as 1 mol of glucose produces the 2 mol of puruvate during its metabolism through E-M pathway, so 4 mol of ATP is generated. All these reactions occur in the absence of O_2. On the otherhand, 1 mol of ATP each is used during the conversion of fructose-6-phosphate to fructose-1-6-diphosphate and phosphorylation of glucose when it enters the cell. Since, when the puruvate is formed from glucose through E-M pathway the net gain of ATP is only 2 mol.

In E-M pathway of glucose metabolism during conversion of phosphoglyceraldehyde (PGD) to phosphoglycerate (PG) 1 mol of NAD^+ is converted to 1 mol of NADH. In the presence of O_2 this H^+ of NADH is transferred to cytochrome system. While in the absence of O_2, pyruvate accepts this hydrogen from NADH, forming NAD^+ and lactate where this NAD^+ is again used for the conversion of PGD to PG. Thus, in absence of O_2 pyruvate can not enter the citric acid cycle.

Pyruvate + NADH $\rightleftharpoons$ Lactate + NAD^+

In this way, glucose metabolism with production of lactate and energy may continue for a while without O_2.

During aerobic glucose metabolism (glycolysis) the net production of ATP is 19 times more than the two ATPs, formed under anaerobic conditions. Six ATPs are formed from two NADH (3 ATPs from one NADH) by oxidation through flavoprotein - cytochrome system. These NADHs are formed when 2 mol of PGD is converted to PG. Then, six ATPs are formed from the two NADHs which are produced when 2 mol of pyruvate is converted to acetyl-CoA for the pyruvate to enter into the citric acid cycle. After that 24 ATPs are formed from the citric acid cycle. Of these, 18 are formed from oxidation of six NADH, 4 from oxidation of two FADH, and 2 from succinyl-CoA when it is converted to succinate. This succinyl-CoA to succinate reaction actually produces GTP, but the GTP is converted to ATP. Thus the net production of ATP per mol of glucose metabolism aerobically by the E-M pathway and the citric acid cycle is 2 + (2 × 3) + (2 × 3) + (2 × 12) = 38.

enzyme found in the inner mitochondrial membrane. Then acetyl-CoA in citric acid cycle is ultimately broken down to CO_2 and H_2O yielding NADH, $FADH_2$ and 2ATP. These NADH and $FADH_2$ then enter in the respiratory chain (cytochrome system) where they are oxidised by giving up H^+. This hydrogen atom is carried out by the cytochrome system or respiratory chain and at the end of the cytochrome system in the presence of O_2, this H^+ form water (aerobic metabolism). Thus, during the oxidation of one molecule of reduced coenzyme (NADH) via the respiratory chain (cytochrome system), metabolic energy equivalent to 3ATP molecule is generated.

$$\text{NAD, 2H} + \tfrac{1}{2}\,O_2 \xrightarrow{\text{Many steps}} \text{NAD} + H_2O + \text{Pi}$$

$$3\ \text{ADP} + 3\ \text{Pi} \longrightarrow 3\ \text{ATP}$$

Thus, from each hydrogenated NAD molecule (i.e. NADH) three molecules of ATP are formed. In the absence of O_2 , the transport of H^+ or electron will proceed only until all the coenzymes/cytochrome has been exhausted.

CARDIAC OUTPUT

The cardiac output (CO) is defined as the total amount of blood pumped out by each ventricle per minute. This is also called the minute volume. The stroke volume means the amount of blood pumped out by each ventricle during each stroke or beat. So, the minute volume or cardiac output is the stroke volume multiplied by the heart rate. As the volume of blood pumped out by both sides of the heart is same, so the cardiac output is to be multiplied by 2 to calculate the total quantity of blood pumped out by the whole heart in a minute (Fig. 5.31).

The ejection fraction of left ventricle is defined as the stroke volume divided by the left ventricular end diastolic volume. It indicates the percentage of blood, ejected per ventricle per beat during the systole. The typical value for ejection fraction in a healthy adult male ranges from 60 to 70%. Values less than 40% represent severe ventricular contractile dysfunction or severe reduction of ventricular preload.

In adults, the average stroke volume is about 70 ml and the minute volume or cardiac output is about 5 to 6 litres/minute. In other words, the total volume of blood present in the body is expelled by each ventricle in every minute. Cardiac output is not the same in all individuals in all the ages. It is shown that CO increases approximately in proportion to the surface area of the body. So, the CO is frequently stated in terms of cardiac index. Thus, the Cardiac Index (CI) is defined as the CO per minute per square meter of body surface area. The average value of CI in healthy adult male is about 3·3 litres/min/m^2 (the surface area of an average sized adult male is about 1·7 m^2). Similarly, the stroke volume per square meter of body surface area is also known as the stroke volume index (SI). The average value of SI in a healthy adult male is about 47 ml/min/m^2.

Since, the venous return to the heart per minute should be the same as the minute output or cardiac output, so it follows that blood flow through all the tissues together

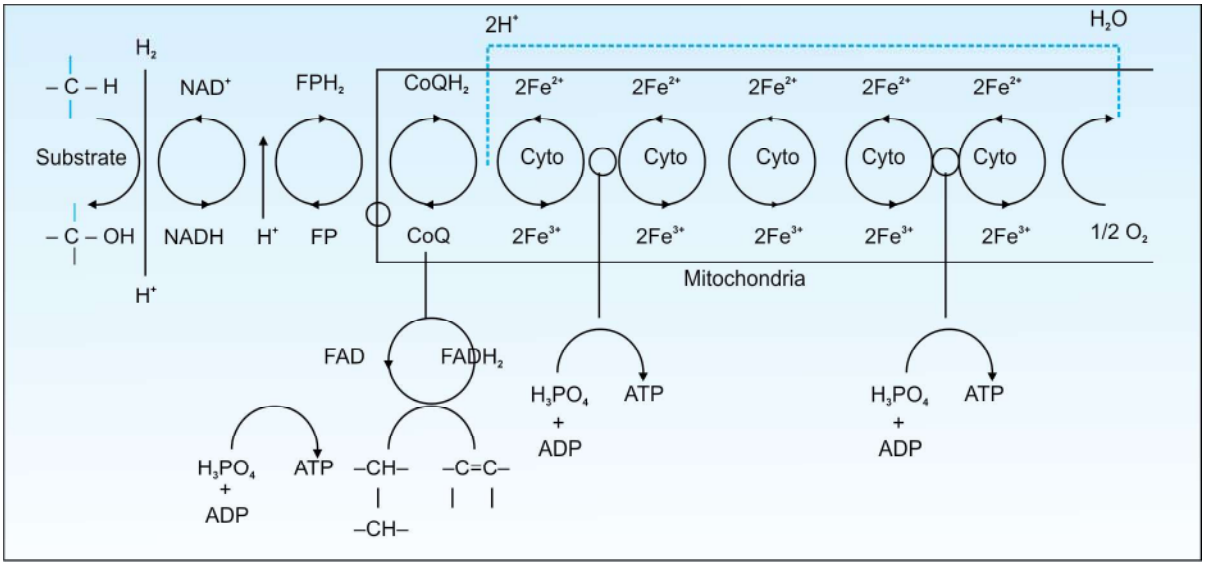

Fig. 5.31: Model of electron transport chain which is found within the mitochondrial matrix. Reducing substances such as $NADH_2$ or $FADH_2$ usually enter at the two points of the respiratory chain. But synthesis of ATP occurs at three separate sites. At the end O_2 accepts electron (H^+) from chytochrome (chy) and yields H_2O. Hydrogen (H^+) or electron flows through the chain in steps from the more electronegative components to the more electropositive oxygen. When substrates are oxidized via NAD linked dehydrogenase and the respiratory chain, 3 molecules of inorganic phosphate are incorporated into 3 molecules of ADP to form 3 molecules of ATP per 1/2 molecule of O_2 consumed. For $FADH_2$ only 2 molecules of ATP are formed. This reaction is called as oxidative phosphorylation

per minute must also be the same as the cardiac output. In other words, 5 litres of blood passes out per ventricle per minute, 5 litres of blood flows through all the tissues per minute and the same 5 litres of blood comes back to the heart to be distributed again to the different tissues per minute, such as Kidney - 1300 ml/min; Brain - 700 to 800 ml/min; Coronary - 200 ml/min; Muscle - 600 to 900 ml/min; Liver - 1500 ml/min, etc. The total quantity of blood distributed in these organs does not exceed 4500 ml/min. So, the remaining amount of blood is distributed to the skin, bones, GI tract and other less perfused tissues.

Cardiac reserve is defined as the capacity of heart which helps to generate the sufficient amount energy to expel a large quantity of blood above the basal level during emergency. Generally, the normal hearts expel about 5 to 6 litres of blood per minute per ventricle. But during exercise this amount may increase up to 30 to 40 litres/minute/ventricle (Fig. 5.32).

Determinants of Cardiac Output

Cardiac output mainly depends on the following four factors. These are: preload, force of cardiac contraction, after load and heart rate.

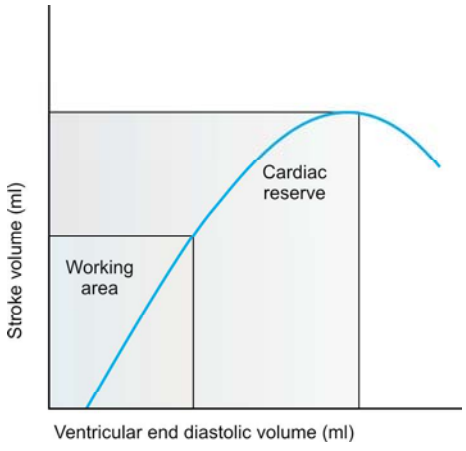

Fig. 5.32: Graphical representation of Starling's law of heart. When end diastolic volume (or the myocardial fibre length) increases, ventricles contract more vigorously and stroke volume increases. The pink area shows the cardiac reserve area and the blue area is the normal functioning area. When the function of heart goes beyond the reserve range, the stroke volume decreases and the relationship is reversed

Preload or venous return

The relationship between the length and tension of cardiac muscle is similar to that of the skeletal muscle. When the muscle is stretched or the length is increased, then the resultant developed tension for next contraction in the muscle fibre also increases. But this is up to a limit, because the developed tension for subsequent contraction declines as the stretch becomes more extreme. This is called the length tension relationship of muscle. On the otherhand, the developed increased tension after the length is increased is proportional to the subsequent force of contraction of the muscle fibre. Then, Starling stated that the energy or force of contraction is proportional to the initial length of the cardiac muscle fibre. This pronouncement has come to be known as the Starling's law or the Frank Starling law, in honour of Frank and Starling who were the two great physiologists of a century ago. So, basically the Frank Starling mechanism means that the greater the heart muscle is stretched during diastolic filling (or muscle fibre length is increased due to increased end diastolic volume) the greater will be the subsequent force of ventricular contraction and the greater will be the quantity of blood pumped out into the aorta or pulmonary trunk. Thus, the relationship between the ventricular stroke volume and the end diastolic volume is called as the Frank Starling curve (Fig. 5.33).

When the force of ventricular contraction is increased without an increase in fibre length or end diastolic volume due to sympathetic stimulation, then more blood that normally remains in the ventricles is also expelled without applying the Starling's law. It means that ejection fraction increases without increasing the preload, venous return or end diastolic volume or applying the Frank-Starling law. Thus the end systolic ventricular blood volume falls. The best example of this phenomenon is compensated hypovolaemia when the venous return falls, but the cardiac output is maintained up to a certain extent by increasing the inherent ability of contraction (contractility) and heart rate which is the function of the sympathetic system. This will be discussed more in detail below. So when there is both sympathetic stimulation and increased end diastolic volume due to good venous return, then there is tremendous increase in cardiac output. This is simply due to application of both Starling law and sympathetic stimulation (Fig. 5.34).

Thus, the preload is defined as the end diastolic fibre length or end-diastolic volume of the ventricle. But preload actually

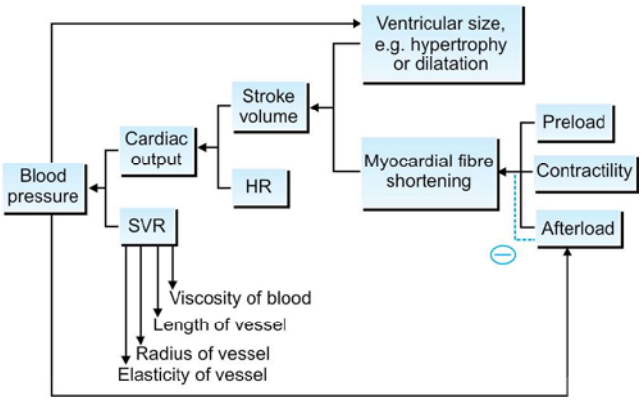

Fig. 5.33: The interactions between the components that regulate the cardiac output and the blood pressure. Solid arrows indicate increase and the red dashed line indicates a decrease

Contractile state of myocardium is influenced by

- Hypoxia
- Hypercarbia
- Acidosis
- Circulating catecholamines
- Sympathetic / parasympathetic nerve impulse
- Intrinsic depression
- Loss of myocardium
- Force frequency relation
- Pharmacologic depression
- Digitalis and other inotropics

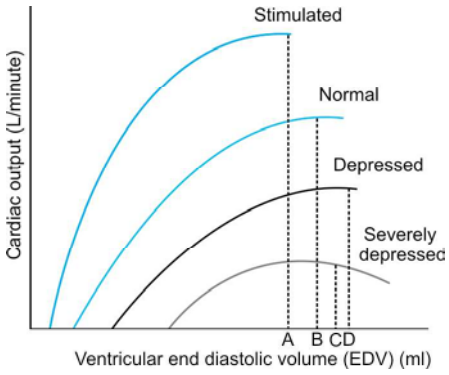

Fig. 5.34: The Frank Starling curve and the effects of changes in myocardial contractility on this curve. The curve shifts downward and to the right (green and black line) as contractility is depressed. The factors influencing the myocardial contractility are summarised in the table. The vertical dashed line ABCD indicates the portion of the ventricular function curve where maximum contractility has been exceeded and correponds with the point on the descending limb of the Frank Starling curve

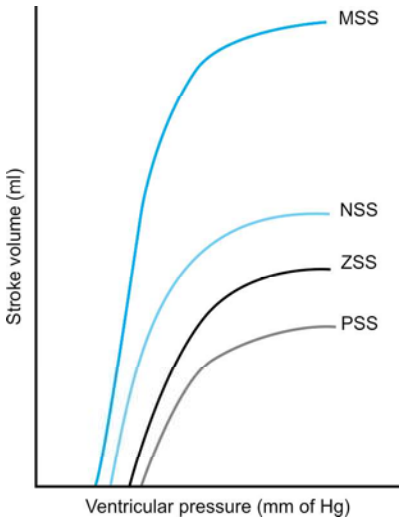
means the pressure within the ventricle at the end of the diastole for a given volume of blood which depends on the venous return or ventricular filling during diastole. Anything that increases or diminshes the venous return will also increase or decrease the preload and the cardiac output accordingly. These are: intravascular volume status, capacitance of venous system and ventricular compliance.

There is pressure difference between the arterioles, capillaries and venules. At the level of the heart, pressure at the arteriolar end of a capillary loop is 32 mm of Hg and at the venous end of the loop is 12 mm of Hg. So mean capillary pressure is 25 mm of Hg. Pressure in the great veins may vary from positive to negative. Venous dilation without arteriolar dilation or without fall of general BP will increase venous return and CO. But the resultant effect may show no increase in BP due to different reflex mechanism which try to maintain the BP at normal level. On the otherhand, arteriolar dilation definitely show the decrease of BP or afterload even though the CO increases. On the contrary arterial dilatation without venous dilatation will cause decrease in venous return and ↓CO and ↓BP. During both the arterial and venous dilatation, there is tremendous reduction of CO and fall of BP which is seen in spinal and epidural anaesthesia (Fig. 5.35).

Vasomotor system control the pump, the lumens of arterioles, the lumens of venules and thereby control the preload, CO and after load. In shock the intravascular volume status is altered definitely or relatively, affecting the preload, CO and after load.

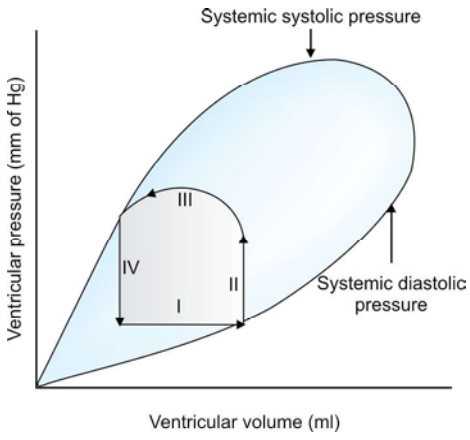


MSS = Maximum sympathetic stimulation
NSS = Normal sympathetic stimulation
ZSS = Zero sympathetic stimulation
PSS = parasympathetic stimulation

Fig. 5.35: The effect of different degree of sympathetic stimulation on the stroke volume

Force of cardiac contraction (contractility)

Within the physiological limits, the heart pumps 70 to 80% of the total blood that returns to it by the way of veins. The amount of blood that returns to the heart accounts for the preload and is estimated by the end diastolic ventricular volume or the initial length of muscle fibres of ventricle before contraction. Cardiac output not only depends on this preload, but also on the inherent pumping action or contractility of the ventricle. So, this pumping action or the force of cardiac contraction is defined as the inherent isotropic or contractile ability of the heart. This is due to the balance between the parasympathetic and sympathetic activity on it. The contractility of myocardium will also exert a major influence on the stroke volume other than preload. This intrinsic contractile ability of heart can not be explained by the Frank Starling mechanism which relates best the intial length of the muscle fibre or end diastolic volume with the subsequent force of contraction. So, it is described previously under the heading of preload (Fig. 5.36).



I = Period of filling, II = Isovolumic contraction, III = Period of ejection, IV = Isovolumic relaxation.

Fig. 5.36: The central square shaped figure represents the relationship between the left ventricular volume and the left intraventricular pressure during diastole and systole. The outer shaded area represents the work performed by the heart

The best way to express the functional or contractile ability of the ventricles is 'ventricular function curve'. It describes that as the intra ventricular pressure increase by ventricular contraction due to sympathetic activity the respective ventricular output also increases.

Thus, the ultimate force of cardiac contraction depends on the following factors:

i. The initial length of the cardiac muscle fibre: Within the physiological limits, greater the initial length, stronger will be the force of contraction (Starling's law). It is an inherent self-regulating mechanism that permits heart to adjust the changing end-diastolic volumes. It is obvious that the initial length of ventricle muscle fibre is proportional to the degree of filling which again depends on the venous return.
ii. The length of ventricular diastolic pause → Filling, rest and recovery of the heart muscle usually takes place during diastole. Hence, with shorter diastolic period which is inadequate for filling, rest, and recovery, the force of cardiac contraction will also diminish.
iii. Ventricular compliance: It determines the ability of the ventricle to be relaxed and dilated and thus the filling capacity.
iv. Nutrition and O_2 supply: An adequate supply of nutrition and O_2 to the myocardium is essential for the efficient cardiac activity. In addition to this, an optimum H^+ concentration, intracellular Ca^{2+} concentration, a proper balance of inorganic ions and appropriate temperature are needed for better cardiac contraction.
v. The pumping effectiveness or contractility of the heart is also controlled by the sympathetic and parasympathetic nerves. By sympathetic stimulation the cardiac output often can be increased more than 100% (both by increasing the heart rate and force of contraction). By contrast, the cardiac output can be decreased to as low as zero by parasympathetic (vagal) stimulation. When the sympathetic nerve to the heart is stimulated, the whole length tension curve of Starling law shifts upward and to the left. This is due to the positive inotropic effect of both norepinephrine and epinephrine.

Under normal condition, the sympathetic nerve fibres, supplying the heart, discharge continuously at a slow rate that maintains the pumping action at about 30% above that when there is no sympathetic stimulation. Therefore, when the activity of sympathetic nervous system is depressed, then this decreases both the heart rate and the strength of ventricular contraction which is as much as 30% below the normal.

The vagal fibres are distributed mainly to the atria and not so much to the ventricles, where the main power of contractions of heart occurs. This explains the effect of vagal stimulation which mainly to decreases the heart rate rather than greatly to decreases the strength of cardiac contraction. Neverthless, the great decrease in heart rate combined with a slight decrease in contractile strength can decrease the ventricular pumping ability or cardiac output to 50% or more (Fig. 5.37).

Afterload

The afterload of the ventricle is defined as the pressure in the principal arteries which are coming out from the ventricle and opposes its ejection. This afterload closely, but not exactly corresponds to the systolic pressure, described by the phase III curve of the volume pressure diagram. Sometimes, the afterload is loosely considered as the resistance in the vessels of circulation rather than the pressure. But it is incorrect. So, only the mean arterial blood pressure is equivalent to the afterload and therefore, it may be defined as the force or pressure opposing the ventricular ejection (the unit of force is dyne or mm of Hg whereas the unit of pressure is dyne/cm^2 or mm of Hg/cm^2).

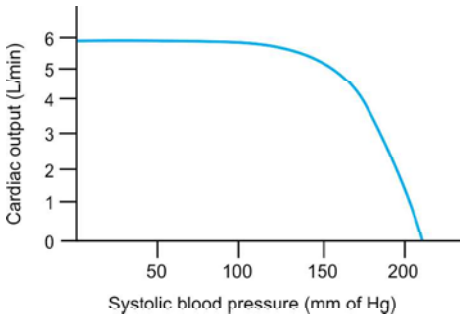


Fig. 5.37: The relationship between the systolic blood pressure and the cardiac output. When the blood pressure rises above 150 mm of Hg the cardiac output falls significantly

The importance of the concept of preload and afterload is that in many abnormal functional states of the heart or circulation, the intraventricular pressure during filling of it (i.e. the end diastolic ventricular pressure or the preload which closely corresponds with end diastolic volume) and the arterial pressure against which the ventricle must contract (i.e. the afterload) or the both are severely altered from the normal.

Increasing the arterial pressure in aorta or after load does not decrease the cardiac output, until the mean arterial pressure rises above the approximately 160 mm of Hg. In other words, during the normal function of heart at normal systolic arterial pressure (80 to 140 mm of Hg), the cardiac output is determined almost entirely by the ease of flow of blood through the tissues which in turn controls the venous return of blood to the heart and cardiac contractility (Fig. 5.38).

Total Peripheral Resistance

It is also an extremely important or principal factor for controlling the cardiac output. We know that the arterial pressure is equal to the cardiac output multiplied by the total peripheral systemic resistance. On the otherhand, we can say that the cardiac output is equal to the arterial pressure divided by the total peripheral systemic resistance. Thus, under most normal circumstances, the cardiac output varies reciprocally with the changes in total

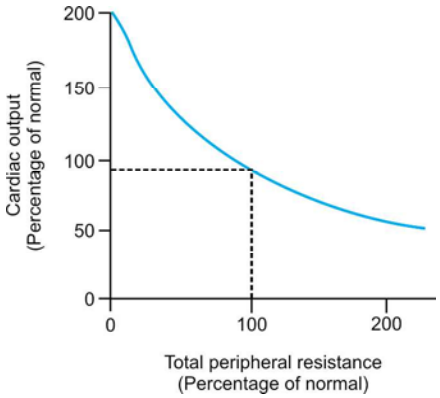

Fig. 5.38: The relationship between the total peripheral systemic resistance and the cardiac output which is reciprocal in nature. Here 100% is taken as normal

peripheral resistance. In the figure when the peripheral resistance is exactly normal i.e. at the 100% mark, the cardiac output is also normal. Then, when the systemic resistance increases above the normal, the cardiac output gradually falls. Conversely, when the resistance decreases, the cardiac output increases.

Thus, one can easily understood this relationship by reconsidering one of the forms of Ohm's law as expressed by:

$$\text{Cardiac output (or flow of current)} = \frac{\text{Arterial pressure (or electromotive force)}}{\text{Total peripheral resistance (electrical resistance)}}$$

Heart rate

Heart rate affects both the stroke volume and the minute volume. It affects the stroke volume by altering the period of diastole and there by altering the degree of ventricular filling (preload) and subsequently the force of contraction. Minute volume is equal to the heart rate multiplied by the stroke volume. So, the heart rate also affects the minute volume by altering one of the determinants of it. It should be noted that blood pressure depends upon the minute volume or cardiac output but not on the stroke volume (BP = CO × SVR) though there are also many other factors which determine the BP.

Venous return remaining constant, the rise of heart rate will reduce the diastolic pause and, therefore, the stroke volume. But the product of stroke volume multiplied by heart rate (i.e. cardiac output - CO) may not fall, even it may rise above the resting value. Thus, minute volume (CO) and therefore, BP may rise even if the stroke volume falls, provided the venous return is maintained. This happens with a moderate rise of the heart rate, i.e. up to 160 per minute. If the heart rate becomes too high, then ventricular filling and the stroke volumes become so low that the minute output (CO) falls far below the normal, though venous return is maintained. Thus, blood pressure may drop and the subject may become unconscious. This happens in paroxysmal tachycardia, when the frequency of heart beat suddenly rises to 150 to 200 per minute. But, muscular exercise is an exception. Here, both the frequency of heart beat and the rate of venous return increases. Therefore, cardiac filling becomes more than normal even during the short diastolic period during exercise. Hence, both the stroke volume and the minute volume increases.

On the other hand, when the heart rate becomes very low (as in heart block or due to any other causes), then although the stroke volume is much higher than normal, yet due to the same reason the total minute volume may fall. This is because the product of heart rate and stroke volume which determine the cardiac output may be less than normal. But, with the moderate slowing of heart rate, the minute volume may not fall at all. In some instances it may rise. Thus, alteration of the heart rate, on either side i.e. not too high or not too low will generally raise the minute volume up to a certain extent. Beyond that limit, the minute volume or cardiac output will fall.

Measurement of Cardiac Output (CO)

In animal experiments, one can cannulate the aorta, pulmonary artery or any other great veins or arteries entering or exiting from the heart and thus can measure the cardiac output directly by using any type of flowmeter (invasive method). But, non-invasively cardiac output can be measured in experimental animal only by an electromagnetic flow meter placed on the root of the aorta or pulmonary artery. In human beings the methods which are used to measure the cardiac output are : Doppler combined with echocardiography method, direct Fick principle method and indicator dilution method (a popular indicator dilution method is thermodilution method where the heat is used as an indicator).

(i) Doppler and echocardiography combined technique:

The wall movement of cardiac chambers and also the other aspects of cardiac function can be evaluated by the echo cardiography. It is a non-invasive technique and thus does not involve injections or insertion of catheter into the any cardiac chambers or in any great vessels. In echo cardiography, pulses of ultrasonic sound waves, commonly at a frequency of 2·25 MHz are made emitted from a transducer. This transducer also functions as a receiver to detect ultrasonic waves which is reflected back from the various parts of the heart. This reflections always changes whenever the acoustic impedance changes. Thus, when this recording of the changing echoes is placed against time on an oscilloscope, it provides a record of the movements of the wall, septum and valves of different cardiac chambers during different phases of cardiac cycle. When this echo cardiography is combined with Doppler principle, then this combined method, can be used to measure the velocity and the volume of flow through the valves and thus cardiac output.

(ii) Fick Principle

Normally, 200 ml of O_2 is absorbed from the alveoli of lungs into the pulmonary blood in each minute. It is found that blood

entering the right side of the heart has an O_2 content of 160 ml per litre. Whereas the blood leaving the left side of the heart has an O_2 content of 200 ml/litre. From these data we can calculate that each litre of blood passing through the lungs absorbs 40 ml of O_2. Therefore, dividing the total quantity of O_2 absorbed into the blood from the lungs i.e. 200 ml by the O_2 absorbed by per litre of blood (which is obtained by the atrio venous O_2 difference) i.e. 40 ml, we can get the total amount of blood passing through the pulmonary circulation per minute which absorb this total amount of O_2. Therefore, the total quantity of blood flowing through the lungs each minute is 200 ml/40 ml = 5 litres. Thus, the cardiac output can be calculated by the following formula : Cardiac output (L/min) = Total O_2 absorbed by the lungs (ml/min) /arteriovenous O_2 difference (ml/L of blood). This is the Fick principle.

In applying this Fick principle for measuring the cardiac output in the human being, mixed venous blood is usually obtained by a catheter which is inserted through the brachial vein of the forearm, passed and through the subclavion vein, and then down the right atrium into the right ventricle or pulmonary artery finally. Systemic arterial blood can be obtained from any systemic artery of the body. The rate of O_2 absorption by the lungs is measured by the rate of disapearance of O_2 from the respired air i.e. from the difference in O_2 concentration in the inspired and expired air, using any type of oxygen meter.

(iii) Indicator dilution technique

In this technique a known amount of any substance, such as a dye or more commonly a radioactive isotope is injected into any vein of a arm and then the concentration of this indicator from the serial samples of arterial blood is determined. The output of the heart (i.e. cardiac output) is equal to the amount of indicator injected divided by its average concentration in arterial blood after a single circulation through the heart. The indicator must of course be a substance that stays in the blood stream during the test and has no harmful hemodynamics effects. A popular indicator dilution technique is a thermodilution technique, in which the cold saline is used as an indicator.

Vascular Resistance (VR)

Blood flows through the vessels primarily because of the forward forces, imparted by the pumping action of the heart. But the elastic recoil property of the walls of the arteries (Fig. 5.39) during diastole, compression of the veins by the contraction of skeletal muscle during exercise and the negative suction pressure in the thorax through venous system during inspiration also help to move the blood forward through arterial system. This flow of blood (F) in a long tube like vessel depends on multiple factors such as the length of the tube (L), radius of the tube (r), viscocity of blood (η) and the pressure difference ($P_A - P_B$) between the two end of the tube, which follows the Poiseuille Hagen formula.

So, according to this formula:

$$F = (P_A - P_B) \times \frac{\pi}{8} \times \frac{1}{\eta} \times \frac{r^4}{L}$$

But, we know from Ohm's law that flow is equal to the pressure difference ($P_A - P_B$) divided by resistance (R).

Current (I) or flow (F) =

$$\frac{\text{Electromotive force (E) or pressure difference}}{\text{Resistance (R)}}$$

So, from here we can calculate the resistance (R) as:

$$R = \frac{8\,\eta\,L}{\pi\,r^4}$$

The resistance to the flow of blood depends very slightly on the viscosity of blood, but mostly on the radius or diameter and the length of the vessels (principally of the arterioles, because they are more in length) (Fig. 5.40).

Plasma is about 1.8 times more viscous than water. Whereas the whole blood is 3 to 4 times more viscous than water. Thus viscosity depends mainly on the hematocrit value i.e. percentage of the volume of blood occupied by the red blood cells. In large vessels, the increase in hematocrit causes appreciable increase in viscosity and therefore the resistance. However, in vessels smaller than 100 µm in diameter, i.e. arterioles, capillaries and venules, etc. the change of viscosity due to per unit change of hematocrit has much less effect on resistance than it is in the large

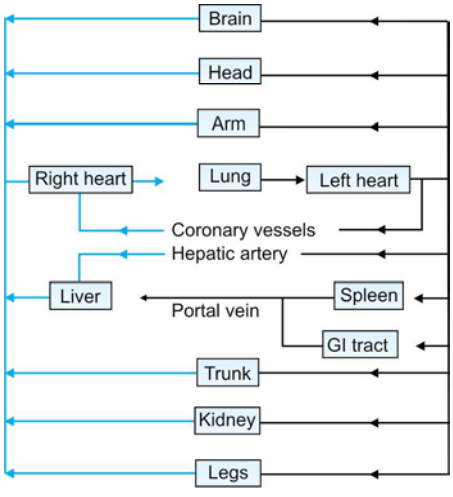

Fig. 5.39: Schematic diagram of different parallel circuits of circulation

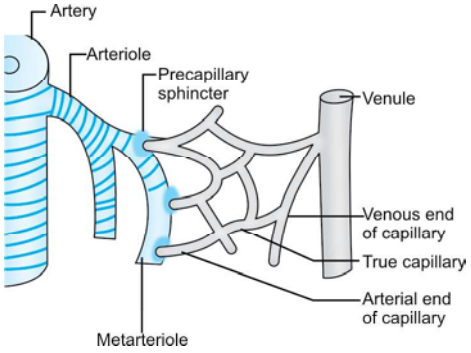

Fig. 5.40: The microcirculation. Arterioles give rise to metaarterioles which give rise to capillary. The capillary drains into the venule. The walls of artery, arteriole and venule contain relatively large amounts of smooth muscles. But the wall of meta arteriole contain few smooth muscle and capillaries have no. The opening of the capillaries are guarded by muscular precapillary sphincters

bore vessels of large diameter. This is due to the difference in nature of flow through the small vessels. Therefore, the net change in viscosity due to per unit change in hematocrit and its subsequent effect on total resistance is considerably smaller in the body as the smaller vessels occupy the larger portion of the total length of blood vessels. This is why the changes in hematocrit value have relatively little effect on the SVR, except when the changes are larger.

The flow of blood through each tissue or organ is regulated by the local chemical and/or the general neural and humoral mechanisms which causes dilatation and constriction of the vessels. The blood flows through the lungs without any change of the circuit. But, the systemic circulation is made up of numerous different circuits which are arranged in parallel. These arrangements permit wide variation in regional blood flow without changing the total systemic flow and resistance.

The walls of the aorta and other arteries of large diameter contain less amount of smooth muscles, but contain a relatively large amount of elastic tissues which are primarily located in the inner and external elastic laminas. They are stretched during systole and recoil on the blood column during diastole which is responsible for the forward motion and circulation of blood. On the other hand, the walls of the vessels of smaller diameter or arterioles contain less elastic tissue, but much more smooth muscle. These muscles are innervated by noradrenergic nerve fibers which function as constrictors, but in some instances they are innervated by cholinergic fibers which dilate the vessels. The arterioles are the major site of the resistance to blood flow and thus is the main determinant of the afterload. Because this after load is the blood pressure which is obtained by multiplying the cardiac output with the resistance imparted by these arterioles i.e. afterload or blood pressure = CO × SVR.

The arterioles divide into smaller vessels which are sometimes called the metarterioles and these in turn feed into capillaries. In some vascular bed these metarterioles are connected directly with venules through fare vessels. The true capillaries are an anastomosing network of side branches of this throughfare vessel. The opening of the true capillaries are surrounded on their upstream side by some smooth muscles sphincter which are called the precapillary sphincters.

The true capillaries are about 5 µm in diameter at the arterial end and 9 µm in diameter at the venous end. When the sphincters are dilated then the diamter of the capillaries is just sufficient to permit a squeezed red blood cells through it. The total surface area of all the capillary walls in the body is near about 6300 m^2 in an adult.

The walls of the venules are only slightly thicker than those of the capillaries. The walls of the large veins are also thin and easily distended. They contain relatively little smooth muscle than the metaterioles. But, considerable venoconstriction can be produced by the activity of the noradrenergic nerves on the veins or by circulating vasoconstrictors such as endothelins, epinephrine, norepinephrine, etc. Variations in venous tone are very important in circulatory adjustments.

Blood always flows from the areas of high pressure to the areas of low pressure. The relationship between the mean flow, mean pressure and the resistance in the blood vessels is analogous to the relationship between the flow of current (I), electromotive force (E) and the resistance (R) in an electrical circuit which is expressed as Ohm's law described before as I = E / R or the flow = Pressure / Resistance.

Thus, the flow of blood in any portion of the vascular system is equal to the effective perfusion pressure in that portion divided by the resistance. The effective perfusion pressure is the mean intraluminal pressure at the arterial end minus the mean intraluminal pressure at the venous end. The unit of resistance (pressure divided by flow) is expressed as dynes/s/cm^5. But to avoid the dealing of such complex units, resistance in the cardiovascular system is sometimes expressed as R units. This is obtained by dividing the pressure in mm of Hg by flow in ml/sec. Thus, for example, when the mean aortic pressure is 90 mm of Hg and the flow is 90 ml/sec, then the resistance is 90 mm of Hg / 90 ml per sec = 1 R units.

When the blood is poured into any segment of the vena cava or other large distensible veins, then the pressure does not rise rapidly until the very large volumes of fluid are injected. So, the veins are called as the blood reservoir. Normally veins remain in partially collapsed state. A large amount of blood can be added to the venous system before the veins become fully distended to the point where further increments in volume produce a large rise in venous pressure. The veins are, therefore, also called the capacitance vessels. On the otherhand, the walls of the arterial system is not distensible. Therefore, the addition of little amount of blood in this system causes precipitous increase in pressure. So, the small arteries and the arterioles are referred to as the resistance vessels, because they are the principal site of producing blood pressure and the peripheral resistance (Fig. 5.41).

At rest, atleast about 50% of the total circulating blood volume remains in the systemic veins, 12% is in the cavities of heart and 28% is in the low pressure pulmonary circulation. However, only 2% is in the aorta, 8% in the arteries, 1% in the

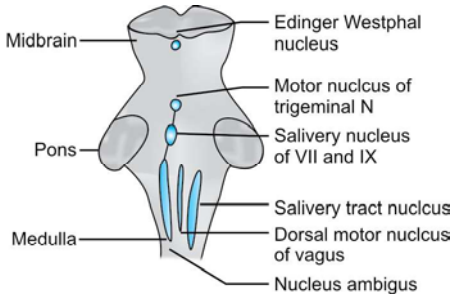

Fig. 5.41: Different nuclei of cranial nerves on the dorsal aspect of the brain stem, with nucleuses of vagus nerve

arterioles and 5% in the capillaries. When extra blood is administered by transfusion, then less than 1% of it is distributed in the arterial system (the high pressure system) and all of the rest is found in the systemic vein, pulmonary circulation and the cardiac chambers of low pressure system (i.e right side of the heart) other than the left ventricle.

CARDIAC REFLEXES

Cardiac reflexes are carried out by afferent pathways, vasomotor centre (VMC) and effarent pathways, lying within the sympathetic and parasympathetic nervous system, whose activities are further modified by the thalamus, hypothalamus and some other higher centers.

Vasomotor Centre

It is situated on the floor of the 4th ventricle in the reticular formation. There are practically two areas in the vasomotor centre. These are pressure centre and depressor centre. The pressure centre situated laterally and rostrally which causes the rise of BP. Whereas the depressor centre is situated medially and caudally which causes the fall of BP. These are the completely physiological areas as there is no clear cut anatomical separation between the presure and depressor areas. In the intermediate region they overlap (Fig. 5.42).

Sometimes it is appropriate to use the term 'medullary cardiovascular centre' instead of vasomotor centre, because it is recognised that the area contains both the neurons which excite and inhibit the thoracolumbar sympathetic centre supplying the heart and blood vessels. Within the VMC lies (i) the nucleus of tractus solitarius which receives the sensory fibres carrying general visceral sensations through the vagus and glossopharyngeal nerve, (ii) the dorsal motor nucleus of vagus which supply motor to the heart, lungs, esophagus, stomach, small intestine and large intestine up to the right two-thirds of the transverse colon and (iii) the nucleus ambigus which contributes fibres to the glossopharyngeal and vagus nerves.

The depressor centre is not the direct vasodilator centre. This centre causes inhibition of the sympathetic vasoconstrictor tone and thus indirectly dilates the vessel. The depressor centre relays the inhibitory impulses to the pressor centre. Pressor and depressor centres form the one functional physiological unit and it is defined as the VMC. The VMC discharges impulses which pass down the lateral white column of the spinal cord through the cervical, thoracic and lumbar segments and form synaptic connection with the lateral horn cells of the spinal cord (spinal sympathetic centre) (Fig. 5.43).

When BP rises, signals from the baroreceptors of carotid sinuses and aortic arch goes to the depressor centre which relays inhibiting impulses to the pressor centre causing slowing of the heart rate and dilatation of arterioles. Thus, vasodilatation and fall of BP is due to inhibition of the vasoconstrictor effect of the sympathetic (depressor reflex) system. On the otherhand, diminuation of blood

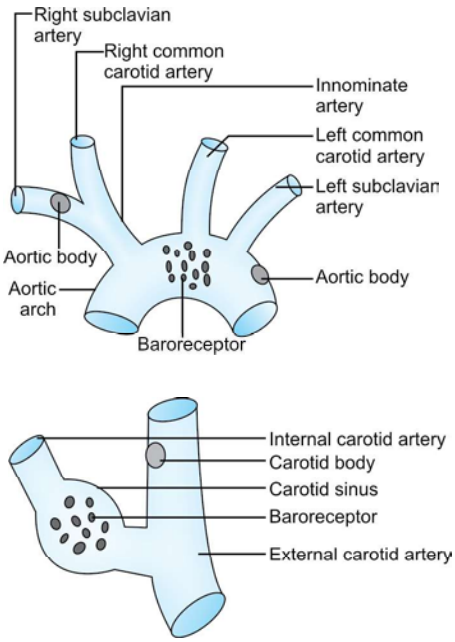

Fig. 5.43: The baroreceptors and chemoreceptors in the carotid sinus and aortic arch

presure fails to stimulate the baroreceptor of the carotid sinuses and aortic arch. Thus, the inhibitory impulses over the pressure centre is withdrawn and BP is raised reflexly through the overactivity of the sympathetic system.

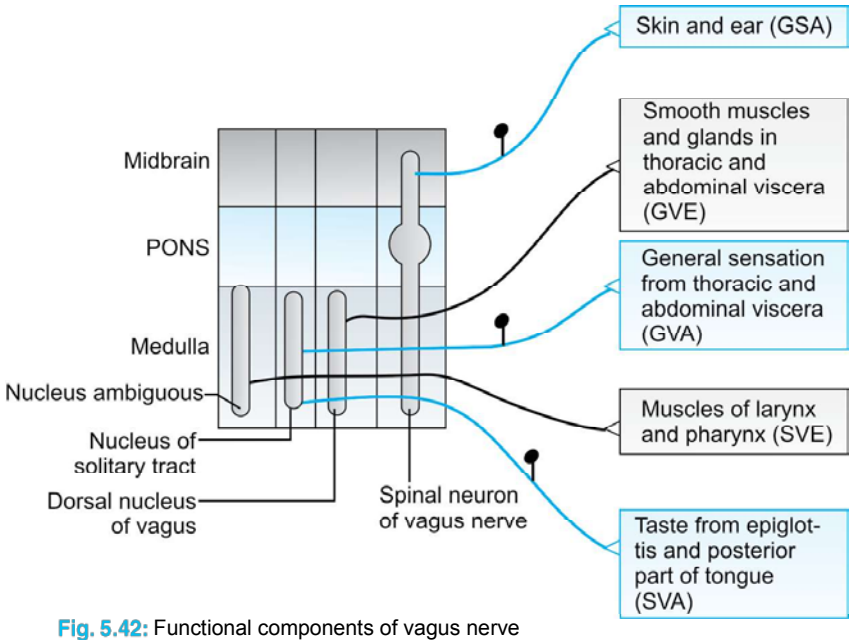

Fig. 5.42: Functional components of vagus nerve
GSA = General somatic afferent, GVE = General visceral efferent, GVA = General visceral afferent, SVE = Special visceral efferent, SVA = Special visceral afferent

Afferent Pathways

The afferent pathways, lying in the nerve fibres, starts from the two sets of receptors that continuously carry information regarding the peripheral circulatory status to the VMC. These sensory receptors are baroreceptors and chemoreceptors. The baroreceptors include the carotid sinus and aoritc arch, whereas the chemoreceptors include the carotid body and aortic body.

Carotid sinus

It is a dilatation at the root of the internal carotid artery, often involving the common carotid artery. The wall of the sinus is thin and is due to the less amount muscle fibres in the tunica media. In the deeper part of the adventitia, an extensive network of afferent nerve fibres is present. The nerve fibres end as the free terminals. These are the pressor receptors and are sensitive to stretch, being stimulated by rise of BP. The nerve arising from the carotid sinuses (baroreceptor) and carotid body (chemoreceptor) is purely afferent and is called the sinus nerve. It passes along the glossopharyngeal nerve and ends in the medulla.

Aortic arch

The stretch receptor and affarent nerves, similar to those of the carotid sinuses, are also present in the adventitia of the aortic arch, the roots of the great vessel arising from aorta and even in the adjoining parts of the left ventricle. They serve the same function as the carotid sinus. The nerve arising from the aortic arch (baroreceptor) and aortic body (chemoreceptor) is called the aortic nerve. It is purely afferent nerve and passes through the vagus to end in the medulla.

Carotid body

It is a small nodular structure situated close to the carotid sinus. It consists of clumps of large polyhedral cells and richly supplied with blood vessel and nerves. Numerous afferent nerve fibres surround these clumps of cells and even the individual cells and terminate in special chemoreceptor. Afferent pathways from these chemoreceptor areas are lying in the sinus nerve.

Aortic body

Like the carotid body, it is also a nodular structure and supplied richly by the blood vessels and the nerve fibres. Affarent pathways from these chemoreceptor areas lie in the aortic nerve and vagus. Their structure, nerve ending and functions are similar to those of carotid body.

Except these above mentined baro and chemoreceptors there are also other baroreceptors and chemoreceptors which are distributed throughout the whole body. These baroreceptors are located in the right atrium, left ventricle, left atrium, at the junction of the superior thyroid artery and common carotid artery, at the junction of the subclavian artery and common carotid artery, throughout the common carotid artery, in between the superior thyroid artery and subclavian artery, thoracic arch of aorta and in the central vein. The chemoreceptor are also located in the ventricular cavity and throughout the whole blood vessel's wall.

Efferent Pathways

Efferent pathways passes through the vagus and the sympathetic nerves which control the cardiovascular system by modifying the cardiac activity and the lumen of the blood vessels. These efferent pathways are divided into vasoconstrictor and vasodilatios fibres, carried by the different nerves.

Vasoconstrictor fibres

These fibres pass mainly through the sympathetic outflow, extending from the lateral horn cells of the first thoracic to the 2nd lumbar segments of the spinal cord and distributed in the following way.

i. To the skin and muscle: pass out through the gray rami communicantes as the postganglionic sympathetic fibres from all the ganglion of the sympathetic chain - to the mixed spinal nerves and finally distributed over the whole body through the somatic motor and sensory nerves. The distribution is strictly unilateral and stops sharply at the midline.
ii. To the head and neck: preganglionic fibres come from the lateral horn cells of the first to the fourth thoracic spinal segments - enter the superior cervical ganglion from which postganglionic fibres arise and pass along the carotid artery and its branches and along the spinal nerves of cervical plexus.
iii. To the fore limbs: preganglionic fibres arise from the lateral horn cells of the 4th to the 10th thoracic spinal segments - enter the stellate ganglion from which the postganglionic fibres arise and pass along the spinal nerves and the blood vessels going to superior extremity.
iv. To the hind limbs: preganglionic fibres arise from the lateral horn cells of the 11th thoracic to the 2nd lumbar spinal segments - relay in the lower lumbar and upper sacral ganglia of the sympathetic chain from where the postganglionic fibres arises and accompany the nerves of the lumbar and sacral plexus.
v. To the abdominal viscera: preganglionic fibres arise from the lateral horn cells of the lower thoracic and upper two lumbar spinal segments pass through the splanchnic nerves to coeliac ganglion - the postganglionic fibres pass along the blood vessels.
vi. To the thoracic viscera: Heart receives the accelerator fibres from the lateral horn cells of the T_1 to T_4 spinal segments through the cardiac plexus. Lungs also receives sympathetic bronchodilator fibres from these segments of spinal cord (Fig. 5.44).

Vasodilator fibres

There are three types of vasodilator fibres: parasympathetic, sympathetic and the antidromic fibres of the posterior spinal root. Among these parasympathetic

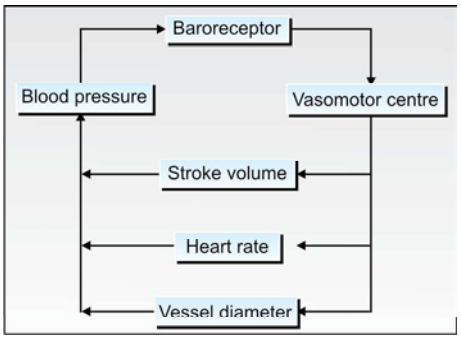

Fig. 5.44 : The feedback control of BP through baroreceptor

efferent is the vagus and control the cardiovascular system. The action of parasympathetic efferent is opposite to the sympathetic efferent. The sympathetic fibres are mostly vasoconstrictor in nature. But some sympathetic vasodilator fibres are also present. For instance, (i) the dilator fibres of the coronary vessels come through the sympathetic nerves, (ii) some sympatheitc dilator fibres also have been demonstrated in the peripheral nerves in human beings, (iii) stimulation of the last anterior thoracic root produces dilatation of the vessels of kidney, (iv) stimulation of the right splanchnic nerve sometimes causes vasodilatation and fall of blood pressure.

Some Common Cardiac Reflexes

Baroreceptor Reflex

This reflex controls the blood pressure via the circumferential and longitudinal stretching of the baroreceptor present in the carotid sinus and aortic arch. Increase in blood pressure stimulates these two receptors and send impulses along the glossopharyngeal and vagus nerve to the depressor centre, containing the nucleus of tractus solitarius, situated in the medullary cardiovascular centre (MVC). Inhibitory impulse then moves from the depressor centre to the pressor centre. Therefore, the response is decreased sympathetic activity and increased parasympathetic activity causing lowering of BP and decrease in heart rate. Typically this reflex works in the range varying between the systolic BP of 170 to 50 mm of Hg. When the systolic pressure falls below 50 mm of Hg then this compensatory mechanism fell. In chronic or poorly controlled hypertensive patients the upper set point of this reflex shifts upward.

Chemoreceptor reflex

This reflex control the arterial PO_2 and PCO_2 (pH status) via the chemoreceptors, present in the carotid and aortic bodies. Increased H^+ ($\uparrow PCO_2$) and hypoxia ($\downarrow PO_2$) stimulates these chemoreceptors and send impulses along the glossopharyngeal (nerve of Hering) and vagus nerve to the chemosensitive area of the medulla. This area then stimulate the respiratory centre and increase ventilation.

Bainbridge reflex

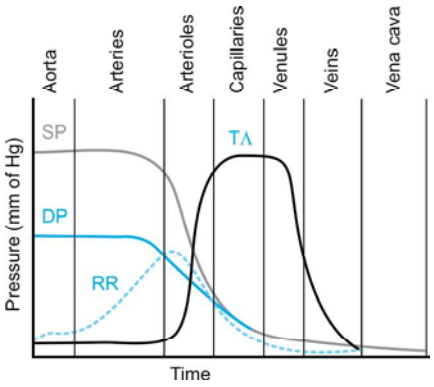
This is actually a baroreflex which involves the stretch receptors, located in the right atrial wall and cavoatrial junction. Increase in right sided filling pressure due to the increased intravascular volume stimulate these receptors and send impulses through the vagal afferent to inhibit the parasympathetic activity and increase the heart rate.

Bezold-Jarisch reflex

Here, the mechanoreceptors present in the left ventricular wall respond to the noxious ventricular stimuli and send impulses along the unmyelinated vagal afferent fibres. Thus, it increases the parasympathetic tone, leading to bradycardia, hypotension and coronary artery vasodilatation.

Valsalva Maneuver

If forced expiration against closed glottis is done - it increases the intrathoracic pressure - decreases venous return to heart - decreases CO - $\downarrow$BP - stimulation of baroreceptor - sympathetic stimulation - $\uparrow$HR. When glottis opens the reverse phenomenon occur and heart rate decrease (Fig. 5.45).



SP = Systolic pressure, DP = Diastolic pressure, TA = Total cross sectional area, RR = Relative resistance

Fig. 5.45: The changes in systolic pressure (SP), diastolic pressure (DP), total cross sectional area (TA) and resistance (RR) as the blood flows through the systemic circulation

Cushing's reflex

This reflex is manifested by increased HR, cardiac contractility and BP in response to increase intracranial pressure. It is the initial response of the reflex in an effort to increase the cerebral perfusion pressure. This is followed by reflex bradycardia mediated by baroreceptor within carotid sinus and aortic arch as a result of the increased peripheral vascular tone.

Oculo Cardiac reflex

This is discussed in the ophthalmic anaesthesia chapter.

CIRCULATION

An average adult has a blood volume of about 5 to 6 litres in his circulation and it is more or less equal to the resting cardiac output. But during heavy exercise this cardiac output may increase up to 25 litres per minute which indicates the increased circulation. The main purpose of this circulation is to supply adequate O_2, carbohydrate, fats, amino acids, hormones, immunological agents etc. to tissues and

to remove the waste products of its metabolism. But for this circulation only a little heart weighing about 300 gm acts as a pump and is highly adequate. Still no engineers has yet been able to develop such a pump with long term performance like it (Table 5.2).

Heart provides energy for circulation. Its phasic ejection of blood into the aorta produces the blood pressure and subsequently the pressure head. This pressure-head may be regarded as the cause of flow of blood or may be regarded as the potential energy for circulation.

During spinal or epidural anaesthesia, in the anaesthetized portion of the body both the pressure gradient (E) and the resistance (R) is reduced. But the ultimate flow (F) which depends on the relative ratio of E and R (according to the Ohm's law) is adequate even though the mean arterial pressure is low. Whereas in the unanaesthetized segment (i.e in the upper part of the body during lumbar spinal or epidural anaesthesia) resistance does not fall, even increases due to the compensatory elevated sympathetic activity in this portion of the body for the fall of systemic BP. Thus, the pressure head responsible for circulation in the unanaesthetized segment severly falls due to the fall of mean arterial pressure and thus blood flow (I) in this segment is tremendously jeopardised. So, BP should not be reduced below 20 to 25% of MAP to maintain adequate supply to the vital organs during central neuroaxial block.

There is different value of resistance in the different parts of the body. But to counter this variable resistance, exhibited in the different parts of the body, the pressure gradient must be adequate to maintain the circulation. Again as the cardiac output is pulsatile, so the pressure head and the flow into the arteries from the heart is also pulsatile. This means that the peripheral arterial system at the capillary level should possess a system of low impedence which will convert the pulsatile flow into the continuous flow. This is because the tissues themselves require a steady flow of blood through the capillaries, so as to benefit maximaly from the diffusion between the blood and the tissues.

On the otherhand, the resistance and subsequently the cardiac work can be lessened by increasing the radius of the vessels into which the blood is delivered. But this reduces the presure gradient. While, on the otherhand, adequate pressure gradient is required to provide an adequate flow. Alternatively, the cardiac work also can be reduced by considerably increasing the distensibility or stretching of the vascular system and this would decrease the pulsatile pressure and hence the impedence. However, such an increase in the distensibility of the vascular tree would prevent the immediate increase in CO and arterial pressure which is needed in biological emergencies and may be of imense important for survival of life. If the system took long time to inflate, then the urgent requirement for blood supply to the brain and the myocardium by increasing BP in emergencies circumstances could not be achieved, because for the pressure head available to such organs would rise too slowly, due to increased distensibility (Fig. 5.46).

So, some compromise should then have to be arrived. The arteries are distensible, but the arterioles convert the pulsatile ejection of heart into a steady flow to the tissue capillaries. The arterioles also offer resistance and step down the hydrostatic pressure within the capillaries. Veins have been equipped to serve as capacitance vessels. This is because by appropriate variation of their diameter the mobilization of blood to the heart are controlled in various circumstances.

The blood enters the right and left atrium at a pressure near about zero. The left ventricle pumps the blood into the aorta when the intraventricular pressure reaches a peak value during the cardiac contraction phase (systole) which is about 120 mm of Hg or so. During diastole the aortic pressure subsides to some 80 mm of Hg. This is due to the some elastic recoil property of the arterial system and due to the resistance to the outflow, offered by the peripheral arterioles. This combination of the elasticity and the resistance converts the pulsatile ejection flow of the heart into a steady outflow at the capillary level.

Table 5.2: Factors affecting the diameter of blood vessels

Factors	*Constriction*	*Dilatation*
Circulating hormone	1. Norepinephrine	1. Epinephrine (skin, muscle)
	2. Epinephrine (except skin and skeletal muscle)	2. Histamine
	3. Angiotensin - II	3. Substance - P
	4. Vasopressin	4. Vasoactive intestinal peptide (VIP)
	5. Neuropeptide - Y	5. Atrial natriuretic peptide (ANP)
	6. Na+ - K+ - ATPase inhibitor	
Local factors	1. Autoregulation	1. ↑CO_2, ↓O_2
	2. Cold	2. ↓pH
		3. ↑K+, ↑Lactate
		4. ↑Adenosine
		5. Heat
Neural factors	1. Sympathetic stimulation	1. Sympathetic inhibition
		2. Activation of cholinergic Vasodilator fibres to skeletal muscle (sympathetic and parasympathetic)
Endothelial factors	1. Endothelin	1. Kinius
	2. Thromboxane A2	2. NO
	3. Serotonin	3. Prostacyclin

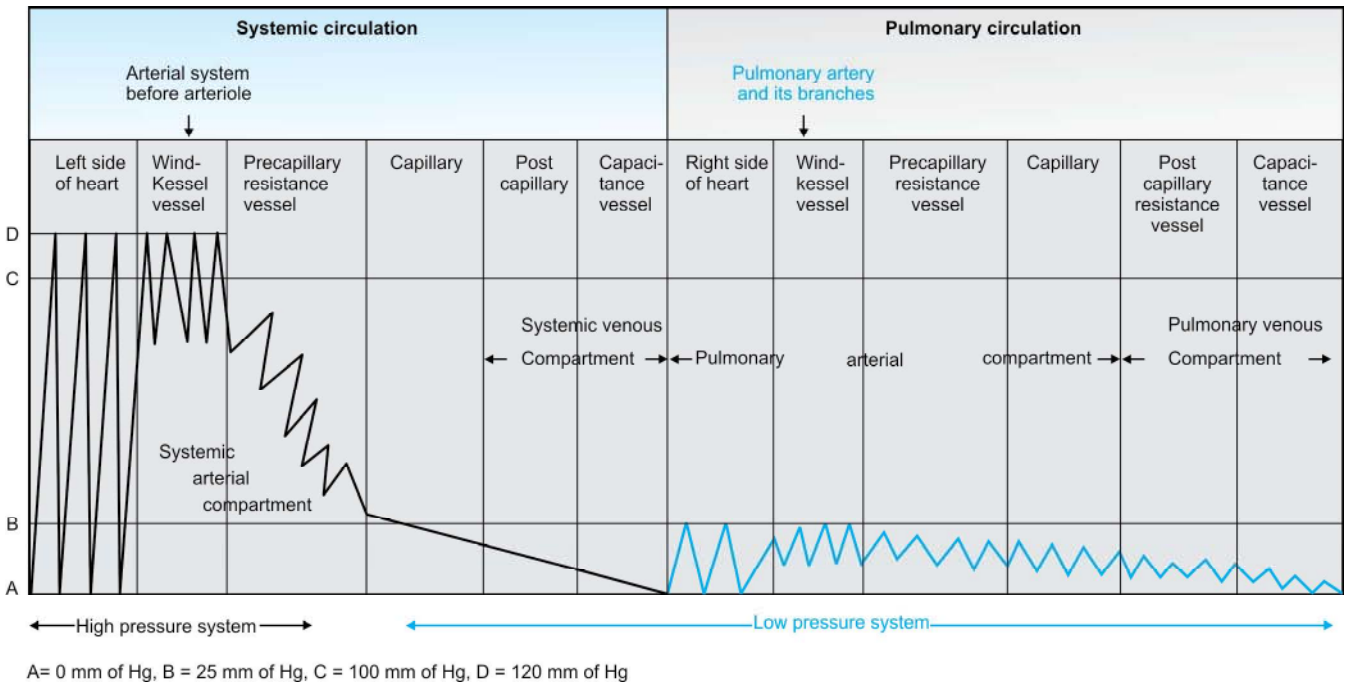


Fig. 5.46: Differential level of pressure in different systemic and pulmonary vessels

So the vascular system can be described as consisiting of

i. Wind Kessel vessels,
ii. Precapillary resistance vessels,
iii. Precapillary sphincters,
iv. Capillary,
v. Postcapillary resistance vessels,
vi. Capacitance vessels.

The concept of Wind Kessel vessels is represented by the aorta and its large branches which are highly elastic. Systolic ejection distends these vessels and during diastole the elastic recoil of these vessels substains the pressure gradient and renders the blood to flow foreward continuously to the periphery. The potential energy, stored during cardiac contraction in the elastic tissue of the aorta and its branches is reconverted into kinetic energy for the circulation during the diastolic phase. In disease process the degenerative changes in the media of the large vessels causes a loss of this arterial elasticity. Thus a high pulse pressure results owing to the lack of this Wind Kessel effect.

The precapillary resistance vessels (arterioles) provide the majority of the systemic vascular resistance. It exibits an efficient local myogenic control of their own vascular radius and on this local myogenic tone is superimposed an extrinsic neural control, effected by the sympathetic constrictor nerves and the parasympathetic vasodilator nerve. Normally these nerves discharge impulse at the frequence of 1 imp s^{-1}, but the rate of discharge may be increased to 10-16 imp s^{-1} in emergency circumstances (e.g. haemorrhage) and entirely suspended (e.g. in the skin vessels) during heat stress.

Blood vessels in the muscles represent by far the most important site for the peripheral resistance. This is due to the high degree of basal sympathetic myogenic tone in the vessels of the muscles. The blood flow in the muscle in resting man is only 2·7 ml/100gm/min. However, during exercise this flow may increase up to 50 to70 ml/100gm/min. This enormous increase in blood flow in the muscles is achieved by vasodilation of the arterioles and the precapillary sphincters, caused by local metabolites produced by the active tissue. But, it is not due to the neural factors. In resting muscle, however, the influence of sympathetic constrictor nerves on the precapillary sphincter is partly responsible for keeping the muscle blood flow at low values. In resting circumstances the skin vessels also manifest a high regional resistance.

The precapillary sphincters which are also themselves of a part of the precapillary resistance vessels, are particularly important in determining the size of the total capillary area. For example, any increase in the patency of the sphincters causes an increase in the number of capillaries open. The radius of the precapillary sphincters is controlled both by the neurogenic factors (sympathetic and parasympathetic) and by the local concentration of tissue metabolites.

Capillaries are consist of single layer of endothelial cells. This allows the exchange of substances across it's wall at the tissue level. Capillaries are not controlled by either nervous or metabolic factors. It is the alteration of the precapillay sphincter tone which determines the number of capillaries patent and hence the surface area, available for exchange between the blood and the interstitial fluid. In resting tissues

only some 20 to 25% of the total capillaries are patent. The onset of tissue activity is attened by relaxation of the sphincters and perhaps maximal opening of the capillary exchange bed.

The capacitance vessels are represented by the venular end of the capillary and the venous compartments. These contribute little to the over all resistance of the vascular circuit, but are important sites for the total capacity of the vascular system. Changes in the luminal configuration (from elliptical to circular cross-sectional profiles) and changes in myogenic tone of the veins, induced by sympathetic constrictor nerves, are of great importance in adjusting of the total capacity of the venous system.

Shunting of vessels occur only in few tissues - most notably in the skin. Such vessels bypass the capillaries and if patent they permit a rapid flow of blood. Their patency is controlled entirely by the sympathetic vasoconstrictor discharge. Thermal stress causes, via central nervous system, abolition of such discharge and the tremendous increase of the cutaneous blood flow which allows dissipation of heat from the body surface.

Wind Kessel concept

The arterial system is a very complex net work of elastic tubes which at the one end accepts the intermittent spurts of blood from the left ventricle of the heart and at the other end through its myriad of termination passes the blood by a steady stream into the resistance vessels, which perfuse the organs and tissues of the body. Thus, the arterial system acts both as conduit and as cushion when delivering the blood with a minimum fall in pressure to peripheral tissue (conduit function) and by reducing the flactuations of pressure imposed by intermittent ventricular action (cushioning function). Thus, this complex network of tubes can be viewed as a simple system, at least as first approximation. This simple idea is the Wind Kessel concept. This concept is based on the elastic property of the blood vessels. During systole the elasticity of the great vessels causes dilatation. This dilatation reduces the BP, resistance and the cardiac work. It also tries to reduce the pulsetality of the blood flow by absorbing the energy. But during diastole, the recoiling property of the elastic tissue helps for the forward movement of the blood during diastole and maintain the diastolic pressure. Thus, a continuous flow of blood is maintained in the tissues. This recoil effect is sometimes called the 'Windkessel effect' and the vessels are called the Windkessel vessels. The Windkessel is a German word which is used for an elastic reservoir. This elastic reservoir is responsible for continuous flow both during systole and diastole which appears to maintain a optimal function of the tissues. If an organ is perfused with a pump that delivers a pulsatile flow, then there would be gradual rise in vascular resistance and tissue perfusion fails.

The blood, forced into the aorta during systole not only moves the blood in the vessels forward, but also sets up a pressure wave on the wall of the vessel due to elastic property of it that travels along the arterial wall. This pressure wave expands the arterial wall and as it travels periphery along the wall of the large vessels, then this expansion is palpated as the pulse. The rate at which the pulse wave travels along the vessel wall is independent and of much higher than the velocity of the flow of blood. The velocity of pulse wave along the arterial wall is about 4 m/s in the aorta, 8 m/s in the large arteries and 16 m/s in the small arteries. Whereas, the velocity of the flow of blood in aorta is 40 cm/s. Actually the velocity of blood flow in aorta ranges from 120 cm/s during systole to negative value during diastole.

ARTERIAL BLOOD PRESSURE

The blood pressure is defined as the lateral pressure which is exerted by blood on the wall of the vessels, while flowing through it. There are four common terms regarding the blood pressure.

i. Systolic pressure - maximum pressure in artery during the systole of cardiac cycle.
ii. Diastolic pressure - minimum pressure in artery during the diastole of cardiac cycle.
iii. Pulse pressure: the difference between the systolic and diastolic pressure.
iv. Mean arterial pressure (MAP): It is the average pressure throughout a single cardiac cycle, i.e. during both systole and diastole. So, it depends on the duration of the cardiac cycle and indicates the arithmetic mean of the systolic and diastolic pressure throughout the cycle. Thus, as the systole is shorter than the diastole, so the mean pressure is slightly less than the value which is halfway between the systolic and diastolic pressure. It can actually be determined by integrating the area of pressure curve which is shown in the figure by the shaded area. However, a close approximation to the mean arterial pressure may be obtained by adding the diastolic pressure with one third of the pulse pressure (Fig. 5.47).

The blood pressure falls very slightly in the large and medium sized arteries though their resistance is small. This is because the flow of blood is high in these vessels due to low resistance. But it falls rapidly in the small arteries and arteriols though they are the main sites of the SVR against which the heart has to pump. Here, yet the resistance is high, but still the pressure is low. This is becuase due to high resistance, flow of blood is low. The mean pressure at the end of the arterioles is 30 to 38 mm of Hg. Pulse pressure also declines rapidly to about 5 mm of Hg at the end of the arterioles. The magnitude of the drop of pressure along the arterioles also varies considerably depending on whether they are constricted or dilated.

Thus, in summary, it is stated that the pressure in the aorta, brachial and other large arteries in a young human adult rises to a peak value (systolic pressure) of about 120 mm of Hg and falls to a minimum value (diastolic pressure) of about 70 mm of Hg during each cardiac diastole. So, the arterial pressure is conventionally written as systolic pressure over diastolic pressure e.g 120/70 mm of Hg. In SI unit, one millimeter of mercury equals 0·133 kPa. So in this unit system, the value of arterial pressure is 16/9·3 kPa.

The height of the systolic pressure indicates :

i. The cardiac output,
ii. The degree of pressure which the arterial walls have to withstand. Diastolic pressure is the measure of peripheral resiatance. It indicates the constant load against which heart has to work.
iii. The extent of work done by the heart.

The height of the diastolic pressure indicates:

i. The constant load against which heart has to work,
ii. The measure of peripheral resistance.

Factors controlling the blood pressure:

There are two main determining factors which can control the blood pressure. These are cardiac output (CO) and systemic vascular resistance (SVR). So, any alteration of CO and SVR will alter the BP according to Ohm's law. Cardiac output again depends on the venous return to heart, force of myocardial contraction or contractility (pumping action of the heart), frequency of contraction or heart rate and ventricular size. Venous return (preload) again depends on the blood volume and the venoconstriction or dilatation. Cardiac output depnding on the factors such as cardiac contractility and the frequency of contraction or heart rate is already discussed previously under the heading of cardiac output. Ventricular size also determines the cardiac output. For example a hypertrophied heart prevents proper diastolic filling and reduces the cardiac output. SVR is also an important determining factor of blood pressure. The chief seat of SVR is the arterioles. SVR depends on : (i) the velocity of blood, (ii) the viscosity of blood, (iii) the elasticity of arterial walls, (iv) the radius of the lumen and (v) the length of the vessel. For a given elasticity of the arterial wall and velocity of blood, the other factors responsible for SVR can be represented by Poiseuille's law.

According to Poiseuille's law the resistance in any blood vessels varies directly with the viscosity of the blood and the length of the blood vessel and inversely with the fourth power of the radius of the blood vessel. Thus it can be represented by the formula :

$$R = \frac{8\eta L}{\pi r^4}$$

Here R stands for the resistance to blood flow, η for the viscocity of blood, l for the length of blood vessel, r for the radius of the blood vessel. The value of π is 3·14 and 8 is the Hagen's integration factor.

According to Ohm's law the relationship between peripheral resistance (PR), cardiac output (CO) and blood pressure is

$BP \propto CO \times PR$

$CO \propto BP / PR$

$PR \propto BP / XO$

6 Electrocardiogram

INTRODUCTION

During each contraction of heart an impulse is generated in the SA node. It is then simultaneously transmitted to the AV node, bundle of His, two bundle branches, Purkinje fibres, ventricular muscle fibres and lastly to the surrounding body tissues in which the heart is bathed in. Thus, an electrical impulse that is initiated in the cardiac muscle is ultimately transmitted throughout the whole body tissues. So, if two suitable electrodes (or leads) are placed on the surface of the body, opposite to the heart and are connected to a very sensitive galvanometer with a recording device, then this electrical potential can easily be recorded. This record is called the electrocardiogram and the machine by which the electrocardiogram is recorded is called the electrocardiograph. However, the process of making graphic records of the variations in electrical potential, caused by the electrical activity of the heart muscles on the body surface is called the Electrocardiography. Practically the electrocardiograph is a sophisticated galvanometer where a sensitive electromagnet detects and records the changes of electrical potential which is generated in the heart and transmitted throughout the whole body. Thus, for detection of changes in the cardiac electrical potential, two electrodes or leads (one +ve and another –ve) are needed. So, the theoretical straight line joining the two electrodes or leads is called the lead axis. However, this should not be confused with the electrical axis of the heart or the cardiac axis.

ECG PAPER (FIG. 6.1)

The electrocardiographic paper is divided into 1 mm small and 5 mm large squares, both horizontally and vertically. Therefore, within one large square there are 5 small squares accomodated both horizontally and vertically. Hence, every large square is 5 mm in length, both vertically and horizontally.

After every 15 large squares, there is a vertical line at the upper border of the ECG paper. Horizontally, the squares measure the time in seconds and vertically they measure the amplitude of deflection in millivolt. Conventionally, the electrocardiogram is always recorded at a paper speed of 5 large squares or 25 mm (25 small squares) per second. So, every small square of 1 mm measures a time of 1/25 seconds or 0.04 seconds and one large square is 0.2 seconds ($0.4 \times 5 = 0.2$). Vertically, one small square measures a deflection of 1 millivolt.

ELECTROCARDIOGRAPHIC LEADS

An electrocardiographic lead can be placed on the body in respect to any three dimensional relationship of the heart, such as frontal (coronal), sagittal and horizontal plane. But, practically we use only 12 conventional leads in frontal and horizontal planes (6 leads in the frontal plane and 6 leads in the horizontal plane). Other different types of leads which are used in different planes in special conditions are discussed later (Fig. 6.2).

So, the leads can be classifed according to the planes where they are situated. These are frontal plane leads, horizontal plane leads and sagittal plane leads. (Fig. 6.3).

Frontal or Coronal Plane Leads

The frontal plane leads consist of standard leads I, II, III and the leads aVR, aVL, aVF.

These leads are oriented or situated on the frontal or coronal plane of the body and looks at the heart from its sides (Fig. 6.4).

The sides or the angles from which it looks at the heart depends upon the lead in question. Thus, the lead aVR looks at the cavity of the heart from patient's right shoulder. Whereas, the lead aVL looks at the cavity of the heart from the left shoulder and the lead aVF looks directly up towards the heart from the foot end of the patient (Fig. 6.5).

In the standard lead I the lead is derived from the placement of positive electrode on the left arm and negative electrode on the right arm. In the standard lead II,

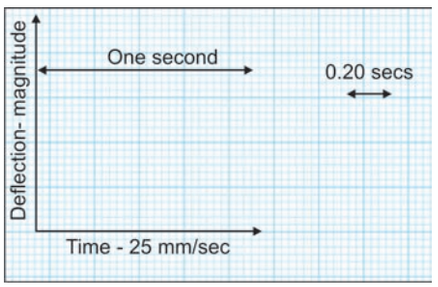

Fig. 6.1: An electrocardiograph paper with a time scale at a recording speed of 25 mm per second

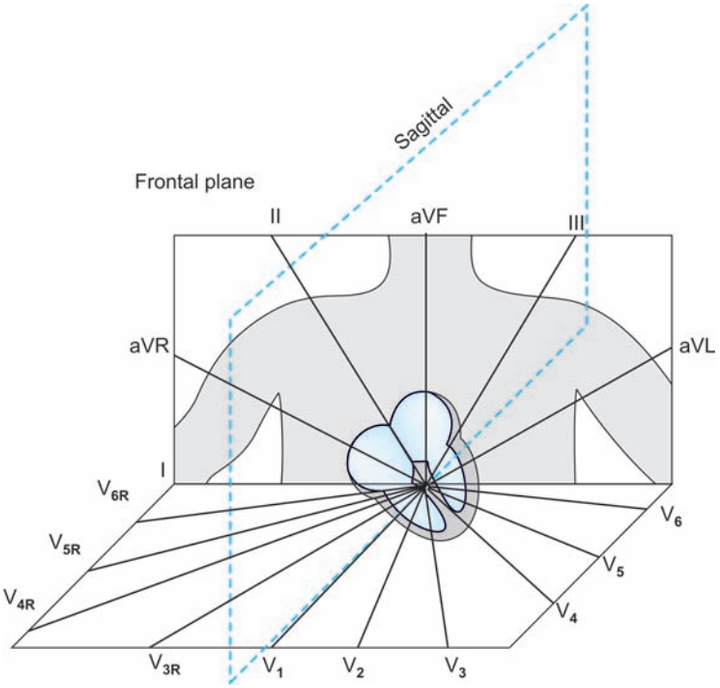

Fig. 6.2: The frontal (coronal) and the horizontal plane leads

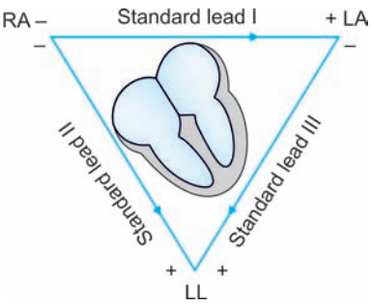

Fig. 6.5: Einthoven's triangle

also called the bipolar leads and are the original leads described by Einthoven. All the ECG machines also have a connection with right leg by electrode and this acts as a ground wire and plays no role in the production of ECG.

Horizontal Plane Leads

These leads are situated or oriented on the horizontal or the transverse plane of the heart and consists of all the precordial chest leads, such as: leads V_1-V_9,V_{3R-9R}, $3V_{1-9}$, $2V_{1-9}$.

Sagittal Plane Leads

These leads are situated on the sagittal plane of the heart and measure the electrical potential of cardiac activity in the sagittal plane. An example of the sagittal plane lead is the oesophageal lead.

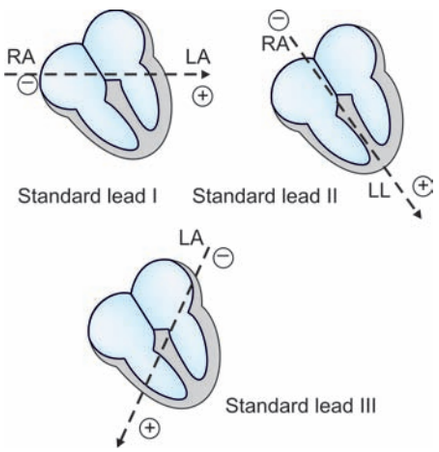

Fig. 6.3: The different electrode placements in standard leads I, II and III. The positive poles in standard leads I,II and III are located respectively at the left arm (LA), left leg (LL) and right leg (LL).The three axes formed by these three leads form a triangle.As the electrodes are situated at equidistant from the heart, so it is also considered that the axes are also situated equidistant from the heart and the heart is located at the centre of the triangle formed by these three axes. This equilateral triangle formed by these three axes is called the Einthoven's triangle

the lead is derived from the placement of positive electrode on the left foot and negative electrode on the right arm. In the standard lead III, the lead is derived from the placement of negative electrode on the left arm and positive electrode on the left foot. These standard I, II and III leads are

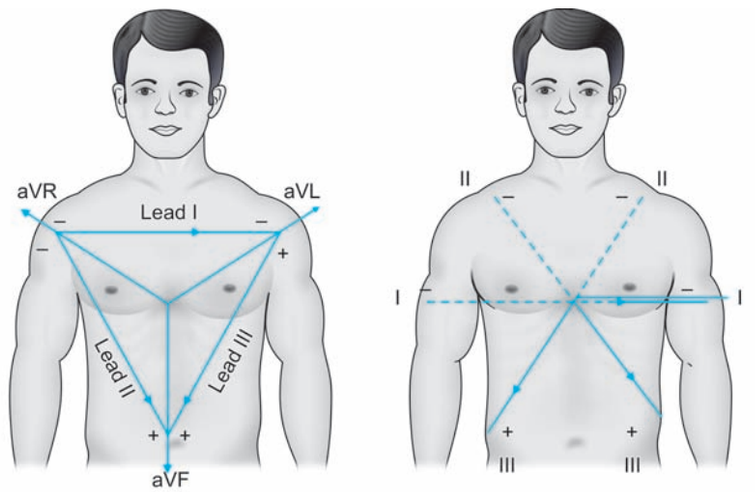

Fig. 6.4: Einthoven's triangle and the frontal plane bipolar leads

According to the polarity the leads can also be classified into two groups: (i) Bipolar leads and (ii) Unipolar leads (Fig. 6.6A and B).

Bipolar leads

The bipolar leads are the original standard leads, selected by Einthoven to record the electrical potential of heart and are situated in the frontal plane. These are leads I, II and III. Actually, the bipolar leads represent the difference of electrical potential between 2 selected sites. Lead I gives the difference of electrical potential between the left arm and the right arm (LA-RA) and the lead axis is directed from RA to LA. Lead II gives the electrical potential difference between the left leg and the right arm (LL-RA) and the lead axis is directed from RA to LL. Lead III shows the potential difference between the left leg and the left arm (LL-LA) and the lead axis is directed from the LA to LL.

The relationship of electrical potential between these 3 bipolar leads is expressed algebraically by the Einthoven's equation. The equation states that:

Lead II = Lead I + Lead III

i.e. amplitude of any deflection in lead II is equivalent to the sum of the amplitude of deflections in lead I and II.

Unipolar leads

The use of unipolar leads in clinical practice was introduced by Wilson in 1932.

The examples of unipolar leads are:

i. Unipolar extremity or limb leads: VR, VL, VF
ii. Unipolar chest leads: V_1 , V_2 , V_3 , V_4, V_5 , V_6 , V_7 , V_8 ,V_9 , $V_{3R–9R}$, $3V_{1–9}$, $2V_{1–9}$, $6V_{1–9}$, $3V_{3R–9R}$.
iii. Oesophageal leads.
iv. Unipolar intracardiac leads.

All the unipolar extremity or limb leads and chest leads are designated as V and unipolar oesophageal leads are designated as E.

Unipolar extremity or limb leads

There are three unipolar limb leads. These are: (i) Right arm (VR) lead, (ii) Left arm (VL) lead, (iii) Left foot (VF) lead, where V denotes unipolarity. In these unipolar limb leads among the two electrodes, one is an exploring electrode and acts as a positive end. The negative end of that lead is not actually negative, but is at the '0' potential. So, these leads are called the unipolar leads and they actually measure or represent the amount of potential at that point of heart for a given lead and not the difference of electrical potential (where as the bipolar leads measure the potential difference) between the two electrodes of the lead. But, technically we may call this unipolar lead as bipolar one, because it has two poles (Fig. 6.7).

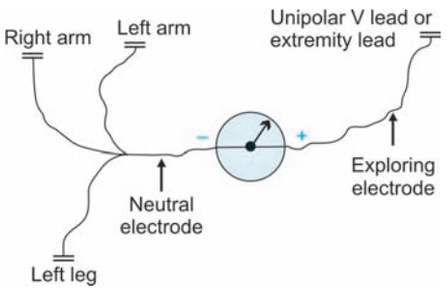

Fig. 6.7: The derivation of the unipolar (chest and extrimity) leads. The neutral limb is connected to the negative pole of the galvanometer. The exploring electrode is connected to the positive pole of the galvanometer

The mechanism by which the unipolar limb lead works is described below. It is considered that the heart lies at the centre of an equilateral triangle, called the Einthoven's triangle which is formed by the three standard limb leads I, II and III. According to Einthoven, the sum of the potential differences of these three leads at any instant is zero (Fig. 6.8).

Therefore, RA + LA + LL = 0

Hence, when these three leads are at first connected together and then finally to one end of a galvanometer and the other end of the galvanometer is attached to the exploring electrode, (now this is how the

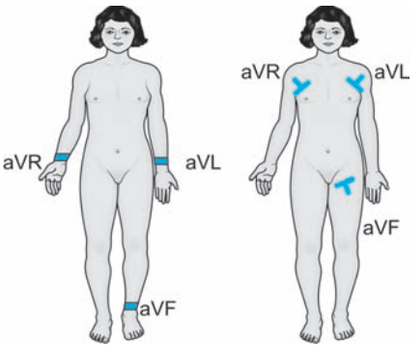

Fig. 6.9: Diagrammatic representation of the unipolar extremity leads

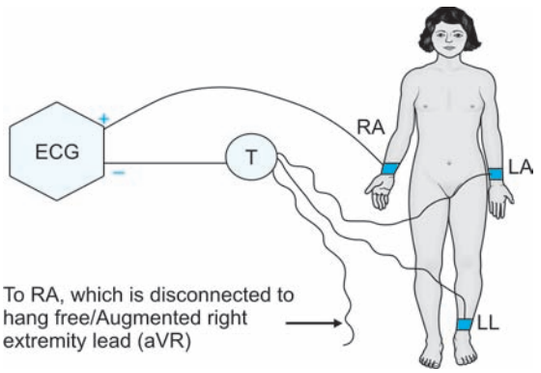

Fig. 6.10: The principle of augmented extremity leads. All modern ECG machines are so designed that the augmented extremity leads can be taken with the same electrode attachment on the body which are used for the standard leads and chest leads by just turning the selector dial to aVR, aVL and aVF. Unipolar chest leads are also taken by applying the electrodes on the chest to any desired position and turning the selector dial of the ECG machine to the V position. If a modern ECG machine is not available, an ECG machine that can record standard leads like I, II, III can also be used to obtain augmented extre- mity leads satisfactorily. To get this, one first constructs an indifferent electrode T by attaching RA, LA and LL electrodes together and then to the negative pole of the machine. Then the connection of the neutral terminal to the limb which is being tested, is disconnected and is allowed to hang free and the exploring positive side of the machine is attached to that limb. This will produce an augmented version of the unipolar limb leads

unipolar lead is formed), then unipolar limb lead will be formed and the machine will record the true potential of body tissue under that exploring electrode (Fig. 6.9).

However, using the above technique the potential obtained by the exploring electrode of unipolar limb lead is of low voltage. This low voltage can be augmented by omiting the connection of the neutral terminal to the limb which is being tested and allowing it to hang free. Then, the unipolar limb lead is called as an augmented limb lead and designated as aVR, aVL and aVF (where 'a' stands for the word augmented) (Fig. 6.10).

Lead aVR (or AVR) is the augmented ('a' or 'A') unipolar (V) right arm (R) lead, and is usually oriented towards the cavity of the heart from the right shoulder. So all the deflections, such as: the P, QRS and T are normally negative in this lead. This is because the vector of electrical current making all these waves pass away from this lead. The aVL (AVL) is the augmented unipolar left arm lead, and is oriented to the anterolateral or superior surface of the heart from the left shoulder. Lead aVF (AVF) is the augmented unipolar left leg lead and is oriented to the inferior surface of the heart from the left leg.

Unipolar oesophageal leads

The unipolar oesophageal leads are taken from within the oesophagus. A nasal catheter which is threaded with a wire and having an electrode attached to its tip is passed through the nares into the oesophagus. Using this as exploring terminal and the zero potential at the other terminal, an unipolar oesophageal lead can be obtained. This is designated as the E lead. The nomenclature of the different types of oesophageal lead is derived as the distance from the tip of the nares to the position of electrode in oesophagus in centimetres. Thus, E_{50} represents an unipolar oesophageal lead at a distance of 50 cm from the nares. Lead $E_{40\text{-}50}$ usually reflects the posterior surface of the left ventricle. The $E_{15\text{-}25}$ reflects the atrial area and $E_{25\text{-}35}$ reflects the region of the atrioventricular groove.

The oesophageal leads are especially useful in recording the atrial complexes which are greatly magnified at this location and also in exploring the posterior surface of the left ventricle.

Unipolar chest leads

The unipolar chest leads are also called the precordial leads and constitute the horizontal plane leads. It is designated as 'V' due to the unipolarity. The landmarks for placement of precordial electrodes are:

V_1: Fourth intercostal space at the right sternal border.

V_2: Fourth intercostal space at the left sternal border

V_3: Equidistant between V_2 and V_4.

V_4: Fifth intercostal space in the left midclavicular line.

All subsequent chest leads ($V_{5\text{-}9}$) are taken in the same horizontal plane as V_4.

V_5: Anterior axillary line.

V_6: Midaxillary line.

V_7: Posterior axillary line.

V_8: Posterior scapular line.

V_9: Left border of the spine.

$V_{3R\text{-}9R}$: Taken on the right side of the chest in the same location as the left sided leads $V_{3\text{-}9}$. V_{2R} is therefore the same as V_1.

$3V_{1\text{-}9}$: Taken as the left $V_{1\text{-}9}$ lead but in the 3rd intercostal space. The same terminology can be applied to leads taken in other intercostal spaces e.g., $2V_{1\text{-}9}$, $6V_{1\text{-}9}$, etc (Fig. 6.11).

Unipolar intracardiac leads

This can be constituted by an electrode, contained in a cardiac catheter and the ECG can then be recorded from the various intracardiac chambers, such as: right atrium and right ventricle. But use of this

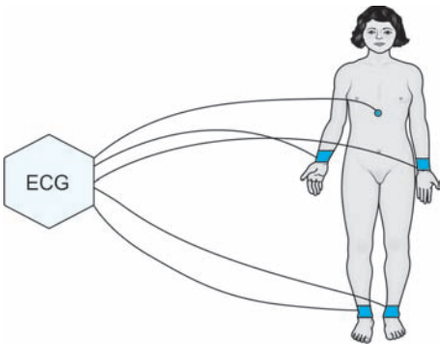

Fig. 6.11: Unipolar chest (precordial) leads in a modern ECG equipment. It records the potential difference in horizontal plane, without being influenced by the actual potential from an indifferent electrode. The unipolar precordial lead does not record only the electrical potential from a small area of the underlying myocardium, but also records all the electrical events of the entire cardiac cycle, as viewed from the selected lead site

technique is limited to cardiac laboratories only.

BASIC MECHANISM OF ACTION OF AN ELECTROCARDIOGRAPH (FIG. 6.12)

In resting state like all other cells of the body, the cardiac muscle cells are also in a polarised state, i.e, the outer surface of the cell is + vely charged and the inner surface of the cell is –vely charged. If the two electrodes of a galvanometer are attached at the opposite ends on the outer surface of a resting cell, then no deflection will occur. This is because the entire outer surface of the muscle cell has the same charge and the measured potential difference will be zero.

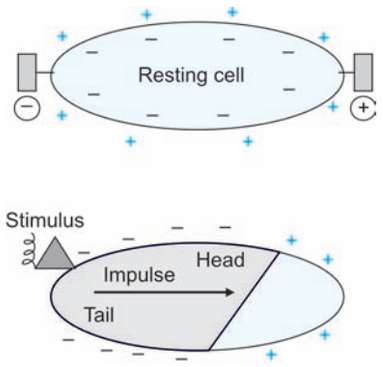

Fig. 6.12: Electrical potential of a resting and a stimulated muscle

But, when the muscle cell is stimulated or activated, then the surface of the stimulated portion of the cell becomes electrically negative (as the positive charges pass into the cell). This process is termed as depolarisation. Then, an impulse of this negative charge will progress along the outer surface towards the other end of the muscle cell which is still positive (Fig. 6.13).

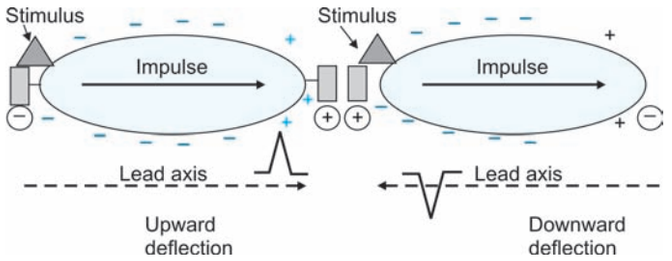

Fig. 6.13: Process of depolarisation

When this impulse passes through many resting (polarized) cells of an organ, then those cells which are initially activated or depolarised will have negative charges on their surface, while those not yet activated will have positive charges on their surface. Therefore, a sum-up potential difference of electrical charges will exist between the surface of the excitable cells and the surface of the adjacent resting cells of the same organ. So, a current will flow from the depolarised area to the polarized area of the organ.

Now, this flow of current will have a positive head and a negative tail. So the positive pole of a bipolar lead or a unipolar lead, oriented towards the oncoming head, will record a positive or upward deflection.

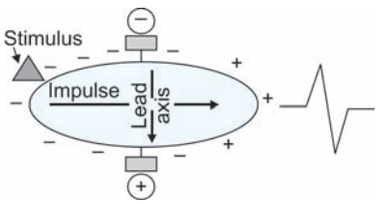

Fig. 6.14: Process of downward deflection

On the otherhand if the positive pole of a bipolar lead or a unipolar lead is oriented towards the receeding tail-end of the flow of curent then it will record a negative or downward deflection in ECG (Fig. 6.14).

Therefore, the direction in which a impulse spreads through the muscle and the position of the positive electrode of a lead in relation to the direction of the spread of the impulse will determine the positive or negative deflection of the ECG tracing. Thus, for example, an upright QRS complex in any particular lead means the flow of current during ventricular depolarisation (i.e. the QRS vector) is directed towards the positive pole of that particular lead. Alternatively, if the QRS is inverted in any particular lead, it means that the QRS vector is directed away from the positive pole of that particular lead. This principle is also applied to all the electrocardiographic deflections, such as: P, T, U and the ST segment (if it is deviated).

If the electrodes of a lead is placed on the mid portion of the path or passage of the current, then the deflection will be biphasic. Because, the initial positive deflection will be upward due to the advancing head of the flow of current and the second negative deflection will be downward due to its receeding tail.

If the two muscle mass is stimulated in the middle with the positive electrodes at either end of the muscle, then both the electrodes will show a positive deflection of depolarisation of equal magnitude. This is because both the electrodes recognise the head of the passing current (Figs 6.15 and 6.16).

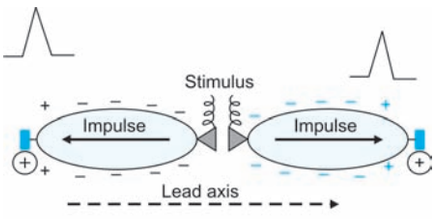

Fig. 6.15: Two muscle masses of equal size

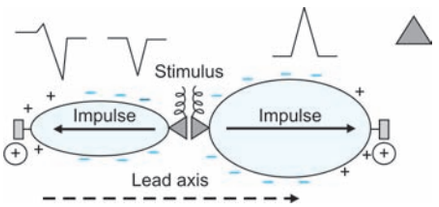

Fig. 6.16: Two muscle masses of different sizes

If the two muscle masses are of markedly different sizes (analogous to the right and left ventricle) and are stimulated at a central point, then a large positive deflection will be produced by the positive electrode over the larger muscle mass and a small positive deflection, followed by a deep negative deflection or a entirely negative deflection will be produced by the electrode over the smaller muscle mass.

This is because depolarization of the smaller muscle mass will be masked by the larger muscle mass and the electrode over the smaller muscle mass will partially or fully recognise the larger muscle mass (Fig. 6.17).

The return of the stimulated muscle mass to the resting state is known as repolarisation. If repolarisation occurs in the same direction as that of depolarisation, then deflection on the galvanometer will be opposite to that of depolarization. But, if the repolarisation occurs in the opposite direction to that of depolarisation, then the deflection will be same as that of depolarization. Since this flow of current is electromagnetic in nature like depolarisation, so it has also a vector. Thus, it also possesses both magnitude and direction (Fig. 6.18).

It must be emphasized that since the electrical activity usually occurs synchronously in more than one region of the heart, so the electrocardiograph at any given moment senses or reflects the net or resultant force of several small synchronous electrical activity, travelling in different directions.

GENESIS OF P WAVE

The P wave is the deflection produced by atrial depolarisation. The initial depolarisation in heart begins in the SA node. But, this initial depolarisation of the SA node cannot be recorded in the clinical ECG. Then the impulse generated from the SA node traverses to the AV node through three internodal pathways (Bachmann, Wenckebach, Thorel) and depolarises the whole atrium, producing the whole atrial contraction and P wave. As the SA node is situated in the right atrium, so the right atrial activation begins first which is followed by the left atrial activation. Hence the P wave is a composit deflection of both the right and left atrial activation. The right atrial activation constitutes the ascending limb and the left atrial activation constitutes the descending limb of the P wave (Fig. 6.19).

There is no clear and normal range for P wave height, but any P wave over 2.5 mm (2.5 small squares) in height should arouse suspicion.

Normally, the width of the P wave is < 0.08 seconds (2 small squares). But, the maximum duration of the P wave is 0.11 seconds (Fig. 6.20).

Normally, the vector of the P wave (the direction of the current flowing from

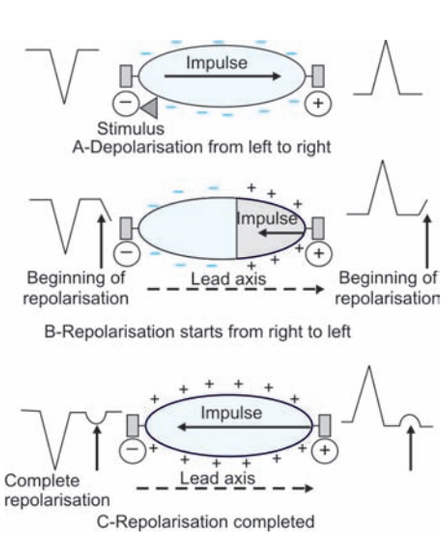

Fig. 6.17: Repolarisation in the direction opposite to that of depolarisation

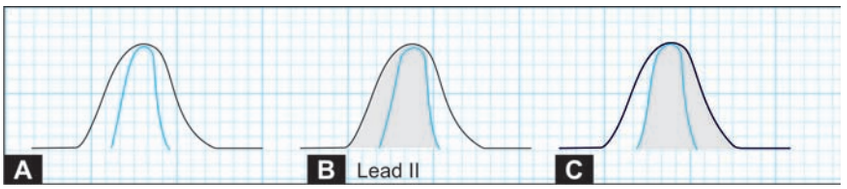
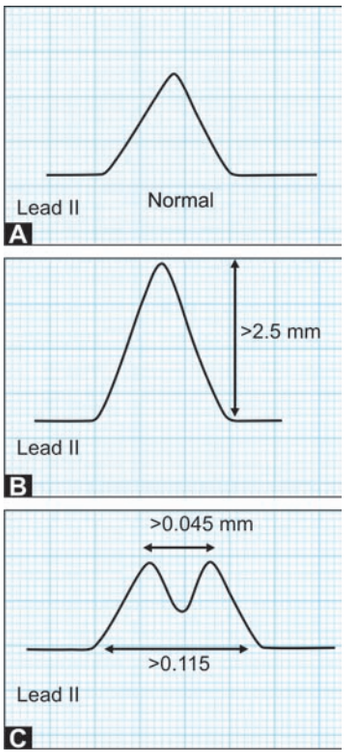


Figs 6.19A to C: The formation of P wave in lead II ECG: **A.** A normal composite P wave. **B.** Contribution of right atrial activation(shaded part) **C.** Contribution of left atrial activation (shaded part)



Figs 6.20A to C: The picture shows-
A- Normal P wave in lead II.
B- P wave due to right atrial enlargement in lead II.
C- P wave due to left atrial enlargement in lead II

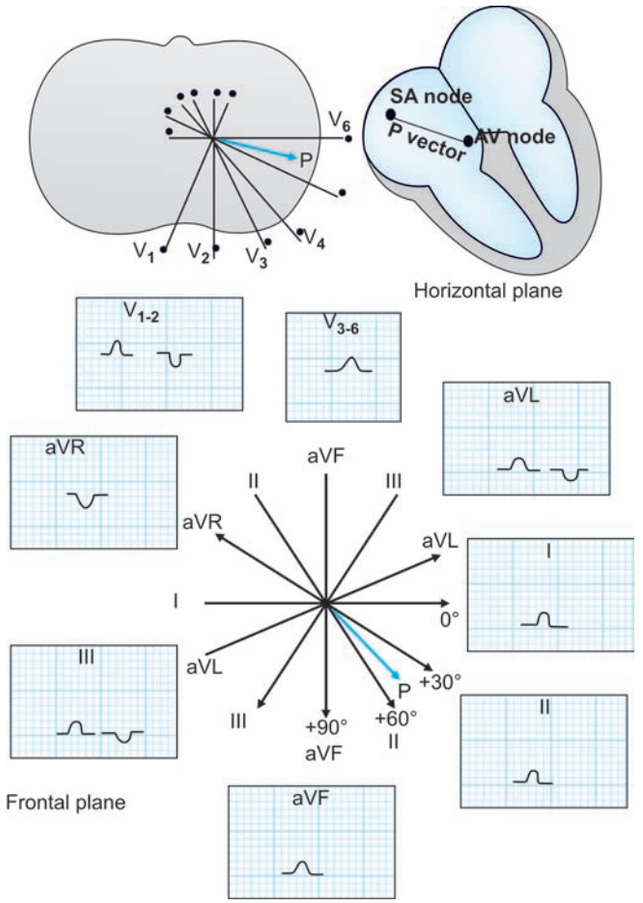


Fig. 6.21: The direction of the normal P vector in the frontal and horizontal planes. The normal P vector in the frontal plane is between 0° and +90°. So, a P vector between 0° and +30° will produce an inverted P wave in lead III and a P vector past +60° will produce an inverted P wave in lead aVL. The amount of clockwise or anticlockwise orientation of the P vector in the horizontal plane will also determine whether the P wave will be upright or inverted in lead V_1 to V_6

the SA node to the AV node) is oriented inferiorly (in the frontal plane) and to the left and slightly anterior (in the horizontal plane). Therefore, the polarity of P wave in any given lead will depend on the relation of positive electrode of that lead to the direction of this vector. In the frontal plane, the P wave vector is usually aligned or parallel to the standard lead II. So, the P wave is best seen and studied in standard lead II (Fig. 6.21).

In other leads of the frontal plane, such as in lead I and aVF and in some leads of the horizontal planes, such as in: V_3-V_6 leads (in the horizontal plane, the P vector is directed leftwards and anteriorly) the P vector is directed toward the positive pole of these leads. So, in the above mentioned leads the P wave is upright. The normal P wave axis is directed between +45° to +65° , clockwise. Hence, a P wave axis of less than +45° is reflected as left axis deviation and a P wave axis of greater than +70° is reflected as right axis deviation. In left axis deviation when the P wave is directed towards the 0°, then it will be best aligned to the standard lead I and is best evaluated in this lead.

Alternatively, during right axis deviation of the P wave when it is directed to the region of +80° to +90° , it is most aligned to the lead aVF and so in this circumstances it is best evaluated in this lead. In lead aVR the P wave is always inverted, as the direction of the vector of P wave is always away from this unipolar lead. In lead III, aVL,V_1 and V_2 the P wave may be upright, biphasic, flat or inverted, according to the direction of the P wave (Fig. 6.22).

The P wave in lead V_1 is usually biphasic, having an initial positive and terminal negative deflection. The explanation for this biphasic P wave in lead I is as follows: The right atrium with the SA node which is activated first is situated anteriorly and to the right of the left atrium. So, the vector of right atrial activation is directed towards the lead V_1. Whereas, the vector of left atrial activation which is situated to the left and is posterior to the right atrium is directed away from the axis of lead V_1.Thus, the P wave in lead V_1 shows the initial upward deflection due to right atrial activation and later downward deflection due to left atrial activation. The P wave in lead V_1 is thus a composite deflection

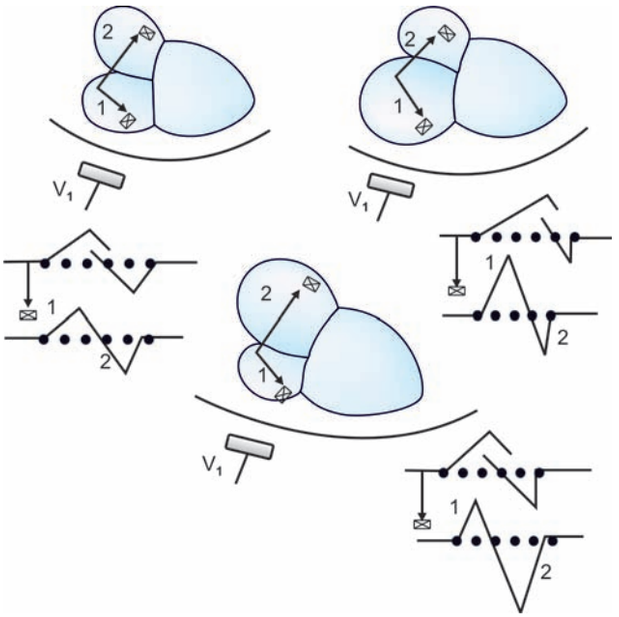

Fig. 6.22: A. Illustrates the normal activation of both the atria, (when they are normal in size), the P vector and its effects on V_1. B. The effect of right atrial enlargement in lead V_1. C. The effect of left atrial enlargement in lead V_1.

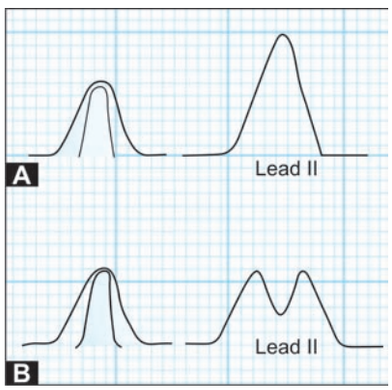
of both the right and left atrial activation, making it biphasic.

The P waves in the oesophageal leads have greater amplitude than any other lead of the conventional 12 lead ECG. As the P vector is directed inferiorly in the frontal plane, so the P wave will be inverted in high oesophageal leads (E_{10-25}) i.e, above the AV groove. In lower oesophageal leads (E_{35-50}), the P wave will be upright. In the region of AV groove (E_{25-35}), the P wave will be large, sharply peaked, a biphasic complex, simulating a RS complex of ventricular depolarisation.



Figs 6.23A and B: The change of a P wave in standard lead II
A. Right atrial enlargement
B. Left atrial enlargement

P Wave in Atrial Hypertrophy

The P wave in left atrial hypertrophy is called the 'P-mitrale'. It is characterised by a broad and notched wave. Normally it is best seen in lead II, when the P wave axis is directed to +50°. But if P wave axis is deviated towards 0° or further leftwards (a not uncommon occurence in the left atrial enlargement), it will then be mostly aligned with the standard lead I and the lead aVL, and 'P mitrale' will be seen in these leads (Fig. 6.23).

The broad P wave in left atrial hypertrophy is due to the delayed activation of the hypertrophied or enlarged left atrium (separation of right and left atrial component in the genesis of P wave). In lead V_1 a wide, slurred, biphasic P wave is characteristically seen in left atrial hypertrophy where the downward component of the P wave is most prominent. Clinically, the left atrial enlargement is found in systemic hypertension concomitant with left ventricular hypertrophy, mitral stenosis, mitral incompetence, etc.

The right atrial hypertrophy is characterised by tall, slender, peaked P waves called 'P-pulmonalae' and is found in lead II, III and lead aVF. Right atrial hypertrophy is found in chronic obstructive pulmonary diseases.

Completely Absent P Wave

There are two reasons for the P waves to be absent from ECG. The first is when there is not a single coordinated full atrial activity, regulated by the SA node. So, as the P waves are not being formed are completely absent. The second is when the P waves are present but are just not clearly seen. (Fig. 6.24).

The lack of SA node regulated and a co-ordinated full atrial activity occurs in atrial fibrillation, and this is the commonest reason for the absence of P waves in ECG. In such situation instead of a definite P wave, chaotic atrial activity produces a low amplitude oscillatory or fibrillatory waves in the ECG. These are called the fibrillatory or 'f' waves. So the atrial fibrillation can be recognised by the absence of P wave, presence of fibrillatory waves and the erratic formation of the QRS complexes. On the otherhand the configuration of QRS complexes is normal, unless there is concomitant bundle branch block. The ECG manifestation of atrial fibrillation is best seen in the frontal plane leads, especially standard leads II, III and aVF. The fibrillatory or 'f' waves are usually of negative deflection in these leads, reflecting caudal to cranial atrial activation. In the horizontal lead V_1, in contrast to the

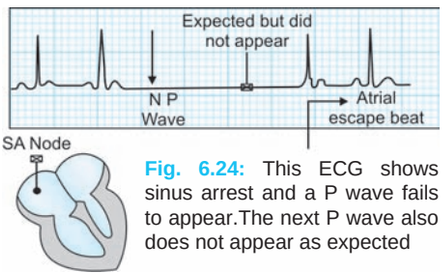


Fig. 6.24: This ECG shows sinus arrest and a P wave fails to appear.The next P wave also does not appear as expected

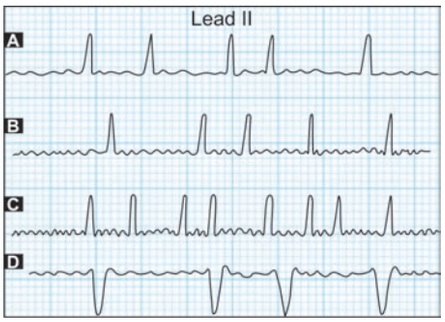

Figs 6.25A to D: ECG tracings in lead II shows the various manifestations of atrial fibrillation
A. Long standing atrial fibrillation, with a smooth slightly undulating baseline and slow irregular ventricular response.
B. Coarser and more recent fibrillation with relatively slow ventricular response. Here, the baseline is irregular and ragged.
C. The same features as B, but with a rapid ventricular response.
C. Atrial fibrillation with complete AV block

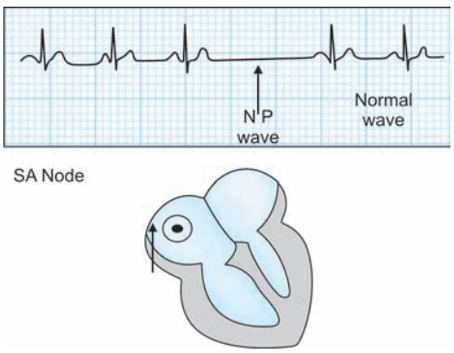

Fig. 6.26: This ECG shows sinoatrial block. P wave fails to appear, but next wave appears where expected

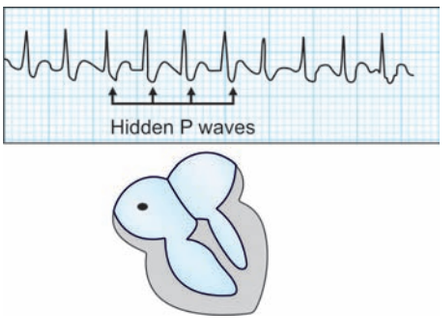

Fig. 6.28: This ECG shows AV junctional tachycardia. Heart rate is 130/min with narrow QRS complexes. These narrow QRS complexes are due to AV conduction through the His-Purkinje system. P waves are hidden within the ST segments

frontal plane leads, the P wave usually shows an isoelectric feature or are usually masked by the f waves.

The P waves will also be completely absent if there is prolonged period of sinus arrest or sino-atrial block. In these conditions the atrial activation does not occur, because SA node either fails to depolarise (sinus arrest) or fails to transmit the depolarisation from the SA node to the atrial musculature (sino-atrial block). Either condition may cause ventricular asystole, but more commonly an escape AV junctional or escape ventricular rhythm occurs. (Fig. 6.25).

During a sinus arrest in ECG, the P wave will suddenly fail to appear at the expected place, and there is a gap of variable length, until the sinus node fires again and a P wave appears or an escape ventricular beat takes over the responsibility. On the other hand, in sino-atrial block the sinus node depolarises normally (which cannot be recorded in the ECG). But this impulse fails to reach the atria. So, it is also called an exit block. However, like the sinus arrest the P wave in exit block also fails to appear at the expected place, but the next one usually appears exactly where it is expected (Fig. 6.26).

Rarely the sino-atrial exit block may occur at regular intervals e.g. 2:1 ratio. This resembles the slow regular rhythm of sinus bradycardia. But the diagnosis can only be established, when in contrast to the gradual acceleration of sinus bradycardia, the rate suddenly doubles with the effect of atropine (Fig. 6.27).

In SA block neither the P wave nor the QRS complex is recorded at the moment of the block. Whereas, in AV block all the P waves are recorded but the P waves of the blocked beat is not followed by a QRS complex. SA exit block is found in the same condition as in sinus bradycardia and is the result of an increased vagal tone. It occurs in normal high vagotonic persons e.g. athletes. It can also be produced by pressure on the carotid sinus or eyeball (during eye surgery) or other vagal reflexes (Fig. 6.28).

It is very mandatory for the P waves to be present except in certain conditions, but sometimes is not evident in many ECG tracings. So, an ECG should be searched carefully for evidence of P wave, before concluding that they are absent. This is because the P waves are often hidden by QRS complexes in any rapid tachycardia. For example, in AV junctional tachycardia (shown in the figure) with a heart rate of 130/min, at a first glance the P waves appear to be absent. On close inspection they can just be seen, buried within the ST segment. Even in sinus tachycardia at high rates the P wave may be overlapped with the T wave of the previous beat, making it hard to identify (Fig. 6.29).

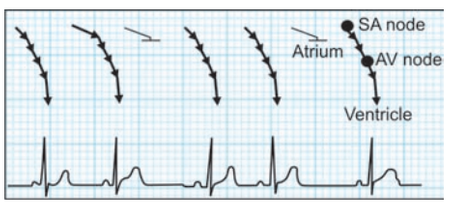

Fig. 6.27: SA node exit block.This is a 3:2 Wenckebach type of block. It is characterised by two repetative sinus conducted beats, followed by a pause. All P wa es are of the same form. The PR inter- val is constant and no AV block or atrial premature beats are evident. In this case the sinus node is firing regularly, but sometimes cannot be seen in the ECG. There is progressive SA exit block, as a result of which every third discharge from the SA node is not conducted to the atrium

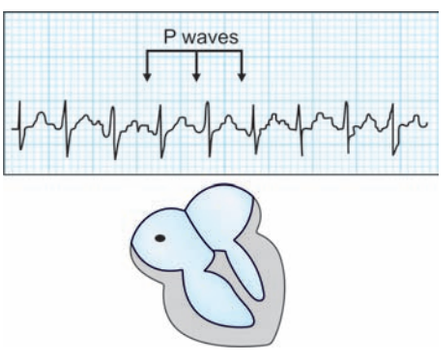

Fig. 6.29: This ECG shows sinus tachycardia with heart rate of 130/min with narrow QRS complexes. All QRS complexes are followed by a P wave and all the P waves are upright. But these P waves are hidden within the previous T waves

In ventricular tachycardia, the retrograde (backward) conduction of ventricular impulses through the AV node may cause each ventricular complex to be followed by an abnormal P wave which may not be immediately obvious and may also be inverted. Even more importantly the independent atrial activity from SA node can occur during ventricular tachycardia and these P waves can be buried anywhere within the QRS complex. So the evidences of independent atrial activity is a very useful clue in the differentiation of the ventricular and supraventricular tachycardia.

Premature Atrial Depolarisation (Atrial Extrasystole) and P Wave

The waves of depolarisation of atrial activity normally spreads from SA node to AV node through atria. If any extra-atrial depolarisation is initiated by a secondary stimulus, arising from any ectopic focus situated anywhere in either right or left atrium except at the SA node, then it is called the premature atrial beat. This depolarisation wave travels in the opposite (retrograde) direction through the atria, if it arises in the lower part of the atria. But, it travels like a normal P wave, i.e. from above downwards, if it arises in the upper part of the atria. However, both of these will cause premature atrial excitation and a P′ wave in ECG. Simultaneously, it will also initiate a ventricular complex with a normal QRS configuration (Fig. 6.30).

From the view point, in most of the positive electrodes of different leads this abnormal P wave which is originating from the lower part of the atrium, will show to move away from them rather than to flow towards them, and thus an inverted P′ waves (instead of an upright P wave) will be produced in most of the leads. However in the aVR lead this retrograde P′ wave will produce a positive deflection as it is moved towards the positive pole of this lead from lower part of atrium. Many abnormal sources of atrial activation which can thus cause retrograde depolarisation and inverted P′ waves includes atrial ectopics, AV junctional rhythm, ventricular tachycardia, ventricular ectopics, etc. (Fig. 6.31).

If an ectopic atrial stimulus arises from the upper end of the atrium, then the resulting abnormal P′ wave will have the same normal direction and configuration like the P wave. However, this premature atrial depolarisation will usually depolarise the SA node, upsetting its rhythmicity. The next normal sinus impulse, therefore, will not occur as scheduled, because the SA node needs to pass through a complete recovery cycle, before it can discharge again. The basic rhythm of the SA node is thus disturbed and a pause will follow the ectopic atrial beat. This is called the compensatory pause of the SA node. This pause is usually incomplete, i.e. it does not fully compensate for the prematurity of the extrasystole. This means that, the sum of the pre and postectopic intervals (Y-Z) is less than the sum of two consecutive normal intervals (X-Y). We should compare these events with those occasioned by a ventricular extrasystole, when the sinus rhythm is not disturbed and where the compensatory pause is subsequently complete (Fig. 6.32).

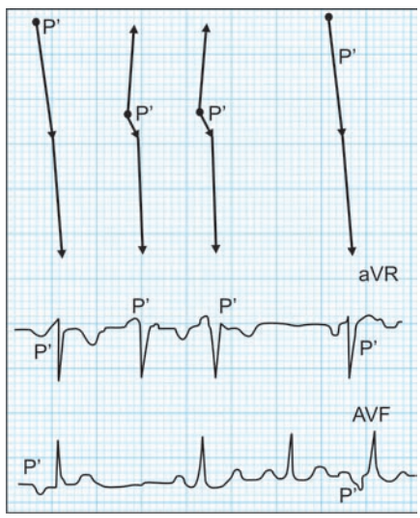

Fig. 6.30: Atrial premature beats with low atrial ectopic focus. The prominant feature is a regular sinus rhythm. The P′ waves occur prematurely. The P′ is upright in aVR and inverted in aVF. This is the reverse of the normal P wave and indicates a low atrial ectopic focus.The QRS complexes are normal

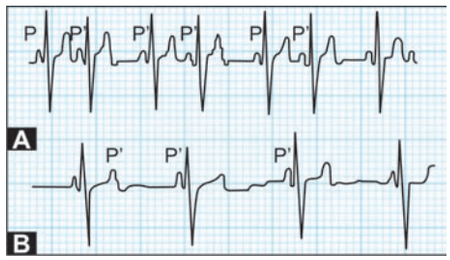

Figs 6.31A and B: This ECG shows alternate atrial extrasystoles
A: Here the ECG shows alternate atrial extrasystole indicated by a P' wave and a sinus P wave. All the atrial extrasystoles are conducted to the ventricle like a normal P wave, causing ventricular bigeminal rhythm. Here the P' wave is of upward direction, which indicates that it originates at the upper part of the atrium
B: Here the atrial extrasystole is indicated by P'. It is superimposed on the T wave and has distorted it. Here any atrial extrasystole is not conducted up to the ventricle, due to their extreme prematurity causing a slow and regular ventricular rhythm

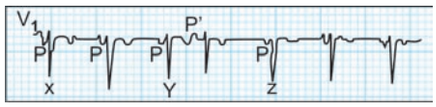

Fig. 6.32: This is an ECG of atrial extrasystole. The fourth P wave, marked as P′, is the atrial ectopic, which is conducted to the ventricle. This P′ is different from the other P waves and is characterised by a positive narrow and pointed wave.The sum of the pre and post ectopic intervals, i.e. Y to Z is less than the sum of the two consecutive normal sinus interval, i.e. X to Y

The unifocal atrial extrasystole tends to have a fixed coupling interval i.e, the interval between the extrasystole and the preceeding beat tends to be the same for all unifocal extrasystoles. This fixed coupling with atrial extrasystoles, however, is usually not as constant as that which occurs with ventricular extrasystoles. If an atrial extrasystole (which is conducted to the ventricle) occurs after every sinus impulse, then it will result in ventricular extrasystolic bigeminal rhythm. If an atrial extrasystole is not conducted to the ventricle and occurs after every conducted sinus impulse, then it will result in an atrial

bigeminal rhythm and a slow regular ventricular rhythm. Three or more consecutive atrial extrasystoles constitute a paroxysmal atrial tachycardia (Fig. 6.33).

Atrial premature beats may frequently occur in normal individuals. At times, it may occur secondary to stimulation due to emotional disturbances, tobacco, tea, coffee,etc. Digitalis may also produce such an arrhythmia. Almost any form of organic heart disease e.g. rheumatic heart disease, chronic coronary artery disease, hyperthyroidism, viral infection, etc, may be responsible for premature atrial beats and in such instances the atrial arrhythmia may be the precursor of paroxysmal atrial tachycardia and atrial fibrillation.

Wandering Atrial Pacemaker

In this type of atrial arrhythmia normally some impulses arise from the SA node, whereas the other ectopic impulses arise from the different ectopic sites of the atrium. It may even be from the AV node. As a result there will be variation of atrial rhythm, changing configuration of the P′ wave (due to atrial activation from different ectopic foci) and changing in P′R interval (Fig. 6.34).

Normally, an inverted P waves in aVR and an upright P waves in aVF will be found from impulses arising in the SA node or from the ectopic focus (P') arising in the upper portion of the atrium. Whereas an upright P′ wave in aVR and inverted P′

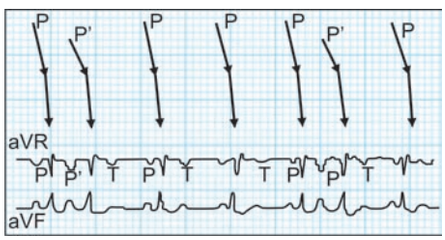

Fig. 6.33: This is an ECG of high atrial extrasystole.The P'R interval is longer than the PR interval. In lead aVR inverted P' indicates that the atrial ectopic focus is high enough. The P' wave is followed by a normal QRS complex, which indicates that the conduction is through the AV node and the Purkinje fibres of ventricle

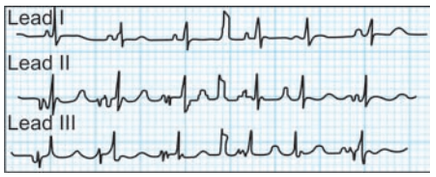

Fig. 6.34: This is an ECG of a wandering atrial pace maker. The rhythm is irregular and each QRS complex is preceeded by a P wave. But there is a marked variation in the morphology of the P wave. Some are tall and upright (sinus origin), while others are inverted and biphasic (ectopic origin). The above is indicative of varying atrial pacemakers

wave in aVF will be found from impulses arising from an ectopic focus situated in the lower portion of the atrium or AV junction.

This type of atrial arrhythmia (wandering atrial pacemaker) may also occur in a normal individuals with increased vagal tone. Digitalis may be the another important aetiological factor for this. Various forms of organic heart diseases, e.g. acute rheumatic disease can also produce this type of arrhythmia.

Paroxysmal Supraventricular (Atrial) Tachycardia (PSVT)

It is due to the rapid electrical discharge from an ectopic atrial focus, causing regular and consecutive atrial extrasystoles. It is characterised by regular atrial rhythm at rate of 160 to 220/min. Atrial tachycardia differs from sinus tachycardia, as the impulses are generated from an ectopic focus, somewhere, within the atrial myocardium rather than the sinus node (Fig. 6.35).

Some claim that re-entry mechanism is mainly responsible for this PSVT, rather

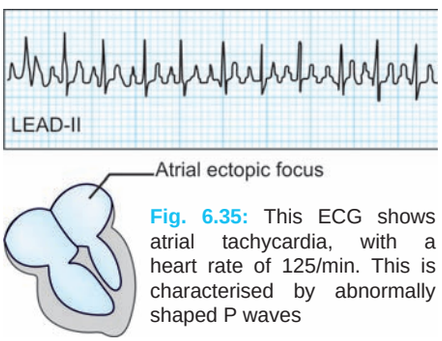

Fig. 6.35: This ECG shows atrial tachycardia, with a heart rate of 125/min. This is characterised by abnormally shaped P waves

than the ectopic focus which simply fire repeatedly on its own. The re-entry mechanism may be localised in the sinus node, atrial muscle or the AV node, involving conduction in an anterograde direction through the AV node or a retrograde conduction through the AV bypass tract. Such a bypass tract may also conduct anterogradely, in which case the WPW syndrome is said to be present. When the bypass tract conducts only retrogradely, then it is termed 'concealed by-pass tract' and in this case QRS complex is normal without any delta waves. In the absence of WPW syndrome (i.e. anterograde conduction through the bypass tract), the re-entry of impulses through the AV node or through a concealed bypass tract constitutes for more than 90% of all the PSVTs. This results in atrial rhythm with the following characteristic features: heart rate greater than 100/min and abnormally shaped P or P waves.

In most instances there is 1:1 AV conduction. But, when the atrial rate goes above 200/min, then the AV node struggles to keep up with the impulse conduction and an AV block may occur. On reaching the AV node,the atrial impulse may be conducted as follows:

i. With a normal AV conduction, resulting in normal P′R interval.
ii. With 1st degree AV block.
iii. With 2nd degree AV block—the passing of impulses through the AV node is so rapid that its cycle is shorter than the AV nodal refractory period. Thus when this occurs, then every alternate impulse is blocked, resulting in a 2:1 AV block.

The atrial tachycardia may also be associated with more complex form of 2nd degree AV block, e.g. 3:2 block. On reaching the ventricles, the atrial impulses may be conducted like normal intraventricular conduction which is manifested as rapid regular or irregular QRS complexes (if block is present) or with aberrant ventricular conduction in the presence of LBBB or RBBB, resulting in broad and rapid QRS

complexes, simulating ventricular tachycardia. The combination of atrial tachycardia and AV block is very common in digitalis toxicity. If the patient is not taking digitalis, then the probable causes of PSVT are: rheumatic heart disease, IHD, SSS, cardiomyopathy etc. (Fig. 6.36).

In atrial premature beats the direction of P′ wave in leads aVR, aVF and the oesophageal leads will indicate the site of origin (high or low) of the atrial ectopic focus. However, the identification of P′ wave is very difficult and the P′ to QRS relationship cannot be established with certainty. So, this rhythm is termed as supraventricular tachycardia, because the exact site of origin of atrial ectopic focus is not diagnosed and whatever may be the site of origin of ectopic focus it is above the ventricle. In this type of arrhythmia, the impulse spreads through the atrial muscle more slowly than a normal sinus beat. Thus P′R interval is often prolonged. The P′ wave may, therefore, be buried in the preceeding ventricular QRS complex, simulating an AV junctional tachycardia (Fig. 6.37).

Fig. 6.36: This ECG shows extrasystolic atrial tachycardia. This is characterised by varying second degree AV block. The P' waves are bizarre and the P'-P' interval measures 0.24 sec, which represents an atrial rate of 250/min. The AV conduction ratio varies between 2:1 and 3:1

Fig. 6.37: This ECG shows multifocal atrial tachycardia, where the ventricular rhythm is irregular. Each QRS is preceeded by a P wave which varies in configuration and direction. PR interval varies from beat to beat, and some of the P waves do not activate the ventricles (blocked atrial beats) The tracing represents an atrial tachycardia, resulting from multiple atrial foci (wandering atrial pacemakers)

When a paroxysmal atrial tachycardia, arises from an ectopic focus which is high in the atrium, then it produces normally directed P waves. This may be indistinguishable from a sinus tachycardia arising from the SA node at rates of approximately 140 to 160/m in one single ECG. A constant RR interval without any change with respiration will favour the diagnosis of paroxysmal atrial tachycardia. The response to carotid sinus pressure may also help in the diagnosis. In PSVT this manoeuvre may abruptly terminate the attack. Whereas in sinus tachycardia there may be slow, gradual and slight slowing of the heart rate. If there is no response to carotid sinus pressure, then one must compare the pattern of the P or (P′) waves of the tachycardia to the pattern present during the previous regular sinus rhythm. If there is difference in configuration of the atrial complexes in these two tracings, then the diagnosis of paroxysmal atrial tachycardia is justified.

PSVT occurs most commonly in normal individuals. It may show no clinical evidence of heart disease. It may occur even in relation to emotional trauma. The lesser common aetiological factors of PSVT are rheumatic valvular disease, pulmonary embolism,cardiac surgery, thyrotoxicosis, coronary arterial disease, etc. It is the most common arrythmia associated with WPW syndrome. Atrial tachycardia with AV block is a common manifestation of digitalis toxicity.

Mechanism of PSVT

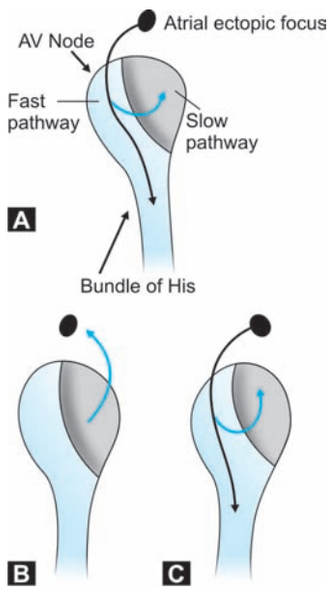
Several mechanisms are responsible for the production of paroxysmal supraventricular tachycrdia or atrial tachycardia. These are explained below.

1. *AV nodal re-entry tachycardia*

This is the most frequent mechanism of PSVT. In this circumstance, there is functional longitudinal dissociation of the AV node which results in dual AV nodal pathways with different functional properties. This dual AV nodal pathway is designated each as 'slow' and 'fast' pathways.The 'slow' pathway has a longer refractory period, and allows anterograde conduction of atrial impulse. The 'fast' pathway has a shorter refractory period and prevents anterograde conduction (Fig. 6.38).

Thus atrial tachycardia is produced sequentially by:

i. An ectopic atrial depolarisation.
ii. An anterograde conduction in one pathway (usually the 'slow' one) which results in ventricular capture, because of an unidirectional anterograde block



Figs 6.38A to C: The mechanism of AV nodal re-entry tachycardia. In such situation the AV node is divided into two parts (Shaded and unshaded in the picture),according to the conducting and refractory characteristics of the nodal tissues

A: An impulse comes from the atrial ectopic beat and tries to pass both through the shaded and unshaded areas. But due to the faster conduction property of the unshaded part,impulse first passes through it and depolarises the ventricle. Passage of impulse through the shaded part is blocked.

B: After a few milliseconds when this shaded area is no more refractory, few impulses from the unshaded area enter the shaded portion and pass back (retrograde conduction) to the atrium,resulting in another atrial depolarisation. Impulses from this second atrial depolarisation again pass through the shaded and the unshaded areas and depolarise the ventricle (antegrade) and atrium (retrograde) like the previous manner.

C: Thus repeat re-entry of impulses in atria causes atrial tachycardia.

in the other pathway (usually the 'fast' one).

iii. A retrograde conduction then occurs through the previously blocked (fast) pathway, resulting in another atrial depolarisation, which in turn again activates the ventricle, like the previous one, which passes through the slower pathway.

iv. Thus there is continuation of this re-entry circuit within the AV node producing tachycardia. Less commonly the anterograde conduction ocurrs via the faster pathway and retrograde conduction through the slower pathway. But, to differentiate between this slow and fast AV nodal re-entry pathways, special electrophysical studies are required.

2. AV re-entry tachycardia with the accessory pathway

The AV re-entry tachycardia is not the same as the AV nodal tachycardia where the defect lies within the AV node itself. In addition to the normal route of conduction via the AV node and the bundle of His, when there is an accessory connection between the atria and ventricles, then also AV re-entry tachycardia arises. By any one of the two routes the impulse travels down (anterograde conduction) and then backs (retrograde conduction) by the other route. In this way the impulse is continuously cycled and causes into repeated activity of firing the atria and the ventricle in rapid succession.

The classic examples of PSVT with this mechanism are the pre-excitation syndrome,WPW syndrome and Lown-Ganong-Levine syndrome.

Wolf-Parkinson-White syndrome

In this condition there is a strip of accessory conducting tissue that allows the electrical impulse to bypass the AV node and spread from the atria to the ventricle rapidly without any delay which occurs in AV node. When the ventricle is depolarised through the AV node though there is presence of accessory pathway, then the ECG shows normal without any delta wave. But, when the ventricles are depolarised through the accessory conducting pathway, then the ECG shows a very short PR interval, delta wave and a broad QRS complex. This is because the accessory pathway has high conduction velocity rate than the AV node. The ECG manifestation of the WPW syndrome may differ in the following ways (Fig. 6.39).

(a) Sinus rhythm

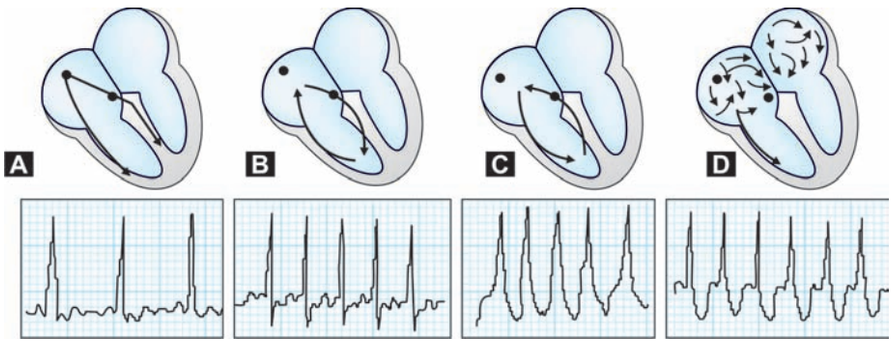
In sinus rhythm with an accessory conducting system, the ventricles are partly depolarised through the AV node and partly through the accessory pathway. Thus, it produces an ECG with a short PR interval and a slurred, broad QRS complex. The characteristic slurring of the upstroke of the QRS complex is known as the delta wave. The ECG depends on the degree of the proportion of electricity passing down the accessory pathway (i.e pre-excitation) and therefore the ECG appearances may vary a lot. Sometimes the ECG may also look normal.

(b) Orthodromic tachycardia

This the most common form of tachycardia in WPW Syndrome. Here the re-entry circuit passes anterogradely from the atrium to the ventricle, through the AV node and then comes back retrogradely through the accessory pathway. The ventricles are therefore depolarised in the normal way and produces a narrow complex tachycardia, that is not distinguishable from other forms of supraventricular tachycardia.

(c) Antidromic tachycardia

Here the re-entry circuit passes anterogradely from the atrium to the ventricle through the accessory pathway, and then comes back retrogradely through the AV



Figs 6.39A to D: The mechanism of WPW syndrome

A. Here the cardiac rhythm is sinus without any tachycardia and the impulse passes through both the pathways. The ventricle is depolarized by impulses which pass partly through the accessory pathway and partly through the AV node. The accessory path way has faster conduction rate than the AV node and is responsible for short PR interval and also delta wave. The next part of the QRS complex (after the delta wave) is as usual, and formed by the impulse coming through the AV node. The ultimate configuration of the QRS complex depends upon the degree of pre-excitation, i.e. the proportion of impulse passing through the accessory pathway and normal AV node. Therefore, the appearance of ECG may vary a lot and it may look normal or abnormal.

B. This shows tachycardia with WPW syndrome. Here, the re-entry circuit passes through the AV node (anterograde) and comes back through the accessory pathway(retrograde or orthodormic). Thus ventricles are depolarised by normal AV nodal path and produces narrow complex tahycardia without delta wave which is indistinguishable from other causes of SVT.

C. This also shows tachycardia with WPW syndrome. But here the impulse first passes through the accessory pathway and then comes back through the AV node(retrograde or antidormic),after depolarising the ventricle. As the ventricle is depolarised first by the accessory pathway,so it produces broad complex tachycardia.

D. This shows atrial fibrillation associated with WPW syndrome where the ventricle is depolarised by impulses passing through the accessory pathway producing broad complex tachycardia.

node. The ventricles are then depolarised through the accessory pathway, producing a broad complex tachycardia.

(d) Atrial fibrillation

In this rhythm the ventricles are largely depolarised through the accessory pathway, producing an irregular broad complex tachycardia (Fact file-I).

Bradycardia Tachycardia (Brady-Tachy) Syndrome

It is one of the presentations of a disease with wide (potential) spectrum of disorder of rhythm, such as: Sick-Sinus Syndrome. It is apparently an paradoxial association of depressed conduction activity with hyperexcitability. But, the precise mechanism of this syndrome is not known.

There is an abnormality of impulse formation and impulse conduction, involving both the SA node, AV node and its appendages, such as: the bundle of His, the right and left bundle branches and the Purkinje fibres. Bradycardia part of this syndrome is due to sinus bradycardia, sinus arrest or sinus block. This bradycardia may or may not be associated with conduction defects in the AV node and its appendages and with or without adequate escape rhythm. The supraventricular tachyarrhythmia often emerges as an adequate escape rhythm in response to an episode of severe bradycardia due to sinus arrest or sinus block.. The supraventricular tachyarrhythmias may also be paroxysmal atrial tachycardia, atrial flutter or atrial fibrillation. This tachyarrhythmias may manifest first or may precipitate as a compensatory response to a long pause due to the sinus arrest or block. The diagnosis of sick sinus syndrome is suspected when following the termination of tachyarrhythmias, there is a period of exceptionally very slow sinus rate manifested as bradycardia which may be as slow as 25 to 35 beats per minute for a short period. This tachyarrhythmia may ultimately establish as atrial fibrillation. The abnormal AV nodal conduction often become apparent when a patient with brady-tachy syndrome develops AF with AV nodal failure to conduct all the atrial impulses leading to slow ventricular response.

The commonest cause of brady-tachy syndrome or sick-sinus syndrome is the degeneration and fibrosis of the sinus node, AV node and the conducting system. Other causes are IHD, drugs (digoxin, quinidine, beta blockers), cardiomyopathy, amyloidosis, etc. The symptoms of brady-tachy syndrome are dizziness, fainting or even syncope due to low cardiac output, caused by severe bradycardia. In addition to symptoms of bradycardia, patients may also experience episodes of supraventricular tachycardia.

The asymptomatic patients of brady-tachy syndrome do not require any treatment. Symptomatic patients may be considered for permanent pacemaker implantation. Medical therapy for tachycardia require anti-arrhythmic drugs which again worsens the phase of bradycardia. Therefore, pacing is also helpful to prevent this serious bradycardia and also permits medical therapy for tachycardia. Paroxysmal tachycardia which arises as an escape rhythm to episodes of bradycardia may also improve as a consequence of pacing.

FACT FILE- I

AV re-entry tachycardia

The accessory pathway is an extra connection between the atria and the ventricles, which is anatomically separated from the AV node. Accessory pathways make the patient susceptible to the episodes of AV re-entry tachycardia, with anterograde conduction via the AV node and retrograde conduction via the accessory pathway. In such circumstances, Delta wave is not seen in the ECG. In variety of re-entry tachycardia, where the impulses take the opposite route i.e, anterograde flow down the accessory pathway and retrograde flow up the AV node, which is very rare, then delta waves are seen (delta waves are seen when anterograde impulse passes through the accessory pathway). The AV nodal re-entry tachycardia is called when the accessory pathway lies within the AV node, in which anterograde conduction usually occurs down the normal AV nodal tissue and returns retrogradely via the abnormal AV nodal tissue.

Both the AV re-entry and AV nodal re-entry tachycardia have the following characteristics :

i. Heart rate is 120 to 240 beats per minute.

ii. There is one P wave for every QRS complex but P waves are not always seen clearly.

iii. QRS complexes are regular if there is no AV block.

iv. QRS complexes are narrow if there is no conduction defect or bundle branch block

If there is a pre-existing bundle branch block, QRS complex will be broad and re-entry tachycardia will be mistaken for VT. So, a previous ECG will be helpful in determining whether a bundle branch block existed before the tachycardia or not. In AV re-entry tachycardia, the inverted P waves are often seen halfway between QRS complexes. Whereas in AV nodal re-entry tachycardia the inverted P waves are impossible to see as they buried within the QRS complexes. Although the position of the P waves may help to distinguish between AV re-entry and AV nodal re-entry tachycardia, still an ECG in sinus rhythm is more helpful, as it may reveal a short PR interval or delta wave, suggesting WPW syndrome. Still, a definite diagnosis is very difficult and sometimes require electrophysiological studies.

Atrial Flutter (AF)

Atrial flutter is the manifestation of rapid and regular extrasystolic atrial excitation. It shares the same mechanism as paroxysmal atrial tachycardia, arising from an ectopic atrial focus or results from a continuous depolarization encircling the atrium through accessory pathway, i.e. the re-entry mechanism.

The ectopic atrial focus producing AF causes rapid discharge from the ectopic site, similar to atrial extrasystole or PSVT (atrial tachycardia). But, this is not a well accepted concept for atrial flutter. However the re-entry mechanism can be described by the re-entry pathway which is situated within the atrium and does not involve the AV node. This is the most acceptable explanation for atrial flutter (Fig. 6.40).

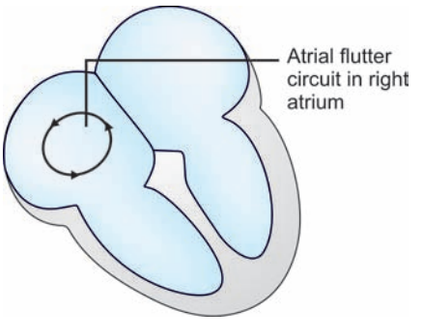


Fig. 6.40: The atrial flutter circuit.It's key point is the circuit of activity, which circles in the right atrium continuously

Except for the mechanism of origin, the atrial-flutter also differs from the atrial tachycardia by the atrial rate (P wave) which is higher in AF and usually 250 to 350/min. The ventricular response to this rapid atrial activity depends upon the efficacy of conduction of impulses through the AV node. AV node cannot keep up with such a high atrial rate, and AV block occurs. Most commonly there is 2:1 block, where only alternate atrial impulses get through the AV node to initiate a QRS complex. Though, 3:1, 4:1, 6:1 or variable other degrees of blocks are also seen. Thus, the ventricular rate is less than the atrial rate and is often 150, 100 or 75/min according to the Av block, but is regular.

We should always suspect atrial flutter with 2:1 block when a patient has a tachycardia with a regular ventricular rate around 150/min. Occasionally, every atrial impulse is conducted to the ventricles with a 1:1 response (i.e. without any block), resulting in a very fast, but regular ventricular rate (Fig. 6.41).

The cardinal sign of atrial flutter in ECG is the presence of regular undulating waves, resulting in the characteristic 'saw tooth' appearance with prominent negative deflection in tracing. These manifestations are usually best seen in standard leads I, II and aVF and chest lead V_1. The T wave is usually masked or deformed by the flutter waves. The QRS complexes are normal, unless there is a coincidental bundle branch block (Fig. 6.42).

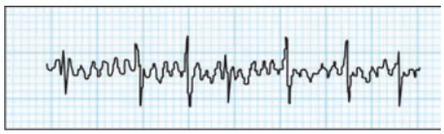

Fig. 6.41: ECG showing atrial flutter associated with fibrillation. So, this is called flutter fibrillation It is still doubtful whether this type of arrhythmia has a definite entity or not. The so-called atrial flutter-fibrillation may probably be a case of a lesser degree of atrial fibrillation. Digitalis can convert atrial flutter into fibrillation. This is due to the shortening of the refractory period of atrium by digitalis. When digitalis is stopped the fibrillation may convert to normal rhythm

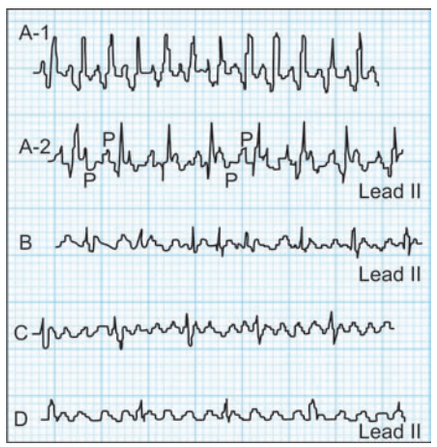
The basic difference between the atrial tachycardia and the atrial flutter are the atrial rate, site of re-entry, presence and degree of AV block, and responses to therapy.

Sometimes, atrial flutter with 2:1 AV block may be mistaken as atrial tachycardia with 1:1 conduction (i.e., no block) or even regular sinus rhythm, because one of the P' wave is buried in the QRS complex. Atrial flutter may also be mistaken the basic difference between the atrial flutter and fibrillation is that in fibrillation due to rapid atrial rates many leads of the ECG



Figs 6.42A to D: This ECG shows various forms of atrial flutter. The key points of atrial fibrillation are - rapid atrial rate, wide saw-tooth deflection in the place of the P wave, and absent or barely noticeable baseline
A-1: This shows atrial flutter with a 1:1 response.
A-2: This shows 2:1 response of atrial flutter after treatment with digitalis in the same patient.
B: This shows atrial flutter with 2:1 response but without treatment with digitalis
C and D: This shows atrial flutter with 4:1 response

will not clearly show the regularly recurring P′ waves. Whereas in atrial flutter P′ waves are regularly and clearly seen. If the ventricular response is irregular, then it will simulate an atrial fibrillation (Fig. 6.43).

Atrial Fibrillation

Atrial fibrillation is much commoner than atrial flutter, affecting 5 to 10% of all the elderly people. It may be permanent or paroxysmal, particularly in younger people. In atrial fibrillation no P waves are seen and the ECG base line consists of low amplitude fibrillatory waves. In atrial fibrillation, the excitation and recovery processes of the atria are completely disorganised and chaotic. The whole atrium is functionally divided into numerous islands of tissue which are in a different chaotic electrical state and in various stages of excitation and recovery. These numerous excitatory wavelets or stimuli pass irregularly through the whole atria without any effectful atrial contraction. Normally, the human atrium can respond and contract regularly to stimulus, only up to a certain rate. This is usually in the range of 350/min. But at a rate faster than this, the atrium can no longer respond completely to each stimulus. So, a chaotic electrical disturbance with asynchronous atrial depolarization and ineffective atrial contractions results in atrial fibrillation.

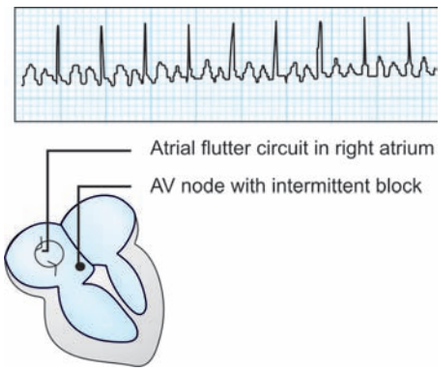


Fig. 6.43: ECG shows atrial flutter with 3:1 AV block. Flutter waves are at a rate of 300/min and QRS complexes at a rate of 100/min. Therefore 3:1 AV block is present

In atrial fibrillation, the atrial activation is manifested in ECG by an undulating baseline or by a more sharply inscribed atrial deflection of varying amplitude and frequency, ranging from 350 to 600 beats per minute (Fig. 6.44).

The ventricular rhythm is totally irregular because the majority of the atrial impulses reaching the AV node are blocked and it is because of the refractoriness of the AV node. There is no fixed 2:1 or 3:1 or 4:1 AV block like the atrial flutter. The AV node can only conduct some of these stimuli, because following conduction of one such stimulus it is refractory for a short period and impulses reaching the AV node during this period are blocked. Only occasional impulses meet during the nonrefractory period of the AV node and are conducted distally to activate the ventricles. This is called 'concealed conduction'. Although around 350 to 600 impulses reach the AV node every minute, but only 120 to 180 of these will reach the ventricles to produce normal QRS complexes provided there is no bundle brunch block.

In ECG the atrial deflections are recorded as irregular, chaotic, fibrillatory waves (F-wave) resulting in a ragged baseline. No P waves and irregularly-irregular ventricular rhythm will be seen. In long standing cases of atrial fibrillation, the deflection may be of a low amplitude and the base line may be found almost straight with minimum and smooth undulation of low amplitude. At times, the rhythm may alternate between the flutter and fibrillation in a single tracing. These are the borderline cases in which a precise differentiation can not be made. In such instances the term 'flutter-fibrillation' may be used. However, it is better to reserve the term 'flutter' for those records, which have perfectly regular atrial depolarisation and fibrillation for all those that are irregular.

A rapid atrial fibrillation with ventricular rate of 200/m may simulate an atrial tachycardia. But, it can be differentiated easily as the ventricular rhythm in atrial fibrillation will show variations whereas the ventricular rhythm in later will be perfectly regular.

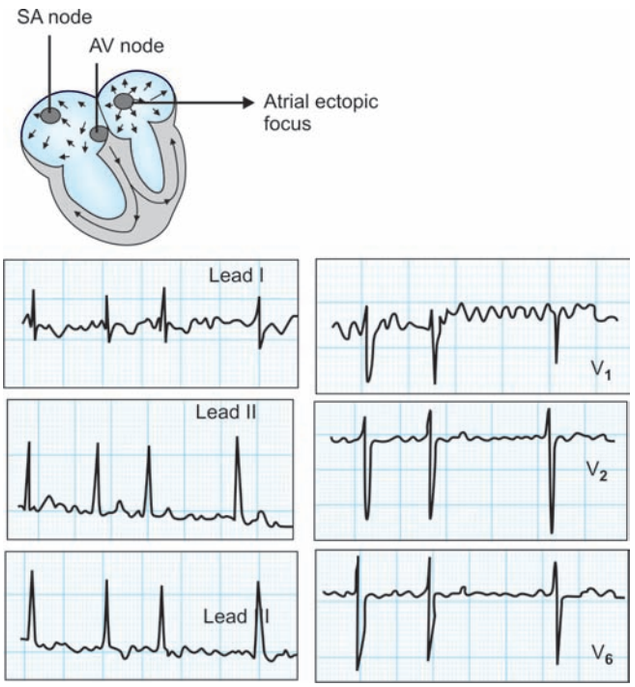

Fig. 6.44: Atrial fibrillation activity is manifested by small rapid irregular fibrillatory waves. The ventricular rhythm is completely irregular

THE GENESIS OF PR INTERVAL

After flowing through the atria from SA node, the electrical impulses reach the AV node which is normally the only entry route of an electrical impulse to the ventricle from the atrium. This is because the rest of the atrial myocardium is separated from the ventricles by a non-conducting ring of fibrous tissue. Activation of the AV node does not produce any obvious wave in the ECG like SA node, but it does contribute to the time interval between the P wave (atrial contraction) and the subsequent Q or R wave heralding the beginning of ventricular contraction. So, sometimes the PR interval is referred to as the PQ interval. By delaying the conduction from atrium to ventricle, the AV node acts as a safety mechanism which prevents the rapid atrial impulses from spreading to the ventricles at the same rate (Fig. 6.45).

So, the time taken for the depolarisation wave to pass from its origin in the SA node, across the atria and through the AV node to the ventricle is called the PR interval. This is measured from the begining of the P wave to the beginning of R wave and is normally between 0.12 to 0.2 seconds (maximally up to 0.22 seconds) or 3 to 5 small squares. Thus it includes (i) the time required for the atrial depolarization to travel from the SA node to the AV node (usually 0.03 sec), (ii) normal conduction delay in AV node (approximately 0.07 sec)

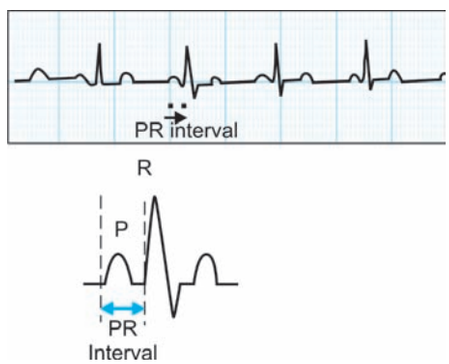

Fig. 6.45: The PR interval.The normal interval is 0.12 - 0.20 seconds

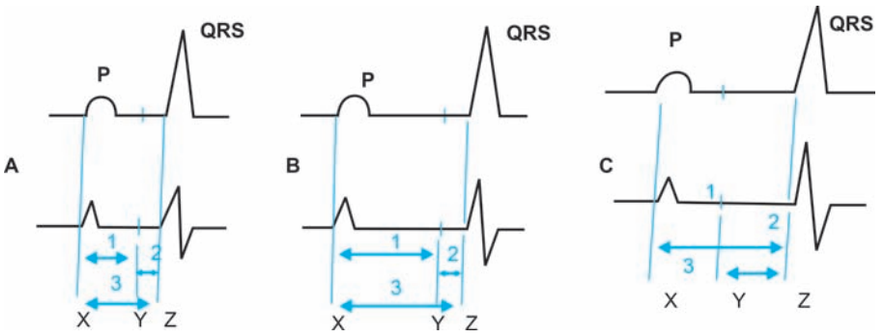
and (iii) the passage of impulse through the bundle of His and the bundle branches to the ventricle.

The PR interval should be correlated with the heart rate (HR). Normally slower the HR, longer the PR interval. A PR interval of 0.2 seconds may be of no clinical significance with a HR of 60/min. But it may be well significant with a HR of 100/min. Though, the interval between the P waves and the QRS complexes changes, but it is approximately constant between 0.12 to 0.2 seconds (Fig. 6.46 and Fact file -II).

Atrioventricular Block

The atrioventricular block is characterised by a delay or interruption in the conduction of atrial impulses to the ventricle through the specialised AV conduction system such as the AV node, bundle of His or bundle branches (right and left bundle branches). The atrio-ventricular (AV) block can be classified into three degrees.

i. In first degree block there is delay in conduction of impulses more than 0.2 sec through the AV node.
ii. In second degree block there is intermittent or incomplete interruption of conduction of impulses through the AV node.
iii. In third degree block there is permanent or complete interruption of conduction of impulses through the AV conduction system. The first and second degree heart block is called the partial or incomplete heart block and the third degree heart block is called the complete AV block or complete heart block.



Figs 6.46A to C: A: This shows normal AV conduction
B: This shows first degree AV block. Here 1 is prolonged but 2 isnormal. So 3 is also prolonged. Therefore the block is proximal to the Bundle of His in the AV node
C: This also shows first degree AV block. Here 1 is normal but 2 is prolonged. So 3 is again prolonged Therefore the block is distal to the Bundle of His in the intraventricular conduction system. The QRS interval is prolonged when there is a block distal to the Bundle of His.

FACT FILE- II

Mechanism and site of AV block

The AV block results either from a functional or pathological defect in the atria, AV node, bundle of His or bundle branches, causing delay in the relay or conduction of impulses through the AV node.The functional block of AV node can occur as a result of increased vagal tone.The AV block produced by digitalis toxicity is also partly due to the vagal stimulation. The PR interval can be subdivided into two segments.

(i) The time from the beginning of the P wave to the end of depolarization of AV node. This is represented in the figure as XY interval.

(ii) The time from the end of AV node depolarization to the beginning of the ventricular depolarization.This is represented in the figure as YZ interval. These measurements are of major clinical significance.

In the presence of first degree AV block (prolonged PR interval) the block may be at the following sites:

(i) Above the bundle of His (therefore in the AV node), giving a prolonged XY interval and a normal YZ interval.

(ii) Below the bundle of His (therefore in the intraventricular conduction system), giving a normal XY interval and a prolonged YZ interval.

(iii) A combination of both (i)and (ii) with prolonged XY and YZ intervals. Even in the presence of a normal PR interval, either the XY or the YZ interval may be prolonged.

The bundle of His recordings, although not available as a routine clinical tool, have resulted in more clarification of the mechanism and sites of first, second and third degree AV block.

First degree AV or heart block

In this condition there is a disturbance or delay in conduction through the AV node and bundle of His. This results in prolongation of the PR interval above the upper limit of normal range (> 0.2 sec), constituting the first degree AV or heart block.

In first degree AV block, all the P waves are followed by QRS complexes. It is usually asymptomatic and in general does not progress to other degrees of heart block. No specific treatment is necessary for first degree AV block in its own right, but needs close observation. It is not an indication for pacemaker implantation (Fig. 6.47).

Second degree AV or heart block

Second degree AV or heart block is again classified into Mobitz type I (Wenckebach phenomenon) and Mobitz type II block.

Mobitz type I of 2nd degree AV block

Here, the PR interval gradually lengthens with each successive beat, until after several, usually 3 to 6 beats when an atrial depolarisation fails to pass and initiate a ventricular response due to a complete block of AV node and thus this beat is

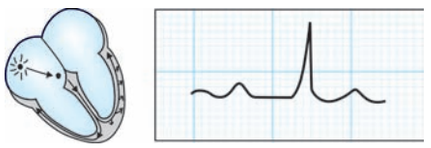


Fig. 6.47: First degree AV block-Delay in conduction through AV node, Bundle of His or atria.This produces length ening of the PR interval

dropped. Hence, a long diastolic pause results. The pause caused by this dropped beat allows the conducting system to recover. The PR interval again resets back to normal and now allows the atrial depolarisation to be further conducted to the ventricle. The sequence is then repeated. Here, the defect lies with in the AV node (Fig. 6.48).

The Mobitz type I AV block is thought to be as the result of abnormal conduction through the AV node itself and can result simply from high vagal activity. So, it sometimes occurs even during sleep. It may also occur in any generalised disease of the conducting system or tissue. It is regarded as a relatively benign form of AV block and permanent pacemaker is not required, unless the frequency of the dropped ventricular beats causes any symptomatic bradycardia. Patients found to have the Mobitz type I of 2nd degree AV block prior to surgery will usually require temporary pacing perioperatively

Mobitz type II of 2nd degree AV block (Fig. 6.49)

Here, there is no gradual progression or prolongation of the PR interval, like Mobitz type I AV block. The PR intervals of all the conducted impulses are constant. But, periodically the ventricles fail to respond to the atrial stimulations and this may occur at any interval. For example, for every 6 atrial complexes there are only 5 ventricular complexes and will be termed as 6:5 AV block. Again it may be of any combination, such as: 3:2, 2:1, 4:3, or 2:1 AV Mobitz Type II block (Fig. 6.50).

The lesion in this form of Mobitz type II of 2nd degree AV block is actually situated in the bundle of His i.e. below the AV node and is always organic or pathological. It carries an adverse prognosis, since it frequently progresses to 3rd degree or complete AV block. So Mobitz type II is more serious than Mobitz type I AV block. It is also an indication for perioperative pacing (Fig. 6.51).

2:1 AV block is a special form of 2nd degree heart block (also termed as '2nd degree constant block') in which alternate P waves are not followed by QRS complexes. Regular sinus rhythm complicated by 3:2 AV block will result in a ventricular bigeminal rhythm (Fig. 6.52).

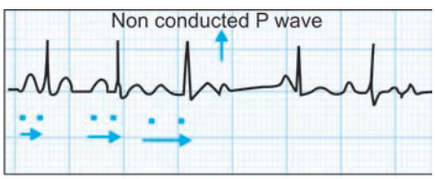
Third degree AV or complete heart block

The third degree AV block is characterised by the complete or permanent interruption of AV conduction. All the supraventricular impulses (sinus rhythm, atrial tachycardia, atrial fibrillation, etc.) are blocked to pass to ventricle at the level of AV conducting system. The ventricles are then activated by a subsidiary ectopic foci acting as a pacemaker for escape rhythm, situated on the AV node but below the level of block or within the ventricles (Fig. 6.53).

The atrium is thus activated by one pacemaker (usually sinus or may be ectopic) and ventricle by another idioventricular pacemaker. Hence the two rhythms—atrial and ventricular run independently and asynchronously.

The features of complete AV block are:

i. P wave has no relationship with the QRS complex and if it is sinus in origin, then the rate is 60 to 80/min. Any



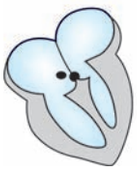


Fig. 6.48: The ECG shows Mobitz type I variety of 2nd degree AV block (Wenckebach phenomena). There is progressive lengthening of PR interval with intermittent failure of P wave to be conducted. Then PR interval again resets and cycle repeats

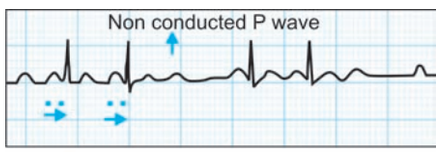

Fig. 6.49: This is an ECG of Mobitz type II variety of 2nd degree AV block. It is characterised by a normal and constant PR interval, but occasional P wave fails to be conducted

Fig. 6.50: This ECG shows 2:1 AV block,where alternate P waves fail to be conducted

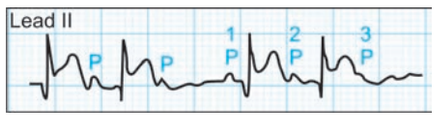

Fig. 6.51: ECG of inferior wall MI in hyperactive phase, with 3:2 second degree AV block of Wenckebach type. This is evidenced by tall R wave, ST segment elevation and tall-wide T wave. The first PR interval is normal,the second PR interval widens and the third P wave is not followed bt a QRS complex

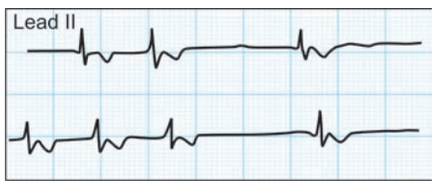

Fig. 6.52: This ECG shows Mobitz type II AV block. This is evidenced by irregularly dropped P waves resulting in successive 3:2, 2:1, 4:3 and 2:1 AV block. The PR interval is prolonged but is same for all the conducted beats

Fig. 6.53: This ECG shows third degree AV or complete heart block.This is characterised by (i) no relation between P waves and QRS complexes, (ii) broad QRS complexes (iii) P wave(atrial rate) is 86/min and QRS complex (ventricular rate) is 50/min

abnormal atrial rhythm can coexist with the third degree heart block and so the P wave may be abnormal or even absent.

ii. There is slow ventricular rate or QRS complex, usually in the range of 35 to 40/min and it is not under vagal influence (since ventricles have no parasympathetic activity). It is thus not usually affected by exercise, emotions or atropine.

iii. If the subsidiary pacemaker arises from the AV node below the block or bundle of His, then the configuration of the QRS complex is normal or near normal in shape.

iv. If the pacemaker is situated peripherally in the Purkinje fibres or in the ventricular musculature, then the QRS complex will be abnormal and broad. Sometimes, the ventricle may be under the control of 2 or 3 alternative pacemakers, resulting in QRS complexes of different configurations.

A combination of bradycardia and broad QRS complexes should alert a suspicion of third degree heart block. For the management of this type of complete block temporary pacing is always indicated, regardless of the patient's symptom or haemodynamic state. Pacing is also necessary perioperatively for patients who are waiting for surgery.

Atrioventricular Junctional Rhythm (Fig. 6.54)

This type of rhythm is also called the AV nodal rhythm, because here the impulse arises from the AV node as an ectopic focus. The impulse then spreads upward into the atrium and downward into the ventricle. This usually produces an upright P′ wave in aVR and in high oesophageal leads and an inverted P′ wave in lead II, aVF and low oesophageal leads. Thus P′ wave is inverted in leads where it is normally upright and vice-versa (Fig. 6.55).

The QRS complex is of normal configuration, as it arises from the AV node

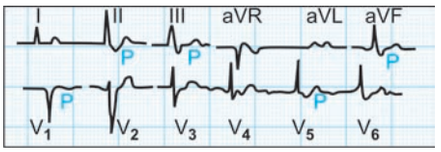

Fig. 6.54: ECG shows AV nodal junctional rhythm with late retrograde conduction and activation of atria. Here P waves follow each QRS complex and are inverted. This inverted P wave is seen in Lead II, III, aVF, V4 and V5

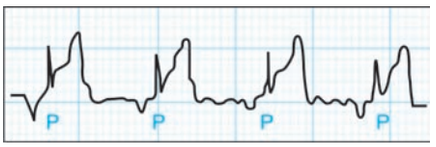

Fig. 6.55: This ECG illustrates the AV nodal rhythm with retrograde conduction to atria. So an inverted P wave precedes each QRS complex

and passes through the normal conducting pathway. If the retrograde conduction to the atria is faster than the anterograde conduction to the ventricles, then P′ wave will precede the QRS complex. But if the opposite occurs, then the P′ wave will follow the QRS complex. If conduction to the atria and ventricles occurs at the same rate, then the P′ wave will be hidden within the QRS complex (Fig. 6.56).

These junctional beats may appear as escape beats when the sinus rate is very slow or as premature beats when an increased automaticity of the AV junction site develops. This increased automaticity of AV junction may be due to digitalis toxicity. The transient or permanent AV junctional rhythm may result from organic heart diseases like IHD, myocarditis,

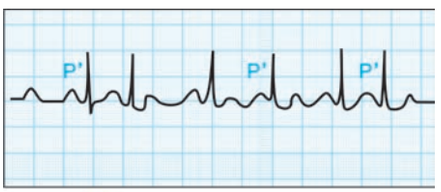

Fig. 6.56: This ECG shows atrial ectopic beats.The key points are (i) P waves are earlier than expected, and (ii) P waves are abnormally shaped

rheumatic heart disease, etc. The significance of these junctional beats or rhythm is similar to that of atrial premature beats. The escape beats are protective in nature as they represent a secondary pacemaker (to SA node) and takes over the responsibility, when the primary pacemaker slows or fails (Fig. 6.57).

AV Junctional Tachycardia (Fig. 6.58)

It is defined as the successive three or more AV nodal extrasystoles. Like PSVT it has an abrupt onset and termination. It is relatively uncommon and the rate can vary from 120 to 200/min. The ventricular rhythm associated with AV junctional or nodal tachycardia is regular. The P′ waves originating from the AV junctional tissue may precede, be buried in, or follow the QRS complexes. The pattern of each QRS complex is identical to that of a junctional premature beat. With a rapid rate during tachycardia it is impossible to identify any single P′ wave. Practically, one cannot

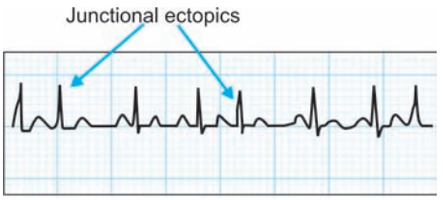

Fig. 6.57: The ECG shows AV junctional ectopic beats. It is characterised by (i) QRS complexes are earlier than expected (ii) QRS complexes are not preceded by P wave, and (iii) QRS complexes are narrow

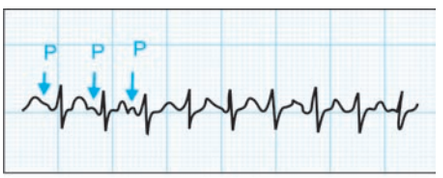

Fig. 6.58: ECG of sinus tachycardia.It is evidenced by narrow QRS complexes and P waves arehidden within the previous T waves

differentiate the ECG pattern produced by AV junctional tachycardia from that produced by atrial tachycardia arisig from a low atrial ectopic focus. Therefore, the appropriate term such as supraventricular tachycardia is more applicable to AV junctional tachycardia and atrial tachycardia. The clinical significance of AV junctional tachycardia is similar to that of atrial tachycardia (supraventricular tachycardia) (Fig. 6.59).

GENESIS OF QRS COMPLEX

The activation or depolarization of ventricle is reflected by a QRS complex in an ECG tracing. The normal QRS complexes have different appearances in each of the 12 ECG leads (Fig. 6.60).

The activation of ventricle starts at the left side of interventricular septum in the bundle of His and then it spreads from the left to the right. This is called the septal force or the septal vector of QRS complex, producing septal activation and is responsible for small positive deflections or r waves in V_1, V_2 leads and small negative deflections or q waves in leads I, V_5, V_6 and aVL. As the amount of electrical activation is little at the septum, so the amplitude of deflection is very small.

The activation of septum is then followed by activation of free walls of both the ventricles. This can be represented by a large right to left force through the thick free walls of the left ventricle, which occur simultaneously with a smaller opposing force directed from the left to the right through the thinner free wall of the right ventricle. The larger right to left force of the left ventricle dominates and counteracts the smaller left to right force of the right ventricle. This results in an effective or net resultant vector which is directed from the right to the left through the left ventricle and produces a large negative deflection i.e. S wave in leads V_1, V_2, aVR (negative deflection because the flow of current is away from these leads) and large positive deflection i.e. R wave in leads I, II, V_5, V_6 (positive deflection because the flow of current is towards these leads) (Fig. 6.61).

The last portion of the ventricular muscle to be activated is the posterobasal portion of the left ventricle, followed by the region of pulmonary conus and lastly the upper most portion of the interventricular septum. The vector of the force of this last part of activation is directed rightwards and anteriorly. So, a small positive deflection will be recorded in lead $V_{1\text{-}2}$, and a small negative deflection S will be recorded in leads I and $V_{5\text{-}6}$. Thus, the right oriented leads (V_1 ,V_2) will therefore, normally reflect an rS or rSr complex, and the left oriented leads (V_5 ,V_6) will reflect an qR or qRs complex. Lead V_3 and V_4 are the transitional leads and reflect the transition from rS complex to qR complex. The transition pattern is usually a RS complex. But, at times the pattern may be relatively bizarre and depends on the presence of clockwise or counter clockwise rotation of the heart. So, the transition pattern should be ignored (Fig. 6.62).

An initial downward deflection after the P wave is called the Q wave (small q is for a small downward deflection) and an initial upward deflection after the P wave is called the R wave (small r for a small upward deflection). After Q and / or R, the next downward deflection is called the S wave. After the S wave the next positive deflection (second positive deflection of the QRS complex) is called the R′ or r′ (r′ for a small amplitude). These different nomenclatures of a QRS complex are given in the picture. The QRS interval is the measurement of total ventricular depolarization time. It is measured from the onset of Q wave or R wave (if there is no

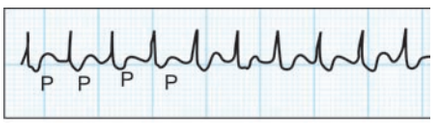

Fig. 6.59: ECG of AV junctional tachycardia. The key points are (i) tachycardia (ii) narrow QRS complexes (iii)P waves follow QRS complexes (iv) P waves are inverted in lead II

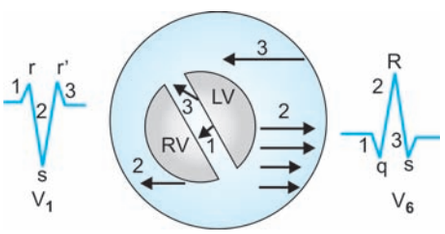

Fig. 6.60: The basic vector of ven tricular depolarisation and its effects on leads V_1 and V_6: LV- Left Ventricle, RV- Right Ventricle

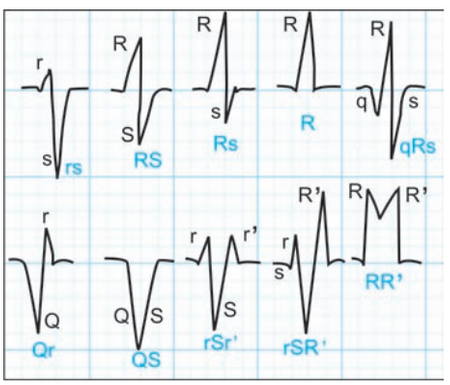

Fig. 6.61: The various forms of the QRS complexes and their nomenclatures

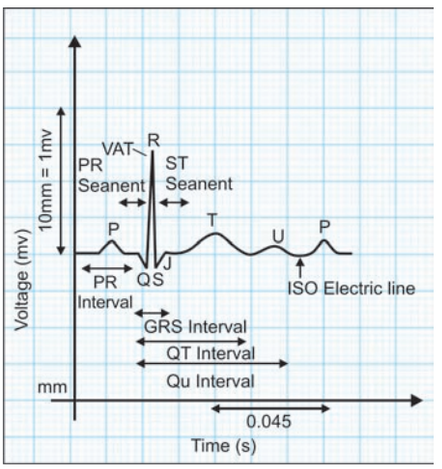

Fig. 6.62: A schematic diagram of ECG complexes, intervals and segments. The graph is magnified for clarity and better understanding

Q wave) to the termination of S wave or r′ wave. The upper limit of QRS interval is 0.12 secs.

The ventricular activation time (VAT) is an indirect measurement of the time which is taken for an impulse to traverse the whole thickness of the left ventricular wall. It is measured from the beginning of the QRS complex (or the beginning of the Q or r wave) to the peak of the R or S wave. The upper limit of VAT is 0.04 secs.

Intraventricular Conduction Defects

The intraventricular conduction defect is the result of conduction abnormality through one or more divisions of the ventricular conduction system which are distal to the bundle of His. The anatomical structures for normal intraventricular conduction are (from the bundle of His to the ventricular muscle fibres): (i) right bundle branch, (ii) left bundle branch, (iii) left anterior fascicle, (iv) left posterior fascicle, (v) septal fibres from the left bundle branch that enter the left septal myocardium and (vi) peripheral Purkinje fibres (Fig. 6.63).

The conduction defect may be a delayed conduction through the conducting pathway or even a total block. But, as the ECG cannot distinguish between the two, so it is better to use the term 'conduction defect'. The conduction defect is only an ECG diagnosis, but not a clinical diagnosis.

The ECG criterias for conduction defects or blocks are:

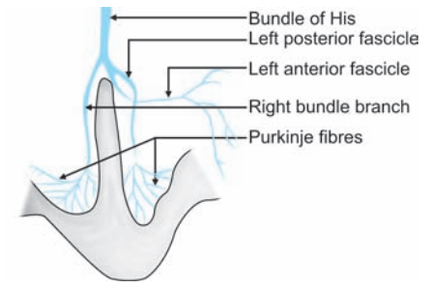

Fig. 6.63: The intraventricular conduction system

i. Abnormal QRS configuration due to abnormal spread of conduction through the conducting system of ventricle
ii. Prolongation of the QRS interval, i.e, more than 0.12 sec
iii. Prolonged VAT
iv. The ST segment is depressed and the T wave is inverted in leads that record abnormal R′ wave

In an incomplete block all the above criteria should be present, except the QRS interval which is not more than 0.12 sec.

Right Bundle Branch Block (RBBB)

It is a very common ECG finding and is not pathognomonic of any organic heart disease. It may be present in association with any type of heart disease and may also be found in normal individuals with an incidence of 1.5 per thousand, between ages of 20 to 40 years and 2.9 per thousand over the age of 40 years. It may also be associated with different types of cardiomyopathies, ASD, coronary artery disease, pulmonary embolism, Ebstein's anamoly, etc (Fact file-III).

Mechanism

Here, the spread of excitation from the SA node to the AV node and then up to the bundle of His is normal. After that the septal activation occurs normally from left to right through the bundle of His. In leads V_1 and V_2 as a result of normal septal activation which is oriented to the right and anteriorly, a small r wave will be recorded. Since, the right bundle branch is blocked, so the excitation wave will next spread down the left bundle branch and through the left ventricular myocardium, resulting in a S wave in leads $V_1$and V_2. The impulse will then pass around the apex of the heart, bypassing the blocked right bundle into the right ventricular myocardium, producing a R′ wave. Thus, a typical pattern of rsR′ will be found in leads V_1 and V_2 in RBBBs. If the S wave is small or absent, then the pattern will be RR′. The ST segment will be depressed and so the T wave is inverted (Fig. 6.64).

The T wave is opposite in direction to the terminal QRS deflection. Thus, if the terminal deflection is R′, for example, in lead V_1, then the T wave will be inverted. However, the associated ST segment will show deflection which is slightly convex upwards or sometimes minimally depressed. If, on the other hand, the terminal deflection is an S wave, for example, in lead V_6 then the T wave will be upright. The associated ST segment will be slightly

FACT FILE - III

Common causes of bundle branch block

RBBB	**Normal variant**
	Coronary artery disease, Congenital heart disease (e.g. ASD)
	Right ventricular hypertrophy or strain
	(e.g. pulmonary embolism)
	Cardiomyopathy
	Ebstein's anamoly
LBBB	Coronary artery disease
	Hypertension
	Coarctation of aorta
	Hypertrophic cardiomegaly
	Aortic valve disease
	Cardiomyopathy
	Fibrosis of the conduction system

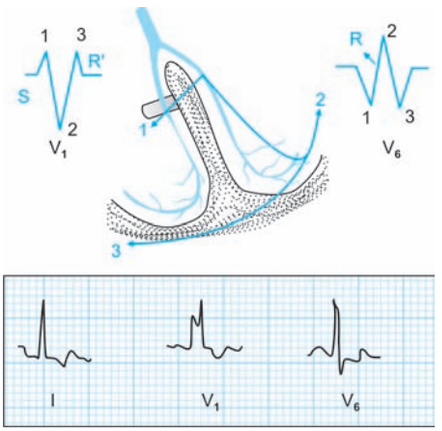

Fig. 6.64: The ECG shows RBBB. The key points are:
i. Broad QRS complexes
ii. R' wave in lead V1
iii. S wave in lead V6.
In RBBB, the QRS looks like 'M' in lead V_1 and W' in lead V_6. In 'M' and 'W'.
1. due to septal activation
2. due to left ventricular activation
3. due to right ventriculae activation

concave downwards and at times is minimally elevated.

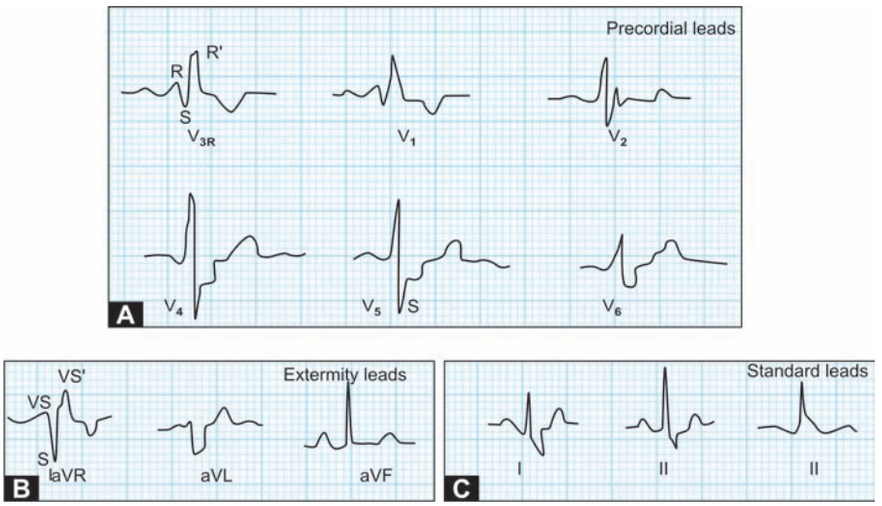
In lead V_5 and V_6 an initial small q wave will be formed as a result of normal left to right septal activation. This will be followed by a R wave, resulting from a large left ventricular activation. Then this R wave will be followed by a S wave which results from the delayed large activation of the right ventricle. The ST segment is isoelectric and the T is upright.

So, in RBBB the QRS will look like 'M' in V_{1-2} and 'W' in lead V_{5-6}. The characteristic feature of RBBB is a delayed electrical force of right ventricular depolarisation, oriented to the right and anteriorly. This late right vector force produces a wide S wave in lead-I, V_{5-6} and a wide R or R′ (RSR′ pattern) in lead aVR and V_{1-2}. The ST and T are opposite in direction to this late force of ventricular depolarisation (R or R′ wave) in the precordial leads. An initial q wave will never be present in V_{1-2} leads in RBBB or an initial q wave in V_{1-2} lead indicates it is not RBBB. Alternatively, an initial q wave in V_{1-2} leads always indicates LBBB (Fig. 6.65).

Incomplete RBBB

A delay, but not a complete stoppage of conduction of impulses through the right or left bundle branches manifests as an incomplete bundle branch block. In case of incomplete RBBB conduction through the right bundle branch is still possible, but is delayed. It is now increasingly clear that this slowed down conduction of impulses is not the only cause for the genesis of an incomplete RBBB. But the increased length of the right bundle branch may also play a significant role for relative delay where conduction itself is not delayed. For example, an increased length of the right bundle branch is responsible for the longer time of conduction producing relative delay and incomplete RBBB. This anatomical factor (increase in length) responsible for the cause of incomplete RBBB is clearly significant when there is dilatation of the right ventricle due to volume or diastolic overload. The causes of this right ventricular dilatation are: ASD, tricuspid insufficiency, chronic corpulmonale, right ventricular hypertrophy, etc.

The pattern of ECG in incomplete RBBB is similar to that of complete RBBB, except that the QRS interval is not greater than 0.12secs. Sometimes, it is impossible to differentiate between the incomplete RBBB and normal QRS pattern in lead V_1.



Figs 6.65A to C: Summary of RBBB-
A: Depicts precordial leads, characterised by
1. RSR1 or rsR_1 complexes in V3R and V_{1-2}. An initial 'q' wave is never present in these leads unless there is associated infarction, right ventricular hypertrophy or dilatation ,or additional left ventricular fascicular block
2. Wide S wave in V_{5-6}
3. QRS interval >0.12s
4. ST depression and T wave inversion in V_{1-3}

B: Depicts extremity leads,characterised by
1. Wide rsr1 complex in aVR
2. Patterns in aVL and aVF will depend on heart position.

C: Depicts standard leads, characterised by wide S wave which is invariably present in lead I Among these many findings are common but are not essential for the diagnosis. So,minimum criteria for RBBB diagnosis is rsR_1 complex in right precordial leads(V3R and V_{1-2}) with QRS interval >0.12 sec and a wide S wave in lead I

Left Bundle Branch Block (LBBB)

Complete LBBB always indicates some form of organic heart disease. It is commonly associated with an ischaemic heart, left ventricular hypertrophy due to a hypertensive heart, and aortic valvular diseases. But, it may occur with almost any form of heart disease. It is rarely seen in individuals, with no clinical evidence of an organic heart disease.

Mechanism

Here, the spread of excitation from SA node to the AV node and the bundle of His is normal. Then as due to the block the impulse cannot enter the left bundle system (left side of the septum), so septal activation starts on the right side and follows to the left, resulting in an initial vector oriented from the right to the left (opposite to normal) (Fig. 6.66).

Therefore, in leads V_{1-2} an initial q wave will (does not normally present in lead V_{1-2}) result which is due to septal activation from right to left. Since the left bundle branch is blocked, so the excitation wave next spreads down the right bundle branch to the right ventricular myocardium, resulting in a r wave in the V_{1-2} leads. Because of the relative thinness of the right ventricular wall, the amplitude of this r wave may or may

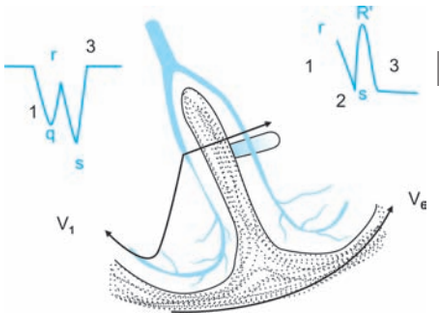


Fig. 6.66: ECG of a fully evolved LBBB

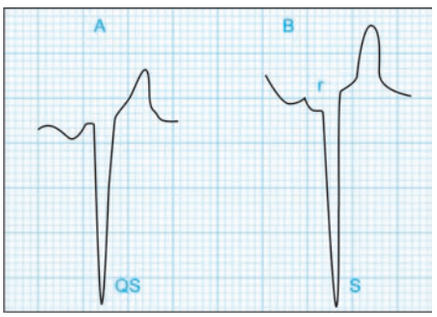
not pass above the isoelectric line or may produce a notch in the qS wave in these V_{1-2} precordial leads. The impulse then passes from the right ventricular myocardium around the blocked left bundle branch into the left ventricular myocardium and produces a deep wide S wave. Thus, a typical W-pattern QRS complex will be developed in leads V_{1-2}. Occasionally, either a small q or r wave cannot be recorded. Therefore, the pattern looks like a rs or QS complex. The ST segment may be elevated and T will be upright (Fig. 6.67).

In leads V_{5-6} as a result of septal activation from the right to the left a small initial r wave will be recorded. Q wave will not be formed (in normal ECG Q wave is a must in V_{5-6} lead). This is followed by activation of the right ventricle and anegative deflection S wave. Because of the thinness of the right ventricle this S wave may not go below the isoelectric line, but may merely produce a notch in the R wave. The impulse then passes around the blocked left bundle branch into the left ventricle through the myocardium and produces a R′ wave. Thus, a typical pattern of rsR′ or RsR′ or a slurred and widened R wave will be formed. The ST segments are usually depressed and T waves are inverted (opposite the direction of the last wave). So, in LBBB the QRS looks like 'W' in V_{1-2} leads and like 'M' in V_{5-6} leads (Fig. 6.68).

Thus, the characteristic feature of LBBB is the absence of normal septal q wave in lead I and in left precordial leads V_{5-6}. Conduction delay is present through most of QRS vector, producing a broad and slurred R wave or rsR′ or RSR′ complexes in lead I and V_{5-6}. The QRS interval is > 0.12 secs.

Significance of LBBB is that it may be permanent or transient. Transient LBBB may occur during the course of MI, heart failure, acute myocarditis and as a result of drug therapy (quinidine, procainamide, amiodarone, etc.). However, the permanent LBBB is always the result of some organic heart disease.

In the right ventricular cavity complex the LBBB will produce a wide QS complex.This is because the septal activation is from the right to the left and the cavity will be negative throughout the ventricular depolarization. In left ventricular cavity complex the initial septal depolarization from the right to the left produces an initial small r wave. Then ventricular depolarization, proceeding from the endocardial to the epicardial surfaces results in a larger negative deflection S wave. The left ventricular cavity complex is therefore rS.



Figs 6.67A and B: A. ECG changes of LBBB in right ventricular cavity complex. B. ECG changes of LBBB in left ventricular cavity complex

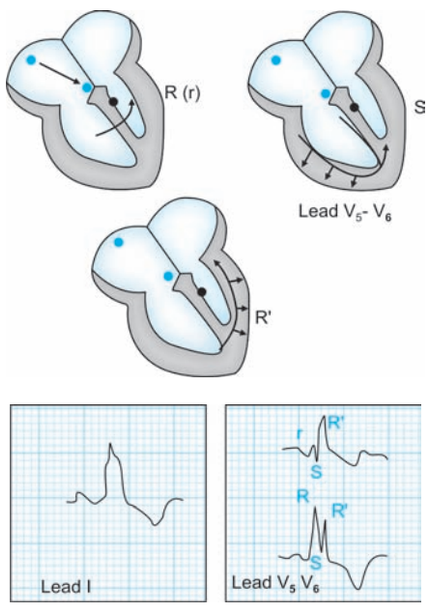


Fig. 6.68: ECG of LBBB in left epicardial complex

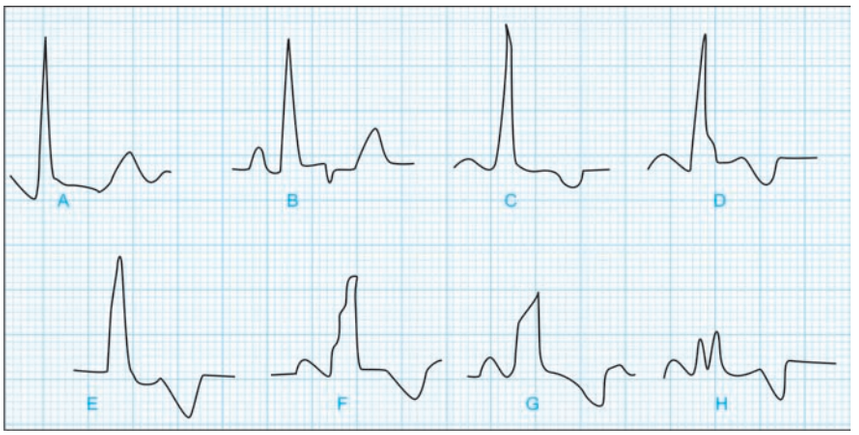
Incomplete LBBB

In case of incomplete LBBB the conduction of impulses through the left bundle branch and its ramifications is still posible. But this is delayed. The type of ECG manifestation which occurs with incomplete LBBB will depend upon the degree of delay of conduction of impulses within the left bundle branch. Progressively increasing delay of conduction within the left bundle branch will result in a progressive sequence of ECG manifestations, leading to a complete block. All grades of incomplete LBBB are illustrated in the picture (Fig. 6.69).

The initial manifestations of an incomplete LBBB are the following:

i. The small initial q wave (due to normal septal activation) of the normal qR complex in the left oriented leads, i.e. V_{5-6} and I disappears. This results in a single tall R wave.
ii. The small initial r wave (due to normal septal activation) of the normal rS complex in lead V_{1-2} disappears. This results in a QS complex.
iii. With further progression a slur appears on the upstroke of QRS complex. This slur becomes increasingly prominent and is accompanied by widening and an eventual notching of the QRS complex, until the fully developed manifestation of complete LBBB is attained. Such a manifestation is due to the increasing dominance of the right ventricular factors due to the increasing delay of conduction within the left bundle branch.



Figs 6.69A to H: This ECG in lead V_{5-6} shows the progression from normal intraventricular conduction through var ious phases of incomplete LBBB to complete LBBB
A: Normal intraventricular conduction, where the small initial normal q wave is still visible
B: Earliest stage of incomplete LBBB. Here the initial q wave has disappeared and there is the beginning of a small initial slur QRS complex
C to G: Reflect progressive increase in the degree of complete LBBB. These are: increasing prominence of the initial slur, progressive widening of the QRS complex,development of a notch in the QRS complex,an increase in secondary ST segment and T wave changes.
H: Complete LBBB

Fascicular Block (Hemiblock)

It is defined as a delay or interruption of conduction within one of the two major divisions or fasciculi of the left bundle branch. The left bundle branch after its origin from the bundle of His divides immediately into 2 major divisions.

i. The anterosuperior division: passes anteriorly and superiorly.
ii. The posteroinferior division: passes posteriorly and inferiorly.

The anterosuperior division of the left bundle branch is more vulnerable to interruption of activity than the posteroinferior division. The reasons are:

i. The anterosuperior division is long and thin, whereas the posteroinferior division is short and thick.
ii. The posteroinferior division has double blood supply, whereas the anterosuperior division has a single blood supply by the septal branch of the anterior descending coronary artery which also supplies the right bundle branch.

Thus, the anterosuperior division is more vulnerable to injury (ischaemia, fibrosis, etc) and interruption of activity than the posteroinferior division.

This also explains the frequent association of RBBB with left anterior fasciculi or hemiblock.

Left anterior fascicular or hemiblock (LAHB)

It is the delay or interruption of conduction through the anterosuperior division of the left bundle branch. It may be due to fibrosis or infarction. The fibrosis may be due to coronary artery disease, cardiomyopathy, longstanding hypertension, long standing chronic heart failure, etc.

When there is an interruption in conduction through the anterosuperior division of left bundle branch, then the entire conduction from the left bundle branch passes through the posteroinferior division, resulting in a mean QRS axis or vector in the frontal plane which is directed superiorly and to the left, i.e. left axis deviation (greater than –30°). Thus, the left-axis deviation is the diagnostic criteria of left anterior hemiblock in ECG. There is no appreciable widening of the QRS complex (Fig. 6.70).

In LAHB the first part of the ventricle to be activated is the inferior septal region and the posterior region of the free left ventricular wall, i.e. the posteroinferior region of the left ventricle. Therefore, it results in initial QRS forces to be directed to the right (q in lead I) and inferiorly (r in II and III and aVF). This initial activation is followed by a delayed activation of the anterosuperior lateral region of the free left ventricular wall by the anterior fascicle via

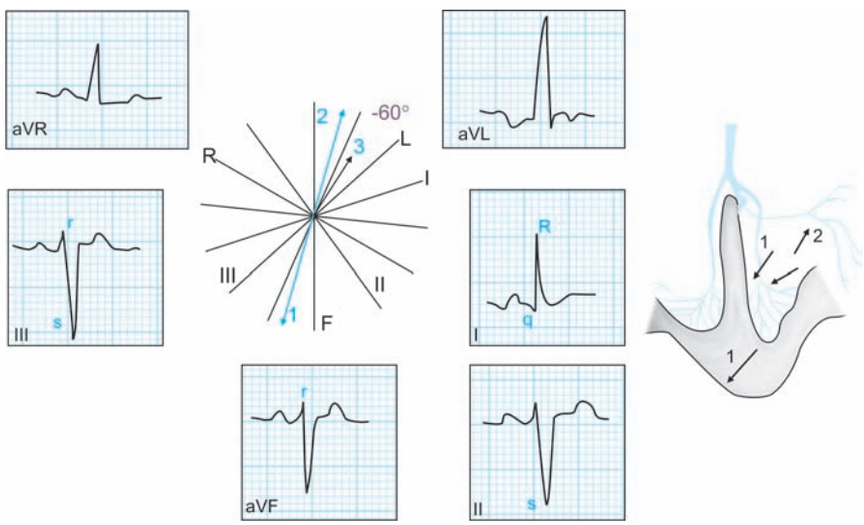


Fig. 6.70: The left anterior fascicular or hemiblock. The initial QRS vector (1) is directed to the right causing q in 1 and inferiorly causing r in II, III and aVF. The terminal QRS vector (2) is directed to the left causing R in I and superiorly causing s in II,III and aVF. Thus, the resultant QRS frontal plane vector (3) is oriented to –60°

the interconnecting Purkinje fibres distal to the site of the block. This results in a QRS vector oriented to the left (R wave in I) and superiorly (S in II, III and aVF). Thus, qR in lead I and rS in lead II diagnose the left axis deviation and left anterior hemiblock. But, other causes mimicking the left axis deviation should be excluded.

Therefore, LAHB causes the following modifications of the QRS complex:

i. A prominent QRS vector which is directed towards the right,
ii. Left QRS axis deviation,
iii. Slight increase in QRS duration,
iv. Increased magnitude of the QRS deflection,

Other causes of left axis deviation are:

i. Myocardial Infarction—inferior wall.
ii. Pacing, arising from the apex of the right ventricle (right or left).
iii. WPW syndrome (some presentation).
iv. Ventricular ectopic beats arising from the apex.
v. Some congenital heart diseases.
vi. Coronary artery disease.
vii. Left ventricular hypertrophy.
viii. Pulmonary emphysema.

Left anterior hemiblock is the commonest cause of left axis deviation and is most frequently due to fibrosis. This fibrosis may be due to chronic cardiac failure, chronic coronary insufficiency or chronic left ventricular decompensation which occur with chronic cardiomyopathy and long standing systemic hypertension. In elderly patients the left anterior hemiblock may be due to the subclinical coronary artery disease. When the left anterior hemiblock is associated with congestive heart failure, then it usually indicates a long standing heart disease.

The isolated left anterior hemiblock in the absence of any overt cardiac disease does not necessarily imply an adverse prognosis or constitute a great risk factor. When LAHB is associated with RBBB (bifasicular block), then it usually indicates an adverse prognosis and may precede to complete heart block.

Bifascicular block in a patient with syncopal attacks is often a sufficient indication for permanent pacemaker implantation. Asymptomatic bifascicular block is not necessarily an indication for pacing.

Left posterior fascicular or hemiblock (LPHB)

It is a very rare occurance and results from a lesion in the posterior fascicle of the left bundle branch. Left ventricular conduction initially spreads through the anterior fascicle, resulting in a QRS vector oriented to the left (r in lead I) and superiorly (q in lead II, III and aVF). So, last part of the anterior hemiblock is manifested first here. Then, the posterior fascicule is activated via the interconnecting purkinje fibres distal to the site of the block. This results in a vector oriented to the right (S in lead I) and inferiorly (R in lead II, III and aVF). First part of the anterior hemiblock is manifested later here. Hence, the mean frontal plane QRS axis is deviated to the right (right axis deviation) (Fig. 6.71).

There are other causes of right axis deviation, such as: right ventricular hypertrophy, lateral myocardial infarction, etc, which can be excluded from the left posterior hemiblock. Therefore, an ECG diagnosis of the left posterior hemiblock can be made only by excluding the possibility of right ventricular hypertrophy and MI.

An easy workout for determination of cardiac axis

i. A predominatly positive QRS complex in both lead I and lead II indicates a normal axis.
ii. A predominantly positive QRS complex in lead I and predominantly negative QRS complex in lead II indicates a left axis deviation.
iii. A predominantly negative QRS complex in lead I and a predominantly positive QRS complex in lead II indicates a right axis deviation.

Bilateral Bundle Branch Block

It indicates conduction defects in both the right and the left bundle branch systems in different combinations. According to this combination they are classified as:

i. RBBB with left anterior hemiblock or fascicular block.

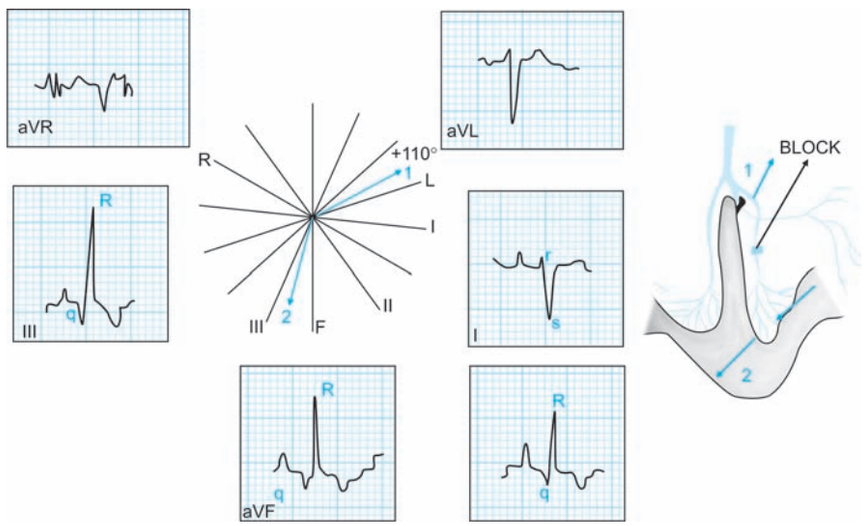

Fig. 6.71: The left posterior fascicular or hemiblock. The initial QRS vector (1) is directed to the left causing r in I and superiorly causing q in II, III and aVF. The terminal QRS vector(2) is directed rightwards causing S in I and inferiorly causing R in II,III and aVF. Thus, the resultant QRS frontal plane vector is oriented to +110°

ii. RBBB with left posterior hemiblock or fascicular block.
iii. Right or left bundle branch block with prolonged AV conduction (PR interval > 0.20 secs).
iv. RBBB with left anterior fasicular block and left posterior fasicular block. This means RBBB with complete LBBB or a complete heart block.

The bilateral bundle branch block is prognostically significant. Because, they greatly increase the probability of complete heart block. The most common cause of bilateral bundle branch block is a degenerative process that involves the upper part of the intraventricular septum and the annulus structure of mitral and/or aortic valve, leading to fibrosis and calcification. The next common cause of this type of block is coronary artery disease. When bilateral bundle branch block is associoated with MI, the prognosis is very poor. When RBBB is combined with left anterior or posterior hemiblock, it is termed as bifascicular block. It means two of the three main conducting pathways to the ventricles are blocked. Again if bifascicular block is combined with a first degree AV block (long PR interval), it is called the trifascicular block. Actually, trifascicular block means all the 3 fascicules (right bundle branch, left anterior and left posterior fascicules) of the interventricular conducting system are blocked and it is not possible for a supraventricular impulse to activate the ventricle. So, it is a situation equivalent to third degree or complete heart block with idioventricular rhythm. But, the term trifascicular block is not used as a nomenclature for complete heart block.

RBBB with LAHB

This condition can be recognised easily in ECG by (i) typical finding of complete RBBB and (ii) left axis deviation of the QRS vector greater than −30° in frontal plane. It is one of the most common types of bilateral bundle branch block or bifasicular block. There is a combination of both the features of RBBB and LAHB, i.e. (i) delayed terminal QRS forces, oriented to the right and anteriorly producing wide S waves in lead I, V_{5-6} and wide R S R′ waves in V_1, V_2 and W in V_{5-6}, (ii) left axis deviation i.e. QRS vector in the frontal plane is greater than −30° (Fig. 6.72).

RBBB with LPHB

This condition can be recognized in ECG by (i) typical findings of complete RBBB and (ii) right axis deviation of the QRS vector greater than +110° in the frontal plane. RBBB alone does not produce such a degree of rightward axis deviation. As in isolated left posterior hemiblock, the right ventricular hypertrophy must be excluded, which is also responsible for right axis deviation (Fig. 6.73).

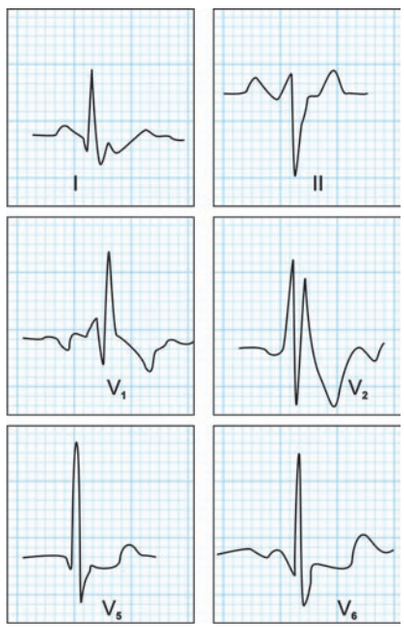

Fig. 6.72: This is an ECG of bifascicular block(RBBB withleft anterior hemiblock-LAHB). Here the QRS pattern in V_{1-2} is rsR' (M pattern) which indicates RBBB.There is also left axis deviation because there is a predominant positive QRS complex in lead I and a predominant negative QRS complex in lead II

Right or left bundle branch block with left anterior hemiblock with prolonged PR interval

This is also termed as trifasicular block, but the term is not appropriate (actual meaning of trifascicular block has been explained previously). Again, this condition should not be included in bifascicular block, because only one bundle branch is affected and the prolonged PR interval is not due to the defect in bundle branch, but due to the defect in AV node.

Ventricular Arrhythmias

There are different forms of ventricular arrhythmias .They are:
i. Ventricular premature or extrasystole or ectopic beats.
ii. Ventricular tachycardia.
iii. Ventricular flutter and fibrillation.
iv. Ventricular escape beat.

Ventricular Extrasystoles

This is due to the premature depolarization and subsequent contraction of ventricles due to the discharge of impulses from an

Fig. 6.73: ECG of RBBB, with left posterior hemiblock (LPHB)-Bifascicular block.The RBBB is evidenced by M-pattern or positive QRS complexes in lead V_1-V_2. Left posterior fascicular (hemi)block is evidenced by right axis deviation, because there is predominant negative QRS complex in lead I and predominant positive QRS complex in Lead II

ectopic focus situated at any portion of the ventricular myocardium. It is less common than supraventricular ectopics, but like it ventricular extrasystoles may occur even in normal individuals. Though ventricular premature beats are commonly seen in association with any form of organic heart disease, but is most common in IHD, infarction, myocarditis, digitalis toxicity, etc. Ventricular extrasystoles may also result from the effect of some drugs, e.g. catecholamines, halothane, digitalis, etc.

Mechanism or pathophysiology

As the ventricular extrasystole results from an irritable extra focus, situated at any portion of the ventricular myocardium,so these impulse does not travel through the normal specialised conductive tissue, i.e. purkinje fibres. Contrarily, the impulse travels through the ordinary ventricular muscle tissue which is a poor conducting medium. As a result the QRS complex is bizarre, widened and slurred, or notched. This premature impulse activates both the ventricles and a premature contraction occurs (Fig. 6.74).

The regular SA nodal rhythm is not disturbed, as the ectopic ventricular impulse does not penetrate the AV node and activates the atria or depolarises the SA node. Again the regular sinus impulse following the premature beat will usually not be able to activate the ventricles, since the latter is still in refractory state from the previous premature contraction.

Thus, the next sinus impulse will activate the ventricles only when the refractory period is over, provided another ventricular extrasystole does not occur (Fig. 6.75).

Therefore, the interval between the two successive sinus beat preceeding and following the premature beat will be exactly twice of the regular sinus interval. The ventricular extrasystole is premature. It arises in the ventricular diastolic period caused by the preceeding sinus beat. It is therefore recorded earlier, than the next anticipated sinus beat.

This ventricular extrasystole fails to penetrate the AV node retrogradely. Thus, the SA node is protected from the ectopic ventricular impulse and is not diturbed from its rhythmic function. Following an extrasystole, as the ventricles remain in a refractory stage, so the regular normal incoming impulses from the SA node fails to initiate regular ventricular contraction. Hence, following an extrasystole, there is a time gap, during which the ventricle is waiting for impulses from the SA node in normal a rhythm. This time gap following the extrasystole is called the compensatory pause. The interval between the ectopic beat and the previous sinus beat is called the coupling interval. It is constant for all the extrasystoles arising from the same focus. This is because the extrasystole is anyway related to or forced by or precipitated by the previous sinus beat.

(i)	**Congenital**
(ii)	**Acquired**
	Idiopathic fibrosis
	Myocardial ischaemia/infarction
	Inflammation (carditis)
	Trauma (cardiac surgery)
	Drugs-digoxin, β-blockers

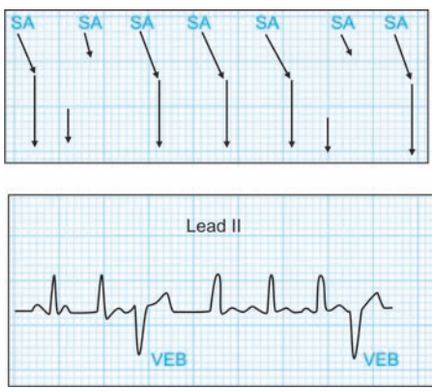

Fig. 6.74: Unifocal ventricular ectopic beats (VEB). Two VEB's are seen in association with a regular sinus ventricular rhythm. Both VEB's are of the same configuration and direction which indicates a single focus of origin

Fig. 6.75: Multifocal VEBs in lead V_1. Here QRS complexes (1, 4, 5, 6, 8 and 10) are sinus conducted. Ectopic QRS complexes (2, 3 and 9) are oriented towards the left (deep S wave in V_1), which indicates right ventricular origin. Ectopic QRS complex (7) is oriented toward right (tall R wave in V_1) which indicates left ventricular origin

ECG pattern

The QRS complexes of ventricular extrasystoles are broad, bizarre, slurred and notched in appearance. The ST segment and T wave is directed opposite to the main deflection of ectopic QRS complex. When the ventricular extrasystoles arise from multiple ectopic foci, then the configuration of extra QRS complexes are

different, even in the same lead. Couplet and triplet terms are used to describe two or three successive ventricular ectopic beats, whereas a run of alternate sinus and ectopic beat is called bigeminy. But, when this arises from a single focus, the configuration is same in one lead. Depending upon the relationship of timing between a ventricular premature beat and a P wave, the later may precede or be hidden or even follow the QRS complex (Fig. 6.76).

Since the normal sinus beat is usually not disturbed, a full compensatory pause follows the ventricular premature beat. If the sinus rhythm is very slow, then a ventricular premature beat can occur between two normal sinus beats without altering the RR interval and without producing a compensatory pause. This is known as the 'interpolated beat' (Fig. 6.77).

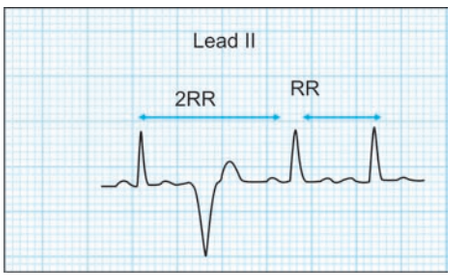

Fig. 6.76: A VEB with a compensatory pause. VEB is seen after the 1st sinus beat. The RR interval between the 2nd and 3rd sinus conducted QRS complex is 0.8 sec. The RR interval between the 1st and 2nd sinus conducted QRS complex is double than the RR interval between the second and third sinus conducted beats. This indicates full compensatory pause

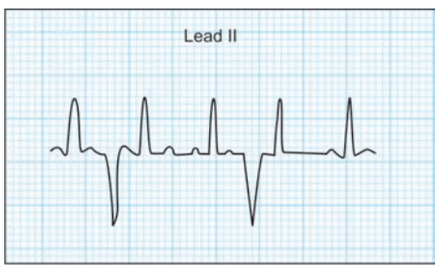

Fig. 6.77: Interpolated ventricular ectopic beats (VEB). This VEB is seen after the 1st and 3rd sinus beats, without any compensatory pause

If the extra QRS deflection is upright, in the right precordial leads (V_{1-2}) and downwards in the left precordial leads (V_{5-6}), then one can safely distinguish that this ectopic focus is situated in the left ventricle. The reverse is true for the right ventricular premature beats. Thus, the left ventricular extrasystole mimics the QRS pattern of complete RBBB and right ventricular extrasystole mimics the QRS pattern of complete LBBB. The ventricular premature beats may occur in association with other arrhythmias also (Fig. 6.78).

The premature ventricular contraction by ectopic beats produce a low stroke volume, because this ventricular contraction is ineffective. The pulse is therefore irregular with weak or missed beats. Patients are often asymptomatic, but may complain of an irregular heartbeat, missed beats or abnormally strong beats. The significance of ventricular ectopic beats (VEBs) depends on the nature of the underlying heart disease.

VEBs may frequently found in normal people and their prevalance increases with age.VEBs are more prominent at rest in patients with otherwise normal hearts and tend to disappear with exercise. The outlook of these type of VEB is excellent and so treatment is unnecessary. Although a low dose β-blocker treatment is sometimes used to suppress the anxiety and palpitation. VEBs are sometimes a manifestation of subclinical heart disease. There is no evidence that such patients are merited by anti-arrythmic therapy. But the discovery of frequent VEBs may prompt some general cardiac investigations (Fig. 6.79).

Fig. 6.78: This ECG shows ventricular premature contractions during a vulnerable period i.e. before completion of the T wave of the preceeding beat (R on T phenomenon)

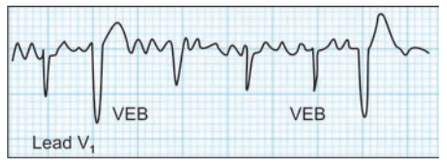

Fig. 6.79: Ventricular ectopic beats (VEB) in association with atrial fibrillation

Frequent VEBs are often observed during acute MI. But, they are of no prognostic significance and require no special treatment. However, persistent and frequent VEBs in patients, who have survived the acute phase of MI are indicative of a poor outcome. Unfortunately, antiarrythmic therapy doesnot improve and may even worsen the prognosis in these patients (Figs 6.80 and 6.81).

VEBs are common in patients with heart failure and are associated with an adverse prognosis. But again, the outlook is not better if they are suppressed

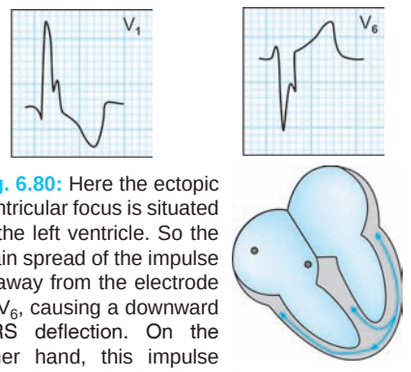

Fig. 6.80: Here the ectopic ventricular focus is situated in the left ventricle. So the main spread of the impulse is away from the electrode at V_6, causing a downward QRS deflection. On the other hand, this impulse spreads towards the electrode at V_1, causing an upward QRS deflection

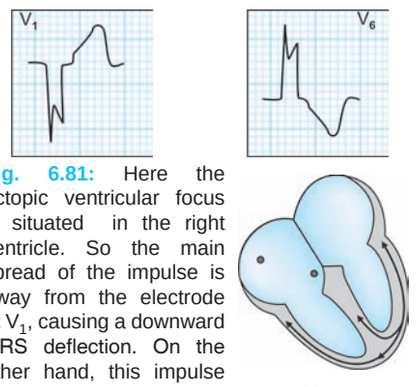

Fig. 6.81: Here the ectopic ventricular focus is situated in the right ventricle. So the main spread of the impulse is away from the electrode at V_1, causing a downward QRS deflection. On the other hand, this impulse spre- ads towards the electrode at V_6, causing an upward QRS deflection

with anti-arrythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats. VEBs are also the feature of digoxin toxicity and may occur as escape beats in the presence of an underlying bradycardia. Treatment should be directed at the underlying causes.

R on T phenomenon

The QT interval approximates the refractory period of the action potential of cardiac myocytes. Ventricular extrasystoles usually occur after the T waves of the previous beat and before the next beat.

Sometimes, the ventricular extrasystole starts at the upstroke or downstroke of the T wave of the previous beat (Fig. 6.82).

This portion of the T wave coincides with the supernormal excitability period of the action potential of cardiac myocyte and is very vulnerable for repetitive firing. So such an ectopic beat is prone to initiate repetitive discharges, i.e. ventricular tachycardia or ventricular fibrillation. This phenomenon is called the R on T phenomenon and has serious clinical significance.

Supernormal excitability

The time period in the action potential curve during which no stimulus will propagate another action potential is known as the absolute refractory period.

This period includes phases 0, 1, 2 and part of the phase 3. Following this, there is a time period when only a strong stimulus can evoke a response. This is called the relative (or effective) refractory period. It begins when the transmembrane potential in phase 3 reaches the threshold potential level (about –60 mV) and ends just before the termination of phase 3. This is followed by a period of supernormal excitability (terminal part of phase 3 and beginning of phase 4) when even a relatively weak stimulus can evoke a response.

Ventricular bigeminy

When a regular sinus beat controlled normal ventricular contraction and a ventricular premature beat (or extrasystole) occurs alternately, then it is called the ventricular bigeminy. Here there is a fixed coupling i.e. there is a constant interval between a sinus beat controlled ventricular beat and a premature ventricular beat. This fixed coupling indicates that the sinus beat controls the VEB by re-entry mechanism, present in the ventricular myocardium (Fig. 6.83).

Significance of Ventricular Extrasystole

Although, ventricular extrasystoles may occasionally occur in normal individuals, still their presence should always be viewed with suspicion. VEB is always significant when it is associated with some myocardial disease. The ventricular extrasystoles from multiple foci with or without chest pain always indicate serious myocardial disease. Unifocal ventricular extrasystoles are usually indicative of cardiac diseases if (i) they occur in persons over 40 years of age, (ii) they occur frequently, i.e in crops or showers, (iii) they occur in association with other cardiac diseases, (iv) they occur in bigeminal rhythm and (v) they are precipated by exercise.

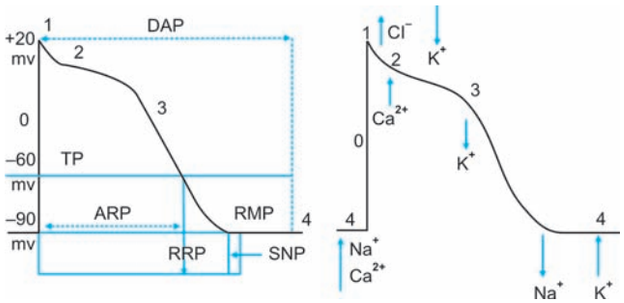

Fig. 6.82: Action potential (AP) of a cell of ventricular muscle
TP= Threshold potential, RMP= Resting membrane potential, DAP = Duration of action potential, ARP = Absolute refractory period, RRP = Relative refractory period, SNP = Super normal period, 0 = Depolarisation phase, 1, 2, 3 = Repolarisation phase, 4 = Diastolic phase
Depolarisation + repolarisation = ventricular systole.
Action potential (AP) occuring cyclically is described below--
Phase 4 = Resting condition or diastole where the resting membrane potential (RMP) is -70 to -90 mv. This mainly depends on the K^+ concentration, as it is more permeable than the Na^+.
Phase 0 = Rapid depolarisation phase due to Na+ and Ca^{2+} influx.
Phase 1 = Initial repolarisation phase. It is due to influx of Cl^- and coming out of K^+
Phase 2 = Plateau phase of repolarisation with slow influx of $Ca^{2+}$and coming out of K^+ from cells. The amount of entry of Ca^{2+} and exit of K^+ is same and balance each other. So a plateau of electrical potential is maintained.
Phase 3 = Rapid repolarisation it is due to the efflux of K^+ causing rapid return of intracellular potential to-70 or -90 mv. It estalishes the normal negative resting potential. But inside of the cell is left with excess Na^+ and deficit of K^+.
Phase 4 = The Na^+ goes out of the cell in exchange of K+, which enters the cell, maintaining the RMP. In the resting state, the outside of the cell is positive while the inside is negative.This is called the polarised state (phase 4). When the outside of the cell becomes negative and the inside is positive, the condition is called the depolarised state(phase 0). Again when the out side of the cell becomes positive and the inside becomes negative, but the intracllular and extracellular concentration of Na^+ and K^+ is opposite to normal. It is called the repolarised state (phases1,2and3). When the polarisation of the cell remains same as repolarisation, but the Na^+ and K^+ concentration becomes normal, it is called the polarised state.

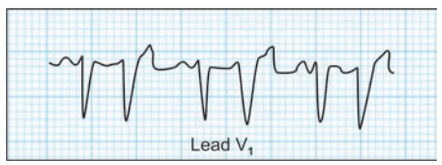

Fig. 6.83: ECG of ventricular bigeminy.It is characterised by regular sinus rhythm followed by a VEB, a pause, a sinus ventricular beat and then repetation of this sequence.The time interval between the sinus beat and the VEB is perfectly constant. This is called fixed coupling. The P waves of the sinus beat are buried in the QRS complex of each VEB

The following classification of ventricular premature beats is commonly used as a clinical guide to indicate the severity:

Grade 0: No ectopic
Grade 1: < 30/hour
Grade 2: > 30/hour
Grade 3: Multiformed complexes
Grade 4: Couplets of 3 or more (ventricular tachycardia)
Grade 5: R on T phenomenon

Ventricular Tachycardia

The ventricular tachycardia is due to the rapid and successive discharge of impulses from an ectopic ventricular pacemaking focus. It may be defined as a series of four or more consecutive ventricular ectopic beats which are recorded in rapid succession. The rate of ventricular tachycardia usually varies between 140 to 220 beats per minute. There are two principal forms of VT. They are (i) idio ventricular tachycardia and (ii) extrasystolic ventricular tachycardia (Fig. 6.84).

The basic principle of idioventricular tachycardia is the idio ventricular rhythm, where there is complete heart block and an increased escape ventricular rate. Actually it is a severe form of accelerated ventricular rhythm. On the contrary, the extrasystolic ventricular tachycardia is not associated with a complete heart block and impulses from the SA node comes to ventricular regularly. But, there is an increased automacity of any ventricular tissue, making ectopic focus.

The ventricular tachycardia is also the result of re-entry mechanism within the ventricular myocardium. It is most commonly associated with a recently manifested acute MI. It may also occur in association with hypertensive and atherosclerotic heart diseases and certain drug (digitalis, quinidine, etc) intoxication. It also occurs in association with WPW syndrome. Ventricular tachycardia is a very serious condition and always indicates a serious heart disease. It should be treated successfully, otherwise mortality rate is very high.

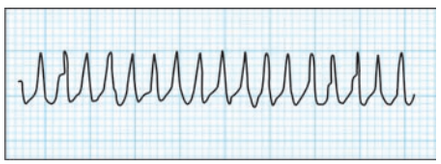

Fig. 6.84: ECG of ventricular tachycardia, characterised by repeated broad QRS complexes (broad complex tachycardia.)

ECG pattern

The ECG tracing of ventricular tachycardia is constituted by a rapid succession of ventricular premature beats, where it may be impossible to separate the QRS complexes from the ST segments and T waves. The abnormal ventricular complexes are regular, and the tracing has the appearance of a series of regular wide and large undulations.

The normal sinus rhythm usually continues independently with the ventricular tachycardia. But, the P waves cannot be seen within the images of ventricular complexes. Ventricular tachycardia may occur independently with sinus rhythm or also in the presence of any atrial arrhythmia. But, it cannot be diagnosed without the use of oesophageal leads or intracardiac monitoring. It has been assumed that ventricular tachycardia originating from the left ventricle would result in ventricular complexes simulating RBBB and that ventricular tachycardia originating in the right ventricle would simulate LBBB.

The ventricular tachycardia differs from ventricular fibrillation by its uniformity, constancy and deflections of relatively large amplitude. The deflections of ventricular fibrillation are small, completely chaotic and irregular.

Torsades De Pointes

This is also called 'the multiform ventricular tachycardia or flutter'. As the name signifies, it is polymorphic type of origin where the QRS complexes arise from multiventricular ectopic foci. Therefore, the QRS complexes vary from upright to inverted in direction and come in a cyclic fashion. The sharp points of the QRS complexes may for a short period be directed upwards which is followed for a short period by a change in QRS contour where the sharp points are directed downwards. Hence, the term 'torsades de pointes' which means twisting or torsion of points is applied. The most common cause of this situation is prolongation of ventricular repolarisation and this is due to drug toxicity such as quinidine, amiodarone, etc. (Fig. 6.85).

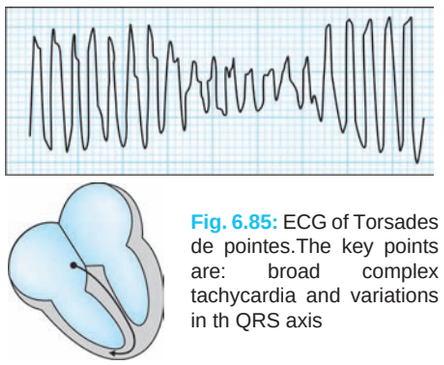

Fig. 6.85: ECG of Torsades de pointes.The key points are: broad complex tachycardia and variations in th QRS axis

Accelerated idioventricular rhythm

The heart has many potential pacemaking cells or tissues such as the SA node, AV node, atrial muscle, ventricular myocardium and special conducting tissues. But, among these only one pacemaking cell which has the highest rate of automacity controls the heart rate. This is because the impulses arising from the tissues with higher automaticity reach the other potential pacemaker cells and abolish their discharge, before they have the time to mature and fire (Fig. 6.86).

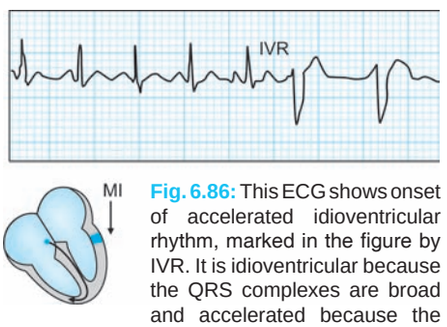

Fig. 6.86: This ECG shows onset of accelerated idioventricular rhythm, marked in the figure by IVR. It is idioventricular because the QRS complexes are broad and accelerated because the rate is ± 88/min

Therefore, the subsidiary pacemaker area gets some protection from the impulses of the fastest pacemaker area. Under certain circumstances the automaticity of these subsidiary pacemakers area becomes enhanced. For example, when the AV nodal discharge rate exceeds the sinus rate, then the AV nodal rhythm manifests as AV nodal tachycardia. Similarly, in a complete heart block when the ventricular myocardium acts as a pacemaker and beats 30 to 40 times per minute, then it is called the idioventricular rhythm.When this idioventricular rhythm is enhanced due to any cause, it is called the idioventricular tachycardia whose rate is usually 150 to 200/min. The accelerated idioventricular rhythm is in between these two conditions (idioventricular rhythm and idioventricular tachycardia) where heart rate varies between 60 to 100/min. Here the term tachycardia is not used, because the heart rate remains below 100/min.

This condition is most commonly seen in association with acute MI. It is usually transient and may not require any therapy at all, especially if the haemodynamic status is stable. It is a much more benign abnormal ventricular rhythm than the slow idioventricular rhythm with complete heart block, or ventricular tachycardia with sinus activity. Therapy is not indicated initially, but close observation is needed for any clinical deterioration and then management is started.

Ventricular Fibrillation

It is the expression of uncoordinated, chaotic, ventricular depolarisation. Electrophysiologically the ventricular myocardium is fragmented into multiple islets of tissues which are in various stages of excitation and recovery. As the coordinated ventricular activation and muscular contractions is lost and the ventricular myocardium starts fibrillating, therefore the haemodynamic pumping action of the heart ceases and death ensues, unless defibrillation is instituted immediately. The diagnosis of ventricular fibrillation must be made electrophysiologically, since the peripheral pulses are not palpable and the heart sound is inaudible (Fig. 6.87).

As the ventricular activation and contractions are completely irregular and chaotic, so the ECG shows completely irregular and bizarre QRS complexes with varying size and configuration. The atria may continue to respond to the sinus rhythm, but the P waves are not visible without the aid of oesophageal leads.

The factors that give rise to ventricular tachycardia may also be responsible for ventricular fibrillation. Among them, the most important factor is MI and this explains many sudden deaths in this disease. It may also occur as the terminal manifestation of many organic heart diseases and hypokalaemia. It may also occur during surgical procedures performed under GA where hypoxia is the commonest precipitating factor. It occurs characteristically with hypothermia, when the body temperature drops below 28°C. The electrical shock may also produce ventricular fibrillation. The ventricular fibrillation can be classified into: (i) primary ventricular fibrillation and (ii) secondary ventricular fibrillation (Fig. 6.88).

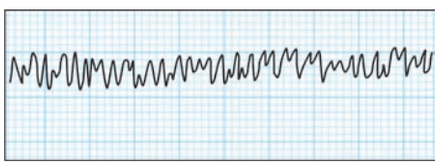

Fig. 6.87: This is an ECG of ventricular fibrillation, characterised by chaotic ventricular activity

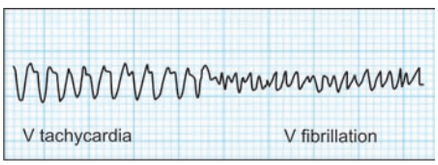

Fig. 6.88: This is an ECG of ventricular fibrillation after a ventricular tachycardia.The QRS complexes are more bizarre during the period of ventricular fibrillation and vary in size and configuration from beat to beat

The primary ventricular fibrillation is defined as the ventricular fibrillation that occurs in patients without any preexisting cardiac diseases e.g. hypotension, (systolic pressure < 80 mm of Hg, due to blood loss), hypokalaemia, heart failure, etc. It responds relatively well to electrical defibrillation and resuscitation is usually successful. The secondary ventricular fibrillation is defined as the ventricular fibrillation which occurs in patients with serious medical disorders in the presence of previous cardiac diseases (e.g. severe uncorrected hypotension, respiratory failure, cardiac failure, liver diseases, electrolyte imbalance, etc). Resuscitation is usually unsuccessful in secondary ventricular fibrillation.

Aetiopathology

Development of VF (Ventricular Fibrillation) is usually caused by the coincidence of following two fundamental events.

1. Development of advanced physiological asymmetry between two ventricular areas, as there is a nonhomogeneous state of myocardial refractoriness. Such asymmetrical refractory state of the ventricular myocardium is due to severe disease processes, e.g. M1 which results in local O_2 lack, local glucose deficiency and local ionic changes such as: Ca^{2+}, Na^{+}, K^{+} etc.
2. Premature repetitive stimulation of the ventricular myocardium which aggravates the out of phase state and precipitates fibrillation. The source of such premature rapid stimulation is ventricular extrasystoles with very short coupling interval. Ventricular extrasystoles with R on T phenomenon represent the most vulnerable type of ventricular excitability and precipitates VF.

Clinical significance and prognosis

VF is the most serious among all the cardiac arrythmias and should be treated promptly. The prompt treatment of patients

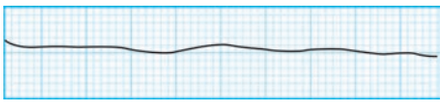

Fig. 6.89: ECG of an asystole, characterised by a 'flat line' with no spontaneous atrial or ventricular activity

with VF which is commonly associated with MI in coronary care units has largely reduced its mortality rate by its immediate recognition and treatment.

VF may occur in transient paroxysms and may be the cause of the Stokes-Adams Syndrome. Prognosis is very poor for such VF and recovery is rare, if arrhythmia continues for over 5 minutes. Prognosis is better when this arrhythmia occurs in the operating room or in the intensive care unit where immediate resuscitative measures including electrical defibrillation can be instituted immediately (Fig. 6.89).

Clinically, VF can not be differentiated from a ventricular standstill, because in both the conditions there is no palpable or auscultatory evidence of cardiac action. So, it is essential to differentiate these two conditions electrocardiographically, since their treatment differs considerably. For example, ventricular standstill may respond to epinephrine, isoproterenol, atropine or even electrical pacing, whereas VF requires immediate electrical defibrillation.

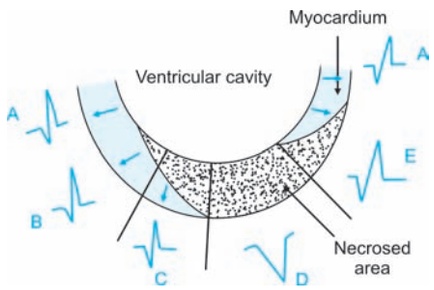
GENESIS OF ST SEGMENT AND T WAVE

In the ECG tracing, the point at which the QRS complex ends and the ST segment begins is called the J point or J junction. The portion of tracing from the J junction to the onset of the T wave is called the ST segment. The ST segment is usually an isoelectric line, but may vary from 0.5 to +2 mm in the precordial leads. It is elevated or depressed in comparison to that portion of the baseline which is situated between the termination of the T wave and the beginning of the next P wave. The ST segment usually merges smoothly and imperceptibly with the proximal limb of the T wave (Fig. 6.90).

The ST segment and the T wave represents the ventricular repolarization. As the normal ST segment is isoelectric, so it does not manifest the axis. Only in abnormal conditions when the ST segment is deviated above or below the baseline, then it produces a measurable axis.

The deviation of the axis of ST segment is based on the same principles as those used for the P, QRS and T wave axes. The first step is to look out for the lead in which the ST segment is more or less isoelectric or equiphasic. Then, it is obvious that the axis of the ST segment in this particular tracing is perpendicular to that lead. For example, if the ST segment is isoelectric i.e. no deviation in the lead aVR, then the ST segment axis is perpendicular to the lead aVR and / or parallel to lead III, where it is maximally deviated from the isoelectric line. Thus, the ST segment is parallel to the positive pole of that lead which is perpendicular to the isoelctric lead.

When the ST segment is deviated above or below the baseline, as a result of coronary artery disease, in both horizontal and frontal plane it is directed towards the surface of the injury (Fig. 6.91).



Figs 6.90A to E: This diagram illustrates-

A. Normal endocardial to epicardial QRS activation.
B. Minimal subendocardial necrosis with slight change or unchanged QRS activation.
C. Significant subendocardial necrosis with dimini shed QRS activation, and a pathological Q-wave
D. Total transmural necrosis with absent QRS activation and presence of Q wave.
E. Subepicardial necrosis with diminished QRS activation

CORONARY INSUFFICIENCY

The impaired coronary blood flow may be an established case (i.e. inadequate coronary blood flow both during rest and increased demand) or may be a relative one (i.e. blood flow being adequate at rest but inadequate when the myocardial demand is increased such as in exercise) or may even be due to some additional transient factors (i.e. coronary vasospasm). In ECG coronary artery disease may be reflected as changes in the QRS complexes, ST segment, T wave and the U wave. Like before, these changes may be present at rest or may be precipitated by factors which induce transient myocardial ischaemia, e.g. exercise.

ECG Effects

The QRS complexes represent the phase of depolarisation of the ventricles, while the ST segment and the T wave represents the repolarisation process of the ventricles. The effects of coronary insufficiency is reflected in both the depolarisation and repolarization processes. But, the earliest changes are usually evident during repolarisation, i.e. on the ST segment and T wave. As a rule the changes in depolarisation due to ischaemia tend to be

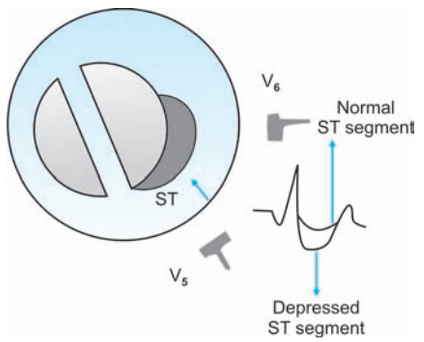


Fig. 6.91: The basic principles of ECG changes in subendocardial and subepicardial injury in angina pectoris. The subendocardial ischaemia results in a ST shift towards the injured surface i.e. the left ventricular cavity in aVR and away from the precordial leads in V_1 to V_6. Thus, it results in ST segment depression in leads V_1 to V_6 and elevation in leads aVR

permanent, whereas the initial changes in repolarisation tend to be temporary.

A. Effects on QRS complex

The effects of coronary insufficiency on QRS complexes are like changes during depolarisation and are permanent e.g LBBB, left axis deviation, etc.

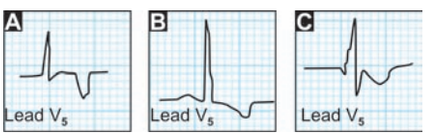
B. Effects on ST segment

Coronary insufficiency may depress and alter the shape of ST segment. Occasionally, it may also present with transient elevation of ST segment. This is the manifestation of variant forms of angina pectoris, such as : Prinzmetal Angina.

C. Effects on T wave

The T wave is the most unstable, but a significant component of an ECG recording. Certain nonspecific changes of this deflection may occur with hyperventilation, heavy meals, anxiety, etc. (Fig. 6.92).

Despite this, there are certain specific T wave changes that are frequently suggestive of coronary insufficiency. The T wave associated with coronary insufficiency has symmetrical limbs and a sharp pointed arrow-head vertex. The changes of T wave configuration from other causes usually show asymmetrical limbs with a relatively blunt vertex or nadir. As a result of ST segment depression, the T wave may be dragged downwards, giving an appearance of inversion. This T wave inversion is of slight to moderate degree. Occasionally, one may see a very deep T wave inversion, simulating that seen in myocardial infarction (Fig. 6.93).



Figs 6.92A to C: ECG shows the ST segment and T wave changes

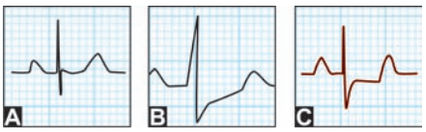
B: The "strain" pattern, associated with ventricular hypertrophy.
C: The effect of digitalis



Figs 6.93A to C: This ECG shows—
A: Normal ST segment
B: Junctional ST segment depression
C: Plain ST segment depression

Depression and Significance of the Shape of ST Segment

Normally the ST segment merges gradually, smoothly and imperceptibly with the ascending limb of T wave, so that a separation between the two is difficult or impossible (Fig. 6.94).

One of the earliest signs of coronary insufficiency is an alteration in the shape of ST segment, resulting in a sharp-angled ST-T junction. This produces a horizontal appearance in the ST segment. A further evaluation of this effect is depression of the ST segment. The depression of the horizontal ST segment gives the appearance of plane depression. The ST segment may also have a sagging depression.

ST Segment Depression

The most significant criteria of ST segment change in coronary insufficiency is depression of 1 mm or more at a point, 0.08 seconds after the onset of the ST segment (J point). Clinically the character of the ST depression has major significance. The various types of ST segment depression are:

i. Down sloping ST segment: There is a ST depression of 1mm or more at the J point. This finding has the highest specificity for the diagnosis of myocardial ischaemia. The false positive incidence is less than 1 to 2%.
ii. Horizontal ST segment: There is a ST depression of 1 mm or more at the J point and then the ST segment continues horizontally in a depressed condition, for 0.8 seconds. Although such a finding has been considered diagnostic of myocardial ischaemia, but the false positive incidence is approximately 15 to 20%.
iii. Slow upstroke of the ST segment: This is defined as ST depression of 1 mm or more at the 'J' point, with an upward sloping of the ST segment, which is not greater than 1 mV/sec. Thefalse positive incidence exceeds 40 %.
iv. Rapid upstroke of the ST segment: There is 1 mm or more ST depression at the 'J' point, but the ST segment goes rapidly upwards and the slope exceeds 1 mV/sec (Fig. 6.95).

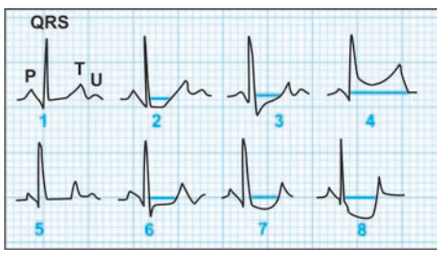


Fig. 6.94: This diagram illustrates-
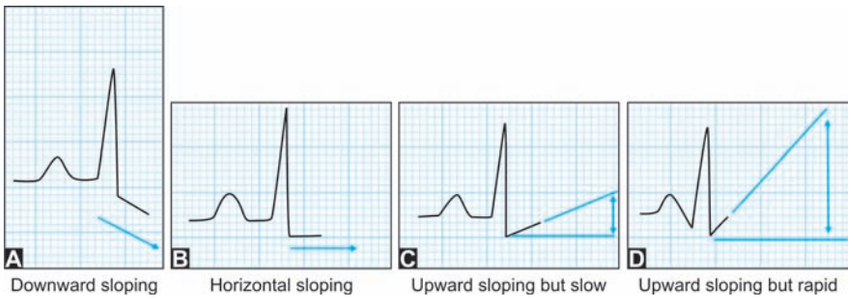
1. Normal P-QRS-T-U complex.
2. Junctional depression.
3. Depression with upward sloping
4. Elevation of ST segment and increase in T wave amplitude
5. Horizontal ST segment with sharp-angled ST-T junction.
6. Plain depression with U wave inversion.
7. Sagging depression.
8. Depression with downward sloping

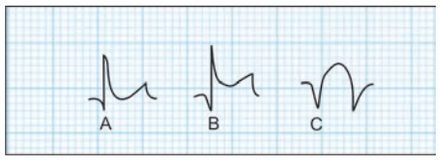
Mechanism of depression of ST segment

Transient myocardial ischaemia, as manifested clinically by the classic form of angina pectoris, results in temporary subendocardial ischaemia at the apical region of left ventricle. This injured surface faces the left ventricular cavity.

The basic principles for the determination of ST segment deviation is that the ST segment vector is always directed towards the surface of the injury. Thus, a lead oriented to the injured surface, (in this case the left ventricular cavity) e.g. lead aVR will reflect the ischaemia by a raised ST segment and an inverted T wave. Leads facing the external surface, mainly leads V_5 and V_6 will reflect a reciprocal ST segment depression.



Figs 6.95A to D: Different types of ST segment depression



Figs 6.96A to C: This diagram illustrates
A. Normal QRST complex.
B. Hyperactive or acute phase of myocardial infarction (MI).
C. Fully evolved phase of MI

ST Segment Elevation

Uncommonly in response to ischaemia, ST segment elevation of more than1 mm can develop. This is generally an evidence of severe transmural ischaemia.

This variant form of angina pectoris is due to the transient subepicardial ischaemic injury. This condition manifests characteristically with transient elevation of the ST segment in leads oriented to the injured surface. This type of angina pectoris was first described by Prinzmetal and his associates, so it is named as 'Printmetal angina'.

Computer Analysis

Recently computers are frequently used to measure accurately the amount of depression and elevation of the ST segment and its slope in ECG records. It is definitely more correct than visual interpretation of an individual. Nowadays, a newer and better computer programs are being developed, which measure the ST segment depression in multiple leads and integrade it with the changes in voltage of R wave, heart rate at which these abnormalities appear, effect of exercise and the duration of such changes. The computer analysis improves the specificity and sensitivity of the ECG recordings.

MYOCARDIAL INFARCTION AND ECG CHANGES

The site of myocardial infarction is actually constituted by three pathological conditions such as necrosis, injury and ischaemia. So the different electrical charges in these three pathological areas are reflected at a time in the ECG and help to constitute a composite ECG picture of MI. Again the myocardial infarction passes through three phases and has different sites of occurrence. So, according to these two factors (different phases of evolution and various sites) the ECG graph also changes. The ECG of MI also changes with the presence of concomitant arrhythmias e.g LBBB, VT, etc. The three phases through which the myocardial infarction passes are: hyperacute phase, fully evolved phase and phase of resolution.

Hyperacute Phase

This hyperacute phase of MI occurs just after its acute onset and it should be distinguished from the next phase, i.e the fully evolved phase. This hyperacute phase of MI is most important because it is very critical from the prognostic point of view and also for the occurance of complications such as: primary ventricular fibrillation and death which is most likely to occur in this phase. So, the manifestation of hyperacute phase is an indication for intense vigilence and proper coronary care monitoring.

ECG Pattern

During the hyperacute phase of MI the ECG is characterised by the following three principal changes in leads, oriented to the infarcted surface (Fig. 6.96).

(i) Slope elevation of the ST segment

The ST segment is markedly elevated up to the apex of the T wave, which becomes widened and tall. The ST segment and the proximal limb of the T wave blends in such a smooth and imperceptible way that they cannot be identified separately. The leads oriented to the uninjured surface opposite to the injured surface, usually reflect marked reciprocal ST segment depression.

(ii) Tall and widened T wave

The T wave becomes widened and is taller (height may even exceed that of the R wave). Its proximal limb blends with the elevated ST segment and the two components cannot be distinguished separately. The classical and pathological diagnostic Q wave of MI does not develop until the large amplitude of T wave regresses.

(iii) Increased ventricular activation time (VAT)

This is due to the delay in onset of intrinsicoid deflection i.e. the time from the beginning of QRS complex to the apex of R wave (X-Y interval in the picture). This delay is due to the activation process of ventricular myocardium which takes a longer time to travel through the injured, but still viable infarcted region.

This hyperacute phase of MI is analogous to the manifestations of a variant form of angina pectoris. But in angina it is transient and in MI it proceeds to the next fully evolved phase of MI.

The Fully Evolved Phase of Acute MI

A fully evolved site of MI has usually three pathological areas—necrosis, injury

and ischaemia. Each area has separate distinguishable reflection in the ECG which is discussed below under the separate headings.

ECG Manifestations of Myocardial Necrosis

Myocardial necrosis is reflected by a deep and wide Q wave in electrodes oriented towards the necrotic area.

Mechanism

Dead tissue cannot be activated or depolarised, because it is electrically inert. Hence, when the dead or necrotic tissue involves the full thickness of the muscle, it produces an electrical sense of a hole or window in the muscle wall. So, an electrode placed over or oriented to this electrical hole (necrotic area) reflects the activity of distant healthy muscle as seen through the window (hole) (Fig. 6.97).

Thus, an electrode placed over an area of dead muscle tissue of left ventricular wall, i.e. left precordial leads (V_{5-6}) reflects the initial septal depolarisation which is passing from the left to the right. So, as this electrical impulse passes away from the lead V_{5-6}, so this is reflected as a negative deflection in these leads. Then, this left precordial lead senses only the distant right ventricular depolarization which is again from the left to the right due to the electrical impulses passing through the right ventricle in the absence of electrically active left ventricular tissue. Thus,

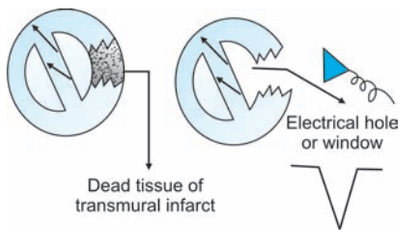


Fig. 6.97: The transmural dead tissue, representing the electrical hole or window. The electrode placed on this electrical hole will sense only the electrical impulse of the interventricular septum and right ventricular wall through the window which is running away from the electrode and producing a Q wave

it produces a further negative deflection. Hence, this results in a broad deep Q wave which is called the pathological Q wave of MI. As there is no R wave, so this Q wave can be termed as the QS wave.

ECG Manifestation of Myocardial Injury

In ECG the myocardial injury is reflected by a deviation (raised or depressed) of the ST segment and this deviation is towards the surface of injured tissue. This is because as discussed previously the current will flow from the uninjured tissue to the injured tissue, so the ST segment will be deviated towards the surface of injured tissue. Thus, if the injury is present dominantly on the left epicardial surface then the ST segment is deviated towards the injured left epicardial surface. It means the current will pass from the uninjured tissue of the right side of the heart to the injured tissue on the left and leads oriented towards this epicardial surface (e.g. lead V_6 in the diagram) will reflect a raised ST segment. On the contrary a lead oriented towards the uninjured surface (e.g. lead aVR in the diagram A) will reflect a depressed ST segment. With a dominant subendocardial injury a lead oriented to the injured subendocardial surface e.g. lead aVR will reflect an elevated ST segment. Whereas in a subendocardial injury a lead oriented to the uninjured surface e.g. lead V_6 will reflect a depressed ST segment. (Fig. 6.98).

Since, as the myocardial injury in most MI is predominantly epicardial with some subendocardial 'sparing' effect, so the manifestation presented electrocardiographically is an elevated ST segment in leads oriented to the epicardial surface. Thus, the ST segment in the leads oriented over the injured epicardial surface in a fully evolved phase of infarction is coved or convex-shaped (Fig. 6.99).

ECG Manifestation of Myocardial Ischaemia

The myocardial ischaemia is reflected by an inverted T wave (in reverse to the acute

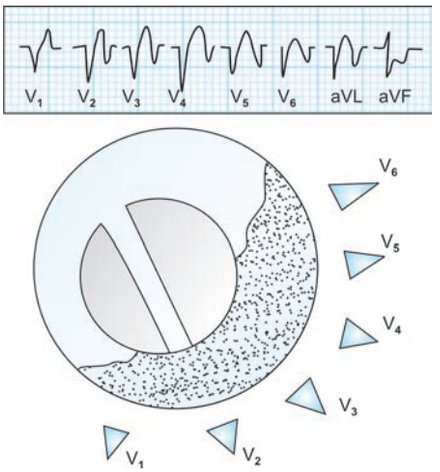

Fig. 6.98: ECG changes in acute extensive myocardial infarction

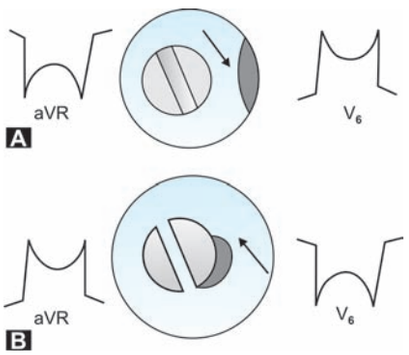
phase of MI where the T wave is upright and tall) in leads oriented to the ischaemic surface. This T wave becomes inverted when Q wave appears in the fully evolved phase of MI. This T wave inversion may be due to many conditions. But, in myocardial ischaemia it has certain characteristics, which tend to reflect their 'ischaemic' origin. These are usually 'arrow headed,' being peaked and symmetrical in appearance.

Total QRS Pattern of The Fully Evolved Phase of MI

As mentioned previously an infarcted area consists of a centrally situated necrotic



Figs 6.99A and B: The deviation of the ST segment in—
A. Subepicardial injury
B. Subendocardial injury

tissue, surrounded by a zone of injured tissue which again is surrounded by a zone of ischaemic myocardial tissue. So, a conventional electrode placed over the heart cannot pin point the individual injured tissue and so cannot reflect the electrical activity of the individual tissue of the infarcted area. Again, as the leads are situated on the body surface i.e. some distance away from the heart and subserves a relatively large area, so such electrodes shall reflect all the three electrical patterns of the three types of tissues such as pathological Q wave (for the necrosed tissue), raised and coved ST segment (for the injured tissue) and pointed inverted-symmetrical T wave (for the ischaemic tissue). This is referred to as the typical infarction pattern (Fig. 6.100).

When an electrode is oriented towards the injured and ischaemic tissue only but not on the necrotic tissue, then it will record only the coved and raised ST segment and an inverted T wave. The pathological Q wave will be absent or insignificant.

On the contrary, the reciprocal depression of the ST segment will occur in leads which are oriented towards the uninjured and healthy surface, opposite to the infarction. However, the diagnosis of infarction must not be based on the depression of the ST segment only. Because, this may also occur in conditions like angina pectoris. The diagnosis of MI must be based on the presence of pathological Q waves and / or a typically raised and coved ST segment, and/or inverted T wave.

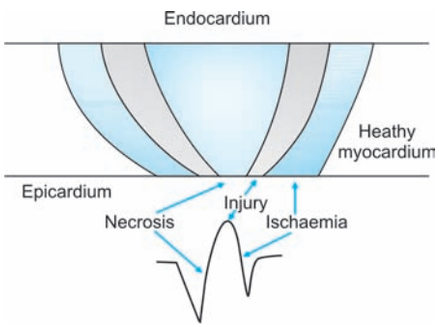


Fig. 6.100: An ideal representation of the fully evolved phase of acute myocardial infarction. The infarct is pyramidal in shape.Its broad base is oriented towards the endocardium

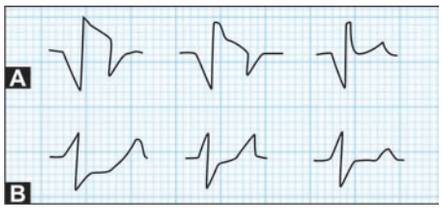

Figs 6.101A and B: The resolution of MI
A. When lead is oriented to the injured surface.
B. When lead is oriented to the uninjured surface

The Phase of Resolution

During the phase of resolution of an acute MI the following ECG changes occur progressively.

i. There is a gradual return of the elevated ST segment to its baseline, over a few weeks.
ii. Simultaneously, there is an appearance of a tall symmetrical T wave in leads oriented to the uninjured surface.
iii. Then, over a few weeks the abnormal T waves gradually return to their normal configuration.
iv. The pattern then stabilises into a residual state. In this state the only evidence of the previous MI is recognised by an abnormal Q wave in leads oriented to the infarcted area (Fig. 6.101).

SUMMARY

i. Acute infarction or the hyperactive phase: Slope elevation of the ST segment, tall widened T wave, Increased VAT.
ii. Fully evolved phase: Pathological Q wave, coved and raised ST segment, inverted symmetrical T wave.
iii. Old infarction: Pathological Q wave, ST segment and T wave may be normal or equivocal.

Significance of Q Waves

Normal Q waves (q)

The small 'q' waves which indicates initial activation of the interventricular septum are normally present in the left precordial leads (V_{4-6}), lead aVL and the standard lead I with the horizontal heart position and in left axis deviation. It is also present in standard leads II, III and lead aVF with the vertical heart position or right axis deviation.

The normal deep wide Q wave or QS complex may normally be present in the lead aVR and in lead V_1. This is because the positive poles of these leads are oriented towards the cavity or the basal region of the heart, so that the ventricular activation process moves away from these leads.

Pathological Q waves

The pathological Q wave which is designated as a capital letter have certain characteristics.

i. It should be wide > 0.04 secs in duration i.e. one small square.
ii. It should be deep > 4 mm i.e. more than 4 small squares.
iii. Pathological Q wave is associated with a great loss of height of the subsequent R wave and the Q: R ratio will be 25% or greater.
iv. Pathological Q wave may appear in several leads where normal q waves are not found. As for example, with anterolateral infarction, the pathological Q waves will be present in standard lead I, lead aVL and the lateral precordial leads V_{5-6}. With inferior infarction Q waves will be present in standard leads II, III and aVF.
v. The above mentioned characteristics of the Q wave must appear in leads which do not normally have deep and wide Q wave (i.e deep Q wave does not indicates infarction if it appear in lead aVR and possibly in lead V_1.)

Q Waves and bundle branch block

In the presence of LBBB the normal septal activation representing q waves is absent in leads oriented to the left precordial leads i.e V_{5-6}. Thus, in the presence of LBBB the manifestations of any small q wave in these leads no matter how small,

is always pathological and usually signifies MI. Alternatively, in the presence of LBBB a deep Q or a QS complex in lead V_1 resembling a pathological Q wave does not necessarily signify an infarction.The significance of the appearance of q or s waves in the presence of RBBB is same as in normal individuals.

Significance of Q wave in standard lead III

It is common for lead III to record a Q wave of 0.04 sec duration and a Q: R ratio greater than 25%. This is especially seen in normal ECG with a mean frontal QRS axis between +30° to 0° (horizontal heart position). When this is seen as normal finding, lead aVF will not record an abnormal Q wave. Therefore, the diagnosis of infarction must never be made on the basis of lead III tracings alone.

Further, pathological Q waves are also present in lead III in conditions other than MI. These are acute pulmonary embolism, left posterior hemiblock, etc. The presence of a Q wave in lead III is suggestive of MI, only if it carries the following criteria. They are:

i. The duration of the Q wave must be minimum 0.04 seconds
ii. The presence of any small q wave in leads aVF and II, along with lead III. The normal q wave present in lead III sometimes disappear when the patient takes a deep inspiration. So, it is always suggested to take a deep inspiration while recording a standard lead III ECG.

Localisation of Infarcted Areas

Myocardial infarction occurs predominantly at the anterior, inferior and posterior walls of the left ventricle, according to the rate of incidence (Fig. 6.102).

Anterior wall infarction (Fig. 6.103)

The anterior wall of the left ventricle is oriented towards all the precordial leads, aVL and standard lead I. Thus, an anterior wall infarction will be reflected by the presence of a typical infarction pattern like pathological Q wave, raised ST segment and inverted T wave in standard lead I, aVL and all the precordial leads. (Fig. 6.104).

The anterior wall infarction is further subdivided into:

i. Extensive anterior wall infarction: It is reflected by the typical infarction pattern in all the precordial leads, standard lead I and lead aVL
ii. Anteroseptal wall infarction: This indicates infarction across the interventricular septum. This is reflected by the infarction pattern in leads V_{1-4}.
iii. Anterolateral wall infarction: It is reflected by the typical infarction pattern in leads V_{4-6}, leads I and aVL (Fig. 6.105).

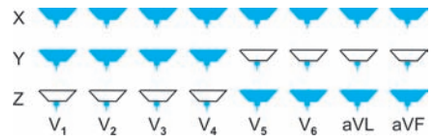

Fig. 6.102: The classification according to the extension of infarction. The black leads indicate the areas of infection
X. Extensive anterior infarction
Y. Anteroseptal infarction
Z. Anterolateral infarction

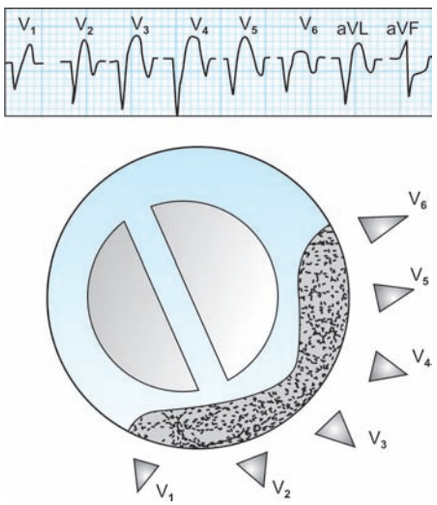

Fig. 6.103: Massive acute MI (extensive as all the leads are involved)All leads from V_1 to V_6 show the fully evolved phase of MI, which indicates acute and extensive anterior myocardial infarction

Inferior wall infarction (Fig. 6.106).

Lead aVF, standard lead II and III are oriented to the inferior surface of the heart. Thus, inferior infarction will be reflected by the presence of a typical infarction pattern in leads II, III and aVF (Fig. 6.107).

Posterior wall infarction

None of the conventional leads are oriented towards the true posterior surface of the heart. So, the diagnosis of true posterior wall infarction is made from reciprocal inverse changes in leads, which are

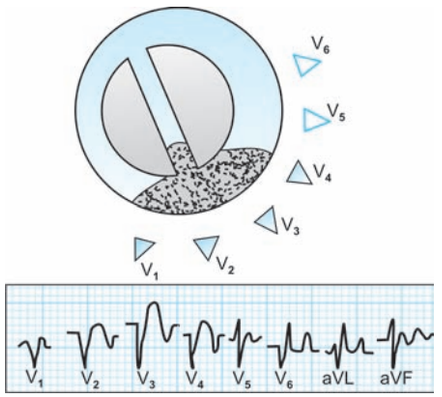

Fig. 6.104: Acute anteroseptal myocardial infarction

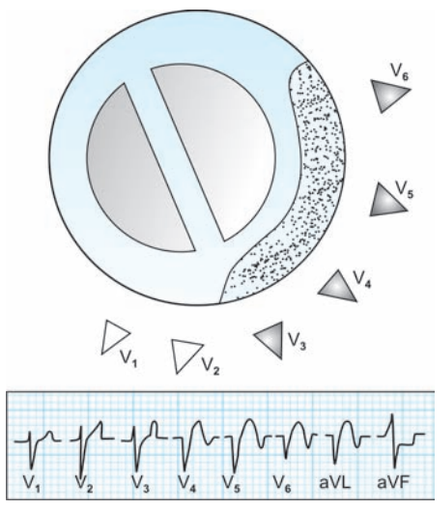

Fig. 6.105: Acute anterolateral myocardial infarction

directed towards the uninjured anterior surface of the heart, i.e. lead V_{1-2}. (Fig. 6.108).

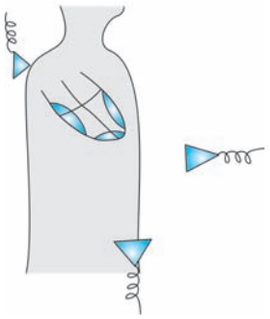

Fig. 6.106: The location of the inferior, anterior and posterior acute myocardial infarction and the corresponding leads by which it can be diagnosed better

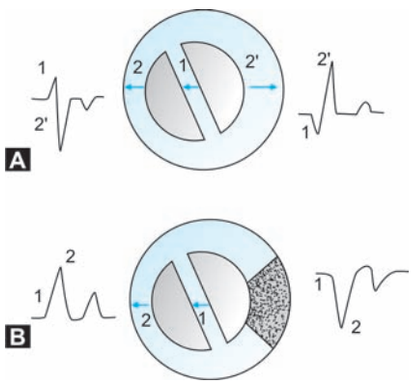

Figs 6.108A and B:

A. The electrode is placed on left and right ventricle and there is no infarction. The subsequent normal ECG shows the pattern which should be formed.

B. There is infarction in the left ventricle ,and the second component (2') of the left ventricular electrical impulse is absent. The subsequent ECG shows how it is formed in the respective electrodes

CARDIAC AXIS AND NORMAL ECG

What is Cardiac Axis?

In simple term the cardiac axis is defined as the general direction, according to which the vector of a wave of any depolarisation and repolarisation of different cardiac activity flows through the atria and the ventricles during different cardiac cycles. The axis is, therefore conventionally referred to the angle of direction of flow of different electrical current, through the atria and the ventricles and is measured in degree. The reference or zero point for the measurement of this angle of direction is taken as the horizontal line which looks at the heart from left. The angle of direction of flow of electrical current which is situated below the horizontal (Figs 6.109 to 6.114) line is expressed as a positive number, i.e. clockwise measurements are positive. When the direction of flow is above the horizontal line, the angle is expressed as negative number, i.e. anticlockwise measurements are negative. Hence, the cardiac axis may be either +1° to +180° (clockwise) or –1° to –180° (anticlockwise).

The six limb leads (three bipolar standard limb leads and 3 unipolar augmented limb leads) look at the heart from six different sides or view points with different angles in the frontal plane.

The different angles from which the different limb leads look at the heart in the frontal plane are given in the table below. The six conventional precordial leads look at the heart from six different view points from anterior side of the heart with different angles in the horizontal plane. Thus, the axes or vectors of different depolarisation and repolarisation waves of heart in both the frontal and horizontal planes give an idea of formation or configuration of different ECG complexes, in all the 12 conventional leads (Table 6.2).

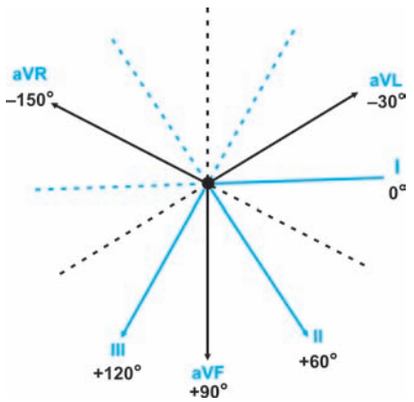

Fig. 6.114: The view points of six limb leads such as bipolar I, II, III and unipolar aVR, aVF, aVL. Each lead looks at the heart from different angles

Table 6.2: Limb leads and their angles of view

Limb leads	*The angles of view*
I	0
II	+60
aVF	+90
III	+120
aVR	–150
aVL	–30

What is Normal Axis of Heart?

The angle of mean QRS vector in the frontal plane determines its frontal axis of heart (I, II, III, aVR, aVL, aVF) and in horizontal plane determines its horizontal axis of heart ($V_{1\text{-}6}$). (Fig. 6.115).

In the frontal plane the normal axis of the heart lies between –30° and +110°.

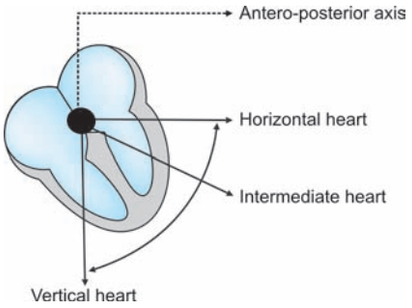

Fig. 6.115: Different position of the heart after rotation in anteroposterior axis

Therefore, the left axis deviation is defined as when the QRS vector lies between –30° and –90° and right axis deviation is defined as when the QRS vector lies between +110° and +/–180° (Fig. 6.116).

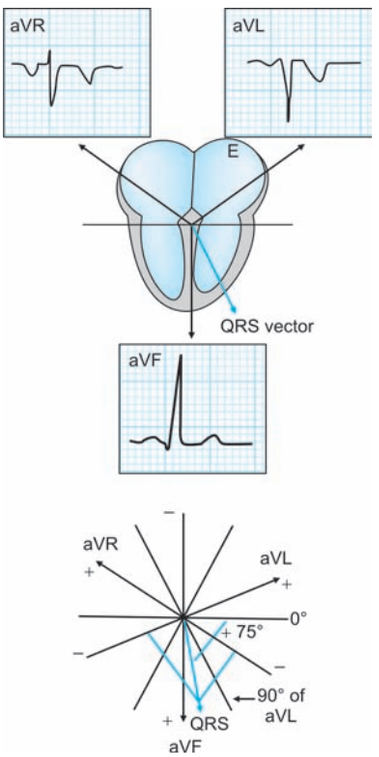

Fig. 6.116: The vertical position of the heart. The mean QRS vector is oriented at +75° left and inferiorly. So it will produce a positive QRS deflection in aVF, because the vector is situated with in 90° of the positive pole of this lead. But it will produce a negative deflection in aVL lead because the QRS vector is situated beyond the 90° of the positie pole of aVL lead. Due to the same reason it will also produce negative deflection in aVR

Rotation of the heart may occur either around the anteroposterior axis, i.e. in the frontal plane, such as: vertical, horizontal, intermediate or around the the long axis, i.e. in the horizontal plane, such as: clockwise or counterclockwise. With clockwise rotation, the transitional zone (V3, V4) is displaced to the left, so the typical left ventricular precordial pattern does not appear until V7-9 lead (Figs 6.117 and 6.118).

The term clockwise rotation is defined by persistant S waves in lead $V_{5\text{-}6}$, i.e. the lead $V_{1\text{-}2}$ configuration is seen in lead $V_{5\text{-}6}$. In counterclockwise rotation, the transitional zone is displaced to the right, resulting in a left ventricular epicardial complex, as early as in lead V_2 (Figs 6.119 and 6.120).

Within the normal axis deviation in the frontal plane, the axis between 0° to –30° represents a normal horizontal heart position and the axis between +75° and +110° represents a normal vertical position of the heart (Fig. 6.121).

Principles

Electrical flow through the myocardium towards the positive pole of a lead causes a positive deflection in this lead in ECG. Similarly a cardiac electrical flow away from the positive pole of lead causes a negative deflection in this lead in ECG (Fig. 6.122).

Using this principle, now we will consider how lead II records ventricular depolarisation. From lead II's point of view, the flow of current in the atria and the ventricles is entirely directed towards the positive pole of it and so the P and QRS complexes are entirely positive in this lead. The lead aVL, however, will see the same flow of current at right angles to lead II and record an isoelectric QRS complex. Because, if the current of the heart flows at right angles to a given lead, then the ECG complex which is analysed by this lead will be isoelectric, i.e. the positive and negative deflections will be equal in magnitude and will cancel each other (Fig. 6.123).

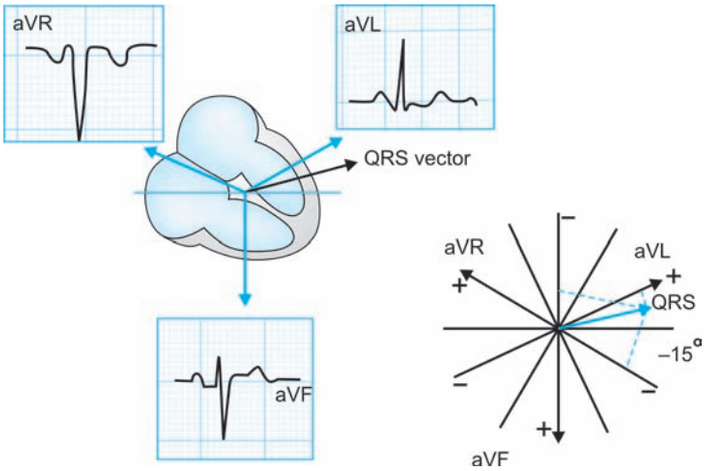

Fig. 6.117: The horizontal position of the heart. The QRS vector is situated at –15°. Thus it is oriented left and superiorly,more towards the positive pole of the aVL leads. Due to the same reasons described in the vertical position of the heart,this orientation of the QRS vector will produce positive deflection in aVL and negative deflection in aVF and aVR leads

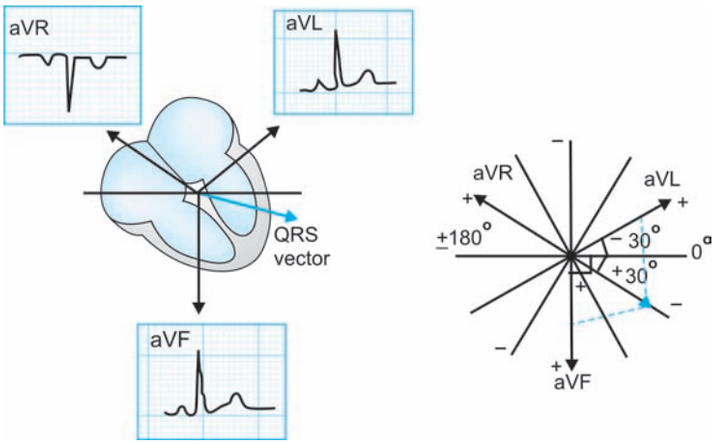

Fig. 6.118: The mean QRS vector is oriented towards the left and inferior at +30o. So it is 60° away from both leads aVF and aVL, that is midway between the positive poles of these two axes. Thus, it will produce a positive QRS deflection of equal magnitude in bothaVL and aVF leads. The QRS deflection is positive in these two leads because it lies within 90° of the positive poles of these two leads (aVL, aVF). Equal magnitude of deflection in aVL and aVF leads indicates that the heart is in intermediate position. Since the QRS vector is situated beyond the 90° of the positive pole of aVR lead, it will produce a downward deflection in this lead

Any lead situated between lead II and aVL will record a QRS complex that becomes increasingly positive. The closer it is to lead II, the greater is the positive deflection. Similarly this principle can be followed in other leads also. For example, lead I and aVF which are at right angle to each other and lead III and aVR which are also at right angle. But these pairs are not taken in normal situation (Fig. 6.124).

Determination of cardiac axis

The two ways of calculating the cardiac axis are:

i. A quick but less precise way
ii. A slow but more precise way

Quick but less precise way to work out cardiac axis

This technique helps us to decide within a moment, if the cardiac axis is normal or abnormal. For this, we will have to look only at the two limb leads that is lead I and II. If the QRS complex in lead I is mainly positive, it indicates that the axis or the main direction of flow of impulse of ventricular depolarisation lies anywhere between –90°

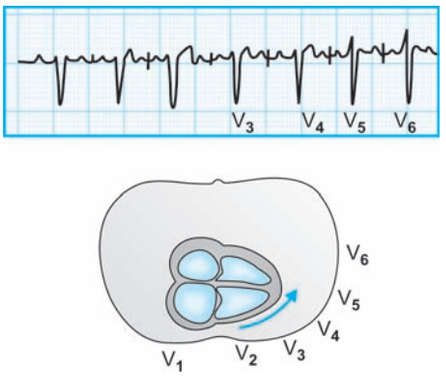

Fig. 6.119: Clockwise rotation-In precordial leads RS complex is still present in V_6,indicating that a left ventricular epicardial complex has not yet been reached and clockwise rotation of heart

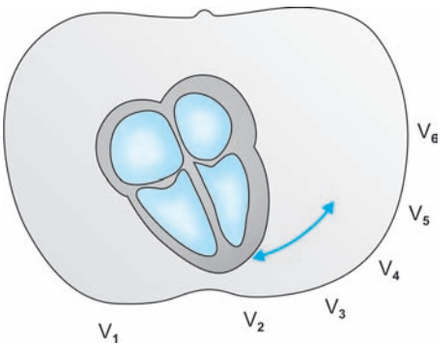

Fig. 6.120: Counterclockwise rotation—A left ventricular epicardial complex is seen in V_2 indicating counterclockwise rotation of the heart

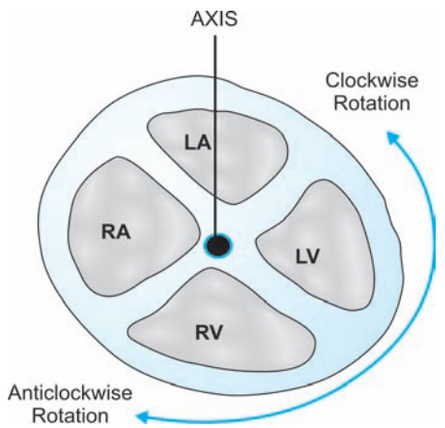

Fig. 6.121: Rotation of the heart around the long axis

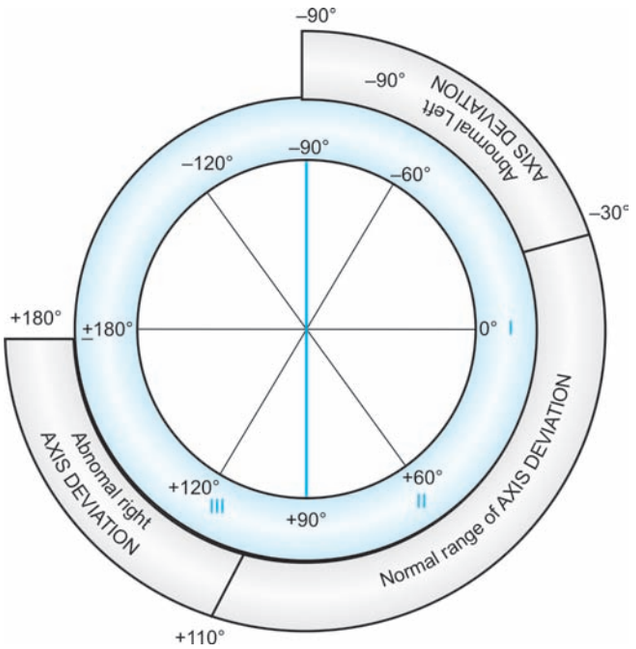

Fig. 6.122: Normal and abnormal axes

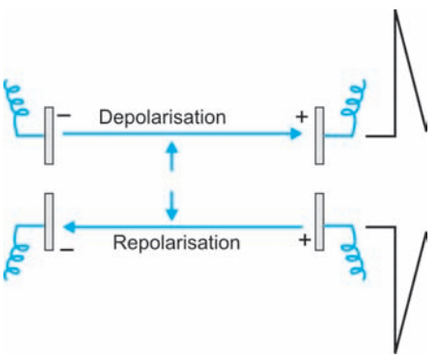

Fig. 6.123: Fundamental vectrial principle which govern ECG

and +90°. An cardiac axis situated exactly at –90° or +90° would produce a precisely isoelectric QRS complex in lead I. Hence, a predominantly positive QRS complex found in lead I rules out right axis deviation (beyond +110°). Because, if the axis goes beyond +90° (see the picture) the deflection in lead I will become negative. But positive deflection in lead I does not exclude left axis deviation (an axis beyond –30°) (Fig. 6.125).

On the otherhand if the QRS complex in lead II is mainly positive, then it confirms

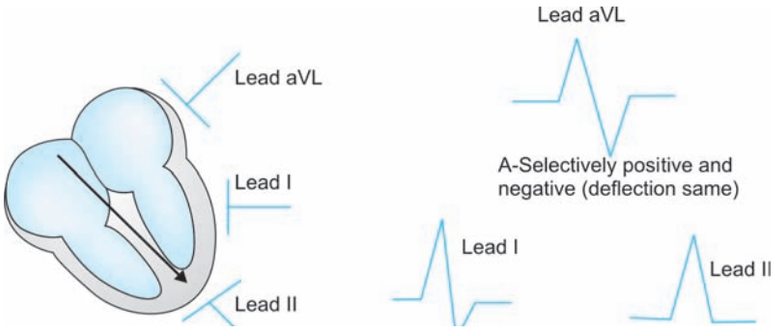

Fig. 6.124: If a current flows at right angles to a lead, the generated ECG complex will be isoelectric because positive and negative deflections cancel each other. Here in this picture it is applicable in the aVL lead. So it can be explained how lead II records ventricular depolarisation. As the flow of the current in the ventricle is entirely towards it, the QRS complex is entirely positive in this lead. Any lead looking towards the heart, between leads II and aVL will record a complex that becomes increasengly positive, the closer it is to lead II

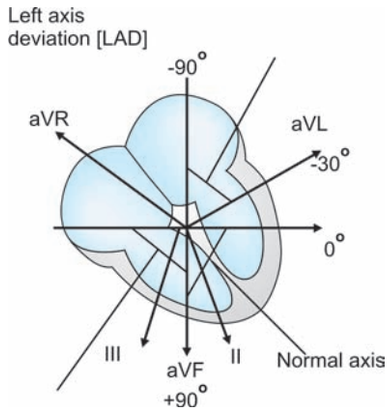

Fig. 6.125: A predominantly positive QRS in lead I puts the axis between -90° and +90°. So, a predominantly positive QRS complex in lead I excludes right axis deviation

that the axis lies anywhere between –30° and +150° (see the picture). Thus a positive deflection of QRS complex in lead II rules out left axis deviation (beyond –30°). Because if the axis is beyond –30° then the deflection in lead II will be negative. But, positive deflection in lead II does not rule out right axis deviation (beyond +110°). Because, if there is a right axis deviation i.e. beyond +90°, there will also be positive deflection in lead II. (Fig. 6.126).

So, now depending on whether the QRS complex is positive or negative in

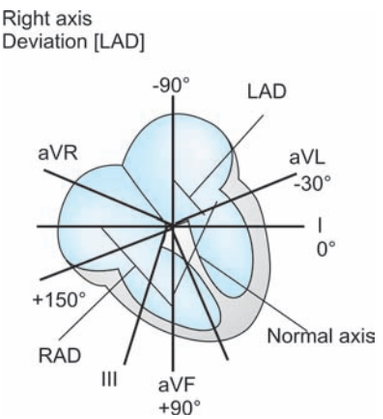

Fig. 6.126: A predominantly positive QRS in lead II puts the axis between -30° and +150°. So a predominantly positive QRS complex in lead II excludes left axis deviation

these two standard limb leads I and II, we are able to say immediately whether the axis is normal or deviated to the left or right (abnormal).

SUMMARY

i. A mainly positive QRS complex in both standard limb leads I and II means the axis is normal.
ii. A mainly positive QRS complex in lead I and mainly negative QRS complex in lead II indicates there is left axis deviation.
iii. A mainly negative QRS complex in lead I and mainly positive QRS complex in lead II indicates a right axis deviation (Table 6.3).

A slow but more precise way to calculate the cardiac axis

For more practical purposes it is sometimes very necessary to determine accurately the axis of heart. Because it is not always sufficient to know simply whether the axis is normal or abnormal. Contrarily, calculation of cardiac axis precisely is not difficult. But, it does take a little time.

The principle for precise calculation of axis is that the net amplitude and direction of the QRS complex in any two of the frontal plane leads that look at the heart at right angles to each other are plotted along the axis of these two leads. For example, we usually take lead I and lead aVF for calculation of the cardiac axis as they are at right angles to each other. The overall size and polarity of the QRS complexes in these two leads should be worked out by substracting the depth of the S wave from the height of the R wave.The polarity (positive or negative) tells us whether the impulse is moving towards or away from the lead. The two QRS vectors should then be plotted according to their amplitude and direction in the lead axes of these two leads (see the picture). Perpendicular lines are next drawn at these two locations. A line is then drawn from the centre of the reference system to the intersection of these two perpendiculars and this represents the approximate mean QRS vector. Its angle is the frontal plane axis. We can thus finally derive an angle in degrees that determines the cardiac axis. The axis in this patient (in the picture) is, therefore, +132° (90° + 42°) and he or she has right axis deviation (Fig. 6.127).

So far, we have concentrated only on the axis of ventricular depolarisation (QRS complex). Because, it flows through the ventricles. This is generaly referred to as the main cardiac axis. However, it is also possible to workout the axis of atrial depolarisation (using P waves) and ventricular repolarisation (using the T waves). But, these measurements are seldom necessary, except where a more detailed analysis of the ECG is required.

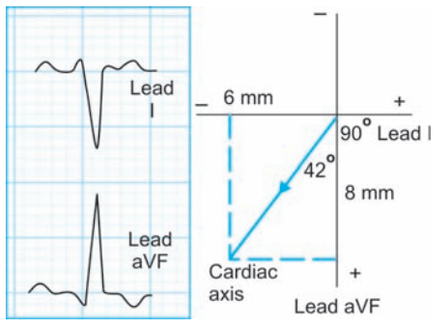

Fig. 6.127: The method of construction of axis from the ECG. First the overall size and polarity of QRS complexes in lead I and aVF is determined. Here the overall QRS height is -6 mm with negative polarity in lead I. On the other hand, the over all QRS height is +8 mm with positive polarity in lead aVF

Table 6.3: Determination of cardiac axis

Lead I	*Lead II*	*Cardiac axis*
Positive QRS deflection	Positive QRS deflection	Normal axis
Positive QRS deflection	Negative QRS deflection	Left axis deviation
Negative QRS delection	Positive QRS deflection	Right axis deviation

ELECTROPHYSIOLOGY OF NORMAL HEART AND PRODUCTION OF NORMAL ECG

Atrial Complex

The initial impulse in the cardiac cycle begins at the SA node due to its depolarisation. This depolarisation of SA node can not be recorded in the clinical ECG. But, it can be recorded by a special electrode placed within the right atrium. The impulse arising from the SA node, then, traverses through the internodal pathways to depolarise the whole atria, producing this P wave and then reaches the AV node. Normally, the impulse is delayed in the AV node by 0.07s econds and then passes on to the bundle of His (Fig. 6.128).

So, the P wave represents the atrial depolarisation and its vector (P vector) is directed leftwards, inferiorly in frontal plane and slightly anteriorly in horizontal plane. The polarity (negative or positive deflection) of P wave in any given lead will, therefore, depend on the relation between the direction of the P vector and the positive pole of the respective lead.

P-wave in frontal plane leads (I, II, III, aVR, aVL, aVF)

Normally, the P vector is oriented inferiorly and leftwards in the frontal plane between 0° and +90°. Therefore, the P vectors are upright in leads I, II, aVF and inverted in aVR. The P vector is upright in lead III, when its axis is greater than +30°. It is inverted when its axis is lesser than +30°. In lead aVL, the P vector is upright if its axis is lesser than +60° and inverted if its axis is greater than +60°.

P wave in horizontal plane leads (precordial leads V_1 to V_6)

In the horizontal plane, the normal P vector is directed leftwards and anteriorly. Depending upon the degree of anterior or leftward orientation, the P wave may be upright, biphasic or inverted in lead V_{1-2}. But it is always upright in leads V_{3-6}.

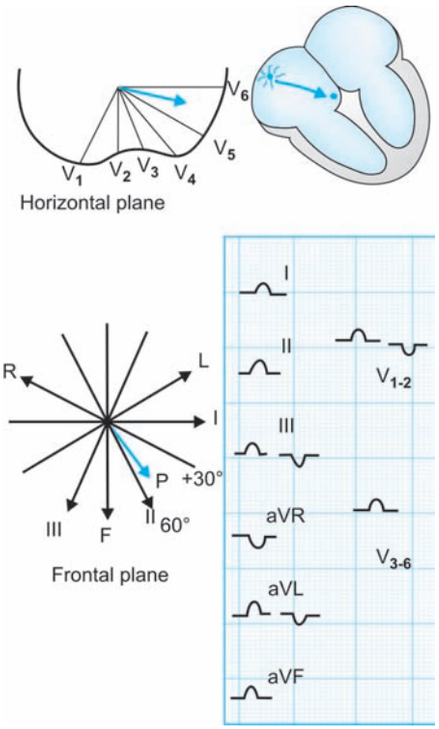

Fig. 6.128: The vectors of P wave in both frontal and horizontal planes,in a 12-lead ECG. Normally the P vector remains in the frontal plane between 0o and +90°. If the P vector lies between 0o and +30° then it will produce an inverted wave in lead III.If it lies beyond +30°, then it will produce a positive P wave(upright) in ECG. AP- vector lying past +60° will produce a negative P wave in aVL.Alternatively if it lies within +60°, it will produce a positive P wave in the same lead. On the otherhand the amount of anterior and right or left orientation or direction of the P vector in horizontal plane will determine the positive or negative deflection in V_1 and V_2 leads

After the impulse reaches the AV node from the SA node, it is normally delayed for 0.07 seconds before the impulse passes on to the bundle of His. This delay of impulse at AV node produces an isoelectric PR segment in all the leads.

Ventricular Complex (Initial)

The initial conduction of impulses from the AV node and bundle of His via the septal fibres of left bundle branch results in primary depolarisation of the left side of interventricular septum which next spread to the right side of it. This produces septal depolarisation from left to right. This vector is, therefore, oriented rightwards in horizontal. Due to the anatomical disposition of the septum, the septal depolarisation force is oriented anteriorly and superiorly or sometimes even inferiorly in frontal plane. It is of a small magnitude.

Initial ventricular complex in frontal plane leads

This initial left to right septal vector records a small negative deflection as q in lead I. Its recording and deflection in ECG in the other frontal plane leads will also depend on its relationship with the other frontal plane axes. Lead II will record an upright deflection r if it lies inferiorly between –30° and +150° and a negative deflection if it lies superiorly between –30° and +150°. Lead aVF will record an upright deflection 'r', if the septal vector lies inferiorly between 0° and +180° and a negative deflection if the septal vector lies superiorly between 0° and –180°. In other leads like aVL, aVR and lead III the same principle is applied (Fig. 6.129).

Initial ventricular complex in horizontal plane leads

The left to right and anterior septal vectors will record a small positive deflection as r in leads V_{1-2}. Reciprocally, it records a small negative deflection as q in leads V_{5-6}.

Ventricular Complex (Major)

After depolarisation of the interventricular septum, the impulse goes down the right and left bundle branches. Then, it passes through the purkinje system and activates the right and left ventricles. After that, the impulses traverse through the ventricular myocardium from the endocardial to the epicardial surfaces.

Vectors of the major ventricular QRS complex in frontal plane leads (Fig. 6.130)

The axis of major QRS vector is directed leftwards between –30° and +90° in frontal

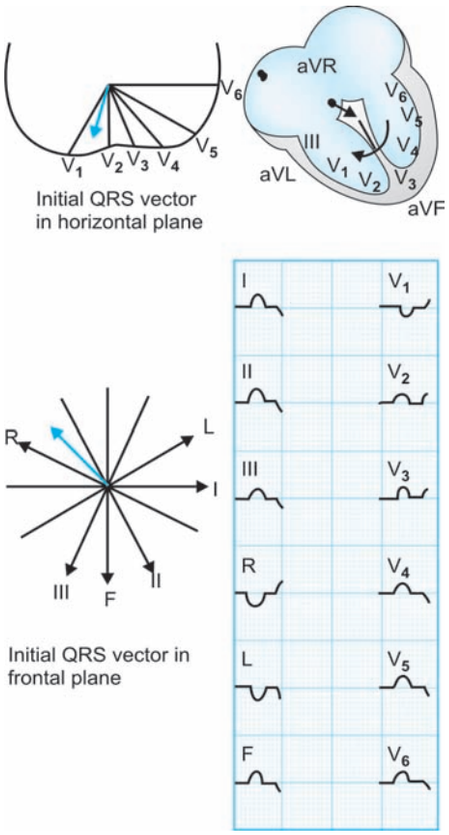

Fig. 6.129: Septal activation which is the beginning of ventricular QRS complex.This force is normally oriented to the right and anteriorly in horizontal plane. It may also be directed superiorly (shown in picture)or inferiorly in frontal plane

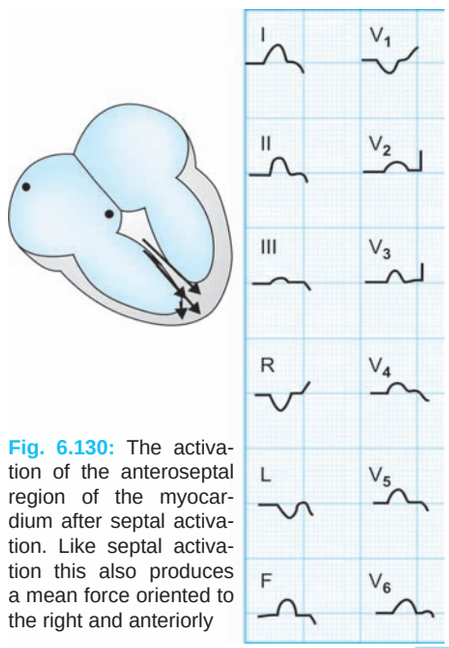

Fig. 6.130: The activation of the anteroseptal region of the myocardium after septal activation. Like septal activation this also produces a mean force oriented to the right and anteriorly

plane, and results in an upright deflection (R wave) in leads I and II. On the contrary, it produces a negative deflection (S wave) in the lead aVR. The recording in other frontal plane leads will depend on the relation between the axis of the frontal plane lead and the axis of this major ventricular vector. Lead aVF will record an upright deflection R, if the axis of the major ventricular vector lies between 0° and +90°. It will record a RS or a rs complex, if the mean axis is 0°. It will also record a negative deflection S, if the axis of QRS vector is directed between 0° and –30°. Lead III will record an upright deflection R, if the axis of major QRS vector lies between +30° and +90°, and a negative deflection S if the same vector lies between +30° and –30°. Lead aVL will record an upright deflection R, if the axis of QRS vector lies between –30° and +60° and a negative deflection S, if it lies between +60° and +90° (Fig. 6.131).

Major ventricular complex in horizontal plane leads

The axis of mean QRS vector in the horizontal plane is directed to the left and posteriorly. So, it produces predominantly negative deflection (S wave) in lead V_{1-2} and predominantly positive deflection (R wave) in lead V_{4-6}.

Ventricular Complex (Late)

The last portion of the ventricular myocardium to be depolarised is the posterobasal portion of the left ventricle and the region of the pulmonary conus. The mean vector of this activation is oriented in many directions. If it is directed rightwards, then a small negative deflection S will be recorded in leads I and V_{5-6}. If it is directed superiorly, then a small negative deflection s will be recorded in lead aVF. If it is oriented anteriorly, a small positive deflection r′ will be recorded in the leads V_{1-2} (Fig. 6.132).

Repolarisation

The sequence of events of ventricular repolarisation is very complex. Simply, it can be said that both the right and left ventricular cavities are negative during ventricular repolarisation.

The epicardial surface of the left ventricle is positive. That of the right ventricle may be positive or negative. The ST segment will be isoelectric in all leads. The usual normal axis of mean T vector is oriented to the left and inferiorly (between 0° and +90°). So the frontal plane leads will record upright T waves in leads I and II and inverted T (Fig. 6.133) waves in lead aVR.

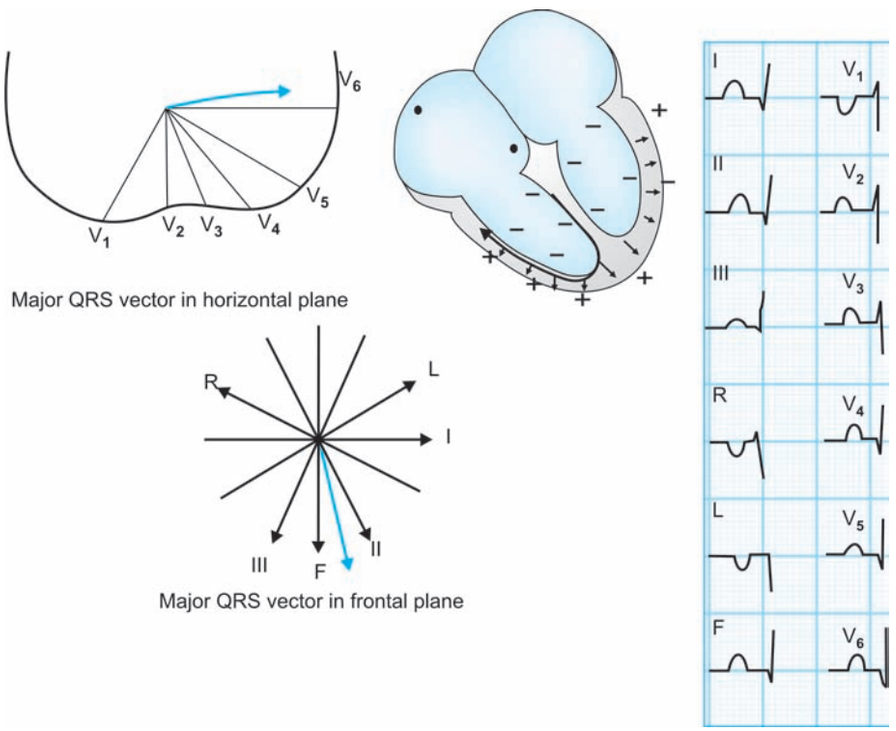

Fig. 6.131 : Right and left ventricular activation.The mean vector of the force is direc ted to the left in the horizontal plane and inferiorly and posteriorly in the frontal plane

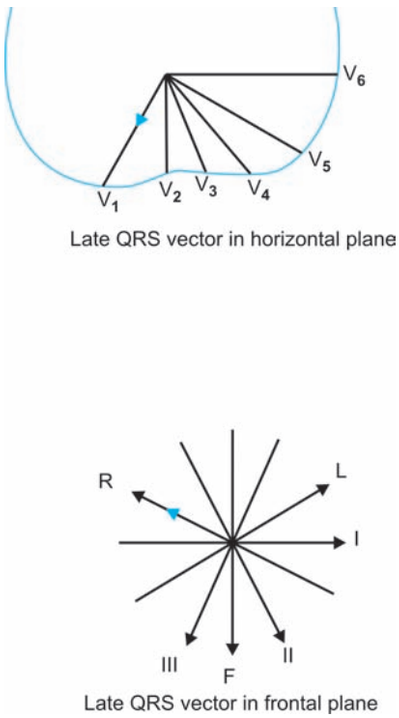

Fig. 6.132 : Late major QRS vector is due to the activation of posterobasal portion of the left ventri-cle,pulmonary conus and the uppermost portion of interventricular septum. This picture illustrates the mean vector of this force which is oriented rightward, superiorly and anteriorly

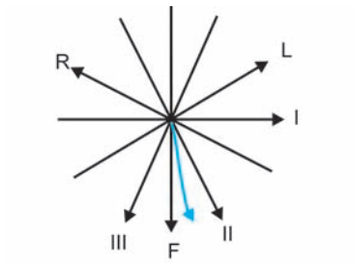
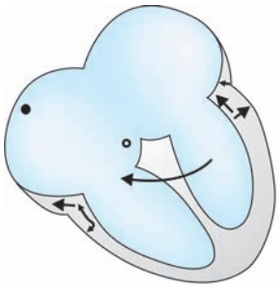
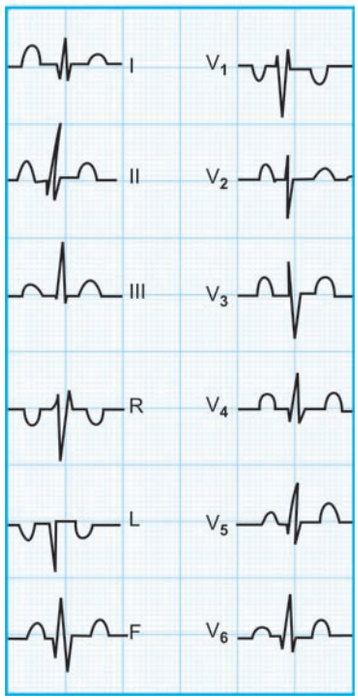


In frontal plane the mean vector of T





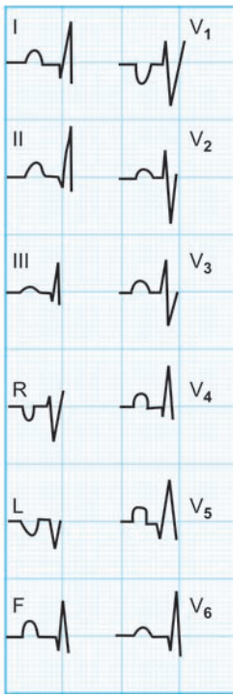


Fig. 6.133: Repolarisation– The mean T vector is oriented left wards (in horizontal plane) and inferiorly and anteriorly (in frontal plane)

The polarity of the T wave in other frontal plane leads (aVL, aVF, II) will depend on the relation between the axis of the vector of the T wave with the axis of this frontal plane, like the P and QRS axes, described before. In horizontal plane leads the mean T vector is oriented anteriorly. Depending on the degree of anterior orientation, the T wave may be inverted, biphasic or upright in lead V_1 and upright in leads V_{3-6}.

7 Neuromuscular Physiology Related to Muscle Relaxants

MORPHOLOGY

A single myelinated axon or nerve fibre after arising from the body of a motor nerve cell, which is situated at the ventral horn of the gray matter of spinal cord runs uninterruptedly through the spinal nerves to supply the muscles. There it branches and ultimately end into several expanded complicated structures which are known as the axon terminals or sole feet. These axon terminals ultimately end on each muscle cell or fibre as neuromuscular junction or motor end plate. Actually the motor end plate is a small depression on the muscle cell where a branch of the nerve terminal ends. It contains many nicotinic cholinergic receptors which are sensitive to acetylcholine. The diameter of this typically discoid or oval shaped neuromuscular junction or motor end plate is 20 to 30 µm. The number of muscle cells supplied by the terminal branches of a single axon or nerve fibre together form one motor unit. In single motor unit there may be 5 to 2000 muscle fibres. Synchronous contraction of all these muscle cells of a motor unit is called fasciculation. Fasciculation usually can not be seen by the naked eye, but sometimes it is often vigorous enough to be observed through the skin when the muscle is very superficial and the patient is lean and thin.

The axon carries electrical signal from the spinal cord to the muscle. At the neuromuscular junction this electrical signal is converted into the chemical signal by the release of neurotransmitter (acetylcholine - ACh) from the presynaptic membrane (which is nothing but the cell membrane of nerve fibre) and this chemical signal is again converted to the electrial signal by the binding of ACh with the nicotinic receptor at the postsynaptic membrane (which is nothing but the cell membrane of muscle fibre), leading to muscular contraction. All the enzymes, proteins, (Fig. 7.1) macromoleculaes and the membrane of vesicles, needed for the nerve ending to synthesise, store and release the acetylcholine for chemical signal are made in the nerve cell body and are then transmitted to the nerve ending by axonal transport. Only the chemical substances such as the choline and acetate are obtained locally at the nerve ending to synthesise ACh. The nerve ending is itself nonmyelinated, because myelin sheath ends before the nerve terminal touches the end plate of the muscle cell. But it is covered with the cytoplasm of Schwann cell with its nucleus. The axoplasm of axon at its terminal end is filled with numerous mitochondrias, endoplasmic reticulum and other materials which are required for chemical synthesis of neurotransmitter, and numerous vesicles to store it (Fig. 7.2).

The gap between the nerve cell membrane (presynaptic membrane) and the muscle cell membrane (postsynaptic membrane) at the neuromuscular junction is called the junctional cleft or synaptic cleft which is measured about 20 nm. The synaptic cleft is filled with extra cellular fluid. This is also called the gap substance. The synaptic cleft, separated by the basal membrane of both the nerve (presynaptic membrane) and muscle cell (postsynaptic membrane) also contains many fibrous strands linking the nerve and muscle cell membrane and enzyme called the cholinesterase (ChE). Multiple secondary cleft arise from the postsynaptic membrane of the muscle cell membrane from the main junctional cleft and thus the total postsynaptic surface area of the end-plate increases many fold. The branched and expanded nerve terminal which come in contact with muscle fibre lie within this corrugated sarcolemma (muscle cell membrane) of the end plate and the corrugation is due to this formation of multiple secondary cleft from the main synaptic cleft. Numerous nuclei and mitochondria are also seen in the sarcoplasm (cytoplasm) of the muscle cell near the nerve terminal or synapse. It is claimed that mitochondria present in the axoplasm take part in the

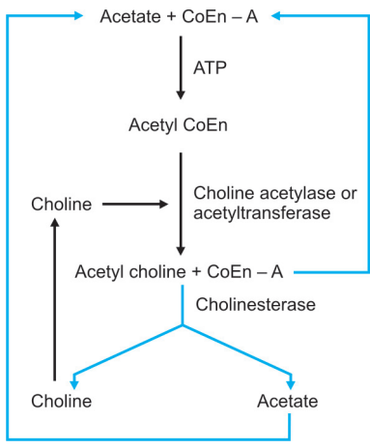

Fig. 7.1: Acetylcholine is broken down locally into acetate and choline which are available locally to synthesise further acetylcholine at the nerve endings

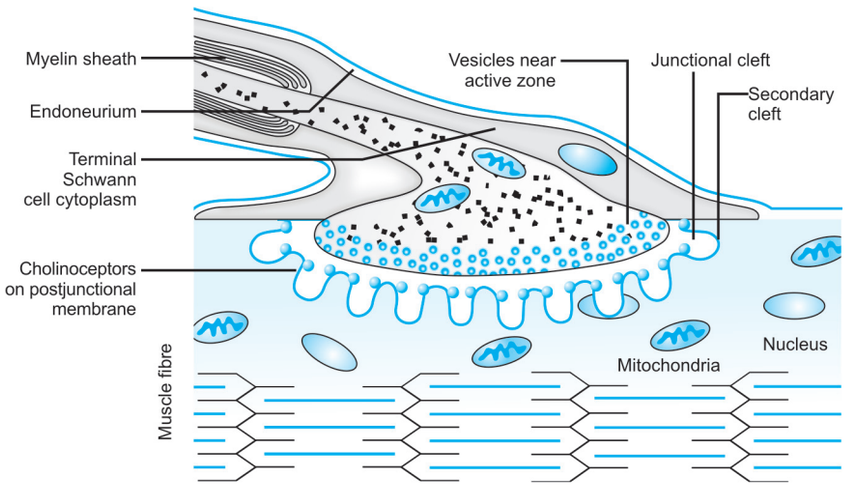

Fig. 7.2: Neuromuscular junction or motor end plate with an axon terminal containing vesicles of acetylcholine. The neurotransmitter is released on arrival of an action potential and crosses the junctional cleft to stimulate the postjunctional receptors on the shoulders of the secondary clefts

synthesis of acetylcholine which is then subsequently stored in the synaptic vesicle of the nerve terminal and released when the propagated impulse through the nerve fibre reaches the terminal. (Fact file-I)

There is only one neuromuscular junction for each muscle cell or fibre except some of extraocular muscles and internal laryngeal muscles which have several neuromuscular junctions or end plates for each muscle cell, locating at short distance from each other and maintain a steady contraction in response to stimulus. These muscles are important to anaesthetists, because instead of causing brief contraction and followed by paralysis, the depolarising muscle realxants cause long lasting contractions in these type of muscles and contribute to a rise in intraocular pressure. Virtually all human muscles (except extraocular and possibly some laryngeal muscles), however, contract in all-or-none principle. On the contrary, short muscle fibres have only one end plate, but long muscle fibres may have 2 to 6 endplates, separated by long distances, typically 100 mm. However, these long muscles also have all-or-none principle of action (Fig 7.3).

The peripheral area of the muscle cell membrane around the neuromuscular junction is called the perijunctional area. It actually indicates the transitional area between the postsynaptic membrane of end-plate and the true cell membrane of muscle fibre. It is very critical for the function of the neuromuscular junction. This is because it is here where the electrical or action potential, developed at the end plate is converted to an electrical impulse that sweeps along the whole muscle cell membrane and initiate muscular contractions. It contains a mixture of smaller number of ACh or nicotinic receptor and higher number of Na^+ channel. The perijunctional area also participates actively in the modulation of neuromuscular transmission and controls the individual's response to muscle relaxant. Moreover some special variants (isomer) of nicotinic receptor and Na^+ channel can appear in this area at different stages of live which are responsible for abnormal decrease or increase in nerve muscle activity. This variability seems to contribute to the quantitative and qualitative differences in response to muscle relaxants that are seen in patient at different clinical status and age. Congenital abnormalities regarding the number and morphology in the ACh receptor and Na^+ channel are also known.

There are many vesicles at the nerve ending which are arranged or congregated towards the presynaptic membrance of neuromuscular junction. On the other hand microtubules, mitochondria and other structures of the nerve terminal are located on the opposite side of the junctional surface of the nerve ending. Vesicles are arranged in a pattern of triangular arrays, with the apex of each triangle directing towards a small, thickened electron dense patch of presynaptic axonal membrane which is referred to as an active zone. This thickened area (or active zone) in a cross section shows many bands running across the width of the synaptic surface of the nerve ending. Vesicles are attached to the active zone before they rupture into the junctional cleft. The attachment sites of the vesicles lie on the sides rather than in the centre of the active zone. Many small particles are also seen along the active zone between the vesicles. Actually

FACT FILE- I

The shoulder of secondary cleft is densely populated with acetylcholine (ACh) receptor. But the depth of the secondary fold is populated with Na^+ channel, which transform the depolarisation (electrical signal) produced by ACh-receptor into the muscle action potential (electrical signal) and triggers contraction of muscle. Muscle cell membrane surrounding the end plate at the periphery is also rich in Na^+ channel and functions as the same i.e. end plate depolarisation into muscle action potential.

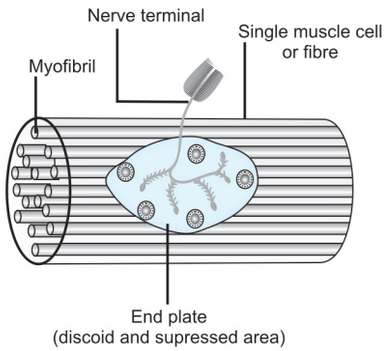

Fig. 7.3: Motor end plate in relation to a muscle fibre— surface view

these particles are the special voltage gated calcium channel that allow the Ca^{2+} to enter the nerve ending from the extracellular space and cause the release of vesicles (Fig. 7.4).

The end plate area of the muscle cell membrane which is a part of the neuromuscular junction forming post synaptic membrance is very convoluted and is due to the presence of multiple secondary cleft or folds which is already discussed. Thus, the muscle cell membrane which is a part of the neuromuscular junction exposes a very large area to the nerve terminal for better transmission of impulses. The crests or shoulders of these folds are aligned opposite to the vesicle release site or active zones of the nerve terminal and contain a high density of ACh receptors (nicotinic receptor channel). But deep in these folds, the endplate membrane contains a high density of sodium channels. There are about 5 million nicotinic receptor at the each neuromuscular junction.

The stimulus or electrical impulse reaching at the nerve ending allows the Ca^{2+} to enter the nerve terminal through the special voltage gated calcium channels situated on the presynaptic membrane and causes the vesicles to migrate to the active zone. Then the membrane of the vesicles fuse with the neural membrane of nerve terminal and discharge their contents of ACh into the synaptic cleft. Since the release sites of ACh are located along the sides of the active zones and immediately opposite to the nicotinic receptors on the postjunctional surface, so normally little transmitter is wasted and the response of the muscle is coupled very directly with the signal from the nerve (Fig. 7.5).

Normally the end plate potential that is produced continuously at rest by the continuous release of uniformly sized packages or quantas of transmitters is called the miniature end plate potential (MEPP). This is 1/100th of the amplitude of the evoked endplate potential when the motor nerve is stimulated and muscle contraction occurs. But this is too big to be produced by a single molecule of ACh.

For each nerve impulse 200 quanta or vesicles containing 5000 ACh molecules in each vesicle is released. Thus, the number of ACh molecules released by each impulse is 10,00,000. Each acetylcholine or nicotinic receptor needs two ACh molecules for its activation. Thus the number of receptors activated by the neurotransmitter (ACh) released by a nerve impulse is also large and is about 5,00,000. But actually each impulse activate only 3,00,000 receptors, requiring only 6,00,000 molecules of ACh (each vesicle activate 1500 receptors requiring 3000 ACh molecule but they have extra amount). Thus the rest of the ACh molecule is either destroyed by acetylcholinesterase or binding solo instead

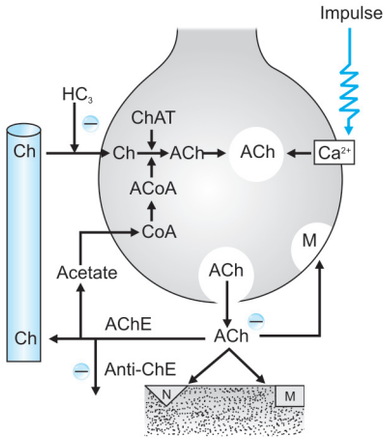

Fig. 7.5: The process involved in synthesis, release and deposit of acetylcholine at cholinergic nerve terminals and receptor site during transmission of nerve impulse

of pairs to a receptor. After coupling of neurotransmitter such as ACh with the postjunctional acetylcholine or nicotinic receptor, the Na^+ ions that flow through the channel of the activated receptor cause maximum depolarisation of the end plate, which in turn causes a full end plate action potential that is greater than the threshold for stimulation of the muscle fibre. Entry of Ca^{2+} inside the nerve ending is most important step for the release of neurotransmitter. Neither only Na^+ in flux, nor only depolarisation of nerve membrane will produce the release of neurotransmitter from the nerve ending if Ca^{2+} is not entered. The introduction of Ca^{2+} into nerve ending by micropippet will also release the neurotransmitter even if the nerve is not depolarised (Table 7.1). Ca^{2+} enter the nerve terminal from extracellular fluid via a special type of protein channels which are called the Ca^{2+} channel. Among the several types of these calcium channels only P and L channels are most important for the release of neurotransmitter from

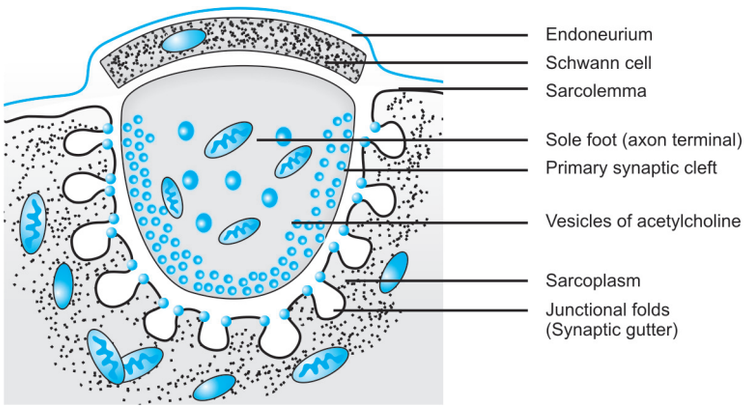

Fig. 7.4: Electron microscopic appearance of myoneural junction at the region of an axon terminal (sole foot) ending in the motor end plate

Table 7.1: Differences between two types of cholinesterases

		True cholinesterase (Acetyl cholinesterase)	*Pseudo (butyryl) or plasma cholinesterase*
1.	Distribution	All cholinergic sites and RBC	Plasma, liver, GI
2.	Hydrolysis of ACh	Very fast	Very slow or nil
3.	Hydrolysis of butyryl-choline	Not hydrolysed	Hydrolysed
4.	Inhibition	More sensitive to physostigmine	More sensitive to organophosphates
5.	Function	Termination of action of ACh	Hydrolysis of synthetic esters such as succinylcholine

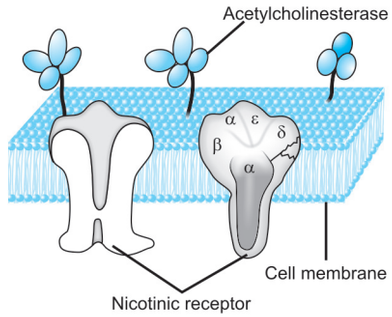

Fig. 7.6: This is a schematic diagram of the postsynaptic membrane. The picture shows two structures in the centre which represent nicotinic acetylcholine receptors. Each is made up of five subunits arranged in a ring around a channel. The three balloon like structures represent acetylcholinesterase (ACh E)

the presynaptic membrane. Again among the P and L channels, P channels are found only in motor nerve ending adjacent to the active zones of the nerve terminals and is responsible (not L type of Ca^{2+} channel) for Ca^{2+} entry and subsequent transmitter release for neuromuscular transmission. They are voltage dependent which means they are opened and closed by the changes in membrane voltage caused by the propagated nerve action potential. On the otherhand, many bivalent organic cations such as Mg^{2+}, cadmium, Mn^{+}, etc, can also block this Ca^{2+} channel and thus profoundly impair the neuromuscular transmission. This is the mechanism for muscle weakness in mother and the foetus when magnesium sulfate is administered to treat the pre-eclampsia. Eaton-Lamber myasthenic syndrome is an another acquired autoimmune disease in which antibodies are detected against this voltage gated calcium protein channel at the nerve ending. Patient with this myasthenic syndrome exhibit an increased sensitivity to the depolarising and non-depolarising muscle relaxant. Normally calcium P channel cannot be blocked by organic calcium channel blocking drugs such as verapamil, diltiasem, nifedipine, etc. Because these drugs have only profound effects on the slower L type of Ca^{2+} channel present in the CVS. So, L-type calcium channel blockers at therapeutic doses have no significant effect on the normal release of ACh from the nerve terminal or on the strength of the normal neuromuscular transmision.

The exact mechanism by which the Ca^{2+} causes the release of neurotransmitter from nerve terminals is not yet known. But its entry into the nerve terminal seems to trigger a series of phosphorylation reaction which disrupt the resting state of nerve terminal and causes the release of neurotransmitter. An effect of the increasing level of calcium at the nerve ending is also seen clinically important in post tetanic potentiation which occurs when a nerve of paralysed patient paralysed with non-depolarising muscle relaxants is stimulated by the current of high tetanic frequencies. During tetanic stimulation calcium enters the nerve ending with every stimulus, but it can not be excreted out as quickly as the nerve is stimulated and Ca^{2+} enters. Thus, it is gradually accumulated during tetanic period. So, when a strong stimulus is applied post-tetanically, then the nerve ending causes the releases of more than the normal amount of ACh due to more availability of Ca^{2+}. This abnormally large amount of released ACh antagonises the effect of muscle relaxant and causes the characteristic increase in the size of post tetanic twitch which is known as posttetanic potentiation (Fig. 7.6).

Two types of vesicles are found at the nerve ending. One is readily releasable smaller vesicles, called VP_2. They are situated very close to the synaptic cleft in the nerve terminal, attaching to the active zones and are ready to release the neurotransmitter present within them. Another is large reserve or store vesicles, called VP_1. They are majority in number and are firmly tethered to the cytoskeleton by proteins, called the synapsins. Some of these vesicles have been recycled after their use by releasing transmitter. But most of the vesicles are new and are formed in the cell body and transported to the nerve ending. The release of neurotransmitter from the vesicles involves many steps, all of which are regulated by the vesicular or synaptic membrane proteins. First the vesicle has to unbind from the storage position and then it binds to a docking protein which is situated on the innerside of the presynaptic membrane. There then fusion occurs between the vesicular and synaptic neural membrane. Next Ca^{2+} enter the nerve ending through the P type of Ca^{2+} channel which is lined up on the sides of the active zone and activate a protein, called synaptophysin, which is situated on the vesicle wall. The activated vesicle wall protein then react with the nerve membrane to form a pore through which the vesicles discharge its contents. Thus, acetylcholine is poured into the synaptic cleft. Hence there is delay in propagation of impulse from nerve fibre to muscle fibre through synaptic cleft. This delay of propagation of depolarisation between the nerve ending and that of the end-plate of the muscle cell is called synaptic delay which is about 0.1 ms. When the nerve is called upon to work (Table 7.2) hard due

Table 7.2: Cholinergic receptors and its sites and action of relaxants

Receptors	*Location*	*Function*	*Relaxant - interactions*
Nicotinic	Postsynaptic neuromuscular junction	Depolarisation of end plate – muscle contraction	Succinylcholine — stimulates, Non-depolariser – block
Nicotinic	Presynaptic neuromuscular junction	Helps in release of ACh	Succinylcholine — stimulates Non-depolarisers – block
Nicotinic	Autonomic ganglion	Depolarisation of ganglionic cell	Succinylcholine — stimulates Non-depolariser – block
Nicotinic	Post-ganglionic neuron terminal	Positive feed back for transmitter release	Succinylcholine — stimulates Non-depolariser – block
Muscarinic	SA node of heart	↓ heart rate	Succinylcholine stimulate — ↓ HR Non-depolariser block — ↑ HR
Muscarinic (M_1)	Autonomic ganglionic interneuron cell bodies	Inhibition of depolarisation	Non-depolariser block
Muscarinic (M_2)	Autonomic ganglia : Ganglion cell bodies	Depolarisation	Atropine blocks, Non-depolarisers do not act

to repeated stimulation at high frequencies, then this reserved VP_1 vessicles replaces the wornout VP_2 vesicles and participate in transmission of impulse. Under such circumstances calcium enter the nerve terminal more deeply also through the L type of Ca^{2+} channel in addition to the P-channel and activate calcium dependent enzymes. These enzymes then phosphorylate and cause the breakage of synapsin links that hold the vesicles to the cytoskeleton, and thereby allow the vesicles to be moved to the release sites.

After discharge of the neurotransmitter into the synaptic cleft, vesicular membrane temporarily becomes the part of the nerve cell membrane. Then a special protein that is present in the vesicular membrane, detaches it from the nerve cell membrane and make it return back again into the cytoplasm of the nerve terminal as a rudimentary vesicle. This rudimentary vesicle then again becomes filled with ACh neurotransmitter and moves into the previous position for release. Thus, these membranes of vesicles are used again and again until finally worn out and transported back to the nerve's cell body for complete destruction. The complex molecules, such as enzymes, proteins and new membrane which are used for the synthesis and storage of ACh in vesicle are made in the nerve's cell body and transported back through the axon to the nerve terminal. For the synthesis of acetylcholine (ACh) the simple molecule, choline, is only obtained by the nerve cell body from the extracellular fluid and is transported to the cytoplasm of nerve ending by a special system.

But the acetate for synthesis of acetylcholine is available from acetylcoenzyme A (acetyl CoA) which is present in the mitochondria of nerve ending and is obtained during the metabolism of glucose, fat and amino acid. Choline and acetate then react with the help of enzyme choline acetyl transferase or cathecol-o-methyltransferase (COMT) to form acetylcholine which is then stored in the cytoplasm and transported into the vesicles. At rest, as the lipid bilayer of the cell membrane is more permeable to K^+ than Na^+, so more K^+ leaks out of the cell than Na^+ gets in. Thus, it creates a slight excess of positive charges on the outside and a negative charges on the inside of the cell membrane, leading to resting membrane potential of about −70 to −90 mV. During the action potential of nerve fibre, Na^+ flows inside of the cell and thus resulting depolarisation opens the voltage gated Ca^{2+} channel. This allows the entry of Ca^{2+} ion into the nerve ending and cause release of acetylcholine from the vesicles.

In resting situation, the concentration of Ca^{2+} ion is many times greater at the outside than the inside of the neural cell membrane, which facilitate the influx of it from extracellular fluid after depolarisation reach the nerve ending. This concentration gradient of Ca^{2+} ion between the intracellular and extracellular fluid of nerve ending is maintained by:

i. A very efficient system, which transports the Ca^{2+} ion from inside to outside of the cell,
ii Sequestrating a huge amount of Ca^{2+} inside the intracellular organelles,
iii. Binding of Ca^{2+} with intracellular proteins (Fact file-II).

After the release of ACh, it reacts with the acetylcholine receptor protein (or nicotinic receptor) on the endplate to initiate muscular contraction. Acetylcholinesterase enzyme remain attached to the endplate by thin stalks of collagen fibres, like bundles of balloon attached to stringes. So, most of the acetylcholine molecule after its release

FACT FILE-II

Depolarisation or opening of Na^+ channel of nerve cell membrane activates Ca^{2+} channel and causes transient and localised rise of intracellular Ca^{2+} concentration in nerve terminal. This inward Ca^{2+} current persists until the membrane potential is returned to normal by outward fluxes of K^+ from the nerve cell. Thus, calcium current can be prolonged by potassium channel blockers (e.g. 4-aminopyridine) which slow or prevent K^+ efflux out of the nerve. Thus prolongation of action potential causes increase in quantal discharge.

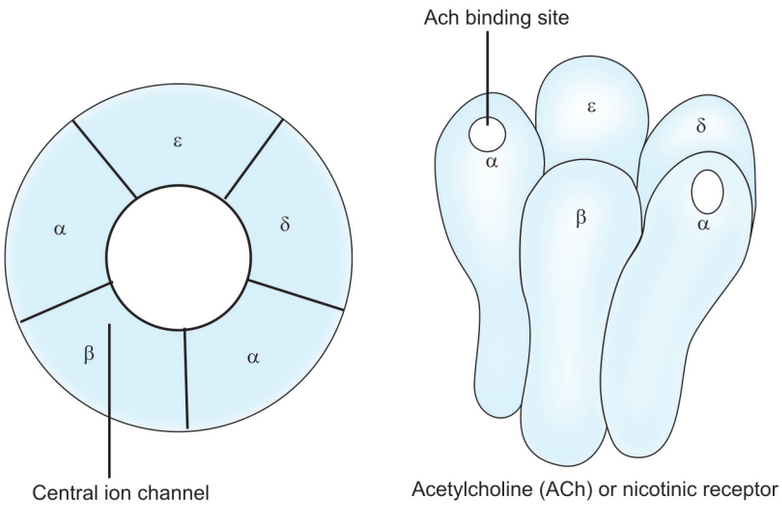

Fig. 7.7: This is a schematic diagram of cholinergic nicotinic receptor

from the nerve terminal pass between the esterase enzymes to reach the post junctional nicotinic receptor. Hence, they are hydrolysed by enzyme acetylcholinesterase during their passage through the synaptic cleft. ACh molecule that is not hydrolysed during their passage through the synaptic cleft react with receptor and are later hydrolysed by cholinesterase. So the action of acetylcholine is very short lived and is destroyed in less than 1 millisecond. Two ACh molecule react with one receptor only for function of the later (Fig 7.7).

Acetylcholine or nicotinic receptors are synthesised at the end plate of muscle cell membrane under the guidance of mRNA. After synthesis, each receptor is inserted into the cell membrane at end plate and held firmly there by 43Kd protein in such way that each receptor crosses from one side of the cell membrane to the other. Each ACh-receptor is made up of 5 protein subunits and are assembled like a cylinder with a channel within it. Each of these protein subunit consists of 400 to 500 amino acids. Normally, the receptors looked like cylinder and the channels within it are closed. But if acetylcholine reacts on the specific sites at the extracellular end of the receptor, then the protein subunits undergo in conformational changes and opens the channel in the centre of the receptor. When the channel is opened then Na^+ and Ca^{2+} flow from outside to inside and K^+ flow from inside to outside of the cell, resulting in an end plate potential that stimulates the muscle to contract. The current that passes through the each opened channel is very minimal, and only of few picoampere. However, burst of each vesicle from the nerve terminal liberating acetylcholine neurotrammitter normally opens about 5,00,000 ACh receptor channels. Hence, the produced total current is more than adequate to cause depolarisation of the end plate and helps its subsequent spread over through the whole muscle cell membrane with contraction. The channel in the receptor is large enough to accomodate many cations other than Na^+, K^+, Ca^{2+} and also electrically neutral molecules. But it excludes anions (e.g. Cl^-) for their passage through this channel.

These nicotinic or ACh receptors are found in pair. Molecular weight of each receptor is 2,50,000 Da and is made up of about total 2000 to 2500 amino acids. Each receptor has five protein subunit (as described before) and is designated as α, β, δ and ε. There are two α subunits and one for each of the rest. The α-subunit is the smallest of the five and is made up of 437 amino acids adding up to a weight of 40000 Da to the receptor. The molecular weight of other subunits range between 50 to 70,000 Da. One of the likely configuration of nicotinic receptor, looking clockwise from the outside of the endplate membrane, is α, ε, α, δ and β.

All the five subunits of the receptor have four membrane spanning domains. It means their string of aminoacids traverse the cell membrane four times and both the end is being on the extracellular side. The channel in the receptor is funnel shaped and is only lined by the 2nd membrane domain of each subunit. Length of each receptor is 11 nm of which half protrudes in the extracellular space and only 2 nm protrudes in the cytoplasm. The larger end of the funnel shaped channel of the receptor is on the outside of the cell. The ACh binding site of the receptor is situated only on both the α-subunit. They are also the site for binding of both the agonist and antagonist. When only both the α-subunit is occupied by agonist, then the protein molecule or subunit of the receptor undergoes conformational changes and the channel opens. On the other hand if only one of them is occupied then channel remains closed. At rest, the channel is closed because the membrane spanning domains of subunits lining the channel in the centre touch each other at one point. Non-depolarising relaxants act by binding with one or both α-subunit of the nicotinic receptor and prevent ACh to bind. So the channel of the receptor remains closed and thus prevent depolarisation and muscular contraction. The interaction between the agonist and antagonist on the receptor site is competitive in nature and the final outcome depends on the relative concentration and binding characteristic of these agents (agonist and antagonist) involved. There is also acetylcholine receptors on the presynaptic membrane which play role in mobilizing the vesicles containing neurotransmitter from its reserve to the immediately releasable position. These receptors are also of nicotinic cholinergic type and are blocked by small doses of non

depolarising agents. Presynaptic receptors also bind agonists such as succinylcholine. This presynaptic action of succinylcholine accounts for fasciculations and the effectiveness of pretreatment with small doses of non-depolarising agents.

Summary of Mechanism of Muscular Contraction by Neuromuscular Transmission

Contraction

When an impulse reaches the nerve terminals or sole feet, then depolarisation of end plate takes place by the help of liberation of acetylcholine (ACh) from the vescicle, with the participation of entry of Ca^{2+} from outside within the nerve terminal. By the propagated impulse along the axon, Ca^{2+} from the extracellular fluid enters into the vesicles of sole feet or nerve terminal and causes the ACh to come out from the vesicles. The acetylcholine (ACh) thus liberated diffuses across the synaptic cleft and reacts with the acetylcholine or nicotinic receptor on the post junctional membrane (PJM), forming the acetylcholine-receptor complex. The acetylcholine-receptor complex at the end plate thus increases the permeability of the PJM to Na^+ and K^+ (Fig. 7.8).

Due to enough release of ACh, a large number of nicotinic receptors in PJM are activated and this state facilitates the entry of enough Na^+ producing depolarisation of the post-junctional membrane. If the depolarisaing potential of PJM attains a threshold level, then an impulse of action potential is propagated in both directions along the sarcolemma (the cell membrane of muscle cell). After that the released acetylcholine at the end plate is rapidly destroyed and its concentration is declined either by the true cholinesterase which is present in high concentration at the rim of the synaptic gutter or by simple diffusion out in the surrounding tissues. From the sarcolemma the action potential is then propagated through a triad system, into the contractile units of the muscle cell. The pair of terminal transverse cisternae and the central T-tubles are collectively called as the triad system. In mammalian muscle cell, the each triad system is present at the junction of A-band with the adjacent I-band of contractile unit of muscle cells. Thus, there are two sets of triad system in each segment of sarcomere and plays an important role in quick transmission of impulses from the cell surface to the whole triad system and contractile unit inside the muscle cell. Depolarisation of the muscle cell membrane causes release of Ca^{2+} from the triad system or sarcoplasmic reticulum which in turn bind with troponin. Then troponin activate the myosin ATPase and helps in the cross-bridging of myosin and actin filaments with the developments of muscle contraction. Troponin is a protein which in resting state prevents actin and myosin filaments from cross bridging (Fact file-III).

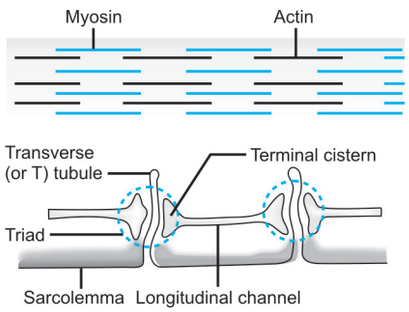

Fig. 7.8: The logitudinal channel, transverse tubule and triad. This tirad is the connection between the surface of the muscle fibre and the endoplasmic reticulum

Relaxation

After contraction when the action potential is over → Ca^{2+} is pumped back again into the sarcoplasmic reticulum → myosin ATPase is depressed→ cross−bridges are broken → myosin is pulled back to its resting site.

Under normal condition, the impulses may be excitatory or inhibitory. When there is preponderence of the excitatory impulses over the inhibitory impulses, then there will be depolarisation of the postsynaptic motorneurone membrane and the discharge of the action potential will be of EPSP (excitatory postsynaptic potential) type. But, when there is predominance of the inhibitory impulses over the excitatory impulses, then there will be hyperpolarisation of the postsynaptic motorneurone membrane. Thus, inhibitory postsynaptic potential (IPSP) will be developed and this will inhibit the discharge of any impulses.

FACT FILE- III

Propagated action potential along the axon → depolarisation of the neurone terminals → ACh is released from synaptic vesicles with the help of Ca^{2+} entry → released ACh diffuses across the synaptic cleft → ACh forms a ACh−receptor−complex with the nicotinic receptor on PJM → opening of the channel of the receptor → increased permeability of Na^+ and K^+ of the PJM → depolarization of end plate → depolarization of Na^+ channel at the perijunctional zone which is a very critical area where potential developed at the end plate is converted to an action potential which sweeps along the muscle sarcolemma cell membrane → transmission of such action potential from sarcolemma to the triads (sarcotubular system – T system + sarcoplasmic reticulum) → release of Ca^{2+} from sarcoplasmic reticulum → binding of Ca^{2+} with troponin → troponin with Ca^{2+} activate myosin ATPase → myosin ATPase is activated → cross−bridges are formed → myosin slides along actin → contraction of muscle is developed.

End plate potential

It can be defined as the potential changes at the motor end plate induced by activation of the acetylcholine receptors which cause the increase in end plate permeability to Na^+ and K^+. End plate potential can be recorded by inserting microelectrode into the motor end plate. When an impulse reaches the neuromuscular junction through an axon, ACh is liberated from the terminal nerve endings and then depolarises the motor end plate of the muscle cell membrane. When this local depolarisation exceedes −30 mV to −40 mV (threshold level), then a spike potential in the muscle cell is initiated with an amplitude of +35 mV and the muscle contracts.

At rest, the neurotransmitter substances are continuously liberated from the vesicles at a very slow rate from the nerve

terminal which is incapable of producing any depolarisation up to the threshold level and failed to initiate a full action potential with any propagated impulse and contraction of muscle. This small end plate potential is called the miniature end plate potential (MEPP) and it is not more than 0.5 mV. However, when the nerve action potential reaches axon terminals, then there is synchronous release of several vesicles full of transmitter substance, causing a threshold end plate potential and muscle contraction.

ACTIONS OF DRUGS ON NEUROMUSCULAR TRANSMISSION

Neuromuscular transmission can be blocked by two ways: (i) by inhibiting the release of acetylcholine (ACh) or (ii) by inhibiting the action of ACh on its receptor at the motor end plate through (a) competitive inhibition or (b) by persistent depolarisation of nicotinic receptor (Fig. 7.9).

Botulinus toxin blocks the neuromuscular transmissions by inhibiting the release of ACh from nerve terminals through its action on presynaptic membrane. Whereas curare muscle relaxants such as tubocuranine, pancuronium, atracurium, etc. blocks the neuromuscular transmissions by competitive inhibition of acetylcholine at the level of nicotinic receptor. It means, the curare competes with ACh for binding on the nicotinic receptor, but does not prevent the release of it from the presynaptic nerve terminal. These curares are called the non-depolarising muscle relaxants.

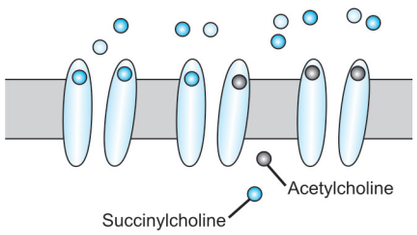

Fig. 7. 9: The classical action of agonists (acetylcholine and succinylcholine) on end plate nicotinic acetylcholine receptors. Any combination of the two agonists molecules causes the channel to open. But different agonists cause action potential of different durations, depending upon the duration of binding of agonist to the receptors. ACh causes few millisecond of binding with depolarization and paralysis. Succinylcholine causes long duration of binding with depolarization (better to say prevent repolarization) and paralysis than ACh

The drugs which block the neuromuscular transmission and produce muscular paralysis by persistent depolarisation are decamethonium and succinylcholine. These act on the nicotinic receptor like ACh, and cause prolonged depolarisation of the motor end plate. Thus, they prevent the further action of ACh and produce muscular relaxation, because ACh can not act on the already depolarised nicotinic receptor. So, they are called the depolarising muscle relaxant. The prolonged depolarisation produced by succinylcholine or decamethonium is because these drugs are metabolized and eliminated very slowly in comparison to ACh. The ACh which is found in normal neuromuscular transmission cannot produce prolonged depolarisation and muscular paralysis because the elimination of it is very rapid (fraction of second) as the true cholinesterase present in the synaptic cleft destroys it.

Non-depolarising Muscle Relaxants and Receptor

Non-depolarising muscle relaxants prevent the depolarisation of the endplate because they bind to the ACh recognition site of α-subunit of the nicotinic receptor. Thus, it prevents the ACh from its binding to the α-subunit of the receptor and cause the ion channel within the receptor not to open. Cholinesterase enzyme present in the synaptic cleft destroys the ACh and removes it from the competition with the non-depolarizing muscle relaxants molecule. Thus, the neuromuscular transmission and subsequently the muscular contraction is prevented. If anticholinesterase is added then cholinesterase enzyme is destroyed and it can not destroy the acetylcholine further. Thus, the concentration of ACh gradually increases in the synaptic cleft and shifts the competition between the ACh and the muscle relaxants (non-depolarising) in favour of ACh, though the nondepolarizing muscle relaxants is still present in the enviornment. Hence, the neuromuscular transmission is improved and muscle contracts (Table 7.3).

Nicotinic receptor channels will not open unless the ACh is attached to the binding sites of the two α-subunit of receptor, i.e. two molecules of ACh per receptor is needed. Whereas binding of single molecule of non-depolarising muscle relaxant to the binding site of single α-subunit of receptor is adequate to prevent the opening of channel. So, the competition between the agonist (ACh) and antagonist (relaxants) is biased in favour of antagonist. Mathematically this bias ness is equivalent to the second power effect of the number of molecule of antagonist (i.e. for 2 molecule of relaxants 4 molecule of ACh is needed). All these explanations indicate that the block produced by high concentration of nondepolarising muscle relaxants is difficult to reverse than the low concentration of it and sometimes impossible (Fig. 7.10).

There are typical features of non-depolarising and depolarising block or muscular relaxation by which we can

Table 7.3: Characteristics of depolarising and non-depolarising block

Feature	*Depolarising or (phase I) block*	*Nondepolarising and phase II block*
Effect on single twitch height	Reduced	Reduced
TOF fade	Not found	Found
Tetanic fade	Not found	Found
Post tetanic facilitation	Not found	Found
Effect of Anti-ChE agent	Potentiation	Reverse
Effect of non-depolarising agent	Reduction of block	Potentiation

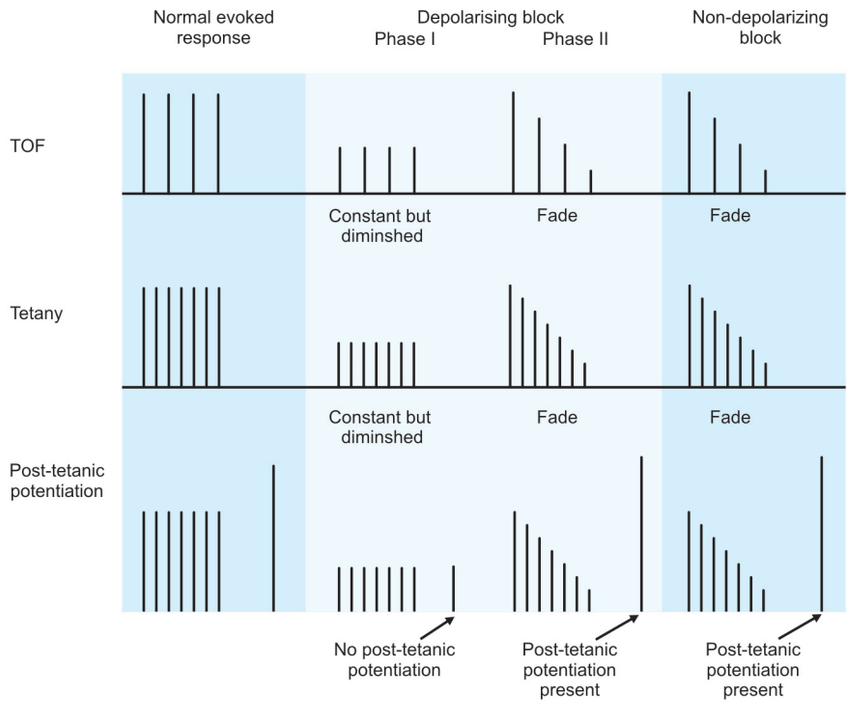

Fig. 7.10: Evoked responses during depolarising (phase I and phase II) and non-depolarising block

differentiate them. The characteristic features of non-depolarising and depolarising block or muscular relaxation are:

i. Generally, in the normal neuromuscular physiology at least 10 seconds must be allowed to elapse between the two successive single twitch stimulus (or pulse) for complete recovery of the motor end plate and subsequent contraction. Therefore, if the interval of two pulses is more than 10 seconds i.e. if the frequency of impulses is < 0.1 Hz, then there is full recovery of motor end plate and no depression or fade on successive impulses will be found. On the other hand, if frequency of impulses is more than 0.1 Hz, i.e. the interval between two successive impulses is <10 seconds, and the end plate does not get adequate time to recover completely then fades appears after successive impulses. Fade increases with frequency up to 2 Hz, when a plateau is reached. This plateau is maintained upto 50 Hz. Fade reaches its maximum value by the fourth impulse from where the idea of train of four (TOF) has come. In non-depolarising and depolarising block, when the block is very intense i.e. one hundred percent (100%) then there is no response to any type of stimulus. This is called the period of no response. Thereafter, with the passing of time when the intensity of block declines then the response to different types of stimulus starts to appear (responsive phase). Then if the frequency of stimulus is < 0.1 Hz, then in the response against the stimulus there is no fade, but only the depression of all the height of response will occur. But if the stimulus is > 0.1 Hz, then gradual depression of the response, i.e. gradual decrease in the height of response or fade appears in non-depolarising type of block, but not in the depolarising type. Clinically in surgical state of anaesthesia, patients usually stay in responsive phase because the intensity of block is not so high that any stimulus will not respond. So, in the therapeutic clinical dose of relaxants for the surgical stage of anaesthesia any single twitch stimulus will produce response, but of low amplitude in both depolarising and nondepolarising block but will so fade in nondepolarising relaxant and no fade in depolarising relaxant provided the stimulus is > 0.1 Hz. (NB 1 Hz = 10 impulses in 10 seconds. 0.1 Hz = 1 impulse in 10 seconds. 2 Hz = 20 impulses in 10 seconds).

ii. In train of four (TOF), the frequency of impulse is 2 Hz and is consists of four impulses separated by 0.5 seconds. With non-depolarising relaxants, fade is seen with TOF stimulus after the first response and is maximum at fourth. In contrast, with depolarising relaxants there is no fade after TOF stimulus but all the responses are low in amplitude than the previous non block one. (2 Hz = 20 impulses in every 10 seconds. So interval between two impulses is 0.5 sec).

iii. Tetanic stimulation (30 to 100 Hz) is also characterised by fade in non-depolarisation relaxation. However, in depolarising relaxation, the response to tetanic stimulation is sustained like normal muscle, but with low amplitude.

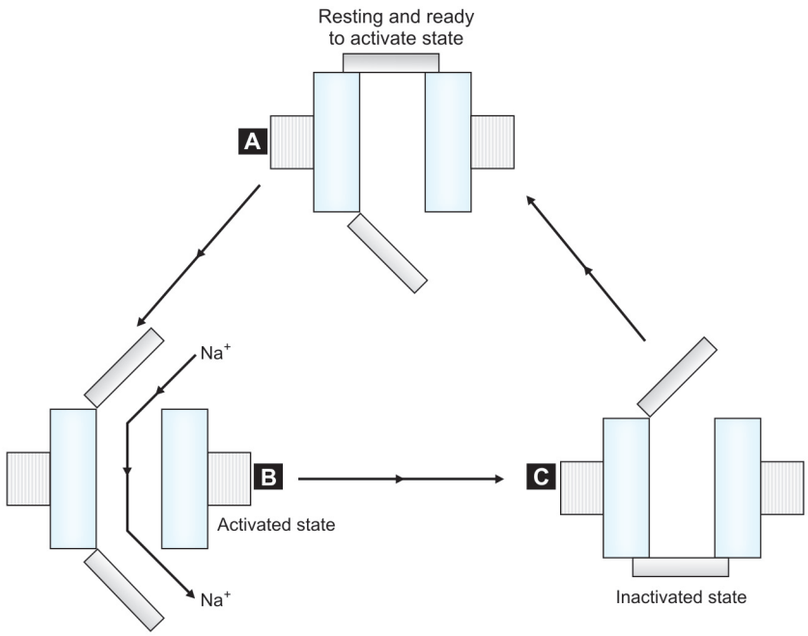
iv. When a single twitch or train-of -four stimulus is applied after a tetanic stimulation, then the response in non-depolarising block is exaggerated or facilitated. This is called the post-tetanic facilitation and the probable explanation is the displacement of non-depolarising muscle relaxant molecules from the motor end-plate by the acetyl-choline which is released maximally during the tetanic stimulation. This post-tetanic facilitation is absent in depolarising block like normal muscle. This post-tetanic facilitation should not be confused with post tetanic potentiation, applied in post-tetanic count (PTC) which is an augmented stimulus of single twitch or T-O-F stimulation after a tetanic stimulation.

v. Non-depolarising block is reversed by anticholinesterase agents, but depolarizing block becomes intense due to potentiation of depolarisation by increased acetylcholine level by these agents. Depolarising agents also antagonize the nondepolarising block or relaxation, provided the dose of depolarising agent is small enough not to produce block in its own right and blockade by non-depolarising agent is intense enough. On the other hand, non-depolarising agents also antagonize the relaxation produced by depolarising block.

Depolarising Muscle Relaxants and Receptors

The depolarising muscle relaxants act in the same way as ACh. They act by attaching on the same binding site of ACh on the α-subunit of nicotinic receptor to open the receptor channel and initiates depolarisation. Like ACh, succinylcholine is not attaches to the receptor very briefly. So, each opening of channel is not so of very short duration, i.e. 1 millisecond or less like ACh. But in contrast to ACh, depolarising relaxant's (succinylcholine) action lasts longer extending from minutes to hours (ACh action lasts only for millisecond) and have a biphasic action on muscle causing it to contract initially and then to relax the explanation of which is discussed below. The difference between the duration of action of ACh and succinylcholine (structurally which is actually two molecules of acetylcholine) is because ACh is rapidly destroyed by true acetylcholinesterase and is cleared from the synaptic cleft very quickly. Whereas succinylcholine is not destroyed by the true choline esterase enzyme present in the cleft. On the other hand, it is eliminated through hydrolysis by plasma or pseudocholine esterase circulating in plasma. So, the rate of clearance of succinylcholine from the whole body will determine how long it will last in the cleft and repeatedly react to open the receptor channels and continuously depolarise the endplate. (Some author's view is that binding of receptor to succinylcholine is prolonged and this produces desensitisation i.e. unresponsiveness of the nicotinic receptor to the further action of ACh). But here, it is explained that the prolonged action of succinylcholine is not due to the prolonged duration of binding with receptor, but due to repeated binding, with sustained depolarisation of end plate (not desentisation or unresponsiveness) that causes the adjacent Na^+ channels of perijunctional area to remain in inactivated state by sustained depolarisation and not getting time for repolarisation and rest which normally help further transmission of impulses causing muscular contraction. So, after first muscle contraction (fasciculation) paralysis prevails (Fig. 7.11A to C). In case of succinylcholine there is quick shift from brief muscle contraction which is seen as fasciculation to relaxation. This is because at the edge of the motor endplate, i.e. at the perijunctional area two different kinds of membrane such as the endplate membrane and the true muscle membrane with their different types of channel come in contact. End plate membrane contain ACh receptor channel that open by ACh or succinylcholine and muscle membrane contain Na^+ channel that do not respond to chemicals such as ACh or succinylcholine but open when they are exposed to postsynaptic transmembrane voltage change due to depolarisation of nicotinic receptor of end plate. Thus the channels on the two parts of membrane (end plate area responds to chemical stimuli) respond to two different type of stimuli i.e. chemical and electrical. End plate area responds to chemical stimuli such as ACh and perijunctional area respond to electrical stimuli, such as depolarisation of end plate created by the previous chemical stimuli.

Na^+ channel like ACh receptor is also a cylindrical protein tube across the



Figs 7.11A to C: This is a schematic diagram of sodium (Na^+) channel. The bright red bars represent the gate of the channel. The upper one is voltage dependent. But the lower one is time dependent:
A. Represents the resting state of the Na^+ channel. With upper gate is closed and lower gate is opened
B. Represents the activated state with both the gates open
C. Represents the inactivated state with upper gate open and lower gate closed. Then it again passes to the resting state where upper gate is closed and lower gate is opened. Thus, the cycle repeats and becomes ready for next impulse

membrane. It responses only to the sharply changing electrical voltage due to the opening of adjacent nicotinic receptor by ACh but not due to the direct responses to chemical like ACh. The Na^+ channel is made up of three protein subunits called α, β_1 and β_2. The α-subunit has the shape of a doughnut and is thicker than the membrane itself. The intracellular portion of the channel is larger than the extracellular portion. The β_1 and β_2 subunit, each lie on the outside of the α-subunit. They are smaller than the α-subunit and occupy only the external half of the cell membrane. The overall size of the Na^+ channel is approximately 13.5 nm in thickness and 10 nm in its largest diameter. The molecular weight of Na^+ channel is 30,000 da.

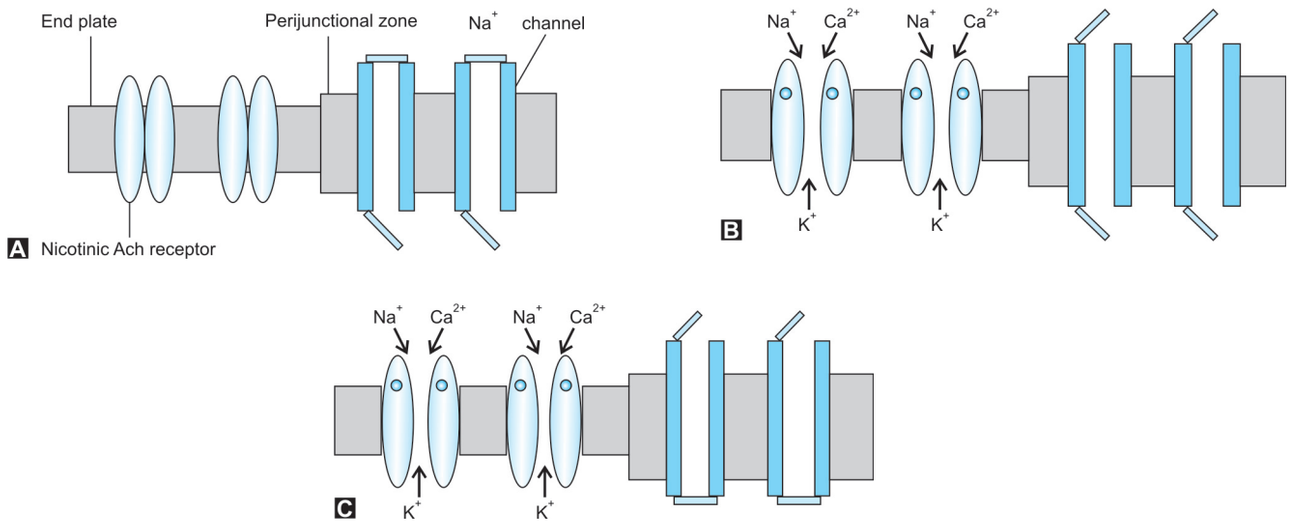
It has two gates which act sequentially. Upper gate is voltage dependant and responses only to voltage changes. Lower gate is time dependant and closes or opens for a fixed time period (1 to 2 millisecond). In resting state, the upper gate remains closed and the lower gate remains opened. So, sodium (Na^+) can not pass through this incompletely opened Na^+ channel. When the Na^+ channel of the perijunctional area is subjected to sudden voltage changes by depolarisation of the adjacent endplate membrane by the activation of ACh or nicotinic receptor channel, then the top gate of Na^+ channel opens. Therefore, since the lower gate is still open, so Na^+ starts to flow through this Na^+ channel driven by the favourable high extracellular concentration and electrical gradients. This state of Na^+ channel is called the activated state. Thus, this entry of Na^+ in the muscle cell fibre from outside initiates the depolarisations of the muscle cell membrane and spread from one Na^+ channel to the next. In that way a wave of depolarisation moves along the whole muscle cell membrane and triggers the muscle contraction which is seen as fasciculation shortly after administration of succinylcholine. Shortly after that the time dependant lower gate closes with still the upper gate open after a fixed time, i.e. after 1 to 2 millisecond and cuts off the flow of Na^+ ions. This state of the Na^+ channel is called the inactivated state. When the activation of the ACh or nicotinic receptor and the depolarisation of end-plate stops and end-plate membrane potential is brought back to its resting value, then the Na^+ channel again comes to the previous resting and ready to activate state from inactivated state with voltage dependant upper gate closes and lower gate opens. But during continuous depolarisation of end plate by succinylcholine, the perijunctienal Na^+ channels remain in this inactivated state (as the lower time dependent gate must closes after a first time under any condition) after the first activated state for which muscle contraction (that is seen as fasciculation) occurs and does not reach the resting and ready to activated state. This prevents the further spread of depolarisation from the end plate which is still now in depolarised state to the other part of the muscle cell membrane causing muscle relaxation.

During depolarization of end plate by ACh the activation of Na^+ channel of perijunctional area also causes activation of the adjacent K^+ channel and opening of it as the inside of the cell becomes electrically positive (due to influx of Na^+). These channels are selective only for K^+ ions and it exit the cell, driven by the high intra cellular concentration of it and electrical gradient. Thus, the waves of action potential spread along the muscle cell membane. So the excitability of the resting cell can also be modified by the K^+ channels. For example, continuous opening of K^+ channel produces a hyperpolarisation state (inside of the cell is more negative) and the cell becomes less excitable (Fact file-IV).

When depolarising muscle relaxants such as succinylcholine is administered, then the initial response of it on the nicotinic receptor at the end plate and causing depolarisation and subsequently the response of depolarisation of end plate on the Na^+ channel at the perijunctional area causing muscular contraction which is seen as fasciculation resembles like ACh. But as this muscle relaxant (succinylcholine) is not hydrolysed by the true choline esterase at the synaptic cleft, so depolarisation of the end plate continues and muscle fasciculates. After that since, Na^+ channel immediately adjacent to the endplate in perijunctional area are influenced by the continuous depolarisation of the end plate, so their voltage dependent upper gates stay open, but consequently their time dependent lower gates stay closed which is called inactivated state and remains in this inactivated state. This inactivated state of Na^+ channel persists until the voltage dependent upper gate closes and lower gate opens. Thus, the sodium channel can not complete its cycle (i.e. untill the end plate comes back its resting state). Since the Na^+ can not flow through a channel that has a closed lower gate in perijunctional area, so the adjacent Na^+ channel in muscle membrane is not further depolarised and due to that the other down stream channels on muscle cell membrane are freed of depolarising influence. So, the muscle remains paralysed as long as the end plate remains depolarised by succinylcholine and Na^+ channel of perijunctional area stay in inactivated state. Infact in junctional zone the first line of Na^+ channels act as buffer which shields the rest of the Na^+ channel of the muscle membrane from the events of the motor end plate (Figs 7.12A to C).

FACT FILE- IV

Normally, ACh is hydrolysed quickly within the synaptic cleft and so depolarisation of endplate is very short. But this acetylcholine induced depolarisation of the end plate causes the Na^+ channel in the adjacent muscle membrane (perijunctional area) to open which subsequently activate the adjacent K^+ channel and depolarise the muscle membrane. This depolarisation on the muscle membrane spreads from one Na^+ channel to another Na^+ channel and like waves spread all over the muscle. Upon the hydrolysis of ACh, end-plate repolarises and the adjacent Na^+ channels quickly complete their cycles. Then it returns to their resting state and muscle relaxes.



Figs 7.12A to C: This is a schematic diagram of nicotinic acetylcholine receptors (red) in the end plate, perijunctional zone and Na^+ channel (blue) in the muscle membrane. Red ACh receptors are chemically sensitive, but voltage insensitive. Blue Na^+ channels are chemically insensitive, but voltage sensitive. Red appendages within Na^+ channel represent gates. The top gates remain closed. But it opens when voltage is applied across the membrane. This top gate of Na^+ channel is called activation gate. The lower gate is called the inactivation gate and normally it remains open. But it closes spontaneously after the voltage dependent upper gate opens and after a fixed time. So, it is called the time dependent gate. To flow Na^+ through the sodium channel both the gates must be opened:

A. Shows resting membrane. Here no current flows through any ACh or Na^+ channel, as they remain in resting state
B. Activation of chemically sensitive ACh-receptor of end plate by acetylcholine or succinylcholine (red dot) by nerve impulse or applied. Thus, the voltage potential which is developed by the flow of current through the ACh receptor channel causes the upper gate of the adjacent voltage sensitive Na^+ channel in the perijunctional zone to open. Therefore, the first Na^+ channel is activated and current (ions) starts to flow through this Na^+ channel. This causes subsequent voltage changes and opens the next Na^+ channel. Thus a wave of depolarisation spreads along the surface of the muscle cell membrane which starts first at the end plate and then by Na^+ channel at the perijunctional zone.
C. The ACh receptors in the endplate are still in depolarized state. So, the voltage dependent upper gate of the Na^+ channel in the perijunction zone next to the end plate remains open. But, the time dependent inactivation lower gate closes spontaneously after a fixed time interval. So, no ion flows through this Na^+ channel situated in the first row of the prijunctional zone. Therefore, there will be no change of voltage potential in the muscle membrane around the end plate. Thus, the gates of the next 2nd, 3rd, 4th and subsequent rows of Na^+ channel return to their resting state. So, the inability of the Na^+ channels which are situated just by the side of end plate, in the perijunction zone to pass sodium current due to continuous depolarisation of the ACh receptor causes blockade of neuromuscular transmission

Thus, during the action of depolarsing muscle relaxant such as succinylcholine the muscle membrane is divided into 3 zones: (i) the motor end plate with nicotinic receptor which is depolarised by succinylcholine, (ii) junctional zone where Na^+ channels are frozen in inactivated state after a brief depolarisation and muscular contraction, and (iii) rest of the muscle membrane where Na^+ channels are in resting state after passing an impulse and producing fasciculation. Since a further burst of acetylcholine from the nerve terminal cannot produce depolarisation of end plate due to the still presence of succinylcholine at the end plate and can not overcome the inactivated state of Na^+ channel in perijunctional area due to continuous depolarisation of end plate. So, neuromuscular transmission is blocked. This phenomenon is called accommodation. During accommodation when the synapse is inexcitable via the nerve, then direct electrical stimulation of muscle will cause muscle contraction. This is because since the sodium channel beyond the perijunctional area are in the resting excitable state.

However, the extraocular muscles are tonic muscles which are multiply innervated with numerous motor end plates. So, most of its surface is chemically excitable with no resting and relaxation zone. Thus, accommodation does not occur. So, these muscles undergo sustained contraction in the presence of succinylcholine and causes increased intraocular pressure. There is also evidence that extraocular muscles contain a special type of receptor which does not become desensitised in the continued presence of succinylcholine or other depolarising agent.

Succinylcholine also has presynaptic action. Binding of succinylcholine to this presynaptic nicotine receptors depolarises the nerve terminals and action potential may be generated which travel backwards retrogradely along the nerve terminals to invade the neighbouring branches and thus produce contraction of a whole motor unit. Fasciculation is probably (some school thought) due to this mechanism rather than the transient depolarisation of the motor end-plate receptors, because small doses of non-depolarising agents are effective in preventing this phenomenon. Another probable explanation of fasciculation is the special sensitivity of muscle spindles (intrafusal fibres) to succinylcholine

which may produce muscular contractions via gamma affarents.

There are many drugs which acts on the nicotinic receptor, but not classically as competitive of ACh like succinylcholine. Because they can not be antagonised by increased level of ACh by anti-cholinesterase. They act by desensitisation of the nicotinic receptor molecule and blockade of ion channel. These drugs react with the ACh-receptors directly or via its lipid environment to change their functional integrity and impair transmission, but not acting via the acetylcholine binding site of the receptors. This reaction between the drugs and the receptor causes changes in the dynamics of the nicotinic receptor, so that the modified receptor channels instead of opening and closing sharply, become fixed or sluggish. They open more slowly and stay open longer or they close slowly in several steps or both. This effect of drugs on nicotinic receptor causes corresponding changes in the flow of ions and distortion of end plate potential. Procaine, ketamine, inhaled anaesthetic agents and other drugs which dissolve in the membrane lipid acts in that way. If the channel is prevented from the opening, then transmission is weakened. On the other hand, if the channel is prevented from the slowed in closing, transmission may be enhanced. Such drugs can be involved in two clinically important reaction: receptor desensitisation and channel blockade.

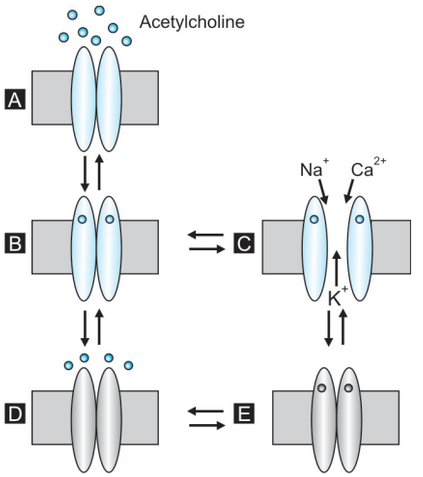
Desensitisation

The ACh or nicotinic receptors are macromolecules. They are not rigid static and fixed. Actually they are flexible dynamic and set in a fluid lipid content of muscle cell membrane and be in a many states. One of these states is desensitized state. In this state agonist bind with the receptor with exceptional avidity and it does not undergo any conformational changes that opens the channel. The mechanism by which the desensitization of nicotinic receptor occurs are not known. Some evidence suggest that densitisation is accompanied by the phosphorylation of tyrosin unit present in the receptor protein. Indeed, normally the receptor molecules undergoes spontaneously in and out of the transformation of the desensitised state and at a particular time the sensitized and desensitised receptors remain in a certain proportion at motor end plate. Therefore, at a certain time, the intensity of neuromuscular transmission depends on the ratio of these sensitized (resting normal) and desensitized (abnormal) receptor concentration. This is because desensitized receptors are not able to take part in neuromuscular transmission. If only few receptor are desensitized, then the system will be more susceptible to blockade of neuromuscular transmission by antagonist (non depolarising relaxants) and vice versa (Fig 7.13A to E).

Agonist such as acetylcholine or succinylcholine binds tightly with the nicotinic receptor and promotes the transition from sensitised to desensitised state. Antagonist also binds tightly to desensitised receptor and its action is augmented by ACh. Many drugs such as halothane, alcohol, pentothal, succinylcholine, neostigmine, local anaesthetic, chlorpromazine etc; promote the shift of the receptor from normal sensitised to abnormal desensitised state and reduce the neuromuscular transmission, augmenting non-depolarising agent's action. These drugs also can weaken the neuromuscular transmission by reducing the margin of safety that normally exists at the neuromuscular junction or they can cause an apparent increase in the sensitivity of the non-depolarising agents to block neuromuscular transmission. As these actions are not based on a competition between the drug and ACh and based on the making more desensitized receptor from sensitized one, so it can not be reversed by anti cholinesterase (Table 7.4).

Channel blockade

The molecules of many drugs (like local anaesthetics and Ca^{2+} channel blockers)



Figs 7.13A to E: Here the picture shows the different states of end plate nicotinic acetylcholine receptors.

A. resting receptor,
B. resting receptor with agonist (acetylcholine) bound to the recognition site. But the channel not yet opened,
C. active receptor with opened channel which allows the flow of ion,
D. desensitised receptor without agonist bound to the recognition site,
E. desensitised receptor with agonist bound to the recognition site. Both D and E are nonconducting. All states of the receptors are in dynamic equilibrium.

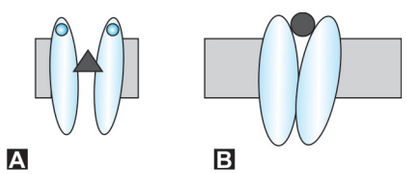
Table 7.4: Some drugs that can cause desensitisation of nicotinic cholinergic receptors

1.	AChE inhibitors
	Neostigmine, pyridostigmine, edrophonium, physostigmine, organophosphorus compounds.
2.	Agonists
	Acetylcholine, succinylcholine, decamethonium, carbachol.
3.	Volatile anaesthetics
	Halothane, isoflurane, methoxyflurane.
4.	Antibiotics
	Polymyxin - B
5.	Alcohols
	Ethanol, butanol, propanol.
6.	Barbiturates
	Thiopental, pentobarbital.
7.	Local anaesthetics
	Lignocaine, dibucaine, prilocaine, etidocaine.
8.	Phenothiazines
	Chlorpromazine, trifluoperazine prochlorperazine.
9.	Ca^{2+} channel blocker
	Verapamil

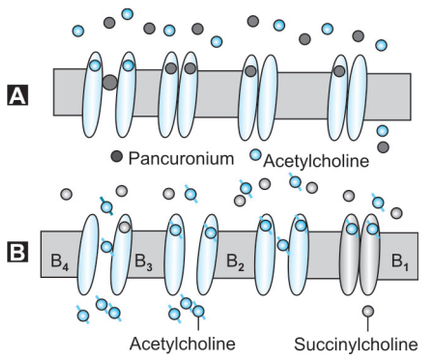
may enter the nicotinic receptor channel and block the flow of ions preventing depolarisation. These are called the channel blockers. There are two types of channel blockade: open channel blockade and close channel blockade. In both opened and closed channel blockade, the normal flow of ions through the nicotinic receptor is impaired resulting in prevention of depolarisation of the motor end plate and a weak or no neuromuscular transmission. However, since the action of these agents is not at the acetylcholine recognition site of receptor, so it is not a competitive antagonist of ACh and is not relieved by the action of anticholinesterase that increases the concentration of ACh (Figs 7.14A and B).

Open channel blockade

Some drugs like muscle relaxant also enter up to the middle of the channel while it is opened by ACh and block it. So, it impedes the flow of ion through it. Thus, it prevents the depolarisation of the end plate. The non-depolarising muscle relaxant is the best example of it. Even though they act at the ACh recognition site, they also block the nicotinic receptor channel directly or physically by this way. A given drug may act preferentially at one or the other site. Pancuronium acts preferentially at ACh recognition site. Gallamine acts equally at two sites. Tubocurarine at low dose purely acts at recognition site and at higher dose at both the sites (recognition site and enter the receptor to block the channel). Increasing the concentration of ACh may cause the channel to open more and it make more susceptible to open channel blockade. So neostigmine and other cholinesterase inhibitors also can act as open channel blocking drug. Decamethonium and succinylcholine act as agonist and open the channels by binding at the selective site of α-subunit of nicotinic receptor. They also enter the channel and block them as open channel blocker. But decamethonium and some other drugs also can penetrate all the way through the open channel and enter the muscle cytoplasm where they interfere the intracellular process and prevent depolarization. Whether prolonged administration of nondepolarizers, as in the intensive care unit, can result in the entry of relaxant in channel and blockade of it or finally entry of drug into the cytosol is unknown. This effect may partially explain the muscle weakness associated with prolonged relaxant therapy in the intensive care unit. In such situation neuromuscular block is complex. At the end, we can conclude that some drug molecules cause depolarisation due to action on the recognition site, while others cause: channel blockade, promote desensitization of the receptor, or interfere with the intracellular process (Figs 7.15A and B).



Figs 7.14A and B: Nicotinic receptor channel blockade. A. Open, B. Closed



Figs 7.15A and B: A. shows some effects of prolonged exposure of ACh receptor to high concentrations of antagonists (pancuronium). The three receptors at the right have recognition site blockade by pancuronium. The single receptor at the left has open channel blockade. B. shows some effects of prolonged exposure of ACh receptor to high concentrations of agonists (succinylcholine). The right most single receptor (B_1) is desensitized (blue). While that to the right of centre (B_2) has open channel blockade. At left (B_3, B_4) succinylcholine has penetrated the open channels of two ACh receptor and entered the cytoplasm

Close channel blockade

In closed channel blockade, drug block the mouth of channel while it is closed. Thus, by their (drug) presence it prevents physiological ions from passing through the channel to depolarise the end plate. This process can take place even when the channel is not open. This type of blocked is the part of action of cocaine, quinidine, tricyclic antidepressants etc.

Phase II Blockade

This is a complex phenomenon which occurs if neuromuscular junction is continuously exposed to a depolarising agent. The characteristic features of this phase II block is similar to the nondepolarising block, but can not be reversed by anticholinesterase agent. Normally the neuromuscular transmission usually remains blocked through out the period of exposure with a depolarising agent by continuous opening of the receptor channel. But, continuous and repeated opening of the receptor channels by large doses of depolarising agent allows the continuous efflux of potassium and influx of sodium. This results in abnormal electrolyte balance of the motor end plate which distorts the function of the perijunctional membrane and Na^+ channel and thus explain the mechanism of phase II block. Ca^{2+} entering the muscle fibre via open channel also cause the disruption of the function of receptor and sub end plate element. This also contribute to the mechanism of phase II block. On the other hand, the activity of the Na^+- K^+-ATPase pump on the muscle membrane increases due to increased intracellular Na^+ and extracellular K^+ concentration. Thus by pumping more Na^+ out of the cell and more K^+ into it, it works hard to restore the normal ionic balance and membrane potential as a compensatory mechanism. Return of the ratio of Na^+ and K^+ to normal level restore the membrane potential toward normal level even though the channel remains open. If depolarising muscle relaxant is applied in

Table 7.5: Difference between phase I and phase II block by succinylcholine

Features	*Phase I*	*Transition*	*Phase II*
Tetanic stimulation	No fade	Slight fade	Fade
Train - off - four	No fade	Slight fade	Fade
TOF ratio	> 0.7	0.4 - 0.7	< 0.4
Post-tetanic facilitation	Nil	Slight	Yes
Anti ChE	Potentiate	Little effect	Antagonise
Recovery	Rapid	Rapid	Prolonged
Dose requirement (mg/kg)	± 2	± 4	≥ 6

high concentration and allowed to remain at the neuromuscular junction for a long time, other things also occur which further explain the mechanism of phase II block. These are that the drug itself enter into the channel to obstruct it, and pass through the channel into the cytoplasm like open and close channel blockade. Similar actions also occur on the (Table 7.5) prejunctional structure. Thus the combination of the pre and post junctional effects plus the secondary changes on muscle and nerve homeostasis results in the complicated phenomenon, known as the phase II blockade. Phase II block is a complex and everchanging phenomenon. Though phase II block shows response to tetanic or TOF stimulation like nondepolarising agent, still it is best not to take any attempt to reverse this type of block by anticholinesterase. Development of phase II block depends on the type of depolarising drug, duration of exposure, concentration of drug and the type of muscle.

Atypical Receptors

In contrast to other cells, muscle cells have hundreds of nuclei. Each of these nuclei have genes which direct to make two types of ACh (nicotinic) receptors at the motor end plate – mature or junctional and immature or foetal or extrajunctional. Other than gene, multiple other factors such as electrical signal coming to muscle (innervation), growth factor, etc, also determine which type of receptor will be formed on the muscle fibre in every individual (Figs 7.16A and B).

The difference in the structure of these two types of receptors cause significant qualitative variations in the response among the individual patient to muscle relaxants and also seem to be responsible for some of the abnormal results to muscle relaxants. At molecular level, these two types of nicotinic receptor differ at ε-subunit of junctional receptor which is replaced by γ-subunit in extrajunctional receptor. This difference is of great enough to affect the physiology and pharmacology of nicotinic receptor and ion channel within it. Although the names of the receptors are junctional and extrajunctional, which imply that each is located in the junctional and extrajunctional area respectively, but this is not strictly correct. Because junctional receptor are always confined to the motor end plate of the muscle membrane. But immature or extrajunctional receptor may be expressed any where in the muscle membrane including motor end plate. When muscle cells loose its nerve connection due to avulsion, stroke, burn or before innervation (foetal life), it produces extrajunctional or immature or fetal form of receptor in place of normal or junctional receptor.

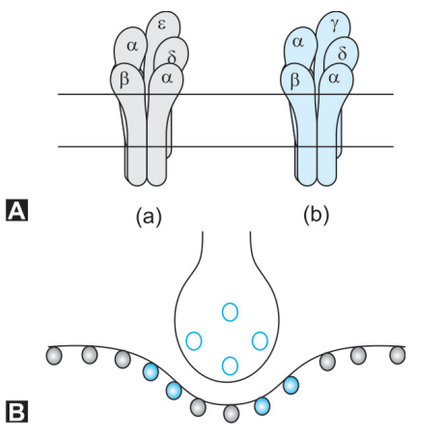


Fig. 7.16A and B: A. Shows junctional (a) and extrajunctional (b) ACh-receptors. Junctional receptors contain ε and extra junctional receptors contain γ subunits.
B. Neuromuscular junction with deficient activity. Muscle membrane contains extrajunctional receptors (blue circle). End plate contains both junctional (red circle) and extrajunctional receptors.

In foetus, before innervation, muscle cells only synthesize the extrajunctional receptors through out the whole muscle membrane including the motor end plate. Then as the fetus develops, muscle becomes innervated and begin to manufacture junctional receptor at the motor end plate and over the whole muscle. In this stage, at the end plate there is mixture of both the junctional and extrajunctional receptor. In a child of about 2 year old, before nerve muscle units are matured both types of receptors are found. Then as the child grows and nerve muscle unit matures, extra junctional receptor diminishes in concentration and disappear, both from the periphery of the muscle and the end plate. Process of making and removing the extrajunctional receptor is very fast. They appear within an hour after diminution of neuromuscular activity and are removed within half-life of 18 hours when activity returns to normal.

Although ACh does not binds with the γ or ε-subunit of receptor, still these subunits influence the ways in which these two kinds of receptors respond to the drug. Extra-junctional receptor are activated by lower concentration of agonist (succinylcholine) than are junctional receptor. So, extrajunctional receptors are more sensitive to depolarising agents. In contrast, extra junctional receptors are less sensitive than junctional to the non-depolarising drugs. In some circumstances, the non-depolarising muscle relaxants act as partial agonist and muscle contracts.

As extrajunctional receptors develop within few hours of stoppage of muscle

activity, so due to denervation or paralysis, patient becomes resistant to non-depolarising agents and then it is become more difficult to block them than ususal. So, the patient with deficient neural activity, demand more than usual dose of non-depolarising agent. On the other hand, as the extrajunctional receptor is sensitive to depolarising agent, so less amount of agonist such as succinylcholine is needed. Patient's receptor mixture and sensitivity to relaxants can began to change with in a day after an nerve injury or hospitalisation. Well built heavy muscular person who exercise vigorously are resistant to non-depolarising agent. This is because their nerve secret more ACh than normal and so transmission is more vigorous and hardened to block.

Patient with muscular paralysis due to denervation are more prone to succinylcholine induced hyperkalaemia. This is because in these patients, extrajunctional receptors predominate over the muscle cell membrane which are sensitive to depolarising agent. So, they remain open for long time by the agonist succinylcholine and allow more K^+ to escape from the muscle and enter the blood.

In infant and children, neuromuscular junctions are not mature. So, there are mixture of junctional and extra junctional receptor at the motor end plate. Their ratio varies with chronological age (with increasing age extrajunctional receptors disappear), muscular activity, health, vigor of child and from one group of muscle to another. Since, the junctional and extrajunctional receptor differ in their sensitivity to depolarising and non-depolarising agent, so, the amount of relaxant needed to produce muscle paralysis differs from one children to another, but in poorly predictable ways. Muscular paralysis produced by succinylcholine is not due to continuous depolarization of the whole muscle. But it is due to inactivated Na^+ channel ring at the perijunctional zone due to continuous depolarisation of endplate which insulate the depolarised motor end plate from rest of the muscle. Therefore, in infant and children as the insulating Na^+ channel ring is not developed properly, so the effect of depolarising relaxant may not be the same in thame as that of an adult.

ANTAGONISM OF NEUROMUSCULAR BLOCK

The competitive neuromuscular block caused by the action of (antagonist) non-depolarising muscle relaxants on nicotinic receptor is overcomed by increasing the concentration of competitor i.e. ACh (agonist). Increasing the number of molecules of ACh in the synaptic junctional cleft changes the agonist / antagonist ratio and increases the probability of agonist molecules such as ACh to bind with the unoccupied recognition site of it on it on nicotinic receptor. Normally, only about 5,00,000 out of 5 million available receptors are activated by a single nerve impulse. So, a large number of receptors are in reserve and could be occupied by a competitor agonist. Actually ACh can not displace from the nicotinic receptor the already bound molecule of non-depolarising agent and has to wait for the antagonist (non-depolarising muscle relaxant) to dissociate spontaneously from the receptor before it can compete with antagonist for free site. So, the length of time for which the nondepolarising agents presents in the synaptic cleft is also important. Non-depolarising relaxants bind to receptor for longer period than the life span of ACh. It indicates that most of the ACh is destroyed before any significant number of antagonist molecules have dissociated. So, prolonging the time for which ACh remain in junction, allows the time for dissociation of antagonist and for receptor to be freed and made available to ACh.

Neuromuscular block can be antagonised by two classes of drugs such as: K^+ blocking agents and acetylcholinesterase inhibitors. K^+ blocking agent such as 4-aminopyridine acts on the prejunction area. By impeding the efflux of K^+, it also prolongs the action potential of nerve ending. So, the duration of depolarisation of nerve axon is prolonged. Thus, indirectly prolonged action potential increases the influx of Ca^{2+} into nerve ending. Therefore, the nerve releases more ACh and for longer time than usual causing antagonism of neuromuscular blockade produced by nondepolarsing agents. As K^+ blocking agent acts only prejunctionally, so it also antagonizes the blockade produced by some antibiotics that act on prejunctional nerve endings such as polymyxin. So, 4-aminopyridine and this class of drugs are used very restrictedly to antagonize some specific neuromuscular block. However these drugs are not specific and act on all nerve endings including motor nerves, autonomic nerves, CNS etc, and is so associated with many side effects. So, this group of drugs is not used routinely to antagonise the neuromuscular block produced by non-depolarising agents.

Acetylcholine is inhibited or hydrolysed by an enzyme called true acetylcholinesterase or cholinesterase (chE) which is present is synaptic cleft. So, acetylcholinesterase inhibitors or anti-cholinesterases such as, neostigmine, pyridostigmine, edrophonium, etc, increase the level of ACh and improve the neuromuscular transmissions by inhibiting the acetylcholinesterase enzyme. Anticholinesterases or acetylcholinesterase inhibitors are ester of carbamic acid. So, they are also called carbamates. ACh is inactivated by its combination with the enzyme, cholinesterase, at its two sites: (i) an anionic site, bearing a negative charge which attracts the quaternary nitrogen atom (N^+) of acetylcholine and (ii) an esteric site which attracts the carboxyl group (COO) of the ACh molecule. As a result of the union of ACh molecule with the cholinesterase enzyme, the esteric site of the enzyme is acetylated by the acetylcholine molecule and this results in splitting of this molecule. Then, the acetyl group from the esteric site of the enzyme is immediately removed

(in nano second) as a result of combination with water, forming acetic acid. Thus, this sets the esteric site of the enzyme (cholinesterase) free for further inactivation of an other acetylcholine molecule. Anticholinesterase or cholinesterase inhibitors such as neostigmine, pyridostigmine, etc, act in the same way as acetylcholine with the cholinesterase enzyme, sparing the acetylcholine. Anticholinesterases are usually of two types: reversible and irreversible. Once irreversible anticholinesterase combines with the cholinesterase enzyme then this binding is not reversed until the whole complex of cholinesterase and anticholinesterase molecule is metabolised. The examples of these irreversible anticholinesterases are organophosphorous compounds.

Reversible anticholinesterase are also capable of combining with the anionic and esteric sites of cholinesterase enzyme like ACh, but does not form fixed cholinesterase and anticholinesterase complex like irreversible anticholinesterase. So, they are called reversible anticholinesterase. The complex which anticholinesterase form with the esteric site of cholinesterase enzyme is hydrolysed, but much less readily (Fig. 7.17) (after many minutes) than the acetyl-esteratic site complex formed with acetylcholine. Thus, this produces a temporary inhibition of the cholinesterase enzyme and prevent the breakdown of ACh and increase its concentration in synaptic cleft. Like ACh, both the reversible and irreversible anticholinesterases also can directly act on the ACh-receptor and may produce muscle relaxation like depolarizing agents, but it needs higher doses. In contrast to other reversible anticholinesterase, edrophonium forms reversible complex only with the anionic site of cholinesterase enzyme and hence has a shorter duration of action.

Organophosphorous compound (irreversible anticholinesterase) combine only with the esteric site of cholinesterase enzyme and consequently the esteric site is phosphorylated. Then the hydrolysis of this phosphorylated esteric site of cholinesterase enzyme is extremely slow and in certain cases does not occur at all. This produces an almost irreversible permanent inhibition or destruction of cholinesterase enzyme. So, they are called irreversible anticholinesterase or cholinesterase inhibitors. Echothiophate (irreversible anticholinesterase) forms complexes with

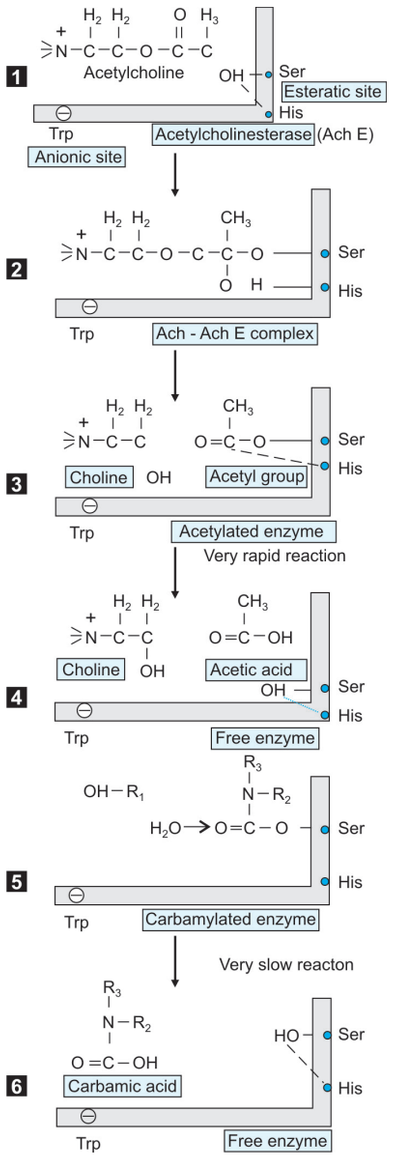

Fig. 7.17: Schematic representation of breakdown of ACh (1 to 4) and mechanism of action of carbamate anticholinesterase (3, 4). Ser = Serine, His = Histidine, Trp = Tryptophan

both anionic and esteratic site of the cholinesterase enzyme and hence is much more potent than other organophosphorus compounds. Thus, organophosphorus compounds permanently inhibiting the cholinesterase enzyme gradually raises the body ACh level which causes prolonged depolarisation of motor end plate, skeletal muscle paralysis, respiratory arrest, cardiac arrest and death.

Edrophonium (reversible anticholine esterase) is neither an ester, nor a carbamate compound. It is attracted and only bound to the anionic site of the cholinesterase enzyme by the electrostatic attraction between the positively charged nitrogen in the drug (edrophonium) and the negatively charged site of the enyme without any hydrolysis of edrophonium. It is removed from the enzyme molecule as in fact form and excreted through kidney. Other than inhibition of cholivesterare enzyme edrophonium also enhances the release of acetylcholine from the prejunctional site and so helps in the reversal from the deep neuromuscular block. The blockade of cholinesterase enzyme by edrophonium is very short lived and departs the enzyme in very short time. So, for decades edrophonium was considered to have short duration of action and to be useful in anaesthesia. But, now it is understood that the duration of action of any anticholinesterase is not determined by the duration of molecular reaction with the cholinesterase enzyme, but by the existence of drug (cholinesterase inhibitor or anticholinesterase) in body which depends on renal clearance. One edrophonium molecule attaches with enzyme (cholinesterase) for short time but as one molecule departs, it is immediately replaced by another edrophonium molecules, so that the cholinesterase enzyme remains inhibited for as long as the drug edrophonium is in the body. Elimination of edrophonium from body is same as neostigmine and pyridostigmine. So the duration of acetylcholinesterase inhibition and blockade reversal is same for all the three drugs.

However, as the patient has normal serumcholine esterase enzyme, so the pharmacokinetic properties of anticholinesterase are the principle determinant factor of the reversal of blockade. Activity of serum or plasma cholinesterase or the lack of it plays a minor role in the recovery of non depolarizing agent. Of the three commonly used anticholinesterase, edrophonium shows by far the greatest selectivity between the true acetylcholinesterase and butyryl or plasma cholinesterase. Butyryl cholinesterase is the serum esterase that hydrolyzes only succinylcholine and mivacurium but not ACh. Edrophonium greatly favours the true cholinesterase enzyme and the most desirable agent to reverse mivacurium. If patient has atypical esterase that does not destroy mivacurium, inhibition of true cholinesterase by neostigmine has no result till mivacurium will be present in the body. Mivacurium, like succinylcholine, is metabolized by pseudocholinesterase. It is only minimally metabolized by true cholinesterase. This introduces the possibility of prolonged action in patients with low pseudocholinesterase levels or variants of the pseudocholinesterase gene. In fact, patients who are heterozygous for the atypical gene will experience a block approximately twice the normal duration. Whereas atypical homozygous patients will remain paralysed for several hours. As atypical homozygotes can not metabolise mivacurium, the neuromuscular blockade may last for 3 to 4 hours. In contrast to succinylcholine induced paralysis, in these patients pharmacological antagonism with cholinesterase inhibitors will quicken reversal of mivacurium blockade once some response to nerve stimulation becomes apparent. Edrophonium more effectively reverses mivacurium blockade than neostigmine because it inhibits true cholinesterase activity only. Again there is no reason to choose one anticholinesterase over another.

Neostigmine, pyridostigmine and edrophonium does not cross the blood brain barrier as they are the quarternary ammonium compound. So, they have less CNS effects. Similarly, quarternary ammonium derivative of atropine such as glycopyrrolate also can not cross the blood-brain barrier. So, frequently glycopyrolate is used to limit the cholinergic effects of anticholin esterase agents on the periphery. Atropine cross blood-brain barrier and may cause CNS problems.

Anticholinesterases are not only selective for the neuromuscular junction, producing the nicotinic action of ACh which causes removal of neuromuscular blockade. But it also acts on cholinesterase in other sites of the body producing muscarinic action of ACh. So, atropine or glycopyrrolate like drug is used to counter the muscarinic effects of acetylcholine that accumulates in the synapses of gut, bronchi, salivary gland, and CVS, etc. Anticholinesterase such as physostigmine, tacrine are not quaternary ammonium compound. So, they cross blood-brain barier and have profound CNS effect. Anticholin esterase like physostigmine, tacrine also inhibit phosphodiesterase enzyme in addition to cholinesterase enzyme which plays important role in transmitter release at many synapses in CNS. This action is used in the treatment of Alzheimer's dementia.

Many anticholinesterase agents have methyl group on its positively charged nitrogen atom. So, it also acts as agonist like ACh on the nicotinic receptor channel, initiating ion flow and enhancing neuromuscular transmission. Mixing of different anti-ChEs (neostigmine, edrophonium etc) is not advisable. Because they do not potentiate each other. Therefore, when additional doses of anti-ChE is needed for treatment of incomplete reversal, then it is better to continue the original drug.

ANTICHOLINESTERASES OR CHOLINESTERASE INHIBITORS

Though discussion under this heading has already been discussed under the previous heading, still it lacks some points which are elaborated here. Anticholinesterases (anti-ChEs) are agents which inhibit the cholinesterases (ChEs) enzyme from destroying the acetylcholine and thus they protect ACh and promote neuromuscular transmission. Except increasing the level of acetylcholine (ACh) at the motor end plate, anti-ChEs have additional direct action on cholinergic nicotinic and muscarinic receptors situated on other places. So, the actions of anti-ChEs are qualitatively similar to that of acetylcholine (ACh) and other directly acting cholinoreceptor stimulants. Hence the action of anti ChEs which is mediated by ACh are divided into two groups – muscarinic action and nicotinic actions like ACh. However, the relative intensities of action of anti-ChEs mediated by ACh on muscarinic (smooth muscle, GI, respiratory tract, urinary system, glands glands) and nicotinic (autonomic ganglion, skeletal muscle, CNS) receptors varies among the different agents.

Classification of Anti-ChEs

Anti-ChEs are primarily grouped into two groups such as reversible and irreversible anticholinesterase.

Reversible anti-ChEs

Carbamates
- Neostigmine
- Pyridostigmine
- Physostigmine
- Edrophonium

Acridine
- Tacrine

Irreversible anti-ChEs

Carbamates
- Carbaryl (sevin)
- Propoxur (Baygon)

Organophosphates
- Parathion
- Malathion
- Diazinon(TIK-20)

Echothiophate
- Tabun

Chemistry

Anti-ChEs are either esters of carbamic acid (carbametes) or derivatives of phosphoric acid (organophosphates) (Fig. 7.18).

In carbamates, R_1 may have a nonpolar tertiary amino N (e.g. in physostigmine), and render the compound lipid soluble. In other reversible inhibitors, R_1 has a quaternary N^+ and render them lipid insoluble. All organophosphates are highly lipid soluble except echothiophate which is water soluble.

Mechanism of Action

The main mechanism of action of anticholinesterases (anti-ChEs) are the reaction (inhibition) with cholinesterases enzyme which destroy the acetylcholine. This results in an increased concentration of acetylcholine at synaptic cleft and thereby increase the likelihood of ACh, occupying the unblocked nicotinic receptors and improve the neuromuscular transmission. The reaction between the anti-ChE and ChE (cholinesterase) differs from the reaction between the ACh (acetylcholine) and ChE in that at the previous reaction the complex molecules (formed by anti-ChE and ChE) have a longer dissociation half-life and is about 7 minute, as the complex molecules are hydrolysed at very slow rate. Whereas the ACh and ChE complex molecule breaks down by hydrolysis within a fraction of second and ChE is freed for further action on ACh molecule. Thus, it quickly breaks all the ACh. In the reversible group of anti-ChE, the ChE is freed after a long time during which period the level of ACh is increased sufficiently to produce muscular contraction. Then free ChE again hydrolyse the ACh. In the irreversible group, the complex formed by anti-ChE and ChE is permanent and is not freed by hydrolysis (so they are called irreversible anti-ChE) So the ChE does not become free and gradually excessive ACh accumulates and death occurs.

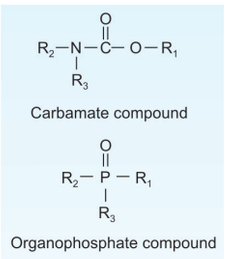

Fig. 7.18: Basic structure of anticholinesterase

The active region of ChE enzyme (such as acetylcholinesterase) makes a groove which contains an aromatic anionic site near trytophan 86 and an esteric site near serine 203 and histidine 447. The quaternary nitrogen atom (N^+) of ACh is attached with the negatively charged anionic site of ChE enzyme and the carboxyl group (COO) of ACh is attached with the esteric site of ChE enzyme. As soon as the carboxyl group of ACh is attached with ChE enzyme at the esteric site, then choline is splitted out from ACh forming actylated enzyme complex. Then acetylated enzyme complex reacts with water exremely rapidly and the esteric site is freed in a fraction of millisecond forming acetic acid and free cholinesterase enzyme (cholinesterase is here known as acetylcholinesterase). Thus, at the end of the reaction we get choline, acetic acid and free cholinesterase enzyme (ChE).

Neostigmine and pyridostigmine (carbamated compound) combines with the both sides of the ChE enzyme in almost the same way as acetylcholine, but with a longer dissociation half-life of about 7 minutes. The carbamate and the ChE complex (carbamylated enzyme) hydrolysed very slowly, so it is reversible. Whereas, organophosphate and ChE complex (phosphorylated enzyme) hydrolyze not at all, (irreversible). It is noteworthy that edrophonium (carbamate) in difference with neostigmine attaches only to the anionic site of the enzyme, while organophosphates attach only to the esteric site of the ChE enzyme. Dissociation of edrophonium from ChE enzyme (reactivation of the inhibited enzyme) does not involve hydrolysis of edrophonium, but involve only its detachment from the ChE. Dissociation of edrophonium from enzyme occurs more readily with much shorter dissociation half-life of about 20 seconds.

Anticholinesterase (anti-ChE) agents, such as neostigmine, pyridostigmine and edrophonium, may also have a direct stimulating effect on the nicotinic receptor, facilitating neuromuscular transmission. Another action of these agents is at the presynaptic level, involving direct enhanced liberation of acetylcholine (ACh). This effect is particularly marked with edrophonium which is thought to act mostly by increasing the liberation of ACh, rather than by inhibition of acetylcholinesterase (AChE).

If anti-ChE agents are administered in large doses or in the absence of muscle relaxants, they produce fasciculations and even a depolarising type of block, similar to that produced by succinylcholine. However, this is unlikely to occur if a nondepolarising muscle relaxant is used, even if almost complete recovery appears to have occured. The likely explanation of it is that a large proportion of the receptors are still occupied by the muscle relaxant.

After treatment with anti-ChEs, the acetylcholine (ACh) released by a single nerve impulse, is not immediately destroyed but rebinds to the same recptor, diffuses to act on neighbouring receptors and activates prejunctional fibres causing repetitive firing, twitching and fasciculations. Force of contraction in particularly curarized and myasthenic muscles are increased. Higher doses of anti-ChE cause persistent depolarisation of end plates resulting in blockade of neuromuscular tranmission with weakness and paralysis.

Pharmacokinetics

Neostigmine and its congenrs are poorly absorbed orally. Oral dose of them is 20 to 30 times higher than their parenteral dose. They do not penetrate the blood-brain barrier. They are partially hydrolysed and partially excreted unchanged through urine. Elderly patients show reduced rate

of clearance of all these three agents with prolongation of half-life. Dose-response curves of these three anti-ChE agents show that pyridostigmine is five times and edrophonium is 10 times less potent than neostigmine. It has also been shown that the dose response curves of neostigmine and edrophonium are not parallel which indicate that edrophonium has a different mode of action. The elderly require a larger dose of neostigmine to attain the same rate of recovery, while the dose should be reduced in children.

Doses

The commonly recommended doses for neostigmine is 0.3 to 0.5 mg/Kg (30 to 50 µg/Kg), for pyridostigmine is 0.2 to 0.25 mg/Kg, and for edrophonium is 0.5 to 1 mg/Kg. Among these three antiChE agents, edrophonium is the most rapid acting with peak effect between 2 and 4 minutes after its administration. While the peak effect of neostigmine is 10 minutes and pyridostigmine is 15 minutes after their administration. Pyridostigmine is, therefore, too slow for routine use. On the other hand, although the edrophonium is faster acting, but it is not always effective in antagonising a relatively deep block. It is also true that higher doses of anti-ChE is required to antagonize the higher depth of block more rapidly and more completely than smaller doses. But this is true upto a limit. Beyond which the increase in dose of anti-ChE does not produce any greater antagonism. Thus the maximum dose of neostigmine and pyridostigmine is 60 to 80 µg/Kg and 1 to 15 mg/Kg, respectively.

Other effects

It is previously stated that the actions of anti-ChEs are qualitatively similar to that of directly acting cholinoreceptor stimulants i.e. acetylcholine (ACh) which is classified as muscarinic, nicotinic and CNS effects. The muscarinic actions are consists of actions on heart, blood vessels, smooth muscles, glands and eye. Nicotinic actions are consist of actions on autonomic ganglia and skeletal muscles. The effects of neostigmine (also other anti-ChEs) on the cardiovascular system are variable and depend upon the prevailing autonomic tone. The drug may cause bradycardia, leading to a fall in cardiac output. It decreases the effective refractory period of cardiac muscles and decreases the conduction time in conducting tissue. In higher doses, neostigmine may cause hypotension secondary to a central effect. Actually cardiovascular effects of neostigmine are complex. This is because muscarinic action of it would produce bradycardia and hypotension, while ganglionic stimulating effect of neostigmine would tend to increase the heart rate and BP. Action of neostigmine on medullary centres further complicates the picture, so does ganglionic blockade with high doses. Thus the overall effects of anti-ChE are often unpredictable and depend on the agent and its dose.

Neostigmine increases the bronchial secretion and may cause bronchoconstriction. The drug also increases the salivation, lower oesophageal and gastric tone, increases gastric acid output and increases gastrointestinal tract motility. So, nausea and vomiting may occur.

In therapeutic doses, the drug has action on skeletal muscle, leading to muscular contaction. But in higher doses, neostigmine may block the neuromuscular transmission by the combination of a direct effect on nicotinic receptor and by allowing the excessive accumulation of ACh.

Lipid soluble antiChE agents such as physostigmine and organo phosphates have more marked muscarinic and CNS effects. They also stimulate ganglia but action on skeletal muscles is less prominent. Whereas the lipid insoluble agents such as neostigmine and other quarternary ammonium compounds have more nicotinic effects producing more marked action on skeletal muscles (direct action on muscle end plate cholino receptors as well) and autonomic ganglia, with less muscarinic effects. They do not penetrate CNS and have no central effects.

In ganglion, local hydrolysis of ACh is less important. But inactivation of acetylcholine is ganglia occurs partly by diffusion and partly by hydrolysis in plasma. Anti-ChEs stimulate ganglia primarily through nicotinic receptors, present there. High doses of anti-ChEs cause persistent depolarization of the ganglionic nicotinic receptors and blockade of transmission.

Muscarinic actions of anti-ChE agents result in bradycardia, hypotension, increased secretions and increased smooth muscle contractions. These effects (muscarinic actions of anti-ChEs) can be prevented by the simultaneous or prior administration of antimuscarinic (anticholinergic) agents such as atropine (20 to 30 µg/Kg or 0.02 to 0.03 mg/Kg) or glycopyrolate (10 µg/Kg or 0.01 mg/Kg). These anticholinergic agents only have antimuscarinic actions (so called antimuscarinic agent) without any antinicotinic actions. Nicotinic antagonists are generally referred as 'ganglion blockers' and 'neuromuscular blockers'.

Atropine and glycopyrrolate is highly selective for muscarinic receptors. But some of its synthetic substitutes do possess significant nicotinic blocking property in addition to antimuscarinic property. Atropine and glycopyrrolate only block ACh induced muscarinic actions but not the actions evoked by histamine, 5 HT. The use of glycopyrrolate is associated with greater stability of the heart rate when neostigmine is used. But, atropine is the preferred agent with edrophonium because of their similar speed of onset of effect. Edrophonium requires a lower dose of the anticholinergics agent as its muscarinic effects are less. Glycopyrrolate has distinct advantages over atropine as it does not cross the blood-brain barrier.

Neostigmine and pyridostigmine but not edrophonium causes prolongation of the effect of subsequently administered succinylcholine and mivacurium, by inhibiting plasmacholinesterase activity. Administration of neostigmine also may be associated with increased incidence of PONV.

8 Acid-Base Balance

INTRODUCTION

In our body, the amount of H^+ (Hydrogen ion) is very small in comparison to other common physiologically important cations and anions such as Na^+, K^+, HCO_3^-, Cl^-, etc. In normal plasma, their concentrations are respectively 140, 4, 24 and 100 mmol/L. Whereas the H^+ concentration in normal plasma is only 0.00004 mmol/L or 0.00000004 mol/L. So this small number of H^+ concentration is commonly expressed either as pH (–ve logarithm of H^+ concentration) or as nmol/L. The concentration of H^+ in normal arterial blood is 40 nmol/L or pH is 7.4 which is considerably an easier expression to write than 0.00004 mmol/L or 0.00000004 mol/L.

Life is an acidogenic process. Because for continuation of life, during production of energy by catabolism of glucose, fatty acids, amino acids, etc. different acids are produced. For example during metabolism of glucose, amino acids and fatty acids through the citric acid cycle, CO_2 and water are produced. This again form carbonic acid ($CO_2 + H_2O \leftrightarrows H_2CO_3$ $H_2CO_3 = H^+ + HCO_3^-$) giving H^+. At the alveolar level, this H_2CO_3 is then broken down and CO_2 is excreted though the lungs. Thus, lung is the main channel of excretion of carbonic or nonmetabolic acids. During metabolism of amino acids through other cycles, different noncarbonic or metabolic acids, such as H_2SO_4, H_3PO_4, etc. are also produced. These also produce H^+ and are mainly excreted through the kidneys. Diet also contains large amount of H^+ ion normally in the form of sulphur containing amino acids in protein. Urine is the main channel of excretion of these noncarbonic or metabolic acid, whereas lung is the main channel of excretion of nonmetabolic or carbonic acid such as CO_2. In a normal (Table 8.1) adult, the average daily oral H^+ intake is 50 to 80 mmol/day. In the resting subject the catabolism of carbohydrates and fats produce an acid load (volatile acids $\rightarrow H_2CO_3$) of approximately 18,000 to 20,000 mmol/day, which is excreted by the lungs as CO_2. Protein catabolism also leads to additional production of 60 to 80 mmol/day of nonvolatile acids, mostly in the form of sulphuric and phosphoric acids, which are excreted by kidney. Again oxidation of carbohydrates and fats in a diseased state or in anaerobic metabolic state leads to the production of more nonvolatile acids, such as, lactic acid (in anaerobic metabolism) and ketoacids (in diabetes mellitus) (Table 8.2).

During intracellular metabolism the various acids, produced from catabolism of different substrates flow into the alkaline extracellular fluid and thus maintains the normal intracellular H^+ concentration. Then this H^+ is excreted through urine as titrable acid or through lungs as CO_2.

Table 8.1: Daily normal input and output of acids and bases through body

	Input (mmol/day)		*Output (mmol/day)*
A. Non volatile acids			
Lactate	1500	Liver, kidney,	1500
Protein	50-80	by titrable	30
Phospholipid	30	Acids	40
Other	12		
B. Volatile acids	13,000		13,000
Carbon dioxide		Lungs	

Table 8.2: The mechanism by which the primary acid-base changes are compensated. If the pH has been fully returned to normal the primary change is said to be fully compensated. Otherwise organic acid base .... it is said to be partially compensated

Respiratory acidosis	Kidney	Metabolic alkalosis with further rise in plasma [HCO_3^-] by increasing its absorption through kidney or with further fall in plasma [H^+] by increasing its excretion through kidney.
Respiratory alkalosis	Kidney	Metabolic acidosis with further fall in plasma [HCO_3^-] by increasing its excretion through kidney or with further rise in plasma [H^+] by decreasing its excretion through kidney.
Metabolic acidosis	Lungs	Respiratory alkalosis with further fall in plasma [H^+] by eliminating more CO_2 through lungs.
Metabolic alkalosis	Lungs	Respiratory acidosis with further rise in plasma [H^+] by decreasing the excretion of CO_2 through lungs.

Hence, body constantly balances this H^+ input with the H^+ output. Small changes in normal H^+ concentration can produce significant alteration in body enzymatic activity. This presents clinically, then, as organ dysfunction. As metabolic process leads to changes in H^+ concentration, similarly the changes in H^+ concentration or acid-base balance is also an indicator of status of current metabolic process, occuring in human body and a real time predictor of the utility of critical therapy. So, the complete understanding of acid-base balance is very important. But, unfortunatley most anaesthetists avoid this chapter. This is because pH is defined complicatedly as the negative logarithm (−log) of the H^+ ion concentration and there is wide spread use of multiple, complex, overlapping, irrelevant terms such as 'standard bicarbonate', 'negative base excess', 'alkali reserve' etc. to describe the acid base status.

Various buffer systems in the cells and in the extracellular fluid work against this accumulation of H^+ or when there is disruption of balance between the amount of intake and output of H^+. The buffer capacity capable of absorbing the H^+ is up to 10 mmol per Kg of body weight, i.e. 500 to 700 mmol in an adult. Tissue hypoxia, starvation, diminished ventilation, diabetes, heart failure, renal failure, etc, which cause increased input of H^+ in body cause strain to this buffer capacity of the body. Therefore, it is important that all this should be brought under control before any surgery as far as possible, with least possible encroachment on the buffer capacity. This is because to deal by buffer system in future with acute rises of H^+ concentration due to any cause, during surgery.

The normal arterial H^+ concentration is 40 nM/L, yielding pH of 7.4. This arterial H^+ concentration reflects the present dynamic balance between the input (from ingestion and metabolism of food) and the output (through lungs as CO_2 and through kidney as nonvolatile acids) of it. Thus when an imbalance between this input and output occurs, then the H^+ concentration in blood will deviate from the normal to the range of viable variability, roughly 160 to 20 nM/L (pH 6.8 to 7.7) beyond which life is not possible.

Table 8.3: Sets of pH – PCO_2 acid-base data forming CO_2 – titration curve

SL	*$PaCO_2$ (mm of Hg)*	*pH*	*Metabolic status*	*Respiratory status*	*Overall status*
N	40	7.4	Normal	Normal	Normal
M	70	7.1	Acidosis	Acidosis	Acidaemia
O	70	7.4	Alkalosis	Acidosis	Normal
P	30	7.3	Acidosis	Alkalosis	Acidaemia
Q	30	7.6	Alkalosis	Alkalosis	Alkalaemia

Two types of acids are produced during metabolism of substrates in the body:

(i) Volatile or carbonic or respiratory acids

This is carbonic acid (H_2CO_3) which is formed by the hydration of CO_2.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrows H^+ + HCO_3^-$$

CO_2 is produced by metabolism of glucose, fatty acids and amino acids through TCA cycle in mitochondria. CO_2 is produced at an average rate of about 200 ml/min or 288 L/day. This gas is eliminated via the lungs and, so, is referred to as the 'volatile' or 'respiratory' acid.

(ii) Nonvolatile or noncarbonic or metabolic acids

These are lactic acid, pyruvic acid, acetoacetic acid, β-hydroxybutyric acid, phosphoric acid, sulphuric acid, hydrochloric acid, keto acids and variety of other organic acids. The lactic acid is produced from pyruvic acid during glycolysis in the absence of O_2. So, lactic acid is often used as a clinical marker of anaerobic metabolism from hypoxia, poor perfusion of tissues or other disturbances of tissue oxygenation. Also, it is important to realise that about 1400 mmol of lactic acid is normally produced each day, principally by skeletal muscles, RBCs and the skin. This lactic acid is then converted in liver to form CO_2 and H_2O. A smaller amount of lactate is also cleared through renal excretion or by conversion through gluconeogenesis in liver.

Keto acids are produced in diabetes mellitus. Phosphoric, hydrochloric and sulphuric acids are produced during the metabolism of amino acids. Hydrochloric acid (HCl) is produced during the metabolism of lysine, arginine and histidine amino acids. Sulfuric acid (H_2SO_4) is the product of cysteine and methionine amino acid metabolism. Phosphoric acid (H_3PO_4) is derived from the normal metabolism of dietary phosphate (Fig. 8.1 and Table 8.3)..

Part of these load of metabolic acid is balanced by the production of bicarbonate (HCO_3^-) from the metabolism of aspartate, glutamate and citrate, and part is excreted through kidney. The sum of these addition and loses of metabolic acids and bases results in a net positive balance of H^+ of about 70 mmol/day or approximately 1 mmol/Kg/day. Metabolic acids are either further metabolised in liver or excreted primarily through kidney. Pyruvic acid, acetoacetic acid and β-hydroxybutyric

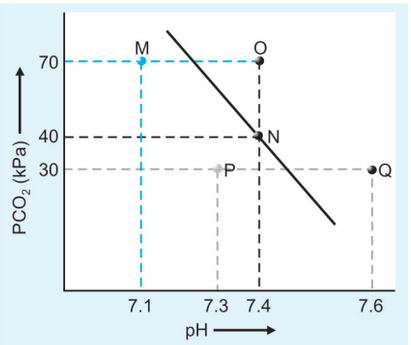

Fig. 8.1: CO_2 titration curve formed by sets of pH – PCO_2 acid-base data

acids which are also obtained from other sources are further degraded to CO_2 and H_2O in liver.

Changes in the carbonic acid component in blood reflect an imbalance between the CO_2 production and its elimination by alveolar ventilation. It is represented by the changes in P_aCO_2 and is termed as the respiratory or carbonic acid-base abnormalities (respiratory acidosis or alkalosis). Whereas, the changes in handling of metabolic acid or alkali result in metabolic or noncarbonic acid-base abnormalities (metabolic acidosis or alkalosis) and is represented by the HCO_3^- level in blood.

The goals of the assessment of acid-base balance

i. To define the types of acid-base imbalance, whether respiratory (carbonic) and/or metabolic (noncarbonic).
ii. To quantify the magnitude of respiratory abnormality by measurement of P_aCO_2.
iii. To quantify the magnitude of metabolic acid-base abnormality by estimation of plasma HCO_3^- level or the extracellular fluid base excess.
iv. To quantify the buffer capacity.

TERMINOLOGY

Chemically, the acidity of a substance is defined by its ability to ionise in the solution and to give the amount of H^+ and base (A^-). Thus, the relationship between the acid and base can be written by the equation as:

$HA\ (acid) = H^+ + A^-\ (base)$

In this reaction HA is termed as the acid or H^+ (proton) donor and the anion A^- is termed as the H^+ (proton) acceptor or conjugate base.

The acid which dissociates more in aqueous solution is called the strong acid e.g. HCl. The stronger is the acid, the weaker is its conjugate base, that is, the less ability of the base to accept H^+, e.g. $HCl \rightarrow H^+ + Cl^-$.

The acid which dissociates to lesser extent in aqueous solution is called the weak acid. The weaker is the acid, the stronger is its base.

For example, lactic acid:

$CH_3CHOHCOOH \rightarrow CH_3CHOHCOO^- + H^+$

Other examples of weaker acids are:

$H_2CO_3 \rightarrow H^+ + HCO_3^-$

$H_3PO_4 \rightarrow H^+ + H_2PO_4^-$ etc.

In our body, only 1/100 of the lactic acid remain in ionised form, while 99/100 remain in unionized form.

The equation of acid base balance follows the Law of Mass Action which states that the product of reaction on one side are proportional to the products of the reaction on the other side. The degree to which a certain acid will remain in dissociated condition in solution is constant for that specific acid and is known as the dissociation constant. This Law of Mass Action can be expressed in the following formula:

$$HA \underset{k_1}{\overset{k}{\leftrightarrows}} H^+ \times A^-$$

Here, the dissociation constant (k or k_1) determines the point at which equilibrium is reached in a specific equation. If k is larger than k_1, then the reaction will proceed preferentially toward the right and will result in more H^+ and A^- ions than HA. This means HA is more acidic in nature. Reversely, if k_1 is larger than k, then there will be more HA than the amount of H^+ and A^- is formed. This means HA is less acidic in nature.

Acidity of a solution is also defined by the H^+ concentration in that solution or more precisely the actibity of H^+ in that solution which is measured by pH electrode. The normal value of arterial plasma pH is 7·4 at $PaCO_2$ of 40 mm of Hg which usually varies within the range between 7.35 to 7.45. Range of pH of venous blood is 7.32 to 7.42. Acidaemia occurs when the arterial blood pH is less than 7.35 or H^+ ion concentration is greater than 44 nM/L. Alkalaemia occurs when the arterial blood pH is greater than 7.45 or H^+ ion concentration is less than 36 nM/L.

Acidosis or alkalosis are abnormal conditions which cause acidaemia and alkalaemia in blood respectively, provided if no secondary changes occur to compensate for the primary changes. Usually, the acidosis or alkalosis of one system (e.g respiratory system) is compensated by alkalosis or acidosis of other system (metabolic system), so that the resulting pH still lies within the normal ranges. But, the actual acid-base status should be known by its primary cause such as the respiratory or metabolic acidosis or alkalosis and by its compensatory phenomenon such as the metabolic or respiratory alkalosis or acidosis and vice versa. That is, though the pH is normal, still the acid-base status should be talked as primary respiratory or metabolic acidosis or alkalosis and compensatory metabolic or respiratory acidosis or alkalosis with their different combination and vice versa.

A respiratory acidosis or alkalosis is said to present when P_aCO_2 is above 45 mm of Hg (6 KPa) or below 35 mm of Hg (4.7 PKa) respectively. Also if the set of pH and PCO_2 value produces a point to the left or right of the normal CO_2 titration curve (in figure) then a respiratory acidosis or alkalosis, respectively is present. But, one has to keep in mind that there is no specific centre for H^+ ion regulation in CNS.

Though the concentration of H^+ in aqueous body solution is very low, still the range of concentration of it that varies normally is large enough which extends from 10^{-1} to 10^{-15} mol/L. So for convenience, these H^+ concentration or $[H^+]$ is expressed by the way of exponential arithmtic method such as:

$[H^+] = 10^{-P} = 1/10^P$

As pH is the negative logarithm of H^+ concentration (as P means —log)

So $pH = -\log [H^+] = -\log [10^{-P}] = P$

(Negative logarithm of $10^{-P} = P$)

The term pH was introduced by Sorensen, in 1909. It is the more convenient way of expression of H^+ concentration than molar expression of it in m.mol/L or nmol/L. Here, the exponent of H^+ concentration, i.e. p, stands for the initial letter of the ward 'potenz' or 'puissance' or 'power'.

The hydrogen ion concentration of pure water is 10^{-7} mmol/L. Using the pH notation, the pH of pure water is 7, because $pH = -\log [H^+] = -\log (10^{-7}) = 7$. The negative log of 10^{-7} is 7. For various reasons, the H^+ concentration of our body is conventionally expressed as the pH which is the negative logarithm of concentration of H^+ ion in mmol/L. Thus, this pH scale indicates the number of H^+ in mmol/L logarithmically.

According to the System of International (SI) nomenclature, the acidity is expressed as H^+ concentration in nmol/L, instead of mmol/L or pH unit. But, such expression of H^+ concentration in favour of nmol/L is sometimes criticised. This is because:

i. the biological activity of a solution is related to the chemical potential of it which is exerted by the activity of H^+ ion and this is logarithmic in nature,
ii. the measurement of H^+ concentration is made according to a standard, operational pH scale,
iii. the blood pH values in the population are probably evenly distributed, but the distribution of H^+ concentration in $nmol^{-1}$/L in population is distorted.

Thus, ideally, the H^+ concentration should be converted to pH units before any statistical analysis for easy and correct result. But, the pH system has a great source of confusion. Because unlike the direct concentration of H^+ in n.mol or mmol/L which is usually expressed as a linear, positive numerical scale, the pH scale is logarithmic which is not linear. On the other hand, the number used to express the pH becomes smaller as the H^+ concentration becomes greater. So, this counter molar system makes the clinician awkard. But once understood, the concept of molar system, expressed as nmol/L is quite workable in the clinical setting. (Table 8.4).

Some important points regarding the pH scale are:

i. As pH scale is expressed as the negative logarithmic of base 10, so it means there is tenfold change of H^+ ion concentration expressed in nmol/L for every one unit change in pH. For example, a solution with pH of 4 has 10 times more H^+ ion concentration in nmol/L than a solution with pH of 5 and 100 times more than a solution with pH of 6.
ii. The changes in H^+ concentration in nmol/L differ vastly at different points of the pH scale, depending upon at which point of the scale these changes occur.
iii. Though the H^+ concentration in nmol/L scale is easier to visualise, still the pH scale is deeply infixed in our mind and is the standard with which we can function.

INTERCONVERSION OF H^+ CONCENTRATION AND pH

This can best be shown by two examples:

i. If the normal pH of whole blood is 7·4, then what will be the H^+ concentration or $[H^+]$

$[\ ]$ is the symbol of concentration.

$pH = 7.4$

$\text{or } -\log H^+ = -\log 10^{-7.4}$

$\text{or } H^+ = 10^{-7.4}$

$\text{So } [H^+] = 10^{-7.4} \text{ mol/L}$

$= 10^{-7.4} \times 10^9 \text{ nmol/L}$

$= 10^{1.6} \text{ nmol/L}$

$= 40 \text{ nmol/L}$

ii. If the hydrogen ion concentration is 100 n.mol, what is the pH ?

$100 \text{ nmol/L} = 100 \times 10^{-9} \text{ mol/L}$

$\therefore [H^+] = 100 \times 10^{-9} \text{ mol/L}$

$\therefore pH = -\log [H^+]$

$= -\log (100 \times 10^{-9})$

$= -\log [1/100^{-1} \times 1/10^9]$

$= -\log [1/10^{-2} \times 1/10^9]$

$= -\log [1/10^7]$

$= -\log [10^{-7}]$

$= 7$

In other simple way, it can also be calculated by

$[H^+] = 100 \text{ nmol/L}$

$= 100 \times 10^{-9} \text{ mol/L}$

$\therefore pH = -\log [H^+]$

$= -\log (100 \times 10^{-9})$

$= -\log 100 - \log^{-9}$

$= -2 + 9$

$= 7$

[The negative log of 100 is –2 and the negative log of 10^{-9} is 9. Thus taking the advantage of log we can add instead of multiplication] (Table 8.5).

Another way of interconvertion between pH and $[H^+]$ is:

i. If the $[H^+]$ of a solution is 2.86×10^{-4} mol/L, then the pH can be calculated as follows:

$[H^+] = 2.86 \times 10^{-4}$

$pH = -\log H^+$

Table 8.4: Conversion of H^+ concentration in mol / Lit and nmol / Lit to pH units

1 nanomole (nmol) = 10^{-9} mole or 10^{-6} mmole
1 mole = 109 nanomole

H^+ (mol / Lit)	*pH*	*H^+ (nmol / Lit)*
$0.001 = 10^{-3}$	3	1000,000
$0.0001 = 10^{-4}$	4	100,000
$0.00001 = 10^{-5}$	5	10,000
$0.000001 = 10^{-6}$	6	1000
$0.000,000,1 = 10^{-7}$	7	100
$0.000,000,01 = 10^{-8}$	8	10
$0.000,000,001 = 10^{-9}$	9	1
$0.000,000,000,000,001 = 10^{-15}$	15	0.000,001

65	7.2	
80	7.1	Acidosis
100	7	
160	6.8	

$$= \log 1/[H^+]$$
$$= \log [1/(2.86 \times 10^{-4})]$$
$$= \log [1/(10^{0.456} \times 10^{-4})]$$
$$= \log (1/10^{-3.544})$$
$$= \log 10^{3.544}$$
$$= -\log 10^{-3.544}$$
$$= 3.544$$

or,

$$pH = -\log [H^+]$$
$$= -\log (2.86 \times 10^{-4})$$
$$= -\log (10^{0.456} \times 10^{-4})$$
$$= -\log 10^{-3.544}$$
$$= 3.544$$

ii. For calculation of $[H^+]$ from a known pH value, the calculation will be reversed. Suppose the pH value of a solution is 3.544 then the $[H^+]$ will be:

$$pH\ 3.544 = \log 10^{3.544}$$
$$= \log (1/10^{-3.544})$$
$$= \log (1/10^{0.456} \times 10^{-4})$$
$$= \log (1/2.86 \times 10^{-4}),$$

Antilog of 0.456 = 2.86

$\therefore$ H^+ concentration of $[H^+]$
$= 2.86 \times 10^{-4}$ mol/L
= 286000 nmol/L

Calculation of pH of Neutral Pure Water

According to the law of mass action the equilibrium, governing the ionisation of water, is as follows:

$H_2O \leftrightarrows [H^+] \times [OH^-]$, or
$K[H_2O] = [H^+] \times [OH^-]$

[ ] is the symbol of concentration.

At a particular temperature (23°C) the product of the number of hydrogen ions multiplied by the number of hydroxyl ions is constant for pure neutral water and this is known as dissociation constant. The dissociation constant of water can be denoted as K_W (w stands for water) and its value in case of pure water is 10^{-14}. Thus, by the law of mass action :

$$[H^+] \times [OH^-] = K_W = 10^{-14}$$

In pure water the concentration of H^+ ions is equal to the concentration of OH^-. Hence,

$[H^+] = 1 \times 10^{-7}$, $[OH^-] = 1 \times 10^{-7}$

Therefore, pH of the pure neutral water will be

$$pH = -\log [H^+]$$
$$= \log [1/H^+]$$
$$= \log (1/1 \times 10^{-7})$$
$$= 7$$

So, pure water having equal number of $[H^+]$ and $[OH^-]$ ions is neutral with pH 7.0.

Here, one thing is to notice that the reduction of pH of 0.3 units represents a doubling of $[H^+]$ and vice versa.

One basic difficulty during the measurement of pH *in vivo* is that it is not possible to measure either the actual H^+ concentration or its activity in biological system. On the other hand, the pH numbers which is produced by electrometric measurement *in vitro*, are defined by an operational scale which is based upon the standard buffer solution and fixed temperature. They do not relate precisely to H^+ concentration and its activity.

ACID-BASE HOMEOSTASIS

The acid base homeostasis means the addition or elimination of acid to compensate the elimination or addition of base and vice versa. But, as life is an acidogenic process, so there is continuous formation of acids. Hence, in normal situation, acid base homeostasis means elimination of acid and addition or recovery of base to balance that small portion of acid that is normally not eliminated or added. In pathological state this normal homeostasis may be failed causing alkalosis (metabolic or respiratory) or moves in opposite direction causing acidosis (metabolic or respiratory). Despite the regulating mechanisms, the H^+ concentration in the tissue varies upto 10 fold from 16 nmol/L to 160 nmol/L (pH 6.8 to 7.8) which is compatible to life. Beyond that range life is not compatible. However, usually the normal range of H^+ concentration in blood is 36 to 44 nmol/L (ph 7.35 to 7.45) after homeostasis. No other ion in the tissue has such a wide range of variablility within which life can exist.

There are three mechanisms that maintain this pH homeostasis. These are: (i) buffering, (ii) compensation and (iii) correction. Buffering is the process in which chemical or buffer agent is used by the body to immediately neutralise or minimize the change in pH or H^+ concentration. Compensation is a process where other systems are acitvated to restore the HCO_3^-/H_2CO_3 ratio to normal. For example, when there is retention of CO_2 or H_2CO_3 due to the downward adjustment of ventilation, then there is excessive loss of H^+ or retention of HCO_3^- by kidney and maintain the normal acid base ratio. Correction refers to the exogenous medical management of the primary metabolic derangement responsible for the abnormality in pH.

Buffer System

Buffer system is composed of weak acid and their salt as strong base or a strong acid and their salt as weak base. It resists the changes of H^+ concentration in a solution after addition of a stronger acid or base in this solution. Stronger acids which are added in the solution are buffered by the base part of the buffer system to form weak acids. Similarly stronger bases which are added in the solution are buffered by the acid part of the buffer system to produce weak bases. For example, HCl is a strong acid which is largely dissociated as H^+ and Cl^-. This H^+ combines with

$NaHCO_3$ (base part of the bicarbonate buffer system) to produce H_2CO_3, which is a weaker acid than HCl. It is less dissociated and, therefore, less H^+ is released by its dissociation than if the HCl was present alone in the solution without a buffer. Similarly, a strong base such as NaOH is buffered by the acid part of bicarbonate buffer system to produce a weak base. For example $NaOH + H_2CO_3 = NaHCO_3 + H_2O$. If NaOH is not buffered, then the large amount of dissociated OH^- from the strong base of NaOH would combine with large amount of H^+ and will decrease the huge concentration of it. Thus, it will raise the pH much. On the otherhand, after buffering as the $NaHCO_3$ is a weaker base than NaOH, it is less dissociated and thereby causes less change in the H^+ concentration. To be maximally effective, a buffering system must be adequate enough to be able to buffer a large amount of acid or alkali which is eliminated or added and have a pK value which is close to the initial pH of the solution to be buffered. It is known that weaker acids and their salts (Na-salts of acids are base) as strong base are more effective buffers than the buffer system which is composed of strong acid and their salts as weak base.

About 3/4 of the chemical buffering power of our body lies within the cells. It is due to the high concentration of intracellular proteins, phosphate, haemoglobin (in RBC) and other inorganic compound. So, protein, phosphate and haemoglobin buffer systems are more important intracellularly. On the other hand, the remaining 1/4th of the buffering power of our body lies in the extracellular fluid. The acid base disturbances due to the respiratory causes is buffered mainly by the intracellular buffers. Whereas the acid base disturbances due to metabolic causes is buffered mainly by the extracellular buffers. The preferential utilisation of extracellular buffer occurs in the initial phase of metabolic acidosis with the contribution of intracellular buffer which is becoming gradually greater as the acidosis increases in severity. The buffer pair of greatest important in the extracellular fluid is carbonic acid (H_2CO_3) and bicarbonate ($NaHCO_3$ or $KHCO_3$), i.e. bicarbonate buffer system. In both the intracellular and extracellular environment the power of action of a buffering system depends on: the pK value of this buffer system, pH at which it is working and on the concentration of the buffer elements.

Although, both the carbonic and non-carbonic buffer systems are located through out the body in both the intracellular and extracellular fluid, but blood is the only window through which we can view the acid-base derangements. So, the pH and PCO_2 electrodes only measure the plasma pH and P_aCO_2, but can not tell anything about inside of the cell. On the other hand, plasma is in close equilibrium with interstitial fluid as far as pH, PCO_2 and $[HCO_3^-]$ are concerned. Thus, measurement of acid-base status of blood gives a reasonable assesment of the acid-base status of extracellular fluid, but offers only indirect insight of the intracellular status from which the actual acid-base disorder is originating.

The tendency of an acid to dissociate in water may be described quantitatively by the law of mass action.

Thus, [HA] (acid) $\propto [H^+] \times [A^-]$, A^- is the base

or $K [HA] = [H^+] \times [A^-]$

Here, K is the dissociation constant which describes the tendency of an acid to dissociate. Large K means stronger acid and vice versa. This equation is called the Henderson equation.

So, $[H^+] = K [HA]$ (acid) / $[A^-]$ (base) (Fact file -I).

The negative logarithmic expression of this equation is:

$-\log [H^+] = -\log k [HA]$ (acid) / $[A^-]$ (base)

or $pH = p^K + \log [A^-]$ (base)/[HA] (acid) ($p = -\log$)

Here, p^K is the negative logarithm of K and also reflects the strength of an acid.

Therefore, $pH = p^K + \text{Log base / acid}$

This is called the Henderson Hasselbalch equation. This equation is used for the determination of pH of a buffer solution or for the determination of relative concentration of the salt (base) and acid which is required to achieve the normal pH. For example, the pH of a buffer solution prepared by mixing 35 ml of (N/10) acetic acid with 15 ml of (N/10) NaOH can be determined by the Henderson-Hasselbalch equation:

$pH = p^K + \log$ (salt A^- / acid HA) where p^K is log (1/k), k is the dissociation constant of acid.

When these two solutions are mixed up, then 15 ml of (N/10) NaOH will neutralise 15 ml of (N/10) acetic acid to form 15 ml of the salt, Na-acetate. So, 20 ml of acetic acid will remain unneutralised. Thus, in the buffer solution, the salt and unneutralised acid ratio will be (15/20). The dissociation constant (k) of acetic acid is (1.86×10^{-5}) and so the p^K will be log (1/k), that is 4.73. So, in Henderson-Hasselbalch equation

$pH = 4.73 + \log (15/20)$

$= 4.73 + \log 0{\cdot}75$

$= 4.73$

$= 4.6$

FACT FILE - I

From the Henderson equation such as, $[H^+] = K[HA]/A^-$, we can calculate any one factor, if other two factors are known. This is as follows:

For bicarbonate buffer system, the Henderson equation can be written as: $[H^+] = K(P_aCO_2$ mm of Hg) / HCO_3^-.

If P_aCO_2 = 50 mm of Hg, HCO_3^- = 24 m.Eq/L, and K = 24 (dissociation constant of carbonic acid),

then $[H^+] = (24 \times 50) / 24 = 50$.

Therefore, the $[H^+]$ concentration is 50 nmol/L. Now from the table we can read the pH as 7.3.

When the pH is 7.4 and the P_aCO_2 is 50 mm of Hg, the HCO_3^- level can be calculated like this:

$H^+ = K(P_aCO_2) / HCO_3^-$

or HCO3– = K (PaCO2) / H^+

or HCO_3^- = (24 × 50) / 40 (H^+ concentration at pH 7.4 = 40 nmol/L).

or HCO_3^- = 30 mEq/L.

If the ratio of salt and unneutralised acid ratio becomes 1:1, then the pH value of the buffer mixture will be equal to p^K of the acid. As for example, if 30 ml of (N/10) acetic acid and 15 ml of (N/10) NaOH are mixed up then 15 ml of salt Na - acetate will be formed and 15 ml of acetic acid will remain as unneutralised acid. So, the salt and acid ratio will be (15/15) = 1. So, interpolating the value in the Henderson - Hasselbalch equation the result will be

$pH = p^K + \log (salt / acid)$
$= 4.73 + \log (15/15)$
$= 4.73 + \log 1$
$= 4.73 + 0$
$= 4.73$

So, the buffering action in this case is at its maximum and can react either as acid or as base.

Each unit change in pH represents a 10 fold change in $[H^+]$. So, when the pH number decreases, the $[H^+]$ increases and vice versa. For any given buffer system, the p^K is constant, so the pH will depend on the log of the ratio of [base]/[acid]. If acid or alkali is added, then the smallest change in this ratio and therefore the smallest change in pH will result if (initially [base] is equal to [acid]) or base = acid.

Under these circumstances, $pH = p^K$ [since base/acid = 1 and log1 = 0]

So, a buffer system resists the pH changes best when it is operating at a pH close to its p^K value.

In the plasma, tissue fluids and in the cells many buffer systems exist. These important buffer systems are: bicarbonate, phosphate, protein and haemoglobin. The buffering of H^+ in extracellular compartment can also be accomplished by the exchange of H^+ for Na^+ and Ca^{2+} from bone. Thus acid loads demineralize the bone and release alkaline compounds such as $CaCO_3$ and $CaHPO_4$. Contrary, alkaline loads increase the deposition of carbonate in bone. The buffering in plasma by bicarbonate is immediate. Whereas the buffering in interstitial fluid compartment by bicarbonate takes 15 to 20 minutes and buffering by intracellular proteins and bone takes 2 to 4 hours. Upto 50 to 60% acid loads may ultimately be buffered by intracellular buffers and bone.

(i) Bicarbonate buffer system (HCO_3^- / H_2CO_3)

$H^+ + HCO_3^- \leftrightarrows H_2CO_3 \leftrightarrows CO_2 + H_2O$ I

This is the main buffer system in blood and interstitial fluid. This system consists of a mixture of H_2CO_3 (weak acid) and its salt $NaHCO_3$ (strong base). Usually $NaHCO_3$ remains in the extracellular fluid and $KHCO_3$ or $Mg(HCO_3)_2$ present in the intracellular fluid. The relationship between the concentration of carbonic acid and their salt (bicarbonate buffer system) and the pH can be described by Henderson-Hasselbalch equation:

$pH = p^K + \log [HCO_3^-] / [H_2CO_3]$
$= 6.1 + \log [HCO_3^-] / P_aCO_2 \times 0.03$

(0.03 is the solubility coefficient of CO_2 and 6.1 is the negative log of dissociation constant of H_2CO_3 or p^K value of the bicarbonate buffer system).

So, the pH of blood is determined by the ratio of $[HCO_3^-]$ / $[H_2CO_3]$. The reaction curve of the bicarbonate buffer system, i.e. the relation between the relative concentration of HCO_3^- and H_2CO_3 with pH is S-shaped. The buffering power of this system is greatest where the slope of the curve is steepest. This is because addition of a certain amount of acid or base cause smallest change of pH to occur in this part. This buffer system is most efficient when the concentration of HCO_3^- and H_2CO_3 are equal or when $pH = p^K$ or $\log [HCO_3^-] / [H_2CO_3] = 0$.

The p^K value of bicarbonate buffer system is 6.1, therefore it is most effective at pH 6.1. Its chemical buffering capacity at pH 7.4 (which is its usual working pH) is poor, but its efficiency increases when the pH of blood decreases (Fig. 8.2). Normally, when this buffer system functions at a pH of around 7.4, then the ratio of bicarbonate to carbonic acid is 20:1 which is well outside its optional working range (once the relative concentration of bicarbonate and carbonic acid exceed about 8:1 in either direction, then the buffering power of the system falls rapidly).

But, on the other hand, at physiological pH of 7.4 the importance of this bicarbonate buffer system lies in the ability of carbonic acid to produce CO_2 which is excreted via lungs. Addition of H^+ and elimination of CO_2 drives the equation-I to the right and compensate the acidosis.

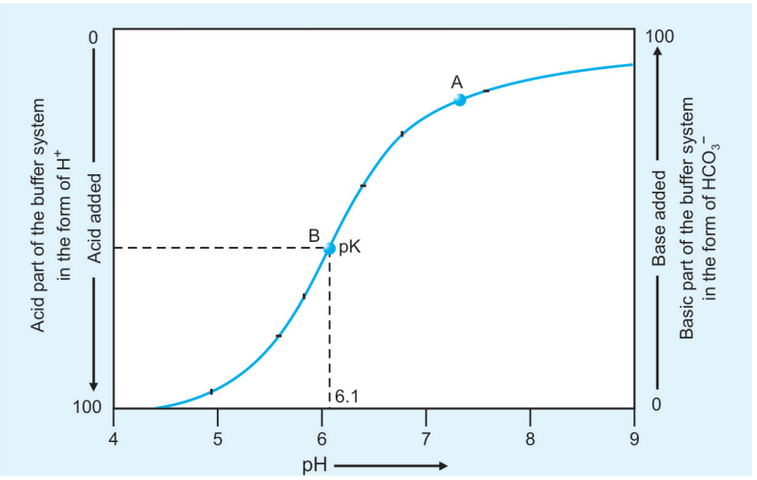

Fig. 8.2: Reaction curve of the bicarbonate buffer system. Point A indicates the normal operating condition where this bicarbonate buffer system works in the body. Point B indicates pK value of this buffer system at which it works maximally

The bicarbonate-carbonic acid buffer system, i.e. the bicarbonate buffer system forms the corner stone of acid-base balance. This is because carbonic acid (H_2CO_3) can be formed by the addition of nonvolatile acids (metabolic or nonrespiratory load), as seen in equation-II. This H_2CO_3 ultimately converts to CO_2 which is then eliminated by ventilation through lungs. CO_2 remains in equilibrium with the HCO_3^-. More H^+ leads more consumption of HCO_3^- and more excretion of CO_2 through stimulated ventilation. It is clinically important to note that the change in HCO_3^- in the body resonably reflects the amount of H^+ added to or removed from the system (in a short time at least until other slower buffer systems have had time to compensate).

Mechanism of Action

Carbonic acid and its salt, primarily $NaHCO_3$ [other salts are $KHCO_3$, $Mg(HCO_3)_3$] which is present in extracellular fluid constitutes the bicarbonate buffer system. It buffers only the metabolic (noncarbonnic) acid or alkali. This system does not function to buffer the respiratory acid load that is CO_2 or H_2CO_3 load.

Excreted through lungs $\leftarrow CO_2 + H_2O$

$$\downarrow\uparrow$$

$$HCl + NaHCO_3 \leftrightarrows H_2CO_3 + NaCl \quad \text{..... II}$$

$$\downarrow\uparrow$$

$$H^+ + HCO_3^-$$

The resulting carbonic acid is weaker acid than the hydrochloric acid which is added in the system of our body. The carbonic acid thus formed, escapes from the blood as CO_2, causing constant P_aCO_2 of 40 mm of Hg. The changes in HCO_3^- level or the amount of consumed HCO_3^- in the form of $NaHCO_3$ to neutralise the acid equals to the amount of acid added. Thus, for bicarbonate buffer system, the change in $[HCO_3^-]$ provides a good measure to know the quantity of H^+ added or removed from the plasma. The major buffering capacity of this system at body pH is physiological, rather than physicochemical. This is an open ended system, because CO_2 can be adjusted immediately by ventilation through normal lungs and HCO_3^- by kidney in long term. The larger amount of plasma HCO_3^-, available in bocarbonate buffer (24·28 m.mol/L), makes this system especially important. In the first instances the strong acid is 'swapped' for a weak acid (H_2CO_3) which is called the chemical buffering. Then, the carbonic acid dissociates into water and CO_2 and the latter is excreted by lungs. This is called the physiological buffering. It is the only buffer system which can be physiologically adjusted to maintain a normal pH. A strong base such as NaOH may also be buffered by carbonic acid (H_2CO_3) of this bicarbonate buffer system.

$NaOH + H_2CO_3 \leftrightarrows NaHCO_3 + H_2O$

$NaHCO_3$ is a weaker base than NaOH. So, it will less dissociate, causing less change in H^+ and OH^- concentration (explained before).

The bicarbonate buffer system functions to neutralise the metabolic acid and base only. It does not buffer the respiratory acids such as H_2CO_3. This is because if carbonic acid is added to a bicarbonate buffer solution, then the H^+ and HCO_3^- level does not change. They are produced in equal amounts.

$CO_2 + H_2O + NaHCO_3 = H^+ + HCO_3^- + NaHCO_3$

Changes in the absolute value of $[HCO_3^-]$ from normal indicate the amount of metabolic (noncarbonic) acid or H^+ is added to or removed from the solution. But, the changes in P_aCO_2 do not cause any measurable alteration in the bicarbonate $[HCO_3^-]$ level in plasma.

A working formula of Henderson - Hasselbalch equation for bicarbonate buffer system is: $H^+ = 24 \times P_aCO_2 / [HCO_3^-]$

Another simple theory is that below 7.4 pH, for every 0·01 unit decrease in pH there is 1.25 n.mol/L increase of H^+ concentration and above 7.4 pH for every 0.01 increase in pH there is 0.8 nmol/L decrease of H^+ concentration. These two theories are very helpful clinically because H^+, pH, P_aCO_2 and HCO_3^- concentration, all can be calculated easily from the above. For example: if pH of arterial blood is 7.26, then the $[H^+] = 40 + [(40 - 26) \times 1.25] = 57.5$ n.mol/L. If P_aCO_2 in the arterial sample is 30 mm of Hg, then

$57.5 = 24 \times 30 / [HCO_3^-]$ or $[HCO_3^-] = (24 \times 30) / 57.5 = 12.52$ mEq/L

(ii) Phosphate buffer system (HPO_4^{2-}/ $H_2PO_4^-$)

$H^+ + HPO_4^- \leftrightarrow H_2PO_4$

This buffer system consists of NaH_2PO_4 (weak acid) and Na_2HPO_4 (strong base). This system work in exactly the same way as the bicarbonate buffer system. p^K value of this buffer system is 6.8. It means this buffer system has the highest working capability at the pH near about 6.8. It is the largest inorganic chemical buffer system in the body. Its concentration in plasma is much lower and, therefore, its capacity as a buffer in blood is also much less. Its importance predominantly lies in the intracellular enviornment and in the urine. Unlike bicarbonate buffer system, this system neutralises both the carbonic (respiratory) and noncarbonic (metabolic) acid or alkali. Thus, this phosphate buffer system neutralises strong acids and alkalis as seen in the following reactions.

$HCl + Na_2HPO_4 \leftrightarrows NaH_2PO_4 + NaCl$

$NaOH + NaH_2PO_4 \leftrightarrows Na_2HPO_4 + H_2O$

Here, NaH_2PO_4 and Na_2HPO_4 are the weak acid and weak base, respectively. These conversions of strong acids and bases to weaker ones result in the liberation of less H^+ and OH^- and therefore smaller changes in pH.

This buffer system has little effect in the extracellular environment. This is because the concentration of this system is less than 10% of the bicarbonate buffer system in the extracellular fluid. The concentration of this system is highest within the cell. Furthermore, its p^K value is about the same as the intracellular pH (intracellular pH is 6.9) which increases its buffering

power in the cell (explained before). For the similar reasons, this buffer system is very important in the renal tubular fluid. In renal tubular fluid, the phosphate buffer is greatly concentrated and the pH of renal tubular fluid is closer to the p^K value of this buffer system which increases its efficacy.

Formation of Urinary Titrable Acidity (TA)

At pH 7.4, the 80% of circulating phosphate is in the monohydrogen form and 20% is in the dihydrogen form. The majority of urinary TA is produced by the conversion of monohydrogen to dihydrogen phosphate ($Na_2HPO_4 \rightarrow NaH_2PO_4$). This occurs throughout the nephron. At maximum urinary acidity, i.e. pH 4.5, all most 99% of the filtered phosphate is in the dihydrogen form (as the pKa of this system is 6.8). At this highest urinary pH, 70% of filtered creatine and 90% of uric acid are in unionized form and may account for 20% of the urinary TA.

Normally 20 to 40 mmol of H^+ is excreted per day as TA. In diabatic ketoacidosis the rate of excretion of nonionised beta hydroxybutyric is 60%. In this condition it produces a large component of urinary TA. Acetoacetic acid is excreted, but forms a lesser component of urinary TA. Almost all of the urinary ketone excretion is in the form of beta hydroxybutyric acid. Excretion of nonionized lactic acid in lactic acidosis is also low. Normally, the urinary excretion of phosphate is determined by the need to maintain phosphate balance rather than acid base homeostasis. Thus, TA appears to play a supportive rather than an active role in H^+ balance.

(iii) Proteins as buffer (Pr− / PrH)

$H^+ + Prot^- \leftrightarrows H\ Prot$

Like haemoglobin, plasma proteins also act as an effective buffer. This is because of the large total concentration of it in the body and the p^K of some proteins approximates 7.4 at which they are likely to work. Proteins are the most important buffers in side of the cells. They contain both acidic group (–COOH) and basic group ($–NH_2$) in one molecule to make up the buffer pairs.

Acidic group dissociate into $−COO^− + H^+$ and donate H^+ to buffer excess base:

$− COOH + OH^− \leftrightarrows − COO^− + H_2O.$

Basic group, commonly in the form of $− NH_2$ buffers excess acid by accepting H^+ to form $–NH_3^+$.

$− NH_2 + H^+ \leftrightarrow − NH_3^+$

As p^K value of most of the protein buffer systems are around 7·4, so at normal condition they work best. They buffer both carbonic (respiratory) and noncarbonic (metabolic) acid or alkali.

(iv) Haemoglobin as buffer (Hb− / HbH)

Hb is responsible for 50% buffering power of the blood. It is an effective buffer between pH of 5.7 to 7.7, because its p^K value is 6.8. It buffers respiratory and metabolic acids only. It does not buffer any alkali. It acts as a buffer, because it is a protein in nature and more importantly due to the ability of the imidazole group (within the histidine molecules which dissociates less in oxygenated than deoxygenated blood) to accept H^+. This H^+ for neutralisation comes from two sources. One, from dissociation of metabolic acids and another from CO_2which is available from metabolism of substrates through TCA cycle. At tissue level O_2 is liberated from Hb and CO_2 enters in the erythrocyte. Erythrocyte is rich in carbonic anhydrase which help in the formation of H_2CO_3 from CO_2 by the reaction:

$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$

When H^+ of H_2CO_3 is buffered by Hb it exists within the erythrocyte as a weak acid (HHb) than carbonic acid (because p^K value of HHb is 6.8 whereas p^K value of H_2CO_3 is 6.1). After buffering of H^+ by Hb, HCO_3^- within RBC is increased proportionally.

The corresponding increase in HCO_3^- in erythrocyte causes a diffusion back of HCO_3^- into the plasma along the concentration gradient. This results in exchange (Fig. 8.3) or shifting of Cl^- in the erythrocyte from plasma which is called the chloride shift. Therefore, while most of the H^+ is buffered within the cell (RBC) most of the change in HCO_3^- is seen in the plasma. After entering into the erythrocyte, CO_2 is also carried as carbino compound after combining directly with the terminal amino acids of the globin part of haemoglobin molecule. The acidity of these imidazole group (or deoxygenation) is influenced by the oxygenation and reduction of Hb. Haemoglobin is a weaker acid in reduced form than when it is oxygenated and increases the availability of buffer sites for H^+. When oxygenated Hb gives up O_2 to the tissue it becomes reduced and is therefore more able to accept CO_2 in the form of H^+. In the lungs reverse effects occur. Upon reaching the lung and

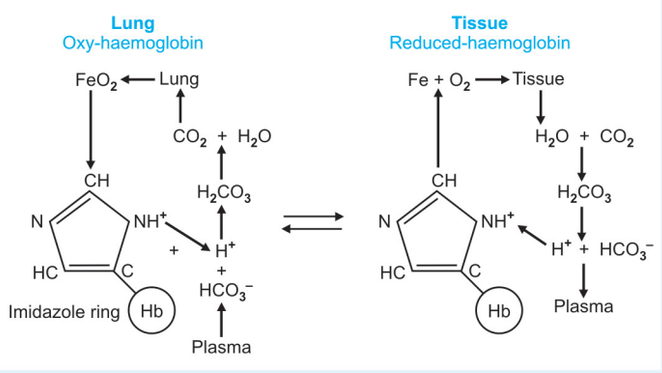

Fig. 8.3: Reduced (or deoxygenated)— Hb is a better buffer than oxygenated Hb

becoming oxygenated, the Hb becomes a stronger acid and buffering capacity is reduced. So, H^+ is released from the Hb to react with $KHCO_3$ and CO_2 is released from the carbamino groups.

$HHb + O_2 + KHCO_3 \leftrightarrows KHbO_2 + H_2O + CO_2$

This effect explains that reduction or deoxygenation of Hb makes it weaker acid and increases its buffering capacity to accept H^+. Whereas oxygenation makes Hb a stronger acid and decreases its buffering capacity to accept H^+. This is known as Haldane effect. Reduced Hb is better buffer than O_2-Hb. Haemoglobin has three times better buffering capacity than plasma proteins in gram for gram comparison and is twice the concentration in blood than plasma protein. Therefore, Hb has six times the total buffering capacity than plasma protein (Figs 8.4A and B).

Thus, the buffers in order of importance are:

i. In blood: Hb, bicarbonate, plasma protein, and phosphate.
ii. In interstitial fluid : Bicarbonate, phosphate, and interstitial protein.
iii. In cells: Proteins, phosphate, ammonia and other inorganic substances. Phosphates and ammonia are also important urinary buffers.

As nonvolatile acids are released from the cellular metabolism, their effect is mainly buffered by the action of bicarbonate buffer system in the extracelular fluid (ECF) and by bicarbonate (50%), Hb (35%), plasma protein (6%) and phosphate buffer system in the plasma.

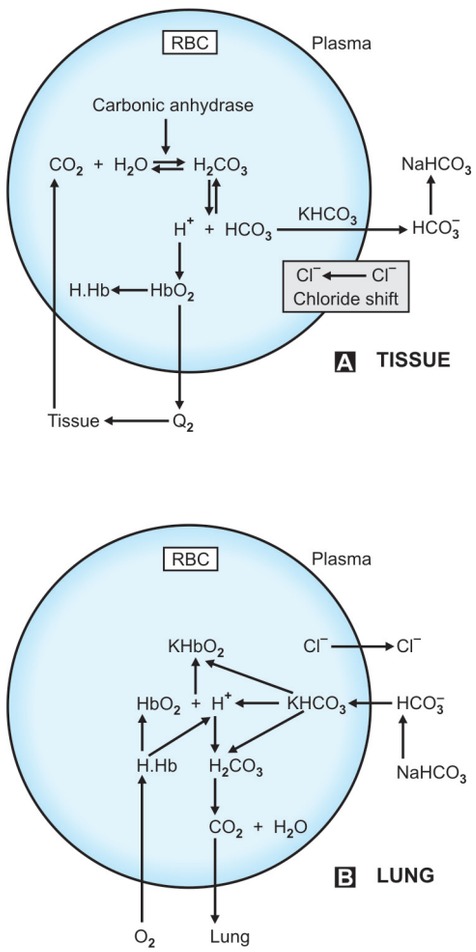
In summary, buffering is the mechanism by which an influx of H^+ is initially dealt with by the body and limits the change in pH. Thereafter, respiratory mechanism becomes activated to elimainte CO_2 and later renal regulation of acid and alkali secretion increases to increase the buffer capacity.

Compensation

The alteration of H^+ concentration also stimulates the compensatory part of the pH homeostatic mechanism and maintain the normal pH by restoring the HCO_3^- / P_aCO_2 or HCO_3^- / H_2CO_3 ratio. So in addition to the buffering mechanism, the homeostasis of acid-base disturbance is also maintained by compensation, played by the pulmonary and renal excretion or retention of acids or bases.

Pulmonary Compensation

Pulmonary compensation is made by increasing or decreasing the ventilation and is only limited to CO_2 excretion by the lungs ($CO_2 \leftarrow H_2O + CO_2 \leftarrow H_2CO_3 \leftarrow H^+ + HCO_3^-$). So the pulmonary compensation is active only during metabolic acidosis or alkalosis, because the respiratory acidosis or alkalosis is caused by the diseases of pulmonary system itself which can not work now as the compensatory organ. Ventilation is controlled by chemoreceptor areas of medulla, and carotid and aortic bodies. Among them the medulla plays the primary role and H^+ is the predominant mediator effecting the chemoreceptors of it. Changes in blood PCO_2 cause rapid changes in PCO_2 of CSF. This is because the blood-brain barrier is highly permeable to CO_2, but not to H^+. Thus, rapid increase in CO_2 concentration and subesquently its tension in CSF is associated with rapid increase in H_2CO_3 in CSF which in turn dissociate into large amount of H^+. But, the buffering capacity of CSF to neutralise the H^+ is limited. So, increase of H^+ in CSF is greater than it would be



Figs 8.4A and B: Schematic diagram of chloride shift in tissue (A) and in lung (B)

in the tissue and stimulate the medullary chemoreceptor centre increasing ventilation and washing out CO_2. Minute ventilation increases 1 to 4 L/min for every 1 mm of Hg increase in P_aCO_2. Usually, lungs are responsible for eliminating approximately 15 mEq of CO_2, produced every day as a byproduct of carbohydrate and fat metabolism.

Metabolic acid-base disturbances are only compensated by ventilation. Among this the metabolic acidosis or alkalosis, caused by the increase or decrease of H^+ from metabolic acid is best compensated by the pulmonary mechanism. The metabolic acidosis or alkalosis caused by the increase or decrease of HCO_3^- concentration is also compensated by pulmonary mechanism. This is described now. Decrease in plasma HCO_3^- level with its concomitant decrease in pH, due to any metabolic causes, will stimulate the ventilation and will excrete more CO_2 and will reduce H_2CO_3 level, despite normal or low PCO_2 in blood. This is only to maintain the ratio of HCO_3^- / H_2CO_3. Conversely, an increase in plasma HCO_3^- concentration with its concomitant increase in pH, due to any metabolic causes will depress the ventilation and retain CO_2. This will increase H_2CO_3 level and maintain the ratio of HCO_3^-/H_2CO_3 and thus pH, though PCO_2 is high. If the decrease of ventilatory drive is very strong to cause hypoxia, ventilatory centre will be stimulated by the effects of hypoxia on carotid bodies.

Renal compensation

Unlike, the pulmonary compensation which is only limited to the metabolic acidosis and alkalosis, the renal compensation extends to both the respiratory and metabolic acidosis and alkalosis. However, the renal compensation is 3 times more active in acidosis than alkalosis. It is performed by three ways: increasing reabsorption or excretion of filtered HCO_3^-, increasing or decreasing the secretion of H^+ from tubular cells in tubular fluid, increasing excretion of $H_2PO_4^-$ as titrable acids, and increasing producion of ammonia. These mechanisms of acid-base balance are probably activated immediately. But their effects are generally not appreciated for 12 to 24 hours and becomes maximum at 5th day.

The amount of HCO_3^- filtered by the kidney is approximately 24 m.mol/L and virtually all are reabsorbed. HCO_3^- is not permeable to cell membrane. So, it can not be reabsorbed directly through the tubular cell membrane. The mechanism of reabsorbtion of filtered HCO_3^- is: H^+ is passed into the tubular fluid through the tubular cells of proximal tubule and react with HCO_3^- to form H_2CO_3 which further dissociates into $H_2O + CO_2$. This reaction is catalysed by carbonic anhydrase present in large amount in the brush border of tubular cells. Then CO_2 is rapidly reabsorbed into the tubular cell. Again carbonic anhydrase within the tubular cell converts the CO_2 back into HCO_3^-. The proximal tubules usually reabsorb 80 to 90% of the filtered HCO_3^- along with Na^+. Whereas the remaining 10 to 20% of HCO_3^- is absorbed in the distal tubules. Unlike the secretion of H^+ in proximal tubules, the secretion of H^+ in distal tubules is not necessarily linked to absorption of Na^+. The secretion of H^+ in distal tubules is capable of generating steep gradient of H^+ between the tubular fluid and tubular cells. Thus, urinary pH can decrease to as low as 4.4 compared to pH of 7.4 in plasma (Fig. 8.5).

Instead of reabsorbtion of HCO_3^- which are filtered through glomerulus, kidneys also generate new HCO_3^- during metabolism of glutamine in proximal tubules to compensate acidosis. The mechanism is: metabolism of glutamine produces CO_2 and NH_3. This ammonia constitutes 60% of urinary ammonia, whereas another 40% comes from blood. Acidosis increases markedly the renal production of NH_3 from glutamine. This NH_3 is secreted into the tubular fluid. It buffers the H^+ of the tubular fluid by forming NH_4^+ which is nondiffusible (NH_3 is diffusible) and excreted through

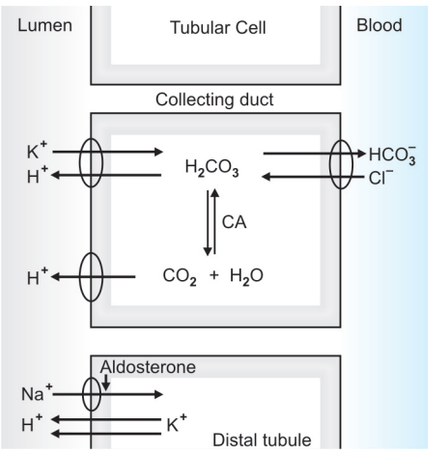


Fig. 8.5: In collecting duct, some H^+ secretion occurs in exchange for K^+. Whereas in distal tubule aldosterone helps in absorption of Na^+ in exchange of K^+ and H^+

urine. Then CO_2 which is produced by the metabolism of glutamine also diffuses in tubular fluid and combines with H_2O to form HCO_3^- which is then absorbed. If the kidneys are unable to excrete NH_4^+ through urine, the retention of NH_4^+ negates the benefit of the new HCO_3^- generation. Systemic acidosis, hypokalaemia, mineralocorticoids increase ammonia production and thus try to combat acidosis.

In addition to recovering of HCO_3^-, the kidneys also excrete an amount of acid (H^+) equal to its daily production. It is approximately 70 mmol/day. This may increase to 300 mmol/day in severe acidosis. These acids (H^+) are not excreted directly through urine. Before being excreted directly through urine, these free acids are first buffered by the weaker acids such as ammonia (NH_3^+ / NH_4^+) and phosphate (HPO_4^{2-} / $H_2PO_4^-$) in renal tubular fluid. These, NH_4^+ and $H_2PO_4^-$ can not be absorbed due to its charge and excreted through urine. Therefore, the net result is: H^+ is excreted as $H_2PO_4^-$ and NH_4^+ from body and the HCO_3^- that is generated in the process of formation of CO_2 from H^+ enter the blood stream. With p^K value of 6.8, this $HPO_4^{2-}/H_2PO_4^-$ buffer pair is normally present in urine. However, when urinary pH reaches 4.4, then all the phosphates reaching the distal tubule is in the form of

$H_2PO_4^-$. In such condition HPO_4^{2-} are no longer available for elimination of more H^+. After complete reabsorption of HCO_3^- and consumption of phosphate buffer, the NH_3/NH_4^+ buffer pair becomes the most important urinary buffer system. However, both the reabsorbtion of HCO_3^- from tubular fluid and secretion of H^+ in it depends on the active secretion of H^+ which in turn is regulated by the changes in plasma HCO_3^-, plasma pH and plasma PCO_2.

During metabolic or respiratory acidosis, due to increase in H^+ concentration or decrease in HCO_3^- concentration, there is direct or indirect increase in concentration of H^+ in tubular cell which in turn stimulates the release of H^+ into the tubular fluids. Increase availability of H^+ in tubular fluid increases the recovery of HCO_3^- ($H^+ + HCO_3^- = H_2CO_3 = CO_2 + H_2O$, $CO_2 \rightarrow$ passed in the tubular cell. Then $CO_2 + H_2O = H_2CO_3 = HCO_3^- + H^+$) and thus try to compensate the acidosis. In acidosis metabolism of glutamine is also stimulated by increasing the availability of H^+ in tubular fluid. But this glutamine mechanism takes up to several days for complete adaptation, because it requires more times for synthesis of new enzymes for more metabolism of glutamine.

Conversely during metabolic and respiratory alkalosis, there is inhibition of reabsorption of HCO_3^- from the tubular fluid due to reduction of the availability of H^+ in tubular fluid and thus compensate alkalosis.

Since, the renal H^+ excretion from tubular cells occurs simultaneously with Na^+ reabsorption for electrical balance, but the process is also affected by aldosterone. Increased aldosterone stimulates reabsorption of Na^+ and simultaneous excretion of H^+ into the tubular fluid, causing an increased reabsorption of HCO_3^-, alkalosis and acidic urine. Thus, Na^+ deficiency and excess of mineralocorticoid is associated with metabolic alkalosis. Na^+ depletion decreases ECF volume and enhances the absorption of Na^+ in the proximal tubule. To maintain neutrality, increased Na^+ absorption causes increased absorption of Cl^-. So, as Cl^- ion decreases in number (< 10 m.mol/L) reabsorption of HCO_3^- must be increased. Thus, metabolic alkalosis is frequently associated with less urinary Cl^- excretion. The opposite effect occurs with decreased levels of aldosterone.

The excretion of H^+ in proximal tubule is a low gradient, but a high capacity system. The proximal H^+ secretion is increased with hypokalaemia, hypercapnia, increased luminal HCO_3^- level, increased tubular Na^+ reabsorption, the presence of nonabsorbable anions (e.g NO_3^-, SO_4^{2-} etc) and increased carbonic anhydrase activity. In the presence of extracellular fluid depletion or metabolic acidosis the Na^+/H^+ exchange mechanism exaggerated, maintaining the extracellular fluid volume at the expense of pH homeostasis. Thus, the maximum HCO_3^- reabsorption capacity of the kidney is not a fixed value and varies in response to the above factors.

Contrary to proximal tubules the secretion of H^+ in distal tubule is a high gradient, but a low capacity system. Unlike proximal tubule, it is influenced by mineralocorticoid acitivity. In hyperaldosteronism distal Na^+ reabsorption and in exchange excretion of H^+ and K^+ are increased. In the presence of hypokalaemia, H^+ loss is further increased due to maintain electroneutrality in tubular fluid. In secondary hyperaldosteronism, the loss of K^+ and H^+ may be less than in primary hyperaldosteronism. This is due to reduction in distal luminal Na^+ flow induced by avid proximal reabsorption of it. Thus an increase in distal H^+ or K^+ urinary secretion may only become evident when distal Na^+ delivery is increased. The example of it is use of diuretics.

CARRIAGE OF CO_2

The discussion of transport of CO_2 in blood is important in this chapter, because it is carried in blood as H^+ and HCO_3^- form which are the important determinants of acid-base balance. Near about, 120 litres of CO_2 is contained in the body at any moment. This CO_2 store can be divided into three compartments depending on the possible rate of exchange of gas between the compartments. These are fast, medium and slow compartment. The fast compartment is consists of brain, heart, and kidney with high blood flow, (Table 8.6) where the tissue PCO_2 levels match with the alveolar PCO_2 very closely. Medium compartment consists mainly of skeletal muscle and slow compartment consists mainly of fatty tissues. The blood flow in these compartments varies from medium to low and also PCO_2 of these compartment do not match well with the alveolar PCO_2. Though, the volume of these three compartments are different, still the slow compartment have the greatest capacity for storing CO_2 and the fast one has the smallest.

Due to the enormous volume of CO_2 storing capacity in the body, the changes in the arterial PCO_2 will not be sudden due to sudden changes of ventilation or other causes. It will take much time for a new equilibrium to be attained. But contrary, following a sudden increase in ventilation a new equilibrium is reached after about 20 minutes (the half time is 3 to 4 minutes). Following a sudden decrease in ventilation the half time for the new equilibrium to reach is 15 to 20 minutes (i.e. delayed).

After CO_2 is produced in the tissues by metabolism, it enters the blood stream through the tissue capillaries and is carried to the lungs where it is liberated. 100

Table 8.6: Differences between venous and arterial blood sample

	Venous sample	*Arterial sample*
PO_2	38-42 mm of Hg	80-100 mm of Hg
PCO_2	44-48 mm of Hg	36-44 mm of Hg
pH	7.36 - 7.39	7.38-7.42
SO_2	75%	95-100%
HCO_3^-	20 -24 mEq/L	22 -26 mEq/L
Na^+	135-145 mEq/L	Same
K^+	3.5-5.5	Same
Cl^-	95-105 mEq/L	Same

ml of venous blood carries about 52 ml of CO_2. Whereas, 100 ml of arterial blood carries 48 ml of CO_2. Therefore, the average normal arterio-venous difference of CO_2 content is about 4 ml. In other words, each 100 ml of arterial blood, while passing through the tissues, takes up 4 ml of CO_2. Similarly, each 100 ml of venous blood, while passing through lungs, also releases 4 ml of CO_2. So that, blood carries a constant volume of CO_2 amounting to about 48 ml per 100 ml of blood. This constitutes the 'alkali reserve', because most of the bicarbonate is obtained from it during equilibrium. Although, much CO_2 is carried in the blood, yet blood reaction does not become acid. This proves that, during CO_2 transport, the blood buffers play a very important role.

After CO_2 is produced by metabolism in the cell, it comes out through the interstitial fluid and enters the plasma. Then, it passes into the red cells to reach lungs. PCO_2 of the venous blood reaching the pulmonary capillary is 46 mm of Hg whereas pCO_2 in alveoli is 40 mm of Hg. Therefore, a pressure gradient of 6 mm of Hg drives CO_2 across the alveolar membrane from venous end of capillary into the alveoli.

CO_2 is Carried by Blood to Lungs

(i) As physical solutions in the plasma

Though, only a small quantity of total CO_2 (5%) is carried in this manner, but it forms a very important portion. Because this portion is responsible for CO_2 tension in plasma and acts intermediatory between alveolar air and the inside of red cell. The solubility coefficient of CO_2 in plasma is 0.03 mmol/L/mm of Hg. Therefore, at P_aCO_2 of 40 mm of Hg and at 37°C only $0.03 \times 40 = 1.2$ m.mol/L of CO_2 is carried by plasma in this physical form. CO_2 is also carried in plasma by H_2CO_3 form. But, the concentration of H_2CO_3 in plasma by which form CO_2 can be carried is only 1/1000 of total CO_2 content, due to the lack of carbonic anhydrase (CA) in plasma.

(ii) As bicarbonate

Most part of the total CO_2 (90%) content in blood is carried in this manner i.e. in bicarbonate form. Bicarbonates are formed in blood by the following ways (Fig. 8.6):

A. In RBC

Hb remains combined with K and forms bicarbonates in the following way:

$CO_2 + H_2O = H_2CO_3$

$KHb + H_2CO_3 = HHb + KHCO_3$

In RBC carbonic anhydrase helps in this process. In the absence of carbonic anhydrase the reaction between CO_2 and H_2O to form H_2CO_3 take 15 to 30 minutes. But, in our body RBC in the tissue capillaries becomes saturated with CO_2 within 1 to 2 seconds and the same time is required for the excretion of CO_2 through lungs. This is only possible due to the presence of carbonic anhydrase. In the blood, it is almost exclusively present in the red cells. All other tissues contain it in traces. But, pancreas and stomach contain it in considerable amounts.

B. In plasma

i. By the phosphate buffers
   Alkaline phosphates combine with carbonic acid and form sodium bicarbonate.
   $Na_2HPO_4 + H_2CO_3 = NaH_2PO_4 + NaHCO_3$
ii. By plasma proteins
   The plasma proteins mostly remain combined with sodium (to be presented as NaPr) and form bicarbonates in the following way.
   $NaPr + H_2CO_3 = HPr + NaHCO_3$
iii. Chloride shift or Hamburger phenomenon.This can be described by the following way.

After entering into the plasma from tissue, CO_2 enters the red cell where with the help of enzyme, carbonic anhydrase (CA), CO_2 react with H_2O to form H_2CO_3. This is because RBC is rich in this enzyme. The

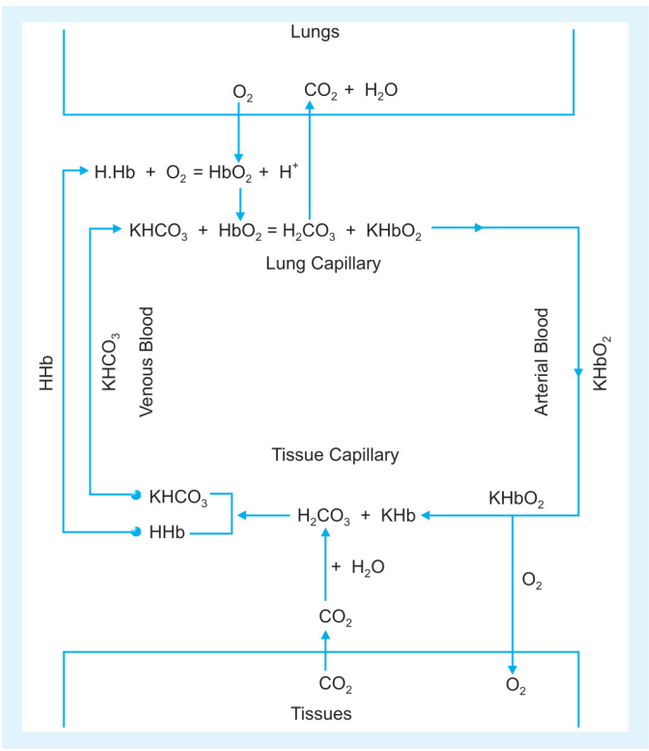

Fig. 8.6: Schematic representation showing inter relation between the carriage of O_2 and CO_2

enzyme carbonic anhydrase is not found in plasma. So, the formation of H_2CO_3 and subsequent bicarbonate can not take place in plasma or in very little amount. Within the RBC, H_2CO_3 is formed and dissociates into H^+ and HCO_3^- ($H_2CO_3 \leftrightarrows H^+ + HCO_3^-$).

At the tissues within red cells O_2Hb after giving up the O_2 combine with this H^+ which comes from the dissociation of H_2CO_3 ($Hb + H^+ \leftrightarrows HHb$) and favour the formation of HCO_3^- by displacing the equilibrium (of the bicarbonate forming equation) to the right according to the law of mass action ($H_2CO_3 \leftrightarrows H^+ + HCO_3^-$). Then, bicarbonate ($HCO_3^-$) diffuses out of the red cell into the plasma and to maintain the ionic equilibrium chloride ions (Cl^-) diffuse back in the opposite direction from plasma into the red cells. This is called the chloride shift or Hamburger effect (phenomenon). Thus, CO_2 is carried to the lungs as bicarbonate (HCO_3^-).

When blood reaches the lung capillaries then all the reactions occur in reverse direction. Due to pressure gradient of CO_2 of 6 mm of Hg (plasma pCO_2 = 46 mm of Hg and alveolar pCO_2 = 40 mm of Hg) CO_2 dissolved in physical state in plasma, diffuses out across the alveolar membrane from plasma. So the physically dissolved CO_2 concentration in plasma falls. Then, the pressure gradient of dissolved CO_2 between RBC and plasma widens. So, CO_2 leaves the red cells and is excreted through the lungs. To produce more CO_2 in red cells, HCO_3^- again enter the red cells in exchange of Cl^- (Cl^- come out of red cell $\rightarrow$ opposite to the chloride shift or Hamburger effect). In the red cell HCO_3^- combine with H^+ to form CO_2. Here, the equation $CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$ is shifted to left. H^+ is obtained from Hb, which take O_2 from alveoli and release H^+. This explains how CO_2 comes out of red cells and excreted through lungs.

Plasma bicarbonate (HCO_3^-), therefore, plays a very important role as the principal store house of CO_2 and carries of it in the blood.

(iii) As a carbamino compound

5% of the total body CO_2 is carried within the plasma in this manner. Here, CO_2 combine with the amino group of globin (protein) part of Hb to form carbamino-haemoglobin. In this process, the NH_2 radicle of the globin part of Hb combines with one molecule of CO_2 as free gas, but not as H_2CO_3. It does not require the help of carbonic anhydrase.

$Hb.NH_2 + CO_2 \leftrightarrows Hb.NH.COOH$

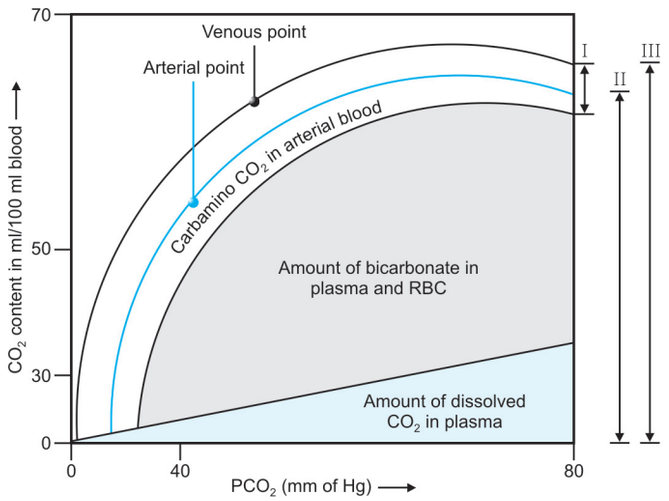
Smaller amount of CO_2 also combines with the amino group of plasma protein in similar fashion, like globin (protein) part of the haemoglobin to form the carbamino compound. The combination between CO_2 and plasma protein also takes place directly and no enzyme is required.

Thus, it will be seen that the CO_2 is carried out in the blood in three forms and 100 ml of venous blood carries about 52 ml of CO_2 as follows:

a. In physical solution (2.7 ml)
b. As bicarbonate (45.7 ml) – Bicarbonates are formed in four ways: (i) with NaPr, (ii) with Na_2HPO_4, (iii) with Na of NaCl helped by 'chloride shift', (iv) with KHb. These are the chief forms in which CO_2 is carried. A large part of this bicarbonate remains permanently in the plasma and constitutes the so-called alkali reserve.
c. As carbamino compounds (3.7 ml) – These are chiefly formed in the red cells (2.6 ml) with the protein of Hb and only in traces in the plasma (1.1 ml) with plasma protein. It constitutes about 5 to 10% of the total CO_2 carriage and is responsible for a large part of the normal arterio-venous difference.

CO_2 DISSOCIATION CURVE (Fig. 8.7)

The relationship between the CO_2 concentration and the CO_2 tension (PCO_2) in blood is depicted by this curve. Oxygenation of blood is the main determitant of position of this curve. Because the more deoxygenated the blood will be the more CO_2 it will carry at a given pCO_2 and change the curve. This is called the Haldane effect. The upper portion of the curve is for the fully deoxygenated blood and the lower portion of the curve



I = Carbamino CO_2 in venous blood
II = Total CO_2 content in arterial blood
III = Total CO_2 content in venous blood

Fig. 8.7: This is a CO_2 dissociation curve of whole blood

is for the fully oxygenated blood. The major part of the Haldane effect is due to the increased carriage of CO_2 by reduced haemoglobin as carbamino compound. In addition, carriage of CO_2 as bicarbonate is also increased.

$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$

Reduced or deoxygenated haemoglobin buffers the H^+. Thus by absorbing H^+ the reduced Hb displaces the equilibrium of this equation to the right and increases the concentration of bicarbonate (HCO_3^-) and produces the chloride shift (Hamburger effect). Thus due to Haldane effect, at the capillary level CO_2 uptake and at the lung level CO_2 elimination is facilitated by shifting the equation once to the right (at capillary level) and then to the left (at lung level) respectively.

ELIMINATION OF H^+

(i) Rapid Elimination by Respiration

CO_2 produced by the oxidation of substrates, produces H^+ load in the body which is excreted again as CO_2 through the lungs, leaving H_2O.

$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$

After production in the cell, CO_2 readily diffuses across the cell membrane and produce changes of pH in both ICF and ECF. H^+ directly can not diffuse through the cell membrane. So, it passes through the cell membrane in disguish of CO_2. Thus increased CO_2 production in normal situation stimulates respiration and balance H^+ concentration (in turn CO_2 concentration) rapidly. The carbonic acid and bicarbonate chemical buffer or the bicarbonate buffer system is ineffective here. Carbonic acid remains in equilibrium with the dissolved CO_2 content of body fluids and can therefore be eliminated through the lungs. Addition of H^+ from the metabolic acids also increases H_2CO_3 at the expense of a reduction in bicarbonate and is eliminated as CO_2.

H^+(metabolic origin) + HCO_3^- = H_2CO_3 = $H_2O + CO_2 \rightarrow$ lungs

(ii) Slow Elimination by Kidney

Slow and long-term control of H^+ elimination by kidney depends on three mechanism.

A. Reabsorption of filtered bicarbonate

Presence of carbonic anhydrase in renal tubular cells facilitate the production of H^+ from CO_2 load.

$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$

This H^+ passes in the luman of the proximal tubule. Normally daily 5000 nmol HCO_3^- is filtered at glomerulus. This HCO_3^- react with H^+ and CO_2 is produced which diffuses back in the tubular cells. Thus no net H^+ excretion results from this action but prevents loss of filtered base. Smaller amount of H^+ is secreted in the distal and collecting ducts to make the urine acidic with pH of 4.6.

During acidosis the excess H^+ passes in the proximal tubular lumen and after preserving all the filtered HCO_3^-, extra H^+ is excreted. This secondary response is slow to develop and take 5 days for full compensation to occur. In the absence of CA or when acetazolamide is used then non availability of H^+ causes HCO_3^- to be excreted as $NaHCO_3$ and plasma HCO_3^- falls. So, in acidosis acetazolamide should never be used.

B. Buffers

20 to 30 mmol of H^+ which is excreted daily through urine as titrable acid, is combined to monohydrogen phosphate and excreted as dihydrogen phosphate (titrable acid).

$H^+ + HPO_4^{2-} \leftrightarrows H_2PO_4^-$

C. Formation of Ammonia

NH_3^+ is formed in the renal tubular epithelium throughout the nephron. Among this 60% is formed from glutamine by deamination and 30 to 35% comes from artery as free NH_3^+. This NH_3^+ diffuses into the renal tubular lumen and binds to neutralise H^+ by producing non-diffusible ammonium ion (NH_4^+). This is excreted daily and may rise to 700 mmol per day in severe acidosis. Thus, the maximum renal acid secretion as in diabetic ketoacidosis is approximately 700-750 mmol per day of which two-third is NH_4^+ and one third is titrable acid.

MEASUREMENT OF ACID-BASE BALANCE

The acid base disturbances in the body occur when the disease processes cause disruption of the normal pH homeostatic mechanisms or when the acid or alkali burden (more rarely) exceeds the adaptive capacity of compensatory mechanisms.

- The normal arterial pH usually ranges from 7.36 to 7.42. It is maintained by intracellular and extracellular buffers. These buffers work through the renal and respiratory regulatory mechanisms.
- The intracellular pH ranges from 6.4 to 7.35.
- pH is −log of the hydrogen ion concentration expressed in mol/L.
- pH of 7.4 represents [H^+] of 40 nmol/L.
- pH rising to 7.5 represents a drop in [H^+] to 32 nmol/L.
- pH of 7 is equal to [H^+] of 100 nmol/L.
- The centre of the understanding of acid-base disturbance is the understanding of carbonic acid and bicarbonate buffer pairing. This is expressed by Henderson - Hasselbalch equation such as $[H^+] = 181 \times P_aCO_2 / [HCO_3^-]$, 181 is the dissociation constant or coefficient of carbonic acid in the presence of carbonic anhydrase. This buffer pairing system is ubiquitous. It is also the dominant physiological buffer system in man and most importantly it is in equilibrium with all other buffer systems of body.
- A combination of both the respiratory and metabolic acidosis or alkalosis may present at the same time with normal pH value compensating with each other.

The dissociation constant (K) is affected by the changes in temperature. For example, the pH of water at 25°C is 7, whereas it is changed to 6.8 at 37°C. So,

during the measurement of pH the temperature should be taken into consideration.

The respiratory acidosis or alkalosis is the change or a potential change in pH, resulting from alteration in the PCO_2. The metabolic acidosis or alkalosis is the change or a potential change in pH, resulting from alterations in the nonvolatile acids in the blood such as lactic acid, keto acid, β-hydroxybutyric acid, sulphuric acid, phosphoric acid, pyruvic acid, etc or when the primary disturbance is in the control of plasma bicarbonate concentration. Though, all the types of combination is possible, so the PCO_2 measurement quantify the respiratory component and the 'base excess' or base deficit measurement quantify the metabolic component of acid-base balance.

Despite the presence of buffer and other compensatory mechanisms, the acid-base disturbances do occur in the body. So, to determine the primary cause of acid-base imbalance, the degree of buffering, the degree of compensation and the ultimate pH, PCO_2 and HCO_3^- level should be measured. There are several methods to measure these parameters. But, due to the presence of complex inter relationships between the buffer systems and the compensatory mechanisms, the measurement of the above parameters are not sometimes correct, indicating the primary cause, the degree of buffering and the degree of compensation. Again, there is loss of precision which is inherent in the simplification of the complex processes of measurement.

The Hendersons-Hasselbalch equation is usually used to measure the bicarbonate buffer system. But several other different methods are also utilised to correct for the presence of other buffer system, by allowing one to evaluate the entire system as bicarbonate buffer. These include alkali reserve, standard bicarbonate, base excess, and buffer base. The alkali reserve and the standard bicarbonate are no longer in use for clinical practice. Base excess and buffer base are still in use and act by compensating the buffering capacity of nonbicarbonic buffer system. In this compensation, other buffer systems are converted to the equivalent of bicarbonate buffer in which the change in HCO_3^- level directly reflects a change in H^+ of the system.

The acid-base disorders also can be evaluated from the CO_2 titration curves, derived from the present values of pH, PCO_2 and HCO_3^- concentration. Clinical values are then compared with the normal human values and the deviation is quantified for both the acute and chronic disorders. This *in vivo* method (titration curve) is superior to the *in vitro* methods (measurement of pH, PCO_2 and HCO_3^-), because it recognises the changes in pH due to specific causes and thus present a very dynamic scenario.

PCO_2

The PCO_2 of a gas mixture, saturated with water vapour at 37°C is given by the equation.

$PCO_2 = FCO_2 \times (P_B - 47)$ mm of Hg

FCO_2 is the fractional concentration of CO_2 in the mixture, P_B is the barometric pressure (760 mm of Hg) and 47 mm of Hg is the saturated vapour pressure of water at 37°C. The PCO_2 in plasma is best understood by considering a gas-liquid system which is in equilibrium. The CO_2 tension in a liquid is equal to that in the gas when no net exchange of CO_2 occurs between these two-phases. At any given equilibrium, the CO_2 content of plasma is a reflection of the PCO_2 of the gas phase. The PCO_2 of blood is thus defined as that PCO_2 in a gas mixture which, when in contact with the blood results in no net exchange of CO_2 between the two phases. The normal value of P_aCO_2 is 35 to 42 mm of Hg.

CO_2 Titration Curve

The consideration and the application of Henderson-Hasselbalch equation is the core to the understanding of acid-base balance. Both the metabolic and respiratory factors are represented in this unique equation. This equation also linked pH to the molar concentration of bicarbonate and carbonic acid in plasma. But, the constants in the equation can not be predicted accurately (Fig. 8.8A).

This equation also says us that any alteration of the PCO_2 will be associated with a predictable change in pH. If the PCO_2 is either increased or decreased and time is allowed for a steady state or an equilibrium to be reached, then CO_2 titration curve (straight line using a pH and PCO_2 plot) is obtained (Fig. 8.7A). When a titration is performed adding deliberately varying amounts of acid, then a family of curves, approximately parallel to and to the left of the normal curve is found. The more acid is added, the further is the curve shifted to the left. Thus, a non-respiratory (metabolic) acidosis produces curves shifted to the left and a non respiratory (metabolic) alkalosis produces curves to the right. With increasing metabolic acidosis, the buffering capabilities will also increase, which causes the left shifted curves to be more vertical and the right shifted curves to be more horizontal (Fig 8.8B).

During the construction of CO_2 titration curve, arterial blood is tonometered with CO_2 gases of two known, but

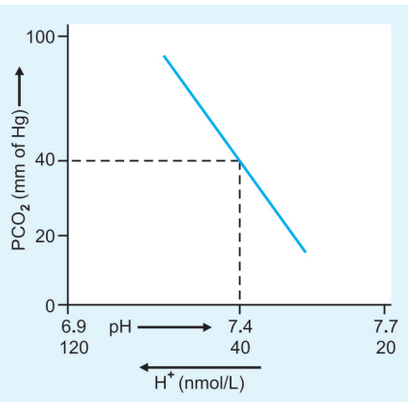


Fig. 8.8A: *In vivo* CO_2 titration curve

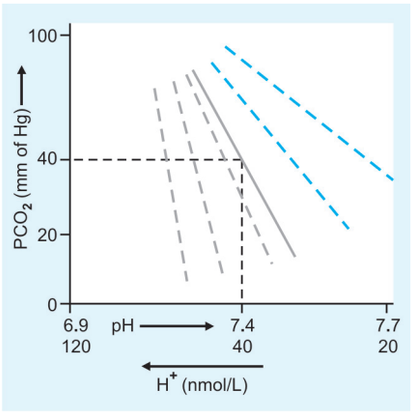

Fig. 8.8B: Family of *in vivo* CO_2 titration curves in non respiratory (metabolic) acidosis (red lines) and alkalosis (green lines)

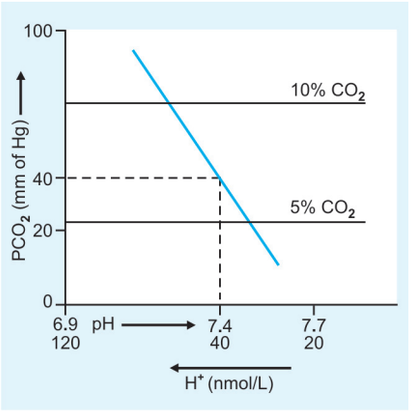

Fig. 8.8C: Measurement of PCO_2 and construction of in vitro CO_2 titration curve

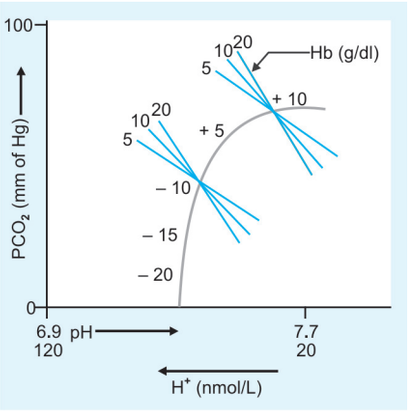

Fig. 8.8D: Construction of 'base excess' curve

different concentration. If pH is measured after tonometry, then an *in vitro* blood CO_2 titration curve could be constructed (Fig. 8.8C). Next the actual PCO_2 of any original blood sample can be determined by interpolation, if its pH is measured. In general, it is realized that the titration curve of blood from acidotic patients lay to the left of this curve and from alkalotic patients lay to the right. But, it was appreciated that the Hb concentration altered the slope of the curve and induces errors. Thus, a number of parameters were used to get rid of these errors. These are base excess, buffer base, and standard bicarbonate (Fig. 8.8C).

When the normal blood is diluted to different Hb concentration and thereafter is equlibrated with gas mixutres of different PCO_2, then this yields a family of PCO_2/pH curves intersecting at pH of 7.4 and PCO_2 of 40 mm of Hg. After that if a strong acid or alkali is added, then different families of curves are produced (Fig. 8.8D). Now, if the intersections of each family are joined, then a base excess curve is produced. The value of this base excess curve is thus independent of Hb concentration and is a useful index of only patient's metabolic acid-base status (not the patient's respiratory acid-base status). It was found emperically that the correction of metabolic acidosis could often be obtained by the infusion of sodium bicarbonate in m.mol/L which can be determined by the formula: 0.3 + base excess × weight in Kg (Fig. 8.8D).

In acute respiratory acidosis, the arterial pH falls according to the CO_2 titration curve. Acute respiratory acidosis follows titration line from N to x in Figure 8.8E. Then, in long standing conditions the kidney excretes an increasing proportion of the acid load producing a shift to the right of the titration curve from x to y in Figure 8.8E. In acute respiratory alkalosis, the pH also increases according to the CO_2 titration curve. Acute respiratory alkalosis follows tritation line from N to O. Then, renal compensation causes a shift to the left of the titration curve from O to P (Fig. 8.8E).

In metabolic acidosis, the CO_2 titration curve is shifted to the left in figure F. In metabolic acidosis, the ventilation is stimulated by the peripheral chemoreceptor drive, so that the CSF and arterial PCO_2 and HCO_3^- concentration are lowered until the pH returns almost to normal. If the pH is corrected rapidly by the administration of bicarbonate, then the PCO_2 of CSF will rise and pH will fall stimulating the central chemoreceptors and replacing the arterial metabolic acidosis with a respiratory alkalosis. In metabolic alkalosis the CO_2 titration curve is shifted to the right in Figure 8.8G (Fig. 8.8F).

There is usually the same respiratory compensation, but less than in a metabolic acidosis. So the PCO_2 is elevated, which reduces the pH of CSF and leads to an increase in CSF the concentration of HCO_3^- (Fig. 8.8G).

Standard Bicarbonate

It is the bicarbonate concentration (HCO_3^- in mmol/L) in fully oxygenated blood which has been equilibrated at 37°C with gas mixture having a PCO_2 of 40 mm Hg. The normal range of standard bicarbonate (HCO_3^-) concentration is 22 to 26 mmol/L. It is an effective evaluation of only the metabolic status of

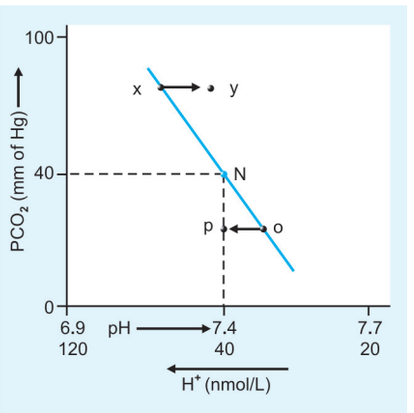

Fig. 8.8E: pH - PCO_2 changes during respiratory disturbances. Acute respiratory acidosis follows titration line N → x and alkalosis N → o. Renal compensation is slow and causes pH change x → y and o → p

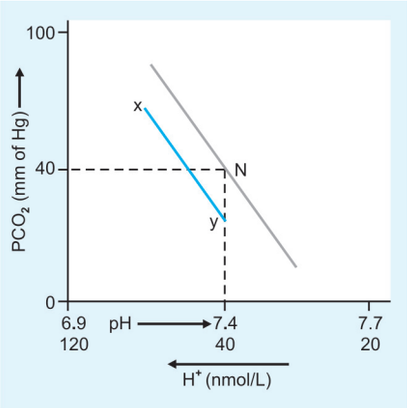

Fig. 8.8F: Acid-base change during non respiratory (or metabolic) acidosis. Respiratory stimulation allows pH to move N → x. In the absence of respiratory compensation, pH would be yF

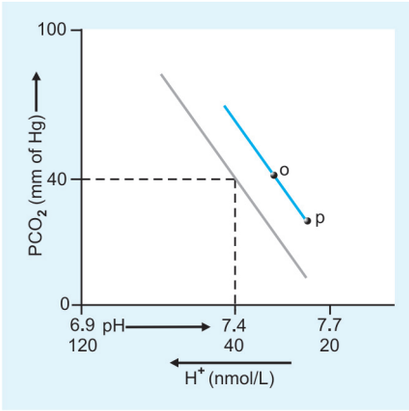

Fig. 8.8G: Acid base changes during metabolic alkalosis. Respiratory compensation allows pH to move N → o. In the absence of respiratory compensation pH would be p

acid-base balance. A standard bicarbonate level in excess of 26 mEq/L (in case of HCO_3^- the numerical value in mmol/L and mEq/L is same as valency of HCO_3^- is one. This is discussed in elecrolyte chapter) is a sign of the presence of a metabolic alkalosis. A standard HCO_3^- level less than 22 mEq/L is a sign of metabolic acidosis. To determine the metabolic acid-base status among the parameters such as the base excess, buffer base and standard bicarbonate, the first one is most useful and widely used. This can be calculated by extrapolation from the pH and PCO_2 value, using Siggaard- Andersen (SA) nomogram. (A nomogram is a graph with several scales line laid on the graph intersects the scale at related values of the variables. The values of any two variables can be used to find the values of the others).

SA Nomogram: $pH = p^K + \log [HCO_3^-]/[H_2CO_3]$

As H_2CO_3 concentration is directly proportional to PCO_2, therefore H_2CO_3 in the above equation for bicarbonate buffering system can be replaced by $\alpha\ PCO_2$. α is the solubility coefficient for CO_2 (0.03 mmol/L/mm of Hg).

The equation then becomes:

$pH = p^K + \log [HCO_3^-] / \alpha\ PCO_2$

The value of p^K for bicarbonate buffer system is 6.1at 37°C. Again at PCO_2 of 40 mm of Hg. the plasma bicarbonate concentration is about 25 mmol/L .

So, $pH = 6.1 + \log 25 / (0.03 \times 40) = 7.4$

Numerous graphic representations of this Henderson-Hasselbalch equation have been suggested. The important graphic representation is a pH − bicarbonate plot and the pH − log PCO_2 plot.

Siggaard-Anderson nomogram is the graphic representation of Henderson-Hasselbalch equation in which pH is plotted against log P_aCO_2 .

Lines can be plotted on this nomogram showing the changes in pH which occur when a sample with normal Hb is equilibrated with various concentration of CO_2. An arterial blood sample is taken and equilibrated with two gas mixture containing different but known concentration of CO_2 and then pH of the sample is measured. Two points are therefore plotted on the nomogram and joined by a straight line. This is called the buffer line and it describes the relationship between pH and P_aCO_2 in that particular blood sample. The pH of the patient's blood is measured anaerobically in the sample. Using this pH value and the buffer line, the CO_2 of the sample can be interpolated from the nomogram. The buffer line will cross the horizontal plasma bicarbonate line at a P_aCO_2 of 40 mm of Hg , where the bicarbonate value can be read. This is the standard bicarbonate.

Base Excess (BE)

It is not uncommon that there may be mixed respiratory and metabolic acid-base disturbance. Thus, the base excess measurement is one way of quantifying the metabolic component, when there is presence of mixed acid-base disturbance. The two examples will best illustrate this term-base excess.

First example

Let the initial measurements of an arterial blood sample are: pH is 7.6, P_aCO_2 is 55 mm of Hg, and Hb is 15 mg/dl. Then the blood sample is kept at 37°C, and equilibrated with CO_2 gas mixture to make the PCO_2 40 mm of Hg. Therefore, it will remove the respiratory component of the acid base abnormality. The pH is now 7.7. Next a strong acid is added to titrate the pH back to 7.4. The amount of acid required is found to be 20 mmol/L. Therefore, the base excess of the original sample is 20 mmol/L

Second example

Let the initial measurement of an arterial blood sample are: pH is 7.3, and P_aCO_2 is 20 mm of Hg, and Hb is 15 gm/dl. Then the blood sample is kept at 37°C and equilibrated with CO_2 gas mixture to make the P_aCO_2 40 mm of Hg. Now the pH is 7. Then a strong alkali is added to bring the pH to 7.4. The amount of alkali required is 15 mmol/L. Therefore, the base excess is −15 mmol/L. This also can be expressed as base deficit which is 15 mmol/L. Both the expressions such as base excess with –ve value or deficit with +ve value are commonly used. Usually, there should normally be neither a base excess nor deficit. So, the normal valve for base excess or deficit is zero.

Therefore, it is defined as a titrable base which can be titrated to pH 7.4 at PCO_2 of 40 mm of Hg and at temperature of 37°C. This is the base concentration of whole blood measured by titration against a strong acid or base to pH 7.4, at PCO_2 of 40 mm of Hg, and at 37°C. For acidosis (base deficit) titration is carried out with a strong base and for alkalosis titration is carried out by strong acid (base excess). Base excess is measured in mmol/L and is an attempt to quantify the excess or deficit of HCO_3^-. The normal range of base excess varies between −2 to +2 mmol/L (or 12 mEq/L). It represents residual buffering capacity.

The BE less than −2 signifies the presence of metabolic acidosis. Whereas, BE more than +2 signifies the presence of metabolic alkalosis. Nowadays, it is not necessary to perform this time consuming titration to measure the base excess. In practice, the base excess is derived from: (a) Siggaard-Anderson nomogram, (b) acid-base slide rule (Severinghans) or (c) mathematically as in many automatic blood gas analysers.

The base excess (unlike buffer base) measurement is independent of Hb concentration. Altering the Hb concentration of a blood sample would result in a change in pH and PCO_2 but no change in base excess.

Buffer Base

It is the sum of concentration of all the buffer anions in the blood such as HCO_3^-, phosphate, protein, Hb, etc. The normal values of buffer base depends on the Hb concentration. So, it is reduced in anaemia. Apart from the changes in Hb concentration, it is increased in metabolic alkalosis and decreased in metabolic acidosis. A rise in PCO_2 in respiratory acidosis does not affect it. Because although $[HCO_3^-]$ increases, the extra $[H^+]$ combine with Hb, so that the concentration of this ion is correspondingly reduced (Table 8.7).

Table 8.7: Uncompensated changes in acid-base status

	Acid-base state	*pH*	*Plasma bicarbonate*	*PCO_2*
	Normal	7.35 - 7.45	22 - 28 m.mol/L	36-46 mm of Hg
1.	Meta acidosis	Low	Low	Normal
2.	Meta alkalosis	High	High	Normal
3.	Res acidosis	Low	High	High
4.	Res alkalosis	High	Low	Low

$$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$$
$$\downarrow\uparrow$$
$$H^+ + Hb^- \leftrightarrows H.Hb$$

pH Measurement

H^+ concentration is measured directly by a glass electrode with a membrane which is only permeable to H^+ ions. Then, derived pH is displayed on a meter. PCO_2 is measured by the Seveinghaus electrode which incorporates a modification of the technique where a CO_2 permeable membrane is used. PO_2 is measured by Clark polarographic electrode (Table 8.8).

Our concept regarding acid-base balance is now changing. In the past, we concentrate on the concentration of the H^+, pH, PCO_2, standard bicarbonate, base excess/base deficit, etc. But, now the world is thinking on: strong ion difference (SID), PCO_2, total weak acid concentration (A_{TOT}), etc. to explain in best way the acid-base balance in physiological system. SID is the sum of all strong, completely dissociated cations such as Na^+, K^+, Ca^{2+}, Mg^{2+} minus the sum of all strong anions such as Cl^-, lactate, HCO_3^-, etc. When we calculate the SID, it indicates some unmeasured ions. PCO_2 is important because it is independent variable as respiration is going on.

TECHNIQUE FOR ARTERIAL BLOOD-GAS SAMPLING

The acid-base status of the most body tissues is reflected in that tissue's venous blood. But the brain is an important exception to this rule, as lactate produced by anaerobic metabolism is confined by the blood-brain barrier ion, the brain cells and CSF. Thus, the assessment of whole body acid-base status may be determined by analysis of mixed venous blood and this can only be achieved by pulmonary artery or at least, right ventricular sampling which is very difficult. So, most investigators use arterial blood as 'oxygenated mixed venous blood' to measure the different parameter of acid-base balance. This has the additional advantage that the arterial PO_2 may be determined from the same sample.

An alternative, which is particularly useful in small childen, is to use a sample of capillary blood. If this is taken from a warm, vasodilated part of the periphery, usually the hand or heel, then it has been shown that the PCO_2 is within 0.5 mm of Hg and the pH is within 0.005 units of simultaneously obtained arterial samples. But this capillary sampling is unsuitable for PO_2 determination.

Table 8.8: Acid-base status

Acid-base state	*Standard bicarbonate in mmol/L*	*Base excess in mmol/L*	*Total buffer base in mnol/L*
Normal	22-26	0 ± 3	44-48
1. Meta acidosis	Low	Negative	Low
2. Meta alkalosis	High	Positive	High
3. Res acidosis	Normal	Normal	Normal
4. Res alkalosis	Normal	Normal	Normal

Samples for arterial blood gas analysis is taken into a syringe whose potential dead space is filled with heparin in concentration of 1000 units/ml. There must not be any air bubble in the syringe and the blood should be well mixed with heparin. Excess heparin reduces the value of measured pH by virtue of its own acidity. Blood should be taken by direct arterial puncture from brachial, radial or femoral artery or withdrawn from an indwelling arterial cannula, taking care to avoid air bubbles.

Measurements should be done immediately after drawing of blood sample because metabolism will continue within the blood cells at room temperature and this will increase PCO_2 and decrease PO_2. Alternatively sample should be capped and stored in crushed ice. Temperature of the patient and the inspired O_2 concentration should be noted. Diffusion of CO_2 across the wall of plastic syringes does not produce a change in CO_2 tension within the first three hours of storage.

Capillary samples are often used in babies and are taken into special preheparinised glass capillary tubes. The PCO_2 and pH of capillary blood are close to those of arterial blood, taken at the same time. The PO_2 is less reliable.

DISTURBANCES OF ACID-BASE BALANCE

During the management of a patient with severe acid-base disturbances, it is very essential to keep in mind the clinical condition of the patient, while evaluating the laboratory results. An isolated pH measurement is totally valueless without an arterial PCO_2, and in the case of respiratory disease without an arterial PO_2, as well. Free H^+ are constantly being produced by the body, but changes in the H^+ concentration are kept to minimum by different buffering mechanisms of the body. Respiratory and renal compensatory mechanism come into play, when plasma buffering capacity is exceeded, in an attempt to achieve a normal plasma pH.

Classically, disturbances of acid base balance are divided into respiratory and metabolic acidosis or alkalosis and should be considered in relation to the Henderson-Hasselbalch equation which normally works in the following manner.

$pH = p^K + \log [HCO_3^- / H_2CO_3]$ I

$= p^K + \log 24 / 1.2$ (Normal plasma $[HCO_3^-]$ is 24 m.mol/L and $[H_2CO_3]$ is 1·2m.mol/L)

$= p^K + \log 20$

$= 6.1 + \log 20$ (p^K of bicarbonate system is 6.1)

$= 6.1 + 1.301$ (log 20 = 1.301)

$= 7.4$ (Fig. 8.8H).

Despite the apparent clear cut disturbances of acid-base balance, in practice there are often a mixed disorders. In such situations, when we are confronted with an estimation of blood gases, then it is important to isolate the most abnormal parameter, since other abnormalities are possibly secondary to this or of a compensatory in nature. So, in these circumstances an acid-base diagram may be very helpful. The Flenley acid-base diagram is an alternative way of looking at the acid-base disturbances and is infact a modification of the Siggard-Anderson nomogram in which bicarbonate buffer system only is considered. In it the linear relationship between the H^+ ion activity and P_aCO_2 is plotted on a graph in which isopleths of equal HCO_3^- concentration radiate out as a fan shapped manner from the origin or centre. The fan shaped radiation represents 95% confidence limits which are shown on the diagram. During acid-base disturbances serial values of blood gases are plotted on it to define the nature of the disturbance and its progress.

On this acid-base diagram, a point to the left of the normal pH of 7.4 implies an acidosis and a point to the right of the normal pH implies an alkalosis. The plasma bicarbonate can be read directly. This diagram is of great value during therapy, to monitor the changes in response to treatment.

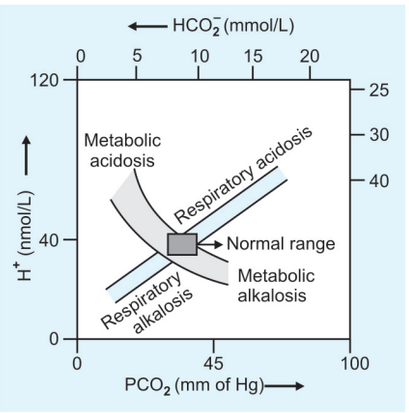

Fig. 8.8H: This is a Flenley acid-base diagram, which shows changes in blood H^+ concentration, PCO_2, HCO_3^- level in stable compensated acid base disorders. The rectangle at the centre indicates limits of normal ranges for H^+ concentration and PCO_2. The bands extending from the central rectangle represent 90% confidence limits for single disturbance of acid base balance. When the point is obtained by plotting H^+ concentration against PCO_2 and it does not fall within one of the bands, then compensation is incomplete or a mixed disorder is present

Siggaard-Andersen Nomogram

This nomogram is very useful to plot the acid-base characteristics of a sample of arterial blood. This nomogram has a vertical axis which indicates PCO_2 and a horizontal axis which indicates pH. Thus, any point to the right of a vertical line through pH 7.4 indicates alkalosis and any point to the left indicates acidosis. Similarly, the position of a point below or above the horizontal line through PCO_2 of 40 mm of Hg indicates the degree of hyper or hypoventilation, respectively (Fig. 8.9).

If a solution containing $NaHCO_3$ and no buffer is equilibrated with a blood sample containing gas mixture of various amount of CO_2, then at equilibrium the pH and PCO_2 value would fall along the line A or a line parallel to it. If buffers are not present, the steepness of the line will be greater and if buffers are present, the slope of the line will be greater. For normal blood containing 15 gm of Hb, the CO_2 titration line will pass through the 15 gm/dl mark on the haemoglobin

scale (point B) which is situated on the underside of the upper curved scale. This line will also pass through the point where the PCO_2 = 40 mm of Hg and pH = 74 lines will interact. When the Hb content of the blood is low, then there is significant loss of buffering capacity. It will cause the diminished slope of the CO_2 titration line. However, blood always contains some buffer in addition to Hb. So, the line drawn from the zero point on the Hb scale and through the normal PCO_2- pH intercept is steeper than the line for a solutions containing no buffers.

For clinical use, the arterial blood is drawn anaerobically and its pH is measured. The pH of same blood is again measured after equilibration with two gas mixtures containing different known amount of CO_2. This pH value at known CO_2 concentration are plotted and connected to provide the CO_2 titration line for the blood sample. The pH of the blood sample before equilibrium is plotted on this line and the PCO_2 of the sample is read from the vertical scale.

The standard bicarbonate content of the sample is indicated by the point at which the CO_2 titration line intersects the bicarbonate scale on the PCO_2 = 40 mm of Hg line. The standard bicarbonate is not the actual bicarbonate concentration. Rather, it indicates the remaining portion of bicarbonate which is present after elimination of any respiratory component. Actually, it is a measure of the alkali reserve of blood and like it, it is also an index of the degree of metabolic acidosis or alkalosis. But the difference is that standard bicarbonate is measured by determining the pH, rather than the total CO_2 content of the sample after equilibration.

The buffer base also can be measured from the additional graduations on the upper curved scale of the nomogram. The point where the CO_2 titration line of the arterial blood sample intersects this scale shows the buffer base in meq/L. The normal value of it in an individual with 15 gm/dl of Hb is 48 meq/L. The buffer base is equal to the total number of buffer anions such as protein, HCO_3^-, Hb^-, etc, which can accept H in blood.

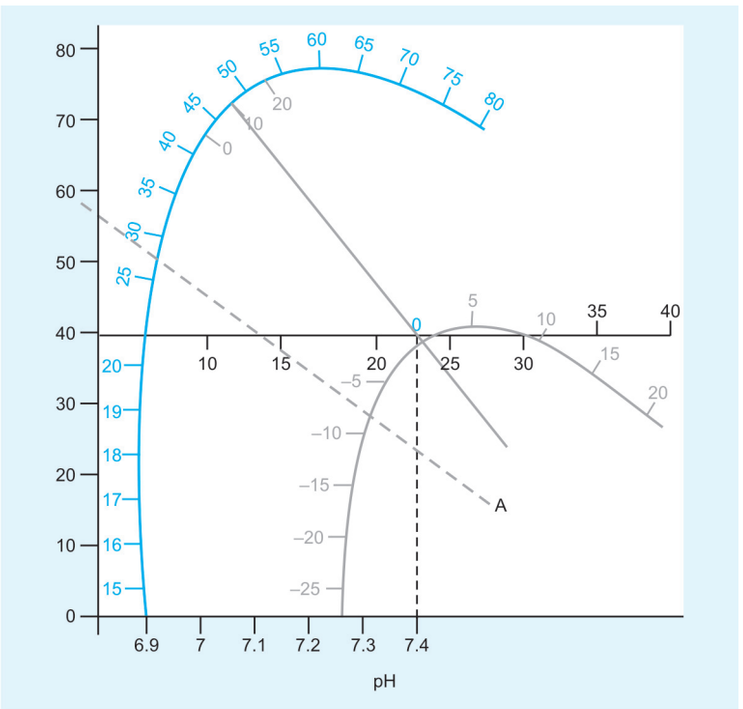

Fig. 8.9: Siggaard -Andersen nomogram (schematic diagram)

Base excess also can be calculated from this nomogram. The point at which the CO_2 titration line intersects the lower curved scale indicates the base excess. It is defined as the amount of acid or base that would restore one litre of blood to normal acid base composition at a PCO_2 of 40 mm of Hg. It is positive in alkalosis and negative in acidosis.

RESPIRATORY ACIDOSIS (TABLE 8.9)

The typical blood picture of pure respiratory acidosis will be like that pH < 7.40, Pa CO_2 > 40 mm of Hg and H CO_3^- > 24 mEq/L. This is due to the the excess of of CO_2 in blood. This excess of CO_2 in respiratory acidosis is due to the the lack of excretion through lungs or excess production from hypermetabolism or excess inhalation of CO_2. It may be acute or chronic in nature. But the compensatory response to acute elevation of PCO_2 in respiratory acidosis is limited. This is because ventilation can not be increased to excrete excess CO_2 as the pathology is within the lungs. Buffering is primarily provided by Hb and the exchange of H^+ (produced by reaction of CO_2 with H_2O) for Na^+ and K^+ from bone and intracellular fluid. The renal response to retain more HCO_3^- as a compensatory process is also very limited in acute condition. Latter slowly renal compensation occurs. The normal arterial CO_2 tension in blood is 35 to 45 mm of Hg. The term 'respiratory acidosis' means that P_aCO_2 is higher than this normal value and this CO_2 becomes hydrated to H_2CO_3, so that the value of log $[HCO_3^-]$ / $[H_2CO_3]$ in equation I falls with a fall in pH. The kidney compensates this respiratory acidosis by retaining more HCO_3^- and excreting more H^+ and thus tries to reduce or compensate the fall in pH. Thus, renal compensation causes to increase in plasma and CSF bicarbonate (HCO_3^-) level, so as to return pH towards normal. But, an acute increase in P_aCO_2 results in acute increase in H_2CO_3 which does not get anytime for

Table 8.9: Causes of respiratory acidosis

1. Parenchymal lung diseases
   Pneumonia, collapse, aspiration, pulmonary emboli, pulmonary oedema, interstitial lung disease, etc.
2. Airway obstruction
   Asthma, foreign body, tumour, laryngospasm, COPD, etc.
3. Skeletal abnormalities
   Myopathies, neuropathies, flail chest, kyphoscoliosis, poliomyelitis, myasthenia gravis, tetanus, etc.
4. Pleural abnormalities
   Pleural effusion, pneumothorax.
5. CNS depression
   Drug overdose, trauma, tumour, CVA, Obesity hypoventilation (Pickwickian syndrome).
6. Ventilator malfunction Increased CO_2 production

Thyroid storm, malignant hyperpyrexia, severe shivering, thermal injury, etc.

compensation by kidney. For every 10 mm of Hg rise of PCO_2, there is 8 nmol/L rise of H^+ but only 0.08 m.mol/L rise of HCO_3^- and the relation between PCO_2 and H^+ concentration is linear. But the relation between the logarithmic scale of H^+ concentration (pH) and PCO_2 is not linear. The approximate relation between pH and PCO_2 is: for every rise of 10 mm of Hg of PCO_2, there is decrease of 0.07 unit of pH within 30 to 60 mm of Hg range of PCO_2. Beyond this range the decrease of pH is more faster. In chronic respiratory acidosis with renal compensation, as the ratio of HCO_3^- to H_2CO_3 (or PCO_2) approaches to normal by the retention of HCO_3^-, so the changes in HCO_3^- is greater and the changes in pH is less than for an acute disturbance. So, in chronic hypercapnia with renal compensation, every 10 mm of Hg increase of PCO_2 results in 4 mmol/L increase of HCO_3^- and 3.2 n.mol/L rise of H^+ with 0.03 unit decrease of pH. The upper limit of HCO_3^- for compensation in acute respiratory acidosis is 30mEq/L and in chronic respiratory acidosis is 50 mEq/L. If the measured HCO_3^- is higher than expected HCO_3^- level, then metabolic alkalosis is also present. On the other hand, if measured HCO_3^- is below the expected HCO_3^- level, then associated metabolic acidosis is present. The expected HCO_3^- after compensation is acute resp. acidosis: $HCO_3^- = (PCO_2 - 40) \times 0.1 + 24$. In chronic resp. acidosis this formula is: $HCO_3^- = (pCO_2 - 40) \times .35 + 24$.

This secondary renal compensatory change in response to respiratory acidosis is slow to develop, and it may take many days for full compensation to occur. The compensatory response to a chronic respiratory acidosis is therefore a metabolic alkalosis (retention of HCO_3^- by kidney) which tends to return the pH to normal. In the presence of acute hypercapnia which happens during GA, there is no time for any appreciable renal compensation to occur. During apnoea the arterial PCO_2 rises about 3 to 6 mm of Hg per minute and H^+ accumulate at a rate of 10 nmol/min. This is 20 times faster than the kidney to excrete them.

The high arterial PCO_2 in respiratory acidosis can be produced by:

i. If CO_2 production remains constant, but alveolar ventilation (V_A) is reduced e.g. COPD, parenchymal lung disease, lung injury, acute respiratory depression by narcotics, impaired neuromuscular function such as relaxant drugs, myasthenia gravis, poliomyelitis, peripheral neuritis etc.
ii. If CO_2 production is raised but V_A does not rise sufficiently to excrete the extra CO_2 e.g. fever.
iii. If CO_2 tension in inspired air ($FiCO_2$) is raised, e.g. rebreathing of CO_2 from expired air due to malfunctioning of anaesthetic apparatus.

Systemic Effects of Respiratory Acidosis (Hypercapnia)

The respiratory acidosis or hypercapnia has multiple systemic effects. The central nervous system effects include: impairment of mental activity, loss of consciousnes, ↑central blood flow due to cerebral vasodilation, ↑CSF pressure, and stimulation of respiration followed by depression if PCO_2 rises gradually.

The general sympathetic over activity also occurs due to hypercapnia. If high inspired O_2 concentration is not delivered during hypercapnia, then hypoxaemia also follows hypercapnia and there after profound effects of these both (i.e hypoxia and hypercapnia) are seen on the CVS. The heart muscles are depressed by high blood CO_2 level. However, this effect is partly offset by the increased sympathetic activity due to hypercapnia. This increased sympathetic activity, accompanied by peripheral vasodilation cause rise in CO but causes pulmonary vasoconstriction. As the arterial PCO_2 rises due to hypo ventilation from low to high values then the cardiac output (CO) increases at first gradually only due to the (Table 8.10) increase in stroke volume. Later, the increase in cardiac output is due to the increase in both the stroke volume and the heart rate. These changes are accompanied by a rise in mean arterial pressure and a fall in peripheral vascular resistance (due to vasodilatation). Thus, the gradual rise of CO_2 tension in blood causes tachycardia. This is followed by bradycardia and depressed conduction in heart, particularly in the bundle of His, when plasma pCO_2 rises to very high. So, in severe hypercapnia the heart block and a slow ventricular rhythm is commonly observed, with an increased myocardial irritability. A rise in the CO_2 tension in blood increases the secretion of catecholamines (mainly epinephrine) from the sympathetic nerve ending within the myocardium. There is also an increase in plasma epinephrine and norepinephrine level due to secretion from the adrenal glands due to high CO_2 level. At the same time during anaesthesia the sensitivity of a target organs to catecholamines by volatile anaesthetics is increased by high plasma PCO_2. So, many anaesthetic agents, primarily halothane, cause arrhythmia in presence of high CO_2 level. Thus, both increased catecholamine level and increased sensitivity make the halothane responsible for frequent arrhythmia during hypercapnia. In such situation, improving

Table 8.10: Characteristic changes in arterial H^+ concentration, PCO_2 and HCO_3^- level in different acid-base disturbances

Disorder	*H^+*	*nmol/L*	*P_aCO_2*	*mm of Hg*	*HCO_3^-*	*nmol/L*
Resoiratory acidosis						
Acute	+	60	+ +	70	WNR	28
Compensated (by renal retention of HCO_3^-)	Slight ↑ or WNR	44	+ +	66	+ +	40
Respiratory alkalosis						
Acute	–	22	– –	20	WNR	22
Compensated (by renal excretion of HCO_3^-)	Slight ↓ or WNR	36	–	30	–	15
Metabolic acidosis						
Acute	+	60	WNR	40	– –	12
Compensated (by ↑ ven)	Slight ↑ or WNR	48	–	30	– –	13
Metabolic alkalosis						
Acute	–	26	WNR	40	+ +	42
Compensated (by ↓ ven)	Slight ↓ or WNR	35	+	60	+ +	40

Normal H^+ concentration = 35 to 45 nmol/L, P_aCO_2 = 35 to 45 mm of Hg, HCO_3^- = 21 to 28 mmol/L, WNR = within normal range, + = increased, – = decreased.

ventilation and reducing the dose of halothane will help to restore the normal rhythm.

During hypercapnia, the blood pressure rises due to sympathetic stimulation. So increased bleeding is seen through surgical wounds. The patient presents with warm skin, dilated veins and bounding pulse. There is also small rise in plasma potassium level. Oxyhaemoglobin dissociation curve is shifted to the right in any acidosis. But it is important to mention that under anaesthesia many of the above signs may be masked.

It is important to emphasise that during anaesthesia the anaesthesists are largely responsible for controlling the arterial PCO_2 at about the normal level. The main difficulty for the anaesthesist is to recognise the minor degrees of hypoventilation clinically. The time-honoured custom of looking only at the reservoir bag and thinking that ventilation is adequate is often grossly erroneous, especially for high risk patients. Fluctuation of P_aCO_2 between 40 and 60 mm of Hg is probably of little consequence in normal, healthy patient. But, when the arterial PCO_2 rises to around 80 mm of Hg, it denotes a severe and dangerous hypoventilation. When CO_2 level rises to 110 mm of Hg, then CO_2 narcosis occurs. In such situation, the patient will not regain consciousness, even when the anaesthetic drugs are withdrawn. If, at this moment, the patient is allowed to breath room air, simply because the operation is over then he will be with the disadvantage, because alveoli filled with anaesthetic gases (usually N_2O) escaping from circulation will cause diffusion hypoxia. This hypoxia will again increase due to the uneven ventilation-perfusion ratio, which normally follows anaesthesia and also due to the reduced quantity of available oxygen from the lungs due to high CO_2 tension. Thus, hypoxia will occur definitely.

Treatment

The treatment of respiratory acidosis is aimed at the underlying causes, for example improving ventilation by using intermittent positive pressure ventilation, if respiration is depressed or totally absent. Rebreathing of CO_2 should be avoided. Dead space of the anaesthetic apparatus should be reduced. Alkali therapy has no place in chronic respiratory acidosis. In COPD, the aim of treatment of respiratory acidosis should be to lessen the H^+ activity just less than 56 nmol/L (pH > 7.25), rather than to normalise completely. This is because the acidity of the blood which is important to maintain the ventilation through the chemoreceptor mediated ventilatory drive by CO_2 in COPD patient and this is modified by renal compensatory HCO_3^- retention. It is too difficult to assess the P_aCO_2 simply by clinical examination. So, repeated blood gas monitoring is of course mandatory. If IPPV is used to produce normal P_aCO_2 then the patient will be left with variant HCO_3^- level and metabolic alkalosis.

The typical blood gases level in acute situation of respiratory depression and acidosis without any compensation are like this:

pH → 7.2,
P_aCO_2 → 70 mm of Hg,
HCO_3^- → 29 mmol/L.

In the more common COPD, where renal compensation has occured, typical blood gases findings are like this:

pH → 7.3,
P_aCO_2 → 60 mm of Hg,
HCO_3^- → 35 mmol/L,
P_aO_2 → 70 mm of Hg.

The alveolar gas equation in a case of respiratory acidosis always predicts that hypoxia is must accompanied with ↑ $PaCO_2$ due to poor ventilation. The resultant fall in PaO_2 limits hypercapnia

to approximately 100–110 mm of Hg. Higher $PaCO_2$ imposes PaO_2 so low that it is incompatible to life. Under such circumstances it is hypoxia, but not hypercapnia which poses the principal threat to life. So, administration of O_2 along with ventilation is the most critical part of the management of respiratory acidosis.

Naloxone and flumazenil is important to treat hypercapnia if it is due to opioid or benzodiazepine overdose. During mechanical ventilation minute ventilation should be gradually raised in such a fashion that $PaCO_2$ will gradually return to higher side of normal base level. Rapid reduction of $PaCO_2$ risks the development of posthypercapnic alkalosis with potential serious consequences. If posthypercapnic alkalosis is developed, then it should be treated with chloride, usually as its K-salt and administering bicarbonate wasting diuretic such as acetazolamide at the doze of 250–350 mg once or twice daily.

Differentiation between primary respiratory acidosis and compensated respiratory and metabolic alkalosis

	pH	*$PaCO_2$*	*HCO_3^-*
Primary respiratory acidosis	7.30	55	24
Compensated respiratory acidosis	7.38	50	30
Compensated metabolic alkalosis	7.42	50	32

Explanation

In primary resp. acidosis HCO_3^- is in normal value. So no renal compensation. In compensated resp. acidosis HCO_3^- elevated, pH is on the acidotic side of normal range compensated metabolic alkalosis looks like compensated respiratory acidosis but diagnostic point is pH is on alkali side.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is the most frequently found acid-base disorder. Because it occurs in normal pregnancy and high altitude dwellers. It is also particularly prevalent among the critically ill patients. In this group of patient it carries band prognosis, because mortality increases in direct proportion to the severity of hypocapnia. The usual blood picture of primary respiratory alkalosis is pH > 7.40, $PaCO_2$ < 40 mm of Hg, HCO_3^- < 24 mEq/L. In most of the cases pH does not exceed 7.55 and severe manifestation of alkalaemia is usually absent.

$pH = p^k + \log [HCO_3^-] / [H_2CO_3]$.

In this situation, CO_2 is washed out due to hyperventilation and this reaction:

$CO_2 + H_2O \leftrightarrows H_2CO_3 \leftrightarrows H^+ + HCO_3^-$

is shifted to the left leaving HCO_3^- in excess in respect to H^+ concentration in plasma. Thus, plasma H_2CO_3 level is reduced in respect to H^+ and log $[HCO_3^-] / [H_2CO_3]$ value is increased with an increase in pH. Compensatory changes occur if the disturbance is prolonged. The kidney compensates for this rise in pH by excreting more HCO_3^- (Table 8.11) and retaining more H^+ and thus restore pH to normal by reducing the log $[HCO_3^-] / [H_2CO_3]$ ratio. By reabsorbing less HCO_3^- and secreting less H^+ it produces an alkaline urine. The secondary response to a respiratory alkalosis is therefore a metabolic acidosis (retention of H^+). But, this secondary compensatory response is reduced in anaesthetised person due to fall in renal blood flow. So it is not uncommon to find mild metabolic acidosis in anaesthetised hyperventilated patient with mild respiratory alkalosis.

An uncompensated respiratory alkalosis leads to the following changes in blood such as low P_aCO_2, low plasma bicarbonate, high pH but normal buffer base, base excess and standard bicarbonate level. In acute respiratory alkalosis or hypocapnia there is decreased level of PCO_2, H^+ and HCO_3^-. But decrease of H^+ in comparison to HCO_3^- is more (reverse of the respiratory acidosis). An acute decrease of 10 mm of Hg of PCO_2 results in decrease of 2 mmol/L of HCO_3^- against 8 nmol/L decrease of H^+. The pH increases by 0.08 unit for every 10 mm of Hg decrease of PCO_2. Renal compensation for chronic respiratory alkalosis causes a decrease in tubular H^+ secretion and diminished HCO_3^- reabsorption. So, plasma HCO_3^- level decreases and the ratio of HCO_3^- to H_2CO_3 (pCO_2) approaches to normal by compensation. In chronic compensated respiratory alkalosis, each 10 mm of Hg decrease in PCO_2 is associated with 6 nmol/L decrease in H^+ and 0.03 unit increase of pH. After compensation, if the measured HCO_3^- is higher than the expected level, then metabolic alkalosis is present along with respiratory alkalosis. On the other hand, if the measured HCO_3^- is lower than the expected level, then associated metabolic acidosis is present along with respiratory alkalosis. The expected HCO_3^- after compensation in acute resp. alkalosis is HCO_3^- = 25 – (40–$PaCO_2$) × .25. In chronic resp. alkalosis this formula is HCO_3^- = 25 – (40 Pa CO_2) × .5.

The main danger of respiratory alkalosis under anaesthesia is cerebral vasoconstriction. This is because it is known that arterial PCO_2 largely controls the diameter of these cerebral vessels. Thus, a severe alkalosis may produce intense cerebral vasoconstriction and decreases intracranial pressure by decreasing CBF. The cerebral effects of hyperventilation or hypocapnia such as euphoria and analgesia also have been demonstrated. But, whether they are only due to cerebral vasoconstriction or due to direct action of low CO_2 tension on the brain cells is not definitely known. However, the latter seems to be much

Table 8.11: Causes of respiratory alkalosis

CNS stimulation causing hyperventilation

Anxiety, pain, fever, infection, drug induced (salicylates), stroke, tumour, hysteria etc.

Peripheral stimulation causing hyperventilation

Hypoxaemia, anaemia, high altitude, shock, pregnancy, pulmonary diseases, etc.

Iatrogenic

IPPV

more likely. It is also true that long periods of severe respiratory alkalosis leading to cerebral damage is still lacking. So most clinicians believe that a mild respiratory alkalosis is more beneficial for the patient, rather than a mild respiratory acidosis.

Other features of respiratory alkalosis are hypokalaemia, increased neuromuscular excitability producing tetany due to decreased ionic Ca^{2+} concentration, a tendency towards increased ventricular irritability and a shift to the left of Hb-O_2 dissociation curve. This causes increased O_2 affinity to Hb and less unloading of it to tissues which is again prevented by rise in 2-3 DPG level by alkalosis. Decrease in the level of 2-3 DPG tries to shift the Hb-O_2 dissociation curve to right and help in unloading of O_2 to tissues.

Alkalaemia reduces the original threshold and predisposes the patient to refractory supraventricular and ventricular arrhythmias. This cardiac effect is more evident in patients with underlying heart disease. Alkalosis also depresses respiration. This effect is of little consequence in healthy patient. But this effect is very prominent in a patient who is on ventilator. In such patient even mild alkalaemia can frustrate the efforts to wean from ventilator.

Hypokalaemia is a almost constant feature of any alkalaemic disorder. But it is more prominent in those of metabolic origin. Translocation of K^+ into cells, and renal losses of it are the cause of hypokalaemia in alkalosis. This hypokalaemia has several adverse effects. These are: neuromuscular weakness, polyuria, increased ammonia production (that can highten the risk of hepatic encephalopathy), digitalis induced arrhythmia, etc. Alkalosis stimulates anaerobic glycolysis and increases the production of lactic acid and ketoacids.

Respiratory alkalosis in commonly associated with hyponatraemia, hypokalaemia, hypocalcaemia (ionised Ca^{2+}) and hyperchloraemia.

During anaesthesia with controlled ventilation the low PCO_2 causes the cardiac output to fall. This is because the main determinants of the cardiac output during anaesthesia is the arterial PCO_2 level.

Causes of Respiratory Alkalosis

The causes of respiratory alkalosis are:

i. Cortical stimulation causing hyperventilation due to pain, fear, anxiety, analeptic drugs, salicylate poisoning, head injury, hepatic failure, pregnancy, labour pain, etc.
ii. Hyperventilation by hypoxic drive due to high altitude, haemorrhagic shock or any other shock. A hypoxic drive from peripheral chemoreceptor occurs at high altitude and probably explain the cause of hyperventilation and respiratory alkalosis.
iii. Cardiopulmonary diseases: asthma, pulmonary oedema, pulmonary embolism, etc. All these factors may also cause respiratory acidosis, but will depend on the degree of stimulation of respiration causing hyperventilation and the lung condition causing the retention of CO_2.
iv. Excessive IPPV during long-term ventilatory support.
v. Hysterical overbreathing.

An important and serious clinical hazard of acute hyperventilation or respiratory alkalosis occurs, when it is super imposed upon pre-existing metabolic alkalosis. Because it may result in severe hypokalaemia, especially in the presence of digitalis leading to severe ventricular arrhythmias. In such situation, severe depletions of body's CO_2 store occurs. When hyperventilation ceases, then the stores of CO_2 are gradually replaced during the period of hypo ventilation. The O_2 consumption is unchanged and the respiratory quotient RQ (CO output/O_2 consumption) is decreased during respiratory alkalosis. The reduction in RQ in respiratory alkalosis causes a decrease in P_aO_2 and is thus another reason why patient should receive additional O_2 during weaning from mechanical ventilation, if there is hyperventilation.

Treatment

Whenever possible the management of respiratory alkalosis must be directed correcting the underlying cause. In most cases, especially chronic cases pose little risk to health and produce few or no symptoms. So in such circumstances measures to treat the deranged acid-base status is not required. In anxiety hyperventilation syndrome sedation and psychotherapy is very helpful. Rebreathing into a paper bag on through any closed system provides prompt relief, but it is short lived.

Differentiation between primary respiratory alkalosis and compensated resp. alkalosis and compensated metabolic acidosis

	pH	*$PaCO_2$*	*HCO_3^-*
Primary respiratory alkalosis	7.55	30	24
Compensated respiratory alkalosis	7.45	28	15
Compensated metabolic acidosis	7.35	30	17

Explanation

In primary respiratory alkalosis as there is no compensation, so HCO_3^- is in normal range. In its compensated form pH comes down, but on slightly alkali side and HCO_3^- falls. In compensated metabolic acidosis $PaCO_2$ falls for compensation and pH is slightly on acidic side after compensation.

Correction of respiratory alkalosis can be made by preventing the increased central or peripheral respiratory drive, if this is appropriate. Mechanical ventilation should be controlled by monitoring the arterial or end-tidal pCO_2.

METABOLIC ACIDOSIS

This occurs when an abnormal amount of metabolic acids (noncarbonic acid) are formed and accumulate or an abnormal loss of base occurs. So, as a compensatory mechanism the level of PCO_2 (marker of respiratory acid base status) in blood is reduced. This is manifested

secondarily by hyperventilation which try to mitigate the ratio of HCO_3^- /H_2CO_3 to normal level (compensatory respiratory alkalosis). Here, the sources of H^+ are nonvolatile acids or fixed acids and not the H_2CO_3, coming from reaction of CO_2 with water. Normally, the different types of nonvolatile acids such as lactate, acetoacetic acid, hydroxybutyric acid, acetone free fatty acids, etc, are produced in variable amounts during metabolism of different substrates (discussed before) and have relatively little renal excretion. They are normally removed by metabolism in the liver with regeneration of bicarbonate. However, fixed acids including HCl, H_2SO_4 and H_3PO_4 can only be eliminated by renal excretion. If uncompensated, then the changes due to metabolic acidosis seen in blood are: low pH, low plasma bicarbonate, normal PCO_2, a negative base excess, and a low standard bicarbonate. But, typical values after compensation are: pH less than 7.36 (H^+ concentration is more than 44 n.mol/L) P_aCO_2 less than 35 mm of Hg (compensated), HCO_3^- less than 18 mmol/L (compensated).

In metabolic acidosis an increase in anion gap may occur and an insight of the overall buffering capacity of the body during this acid base disturbance may be available by calculating this anion gap. These represents those negative ions which is not normally measured in clinical practice, including phosphate, sulphate, lactate, ketoacids and albumin. The working formula is: anion gap = plasma Na^+ − (plasma Cl^- + plasma HCO_3^-). Normally the value of anion gap varies between 8 to 14 mmol/L. Where excessive acid is added to the plasma, either by metabolic disorder or by addition of exogenous acid or there is failure of acid excretion, then this anion gap is increased. In metabolic acidosis, the value of log HCO_3^- / H_2CO_3 will be reduced due to low HCO_3^- or high H_2CO_3 level and hence pH falls. In metabolic acidosis though CO_2 does not accumulate excessively to form much H_2CO_3, but it is formed excessively by the reaction of $H^+ + HCO_3^- = H_2CO_3$ where the equation is shifted to the right and further reduces the HCO_3^- level. This H^+ comes from metabolic acids, such as lactic acid, keto acids, pyruvic acid etc. This H^+ stimulates chemoreceptors and increases ventilatory drive to washout CO_2 for compensation (compensatory respiratory alkalosis). Thus, CO_2 is excreted ($H_2CO_3 \leftrightarrows H_2O + CO_2$) from H_2CO_3 through lungs as a compensatory process, resulting in decrease in PCO_2 or H_2CO_3 level and attenuation of the fall in pH. Although the reduction in PCO_2 is rapid, still the respiratory response is only capable of 50 to (Fact file- II) 70% compensation for the metabolic acidosis. In other word, an uncorrected metabolic acidosis which would reduce the pH to 7 is normally compensated to a pH of 7.2 to 7.3.

The typical blood picture of a metabolic acidosis is pH < 7.40, $PaCO_2$ < 40 mm of Hg, and HCO_3^- < 24 mEq/L. If the measured $PaCO_2$ from a blood sample is higher than the expected $PaCO_2$ (which should be reduced), then it should be thought that additional respiratory acidosis is present. On the other hand, if the measured $PaCO_2$ is less than the expected $PaCO_2$, then an additional respiratory alkalosis is present. There are the mixed disorders. In a compensated metabolic acidosis the expected $PaCO_2$ is calculated as: $(1.5 \times HCO_3^-) + 8 \pm 2$.

Profound derangements of K^+ level occur in metabolic acidosis. For every decrease in 0.1 pH, there is equivalent 0.8 increase in K^+ level. Correction of it usually not required, unless there is threat to life. Because correction of acidosis will correct it.

Causes of Metabolic Acidosis

The causes of metabolic acidosis are:

A. *Accumulation of acid:*

a. Diabetic ketoacidosis where blood levels of lactic acid, aceto-acetic acid,

FACT FILE - II

Anion Gap (AG)

It is a very useful clinical tool for (i) narrowing the differential diagnosis of metabolic acidosis, (ii) identifying the variety of acids originated in metabolic disorder and (iii) recognising certain mixed acid base disturbances. The anion gap is generally measured from the concentration of four common electrolytes such as Na^+, K^+, Cl^- and HCO_3^-. Sometimes K^+ is excluded from the calculation. Then the calculation will be:

$Na^+ = Cl^- + HCO_3^- + AG$

or $AG = Na^+ - [Cl^- + HCO_3^-]$

Otherwise, the usual formula is (if K^+ included in the calculation):

Na^+ (140) + K^+ (5) = Cl^- (105) + HCO_3^- (25) + AG (15)

or $AG = [Na^+ + K^+] - [Cl^- + HCO_3^-]$

The normal range of AG is 12 ± 4 mEq.

Some causes of metabolic acidosis release anions in extracellular fluid which are not normally measured. But, when this occurs there will be an unexpected discrepeancy between the sums of the principal cations and anions. When there is some additional unmeasured anions, they become part of the gap which will be the larger. A anion gap larger than 30 mEq suggests that there is an increase in the concentration of the unmeasured anions. An increased AG is the only clue that metabolic acidosis is present isolatedly or in a mixed acid base disorder. The AG indicates the quantity of added acids. The fall in HCO_3^- also equals the rise in AG. It is useful in following the response of patient treating for diabetic ketoacidosis or other metaboic disorder.

In anion gap metabolic acidosis (AG > 12 mEq), there is decrease in HCO_3^- level. This is due to buffering of an acid whose anion is other than Cl^- (such as H_2SO_4, lactic acid etc). Hence, it is called normochloraemic acidosis. These acids may be endogenous (lactic acid, keto acid, uraemic acid) or exogenous (salicylates) or the endogenous metabolic products of exogenous toxins (such as methanol, ethanol, etc). Other unmeasured anions are proteins, phosphates, sulphates etc.

There is another metabolic acidosis where there is no anion gap (AG = 8 to 12 mEq), but decrease in HCO_3^- level. This is due to buffering of an acid whose anion is Cl^- (such as HCl acid). So, this is called hyperchloraemic acidosis.

betahydroxybutyric acid, α-ketoglutaric acid, and acetone are increased.

b. Lactic acidosis due to starvation. C. Administration of large volume of stored blood, where ACD is used as an anticoagulant. It produces an acute acidosis, although hepatic metabolism of the citrate in the next 2 to 3 days will convert this to a non-respiratory alkalosis.

c. Renal tubular acidosis (RTA) – The RTA is a type of metabolic acidosis where the cause is in renal tubule. It results either from a defect in reabsorption of bicarbonate in the proximal tubule or from a defect in failure of secretion of H^+ (failure of acidification of urine) from collecting tubules. Decreased reabsorption of bicarbonate causes large amount of losses of HCO_3^- in urine and marked reduction in plasma HCO_3^-. In failure of secretion of H^+, there is also failure of secretion of Cl^-. So there is persistant hyperchloraemic acidosis. It is also associated with hypercalciuria, hyperphosphaturia and loss of Na^+ in urine.

d. Salicylate over dose.

e. Hypoxia – It causes acidosis by metabolising pyruvate to lactic acid, but not to acetyl CoA which is the gateway of pyruvate to TCA cycle in the presence of O_2.

f. Low cardiac output (CO) − producing tissue hypoxia.

g. Following cardiac arrest − Anaerobic metabolism and acidosis occurs in cardiac arrest.

Substances such as paraldehyde, methyl alcohol, ethylene glycol, fructose, sorbitol, xylitol, ethanol, etc, may also cause metabolic acidosis. There may also be an increase in H^+ concentration from accumulated HCl which is released during the metabolism of arginine and lysine present in synthetic amino acid solution and following the therapeutic use of NH_4Cl.

An uncommon, (but probably over emphasised), form of metabolic acidosis also occurs when sometimes extracellular bicarbonate is diluted with saline which is used excessively during over enthusiastic replacement therapy. Such administration of excessive NaCl only occurs during the resuscitation of a severly hypovolaemic patient, in whom the restoration of circulatory volume by an isotonic fluid is an urgent requirement to restore the tissue perfusion and aerobic metabolism. A mild metabolic acidosis occurs in GA. It is also commonly observed after a period of extra corporeal perfusion, after circulating arrest, after hypothermia, following temporary occlusion of a major vessel such as aorta, massive blood transfusion, etc.

B. *Loss of Bicarbonate:*

i. From GI Tract
   a. fistula of small intestine, pancreatic fistula or biliary fistula.
   b. diarrhoea.
   c. uretero enterostomy.
   d. cholestyramine.

ii. From Kidney
   a. renal tubular acidosis.
   b. Use ofcarbonic anhydrase inhibitor (CAI) such as acetazolamide (explained before).

In metabolic acidosis, the body will try to compensate this fall of pH by stimulation of respiration, leading to fall in P_aCO_2 which will try to return the pH towards normal by reduction the H_2CO_3 level in blood. Although the fall in pH is modified but it does not return completely to normal (Table 8.12).

Effects of Metabolic Acidosis

The effects of metabolic acidosis are :

i. Initially, the acidosis stimulates the CVS and increases CO and BP. But later the heart muscles are depressed and CO falls. The cardiovascular responses to sympathetic activity or sympathomimetic drugs are initially increased and then reduced. Intense peripheral vasoconstriction occurs initially. These changes further tend to intense the acidosis, so that a vicious cycle is set up.

ii. Increase in circulating catecholamines.

iii. Increased H^+ will tend to displace K^+ from the intracellular fluid which result in hyper kalaemia.

iv. Cardiac arrhythmias and arrest.

v. Pulmonary hypertension.

vi. Mental changes.

vii. Metabolic acidosis stimulates the peripheral and central chemoreceptors by increased H^+. Thus, ventilation is increased and arterial and CSF PCO_2 and HCO_3^- are lowered, untill the pH returns almost to normal. If the pH is corrected rapidly by $NaHCO_3$, then the blood and CSF pCO_2 will rise and pH will fall stimulating central chemoreceptor and replacing metabolic acidosis with respiratory alkalosis.

viii. Hb-O_2-dissociation curve will shift to the right.

Management

The treatment of metabolic acidosis is directed towards the underlying causes.

Table 8.12: Causes of metabolic acidosis

With increased anion gap (AG)	
A.	Increased production of acid
	Starvation, diabetic ketoacidosis, lactic acidosis, inborn errors of metabolism, alcohol, etc.
B.	Reduced excretion of acid
	Renal failure.
C.	Administration from outside
	Salicylates, para-aldehyde, ethylene glycol, methanol.
With normal anion gap	
A.	Loss of bicarbonate
	i. Renal—Renal tubular acidosis, carbonic anhydrase inhibitors, hypoaldosteronism, etc.
	ii. Extrarenal — Diarrhoea, fistula (biliary, pancreatic, small bowel), ileostomy, ureterosigmoidostomy, etc.
B.	Addition of acids (chloride containing)
	Administration of NH_4Cl, HCl, lysine hydrochloride, arginine hydrochloride, total parenteral nutrition (Cl^- salts of amino acid), etc.

It is generally more serious than respiratory acidosis, because aetiology of metabolic acidosis is more life threatening. Treatment of metabolic acidosis is also very difficult and more complex than treating respiratory acidosis. Therefore, therapy with $NaHCO_3$ should be reserved for fairly severe disorders, since it is not without hazards.

If the pH is very low (< 7.2), then the metabolic acidosis itself becomes life threatening, because of its serious effects on the heart. Therefore, in such circumstances $NaHCO_3$ should be given IV without delay. If the acidosis is less severe, then the management depends upon: the diagnosis of the causes, associated disorder of electrolyte and fluid balance, and whether the acidosis is still developing or not. Thus, for example, a patient with diabetic ketoacidosis and base excess of –12 mmol/L (base deficit 12 mmol/L) will correct his own acidosis if only saline and insulin is given. It probably does not require any bicarbonate. But, patient with a base excess of –8 mmol/L during any major surgery probably requires bicarbonate, because they can not tolerate the depressant effect of the slight decrease of pH on the myocardium. On the other hand, it is important not to give too much $NaHCO_3$, as this may have several undesirable effects.

Sodium Bicarbonate ($NaHCO_3$)

$NaHCO_3$ solution is available in a variety of concentration. The concentration of $NaHCO_3$ that commonly used clinically for resuscitation is 8·4% which contains 1 mmol of Na^+ and HCO_3^-. Therefore, there is a danger of high Na load, precipitating heart failure. The sodium bicarbonate solution of this concentration is hypertonic and irritating to veins. Thus, it may also result in extensive skin necrosis, if the solution leaks from the vein into the tissues. Sometimes a hyperosmolality syndrome may be precipitated by 8.4% $NaHCO_3$ solution. Therefore, 8.4% $NaHCO_3$ should be reserved for acute situations such as cardiac arrest and should preferably be given via a central line.

Disadvantages of $NaHCO_3$

The disadvantages of IV administration of $NaHCO_3$ are the following:

i. Administration of 8·4% $NaHCO_3$ causes excess of sodium load which is especially dangerous in patients with heart disease. The administration of 50 ml of 8.4% $NaHCO_3$ will increase the serum osmolarity by 3 mmol/L in the normal adult (Fact file- III).

ii. During cardiac arrest there is both respiratory and metabolic acidosis which develop rapidly in the tissues. In such situation of complete absence of circulation and respiration, administration of $NaHCO_3$ evolves large amount of CO_2. This huge amount of CO_2 can not get its exit through lungs due to absence of circulation and respiration (if circulation and ventilation is not started). Then it leads to more severe hypercapnia and acidosis and more and more depression of myocardium. Thus a vicious cycle will set up.

$$NaHCO_3 + H^+ \leftrightarrows H_2CO_3 \leftrightarrows CO_2 + H_2O$$

During cardiac arrest lactic acidosis results from anaerobic metabolism and there is no formation of CO_2 due to stoppage of TCA cycle in the absence of O_2. Therefore, sudden increase in CO_2 level in blood after administration of $NaHCO_3$ reverses the diffusion gradient and CO_2 will easily enter the cell, causing intracellular acidosis. This intracellular hypercapnia will compound the existing intracellular lactic acidosis which will further reduce the intracellular pH and will decrease the myocardial contractility. Thus, it will exacerbate an already compromised low cardiac output state. The CO_2, thus, produced in the blood will also easily cross the blood-brain barrier and will cause a disproportionate acidosis of CSF. Infact, 50 ml of 8.4% $NaHCO_3$ will be converted to 200 ml of CO_2 which is equivalent to the production of it by the basal metabolism of a normal adult in 1 minute.

iii. $NaHCO_3$ administration causes an extracellular alkalosis and movement of oxyhaemoglobin dissociation curve towards the left. This will impair O_2 delivery to the tissues. In uncontrolled diabetes mellitus, the acidosis exists with high level of 2, 3 DPG level. Acidosis itself shifts the O_2 dissociation curve to the right and on the other hand high 2, 3 DPG shifts it to the left, so that the net effect of oxygen delivery to the tissue remains normal. If $NaHCO_3$ is administered in these circumstances

FACT FILE- III

High anion gap metabolic acidosis (HAGMA)

Ketoacidosis is one of the example of HAGMA. It is found in starvation, alcoholism and insulin dependent diabetics. It is characterised by elevated level of β-hydroxybutyric acid and acetoacetic acid. The elevation of level of these two acids are due to:

(i) An increased hepatic synthesis caused by an increase in free fatty acid (FFA) which is liberated from adipose tissue due to reduced insulin and increased catecholamine level.

(ii) An altered hepatic metabolism due to reduction in insulin, promoting ketogenesis rather than triglyceride synthesis.

Betahydroxybutyrate, acetoacetate and acetone are together called as ketone bodies. Among these acetoacetate undergoes spontaneous decarboxylation and yields CO_2 and acetone. Acetone is not an acid and excreted largely through lungs like CO_2. Acetoacetate and betahydroxybutyrate remain in equilibrium in plasma and the normal ratio is 3:1 (vary between 1:1 to 10:1). This level increases during hypoxia. The normal fasting level of betahydroxybutyrate is < 1.2 mEq/L. In prolonged fasting it may rise to 2 to 5 mEq/L. Normally, the FFA concentration in plasma ranges between 0.4 to 0.8 mEq/L and seldom rises more than 1 mEq/L. But, in diabetic ketoacidosis, the FFA level may rise upto 2 to 4 mEq/L and ketoacids may increase upto 10 to 15 mEq/L.

then the pH will rise, leaving the unopposed effect of high 2, 3 DPG level and further shifting the O_2 dissociation curve to the left. This will cause service impairment of delivery of O_2 to the tissues. The 2, 3 DPG level takes several days to return to normal and it is important in this respect to ensure a normal plasma phosphate.

iv. In diabetes acidosis, $NaHCO_3$ may precipitate the disequilibrium syndrome.

v. Rebound alkalosis may occur, if excessive dose of $NaHCO_3$ are used. This alkalosis will also reduce serum ionised Ca^{2+} level by 25% and can further decrease the myocardial contractility.

vi. Administration of $NaHCO_3$ results in rise of P_aCO_2. If the patient is able to hyperventilate, then this excess CO_2 will be excreted via lungs. But, in a patient with an impaired consciousness, mechanical ventilation at high minute volume may be required to washout this excess CO_2 with repeated measurement of blood gas tension.

vii. In hypokalaemic patients $NaHCO_3$ administration will increase pH. This will promote further K^+ uptake by the cell and thus lethal hypokalaemia may occur.

In summary, $NaHCO_3$ is a dangerous drug, but may be very essential after cardiac arrest for the successful action of inotropic agents, only if the circulation and ventilation is established.

Doses of bicarbonate

The doses of bicarbonate for the acute management of metabolic acidosis can be calculated from the base excess, assuming that the equilibrium will occur throughout the extracellular fluid which is about 20% of the total body weight or lean body mass (LBM).

So, the dose of $NaHCO_3$ (mmol) = [Base excess × Body weight (Kg)] / 3

It is often recommended that at the initial phase about half of the total calculated dose of $NaHCO_3$ is given. After that blood gases must be checked again. It is much better to undercorrect the acidosis than to overcorrect it. The results, after administering the total dose of bicarbonate as suggested above, are not always predictable. This is due to the possible development of further acidosis and because the original blood sample which was taken during altered equilibrium, does not indicate the actual base excess level. Also it will have to keep in mind that measurement of the acid-base state of the blood may give a very inaccurate index of the actual metabolic state of the whole body, as the measurement of intracellular pH by a clinical procedure is not yet possible. For this reason it is essential to reassess the acid-base status of the arterial blood after half of the recommended dose of bicarbonate has been given and to correct further, if it is necessary only. Sodium bicarbonate is a poor buffer in its own right (as explained previously) and acts mainly by combining with H^+ ions to form CO_2 and H_2O. Administration of bicarbonate to correct a metabolic acidosis, therefore, presents a CO_2 load on the lungs. So, the efficient buffering of metabolic acidosis by $NaHCO_3$ depends mainly on the adequate pulmonary ventilation.

Trihydroxymethyl amino methane (THAM)

It is a non-sodium containing buffer which has been used in some parts of the world, with a variable degree of success, to treat metabolic acidosis instead of $NaHCO_3$ (Fig. 8.10).

Lactic Acidosis

Glycolysis is the process of breakdown of glycogen or glucose into pyruvic or lactic acid through Embden-Meyerhof or glycolytic pathway. Glycogen may leave the liver in the form of glucose, but it leaves the muscles in the form of pyruvic or lactic acids only, and not in the form of glucose. This difference is probably due to the fact that the enzyme systems and the chemical reaction responsible for metabolism of glucose in the liver and muscle are

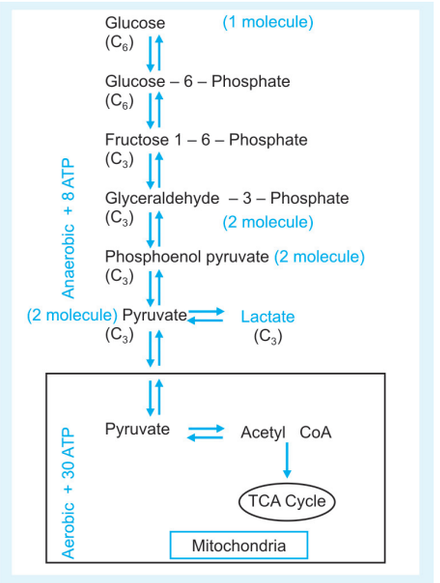

Fig. 8.10: Pyruvate and lactate metabolism.

not the same. Pyruvic or lactic acid that emerges from the muscles is carried to the liver through the blood stream where it is reconverted into glycogen. This glycogen in liver is again remobilised to form glucose which enters into the blood stream. Muscles take up this glucose from the blood stream and recovers its lost glycogen from where again pyruvic or lactic acid is produced due to metabolism. This cyclic process of circulation of carbohydrate in different forms in different tissues is known as Cori cycle, through which muscle lactic acid and liver glycogens become readily interchangeable. In normal condition, 1/5th of the muscle lactate is broken down to CO_2 and H_2O and 4/5th is reconverted into glycogen in the liver (Fig. 8.11).

In the skeletal muscles, the pyruvic acid but not the lactic acid is the end product of the glucose metabolism. It is converted into lactic acid only in anaerobic conditions. Lactic acid from muscles also enters the blood stream during heavy muscular excercise when O_2 supply is inadequate. In the muscle pyruvic acid is also finally oxidised into CO_2 and H_2O through citric acid or TCA cycle in the presence

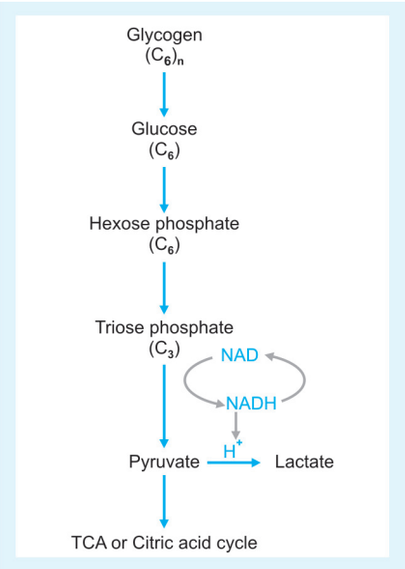

Fig. 8.11: Mechanism of formation of lactate in anaerobic metabolism. H^+ which is formed in step 3 is used for conversion by pyruvate to lactate

FACT FILE- IV

Lactic acidosis may be caused by an increased lactate production due to hypoxia or due to decrease in rate of lactate utilisation by liver and kidney. Normal arterial lactate level is < 2 m.mol/L. Lactate level between 2 to 4 m.mol/L are abnormal, but of uncertain clinical significance. Plasma lactate level greater than 5 m.mol/L is used to diagnose lactic acidosis. But in most cases of lactic acidosis the lactate level runs between 10 to 30 m.mol/L. Plasma lactate is measured in a heparinised arterial blood sample, stored in ice. It should be assayed within 1 hour, after sample is drawn. Lactate level can also be measured from blood, collected in a fluoride oxalate tube which is normally used for glucose estimation. Though lactic acidosis is classified into type A and type B, still some believe that there is little utility in this division, as both types often share mechanisms of over production or under utilisation.

of O_2. Cardiac muscle utilises lactic acid directly and completely in preference to glucose. Glucose utilisation by the heart of a diabetic person is less than normal, but as regards lactate, the diabetic heart uses it almost as readily as the normal heart. On the other hand, there is very little glycogen store in the brain. It uses sugar in the form of galactose only which is locally synthesized from the blood glucose. In the brain galactose is also metabolised to lactic acid. It is also interesting to note that the brain tissue is very rich in fat, but it derives its energy from sugar. The RBC also readily form lactic acid from sugar.

Lactic acidosis is best defined as the acidotic condition when pH is less than 7.25 and the blood lactate concentration is more than 5 mmol/L. But, the care must be taken to exclude other conditions which are responsible for acidosis with increased level of lactic acid such as renal failure, ketoacidosis, and other conditions where the elevation of lactic acid is not alone responsible for the acidosis.

Lactic acid is formed from pyruvic acid and is the (Fact file- IV) final product of the glycolytic pathway in the absence of O_2. Thus, glycolysis unlike the citric acid cycle can continue in anaerobic condition also. But, normally further metabolism of pyruvate requires its entry in the presence of O_2 into the oxidative tricarboxylic acid (TCA) cycle which is present within the mitochondria. In the absence of O_2, the TCA cycle stops and pyruvate accumulates. In hypoxia, this accumulation of H^+ and pyruvate would allow transformation of pyruvate to lactate with production of energy which will allow to continue the reaction (Embden-Meyerhof) for some period. Thus lactate accumulation occurs during anaerobic metabolism (i) by increased production or (ii) by decreased gluconeogenesis from lactate in the liver and kidney or (iii) by the failure of pyruvate to enter the tricarboxylic acid (TCA) cycle. Hepatic utilization of lactate usually acounts for 1500 m.mol/day with the ability to rise it to 3400 mmol/day.

Aetiology of lactic acidosis

Lactic acidosis is classified into two types– type A and type B. Type A is due to tissue hypoxia and anaerobic metabolism. Type B is due to other causes which will be described later. (Fig. 8.12).

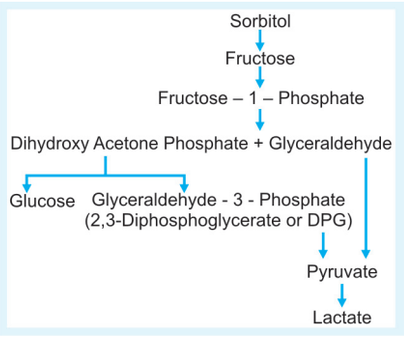

Fig. 8.12: Metabolism of fructose and sorbitol

(i) Type A lactic acidosis

The association between the metabolic acidosis, circulatory collapse and hypoxia is well recognised. The impaired tissue perfusion from circulatory collapse causing tissue hypoxia is the result of any form of shock. Tissue oxygenation is further compromised by added severe hypoxaemia (low P_aO_2) and anaemia. So, the blood lactate concentration, although seldom measured, closely correlates with mortality rate. There is a mortality rate of about 75% in patients with blood lactate concentration which rises from 4.4 to 8.9 mmol/L. But, there is only 10% mortality rate with lactate concentration which rises from 1.3 to 4.4 mmol/L. However, the treatment of type A lactic acidosis entails the removal of causes and the subsequent O_2 and alkali therapy.

(ii) Type B lactic acidosis

The causes of type B lactic acidosis are:

a. Common Disorders—diabetes mellitus, renal failure, hepatic failure, severe infection, leukaemia.
b. Drugs—phenformin, metformin, salicylates, paracetamol.
c. Parenteral nutrition - fructose, sorbitol, xylitol.
d. Inherited—glycogen storage disease, fructose 1-6 diphosphate deficiency, leigh's syndrome, methylmalonic acid aemia.
e. Toxins – ethanol, methanol.

The commonest cause of acute and serious Type B lactic acidosis is biguanide

therapy for diabetes mellitus. Among the biguanides, phenformin is ten times more likely to produce an attack of lactic acidosis than metformin. The mortality of Type B lactic acidosis is 50%. Biguanides produce hypoglycaemia by (a) reducing the alimentary absorption of glucose and amino acids, (b) decreasing the hepatic gluconeogenesis and (c) increasing the glycolysis. Thus, lactic acidosis by biguanides is inherent and is produced by the hypoglycaemic actions of it mentioned in (b) and (c). Usually during biguanide therapy blood lactate is less than 2 mmol/L, but impaired renal excretion, hepatic dysfunction or cardiovascular disease may easily induce lactic acidosis.

Fructose, sorbitol, xylitol, etc, have been used as energy substrates instead of glucose in diabetic patient. Because they all can be metabolised without insulin. This is of particular importance in very sick patients who are insulin resistant. In addition, these agents are less irritant to veins than glucose. However, all these agents result in the increased production of lactate. 35% of fructose infusion is converted rapidly into pyruvate and then into lactate by the liver.

Ethyl alcohol (ethanol) infusion inhibits hepatic neouglucogenesis. In the presence of hepatic disease or when administered with fructose, sorbitol or biguanide, then lactic acidosis may result from ethanol.

Treatment

Like the treatment of type A lactic acidosis, the treatment of type B lactic acidosis should also always be directed at the underlying causes and ensuring adequate oxygen delivery to the tissues. The treatment of type B lactic acidosis is very difficult than type A lactic acidosis. If possible, causes should be removed first then symptomatic treatment is started. Large amounts of alkali are necessary for treatment of this type B lactic acidosis, due to the continuing lactate production. Therefore, alkalinisation with $NaHCO_3$ is the main stay of therapy of this type of lactic acidosis. Isotonic $NaHCO_3$ (1·4%) should be used to bring the pH back to normal, but slowly over about 6 hours. If hyperkalaemia coexists, then this therapy will be beneficial for it, as the K^+ will enter the cells with the pH rises. If hyperglycaemia exists insulin may be required.

Attempts have also been made to remove the lactate by dialysis or by stimulating the pyruvate dehydrogenase, which will encourage the conversion of lactate to pyruvae and will remove the latter via the TCA cycle. Glucose and insulin seldom help in the treatment of type B lactic acidosis as glycolysis is stimulated and gluconeogenesis is inhibited.

CVP line and urinary catheter should always be inserted to monitor the progress of therapy, as circulatory overload with cardiac failure is a serious complication during the treatment of type B lactic acidosis. Haemodialysis may be required to treat cardiac failure. Repeated estimation of blood-gas is essential in any disturbance of acid-base balance and in these circumstances it is of great practical value for repeated measurement of lactate levels.

METABOLIC ALKALOSIS

Metabolic alkalosis is less common than metabolic acidosis. It occurs due to the excess production of base or excess loss of noncarbonic acid (H^+), preserving HCO_3^-. It is characterisied by increase in plasma bicarbonate, a fall in blood H^+ concentration and a small compensatory rise in PCO_2. In a healthy normal person when the plasma HCO_3^- rises above normal, then the urinary excretion of HCO_3^- increases rapidly. It is, therefore, very unusual to observe metabolic alkalosis in the presence of normal renal function. Uncompensated severe metabolic alkalosis has very high mortality rate. Typical findings of metabolic alkalosis are pH > 7.4, P_aCO_2 > 45 mm of Hg, H^+ concentration < 36 nmol/L, HCO_3^- concentration > 32 mmol/L.

In metabolic alkalosis log HCO_3^-/H_2CO_3 component of Henderson-Hasselbalch equation is increased due to the raised HCO_3^- concentration and thus pH rises. Compensation occurs by hypoventilation (respiratory acidosis). This conserves CO_2 and increases PCO_2, so that H_2CO_3 rises and thereby modifies the increases in pH by restoring the ratio of HCO_3^-/H_2CO_3 to normal.

$H_2CO_3 \leftrightarrows CO_2 + H_2O$ ..... Equation shifts to the left.

This compensation may be limited till hypoxaemia results from hypoventilation, particularly if the pateint is breathing room air. It appears that respiratory stimulation from hypoxaemia is stronger than the compensatory depression due to alkalosis and thus oxygenation is often maintained despite a metabolic alkalosis.

The formula for the expected raised $PaCO_2$ which occur during compensation in a metabolic alkalosis is: .6 × (measured HCO_3^- – 24) + 40. If the measured $PaCO_2$ is higher than expected, then one should think that this present metabolic alkalosis is mixed with respiratory acidosis. On the other hand, if the measured $PaCO_2$ is less than expected $PaCO_2$, then it can be thought that this metabolic alkalosis is partially compensated or mixed with respiratory alkalosis. The compensation of metabolic alkalosis by elevating $PaCO_2$ is more erractic than that of metabolic acidosis and $PaCO_2$ usually does not rise above the level of 55 mEq/L. This is because the hypoxaemia which is caused by hypoventilation will limit the compensatory rise of $PaCO_2$ that is described before.

The differential diagnosis of metabolic alkalosis is based on urinary Cl^-, i.e. urinary Cl^- < 2D mEq/L and urinary Cl^- > 20 mEq/L. This is because: due to compulsion of electroneutrality there are only two methods to add HCO_3^- to a compartment of ECF – either loss of Cl^- or retention of Na^+. In the ECF the only anion that is present in sufficient quantity is Cl^-. Cl^- is lost with H^+ or NH_4^+. So the loss of H^+ or

NH_4^+ is equivalent to gain of HCO_3^-. The net effect is loss of Cl^- and gain of HCO_3^- leading to metabolic alkalosis.

Classification of metabolic alkalosis according to urinary Cl^-.

A. Chloride responsive or urinary Cl^- $\leq$ 20 mEq/L.
   1. *Renal loss*: Diuretics, cystic fibrosis.
   2. *GI loss*: Suction, vomiting, chloride wasting diarrhoea
B. Chloride resistant or urinary Cl^- > 20 mEq/L
   1. Excess mineralocorticoids: Cushing and Conn syndrome
   2. Excess steroid administration.
   3. Bartter's syndrome.

Causes of Metabolic Alkalosis

1. Loss of H^+ ions

i. Renal— Primary and secondary hyperaldosteronism (discussed later).
ii. K^+ depletion— Acid (H^+) may be lost from the kidney by hypokalaemia with its paradoxical combination of acid urine and alkaline ECF.
iii. Conn's syndrome and Cushing's syndrome.
iv. Drugs—Diuretics (thiazide, frusemide) and corticosteroids
v. GI Tract—Vomiting, nasogastricsuction, pyloric stenosis, high intestinal obstruction etc.
vi. Chloride deficiency (Fact file- V).

2. Gain in alkali (HCO_3^-)

Metabolic alkalosis is also caused by administration of large amount of alkali by ingestion of oral antacids or infusion of $NaHCO_3$. There is also metabolic conversion of organic acid anion such as lactate and citrate to HCO_3^-, causing alkalosis. This situation is observed after a massive blood transfusion when the citrate is metabolised by liver over the next 48 hours to HCO_3^-, resulting in metabolic alkalosis.

There are important relationships between the handling of Na^+, K^+ and H^+ by kidney. Metabolic alkalosis is perpetuated when there is a reduction in ECF volume. The explanation is that in collecting duct final adjustment of urine composition is made by reabsorption of Na^+ in exchange of secretion of both K^+ and H^+ from tubular cells into the lumen. Thus, if the kidney avidly retains Na^+ (in hypovolaemic), it can not retain K^+ or H^+, leading to metabolic alkalosis (Table 8.13).

If, in addition to metabolic alkalosis, there is low intracellular K^+ concentration because of potassium depletion (hypokalaemia due to any cause), then there is obligatory more secretion of H^+ in place of K^+ and the resulting alkalosis will be even greater. When aldosterone and other mineralocorticoids (which increase the drive of tubular Na^+ reabsorption) present in excess such as in primary or secondary hyperaldosteronism, then they have the similar effect.

Chloride is also very important in this context, because normally at various sites in the nephron Na^+ can be reabsorbed along with either chloride or bicarbonate. To maintain neutrality with raised

FACT FILE - V

Metabolic alkalosis causes hypoventilation and elevates PCO_2 as a compensatory mechanism. But, this compensation is more erratic than for acidosis and generally PCO_2 does not exceed 55 mm of Hg. To maintain the electroneutrality in alkalosis due to addition of more HCO_3^-, there are two ways: either loss of an anion such as Cl^- or retention of cation such as Na^+. So the most useful biochemical parameter is to measure the level of urinary chloride which forms the basis of classification of metabolic alkalosis. The only anion that is present in sufficient quantity in extracellular fluid (ECF) to be lost is Cl^-. It is lost with H^+ or NH_4^+. The net effect is loss of HCl or NH_4Cl to gain HCO_3^-. The loss of HCl or NH_4Cl is equivalent to loss of Cl^- for $HCO3^-$. The two organs which are capable of inducing a loss of Cl^-, together with gain of HCO_3^- are stomach (vomitting, intestinal obstruction, etc) and the kidney (absorption of Na^+ as bicarbonate to maintain ECF volume).

Hypokalaemia is an almost constant feature of alkalaemic disorder (alkalosis produces hypokalaemia or hypokalaemia produces alkalosis), but is more prominent in those of metabolic origin. This is due to renal or extra renal losses of K^+ (diarrhorea, suction, vomitting etc) in varying degrees. This condition also commonly occurs after several days of IV therapy where K+ replacement is inadequate, diuretic therapy, diarrhoea, hyperaldosteronism and other common causes of hypokalaemia.

Normally 98% of total body K^+ remains as intracellular. K^+ depletion causes metabolic alkalosis by two mechanism: (a) during K^+ depletion, kidney vigorously attempts to conserve it, causing increased secretion of H^+ and concomittant increase in blood base. (b) K^+ is the major intracellular cation. Hypokalaemia induces intracellular K^+ to enter the extracellular space to maintain near normal serum level. This extracellular migration of K^+ forces the intracellular migration of H^+ and alkalosis. The net result is extracellular increase of $HCO3^-$. This explains how mineralocorticoids causes hypokalaemia and alkalosis.

This also explains how low serum K^+ level (hypokalaemia less than 3.5 mmol/L) reflects a severe depletion of intracellular K^+. In turn hypokalaemia have several adverse effects. It includes neuromuscular weakness, polyuria, sensitisation to digitalis induced arrhythmia and increased ammonia production which can highten the risk of hepatic encephalopathy. Alkalosis stimulates anaerobic glycolysis and increases the production of lactic acid and ketoacids. Alkalosis reduces the release of O_2 to the tissues by tightening the bond between O_2 and Hb. But chronic alkalosis negates this effect by increasing the concentration of 2-3-DPG level in RBC.

Table 8.13: Causes of metabolic alkalosis

Chloride responsive (urinary chloride < 20 mmol/L)
Renal
Diuretics, hypercapnia
GI
Vomiting, diarrhoea, nasogastric suction,
GI fistula, abuse of antacids, villous adenoma,
excessive administration of alkali ($NaHCO_3$), etc.
Chloride resistant (urinary chloride > 20 mmol/L)
Primary hyperaldosteronism
Secondary hyperaldosteronism
Severe hypokalaemia
Cushing's syndrome, Bartter's syndrome, etc.
Miscellaneous
Milk alkali syndrome, alkali therapy, massive blood transfusion, etc.

HCO_3^- absorption, the Cl^- is excreted through kidney. So, urinary Cl^- level is increased in hyperaldosteronism, Cushing's syndrome and in K^+ deficiencies, etc. But, urinary chloride is low when HCl is lost from stomach or intravenous $NaHCO_3$ and diuretics are administered. In such condition when chloride is deficient, there is preferential reabsorption of bicarbonate instead of Cl^- which will make an alkalosis more worse. This will also prevent the additional excretion of bicarbonate by the distal tubule which is usually necessary as a compensation to correct an established metabolic alkalosis.

The classic typical example of metabolic alkalosis is sustained vomiting due to any cause. In normal condition, when H^+ are secreted into the gastric lumen, then HCO_3^- (byproduct of H^+ formation) from parietal cells is absorbed in the blood. This subsequently is neutralised by reabsorption of the secreted H^+ from the small bowel. In sustained vomiting, the initial loss of H^+ from the body initiates the alkalosis. But the kidney is unable to restore the homeostasis by retaining H^+. Because there is also deficit of Na^+ and water due to constant vomiting, causing enhanced tubular Na^+ reabsorption in exchange of K^+ and H^+ (explained before). As K^+ is also lost in vomiting, there is an intracellular K^+ deficit. So in the absence of K^+, tubular H^+ secretion or lost in the lumen is magnified and alkalosis is sustained. Chloride is also lost in the vomit, so there is enhanced bicarbonate reabsorption by the renal tubule (Fig. 8.13).

Use of diuretics, particulary if it is aggressive leading to ECF volume depletion, may have similar effects. Due to inhibition of Na^+ absorption at proximal tubule by diuretics, more Na^+ is delivered to the collecting duct for reabsorption which causes more secretion of H^+. ECF volume depletion by diuretics also enhance the level of renin, angiotensin and aldosterone which increases the drive of Na^+ reabsorption at collecting tubule in exchange of H^+ and K^+ causing sustained alkalosis.

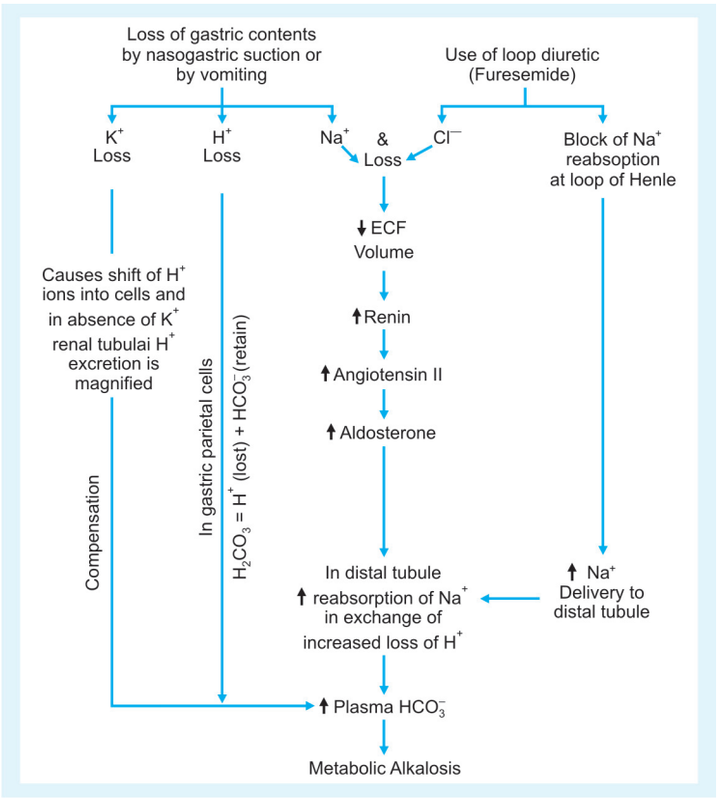

Fig. 8.13: Pathogenesis of metabolic alkalosis. This is due to the loss of gastric contents or use of loop diuretics

Kidney

In the proximal tubule there is obligatory Na^+ absorption, the extent of which is controlled by ECF volume. In the distal tubule Na^+ is reabsorbed in exchange for K^+ and H^+ under the influence of aldosterone. This is the cause of alkalosis in aldosteronism. Thus, hypokalaemia occurs with alkalosis due to the increased excretion of both K^+ and H^+ for increased reabsorption of Na^+. In renal cause of retention of HCO_3^-, causing alkalosis, correction of pH alone without treatment of the underlying disease will result in recurrence and persistence of the metabolic alkalosis.

Clinical Effects of Metabolic Alkalosis

The clinical effect of metabolic alkalosis are tetany, hypocapnic vasoconstriction, left hand shift of O_2 dissociation curve, mental changes, and hypokalaemia.

Treatment of Metabolic Alkalosis

Severe metabolic alkalosis may be a life threatening condition, especially if it is accompanied by hypokalaemia. But, it is uncommon. Treatment of this form of alkalosis includes the following:

i. Restoration of ECF volume: This may involve transfusion of NaCl, plasma or blood. It is important to say that to give chloride, NaCl is the simplest form, if Na load is not contraindicated.
ii. Restoration of plasma K^+ concentration: It is possible by using KCl or K^+ conserving diuretics, such as triamterene or amiloride, if not contraindicated.
iii. Inhibitiion of aldosterone (where appropriate): This is done by using spironolactone.

iv. Inhibition of carbonic anhydrase: This is performed by acetazolamide which will produce retention of H^+ ions.
v. Direct acidification: sometimes HCl, NH_4Cl, lysine or arginine may be used for the correction of metabolic alkalosis. These may all be given intravenously and will result in the release of free H^+ ions. HCl should only be administered through a central venous line at a rate of 0.2 m.mol of H^+/Kg/hour. The maximum dose of H^+ which is about 300 to 500 mmol/day should not be exceeded.

One sixth molar NH_4Cl has also been used as a source of acid, because two molecules of NH_4Cl condense to form one molecule of urea and two molecules of HCl. But it is contraindicated in hypokalemic patient as further K^+ loss is induced.

vi. Loss of H^+ by vomiting or gastric suction causing alkalosis: This can be controlled easily by ranitidine which reduces the H^+ concentration of gastric secretion.

MORE ABOUT ANION GAP

For electrical neutrality to exist, the number of anions (negatively charged ions such as Cl^-, HCO_3^- etc) must be equal to the number of cations (positively charged ions such as Na^+, Mg^+, etc.). When these two numbers are not equal, the difference between them is called the anion gap. The anion gap may be calculated in several ways and the normal range will therefore vary between different laboratories. One method of calculation which can be done on a routine electrolyte estimation is $(Na^+ + K^+) - (Cl^- + HCO_3^-)$. This gives a value between 11 to 19 m.mol/L. It represents approximately the sum of some anions such as protein, phosphate, lactate and 3-hydroxybutyrate, etc. which are usually not measured. Some laboratories also exclude K^+ from the calculations of anion gap which gives a lower normal range.

Causes of high anion gap

i. Uraemic acidosis.
ii. Keto acidosis.
iii. Salicylate poisoning.
iv. Lactic acidosis.
v. Methanol, ethylene glycol and paraldehyde toxicity.

All of these above mentioned factors causes acidosis with high anion gap. But there are many other causes of acidosis in which the anion gap is not abnormal. Because in such cases chloride replaces bicarbonate, for example, diarrhoea.

vi. Dehydration.

Causes of low anion gap

i. Dilutional states
ii. Hypoalbuminaemia − albumin, at normal blood pH, has marked negative charge and therefore accounts for most of the anion gap.
iii. Hypernatraemia, hypermagnesaemia, hypercalcaemia
iv. Paraproteinaemia— Here the increased viscosity of blood interferes with blood sampling. Paraprotein: immunoglobin produced by neoplastic plasma cells proliferating abnormally, e.g. myeloma protein.

Minor variations in the anion gap should be interpreted with care, since it is calculated from four variables. However, it is of value in detecting an abnormality before more specific investigation can be undertaken.

EFFECTS OF ACID-BASE DISTURBANCES

Continuously, acid-base disturbances due to metabolic ($\uparrow\downarrow H^+$ and $\uparrow\downarrow HCO_3^-$) or respiratory ($\uparrow\downarrow PCO_2$) causes are going on in our body. So, homeostatic mechanisms are also acting dynamically to meet with these disturbances and to bring back the plasma pH to normal. But, acute or prolonged disturbances can outpace these homeostatic mechanisms and result in a variety of clinical responses. Among these the most frequently found acid base disturbances is acidosis. Alkalosis occurs less frequently, but is more harmful than acidosis. Acid-base disturbances cause multiple changes in different organs, with myriad of interrelations and interactions. So, it is sometimes very difficult to understand the cause or effects of acid-base disturbances on different systems.

Effects on CVS

There are different separate responses of CVS due to separate changes for PCO_2 and pH. Again, it is very difficult to separate the responses of CVS due to changes in CO_2 tension alone from the changes for sympathoadrenal stimulation which occurs during hypercapnia. So, it is very difficult to elucidate the actual effect of acid-base alteration on the CVS system. In general, if PCO_2 is maintained constant then an increase or decrease in pH causes depression of myocardial contractility with fall in stroke volume and cardiac output, associated with a decrease in peripheral vascular resistance. In addition, the responsiveness of heart to the catecholamine is also diminished in metabolic acidosis. On the other hand, hypercapnia produces increased stroke volume and cardiac output by increasing sympathetic activity. The effect of hypercapnia on the peripheral vascular tissue depends on the degree of sympathetic innervation of it. Richly innervated organ (kidney) respond to hypercapnia by vasoconstriction, whereas poorly innervated organs (cerebral cortex) respond by vasodilation. On the other hand, during hypocapnia there is generalised vasoconstriction independent of sympathetic innervation (Table 8.14).

The effects of acid-base disturbance on heart rate (HR) should be discussed in steps: (i) effect of changes of pH directly on HR, and (ii) effect of catecholamine and ACh due to changes in pH on HR. In an isolated heart preparation (denervated or blocked) acidaemia causes

Table 8.14: Clinical effects of acidosis and alkalosis

	Direct effect	*Indirect effect*	*Net clinical effect*
Decreased pH (acidosis)			
Heart rate	↓	↑↑	↑↑
Cardiac contractility	↓	↑	0
Arterial resistance	↓↓	↑	↓
Venous resistance	↑	↑	↑↑
Pulmonary resistance	↑	↑	↑↑
Cerebral blood flow	↑	↑	↑↑
Airway resistance	↓	↑↑	↑
Renal circulation	↑	↓↓	↓
Serum K^+	↑	0	↑
Ionised Ca^{2+}	↑	0	↑
Increased pH (alkalosis)			
Heart rate	0	0	0
Cardiac contractility	0	0	0
Arterial resistance	↑	0	↑
Venous resistance	0	0	0
Pulmonary resistance	0	↓	↓
Cerebral blood flow	↓	0	↓
Airway resistance	↑↑	↓	↑
Renal circulation	0	0	0
Serum K^+	↓	0	↓
Ionised Ca^{2+}	↓	0	↓

↓ = Decreased, ↑ = Increased, 0 = No effect

bradycardia. But, in normal heart with intact nerve supply the effect is different. When pH decreases from 7.4 to 7.1, the HR increases indirectly as a result of the effect of epinephrine which is released from the adrenal medulla in response to acidaemia. In severe acidosis, when pH further decreases below 7.1 then the effect is bradycardia. This bradycardia is due to the increased vagal tone and accumulation of ACh (acetylcholine) as a result of decreased metabolism of it in the acidic environment. So, clinically in normal healthy patient, acidosis (respiratory or metabolic) will cause initially tachycardia which is followed later by bradycardia, as the depressant effect of parasympathetic system overworks on the initial stimulating effect of sympathetic system.

Myocardium is also sensitive to the changes in PCO_2 and pH both. So, atrial and ventricular arrhythmias are common in acid-base disturbances. But, it is not clear whether the arrhythmia is directly due to the changes in pH or due to the changes in extracellular K^+, secondary to pH changes. Arrhythmia may also be due to pH related changes in Ca^{2+}, Mg^{2+} and catecholamine levels. A change of 0·1 unit of pH is related to change in K^+ level of 0.5 to 1.5 mmol/L in opposite direction. In acidosis, high intracellular H^+ concentration causes hyperkalaemia, but causes reduction of intracellular K^+ concentration. This alters the resting membrane potential of myocardium and causes arrhythmia. Decreased pH lowers the threshold value for ventricular fibrillation and increased pH elevates it. Therefore, acid-base disturbances are frequently accompanies by ventricular arrhythmia. Decreased pH also causes an increase in ventricular ectopic by elevating the level of circulating catecholamines. Among all the volatile anaesthetics halothane sensitises the myocardium maximally to the catecholamines. But in healthy patient, this is of little clinical significance.

Acidosis itself causes depression of myocardial contractility. This direct effect of depression of myocardial contractility is due to the impairment of Ca^{2+} entry into the cells or decreased release of Ca^{2+} from the intracellular storage site such as sarcoplasmic reticulum (SR). On the other hand, acidosis increases the level of circulating catecholamines. This increased level of catecholamines stimulate the myocardial contraction and overcome the direct depressant effect of acidosis. Therefore, the net result of acidosis is increased myocardial contraction. But, this occurs till the fall of pH upto 7, beyond which the direct depressive effect of acidosis predominates over the sympathetic stimulating effects. Thus mild acidosis, i.e. fall of pH upto the level of 7 will increase catecholamine level which will elevate the cardiac output as a result of (i) increased in heart rate, (ii) myocardial contractility, (iii) venous tone (pre load), and (iv) simultaneous decrease in SVR (after load). But, when the pH goes further down below 7, then the cardiac depressant effects of acidosis are greater than the stimulant effects of catecholamine on myocardium and cardiac output will fall. This also explains why a patient taking Ca^{2+} channel blocker will demonstrate decrease in contractility at a relatively slight change in pH.

Alkalosis does not induce the increased catecholamine secretion, but increases the responsiveness of myocardium to the circulating catecholamines. Thus, it produces an elevation of myocardial contractility and O_2 consumption. On the other hand, alkalosis or hypocapnia constricts coronary vessels and elevates coronary vascular resistance, thereby providing less O_2 to the myocardium. On the other hand, hypocapnia or alkalosis shifts O_2 dissociation curve to the left, providing less O_2 extraction by the myocardium or

less tissue unloading. So, the net effect of alkalosis on myocardium is increased myocardial contractility, less O_2 supply to the heart and small myocardial O_2 reserve. In severe alkalosis, unbound plasma Ca^{2+} level decreases which possibly further reduces the myocardial contractility.

The effect of acid-base disturbances on peripheral vasculature is also very complicated. In general, the direct effect of acidosis on systemic arterial bed (not the pulmonary) is vasodialtation. But, this is not true in metabolic acidosis which causes vasoconstriction. In respiratory acidosis there is elevation of CO_2 level in blood which crosses the cell membrane of vasculature smooth muscle more readily than H^+. Intracellularly this CO_2 is converted to carbonic acid and the resultant decrease in intracellular pH is responsible for the decrease in vascular smooth muscle tone. In metabolic acidosis reduction of intracellular pH is not so great as respiratory acidosis, because H^+ has the limited intracellular diffusibility compared with CO_2. On the other hand, due to release of more catecholamines vasoconstriction is the result of metabolic acidosis. This vasoconstriction induced by metabolic acidosis continues, until the pH falls to 7·2. Below that level vasodilation will again occur in response to metabolic acidosis. On the other hand, both metabolic and respiratory acidosis causes pulmonary vasoconstriction. But, when compared with hypoxic pulmonary vasoconstriction, vasoconstriction caused by acidosis or alkalosis is less. Acidosis or alkalosis also enhances the normal hypoxic pulmonary vasoconstriction response. Thus acidosis increases the pulmonary artery pressure and resistance. This is due to the constriction of pulmonary capillary sphincter and also due to the increase in venous return, secondary to acidosis induced peripheral vasoconstriction. Furthermore, catecholamine induced increase in cardiac output due to acidosis produces an increase in pulmonary blood flow and causes further increase in pulmonary artery pressure.

The individual vascular bed responses differently to acidosis. This is because of the varying contributions of direct and indirect effect of acidosis, type of acidosis, and the degree of sympathetic innervation. Metabolic acidosis will directly dilate the arterial bed of skin, skeletal muscles, kidney, splanchnic, uterine and coronary vasculature. Indirect effect of acidosis is mediated through the sympathetic system causing constriction. Thus, the net effect of acidosis on vascular bed is: (a) richly innervated organ such as kidney responses by vasoconstriction, (b) poorly innervated cerebral cortex responses by vasodilatation, (c) splanchnic beds response by vasoconstriction and (d) other vascular beds have variable changes.

Normally the coronary vascular constriction or dilatation, its resistance, and its blood flow mainly depends on the local myocardial O_2 demand which is controlled by heart rate, force of myocardial contraction and after-load, etc. These are again varied by acid-base changes. So, it is very difficult to define the coronary response to acid-base changes. But, the general rule is that acidosis causes dilatation and alkalosis causes constriction of the coronary vascular beds. Therefore, hyperventilation can increase the myocardial ischaemia and lactate levels by significantly reducing the coronary blood flow.

The venous side of vascular bed responses by constriction to both the metabolic and respiratory acidosis, acting both by directly and indirectly. Alkalosis also tends to produce vasoconstriction, except the pulmonary vasculature which dilates in alkalosis.

Effects on Respiratory System

Alteration of acid-base status also effect the respiration and O_2 delivery to tissues through the changes on minute ventilation and the O_2-dissociation curve. Acidosis increases minute ventilation and causes right wards shifting of O_2-dissociation curve (i.e better delivery of O_2 to the tissues). The increase in minute ventilation is accomplished by a substantial increase in tidal volume and little increase in respiratory rate (Kussmaul breathing). The rise of minute volume is about twice as great, if the fall in pH is due to the rise in PCO_2 (respiratory acidosis) than if the same fall in pH is due to the increase in metabolic acidosis (H^+). This is because CO_2 produced by respiratory acidosis diffuses more readily across the blood-brain barrier than H^+, produced from the metabolic acids.

Hypercapnia increases the ventilation by stimulating the central and peripheral chemoreceptor upto maximum PCO_2 of 80 to 90 mm of Hg (11 to 12 KP_a). But above that level of PCO_2 ventilation decreases. 80% of the changes in minute volume is caused by the effect of PCO_2 on the medullary chemoreceptors, while the lesser percentage of changes in minute ventilation is due to the stimulus, originating from the peripheral chemoreceptors. However, as the peripheral chemoreceptors are stimulated by changes in both the pH and PCO_2, but the medullary receptors are stimulated only by the passage of CO_2 across the blood-brain barrier and the subsequent increase in H^+ concentration in CSF. CO_2 stimulates the centrally mediated respiration by decreasing the pH of ECF of brain which perfuse the central chemoreceptor on the ventrolateral surface of the medulla. This takes place slowly over several minutes. But the increase of PCO_2 and reduction of pH produce a more rapid effect, within seconds, through the peripheral chemoreceptor of the aortic and carotid bodies. The respiratory stimulation by CO_2 among normal healthy individual varies widely (0.5 to 5 L/minute/mm Hg), but in the same individual the CO_2 response curve is similar at different times. The normal CO_2 response curve shows that respiratory acidosis will increae the minute ventilation by 2 to 3 L/minute for each 1 mm of Hg increase in PCO_2. The CO_2 response curve is shifted

to the left by acidosis and to the right by alkalosis (opposite to the O_2 dissociation curve). The volatile anaesthetic agents decrease the slope of CO_2-response curve in a dose dependent manner.

The acid-base disturbances also modify the airway resistance by direct (local) and indirect (through sympathetic − parasympathetic axis) way. Directly, the increased CO_2 level, by easily diffusing inside the cell, increases the intracellular H^+ and causes smooth muscle relaxation and reduction of airway resistance. Indirectly, the effects of hypercapnia causes bronchoconstriction by means of vagal stimulation. In normal healthy patient, the indirect constricting vagal effect predominates over direct local bronchodilating effects, causing net increase in air way resistance and work of breathing. Conversely, reduced PCO_2 level (in hypocapnia or respiratory alkalosis) produces a direct bronchoconstrictive effect, which is partially reduced by a centrally mediated bronchodilating effect. However, the direct bronchoconstrictive effect of hypocapnia is clinically predominant and useful in matching the ventilation with blood flow in both healthy and pathological lungs such as in pulmonary embolism.

Both the CO_2 level and pH of blood alter the position of O_2-dissociation curve. An increase in PCO_2 or decrease in pH (i.e acidosis) shift the O_2 dissociation curve to the right, causing an increased P_{50} level. P_{50} is the partial pressure of O_2 in blood when Hb is 50% saturated and the normal value of P_{50} is 27 mm of Hg. An increased P_{50} means high O_2 partial pressure with same 50% saturation of Hb, which helps in better or more delivery of O_2 to tissues at the same 50% saturation of Hb. On the other hand, hypocapnia and alkalaemia cause a shift to the left of O_2 dissociation curve and decrease in P_{50} level which means low O_2 partial pressure with same 50% saturation of Hb i.e. lesser delivery of O_2 to the tissues. During acidosis the P_{50} is increased by about 2 mm of Hg by a reduction of pH of 0.1units (10 nmol/L). Another cause of increased O_2 delivery to the tissues in acidosis is Bohr effect. The Bohr effect describes that the affinity of Hb for O_2 decreases as the level of H^+ in Hb increases. Thus, it increases the availability of O_2 to the tissues. Contrary, alkalosis or decrease in H^+ concentration in Hb increases the affinity of Hb for O_2. This causes less delivery of O_2 to the tissues and increases its absorption by Hb in the lung. In normal healthy patient, this Bohr effect has an overall important effect on absorption of O_2 by Hb at pulmonary level and delivery of O_2 by Hb at the tissue level. This is because O_2 affinity of Hb is greater in the normally somewhat alkalotic lung and lesser in the more acidotic tissue. In acidosis, the rightward shift of the O_2-Hb dissociation curve occurs immediately. But after 20 to 30 hours, the concentration of 2, 3 DPG (2,3 diphosphoglycerate) level falls and restores the O_2 affinity of Hb. Thus it shifts again the O_2-Hb dissociation curve back to the left. The 2, 3-DPG concentration decreases in acidosis because glycolysis in RBC is impaired in an acid environment and the glycolytic intermediates for the 2, 3-DPG production is depleted. Thus, the right shift of O_2 dissociation curve produced by a decrease in pH is partially antagonized by the decrease in 2, 3-DPG level induced by a decrease in intracellular pH.

Tissue oxygen delivery is the product of cardiac output and arterial oxygen content ($CO \times Hb \times SO_2$ and dissolved oxygen). A metabolic acidosis decreases delivery of O_2 to tissues by reducing CO which is partially compensated by the right shift of the O_2 dissociation curve. Whereas a metabolic alkalosis reduces O_2 delivery by both decreasing CO and shifting the O_2 dissociation curve to the left.

So, consequently correction of metabolic acidosis should always be the under correction and not the over correction.

Effects on Nervous System

Like other vascular beds, a rise in arterial PCO_2 also results in cerebral vasodilatation and increased cerebral blood flow. At P_aCO_2 of 80 mm of Hg, the cerebral blood flow becomes double. When P_aCO_2 is reduced to 20 mm of Hg, the cerebral blood flow will become half of the normal value due to the cerebral vasoconstriction. But below 20 mm of Hg of arterial CO_2 tension, the cerebral blood flow does not further reduce. This is due to accumulation of lactate by hypoxia which again stimulate the vasodilatation and limit further the reduction of blood flow.

As the H^+ can not cross the blood-brain barrier, so the neurological changes from acid-base imbalance are only due to the changes of PCO_2 which crosses the blood-brain barrier. The changes of CO_2 concentration on both the direction also causes changes in the pH of CSF on both the direction which impairs neuronal function and may lead to changes of mental status and coma. Increasing the pain threshold during hyperventilation are also probably the result of this. These clinical effects are more pronounced in respiratory acidosis or alkalosis than metabolic acidosis or alkalosis, because CO_2 originating from respiratory acidosis rather than H^+ originating from metabolic acids (H^+) is permeable to blood-brain barrier. Cerebral metabolism increases with acidosis and is maximum at pH of 7. But CO_2 has little direct effect on cerebral metabolism.

Respiratory acidosis causes hypothermia. It is due to the impairment of function of central thermoregulation centre and also due to the cutaneous vasodilatation, increasing heat loss.

Acidosis also causes an increase in the level of circulating catecholamines and stimulation of the sympathetic nervous system. Epinephrine is released from the adrenal glands and norepinephrine is released from the nerve terminals. In mild acidosis, this elevated catecholamine level tend to counteract the direct depressant effects of acidaemia on organ function. However, in severe acidosis the cellular response to catecholamine stimulation decreases and the direct depressant effect of acidosis on

cellular function becomes more apparent, despite the increased catecholamine levels.

Effects on Enzymic Activity

Each enzyme has its optimal pH level for its optimal activity. Again the cellular functional integrity depends upon the balance of activity of different intracellular enzymes. So if the pH varies beyond its normal limits, then enzymic chaos results and the cellular functions are deranged. This is because the activity of some enzymes are enhanced, while that of others are reduced.

Renal Effects

The response of renal vasculature to acidosis is vasoconstriction. As acidosis worsens, the renal vascular resistance also gradually increases and blood flow decreases. This renal vasoconstriction is the ultimate response after a balance between the direct, indirect and systemic effects of acidosis on renal vasculature. Metabolic acidosis causes increased renal vascular constriction than the respiratory acidosis for an equal change of pH. This is because increased PCO_2 in respiratory acidosis increases the availability of CO_2 to cross the cell membrane and relaxes the vascular smooth muscle cells, reducing the intracellular pH. Catecholamine mediated vasoconstriction of renal vasculature predominates over the vasodilating effect of acidosis (Fact file - VI)

Uteroplacental Effects

The acid-base disturbances affect the foetus in two ways − directly and indirectly. Directly the acid-base disturbance acts on the foetus through changes of PCO_2, as CO_2 is readily diffusible across the placenta. Passage of H^+ and HCO_3^- through the placenta is very slow and, therefore, metabolic acidosis or alkalosis will cause little change in foetal pH for several hours. The acid-base disturbances indirectly acts on the foetus through the changes in placental blood flow. The changes in foetal pH also produce the similar effects in foetal organ function as seen in adult. The direct effect of acidosis on the uteroplacental blood flow is vasodilatation. But, in severe acidosis, the overall effect on uterine blood flow is minimum. This is because the vasodilating effect of acidosis is opposed by the vasoconstricting effects of sympathetic stimulation by acidosis.

The direct effect of alkalosis on uteroplacental vasculature is vasoconstriction. Alkalosis also causes a leftward change in the maternal O_2-Hb dissociation curve which increases the affinity of maternal - Hb for O_2 and less delivery of it to the foetus. So, severe maternal alkalosis causes foetal hypoxaemia and foetal acidosis due to the combined effects of uteroplacental vasoconstriction and decreased O_2 delivery to the foetus.

Effects on Ca^{2+} and K^+

There are three forms of Ca^{2+} in plasma. Approximately, 50% of plasma Ca^{2+} remains in unionised form and bound to plasma protein which is available for diffusion into the tissues. Another 45% of the plasma calcium remains in ionised form and chemically active. Remaining 5% plasma Ca^{2+} present as nondiffusable form, but bound to other

FACT FILE - VI

Intracellular pH

Attempts have been made to measure the intracellular pH (pHi) by inserting microelectrodes with tips smaller than 1 micron in diameter into the cell. Rough estimations of intracellular pH also can be made after the administration of indicator drugs or by examining the rates of pH dependent intracellular enzymic reactions. But all these methods, currently available, are open to methodological criticism. In addition, it is unlikely that the cells of all parts of the organism or indeed all parts of the same cell, are at the same pH level.

Neverthless, many studies have shown that during normal healthy circumstances the intracellular pH is roughly related to the extracellular pH (pHe), but is always lower than it i.e. when pHe is 7.4, the pHi is usually less than 7.

During acid-base disturbances the pHi: pHe ratio may alter. CO_2 is freely permeable across the cell membranes, so that respiratory changes are reflected by similar changes in pHe and pHi ratio. But the highly ionized substances such as HCl and $NaHCO_3$ do not cross the cell membrane. So, changes in their extracellular concentration have a negligible effect on pHi and pHe ratio.

Changes in the intra: extracellular ratio of the electrolytes such as sodium and potassium also do alter the ratio of pHi: pHe. However, as the concentration of H^+ is one-thousand to one-hundred-thousandth of the concentration of K^+, so the changes are not the result of a one to one exchange across the cell membrane. Moreover the total replacement of intracellular H^+ by extracellular K^+ would produce no measurable change in K^+ concentration. Neverthless in potassium deficiency the intracellular cation deficit is partly compensated by the movement of H^+ resulting in extracellular alkalosis and intracellular acidosis.

Cerebrospinal Fluid pH

The pH of CSF is controlled within very narrow range than the rest of the ECF of body. Compared with the arterial blood the CSF pH is lower by 0.1 units and the PCO_2 is higher by 7 to 9 mm of Hg, but the bicarbonate concentration is similar. As the elevation of PCO_2 increases the cerebral perfusion thus it eliminates more CO_2. So, the blood-brain PCO_2 difference is decreased in hypercapnia and increased in hypocapnia.

The CSF acid-base status can be modified only by the changes in PCO_2 of CSF. So the changes in metabolic acid-base status are not mirrored in the pH of CSF, because the blood-brain barrier is relatively impermeable to H^+ and HCO_3^-, although CO_2 equilibration is rapid. Consequently, respiratory acid-base disturbances cause an plasma equivalent CSF change. So, during long-standing metabolic disturbances, lasting several hours and days, the pH of CSF remains almost unchanged, whilst the change of it in respiratory acidosis or alkalosis is corrected within hours. The compensation for respiratory change is accompanied by a change in HCO_3^- (not H^+) of CSF, so that the pH of CSF returns towards normal values. Although occasionally incomplete, such compensation for respiratory disturbances and the minimal response to non-respiratory changes, result in the relative constant pH of CSF. But till now, the parts played by the active and / or passive mechanism in the adjustment of HCO_3^- of CSF are so far uncertain. Similarly, the role of the brain cells in generating HCO_3^- is not known.

plasma components. In acidosis, H^+ ions compete for the negatively charged binding site of albumin where Ca^{2+} is attached. Thus, H^+ displaces the Ca^{2+} from its binding site and increases its ionised serum level. Reversly, alkalosis causes an increase in the available protein binding sites and reduction of ionised Ca^{2+} concentration with hypocalcaemia. This causes tetany or mild disturbances in cardiac contractility.

Serum K^+ and pH levels are usually inversely related. So, when pH falls plasma K^+ level rises and vice versa. In acidaemia, H^+ enters the cell along the concentration gradient and displaces the intracellular K^+ to maintain the intracellular electrical neutrality. K^+ comes out of the cell and causes hyperkalaemia. It is estimated that for each 0.1 unit change in plasma pH causes 0.6 mmol/L change in K^+ concentration in plasma. But this relation is not always linear.

PRACTICAL APPROACH

1. pH 7.39
   $PaCO_2$ 43 mm of Hg
   PaO_2 90 mm of Hg
   HCO_3^- 25 mEq/L
   This patient has normal acid-base balance or fully compensated any acid-base disorder. History and clinical examination will suggest.
2. pH 7.41
   PaO_2 64 mm of Hg
   $PaCO_2$ 40 mm of Hg
   HCO_3^- 23 mEq/L
   SaO_2 90%
   BE 0
   This patient has normal acid-base balance or near fully compensated any acid-base disorder with mild hypoxaemia.
3. pH 7.20
   $PaCO_2$ 80 mm of Hg
   PaO_2 82 mm of Hg
   HCO_3^- 26 mEq/L
   BE 0
   SaO_2 92%
   This patient is suffering from uncompensated severe respiratory acidosis with no hypoxia. Uncompensated because HCO_3^- within normal range.
4. pH 7.33
   $PaCO_2$ 66 mm of Hg
   PaO_2 75 mm of Hg
   HCO_3^- 34 mEq/L
   This patient has partially compensated respiratory acidosis with mild hypoxia.
5. pH 7.39
   $PaCO_2$ 55 mm of Hg
   PaO_2 60 mm of Hg
   HCO_3^- 38 mEq/L
   This patient has completely compensated respiratory acidosis with moderate hypoxia.
6. pH 7.50
   $PaCO_2$ 30 mm of Hg
   PaO_2 100 mm of Hg
   HCO_3^- 25 mEq/L
   This patient is suffering from uncompensated respiratory alkalosis. Respiratory alkalosis because $PaCO_2$ falls. Uncompensated because HCO_3^- does not rise. It is within normal range.
7. pH 7.42
   $PaCO_2$ 32 mm of Hg
   PaO_2 98 mm of Hg
   HCO_3^- 20 mEq/L
   The patient has compensated respiratory alkalosis. Respiratory alkalosis because $PaCO_2$ falls to 32 mm of Hg and compensated because HCO_3^- comes down.
8. pH 7.44
   $PaCO_2$ 25 mm of Hg
   PaO_2 99 mm of Hg
   HCO_3^- 20 mEq/L
   This patient has partially compensated respiratory alkalosis. If it is fully compensated, then HCO_3^- is expected to fall more.
9. pH 7.13
   $PaCO_2$ 42 mm of Hg
   PaO_2 140 mm of Hg
   HCO_3^- 14 mEq/L
   This is a case of uncompensated metabolic acidosis. Acidosis and uncompensated because the present pH value is far below the normal value. Metabolic acidosis because only the HCO_3^- falls far below the normal range. Uncompensated because $PaCO_2$ does not change. In compensated stage it will fall.
10. pH 7.26
    $PaCO_2$ 30 mm of Hg
    PaO_2 130 mm of Hg
    HCO_3^- 10 mEq/L
    This is a case of partially compensated metabolic acidosis with hyperoxaemia. Metabolic acidosis because the level of HCO_3^- fall with the fall of pH. In a case of fully compensated stage the formula for expected $PaCO_2$ is: $(1.5 \times HCO_3^-) + 8 \pm 2$. So, here if it was a fully compensated metabolic acidosis, the expected $PaCO_2$ is: $(1.5 \times 10) + 8 \pm 2 = 23$ m Eq/L. But here $PaCO_2$ falls up to 30 mm of Hg. So, it is partially compensated.
11. pH 7.55
    $PaCO_2$ 38 mm of Hg
    PaO_2 120 mm of Hg
    HCO_3^- 34 mEq/L
    This is a case of uncompensated metabolic alkalosis with hyperoxaemia. Metabolic alkalosis because pH is elevated and HCO_3^- is raised. Uncompensated because $PaCO_2$ is not raised. It is within normal range.
12. pH 7.55
    $PaCO_2$ 50 mm of Hg
    PaO_2 84 mm of Hg
    HCO_3^- 50 mEq/L
    This is a case of partially compensated metabolic alkalosis. Why it is metabolic alkalosis is easily understood. In a fully compensated case the formula for expected rise of $PaCO_2$ is: $6 \times (\text{measure } HCO_3^- - 24) + 40$. So, here if it is a fully compensated metabolic alkalosis, then the expected $PaCO_2$ should be: $.6 \times (50 - 24) + 40 = .6 \times 26 + 40 = 55.6$ mEq/L. But here $PaCO_2^-$ is elevated only up to 50 mm Hg. So, this metabolic alkalosis is partially compensated.

9 Water Balance

INTRODUCTION

Water is the most vital and abundant component of the body. It constitutes about 60 to 70% of our total body weight or lean body mass (LBM) (It is better to use the term LBM than total body weight.) within which the major cations like Na^+, K^+, Ca^{2+}, H^+, Mg^{2+} and anions like Cl^-, PO_4^-, HCO_3^- and proteins are dissolved. Without water there will be no form of life. It forms the intracellular medium within which the metabolic reactions of cell, responsible for life, takes place and also forms the extracellular medium through which the transport and exchange of different solutes between the intracellular and extracellular spaces take place. Water deprivation brings about death more earlier and easily than that of food. If water is given instead of food, then life may continue for several weeks by the loss of body fat and tissue proteins.

Total body water (TBW) in an average human being weighing about 70 Kg varies between 45 to 50 litres it is 60 – 70% of 70 kg. In female, it is 10% less than male. So, in female the TBW constitutes about 50 to 60% of lean body mass (LBM). Therefore, TBW in female weighting about 70 Kg is 40 to 45 litres. But the above values vary mostly with the relative degree of obesity of an individual, because body water content is inversely related to the adiposity of organism. Hence, as female has more body fat, it contains less TBW in relations to LBM than male and in a lean person the value of TBW is higher thant that of an obese person. Therefore, in general woman contains more fat and less water than man.

The total water of a body is considered to be distributed within two main components: the intracellular (IC) and the extracellular (EC). The water of intracellular component constitutes about 55% of TBW or 40% of total (or lean) body weight (LBM). The remaining 45% of the TBW constitutes the extracellular fluid component or 20% of total body weight or lean body mass (LBM). Of this 20% extracellular body water, 15% remains in the interstitial compartment and 5% remains in the intravascular compartment. The cell membrane actually provides the boundary between these two IC and EC components (Table 9.1).

The IC fluid component represents the sum of fluid contents of all the cells in a body. It is neither a continuous nor a homogenous phase. The cell membrane plays an important role, controlling the IC and EC fluid volume and their composition. This is done in the following way. A membrane bound ATPase dependent Na^+-K^+ pump exchanges K^+ inside the cell and Na^+ outside of the cell in 2:3 ratio. This is due to the relative impermeability of cell membrane to Na^+ in relation to K^+. Therefore, Na^+ is concentrated in the EC fluid and is the most important determinant factor for extracellular osmotic pressure and osmolality. Whereas K^+ is concentrated in the IC fluid and acts as the most important determinant factor for IC osmotic pressure and osmolality. This IC and EC osmotic pressure and osmolality determines the IC and EC fluid volume. Protein (anion) is a nondiffusible solute and impermeable to cell membrane. This results in high IC protein concentration and is also responsible for intracellular (IC) osmotic pressure and osmolality. The unequal exchange of 2 ion of K^+ going into the cell against 3 ion of Na^+ going out of the cell by the Na^+-K^+-ATPase pump, situated on the cell membrane, maintains this relative IC hyperosmolar condition and is critical for functions of the cells. Therefore, interference of this Na^+-K^+-ATP pump due

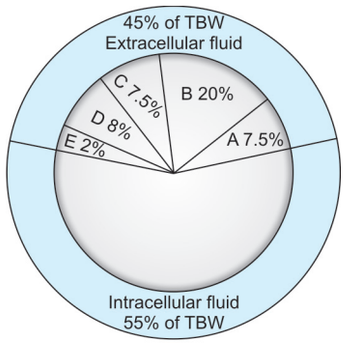
Table 9.1: Percentage of body fluid compartment of a 70 Kg adult male

Compartment	*Fluid as percent of total body wt (%)*	*Fluid as percent of total body water (%)*	*Total fluid volume (L)*
Intracellular	40	55	28 L
Extracellular	20	45	14 L
(i) Interstitial including connective tissue, bone, lymph, cartilage, transcellular etc.	15	37	10.5 L
(ii) Intravascular	5	8	3.5 L
Total	**60%**		

to any cause such as ischaemia, hypoxia, poison, etc; leads to progressive swelling of cells and ultimately its death.

Like intracellular (IC) fluid component, the extracellular (EC) fluid component is also not a continuous or homogenous phase. Rather, it is a heterogenous collection of fluids. It is postulated that 55% of TBW is present in the IC component and the rest 45% of TBW is in the EC component. The EC fluid component is again divided into the following subcompartments : interstitial fluid and lymph (20%), intravascular fluid (8%), fluid in dense connective tissue and cartilage (7.5%), inaccessible bone water (7.5%), transcellular water (2%). The transcellular fluid is the part of EC fluid component which is separated from other extracellular fluid by an epithelial membrane. Thus, the transcellular fluid includes : CSF, joint or synvial fluid, intraocular fluid, fluid in pleural or pericardial or peritoneal cavity, fluid in the duct of digestive gland, intraluminal fluid of GI system, etc. The EC fluid provides medium for different electrolytes, nutrients, waste products, enzymes, hormones, gases, etc, to move from one place of its origin to another. Therefore, maintenance of EC fluid volume is also very critical. The Na^+ is quantitatively the most important EC fluid cation and is the major determinant factor for the EC fluid volume and pressure which is parallel to the intravascular fluid volume and pressure. The changes in total body Na^+ content is, therefore, related to the EC and intravascular fluid volume and pressure. The total body Na^+ content further depends on its intake through oral or intravenous route and excretion through renal, and extrarenal route (Fig. 9.1).

Normally, very little amount of interstitial fluid remains in free form, because it is usually present in chemical association with an extracellular substance, called proteoglycans forming a gel. This interstitial or tissue fluid is formed from the plasma by the process of diffusion



A = Dense connective tissue and cartilage
B = Interstitial fluid and lymph
C = Bone water
D = Intravascular compartment
E = Transcellular water
TBW = Total body water

Fig. 9.1: Schematic representation of distribution of body water in different compartment (in % of TBW)

or filtration through capillaries. This fluid occupies the intercellular space and forms the connecting link for the transport of nutition, gases and metabolic end products between the blood capillaries, tissue cells and lymph. It constitutes the internal enviornment of body which surrounds the cells. Interstitial fluid is also derived from the cells due to intracellular activities. The amount of interstitial fluid formed from blood depends upon : (i) the capillary permeability, (ii) the differences of hydrostatic pressure between capillary and the interstitial fluid, (iii) the difference of collidal osmotic pressure of blood and interstitial fluid. It is obvious that anything that increases the capillary permeability will also increase the amount of interstitial fluid that is formed. Regarding the blood presure and osmotic pressure, it is known that at the arterial end of capillary, the average blood pressure (hydrostatic pressure) is about 32 mm of Hg and at the venous end it is about 10 mm of Hg. On the other hand, the colloidal osmotic pressure of blood at both the ends of capillary is same and is about 25 mm of Hg. Therefore, at the arterial end the net filtration pressure is 32 − 25 = +7 mm of Hg which is directed towards the interstitial fluid. On the otherhand, at the venous end, due to fall in blood or hydrostatic pressure the net filtration pressure is negative which is 10 − 25 = − 15 mm of Hg and in the opposite direction i.e. from interstitial fluid to the capillary. Thus, at the arterial end of capillary water, electrolytes, nutrients, gases and the other solutes pass from the intravascular to interstitial compartment and at the venous end they pass in opposite direction and maintain the homeostasis of water in interstitial compartment. Moreover, the magnitude of these forces differs at the various tissue beds. Arterial capillary pressure is determined by the precapillary sphincter tone. When the tone of sphincter increases, there is less flow of blood through the capillaries and the capillary pressure is reduced. Thus, some capillaries which require high pressure (e.g. glomeruli) maintain low precapillary sphincter tone, while high sphincter tone is maintained for low pressure capillaries of muscles (Table 9.2).

The amount of interstitial fluid formed from the tissue cells, depends upon the degree of metabolic activity of the cells. It should be noted that the tissue cells produce water as an end product of the carbohydrate, fat and protein metabolism.

Table 9.2: Composition of fluid in different compartment of body

Intracellular (mEq/L)				↔	*Interstitial (mEq/L)*				↔	*Intravascular (mEq/L)*			
Na^+	10	Cl^-	4		Na^+	140	$Cl-$	110		Na^+	140	$Cl-$	100
K^+	140	PO_4^{2-}	100		K^+	4	HCO_3^-	30		K^+	4	HCO_3^-	26
Ca^{2+}	1	SO_4^{2-}	2		Ca^{2+}	3	PO_4^{2-}	2		Ca^{2+}	3	PO_4^{2-}	2
Mg^{2+}	40	HCO_3^-	10		Mg^{2+}	3	SO_4^{2-}	1		Mg^{2+}	3	SO_4^{2-}	1
		Protein (or 16 gm/dl)	50				Protein	6				Protein (or 7 gm/dl)	24

This metabolic water is added to the already existing interstitial fluid. More the degree of activity, more will be the metabolic water formed and consequently the amount of interstitial fluid will increase. Two important exceptions of the usual haemodynamic events of the capillary pressure are : (i) the capillaries of lungs where hydrostatic blood pressure is about 0.6 mm of Hg and (ii) the capillaries of kidney where glomerular hydrostatic pressure is about 60 to 80 mm of Hg. If hydrostatic blood pressure is increased within capillaries, then it will interfere the return of water to the venous end of capillaries and if it is excess than the amount which is drained by lymphatics then it will result in excess accumulation of interstitial fluid, causing oedema.

It is believed that the composition of interstitial fluid is same as that of the lymph, except that its protein content is negligible. So, its colloidal osmotic pressure is very low. The composition and volume of interstitial fluid is regulated by the constant interchange of it between the blood and lymph. The specific gravity of interstitial fluid varies between 1.015 to 1.023. It may contain few erythrocytes. But regarding the white cells, the interstitial fluid contains a good number of lymphocytes and a small number of granulocytes. Blood proteins and nutrient contents of it are very low. It does not contain platelets, but may also clot very slowly. It contains higher concentration of waste products, but glucose, salt and water contents of it are more or less same as that of plasma (Fact file- I).

The interstitial fluid constitutes the internal media or enviornment in which the tissue cells are bathed. The cells draw in O_2 and nutrition from this fluid and excrete their metabolites into it. Hence, interstitial fluid may be regraded as the medium which supplies all the immediate requirement of the cell. Interstitial fluid also acts as a great reservoir of water, salts, nutrition, etc. This function is very important. Because in any condition, when the blood volume is increased or diminished, then the new physical forces are set up by which the blood volume is kept constant with the help of this tissue reserve. For example, during haemorrhage the capillary pressure becomes very low and goes below the colloidal osmotic pressure of the capillary which remains same. Due to this relative higher colloidal osmotic pressure in the capillaries water is drawn in from the tissue or interstitial space, so that blood volume is restored. When water is drawn away from blood, such as due to diuresis, excessive sweating, diarrhoea etc, blood volume and blood pressure will be lowered. But the plasma proteins will be more concentrated. This will increase the colloidal osmotic pressure of blood. This increased osmotic pressure of plasma and reduced blood pressure will increase the rate of absorption of water from the tissue fluid and thus the blood volume will be kept constant. On the other hand, when blood volume increases as for instances by IV infusion of large quantities of isoosmotic saline, then the fluid will pass out into the tissue spaces due to two causes: (i) saline will dilute the colloids and reduce the capillary colloidal osmotic pressure and at the same time, (ii) by increasing the volume of blood will raise the blood pressure, and will cause more filtration. Both these factors will cause more fluid to run out into the tissue spaces, until blood volume comes back to the original level.

FACT FILE - I

The capillary endothelium acts as freely permeable membrane to water, anions, cations and many diffusible substances such as urea, glucose, amino acids, etc, except protein. As a result the solute concentration between the plasma and interstitial fluid is same. Each contains sodium and chloride as the principle cations and anions, respectively. As protein is a non diffusible anions, it remains in plasma at a higher concentration. The concentration of Cl– is slightly higher in interstitial fluid. This is due to maintain electrical neutrality which is called Donnan equilibrium.

The intravascular fluid compartment is restricted to the vascular space, enclosed by endothelium and the fluid in it is called plasma. Most electrolytes, glucose, amino acids, enzymes, hormones, water, etc, can freely pass between the plasma and the interstitial space, resulting in nearly identical composition of interstitial fluid and palsma. But protein can not pass freely between the plasma and interstitial space. This is due to tight intercellular junction between the adjacent endothelial cells. As a result plasma protein mainly albumin remain in high concentration in the intravascular compartment and act as only osmotically active solute.

Different Nomenclatures and Definitions

To understand the water and electrolyte balance properly, it is mandatory to know the concentration of electrolytes and other solutes in the solution accurately. Usually, the concentration or quantity of solutes in a solution is expressed as percentage, gram moles, equivalent, etc; per litre. Furthermore, to complicate the things the concentration of solution can be expressed as quantity of a solute per volume of solution or per weight of solvent. At present the concentration of solution is expressed by the system of international unit (SI). These systems of international units are : molarity, molality, osmolality, osmolarity, etc.

According to Avogadro's principle the number of molecules represented in one mole of substance is 6.023×10^{23}. A mole or gram molecular weight (i.e. molecular weight in gram) is the amount of substance equal to its molecular weight expressed in grams. When the amount equal to the molecular weight in grams of a solute is dissolved in 1 L of solvent, then it is called the one molar (M) solution. For example, when 98.016 gm of H_2SO_4 (molecular weight of H_2SO_4 is 98.016) is dissolved in 1 L of water, then it produces one molar solutions. When molecular weight in gram

of a solute is dissolved in 1 Kg of solvent then it is called one molal (m) solution. Therefore, the number of moles of a solute per litre of solution is called molarity. On the otherhand, the number of moles of a solute per kilogam of solution is called molality.

Osmosis refers to the movement of solvent (e.g. water) across a semipermeable membrane into the region where there is higher concentration of non diffusible solute. This non diffusible solute is known as the osmotically active particles. The term osmosis and osmoles is only applicable to non diffusible solutes. The amount of this non diffusible (or non dissociable or osmotically active particles) solutes present in solution is expressed as osmoles, like moles. One osmole of non dissociable solute is equal to the 1 mole or molecular weight in gram of dissociable solute. The number of osmoles of nondissociable solute per litre of solution is called osmolarity. On the otherhand, the number of osmoles of non dissociable solute per Kg of solvent is known as osmolarity (Fact file- II).

The relation between the osmole and mole is that when each mole of dissociable solute ionizes then it results in n × osmole, where n represents the number of different types of ions produced by dissociate solutes. For example, when one mole of highly dissociable solutes such as NaCl is dissolved in water it produces 1 osmole of Na^+ and 1 osmole of Cl^- or 2 osmole of ions. Therefore, one osmole (osm) of dissociable solutes (such as NaCl) is equal to the one mole of that substance, divided by the number of freely moving particles or ions that each molecule of that substance librates in solution. Therefore, 1 mole of NaCl = 2 osmol of NaCl. Hence 1 osmol of NaCl = ½ mole of NaCl. In another exampl, one mole of Na_2SO_4 would dissociate into Na^+, Na^+ and SO_4^{2-}, supplying 3 osmol. So, 1 osmol of Na_2SO_4 is 1/3 mole of it. Therefore, osmolality is the number of particles (different ions) per litre of water and osmolarity is the number of particles per Kg of water.

The molecular weight of glucose is 180. Therefore, one mole or one gram molecular weight (gm mole) of glucose is 180 gm. Hence, if 180 gm of glucose is dissolved in 1 litre of water, then this solution will represent molar concentration of 1 mol/L and as the glucose is non dissociable and non diffusible solute (or osmotically active particles), so the solution will also represent osmolar concentration of 1 osmol/L. On the otherhand, NaCl is a dissociable solute. It ionizes in solution and each ion represents an osmotically active particles. Molecular weight of NaCl is 23 + 35.5 = 58.5. Therefore, if 58.5 gm of NaCl is dissolved in 1 litre of water then the molarity of this solution is 1 mol/L and osmolarity is 2 osmol/L.

In body fluids, the concentration of different solutes are much lower. So, they are expressed as millimole per litre (m.mol/L) which is equal to the one thousandth of one mole per litre. Thus, 1 mol of NaCl is 58.5 gm and 1 m.mol = 58.5 mg.

In vivo or in the body the dissociation of dissociable solutes remains incomplete. So, a solution of NaCl containing 1 m.mol/L of solute contributes osmolarity slightly less than the theoretical 2 m.osmol/L.

Equivalent is also commonly used as measuring unit for solutes that ionizes in solution and produces ions. Actually it is the measuring units of ions in a solution produced from dissociable solutes. The number of equivalent of each ion is the number of moles of these ions divided by its valency or charge. Thus, 1 mole (M) solution of NaCl yields 1 equivalent of Na^+ and 1 equivalent of Cl^- per litre of solution. Hence, one equivalent of Na^+ = 23 and one equivalent of Cl^- = 35. Similarly, one molar solution of $CaCl_2$ yields 2 equivalent of Ca and 2 equivalent of Cl^-, but 1 equivalent of Ca^{2+} is 40 ÷ 2 = 20. Gram equivalent is the molecular weight in gram divided by the number of valency of ion present or equivalent which is expressed in gram. One milli equivalent (mEq) is one thousandth of one equivalent.

The concentration of solution is also measured by percentage. This percentage can be expressed as percent by weight or present by volume. Weight in grams of a solute per 100 gms of solution is known as percent by weight and the same amount of solute in gram dissolved in 100 ml of solution is known as percent by volume.

Electrolytes and Colloides

The electrolytes are the compounds which can be dissociated into anions and cations, when it is in molten state or in solution. The example of electrolytes are: salts, acids, bases, etc. On the otherhand, the non electrolytes are the compounds which can not be dissociated in its solution of water, after the passage of currents.

When sugar, urea, NaCl, etc, are dissolved in water, they result in a clear solution. This is called true or crystalloids solution. On the otherhand, when the protein, starch, glycogen, etc, are dissolved in water they result in thick, opalescent solution. This is called colloidal solution. But, the actual difference between a crystalloid and colloid solution depends on the size of the molecules of solute in the solvent. If the size of the molecules of a solute is greater than 200 mμ, they remain as suspension. While, if the size of the molecules of a solute is less

FACT FILE - II

Tonicity is a physiological term, whereas osmolality is a chemical term and may be confused with the previous one. But, it should not be done. The critical difference between these two terms is that all solutes contributes to the osmolality, but only solutes which do not cross the cell membrane is responsible for tonicity. Because, the term tonicity is used to describe the osmotic pressure created by nondiffusible solid of a solution in relation to that of plasma. The substances such as urea, glucose, ethanol, methanol, etc, can diffuse across the cell membrane freely. Therefore, they do not alter the distribution of water between the IC and EC fluid compartments and can not contribute to tonicity. But, they contribute to osmolality. Whereas, the substances such as mannitol and sorbitol can not cross the cell membrane and is only restricted to the EC fluid compartment. Therefore, they contribute both to the osmolality and tonicity.

than 1 mμ they remain as true clear solutions. Therefore, the size of the molecules in a colloid solutions varies between 1 to 200 mμ. To understand the difference between a crystallod and a colloid one should have a clear idea regarding the forces that help the solute particles to stay in solution which are roughly as follows :

i. Inherent movement of the solute particles i.e. diffusibility of solute.
ii. Inherent movement of the solvent molecules which continuously dash against the solute particles and thus help to keep them in solution.
iii. Electric charge – positive or negative - carried by the solute particles which by constant attraction or repulsion also help to form uniform solution.
iv. Hydration or carrying water molecules with the solute molecules.

If the solute particles are very small (below 1 μm), then all these above mentioned forces will act to their maximum. Thus, it will result in a permanent true clear solution. Now, if the solute particles be gradually made larger and larger, their own movement or diffusibility will gradually be reduced and ultimately will be almost nil. Then, the other forces such as the dashing forces of the solvent molecules, electric charges, etc, will further try to keep the large solute particles somehow in solution and will be able to do so upto a certain extent. This is called colloid solution. If then the solute particles be made still larger (over 200 μm), then all the forces will completely fail and the solute particles will not go into solution at all. Then they remain in suspension or as insoluble state. Hence, if the relation between solute and solvent be studied as a series of phenomenon, it will be found that at one extreme end there is complete solubility or true crystalloid solution and at the other extreme end there is complete insolubility. While in the intermediate stages there will be a phenomenon of semi solubility. This is called the colloidal solution (Fact file- III).

FACT FILE - III

The difference between the IC and EC fluid compartment is that in IC fluid the principal cation is K+ and the principal anion is phosphate (PO42–). Further, there is high protein content inside the cell due to impermeability of it to the cell membrane. But the cell membrane is permeable to different ions, glucose, urea, water, etc. Therefore, there is continuous movement of water across the cell membrane and equalizes the osmotic pressure between the IC and EC fluid compartment. However, at equilibrium the osmolality between the IC and EC fluid compartment is not equal. This is also due to the active movement of water and diffusable particles across the cell membrane and produces any induced osmolal gradient. This is the fundamental principle which help to understand the physiology of fluid and electrolytes.

Thus, other factors remaining constant the real difference between a true crystalloid solution and colloid solution lies in the size of the solute particles and not upon their chemical nature. Hence, a colloid may be defined as a substance which by the reason of the size of its molecules is slowly diffusible rather than soluble in water and is incapable of passing through an semipermeable membrane. In this substance the solute particles are proportionally larger than the solvant molecules.

Method of Exchange of Substances Between Different Fluid Compartments

The exchange of different substances and water between the different fluid compartment in the body mainly occur by three processes. These are: filtration, diffusion and osmosis.

Filtration

It is the process by which undissolved particles are separated from a liquid through a membrane as a result of a mechanical force which is called the filtering force. It is done through a porous substance. This filtering force is either gravity or hydrostatic pressure which may be positive or negative. The important examples of filtration are: (i) absorption from the small intestine, (ii) passage of water, salts, food stuffs, etc. from the blood stream to the interstitial fluid, (iii) filtration in glomeruli.

Diffusion

Molecules of a substance are continuously in motion. This motion is least in the solids, intermediate in the liquids and maximum in the gases. When the two such substances are kept in contact or is separated by a membrane, the molecules of the two substances will pass into each other, until an uniform admixture is obtained. This spontaneous admixture of the molecules of the two substances due to their inherent molecular movement is called the diffusion. Anything that alters the molecular movement of the substances also alter the rate of diffusion, proportionally. The rate of diffusion of a substance across a membrane depends on: (i) the concentration of substances on the two sides of membrane, (ii) for charged substances the electrical potential across the membrane, (iii) permeability of these substances through the membrane, (iv) pressure difference between the two sides of the membrane, because pressure imparts the greater kinetic energy. In human some clinical examples of diffusion are: (i) absorption from intestine, (ii) exchange between plasma and red cells, (iii) exchange at the capillary bed such as nutrients, O_2, CO_2, metabolic waste products etc, (iv) exchange at the lung capillaries of O_2 and CO_2, etc.

Diffusion of substances through the cell membrane between the intracellular and interstital fluid take place by the following mechanism: (i) through different protein channels in the cell membrane, (ii) directly by diffusion through the cell membrane, (iii) by carrier protein situated on the cell membrane such as glucose, amino acids, etc. Water, O_2, CO_2 and many other different lipid soluble molecules diffuse through the cell membrane directly. Different ions such as Na^+, K^+, Cl^-, etc, diffuse the cell membrane poorly, because of the unfavourable voltage

potential across the membrane which is created by the Na^+-K^+ pump. Therefore, these ions can only diffuse by the help of specific protein channels.

The capillary endothelial cell wall is only 0.4 to 0.6 µm thick, consisting of a single endothelial cell layer situated on the basement membrane. The gap or cleft between the two adjacent endothelial cells is only 5 to 6 nm. Water, O_2, CO_2 and other many lipid soluble substances can diffuse directly through the endothelial cell membrane from both the sides which is governed by the hydrostatic and colloidal osmotic pressure of tissue and capillary. Only glucose, Na^+, K^+ and other water soluble substances with low molecular weight cross the intercellular clefts.

Osmosis

When the solute dissolved in water at two different concentrations are separated by a semipermeable membrane, then the diffusion of water, (but not the solute) from lower to higher concentration through this semipermeable membrane is called osmosis, provided the solute itself is not permeable to the membrane. The water moves on both direction, but from lower solute concentration to higher solute concentration is more. Then, a time will come when the movement of water molecules from both the side is same, so that no further alteration of volume of solution on any side of the membrane will take place. At this stage, the hydrostatic pressure of solution at the concentrated side neutralizes the attractive force of this higher concentrated solution for water molecules. This attractive force is called the osmotic pressure. This is the force under which a solvent moves from lower solute concentration to higher solute concentration, when a selectively permeable membrane separates these two solutions of different concentration. The osmotic pressure does not depend on the size of the molecules of solute, but upon the total number of discrete particles of solute per unit volume of solution. If the solute is ionisable, the osmotic pressure will be proportionaly more. If more hydrostatic pressure is applied on the side of the solution of higher concentration, then water will pass from higher concentrated solution to the lower concentrated solution, opposite to osmosis. This is called ultrafiltration.

If the two solutions are separated by a semipermeable membrane and have the same osmotic pressure, then they are called isotonic. But if one have the less osmotic pressure than another, then it is called the hypotonic and if one have higher osmotic pressure than another, then it is called the hypertonic. For example, 0.9 percent NaCl solution is isotonic with blood or plasma and commonly known as normal saline. A5 percent solution of glucose has also similar osmotic pressure like plasma and is isotonic. Therefore, these two solutions such as 0.9% NaCl and 5% dextrose is isotonic, but they are not isosmotic. Because, they have not similar number of solute particles per unit volume of solutions. Clinical examples of osmosis are: absorption from the intestine, exchange in the capillary bed, regulation of urine formation, reabsorption of CSF, etc.

Water Metabolism and Its Balance

Life first evolved in an aquatic medium. So, there will be nothing to be astonished that water is the most essential component of life. Of the three factors such as water, salt and food, water is the most important for survival of life. So, deprivation of water will kill a subject much earlier than deprivation of salt and food. It must be remembered that the water content of the body is derived from two sources: (i) from the food and drink, and (ii) from the cells as the end product of metabolism. The former is called as the exogenous water and the latter is called as the endogenous water. The body water remains in two states: (a) Free states i.e. not combined with anything. Most of the body water remains in this from. Various substances can remain dissolved in this form of water and be removed by ultrafiltration. (b) Bound water. This is very small in quantity and remains combined with colloids and other substances.

The endogenous water comes from the cells as an end product of metabolism. Almost the whole amount of H^+ ion coming from solid food is converted into water, but only about 5 gm of hydrogen is excreted in the form of ammonia, urea etc. Different food stuffs yield different amount of water. Its approximate figures are given below:

100 gm of fat gives 100 gm of water
100 gm of starch gives 50 gm of water
100 gm of protein gives 40 gm of water
100 gm of alcohol gives 120 gm of water

Water is continuously being lost and supplied to the body. But, still the total water content of the body is kept more or less constant, by maintaing a balance between the supply and loss. This indicates that there must be an efficient machinery for maintaing the water balance.

Water requirement and loss

The total water requirement of an adult under ordinary conditions is about 2500 to 3000 ml. This is about 1 ml per calorie of energy intake. Half of this quantity i.e. 1500 ml or ½ ml of water per calorie intake should be taken as free drinks.

Supply of water		
1. Drink		1400 ml
2. Solid food (all solid foods contain some water as free form)		800 ml
3. Metabolism		400 ml
	Total	2600 ml
Loss of water		
1. Kidney		1500 ml
2. Skin (visible and unvisible perspiration)		600 ml
3. Lungs		400 ml
4. Faeces		100 ml
	Total	2600 ml

The above figures are average and the approximate gain or loss by any one of these routes may rise or fall under various conditions. The loss of water through skin varies according to the temperature and the humidity of atmosphere and also upon

the amount of muscular exercise done. In hot climates and with exercise this excretion of water through skin may vary from 3 to 10 litres per day. Higher atmospheric humidity reduces the water loss through the skin. Water excretion by lungs also increases in hot dry weather. In diarrhoea, dysentry, cholera, etc, more water is lost through the faeces. While in condition of diuresis more water is passed out by the kidneys. The water secreted in the digestive juices is not lost. Because it is completely reabsorbed and about 5 to 7 litres of water circulate in this way per day. The loss of water through saliva and lacrymal secretions is negligible under normal conditions (Fig. 9.2).

Positive and negative water balance

Physiologically water balance is said to be positive in growing infants, children, convalescents, athlets, pregnant women, etc, who are storing water and building their body tissues. During positive water balance each gram of protein is laid down with about 3 gm of water. Whereas fat and glycogen are deposited with less amount of water. When diet is changed from higher fat to higher carbohydrate, then more water retention takes place and the balance becomes more positive.

Water balance is negative under the follwoing conditions: (i) when the subject is thirsty, (ii) when a preexisting oedema is clearing up due to diuresis, (iii) when diet is changed from high protein to carbohydrate and fat. In any condition of increased water loss, the relative proportion of Na^+ and K^+ content of the fluid which is going to lost will indicate whether the water is coming chiefly from the extracellular or the intracellular sources. The fluid with high Na^+ content will indicate extracellular source, whereas the fluid with high K^+ content will indicate intracellular source, provided intake of these two electrolytes remains constant.

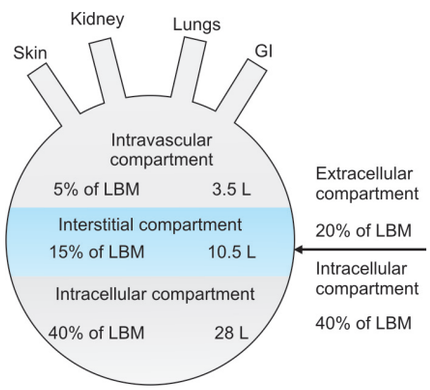


Fig. 9.2: Distribution of total body water (TBW) in the different compartment of body. (LBM = Lean body mass)

Regulation of Water Balance

Inspite of large amount of water is constantly appearing in and disappearing from the body, a fairly accurate balance is maintained between its gain and loss which indicates that there must be a strong regulating machinery. The mechanism which regulates this water balance in our body is very intricate and is not yet fully known. However, the following factors are closely involved in it. These factors are: endocrine, renal, respirations and thirst.

Endocrine

A number of endocrines take part in water regulation. These are posterior pituitary, hypothalamus and adrenal cortex.

Posterior pituitary and hypothalamus

From the posterior pituitary gland antidiuretic hormones (ADH) or vasopressin is secreted which has got immence influence upon the water balance. It increases the reabsorption of water from the distal renal tubules and thus reduces the urine volume. It is very interesting to note that the secretion of this hormone is controlled by the water content of the body. Excess of water depresses, while dehydration stimulates the secretion of this hormone. This is constituted through hypothalamus. The hypothalamus controls the secretion of ADH from posterior pituitary through the supra-optico-hypophyseal tract. Excess of water dilutes blood and reduces the osmolality of ECF as a result of which the hypothalamus is depressed (the specialised neuron in the supraoptic and paraventricular nuclei of the hypothalamus are very sensitive to the osmolality of ECF) leading to less secretion of ADH from the posterior pituitary and consequently diuresis is produced with the maintenance of blood volume and osmolality of tissue fluid. When body water is reduced, osmolality of ECF increases and subsequently hypothalamus is stimulated. Thus, more ADH is secreted and consequently urine volume is reduced with maintenance of blood volume and osmolality of tissue fluid. Hypothalamus also controls the formation of urine by regulating the renal circulation and general blood pressure through sympathetic nervous system.

Adrenal cortex

Adrenal cortex secretes aldosterone which plays an important part in the maintenance of water balance of body. The secretion of aldosterone is controlled by the angiotension II and also by the high serum K^+ and low serum Na^+ level. The aldosterone regulates the water balance through release of ADH from posterior pituitary, mediated through serum K^+ and Na^+ level, causing retention of water and thus increase the blood volume. In adrenal cortical insufficiency there is decreased reabsorption of Na^+ and as a result more Na^+ is lost through the urine. This causes increased reabsorption of K^+. Along with the decreased reabsorption of Na^+ the reabsorption of Cl^- is also depressed. Therefore, there is consequential changes in the composition of body fluids. The intracellular crystalloid osmotic pressure exceeds that of the extracellular crystaloid osmotic pressure and water flows from the extracellular fluid to the intracellular fluid. Plasma volume decreases and there is haemoconcentration.

Renal

In physiological condition when water content of the body rises such as by excess

water intake or by the infusion of saline, etc, then kidneys excrete more water. This effect is due to: (i) Incresed blood volume and consequently the rise of blood pressure and thereby increased filtration pressure. (ii) Dilution of plasma protein reducing colloidal osmotic pressure and consequently increasing the available filtration pressure. (iii) Increasing the number of active glomeruli which was dormant till now. (iv) Depressing the degree of water reabsorption by the renal tubules through direct inhibition of hypothalamus and pituitary ADH mechanism. (v) Increase of central blood volume enhances the urine output through the inhibition of secretion of ADH. It is also suggested that inhibition of ADH secretion takes place reflexly through the stimulation of stretch receptors present in the left atrial wall. (vi) Less secretion of renin, angiotensin II, aldosterone and decreased absorption of water. Among these, the forth and sixth factors are most important in regulating the water excretion by the kidneys under physiological conditions.

Lungs and skin

These channels also take considerable part in regulation of water balance by excreting the variable amounts of water.

Thirst

When more fluid is lost such as in diarrhoea, vomiting, diuresis, sweating, haemorrhage, etc, then the subject feels thirsty and drinks water. So, thirst may be defined specifically as the 'hunger for water'. In this way the amount of lost water is replenished. In hybernating animals metabolism is so slow that the water produced by the oxidation of food stuffs within the cell is enough to equalise the water loss. Hence, under such condition no thirst is felt. During thirst drinking is stimulated by two types of stimulli acting on the hypothalamus: (i) rise in ECF osmolarity even with or without any change in blood volume, and (ii) a fall in blood volume even with or without any change in ECF osmolarity (Fig. 9.3).

Osmoreceptors in the lateral preoptic area of the hypothalamus are very sensitive to the changes in blood volume or extracellular osmolarity. Activation of these receptors by decrease in blood volume or increase in ECF osmolarity induces thirst and causes individual to take water. This is the major defense mechanism of body against hypovolaemia and hyperosmolarity. Because it is the only mechanism that increases water intake voluntarily. On the otherhand, ADH and aldosterone is the protective mechanism and acts only when the excess water has been accumulated or lost. Contrary, when an appropriate amount of water has been drunk the sensation vanishes because of the acitivity of oral and gastric receptors. Unfortunately, the thirst mechanism is only operative in conscious patient who is capable of drinking.

Plasma Osmolality

There is a great confusions regarding the use of apparent inter changable terms such as the osmolarity (measured in osmol/L) and osmolality (measured in osmol/Kg). The term osmolality is defined as the number of osmoles per unit of total weight of solvent in Kg. Whereas, the term osmolarity is defined as the number of osmoles per unit of total volume of solutions in litre. Therefore, unlike osmolarity, osmolality is not affected by the presence of various solutes in solution (as it refers only one solute). In plasma the osmolality and osmolarity is same and varies between 280 to 300 m.osmol/Kg and 280 to 300 m.osmol/L respectively. This numerical equivalent is explained by the almost negligible amount of solute, contained in biological fluid and by the fact that most osmotically active particles which are dissolved in water has density of one. Therefore, in plasma m.osmol/L is equal to m.osmol/Kg, but still the more accurate term to use in clinical practice is osmolality.

The osmolality of plasma and ECF is equals (as they remain in equilibrium) and is equivalent to the sum of the concentration of all dissolved solutes, but Na^+ (cation) and its anion such as Cl^- and HCO_3^- constitutes the major (90%) osmotically active particles in plasma. Plasma glucose and urea make a smaller contribution. Therefore, plasma osmolality (Posm) is estimated from the follwoing formula:

Posm = Na^+ conc. + plasma glucose conc. + plasma urea conc.

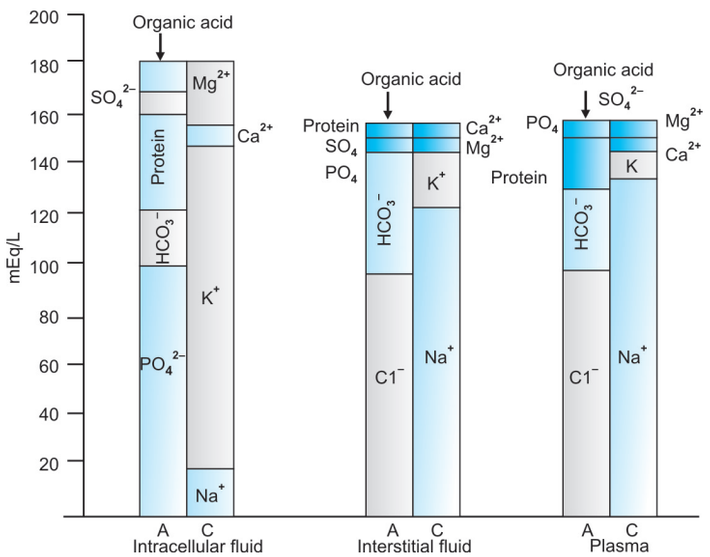

Fig. 9.3: This figure shows the distribution of electrolytes in intracellular fluid, interstitial fluid and plasma. A = Anion, C = Cation

= 1.86 (Na^+) + Glucose /18 + BUN/2.8
(all unit in m.osmol/Kg)
=290 m.osmol/Kg
[NB: NaCl does not dissociate completely *in vivo* and thus contributes 1.86 m.osmol/L. 180 gm of glucose contributes 1 mosm of particles. When glucose concentration is expressed in mg/dl, it is divided by 18 to convert it to m.osm/Kg of H_2O. Urea does not dissociate. The molecular weight of urea is not 28 but it contains 2 atoms of nitrogen per molecule and the concentration of nitrogen is not measured as urea concentration but as blood urea nitogen concentration. Thus, the molecular weight of 2 nitrogen molecules (14 each) rather than the molecular weight of urea is used in calculation. As urea does not dissociate therefore, 28 mg of urea nitrogen contributes 1 m.osm. Blood urea nitrogen (BUN) concentration is usually expressed as mg/dl. Thus, urea nitrogen concentration is divided by 2 to 8 to calculate the m.osm/Kg].

Osmolal gap

The difference between the measured and theoretically calculated value of osmolality of plasma is known as the osmolal gap. The normal value of plasma osmolality gap is 280 to 300 m.osm/L. This gap increases when there is presence of high concentration of osmotically active abnormal particles in plasma which are not usually come during the measurement of normal osmolality. These abnormal osmotically active particles are: mannitol, keton bodies, glycine (used during transurethral resectomy), ethanol etc. The osmolal gap may also be present and become high during hyper protenaemia and hyper lipidaemia. This is because during both these conditions there is increase of plasma volume without increase of Na^+ concentration. Osmolal gap may also increase during the renal failure, because of retention of many small solutes which are not meauserd during the measurement of osmolality.

Calculation of Water Requirement

Assessment

Before calculation of water requirement, it needs the assessment of loss. The loss of water is called dehydration. It is assessed clinically by history, clinical examination and laboratory investigation.

From history we can know how long the patient is suffering from the loss of fluid and its severity, as for example the frequency and the volume of vomitting, diarrhoea, bleeding, etc. The specific clinical features of dehydration are : dryness of mouth, thirst, hypotension, loss of skin turgor, tachycardia, ↓jugular venous pressure, ↓urine output, ↓CVP, etc. With normal renal function the loss of water is associated with less urine output than 0·5 ml/Kg/hour. Therefore, by clinical examination the patient can be assessed for severity of dehydration. Clinically the severity of dehydration is classified as mild, moderate and severe. Mild dehydration is described as loss of 3L of water (4% of total body weight) which is manifested as sunken eyes, dry mucous membrane and loss of skin turgor. Moderate dehydration is described as loss of 4 to 6 L of water (5 to 8% of total body weight) which is manifested as hypotension, oliguria and tachycardia in addition to the manifestation of mild dehydration. Severe dehydration is described as loss of > 7 L of water (8 to 10% of total body weight) which is manifested as severe oliguria and compromised cardiovascular function.

The laboratory investigation to assess the severity of dehydration are : the degree of haemoconcentration, ↑albumin concentration in blood in absence of anaemia and hypoprotinaemia, ↑BUN concentration, ↑urine osmolality (> 650 m.osm/Kg).

Calculation

Regardless of the disease process, there is both sensible and insensible loss of water and electrolytes from the body. In normal healthy individual the sensible water loss occurs through urine, sweat and faeces, but the insensible loss of water occurs through skin and lungs. The insensible water loss per day accounts for about 25 to 30% of total water loss of a day. The major route of sensible water loss is kidney. Kidney also excretes the solute overload which is taken with food and is produced by metabolism through urine, mixing with water. The final solute concentration in the urine varies from 1200 to 50 m.osm/L of H_2O.

Protein is catabolized to urea, PO_4^{2-} and SO_4^{2-}. One gram of protein contains 150 mg of nitrogen and this 150 mg of nitrogen is converted to 5 m.mole of blood urea nitrogen BUN). Thus, 5 m.osm of solute is yielded from each gram of protein. On the otherhand, the normal daily protein requirement is 1 to 2 gm/Kg/day. Therefore, the protein used per day produces 5 to 10 m.osm of solute/Kg/day as BUN. The second major solute load comes from electrolyte balance. The daily Na^+ requirement is 1 m.mol/Kg/day and the daily K^+ requirement is also 1 m.mol/Kg/day. Hence, the daily total Na^+ and K^+ requirement is 2 m.mol/Kg/day. This same amount is also excreted perday with the equal amount of added anions to maintain homeostasis. Therefore, the total load of excreted electrolytes is 4 m.mol/Kg/day (the additional solute of 2 m.mol/Kg/day is due to other electrolytes such as Cl^-, HCO_3^-, Mg^{2+}, SO_4^{2-}, etc). In addition, a small amount of osmoles are produced by metabolism of lipids which release phosphates and uric acid. Hence, the total solute load which is to be excreted is 10 to 15 m.osm/Kg/day. But it may be higher in catabolic patients who receive large amount of electrolytes and lower in starving patient. To excrete this normal solute load in a normal individual, the usual urinary output is 0.5 ml/Kg/hour with normal urine osmolality. In extreme cases, it may vary in any direction such as very low urinary volume (500 ml/day which is called obligatory urine output) with very high osmolality or very high urinary volume with very low osmolality (Fig. 9.4).

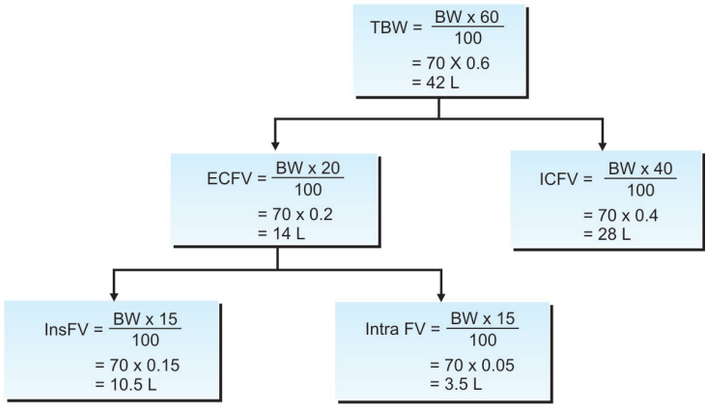

Fig. 9.4: Distribution of total body water (TBW) in litre of a 70 Kg body weight (BW) adult male

In the previous part of this chapter, we have already discussed that a normothermic 70 Kg patient with normal metabolic rate may loss about 2600 ml of water per day. So naturally this patient will need the same amount of water to maintain this water balance. Allowing 400 ml of water to gain from cellular metabolism, now this healthy patient needs 2600−400 = 2200 ml of water/day from external source. Hence, the thumb rule for daily water requirement of a 70 Kg individual is 30 to 35 ml/Kg/day. With this water, the normal Na^+ requirement is 1 m.mol/kg/day or 60 to 80 m.mol/day and like Na^+, the K^+ requirement is also 1 m.mol/Kg/day or 60 to 80 m.mol/day. Thus, a 70 kg healthy individual requires the daily provision of 2200 to 2600 ml of water with approximate 70 m.mol of Na^+ and K^+each. This can be provided by 1500 to 2000 ml of 5% dextrose and 500 ml of 0.9% NaCl, with 1 gm of KCl (15 m.mol) is each 500 ml of fluid.

Perioperative Fluid Therapy

For operative procedures, the patients are kept fasting for prolonged periods before operation, during which time the patient has both sensible and insensible loss of water. Again during surgical procedures, they also loss blood, ECF into the third space, and also water through the kidney as urine. They also loss water from skin, gut and lungs during the whole perioperative period. So, every patient needs the amount of water which is required for the normal maintenance plus the extra loss. For the loss of small amount of blood (< 20% of total blood volume) the patient does not need any blood transfusion. In such circumstances, only crystalloids electrolyte solution such as compound sodium lactate is sufficient. But, unfortunately, the crystalloid solutions quickly leave the intravascular compartment and is distributed in ECF compartment. Therefore, the blood volume is maintained only by infusion of crystalloid if atleast 3 times of the volume of blood loss is infused. Alternatively, the colloid solution which remain in intravascular compartment for longer period may be infused in a volume equal to that of the estimated loss.

During surgery, at the site of operation due to tissue injury there is sequestration of fluid from the intravascular compartment to the interstitial compartment. But this fluid does not take part in the normal metabolic process and is frequently referred to as the 'third space loss'. This loss of fluid volume in third space is proportional to the severity of tissue injury. This plasma like third space fluid is not contained in any anatomically separate space and can not be measured easily. It is reabsorbed 48 to 72 hours after surgery.

In minor surgery any IV fluid in the dose of 1 to 1.5 ml/Kg/hour is sufficient to meet the requirement for the normal maintenance. But, for any major abdominal surgery a volume of 5 to 6 ml/Kg/hour of fluid during operation, in addition to 1.5 ml/Kg/hour as normal maintenance requirement and transfusion of blood for any excessive blood loss is the rule. For any major surgery the volume of IV fluid and the volume of blood needed to be tansfused should be guided by the CVP, urine output, plasma osmolality, cardiac output, preload, intra arterial blood pressure, serum electrolyte concentration, etc. In the postoperative period, after replacing the total loss, the fluid should be administered only in the maintenance dose. Additional fluid in the form of compound sodium lactate or 0.9% NaCl is needed in the following condition such as loss of gastrointestinal fluid through nasogastric tube or fistula, loss of serum or blood through the drains or continued third space loss for first 24 to 48 hours after very major surgery. Usually, K^+ is not administered for the first 24 hours after surgery. This is because there is large release of endogenous K^+ from catabolism and tissue trauma which impose restriction of its use.

During the postoperative period there is increased release of ADH, cortisol, aldosterone, etc, due to the stress. These cause renal retention of Na^+ and water and excretion of K^+. But, still the restriction of water and Na^+ during the immediate postoperative period is inappropriate. This is becuae there is increased loss of water and Na^+ by evaporation and into the third space during the immediate postoperative period. Patients with renal failure also require fluid replacement for abnormal losses, but the total volume needed should be determined by the urine output and serum electrolyte concentration. Fluid and electrolyte requirement in infants and small children differ from those in the adults.

10 Electrolyte Balance

SODIUM BALANCE

Introduction

Although Na^+ is abundantly present in drinking water, milk and all the ordinary diet, but it is most commonly taken as eating salt. The normal daily requirement of Na^+ in an adult person is 1 to 1·5 mEq/Kg/day (or 5 to 10 gm/day). But usually the average intake of sodium is much higher than its daily requirement and is about 8 to 10 gm/day. So, naturally Na^+ deficiency is very rare. Daily Na^+ excretion is generally same as daily intake. To maintain a normal balance, usually, it is lost through sweat and faeces, but the final adjustment is made by kidney through urine. Urinary Na^+ excretion may be as little as 2 mEq/day during salt restriction and may go upto 700 mEq/day after salt loading. In case of Na^+ the mEq and m.mol are numerically same as the valency of Na^+ is one and m.mol is obtained by dividing the mEq by valency (Fact file-I). It is discussed in more details in chapter—water balance.

The Na^+ in plasma provides 90% of the total base of the body. It works in the body in two forms: sodium ion and sodium compound. All the functions of Na^+ ion are usually accomplished by maintaining the normal resting membrane potential. Therefore, the function of Na^+ ions in body are:

i. It initiates and maintains the contraction of heart.
ii. It is essential for the normal functions of cells.
iii. It is essential for the contraction of voluntary and involuntary muscles.
iv. It excites nerves as opposed to Ca^{2+} ions, which reduces the excitation of nerves.

On the other hand, sodium compounds are present in our body as bicarbonate, phosphate, chlorides, proteinates, etc. The functions of sodium compounds in our body are:

i. Maintains blood reaction: This is done in many ways. For instance (a) sodium bicarbonate is the chief buffer of blood and other body fluids. (b) The acid and alkaline sodium phosphates (NaH_2PO_4 is acid and Na_2HPO_4 is alkali) also constitute an important buffer system. (c) Sodium which remains combined with plasma proteins (sodium proteinates) can also act as a buffer. (d) Sodium of NaCl can also fix acids with the help of phenomenon known as chloride shift.
ii. Controls reaction of urine: Kidneys regulate the urine reaction by altering the proportion of acid and alkaline sodium phosphate in the urine.
iii. Reaction of pancreatic juices and bile: This is due to the presence of sodium carbonate.
iv. Maintain osmotic pressure: NaCl is the chief regulator of the osmotic pressure of body fluids.
v. Helps in the formation of HCl in gastric juices: NaCl takes part in the series of reactions and as a result of which HCl is manufactured by the stomach.
vi. Maintains water balance:

The Na^+ balance in our body is intimately related to the ECF volume and water balance. This is because it is widely distributed primarily in the extracellular fluid space, including the interstitial and intravascular space (whereas intracellular space is primarily dominated by K^+) and crosses the capillary bed readily. On the otherhand the distribution of the Na^+ between the intracellular and extracellular fluid space is restricted and determined by Na^+-K^+-ATPase pump, situated on the cell membrane. There are two types of disorder of Na^+ balance: hypernatraemia and hyponatraemia.

FACT FILE - I

1 gm of NaCl gives 17 mEq of Na^+ ions, whereas 1 gm of sodium itself gives 43 mEq of Na^+ ions. In the body the net Na^+ balance is equal to total Na^+ intake which is average 150 to 200 mEq/day minus both extrarenal and renal Na^+ loss. The kidneys play an very important role in Na^+ balance, because it has enormous variable capability to excrete Na^+ which varies between 1 mEq/L to more than 100 mEq/L.

Hypernatraemia

It is defined as plasma Na^+ concentration above 150 m.mol/L. It is nearly always the result of either loss of water in excess of Na^+ where Na^+ may be lost or not (hypotonic fluid loss or only water loss) or retention of large quantities of Na^+ itself with retention of water or not. In the first condition the hypernatraemia is a relative one because the total Na^+ content in body remains same as only the water is lost and is associated with reduced ECF volume and hyperosmolality. Contrary, in the second condition there is true hypernatraemia because the total Na^+ content in the body is increased even if the water content is increasd or not and is associated with

increased ECF volume and also hyperosmolality. So, the clinical assessment of volume status and osmolality of blood is important in the diagnosis and management of hypernatraemia. Therefore, hypernatraemia is classified into three forms: (A) hypernatraemia with increased body Na^+ content, (B) hypernatraemia with normal body Na^+ content, (C) hypernatraemia with low body Na^+ content. Now, though there is different types of hypernatraemia, the common abnormality of all these hypernatraemic states is hyperosmolality of ECF which causes drawing of excess fluid from the intracellular compartment and intracellular dehydration (Fact file- II)

A. Hypernatraemia with increased total body Na^+ content

Usually this is an iatrogenic condition in origin and is mainly due to the excessive exogenous salt gain. It commonly results from the administration of hypertonic saline or administration of excessive amount of sodium bicarbonate during cardiopulmonary resuscitation. It is also caused when the isotonic fluids are given to patients who have only insensible loss of hypotonic fluid, containing less Na^+. Patients suffering from primary hyperaldosteronism and Cushing's syndrome may also have this condition. Management of this condition is comprised of induction of diuresis by loop diuretic, which excretes Na^+ provided the kidney function is normal. Urine or water output is balanced in part by 5% dextrose which does not contain any Na^+. If the patient suffers from renal dysfunction, then dialysis or haemofiltration is the way of management of this type of hypernatraemia.

FACT FILE - II

Total body Na^+ content is directly proportional to the extracellular fluid (ECF) volume. Therefore, changes in total body Na^+ content results in variation of ECF volume. A positive Na^+ balance increases the ECF volume. Contrary a negative Na^+ balance reduces the ECF volume. On the otherhand, Na^+ is the predominant extracellular cation. So, Na^+ in the ECF reflects the total body Na^+ content. Na^+ in the ECF compartment remains in equilibrium between the interstitial and intravascular fluid compartment. Hence, plasma Na^+ content more or less indicates total body Na^+ content and the water balance.

B. Hypernatraemia with normal total body Na^+ content

This condition occurs when there is only loss of water, containing no or minimal amount of Na^+. Therefore, the total body Na^+ content remains normal or slightly decreased, but in relation to water its concentration is always higher. So, there is hypervolaemia (drawing of fluid from cells), hyperosmolality and hypernatraemia. Without loss of Na^+ the excessive loses of pure water via skin and respiratory tract is very rare. But some examples of this condition are fever, hyperventilation, thyrotoxicosis, etc. However, the most common cause of this condition is diabetes insipidus. In diabetes insipidus, there is either decrease in ADH secretion from the posterior pituitary gland or failure of the renal tubules to respond to the normally circulating ADH. Hence the first condition is called the central diabetes insipidus and the later is called the nephrogenic diabetes insipidus (Table 10.1).

In central diabetes insipidus the lesion or pathology is usually found in and around the hypothalamus or pituitary gland. So, it is commonly seen following pituitary tumour, neurosurgical procedures of brain, head trauma, etc. It is also developed following the brain death. The central diabetes insipidus is diagnosed by history of polyuria (> 8 L/day), polydypsia (even in the absence of hyperglycemia) and low urinary osmolality than plasma. In unconscious patient absence of thirst associated with diabetes insipidus can easily produce marked water loss and hypovolaemia. The diagnosis of central diabetes insipidus can be confirmed by increase in urinary osmolality by administration of ADH (or vasopressin) from exogenous source. There are two preparations of vasopressin such as in aqueous solution and in oil. However, the aquous preparation of ADH is the treatment of choice. It is used in the dose of 5U at the interval of every 4 hours through subcutaneous route. Oil preparation of vasopressin is also used in the dose of 0·3 ml/day only through IM route. It is long acting and therefore frequently causes water intoxication. There is another synthetic analogue of vasopressin, called desmopressin (DDAVP) with 12 to 24 hours duration of action. It is available as an intranasal preparation and can be used both for the ambulatory or preoperative patient in dose of 5 to 10 mg per day or twice daily.

Nephrogenic diabetes insipidus is commonly due to (i) chronic renal disease, (ii) secondary to side effects of certain drugs such as lithium, mannitol, amphotericin B, etc, (iii) certain electrolyte disturbances such as hypercalcaemia and hypokalaemia, (iv) certain other diseases such as sickle cell disease, hyperproteinaemia,

Table 10.1: Causes of hypernatraemia

A.	**Hypernatraemia with increased body Na^+ content**
	Excessive Na salt ingestion
	Infusion of hypertonic saline
	Administration of excess $NaHCO_3$
	Administration of excess of steroid
B.	**Hypernatraemia with normal body Na^+ content**
i.	Extrarenal loss of only water without Na^+
	Fever
	Hyperventilation
	Thyrotoxicosis
ii.	Renal loss of water without Na^+
	Central diabetes insipidus
	Nephrogenic diabetes insipidus
	Chronic renal failure
C.	**Hypernatraemia with decreased body Na^+ content**
	Renal hypotonic fluid loss
i.	Osmotic diuresis (mannitol, urea, glucose)
ii.	Extrarenal hypotonic fluid loss
	Vomitting
	Diarrhoea
	Excessive sweating

etc, (v) sometimes congenital. In these condition there is normal plasma level of ADH (vasopressin), but the kidneys fail to respond to normally circulating ADH and unable to concentrate the urine, resulting in excretion of huge amount of hypoosmolal urine. The diagnosis can be confirmed by the failure of kidney to produce a hyperosmolal urine, still following the administration of exogenous vasopressin. The treatment of this condition is intake of adequate fluid which will try to keep the water balance of our body normal and specific management of underlying aetiology. Administration of loop diuretics in nephrogenic diabetes insipidus paradoxically reduces the urine output as it reduces the water load to the collecting tubules where ADH acts. Proteins and sodium restriction can similarly decrease the urine output.

C. Hypernatraemia with low total body Na^+ content

In this condition, the patient losses both Na^+ and water, but the Na^+ loss is less than the loss of water (loss of hypotonic fluid). Therefore, there is low body Na^+ content (due to Na^+ loss) but still hypernatraemia (due to more loss of water than Na^+). The loss of hypotonic fluid may be due to renal or extrarenal cause. The example of renal loss of hypotonic urine causing hypernatraemia and low body Na^+ content is osmotic diuresis by mannitol, glucose, etc, where water is lost more than Na^+. On the otherhand, the example of extrarenal loss of hypotonic fluid causing this condition are vomitting, diarrhoea, exercise, excessive sweating, etc, where there is more water than Na^+ loss.

Clinical Manifestation of Hypernatraemia

The clinical manifestation of hypernatraemia is mainly due to the hyperosmolality of ECF which causes shifting of water from the intracellular compartment and cellular dehydration. The major consequences of hypernatraemia and hyper osmolality of ECF involve the CNS and the severity depends on the rapidity with which the hyperosmolality develops. The cellular dehydration causes reduction of cell volume and water content of the brain which produces restlessness, hyperreflexia, seizures, coma and ultimately death. The reduction of cell volume and water content of brain causes rapid decrease of brain volume and increased permeability of vascular structure which may produce rupture of cerebral veins resulting in focal intracerebral and / or subarachnoid haemorrhage. Hence, patient may present with pyrexia, nausea, vomitting, convulsion, coma or virtually any type of neurological syndrome. Chronic form of hypernatraemia is better tolerated than its acute form. Serious neurological damage and convulsions are more common in children and particularly when the plasma Na^+ concentration exceeds 158 m.mol/L.

Treatment of Hypernatraemia

The majority of hypernatraemic patients are hypovolaemic because though water in ECF compartment is increased, but the total water content of body is decreased due to intracellular dehydration. Therefore, the aim of management of hypernatraemia is the restoration of volume of ICF compartment and osmolality of ECF compartment and correction of underlying problem. The water deficit can be corrected by the following way:

Water deficit = Normal TBW − Present TBW

If a 60 Kg man is found to have a plasma Na^+ concentration of 160 m.mol/L then the present TBW can be calculated from the following equation, such as:

Nomal TBW × 140 = Present TBW × 160

[Normal plasma Na^+ concentration = 140 m.mol/L]

∴ Present TBW =

[Normal TBW × 140] ÷ 160

= [60 × 0·6 × 140] ÷ 160

[0·6 = 60% of body weight is water]

= 31.5 L

∴ Water deficit =

Normal TBW − Present TBW

= [60 × 0.6] − 31.5 L

= 36 − 31.5 L

= 4.5 L

This hypernatraemia and hypovolaemia should be corrected slowly over 48 to 72 hours. Because rapid correction of hypernatraemia and hypovolaemia may cause cerebral oedema, convulsions, permanent neurological damage and even death. During this management serial measurement of Na^+ concentration is performed and plasma Na^+ concentration should not be reduced faster than 0·4 to 0·6 m.mol/hour. Regarding the type of fluid, hyper natraemic patients with decreased total body Na^+ should be given isotonic saline to restore the both plasma volume and body Na^+. Because this isotonic saline is taken as relative hypotonic in patients with severe hypernatraemia and the Na^+ in normal saline helps to restore the depletion of total body Na^+. Once volume and Na^+ depeltion has been corrected, further correction of any water deficit can be accompanied with isotonic 5% dextrose.

Until the aetiology of hypernatraemia and fluid deficit is corrected properly all elective surgeries should be cancelled in patients suffering from severe hyper natraemia (> 150 m.mol/L).

Hyponatraemia

It is a very common hospital finding and is defined as plasma Na^+ concentration of less than 135 m.mol/L. It may occur relatively as a result of water retention (dilutional) or as a result of true Na^+ loss (depletion) or both. Therefore, hyponatraemia is associated with normal, decreased or increased ECF volume. But in all these forms there is hypo osmolality of the ECF compartment. Due to this reduced osmolality, water moves from the ECF compartment to the IC fluid compartment and swelling of cells (mainly brain) with water intoxication occurs.

Na^+ ion is present only in the water portion of plasma which constitutes about 93%

of whole plasma. But, in the laboratory, it is measured against the whole (100%) plasma and is expressed as m.mol per litre of whole plasma. In hyperlipidaemia and hyperprotenaemia this water portion of plasma is decreased, but the whole plasma volume remains same. Hence, in such condition the measurement of concentration of Na^+ against whole plasma is decreased (as water content decreases), but its concentration against only water portion of plasma (which is not constituted by lipids, proteins, etc) is normal. Therefore, the measurement of Na^+ against whole plasma in these conditions show false hyponatraemia. Hence, this type of hyponatraemia is called pseudohyponatraemia. However, the routine measurement of plasma osmolality with Na^+ level in hyponatraemic patients rapidly excludes this pseudo form. This pseudo form of hyponatraemia will not confuse us, if plasma Na^+ concentration is measured by ion specific electordes. Because this method directly assess the aquous phase of Na^+ and produce exact result.

Like hypernatraemia, hyponatraemia is also classified according to the presence of relative water retention (dilutional) without loss of Na^+ or true Na^+ loss (depletion) into three forms:

a. hyponatraemia with decreased total body Na^+ content,
b. hyponatraemia with normal total body Na^+ content,
c. hyponatraemia with increased total body Na^+ content.

A. Hyponatraemia with decreased total body Na^+ content

This is caused by progressive loss of both Na^+ and water, but the Na^+ loss exceeds the water loss. Hence, there is hypo natraemia and decreased total body Na^+ content. (If water loss exceeds the Na^+ loss, then this causes hypernatraemia with decreased total body Na^+ content). Assessment of volume status reveals hypovolaemia. This Na^+ and water loss may be renal or extrarenal. The examples of renal loss are: administration of diuretics, Addison's disease, renal tubular acidosis, salt losing nephropathies etc. In such renal causes of hyponatraemia usually the urinary Na^+ concentration exceeds 20 m.mol/L. The examples of extrarenal Na^+ and water loss are from GI tract such as diarrhoea, vomiting, etc; or in the third space such as during peritonitis, surgery, etc. In such extrarenal cause of hypo natraemia the urinary Na^+ loss is less than 10 m.mol/L, except vomiting. In vomiting there is metabolic alkalosis which obligates the concomitant excessive excretion of Na^+ and HCO_3^- through kidney to maintain electrical neutrality in the urine.

B. Hyponatraemia with normal total body Na^+ content

In this condition there is no Na^+ loss, but hyponatraemia is due to only water overload. This situation is caused by: glucocorticoid insufficiency, hypothyroidism, drug therapy by cyclophosphamide and SIADH (syndrome of inappropriate ADH secretion). Hyponatraemia associated with glucocorticoid insufficiency is due to excessive secretion of ADH along with hypersecretion of corticotrophin releasing factor in the absence of adequate glucocorticoides. In this condition there is modest excess of TBW and modest increase of ECF volume with normal total body Na^+ content showing hyponatraemia. It also may be due to iatrogenic origin. This iatrogenic cause is due to the excessive administration of IV fluids with low Na^+ content in the patient with loss of isotonic fluid (Table 10.2).

C. Hyponatraemia with increased total body Na^+ content

In this condition there is an increase in both the TBW and total body Na^+ content, but overload of water exceeds that of Na^+. Hence, hyponatraemia occurs. The examples of this situation are: congestive heart failure, renal failure, nephrotic syndrome, cirrhosis of liver, etc. In these circumstances hyponatraemia results from the progressive impairment of excretion of both Na^+ and free water by kidney, but the accumulation of water exceeds the accumulation of Na^+. The pathophysiology of this condition parallels the severity of underlying disease process (Fig. 10.1).

Clinical Manifestation of Hyponatraemia

The clinical manifestation of hyponatraemia is primarily due to the increase

Table 10.2: Causes of hyponatraemia

A.	Hyponatraemia with decreased total body Na^+ content (hypovolaemia)
i.	Renal loss (urine Na^+ > 20 m.mol/L)
	Diuretics
	Osmotic diuretics (mannitol, glucose)
	Mineralocorticoid deficiency
	Renal tubular acidosis
	Salt losing nephropathy
ii.	Extrarenal loss (urine Na^+ < 10 m.mol/L)
	Diarrhoea
	Vomitting
	Third space loss
B.	**Hyponatraemia with normal total body Na^+ content (normovolaemia or hypervolaemia)**
i.	Low plasmaosmolality
	Syndrome of inappropriate ADH
	Glucocorticoid insufficiency
	Hypothyroidism
	Drug therapy
ii.	Normal plasma osmolality
	Pseudohyponatraemia—hyperlipidaemia, hyperproteinaemia and hyperglycaemia
C.	**Hyponatraemia with increased total body Na^+ content (hypervolaemia)**
	Congestive heart failure
	Renal failure
	Nephrotic syndrome
	Cirrhosis of liver

Group A is a depletional syndrome. So saline is required. Group B and C (except pseudohyponatraemia) is dilutional syndrome. So fluid restriction is required.

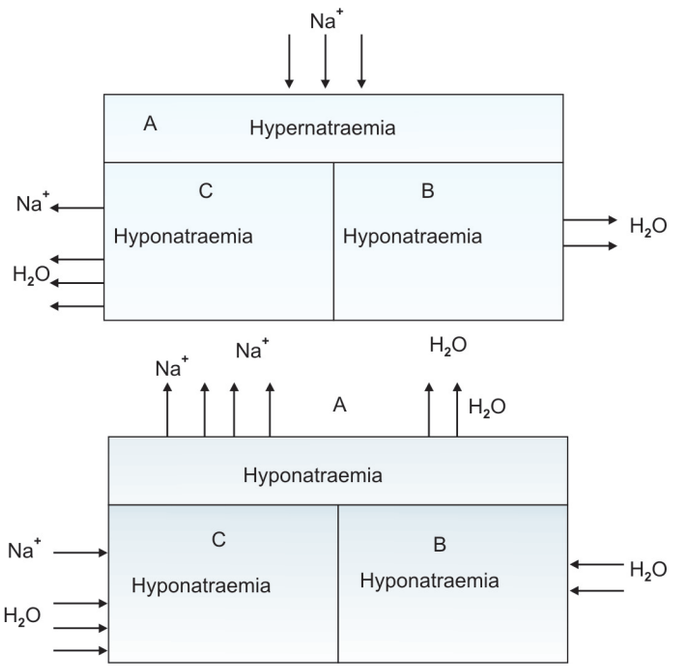

Fig. 10.1: Pathophysiology of hyponatraemia

in intracellular fluid volume and affects mainly the brain cells. So, there is subsequent cerebral oedema and increase in ICP causing nausea, vomitting, delirium, convulsions, coma and even death. But the symptoms vary with the magnitude of reduction of plasma Na^+ level and the rapidity with which the plasma Na^+ level falls. Patients with mild hyponatraemia (Na^+ level between 125 to 135 m.mol/L) are usually asymptomatic or associated with mild symptoms such as anorexia, nausea, vomiting, weakness, etc. Moderate hyponatraemia (Na^+ level between 120 to 125 m.mol/L) is associated with symptoms such as lethargy, confusion, etc. While the severe hyponatraemia (Na^+ level < 120 m.mol/L) is associated with convulsions, coma or death. Chronic hyponatraemia is less symptomatic than acute hyponatraemia. This is because in previous condition there is enough time for compensation by losing intracellular solutes along with extracellular loss of Na^+ which help to restore the cell volume to normal. In chronic hyponatraemia, the neurological manifestation are not due to the changes of cell volume, but rather due to the changes in cell membrane potential by low extracellular Na^+.

Treatment of Hyponatraemia

Like hypernatraemia the management of hyponatraemia also includes the correction of plasma Na^+ level and the underlying disease process. Acute sympomatic hypo natraemia is a medical emergency condition. So, it needs prompt intervention by using isotoic saline, but the rapidity with which hyponatraemia is corrected is a matter of controversy. This is because very rapid correction of hyponatraemia is associated with serious permanent neurological sequelae. But the general agreement is that correction period should not be less than 12 hours, and after which the plasma Na^+ level should not be less than 125 m.mol/L. The rapidity with which the hyponatraemia can be corrected slowly or very slowly depends on the severity of symptoms. However, the following tailored correction rate is followed: for mild hyponatraemia < 0.5 m.mol/L/hour, for moderate hyponatraemia < 1 m.mol/L/hour, and for severe hyponatraemia < 1.5 m.mol/L/hour.

In hyponatraemia the amount of Na^+ which is needed (Na^+ deficit) to make the desired plasma level can be calculated as follows :

Na^+ required or deficit = TBW × (desired or required Na^+ conc. − measured Na^+ conc). Here, TBW is total body water and not the total body weight.

If the weight of a patient is 70 Kg and the present plasma Na^+ concentration is 120 m.mol/L.

Then the required total Na^+ in m.mol/L = $70 \times 0.6 \times (130 - 120) = 420$

[0·6 indicates TBW and is approximately 60% of body wight, 130 m.mol/L is the desired level of plasma Na^+ level to be raised]

Normal saline contains Na^+ = 154 m.mol/L.

Hence, the patient should receive $420 \div 154 = 2.72$ L of normal saline.

Isotonic saline is generally the treatment of choice for hyponatraemia with decreased total body Na^+ content. On the otherhand, hyponatraemic patients with normal or increased total body Na^+ content should be treated with more water restriction. More specific treatment also can be instituted for hyponatraemia. For example, hormone replacement for thyroid or adrenal hypofunction which can be started to correct hyponatraemia. For heart failure patient, the aim of management is to increase the cardiac output.

Problems during anaesthesia of a patient suffering from altered Na^+ balance results from the changed patho physiology due to hyper or hyponatraemia and as well as from the underlying disorders. Hyper or hyponatraemia present either as hypo or hypervolaemia. Therefore, both these manifestation should be corrected before elective surgery. Hypovolaemic patients are sensitive to hypotension. Therefore, vasodilating and negative inotropic agents such as volatile anaesthetics, histamine releasing agents, barbiturates, etc; should be used cautiously. Due to the reduction of the volume of distribution of drugs in

hypovolaemia the doses of all the therapeutic agents also should be reduced. Regional anaesthesia is also very sensitive to develop hypotension due to hypovolaemia. If there is hypervolaemia, it should also be corrected by diuretics before surgery. Any abnormalities of cardiac, renal and hepatic function also needs proper evaluation and correction before anaesthesia and surgery.

POTASSIUM BALANCE

Introduction

K^+ is the major intracellular cation. The intracellular concentration of it is 140 to 150 m.mol/L and this intracellular K^+ constitutes about 98% of total body K^+ content. Only 2% of total body K^+ content remains in the extracellular space or fluid. This extracellular K^+ concentration is 4 m.mol/L. The regulation of intracellular K^+ concentration is poorly understood. The extracellular K^+ concentration generally reflects the plasma concentration and the balance betwen the K^+ intake and excretion of it. Under some pathological conditions, the redistribution of K^+ between the ECF and ICF compartment can result in marked changes in the extraellular K^+ concentration without the change in total body K^+ content or change in intake and excretion. This extracellular concentration of K^+ is regulated precisely, because many of the cell functions are very sensitive to this change in ECF potassium concentration. For example, slight changes of plasma K^+ concentration has an important impact on neuromuscular transmission and cell membrane potential, most significantly on myocardial cell. An increase in plasma K^+ concentration (which is in equilibrium with ECF K^+ concentration of only 3 to 4 m.mol/L) from its original value can cause cardiac arrhythmia or even cardiac arrest.

The daily intake of K^+ usually ranges between 50 to 200 m.mol/day (average 80 m.mol/day) but in a single meal this K^+ intake may rise as high as 500 m.mol. Therefore, the failure to rapidly rid of the ECF from this high ingested K^+ load could cause life threatening hyperkalaemia. Similarly, a small loss of K^+ from the ECF could may cause severe hypokalaemia in the absence of rapid and appropriate compensatory response.

Normally, the daily intake of K^+ is equivalent to the daily excretion of it. Renal excretion of K^+ can vary from as little as 5 m.mol/L to over 100 m.mol/L, according to the intake and output in the absence of any renal pathology. This maintenance of K^+ balance depends primarily on excretion by the kidney. Kidney excretes 90 to 95% of the ingested K^+, whereas the remaining 5 to 10% K^+ is lost through the faeces and sweat. Thus, kidney is the principal organ to control the body K^+ rapidly and precisely in wide variations of intake and abnormal loss. In the kidney about 90 to 100% of filtered K^+ is reabsorbed actively by the proximal tubules and the thick ascending limb of the loop of Henle. Therefore, nil to 10% of filtered K^+ escapes this reabsorption and which is excreted through urine. Normally, the K^+ which is excreted in the urine is the result of distal tubular secretion. This K^+ secretion in the distal tubules is coupled to aldosterone mediated reabsorption of Na^+. Therefore, if the GFR is normal, then this amount is adequate to maintain K^+ balance by excreting it through urine. For this reason, hyperkalaemia is very uncommon in the presence of normal renal function. However, if the GFR is reduced then excessive active secretion of K^+ by the distal nephron is necessary to avoid the progressive accumulation of K^+ in the the blood and eventual hyperkalaemia.

The control of K^+ distribution between the ECF and the ICF compartment also plays an important role in K^+ homeostasis. This is because 98% of the total body K^+ remains in the cell and they can serve as a soaking site for the excess of K^+ from the ECF compartment during hyperkalaemia or as a source of K^+ during hypokalaemia. Thus, the redistribution of K^+ between the ICF and the ECF compartment provides a first line of defence against the changes in K^+ concentration in ECF compartment. The K^+ of ECF compartment is pumped into the cell in exchange of Na^+ by the ubiquitous Na^+-K^+ ATPase pump, situated on the cell membrane in a ratio of $3Na^+$ to $2K^+$ ions. This creates a–ve intracellular voltage and is responsible for resting membrane potential. The intracellular K^+ concentration remains constant at around 140 m.mol per litre though a Na^+-K^+ ATPase pump acts continuously. This is because of some passive leakage of K^+ from cells through some separate K^+ selective ion channels, other than Na^+-K^+ ATPase pump. This Na^+-K^+ ATPase pump is stimulated by insulin and β-adrenergic agonist and this effect is exploited to treat hyperkalaemia. It is inhibited by acidosis. Therefore, hyperkalaemia is commonly associated with acidosis, diabetes and use of β-blocker. The plasma K^+, therefore, is a very sensitive factors, influencing the shift of K^+ between the ECF and ICF compartment of muscle cells which are the principal storing site of K^+.

Urinary Excretion of Potassium

Generally, the extracellular concentration of K^+ parallels with the excretion of it through urine. It is excreted mainly by the secretion of tubular cells in the distal nephron and the whole things are mediated by the aldosterone hormone. Extracellular concentration of K^+ is the major determinant factors of aldosterone secretion from the adrenal gland. Hyperkalaemia stimulates the secretion of aldosteone, whereas hypokalaemia suppresses it. The other major stimulus to aldosteroen secretion is angiotensin II. Thus, any factors that inhibit the renin-angiotensin system will inhibit the secretion of aldosterone and blunt the renal response to rise in plasma K^+. These include ACE inhibitors, NSAID (by blocking prostaglandin mediated renin

release) and β-antagonists (by inhibiting the release of renin mediated by the renal nerves). Drugs which block the action of aldosterone such as spironolactone, amiloride, etc, also cause hyperkalaemia, particularly if the GFR is low.

Intercompartmental Shifts of Potassium

It is already discusssed that like urinary excretion the intercompartmental shifting of K^+ between the ECF and ICF is also very important to maintain the homeostasis of it or the concentration of it in ECF which is most important for life. This intercompartmental shift of K^+ is mediated by changes in: extracellular pH, levels of circulating catecholamines, levels of circulating insulin, hypothermia and plasma osmolality. Except these, exercise also transiently increases the plasma K^+ level due to the release of it from muscle cells. This increase of plasma K^+ concentration is parallel to the duration and intensity of muscular activity.

The changes in extracellular pH directly affects the extracellular K^+ concentration. This is because the intracellular fluid buffers upto 50% of an acid load or H^+ and the remaining are excreted through kidney. During acidosis extracellular H^+ enters the cell and displaces the intracellular K^+. Thus K^+ comes out of the cell to maintain the intracellular electrical balance and increases the plasma K^+ level. During alkalosis the reverse occurs and plasma K^+ concentration decreases. A thumb rule of maintaing the relationship between the plasma K^+ concentration and blood pH is that plasma K^+ concentration changes nearly 0.5 to 0.7 m.mol/L for every 0.1 U change of arterial pH in any direction.

The increased level of catecholamines by sympathetic stimulation also decreases the plasma K^+ level by enhancing the intracellular uptake of it. This is mediated by the Na^+-K^+ATPase pump which is contolled by β-adrenergic receptors. Catecholamines through β-receptors stimulate this pump which pushes two K^+ ions inside the cell inexchange of drawing three Na^+ ions out of the cell. Therefore β-adrenergic stimulant decreases the level of plasma K^+ concentration. Contrary, β-blockers increases the concentration of plasma K^+. On the otherhand, α-adrenergic activity impair the intracellular movement of K^+ and increases the concentration of plasma K^+.

Changes in the circulating levels of insulin also alter the plasma K^+ concentration. It also acts the same way through Na^+-K^+ATPase pump, like catecholamines and increases the uptake of K^+ in the liver and skeletal muscle cells. Thus, administration of insulin decreases the plasma K^+ level and helps to treat hyperkalaemia.

Hypothermia decreases the plasma K^+ level by increasing the cellular uptake of it. Contrary, the increased temperature of body reverses this shifting and increases the plasma K^+ level. Changes of plasma osmolality also changes the plasma K^+ level. Increased plasma osmolality due to hypernatraemia, hyperglycaemia or administration of mannitol, etc, increases the plasma K^+ concentration. The explanation of it is like that increased plasma osmolality causes the shifting of water from ICF to ECF compartment. This causes cellular dehydration and increased intracellular K^+ concentration which results in movement of K^+ from inside to outside of the cell and increased plasma K^+ level.

There are two types of disturbances of K^+ balance in our body. These are hypokalaemia and hyperkalaemia.

Hypokalaemia

It is defined as plasma concentration of less than 3.5 m.mol/L. It occurs as a result of : (i) inadequaqte intake or (ii) excessive loss or (iii) both. Excessive loss may be of two types — loss through urine, stool, sweat or shift from ECF to ICF compartment. In this circumstances of shifting from ECF to ICF compartment, the total K^+ content in the body remains same.

When the K^+ intake is very low, then the reabsorption of it in the nephron is enhanced. This causes gradual fall of urinary excretion of K^+ to about 5 m.mol/day which is obligatory. But this continuous minimum loss of K^+ through urine and further daily continuous loss of K^+ which is near about 5 to 10 m.mol/day through stool and sweat can result in gradual depletion of body K^+, provided this minimum amount is not replaced daily by intake. On the otherhand, if K^+ reabsorption in renal tubules is impaired, then urinary loss will be greater and there will be quick manifestation of hypokalaemia, provided intake of K^+ is still inadequate. As kidneys have enormous ability to reabsorb the filtered K^+ and decrease the urinary K^+ excretion to only 5 m.mol/day, therefore marked reduction in K^+ intake are required to produce hypokalaemia. In hypokalaemia the plasma K^+ level correlates very poorly with the total body K^+ deficit. A decrease in plasma K^+ from 4 to 3 m.mol/L usually represents 100 to 200 m.mol of deficit. Whereas a plasma K^+ level below 3 m.mol/L can represent a deficit between 200 to 400 m.mol (Table 10.3).

Hypokalaemia also occurs, even though, intake is adequate. This is due to the presence of excessive loss. This excessive loss of K^+ is either through renal route or through gastrointestinal tract. Excretion of K^+ through the urine rises, whenever there is increased delivery of Na^+ to distal tubule. This increased delivery of Na^+ to distal tubule causes increased reabsorption of it in exchange of increased K^+ secretion which is lost through the urine. This mechanism of excessive renal K^+ loss is found in uncontrolled diabetes, and use of loop diuretics such as frusemide, thiazides etc. Excretion of K^+ through the urine is also increased, whenever there is high concentration of aldosterone which promotes the excessive reabsorption of Na^+ in the distal tubule in exchange of excessive loss of K^+. The causes of this high concentration of aldosterone is: Conn's syndrome,

Table 10.3: Causes of hypokalaemia

A.	**Reduced intake**
	Inadequate dietary intake
	K^+ free IV fluid
B.	**Increased loss through urine**
	Conn's syndrome (pri. hyperaldosteronism)
	Secondary hyperaldosteronism such as heart failure, ECF depletion, renal artery stenosis, cirrhosis, nephrotic syndrome etc.
	Cushing's syndrome
	Renal tubular acidosis, hypomagnesaemia
	Renin excess
	Diuretics
	Batter's syndrome
	Uncontrolled diabetes
	Amphotericin's B, Carbenicillin
	Liddle's syndrome
C.	**Increased loss through GI tract**
	Vomitting, Diarrhoea, malabsorbtion sysdrome
	Aspiration of upper GI contents
	Drainage through fistula
	Villous adenoma of colone
D.	**Intercompartmental shift**
	Metabolic alkalosis
	Insulin, β-blocker
	Hypothermia

secondary hyperaldosteronism, Cushing's syndrome, etc. Most often the secondary hyperaldosteronism results from enhanced secretion of renin in response to inadequate renal perfusion (e.g. heart failure, hypoalbuminaemia, renal artery stenosis, Cirrhosis, nephrotic syndrome etc). Enhanced secretion of renin increases the secretion of aldosterone through angiotensin I and angiotensin II pathway. In patients with ECF depletion there are high plasma levels of renin, angiotensin I, II and aldosterone. The GFR is maintained by angiotensin II mediated efferent arteriolar constriction. So the distal Na^+ delivery is relatively preserved but the aldosterone drives the urinary losses of K^+. The other causes of renal loss of K^+ are: renal tubular acidosis, hypomagnesaemia, ketoacidosis, some drug therapies such as carbenicillin, amphotericin B etc, and salt wasting nephropathies. The causes of increased loss of K^+ through GI route are: vomitting, diarrhoea, malabsorption syndrome, abuse of laxative, nasogastric suction, losses of secretin through fistula, villous adenoma, etc. Dialysis by low K^+ containing fluids also causes hypokalaemia. Continuous increased sweat formation sometimes cause hypokalaemia, provided when it is associated with low K^+ intake. Uraemic patient have normal or high plasma K^+ concentration, though it has total body K^+ deficit. This is due to the acidosis which causes shifting of K^+ from ICF to ECF compartment. Any factor which moves K^+ into the cells will cause the increased intracellular K^+ concentration, including that in the cells of the distal tubule. This also enhances the secretion of K^+ and hence its urinary losses. This mechanism operates in alkalosis from any cause. Therefore, alkalosis and hypokalaemia are commonly associated with each other.

Except alkalosis, hypokalaemia due to intracellular movement of K^+ also occurs during insulin therapy, β-adrenergic agonists and hypothermia. Hypokalaemia also occurs following transfusion of frozen red cells. Because these cells lose K^+ during the preservation process and take up K^+ from plasma following reinfusion.

Clinical Manifestations and Diagnosis

Hypokalaemia can produce widespread dysfunction of organs by increasing the threshold for initiation of action potential. Most patients remain asymptomatic until plasma K^+ concentration falls below 3 m.mol/L. At first the diagnosis of hypokalaemia may be suggested by tiredness and muscular weakness. Other neuromuscular effects of hypokalaemia include muscle cramping, tetany and rarely rhabdomyolysis. In extreme cases the patient may be unable to walk or climb stairs. Reduced intestinal motility or paralytic ileus may occur in hypokalaemia. Cardiovascular effects in hypokalaemia are most prominent and include ventricular arrhythmia, decreased cardiac contractility, low BP, potentiation of the adverse effects of digitalis, etc. Typical ECG changes occur during hypokalaemia and these are: (i) sinus rhythm with normal QRS complex, (ii) increased P-wave amplitude, (iii) prolongation of the P-R interval, (iv) depression of ST segment, (v) T-wave flattening and inversion, (vi) increasingly prominent U-wave.

Hypokalaemia induced by diuretics is often associated with metabolic alkalosis. This is because kidneys absorb more Na^+ to compensate for intravascular volume depletion due to diuretics in exchange of K^+. In presence of hypokalaemia as there is less availability of K^+, so Na^+ will absorb in exchange of H^+ causing alkalosis. Also bicarbonate is absorbed to compensate the diuretic induced hypochloraemia. Therefore, the end result of diuretics is hypokalaemia and hypochloraemia assoicated with metabolic alkalosis. Long standing hypokalaemia damages renal tubular structure and results in failure of the antidiuretic response to ADH. Therefore, gradually patients with hypokalaemia may present with nocturia or polyuria and polydipsia (Fig. 10.2).

In most cases of K^+ depletion, the plasma K^+ concentration is low. But, in some cases the factors that move K^+ out of the cell, may help to maintain a normal plasma K^+ level in spite of the low body K^+ content as for example diabetic ketoacidosis. On the otherhand, patients with metabolic alkalosis or who have been taking excessive insulin or β-adrenoreceptor agonists may have a low plasma K^+ level, despite a normal total body K^+ content. This is because of movement of K^+ into the cells. Therefore, in mentioning the cause of hypokalaemia, the measurement of urinary K^+ excretion may be helpful. A value of urinary K^+ concentration less than

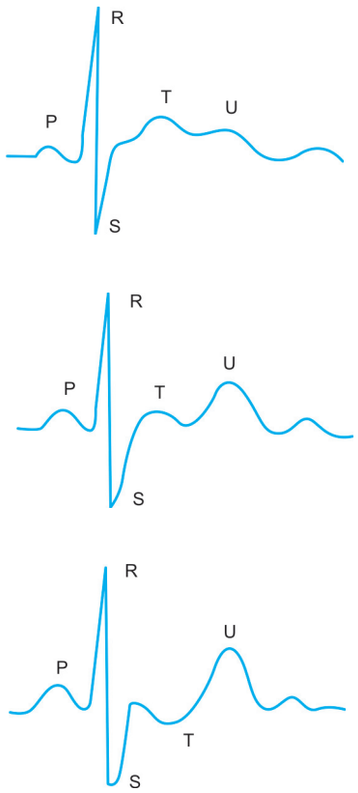

Fig. 10.2: The effects of hypokalaemia on ECG. It is characterised by: gradual increase in amplitude of P-wave, progressive increase of P-R interval, depression of ST segment, progressive flattening of T-wave and increasingly prominent U-wave

20 m.mol/day makes abnormal renal K^+ loss unlikely. While a urinary K^+ excretion more than 50 m.mol/day in the presence of hypokalaemia suggest a renal cause.

Management

Giving K^+ salt orally or through IV route treats hypokalaemia. But the mode of treatment of hypokalaemia (either oral or through IV route) depends on the severity of organ dysfunction and the degree of hypokalaemia. IV replacement of K^+ should usually be reserved for patient with serious cardiac dysfunction or severe muscle weakness. Otherwise, oral replacement of K^+ is the choice of management. During IV replacement of K^+ continuous ECG monitoring and periodic assessment of muscle strength is mandatory. The goal of IV K^+ therapy is to manage the emergency and not necessarily to correct the entire K^+ deficit. For IV K^+ replacement KCl is usually used. Any other associated salt and water deficit with hypokalaemia should be replaced first. This is because any IV administration of K^+ is avoided, until adequate urine output is established. Dextrose containing solutions should generally be avoided for IV replacement of K^+. Because the resulting hyperglycaemia and secondarily increased secretion of insulin may actually lower the plasma K^+ level, even further. During IV replacement the dose of K^+ should not exceed 10 to 20 m.mol/hour or 240 m.mol/day.

The oral route for K^+ replacement is most commonly practised and safer. It is used for non emergency circumstances. Oral KCl (1 gm = 13·4 m.mol of K^+) is a satisfactory preparation, unless metabolic acidosis is present. Otherwise, in acidosis $KHCO_3$ is used. This oral KCl preparation may cause GI irritation, oesophageal and small bowel erosion, strictures, etc. In alkalosis KCl is preferred, because it also corrects the chloride deficit. The dose of oral preparation of KCl is 80 to 100 m.mol/day. A diet rich in K^+ such as bananas, citrous fruit, milk, chocolate, etc, are also helpful in hypokalaemia. If hypokalaemia is found to be difficult to correct in patient who have had diuretics, then it should be thought that there may be an associated Mg^{2+} deficiency. Therefore, correction of this Mg^{2+} deficiency is necessary before hypokalaemia is treated to normal. Oral replacement of K^+ deficit usually requires several days.

Anaesthetic Consideration

Hypokalaemia is a very common perioperative finding. It is found that patients with plasma K^+ concentration of less than 3 m.mol/L are at increased risk of cardiac arrhythmia. So, these patients should be taken as serious and all the precautionary measures like continuous ECG, IV replacement of K^+, acid-base balance, use of nerve stimulator, etc, should be taken. But the patients who have plasma K^+ concentration between 3 to 3.5 m.mol/L produce problem to take the decision, especially in such circumstances if elective surgery should be done or not. This is because in such circumstances the incidence of intraoperative cardiac arrhythmias do not increase in asymptomatic patient with chronic K^+ level between 3 to 3.5 m.mol/L. Further it is not suggested to infuse K^+ preoperatively, depending sloely on the plasma K^+ level in the absence of any symptoms. Therefore, the decision regarding the performing an elective surgery in hypokalaemia with plasma K^+ level between 3 to 3.5 m.mol/L should depend on the presence or absence of any symptoms or organ dysfunctions such as cardiac arrhythmia, etc, and the rapidity and the magnitude of change of plasma K^+ level from the previous one. In general, chronic mild hypokalaemia where plasma K^+ level runs between 3 to 3.5 m.mol/L and there is no cardiac arrhythmia or other organ dysfunction does not appear to increase the anaesthetic risk appreciably. But this will not be applicable to patient who is taking digitalis, though his plasma K^+ level is near about 4 m.mol/L. So, it is reasonable to repeat the measurement of plasma K^+ level and to obtain an ECG for detection of cardiac arrhythmia before any induction of anaesthesia in patients who are considered at the increased risk from the effects of hypokalaemia (Fig. 10.3).

No specific anaesthetic drugs or technique appear to be superior for use in hypokalaemic patient. But, it is important to monitor the ECG continuously, during the perioperative period for evidence of any adverse effect of hypokalaemia. Any new evidence of hypokalaemia on the ECG requires prompt treatment with IV administration of K^+ in the dose of 0.5 to 1 m.mol repeatedly, until the ECG reverts to normal. As the K^+ depleted heart is vulnerable to the arrhythmogenic effect

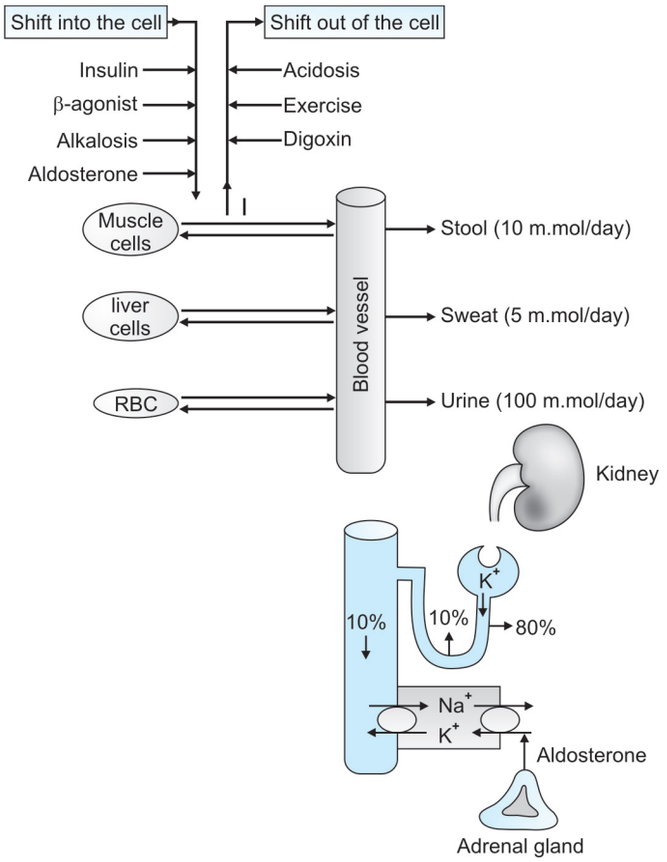

Fig. 10.3: The total body K^+ metabolism by the mechanism of secretion of K^+ in distal renal tubule, intercompartmental shifting and excretion through stool, urine and sweat

of catecholamines, digitalis and calcium, so their perioperative use should be very carefuly restricted. During surgery, IV fluid should be selected to avoid glucose load. This is because hyperglycaemia may contribute to more hypokalaemia, the cause of which is explained before. Continuous capnography and measurement of arterial blood gas and pH are helpful for confirming the proper management of ventilation. Because hyperventilation can produce further alkalosis and hypokalaemia. Hypokalaemic patients have increased sensitivity to neuromuscular blocking agents. So, a prudent approach is to reduce the dose of muscle relaxant to 30 to 50% and use of nerve stimulator to follow the degree of muscular paralysis and the adequacy of reversal. Chronic hypokalaemia is associated with decreased myocardial contractility and hypotension. Therefore, patient with chronic hypokalaemia might be unusally sensitive to the cardiac depressant effect of volatile anaesthetic agent. There is also evidence that epinephrine used with local anaesthetic agents to perform axillary block in hypokalaemic patient is associated with arrhythmia shown by ECG. So, it is prudent to avoid the use of epinephrine with local anaesthetic agent in patient suffering from hypokalaemia.

Hyperkalaemia

Hyperkalaemia is defined as plasma K^+ concentration greater than 5·5 m.mol/L, where the usual normal plasma value of it varies between 3·5 to 5·5 m.mol/L. It is a less common disturbance of K^+ balance than hypokalaemia, becaue the kidneys have enormous capacity to excrete K^+ which may go upto 400 to 600 m.mol/day (average 500 m.mol/day). Usually the hyperkalaemia can result from: (i) decreased renal excretion of K^+, (ii) shifting of K^+ from intracellular to extracellular compartment, without any change in total body K^+ content (iii) increased intake of K^+ and (iv) combination of these factors.

Increased intake of K^+

Increased intake of only K^+ is a rare sole cause of hyperkalaemia. This is because there is enormous capabilities of adaptation for excretion of K^+ by kidneys which ensures rapid elimination of it, in response to increased dietary load or consumption. However, iatrogenic hyperkalaemia may result from over zealous parenteral K^+ replacement or usual amount of replacement of K^+ in patients with renal insufficiency or patients taking insulin or β-blockers. Other source of iatrogenic hyperkalaemia are: transfusion of stored blood, chronic consumption of potassium preparation of any drug (such as potassium penicillin), taking K^+ salt as substitute of Na^+ salt where much Na^+ intake is prohibited, etc. The K^+ concentration in one unit of stored blood can increase from 25 to 35 m.mol/L after 24 days of storage. Therefore, where there is risk of hyperkalaemia large transfusion of old whole blood should be avoided. On the otherhand, this hyperkalaemia can be minimised by transfusing only the packed red cells (Table 10.4).

Decreased renal excretion of K^+

Chronic hyperkalaemia is also virtually associated with decreased excretion of K^+ by kidney due to: (i) decreased GFR, (ii) decreased aldosterone acitivity or reduced K^+ secretion from the distal nephron. The reduced GFR is due to the reduced circulation or hypovolaemia which causes acute oliguric renal failure. This acute renal failure causes hyperkalaemia due to decreased excretion of K^+. On the otherhand, reduced

Table 10.4: Causes of hyperkalaemia

A.	**Increased intake**
	High K^+ intake through food
	Chronic ingestion of drugs containing K^+ compound
	Excessive IV therapy with K^+
	Na+ salt subsitute by K^+ salt
B.	**Impaired renal excretion**
	i. Reduced GFR
	Renal failure, reduced renal blood flow (shock)
	Urinary tract obstruction
	ii. Impaired tubular secretion of K^+
	Hypoaldosteronism
	Addison's disease, 21-hydroxylase deficiency
	ACE inhibitior, NSAID
	β-blockers, K^+-sparing agents
	SLE, Sickle-cell disease
C.	**Intercompartmental shift of K^+**
	Acidosis, diabetes, β-blockers
	Tissue hypoxia, succinylcholine
	Strenous exercise
	Water depletion (ECF hypertonicity)
	Rhabdomyolysis
D.	**Enhanced Cl^- reabsorption**
	Cyclosporine
	Gordon's syndrome
E.	**Psudohyperkalaemia**
	Incorrect blood sampling
	Tissue damage during venepuncture
	Red cell haemolysis
	Marked leukocytosis and / or thrombocytosis

circulation or shock is also associated with acidosis and increased catabolism which again causes hyperkalaemia. Therefore, this hyperkalaemia further aggravates the hyperkalaemia which is already produced by oliguric renal failure.

Hyperkalaemia due to decreased excretion of K^+ from renal tubule may be due to decreased aldosterone activity. At the distal nephron aldosterone causes reabsorption of Na^+, inexchange of K^+ which is excreted through urine. In the absence of aldosterone Na^+ is not absorbed, so K^+ is not secreted and causes hyperkalaemia. Hypoaldosteronism may be due to primary defect in the synthesis of aldosterone hormone or a defect in the renin - angiotensin - aldosterone system. The defect of aldosterone synthesis again may be due to primary adrenal insufficiency (Addison's disease) or congenital 21 hydroxylase adrenal enzyme deficiency, which is needed to synthesize the mineralocorticoids. These patients show impaired ability to increase the secretion of aldosterone in response to hyperkalaemia as a positive feed back compensatory mechanism. They are usually asymptomatic but create problem when they are given with K^+ sparing diuretics or intake of K^+ increases.

Factors which also interfer the action of renin angiotensin aldosterone system may cause the hyperkalaemia. This is even more apparent when this renin angiotensin aldosterone interference is accompanied by impairment of renal function and reduced excretion or secretion of K^+ due to this renal dysfunction. ACE-inhibitors interfer the secretion of angiotensin II mediated release of aldosterone and thus also cause hyperkalaemia. NSAID inhibit the secretion of renin by inhibiting the synthesis of prostaglandin and thus causes hyperkalaemia. Heparin, including the low molecular weight compound also inhibits the production of aldosterone by the cells of zona glomerulosa and can lead to sever hyperkalaemia in a subset of patients with underlying renal disease, diabetes mellitus and those receiving K^+ sparing diuretics.

Decreased secretion of K^+ by the distal and collecting tubules may be the principal cause of hyperkalaemia. It results from either impaired Na^+ reabsorption or increased Cl^- reabsorption. So, they also often have varying degree of Na^+ wasting or loss and hyperchloremic metabolic acidosis. This may be intrinsic or acquired defect. Such defect may even occur in the presence of normal renal function. It is characterised by unresponsiveness or resistance to aldosterone therapy. So, it may be called as pseudoaldosteronism. The other acquired causes of decreased secretion of K^+ in distal tubule are SLE, diabetic neuropathy, sickle cell anaemia, etc. The decreased secretion of K^+ is also caused by K^+ sparing diuretics which antagonize the action of aldosterone activity and produce the effect of pseudoaldosteronism.

Shifting of K^+ from ICF to ECF

The hyperkalaemia may also occur due to the movement of K^+ out of the cells. This is commonly due to the administration of succinylcholine, intravascular haemolysis, break down of cells due to any cause, acidosis, excessive exercise, massive tissue trauma, rhabdomyolysis, etc. The average increase of plasma K^+ concentration after administration of succinylcholine is 0.4 to 0.6 m.mol/L. But it may be exaggerated following severe trauma, massive burn, or following lower motor neuron disease. Insulin deficiency and hypertonicity (e.g hyperglycaemia) promote K^+ shift from the intracellular compartment to the extracellular compartment. The severity of exercise induced hyperkalaemia is related to the degree of exertion. It is due to the increased release of K^+ from muscles and is rapidly reversible which is often associated with rebound hypokalaemia. Treatment with β-blockers rarely cause hyperkalaemia, but may contribute to the elevation in plasma K^+ concentration, seen with other conditions. Hyperkalaemia may also occur with severe digitalis toxicity due to the inhibition of Na^+-K^+ ATPase pump. Uraemia may also impair the activity of Na^+-K^+ ATPase pump and produce hyperkalaemia. Arginine hydrochloride is used to treat metabolic alkalosis. But it may cause hyperkalaemia because the arginine cations enter the cells and potassium anions move out of the cell to maintain the electrical neutrality.

Pseudohyperkalaemia is a condition where there is artificial or spurious elevation of plasma K^+ concentration during its measurement in laboratory. This is due to the release of K^+ out of the red cells,

because of haemolysis in a blood specimen immediately following venipuncture. The other contributing factors for pseudohyperkalaemia may also include prolonged use of tourniquet causing haemolysis, repeated fist clenching, release of K^+ from lysis of white cells and lysis of platelets in marked leucocytosis and thrombocytosis, etc. (Figs 10.4A to C).

Clinical Manifestation

The most important and common effects of hyperkalaemia are found on cardiac and skeletal muscles. Hyperkalaemia reduces the threshold for initiation of action potential and thus causes sustained spontaneous depolarization of muscle cells like succinylcholine. This is the mechanism of manifestation of hyperkalaemia. Cardiac manifestation of it are likely to occur when plasma K^+ concentration crosses over 7 m.mol/L. In general the plasma K^+ values over 6 m.mol/L should be treated. The earliest ECG changes during cardiac manifestations of hyperkalaemia includes increased T-wave amplitude (peaked T-wave). More severe degree of hyperkalaemia may also result in prolonged PR interval, prolonged QRS duration, delay in AV conduction and loss of P-wave. Then, with gradual increase in plasma K^+ concentration there is loss of R-wave amplitude with progressive widening of QRS complex which merges with the T-wave and produces a sine wave pattern in ECG. More severe hyperkalaemia produces VF and asystole.

Since, the resting membrane potential of cell is related to the ratio of intracellular and extracellular K^+ concentration, so the hyperkalaemia partially depolarizes the cell membrane. This partial, prolonged and sustained depolarization impairs the membrane excitability which is manifested as muscular weakness. This may progress to flaccid paralysis (like succinylcholine) and hypoventilation if the respiratory muscles are involved. Hyperkalaemia also inhibits the reabsorption of NH_4^+ in the thick ascending limb of the loop of Henle and renal aminogenesis. Therefore, the net renal acid excretion is impaired which resluts in metabolic acidosis. This may further exaccerbate the hyperkalaemia due to the movement of K^+ out of the cells.

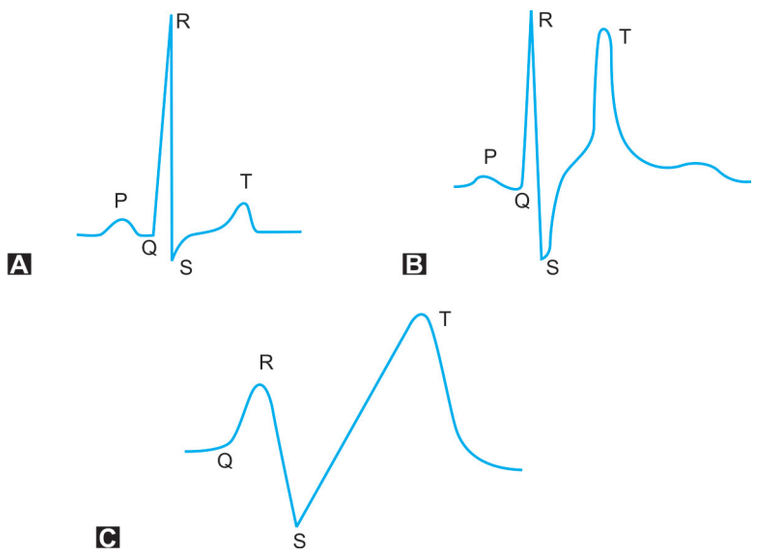

Fig. 10.4A to C: The effects of hyperkalaemia on ECG. It is characterised by : loss of P wave, decrease in amplitude of R-wave, ST-segment depression, widening of QRS complex, shortened QT interval and peaked T-waves. Thus the graph of ECG resembles a 'sine wave'.
A = Normal ECG, B = Transition, C = Sine wave

Treatment

Chronic hyperkalaemia is commonly due to the impaired K^+ excretion by kidney, except some rare causes. If the aetiology is not readily apparent and the patient is asymptomatic, then the pseudohyperkalaemia should be thought first and excluded. The severe chronic renal insufficiency due to oliguric acute renal failure, caused by hypovolaemia also should be ruled out. The history will also guide regarding the excessive K^+ intake or any drug that impairs the handing of K^+ causing hyperkalaemia. The estimation of effective circulating volume, extracellular fluid component or urine output are also essential part of the physical examination which help to find out the exact aetiology of hyperkalaemia. The severity of hyperkalaemia is determined by the symptoms, plasma K^+ concentration and ECG abnormalities.

The appropriate renal response to hyperkalaemia is to excrete at least 200 m.mol/day of K^+. In most cases, the reduced renal K^+ loss is due to the impaired K^+ secretion. This impaired K^+ secretion again may be due to either hypoaldosteronism (less synthesis) or resistance to its renal effect. This can be determined by evaluating the K^+ loosing response of aldosteron after administration of exogenous mineralocorticoids. Primary adrenal insufficiency should be differentiated from secondary hypoaldosteronism (hyporeninemic hypoaldosteronism) by examining the renin aldosterone axis. Therefore, the plasma renin and aldosterone levels should be measured.

The approach to therapy for hyperkalaemia depends on its degree which is determined by the plasma K^+ concentration, associated muscular weakness and changes on the ECG. Potentially the fatal effect of hyperkalaemia rarely occurs unless the plasma K^+ concentration goes above 7 m.mol/L which is associated with profound weakness, QRS widening, absence of P-waves or vantricular arrhythmia with cardiac arrest. Hence, to avoid this lethal outcome, plasma K^+

concentration exceeding 6 m.mol/L should always be treated immediately. The treatment of hyperkalaemia is aimed at reversing the cardiac manifestation, removing the muscle weakness and restoring the plasma K^+ concentration to normal. The treatment modalities should depend on the severity of manifestations and the cause of hyperkalaemia.

Severe hyperkalaemia requires emergency treatment directed at minimizing the membrane depolarization, shifting K^+ into the cells and promoting the K^+ loss. In addition the exogenous K^+ intake and antikaliuretic drugs should be discontinued. In emergency, calcium gluconate is the drug of choice and reduces the membrane excitability. The usual dose of calcium gluconate is 5 to 10 ml of 10% solution which is administered over 2 to 3 minutes. Its effects are very rapid (within minutes) and antagonizes the cardiac effects of hyperkalaemia. But, unfortunately, the results is very short lived (30 to 60 minutes) and the dose should be repeated. If the initial dose of calcium gluconate can not produce any change in ECG, then the 2nd dose also can be repeated after 5 to 10 minutes. Instead of calcium gluconate, calcium chloride also can be used in the dose of 3 to 5 ml of 10% solution.

Insulin causes K^+ to shift into the cells by mechanism described before and is so used to treat hyperkalaemia. It is used with glucose, because glucose also stimulate the secretion of endogenous insulin and prevents hypoglycaemia if occurs. Only glucose also can be used to treat hyperkalaemia by stimulating the pancreatic β cells to release insulin. But this action is very delayed. The recommended dose of exogenous insulin is 10 to 20 units of regular veriety with 25 to 50 gm of glucose. If effective the plasma K^+ concentration will fall by 1 to 1·5 m.mol/L in 20 to 30 minutes and the effect will last for several hours. Hyperglycaemic patients should not be given glucose. They will only receive insulin. Acidosis causes shifting of K^+ out of the cells and hyperkalaemia. Therefore, alkali therapy with intravenous $NaHCO_3$ shifts K^+ into the cells and reduce hyperkalaemia. This is administered as an isotonic solution in the dose of 130 m.mol/L and will decrease the plasma K^+ conc within 20 minutes. Ideally alkali should be reserved for severe hyperkalaemia which is associated with metabolic acidosis. β-adrenergic agonist also promote the cellular uptake of K^+. Thus, it may be useful in acute hyperkalaemia associated with massive transfusions. When it is administered pareterally or in nebulized form, the onset of action is 30 minutes and lowers the plasma K^+ concentration by 0·5 to 1·5 m.mol/L. This effect lasts for 2 to 4 hours.

If the renal function is adequate, then the loop and thiazide diuretics (often in combination) may enhance K^+ excretion. So, they may be used as an adjunct to the management of hyperkalaemia. Sodium polystyrene sulfonate is a cation exchange resin. It also pormotes the excretion of K^+ in exchange of Na^+ in the GI tract. It is used through oral or rectal route and each gram binds with 1 m.mol of K^+ and release 2 to 3 m.mol of Na^+. When given by mouth the usual dose of sodium polystyrene is 25 to 50 gm which is mixed with 100 ml of 20% sorbitol to prevent constipation. This will lower the plasma K^+ concentration by 0·5 to 1 m.mol/L within 1 to 2 hour of its administration and the action lasts for 4 to 6 hours. Another way of treating hyperkalaemia is dialysis. It is effective in severe and refractory hyperkalemia. Among the dialysis, haemodialysis is more safer and effective than peritoneal dialysis. The rate of decreases of plasma K^+ level by haemodialysis is 50 m.mol/h, whereas the rate of removal of plasma K^+ level by peritoneal dialysis is only 15 to 20 m.mol/hour.

Anaesthetic Consideration

It is the general agreement that plasma K^+ concentration should be kept below 5·5 m.mol/L before any elective anaesthesia and surgery. If this is not possible elective anaesthesia and surgery should be postponed in patients with hyperkalaemia. In emergency circumstances anaesthetic technique should be adjusted simultaneously at both direction such as by preventing any further increase and lowering the plasma K^+ concentration by previously mentioned different techniques. Ventilation always should be controlled and monitored by capnography to prevent the accumulation of CO_2 causing respiratory acidosis which could result in transfer of K^+ from intracellular to extracellular sites. It is found that 10 mm decrease in P_aCO_2 causes decrease in plasma K^+ concentration by about 0·5 to 1 m.mol/L. Metabolic acidosis due to arterial hypoxaemia should also be considered which prevents hypokalaemia. The use of succinylcholine is contraindicated in the presence of hyperkalaemia, because there is no reliable method to prevent succinylcholine induced K^+ release.

Care should be given regarding the periopertive intravenous fluid, because most of the solutions contain K^+, as for example lactated Ringer's solution contain K^+ in the concentration of 4 m.mol/L. Hyperkalaemia accentuates the effect of muscle relaxants and decreases its intraoperative requirements. So, the practical approach in such circumstances is to titrate the dose of neuromuscular blocking agent by the use of nerve stimulator. Unlike the plasma Na^+ concentration, hyperkalaemia is not associated with alterations in the dose requirement of volatile anaesthetics.

Intraoperatively all the patients should be monitored carefully and continuously by ECG. Drugs such as Ca^{2+}, glucose and insulin should be kept ready for any acute hyperkalaemia.

CALCIUM BALANCE

Introduction

Calcium (Ca^{2+}) is the principal component of human skeleton and is the 4th most common inorganic element in the body. The total calcium content of a normal

adult human body is about 20 to 25 gm/Kg of lean body mass (LBM). The bone and teeth constitutes about the 98% of the total body calcium. The remaining 2% of it is distributed in different tissues of body such as muscle, plasma, lymph, liver, etc. In plasma the Ca^{2+} level (ionized plus nonionized) varies between 9 to 11 mg/100 ml of blood. This level is maintained fairly constant and is very critical. Calcium (Ca^{2+}) in the plasma is remained in the following form: diffusible and nondiffusible. Diffusible calcium again remains in two forms— ionized and non ionized. The examples of ionized Ca^{2+} in plasma are : $CaCl_2$, Ca-gluconate, etc and the examples of non ionized Ca^{2+} in plasma are Ca-citrate, Ca-bicarbonate, Ca-phosphate, etc. The nondiffusible Ca^{2+} remains in plasma in combination with plasma protein, specially albumin (Fact file- III).

Among the total plasma Ca^{2+}, 50% remains as free ionized form and the remaining 40% stays as protein bound. Then, another 10% remains as complex with anion such as citrate and amino acids. Within these, it is the free ionized Ca^{2+} which is the most physiologically important. Normally, the concentration of free ionized Ca^{2+} in plasma is 4·5 to 5·5 mg/dl or 2·38 to 2·66 mEq or 1·19 to 1·33 m.mol/L. (Here mEq and and m.mol are not numerically same as the valency of Ca^{2+} is two and m.mol is obtained by dividing the mEq by valency). Lowering of this free ionized Ca^{2+} concentration due to any cause produces tetany. However, the reduction of the total calcium content in the body or the non diffusible portion in the plasma due to diminished plasma protein does not cause tetany. It proves changes in plasma protein (mainly albumin) concentration affect the total Ca^{2+} content of the body, but not the ionized Ca^{2+} concentration. The general rule is that for each increase or decreae of 1 gm/dl of albumin, the total plasma Ca^{2+} level increases or decreases approximately 0·8 to 1 mg/dl, respectively. The free ionized plasma Ca^{2+} level also changes directly with the changes of blood pH. This is due to the changes of degree of protein binding capacity of Ca^{2+} (Fig. 10.5).

FACT FILE - III

Molecular weight of calcium is 40. Body content of it is regulated by PTH-related protein, vit D and calcitomin. The intracellular Ca^{2+} concentration is very low which is 100 n.mol/L. This is due to active pumping out of Ca^{2+} from the cell and active pumping in into the sarcoplasmic reticulum. The extracellular concentration of Ca^{2+} is 1 m.mol/L.

Alkalosis decreases the concentration of ionized Ca^{2+} and acidosis increases it. The thumb rule is that the concentration of ionized Ca^{2+} increases approximately 0·16 mg/dl for each decrease in 0·1 unit of plasma pH and vice versa. The plasma phosphate concentration also varies inversely with the plasma Ca^{2+} level. An increase in the phosphate ions cause a corresponding decrease in Ca^{2+} ion and vice versa. However, the product of calcium and inorganic phosphate of blood (10 mg Ca^{2+} × 5 mg PO_4^{2-}) is kept constant and is about 50. This inverse relation of pH and phosphate concentration of plasma with Ca^{2+} in blood may be due to the increased excretion or deposition of Ca^{2+} in the bones.

Ca^{2+} has enormous importance for the function of body. It is involved in nearly all the essential biological functions. These are: contraction of heart muscle, coagulation of blood, maintenance of normal neuromuscular excitability, release of different neurotransmitter and hormones, activation of different enzymes, control of permeability of capillary endothelium, formation of bones and teeth, etc. Although 2% of body weight is constituted by calcium and 98% of this total body calcium is in the bone and teeth, still the maintenance of remaining small extracellular or plasma Ca^{2+} concentration is crucial for homeostasis. In adult the Ca^{2+} intake and loss are same. This is called the calcium balance. When Ca^{2+} is retained in the body, then the balance is called positive. It is found during growth, pregnancy, etc or during recovery after calcium starvation. On the otherhand, when the loss of Ca^{2+} is more than the intake, then the balance is called negative. It is found during the hyperactive condition of thyroid and parathyroid, in calcium deficiency and in certain other diseases such as rickets, osteomalacia, etc.

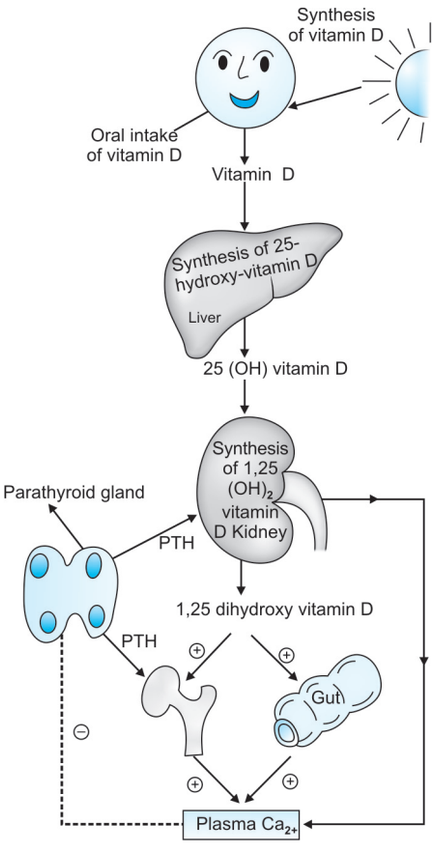

Fig. 10.5: The homeostasis of Ca^{2+} which is maintained by interaction between PTH and vitamin D. Only ionized free Ca^{2+} controls the secretion of PTH. Normally 50% of total plasma Ca^{2+} exists in serum as free ionized form. Remaining 40% of Ca^{2+} exists as protein bound, mainly with albumin. Next remaining 10% of Ca^{2+} exists as complexed form with organic compound such as citrate, phosphate, etc.

The average intake of Ca^{2+} in adults is about 700 mg/day. It is absorbed mainly through the upper part of small intestine under the influence of vit D and parathyroid hormone (PTH). Its absorption varies greatly according to the different types of food. On high protein diet only 20% of dietary Ca^{2+} is absorbed, while on low protein diet it is

only 5%. Upto 80% of the daily Ca^{2+} intake is normally lost through faeces. Soluble inorganic forms of Ca^{2+} is much better absorbed. It is probable that the organic Ca^{2+} in food is converted to inorganic form, before it can be absorbed. Insoluble Ca^{2+} compounds are never absorbed. Thus, the presence of phytic acid in cereals produces formation of calcium phytate which is insoluble and does not absorbed. Oxalates may have the similar effect. Calcium phosphates are also not absorbed.

Ca^{2+} is also excreted through urine which is about 150 to 200 mg/day, but it may varies from as low as 50 mg/day to 300 mg/day. About 98% filtered Ca^{2+} is reabsorbed through the proximal renal tubules and the ascending limb of the loop of Henle. This is parallel to the reabsorption of Na^{+}. But the difference is that the distal renal tubular reabsorption of Ca^{2+} is controlled by parathyroid hormone (PTH). This is unlike the Na^{+} whose reabsorption is controlled by aldosterone at the distal site. The PTH is secreted by the chief cells of parathyroid gland. It also increases the absorption of Ca^{2+} from the gut and mobilises Ca^{2+} from bone into the plasma. The increased secretion of PTH also enhances the reabsorption of Ca^{2+} in the distal nephron and decreases its excretion and vice versa.

Control of Calcium Metabolism

The plasma Ca^{2+} level is normally maintained by equal amount of input and output. The input of Ca^{2+} is related to: absorption from GI tract, reabsorption from bone, and reabsorption by kidney. In contrast the output of Ca^{2+} is related to: depostion in bone, urinary excretion, secretion into the GI tract, and sweat formation. All these input and output and the subsequent plasma Ca^{2+} level is closely regulated by three hormones: PTH, vit D, and calcitonin which act primarily on bone, distal renal tubules and the small bowel.

Among these factors, PTH is the most important agent for regulation of plasma Ca^{2+} concentration. Normally, it increases the plasma Ca^{2+} level by: mobolizing Ca^{2+} from bone, increasing renal reabsorption of Ca^{2+} and excretion of PO_4^{2-} at distal tubule and increasing indirectly the intestinal absorption of Ca^{2+} via acceleration of 1,25- dihydroxy cholecalciferol (DHCC) synthesis in kidney. The secretion of PTH from parathyroid gland is regulated by the plasma Ca^{2+} level (Fact file- IV). Increase in plasma Ca^{2+} concentration decreases the secretion of PTH and vice versa.

Vitamin D also helps in Ca^{2+} homeostasis in body. It exists in several form, but the most active biological form of it is 1,25-DHCC. It is formed from the cholecalciferol, first in the liver by conversion to 25-cholecalciferol and then in the kidney by conversion to 1,25-DHCC. The last conversion of vit D is catalyzed by PTH. Like PTH, the active biological form of vit D also helps in intestinal absorption of Ca^{2+}, renal reabsorption of Ca^{2+} and potentiation of the action of PTH on bone.

Calcitonin is another polypeptide hormone whose action is opposite to PTH. It also helps in Ca^{2+} homeostasis in the body. It is secreted from the para follicular cells of the thyroid gland. It inhibits the mobilisation of Ca^{2+} from bone and increases the excretion of Ca^{2+} through urine by inhibiting its reabsorption at distal renal tubules. Thus, the calcitonin tries to decreases the plasma Ca^{2+} level in oppose to the action of PTH. Hence, hypercalcaemia stimulates its secretion and hypocalcaemia inhibits its secretion from parafollicular cells of thyroid glands.

There are two types of disturbances of Ca^{2+} balance: hypercalcaemia and hypocalcaemia.

FACT FILE - IV

Parathyroid hormone (PTH) has direct effect on bone and renal tubules. It promotes reabsorption of Ca^{2+} from bone and renal tubules. It has also indirect effect which is mediated by increasing the conversion of 25-hydroxycholecalciferal to the more potent hormone 1,25-dihydroxycholecalciferol (DHCC). This results in increased Ca^{2+} absorption from food in gut and increased mobilisation of Ca^{2+} from bone. In regulating Ca^{2+} homeostasis, PTH plays an important role. This is because dietary Ca^{2+} and vit D are rarely deficient. 98% of total body calcium is in bone. This remains in dynamic equilibrium between extracellular fluid and store, by the process of deposition and reabsorption.

Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities. It is detected most frequently during routine biochemical analysis in asymptomatic patients. It may present with chronic symptoms or occasionally patients present as acute emergencies with severe hypercalcaemia and dehydration. It occurs as a result of variety of disorders which are associated with increased or decreased secretion of PTH. In primary hyperparathyroidism the primary or intital defect lies in the parathyroid gland which causes independent increaed secretion of PTH and hypercalcaemia. In hypercalcaemia due to other cause (described in table) there is decreased secretion of PTH. This decreased secretion of PTH (effect not the cause) is due to the reflex suppression of its secretion by hypercalcaemia due to other causes. In chronic hypocalcaemia due to other causes there is reflex compensatory increase in hypersecretion of PTH. This secondary hyperparathyroidism can however sometimes result in gradual autonomous secretion of PTH and subsequent hypercalcaemia. This is called tertiary hyperparathyroidism.

Hypercalcaemia is also associated with malignancy. In malignancy this hypercalcaemia is due to abnormal secretion of some humoral mediators (such as PTH like substances, prostaglandins, cytokines etc) from tumour cells which release Ca^{2+} from bones or due to direct bony metastases. In Paget's disease and chronic immobilization, hypercalcaemia is due to increased turnover of Ca^{2+} from bone. Hypercalcaemia in the milk alkali syndrome, granulomatous disease (e.g. sarcoidosis), hypervitaminosis of vitamin D,

etc. is due to the increased GI absorption of Ca^{2+}. Still in many circumstances, the mechanism responsible for hypercalcaemia is poorly understood.

Clinical Manifestations

The most of the patients of hypercalcaemia are asymptomatic. About 50% of patients with primary hyperparathyroidism and hypercalcaemia may go unregonised until patient presents with some renal calculi. 10% of first stone formers and 20% of recurrent stone formers have primary hyperparathyroidism. Patients of hypercalcaemia due to malignancy can have a rapid onset of symptoms or may have clinical features according to the site of malignancy which help to localise their pathology. Hypertension is common in hypercalcaemia. Other symptoms and signs of hypercalcaemia include polyuria, polydypsia, renal colic, anorexia, nausea, lethargy, dyspepsia, etc. Peptic ulcer, pancreatitis and renal failure may also complicate the hypercalcaemia. The ECG signs of hypercalcaemia include shortened ST segment, shortened QT interval, premature ventricular contraction due to depressed cardiac conductions, etc. (Table 10.5).

Table 10.5: Causes of hypercalcaemia

A.	**With elevated PTH levels**
	• Primary hyperparathyroidism
	• Tertiary hyperparathyroidism
	• Lithium induced hyperparathyroidism
B.	**With low PTH levels**
	• Milk-alkali syndrome
	• Malignancy
	• Multiple myeloma
	• Paget's disease of bone
	• Vitamin D hypervitaminosis
	• Granulomatous disorder (tuberculosis, sarcoidosis)
	• Thiazide diuretics

Diagnosis and Treatment of Hypercalcaemia

The most important step in the management of hypercalcaemia is the measurement of PTH level by specific radioimmunoassay. If the PTH and urinary calcium level is elevated, then diagnosis about hyperparathyroidism is confirmed. On the other hand, if PTH level is low, urinary Ca^{2+} is high and no other apparent cause of hypercalcaemia is found, then malignancy with or without bony metastases is very likely. Low plasma phosphate and increased alkaline phosphate level support the diagnosis of primary hyperparathyroidism or malignancy. Hypercalcaemia may cause nephrocalcinosis and impairment of renal tubular function, causing hyperuricaemia and hyperchloraemia. Unless the source of hypercalcaemia is obvious, all the patients should be screened for malignancy with X-ray, MRI or isotope bone scan. The patient should also be screened for myeloma by ESR, serum protein electrophoresis, level of immunoglobulins, and urinary Bens Jones protein.

Symptomatic hypercalcaemia is usually associated with dehydration. So, it requires rapid treatment by rehydration which is accomplished by administration of IV saline (to replace as much as 4 to 6 L deficit of water or to keep urinary output at 20 to 30 ml/h). This rehydration should be followed by brisk diuresis to accelerate the excretion of Ca^{2+}. Regarding diuresis the clinician should be cautious that premature diuresis or excessive diuresis after rehydration may increase the plasma Ca^{2+} level by additional fluid depletion. During rehydration the patient may need monitoring with CVP in old age or who is suffering from renal impairment. After rehydration and diuresis the plasma Ca^{2+} level may come down, but still remains above the normal level, though the potential risk for cardiovascular and neurological complications of hypercalcaemia are removed.

Patients who are not responding to proper rehydration and mild diuresis or have severe hypercalcaemia (total Ca^{2+} >15 mg/dl) may require additional therapy by bisphosphonates, glucocorticoids or calcitonin. Among the bisphosphonates, pamidronate is used in the dose of 90 mg IV slowly over 4 hours. It is the agent of choice in hypercalcaemia, because of its prolonged duration of action. Pamidronate causes a fall in plasma level of Ca^{2+} which is maximum at 2 to 3 days and lasts for few weeks. Unless the cause of hypercalcaemia is removed such as by the surgical removal of parathyroid gland, the patient should be followed up with an oral bisphosphonate after an emergency IV therapy. Calcitonin for the treatment of hypercalcaemia is used in the dose of 2 to 5 U/Kg through subcutaneous route. Haemodialysis for the treatment of hypercalcaemia may be necessary in the presence of cardiac or renal failure. Glucocorticoids is helpful in the setting of vit D induced hypercalcaemia such as granulomatous disease states.

Hypercalcaemia in patients with primary hyperparathyroidism responds less well to pamidronate and glucocorticoids than the hypercalcaemia due to malignancy. Urgent removal of parathyroid gland in primary hyperparathyroidism (such as adenoma, hyperplastic gland) is occasionally required, but strenous attempts should be made to replace the fluid deficits and lower the plasma Ca^{2+} level before administering anaesthesia in such patient. Post operative hypocalcaemia is not uncommon after the removal of parathyroid gland during the first two weeks after surgery. But the residual suppressed parathyroid tissue gradually recovers and plasma Ca^{2+} level comes to normal.

Anaesthetic Consideration

Before and during the operation of a hypercalcaemic patient every attempt should be made to normalise the ionised plasma Ca^{2+} level, if it is already high and to avoid the circumstances which will raise it. So, perioperative acidosis should be checked by any cost. Therefore, ventilation must be controlled and monitored by capnography during GA. Adequate hydration should

be continued pre and intraoperatively with great care to avoid hypervolaemia. So, IV fluid therapy in hypercalcaemic patient should be monitored by CVP or pulmonary artery pressure, especially in patients with decreased cardiac reserve. The periodic measurement of K^+ and Mg^{2+} level in plasma also should be done during rehydration and diuretic therapy for detection of any iatrogenic hypokalaemia and hypomagnesemia in hypercalcaemic patients. At last patient should be monitored periodically by checking the plasma ionized Ca^{2+} level through out the whole perioperative period.

Table 10.6: Causes of hypocalcaemia

	Ionized Ca^{2+} concentration	*Total Ca^{2+} concentration*	*Plasma PTH concentration*	*Plasma phosphate concentration*
Hypoparathyroid	↓	↓	↓	↑
Pseudohypoparathyroid	↓	↓	↑	↑
Alkalosis	↓	N	N	N
Renal failure	↓	↓	↑	↑
Vitamin D deficiency	↓	↓	↑	↑
Hyperphophatemia	↓	↓	↑	↑
Precipitation of Ca^{2+}	↓	↓	↑	↑
Pancreatitis				
Fatembolism				
Chelation of Ca^{2+}	↓	↓	↑	↑

↑ = Increased, N = Normal, ↓ = Decreased

Hypocalcaemia

The incidence of hypocalcaemia is less common than that of hypercalcaemia. It should be diagnosed only on the basis of plasma ionized free Ca^{2+} concentration, but not on the basis of total plasma Ca^{2+} concentration or total body Ca^{2+} content. Because the most common cause of hypocalcaemia is low plasma albumin with normal free ionized Ca^{2+} concentration. Contrary, ionized free Ca^{2+} level may be low in the face of normal plasma Ca^{2+} concentration during alkalosis as a result of hyperventilation. Therefore, when the direct measurement of plasma free ionized Ca^{2+} level is not available then the total plasma Ca^{2+} concentration should be corrected for increase or decreae of plasma albumin level. Hence, as almost all the laboratories routinely report the total serum Ca^{2+} concentration, but it is the ionized concentration which is biologically important and should be measured (Table 10.6).

Symptomatic hypocalcaemia is most commonly due to decreased plasma Ca^{2+} concentration resulting from hypoparathyroidism. On the otherhand, this hypoparathyroidism may be due to surgical, idiopathic or pseudo causes. Surgical hypoparathyroidism commonly occurs during thyroid surgery, but this complication is only permanent in 1% of thyroidectomy. Transient hypocalcaemia develops in 10% of patients after 12 to 36 hours, following subtotal thyroidectomy for Grave's disease. Idiopathic hypoparathyroidism is sometimes occurred with autoimmune disease of the adrenal gland, thyroid gland or ovary at any age. Pseudo hypoparathyroidism is usually an autosomal dominant syndrome where there is development of tissue resistance to PTH. Hypoparathyroidism may be associated with hypomagnasemia, because deficiency of magnesium is postulated to impair the secretion of PTH and antagonize its effects on bone. In chronic renal failure, hyperphosphotemia may also be the common cause of hypocalcaemia. Hypocalcaemia may also occur as the result of vitamin D deficiency which again may result from malabsorption, reduced intake or abnormal metabolism of vitamin D.

Acute severe ionized hypocalcaemia may also occur when the large amount of Ca^{2+} chelating agents such as citrate are administered during blood and plasma transfusion. The degree of hypocalcaemia during transfusion of blood depends on the rate of administration and the ability of bone to provide additional Ca^{2+} and the liver which metabolises the citrate. Similarly, transient hypocalcaemia may also result following the rapid infusion of large amount of albumin. Another cause of hypocalcaemia is pancreatitis. It is due to precipitation of Ca^{2+} with fats, following the release of lipolytic enzymes and fat necrosis.

Other less common cause of hypocalcaemia include: hypersecretion of calcitonin (e.g. calcitonin secreting medullary carcinoma of thyroid) and use of large dose of heparin, protamine, glucagon, etc.

Clinical Manifestations

The fall of ionized Ca^{2+} concentration increases the relative proportion of neuroexcitatory ions such as Na^+, K^+, PO_4^{2-}, etc, and produces hyper excitability of peripheral nerves. This is called tetany. It is the clinical manifestation of hypocalcaemia and occurs when the ionized free Ca^{2+} concentration goes below 0·8 m.mol/L (3·2 mg/dl) in the absence of alkalosis or total plasma calcium level is < 2m.mol/L (or < 4 mEq/L). Alkalosis may be produced by excess intake of alkali, profuse vomiting or increased breathing. It causes tetany without reducing the total plasma Ca^{2+}. This is because alkalosis alters the ionic balance and decreases the amount of ionic free Ca^{2+} without affecting the total Ca^{2+}concentration. Also alkalosis increases the proportion of the neuroexcitatory ions and makes the peripheral nerve fibres and central nervous system more excitable. Children are more sensitive to tetany than adult. Magnesium depletion should also be considered as a possible

contributing factor for hypocalcaemia and tetany.

Tetany is commonly manifested in children as a triad of carpopedal spasm, laryngeal stridor and convulsion, though one or more of these signs may be found independent of others. In carpopedal spasm the hand adopts a characteristic figure which include flexed (Fig. 10.6) metacarpophalengeal joint, extended interphalangeal joint of fingers and thumb, and apposition of thumb with fingers. Stridor is caused by the closer of glottis. Furthermore, the adult patients complain of feeling of tingling sensation in the hands and feet, and around the mouth. The latent tetany also may be present when the signs of overt tetany are lacking. It is best recognised by eliciting the carpopedal spasm by inflating the sphygmomanometer cuff on the upper arm above the systolic BP. A less specific sign of hypocalcaemia is Chvostek's sign where tapping on the facial nerve near the styloid process causes twiching of the facial muscles.

Other clinical manifestations of hypocalcaemia include paresthesia, confusion, lethargy, cardiac irritability leading to arrhythmia, decreased cardiac contractility causing hypotension, etc. ECG findings are not chracteristic of hypocalcaemia.

Treatment

Symptomatic hypocalcaemic or tetany is a medical emergency condition. So, it should be treated immediately. Instant IV injection of 10 to 20 ml of 10% Ca-gluconate will gradually raise the serum free Ca^{2+} concentration and control the situation. Instead of a Ca-gluconate, 3 to 5 ml of 10% $CaCl_2$ also can be used. However, during IV administration of calcium, it should be remembered that 1 gm of Ca-gluconate contains 90 mg (or 45 mEq or 225 m.mol) of calcium and 1 gm of $CaCl_2$ contains 272 mg (136 mEq or 68 m.mol) of calcium. Also, it should be kept in mind that 1000 mg of Ca-gluconate and 400 mg of $CaCl_2$ provides the same 100 mg of elemental calcium and when any commercial preparation of Ca^{2+} is given as equal amount of elemental calcium, the influence of different preparation on ionized Ca^{2+} is equivalent. During the management of hypocalcaemia, serial measurement of ionized free Ca^{2+} level in plasma is mandatory. The Ca^{2+}, Mg^{2+}, PO_4^{2-} and K^+ are predominantly intracellular ions. So, their abnormalities frequently coexist with hypocalcaemia. Therefore, their plasma concentration should be checked periodically, particularly PO_4^{2-} and Mg^{2+} and should be treated. After the initial bolus dose, repeated bolus doses or continuous infusion of Ca^{2+} in the dose of 0·5 to 2 mg/Kg/hour may be necessary to obtain a prolonged effect of calcium therapy.

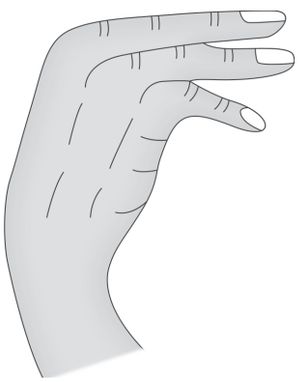

Fig.10.6: Carpopedal spasm or Trousseau's sign

An intramuscular injection of 10 ml Ca-gluconate may also be given to obtain a more prolonged effect. To control tetany alkalosis should also be reversed acutely. This can be accomplished by encouraging the rebreathing of expired air in a paper bag or administering 5% CO_2 in O_2.

Anaesthetic Consideration

During anaesthesia of a hypocalcaemic patient in the perioperative period, one should always try to recognize and treat the adverse effects of hypocalcaemia. An anaesthesiologist will also give his full effort preventing the further decrease of plasma Ca^{2+} level in the face of hypocalcaemia, once it is checked. Therefore, alkalosis should be prevented by avoiding hyperventilation and monitoring it by capnometre. During treatment of metabolic acidosis by $NaHCO_3$, hence, one should be careful about the overdrive alkalosis and will repeatedly check the ionized plasma free Ca^{2+} level in patient with the history of hypocalcaemia. There is chance of developing life threatening hypocalcaemia during GA, in patient with renal insufficiency, under going vascular surgery. In such circumstances a clinician should be very careful and will take proper measures.

Normally, administration of few units of whole blood, containing citrate as preservative, does not cause any probelm. This is because Ca^{2+} is rapidly mobilised from body stores which is kept as reserve and maintain the normal plasma Ca^{2+} level. But, during emergency, when the citrated blood is transfused very rapidly e.g. 500 ml in every 10 minutes, then there is chance of patient developing hypocalcaemia. This chance of hypocalcaemia is further aggravated in the presence of cirrhosis of liver, hypothermia and renal dysfunction where metabolism of citrate is impaired.

Continuous monitoring by ECG is useful during perioperative period to facilitate the diagnosis of hypocalcaemia. It produces cardiac depression and hypotension. Hence, anaesthetic agents which have negative inotorpic effects on heart such as barbiturates, volatile agents, etc; should be used carefully. Responses to neuromuscular blocking agents can be potentiated by hypocalcaemia. So, their use should be monitored by nerve stimulator. Lastly, during intraoperative interpretation of plasma free Ca^{2+} level, importance should be given to the transfusion of protein (albumin) and colloid during hypotension due to surgical trauma. This is because plasma albumin and colloid level change the free ionized Ca^{2+} level, though the total plasma Ca^{2+} level remains same.

11 Autonomic Nervous System and its Pharmacology

INTRODUCTION

All the functions of our body are controlled by nervous system. It is divided anatomically into peripheral nervous system (consists of peripheral nerves) and central nervous system (consists of the brain and the spinal cord) and physiologically into somatic nervous system and autonomic nervous systems (ANS). The somatic nervous system controls the function of our body's voluntary muscles and helps in carrying different somatic sensations from the skin, joint, muscles, and the other structures of body. On the other hand, the autonomic nervous system is a part of the nervous system which controls different activities of visceras, blood vessels, glands, and other parts of our body which are not under our direct control. Almost a century ago, in 1898 the autonomic nervous system was actually described first by Langley. It was called at that time as the visceral, vegetative or involuntary nervous system. Unlike the somatic nervous system, in periphery the ANS consists of nerves, ganglia and plexuses which innervate the heart lungs, blood vessels, glands, other viscera and smooth muscles in various tissues. Therefore, it is widely distributed throughout the body and regulates their function over all visceras except voluntary muscles and somatic sensation, without a person's conscious control. So, its actions are generally independent of a person's will and below the level of consciousness.

Like the somatic nervous system, ANS also has both the central and peripheral divisions and afferent and efferent paths. But, unlike the somatic nervous system, the control of ANS is mostly homolateral. On the other hand, like the somatic nervous system it has got both the spinal (Fig. 11.1) and cranial outflows. Higher centres like the hypothalamus, thalamus, corpus striatum and cerebrum control this autonomic nervous system. Certain other special higher centres, situated in the medulla, pons and midbrain are also included in this system and control it.

The activities of the somatic and autonomic nervous system always run in parallel. But, at many important levels of the central nervous system, there are free intercommunications between these two nervous systems. However, cerebrum controls both these systems. Although involuntary, yet the autonomic nervous system is not altogether beyond the voluntary control. For example, by meditation and yoga the HR, BP, visceral sensation, etc, which are controlled by the ANS can be modulated.

All the innervated structures of our body, except some parts of the skeletal muscles and cutaneous sensory structures, which are innervated by the somatic nerves are supplied by the ANS. The important difference between the autonomic and the somatic nervous system is that the most distal synaptic junction in the ANS which occur in the ganglia are situated entirely outside the cerebrospinal axis. This is unlike to the somatic nervous system where the most distal synaptic

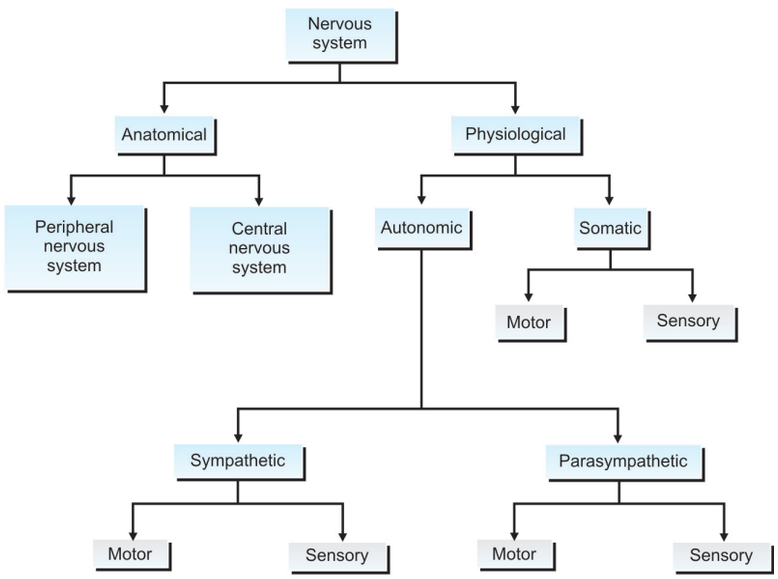

Fig. 11.1: Classification of the nervous system

connections lie with in the spinal cord, or anywhere within the cerebrospinal axis. These ganglia of ANS which are situated outside of cerebrospinal axis are small and complex in structures and contain axodendritic synapses between the preganglionic and postganglionic neurons. Whereas the somatic nervous system contains no peripheral ganglia and the most distal synapses between the pre- and post-ganglionic neurons are located entirely within the cerebrospinal axis.

The autonomic nerves which are situated outside (Table 11.1) the cerebrospinal axis form an extensive peripheral plexuses on organs, but such network is absent in somatic nervous system. All the nerves of somatic nervous system are myelinated and has no peripheral ganglion. So there is no question of preganglionic or postganglionic fibres in the somatic nervous system, as it comes directly from the anterior horn cells of spinal cord or from the nuclei of cranial nerves as postganglionic fibres. On the other hand, the preganglionic fibres of the ANS is myelinated, but the postganglionic fibres are non-myelinated.

A major goal during the administeration of anaesthesia on a patient is to maintain an optimum level of homeostasis or equilibrium between the two divisions of ANS i.e. sympathetic and parasympathetic nervous system during maximum surgical stress and strain. This is because modification and ablation of these stress and strain responses controlled by ANS may improve the perioperative outcome. So, an intelligent administration of anaesthetic care to a patient requires a full and comprehensive knowledge of ANS and its pharmacology. In addition, many diseased states such as diabetes may impair the functions of the ANS to a significant extent and may thereby alter the expected responses of a patient to surgery and anaesthesia.

Like the somatic nervous system, the ANS is also divided into two parts the centres of ANS and the peripheral autonomic nerves (Fig. 11.2).

Centres of ANS

Extensive ramifications of ANS exists in the brain above the level of spinal cord. But, there is no exclusive localised central controlling area for ANS (i.e. the centre of ANS) in the brain. Considerable intermixing and integration of the somatic and the autonomic nervous systems occur there. So, somatic responses are always accompanied by autonomic visceral responses and vice versa. The probable theory is that the highest centre in the brain, regulating ANS is situated in the hypothalamus. Within it the posterior and lateral nuclei are primarily sympathetic, while the anterior and medial nuclei are primarily parasympathetic. Many higher centres of ANS are also located in the pons, midbrain and medulla which are related to the cranial nerves. Therefore, the centres of ANS in the brain and spinal cord consist of the following:

i. Area of ANS controlling the visceral function is located in the cerebral hemisphere. These constitute the limbic system.
ii. Autonomic centres in the brain-stem and medulla are located in the reticular formation and is related to the cranial nerves outflow.
iii. Autonomic centres in the spinal cord are located in the intermedio-lateral column of gray matter of it. In it the intermedio-lateral group of neurons are present in the segments of spinal cord extending from T_1 to L_2 (lateral horn cells) and from S_2 to S_4 vertebral level, constituting the spinal sympathetic and parasympathetic outflow respectively.

The hypothalamus and the nucleus tractus solitarius are generally regarded as the principle loci for integration of all the functions of ANS which include the regulations of body temperature, water balance, metabolism of protein, cardohydrate and fat, regulation of blood pressure, emotions, sleep, respiration, control of sexual responses, etc. During the function of ANS signals are received from different parts of the body through the ascending spinobulbal pathways and also from the limbic system, neostriatum, cerebral cortex and other higher brain centres. Then it reaches to the hypothalamus and nucleus tractus solitarius. Subsequently stimulation of the nucleus tractus solitarius and the hypothalamus activates the descending bulbospinal pathways, and stimulates the hormonal output (which are known as the neurotransmitters of the sympathetic and the parasympathetic system) to mediate the autonomic responses.

Table 11.1: Some differences between autonomic and somatic nervous system

	Autonomic	*Somatic*
Organ innervated	All the visceral organs, blood vessels, glands, etc. except skin and skeletal muscles	Skeletal muscles and skin
Nerve fibres	Preganglionic-myelinated Postganglionic - nonmyelinated	Myelinated (no pre- or postganglionic fibres)
Distal most synapse	Outside CNS (in ganglia)	Within CNS
Efferent transmitter	Acetylcholine and noradrenaline	Acetylcholine
Peripheral plexus	Present	Absent
Effect of nerve section on organ supplied	Activity maintained and no atrophy of organs	Paralysis and atrophy of skeletal muscle and loss of sensation of skin

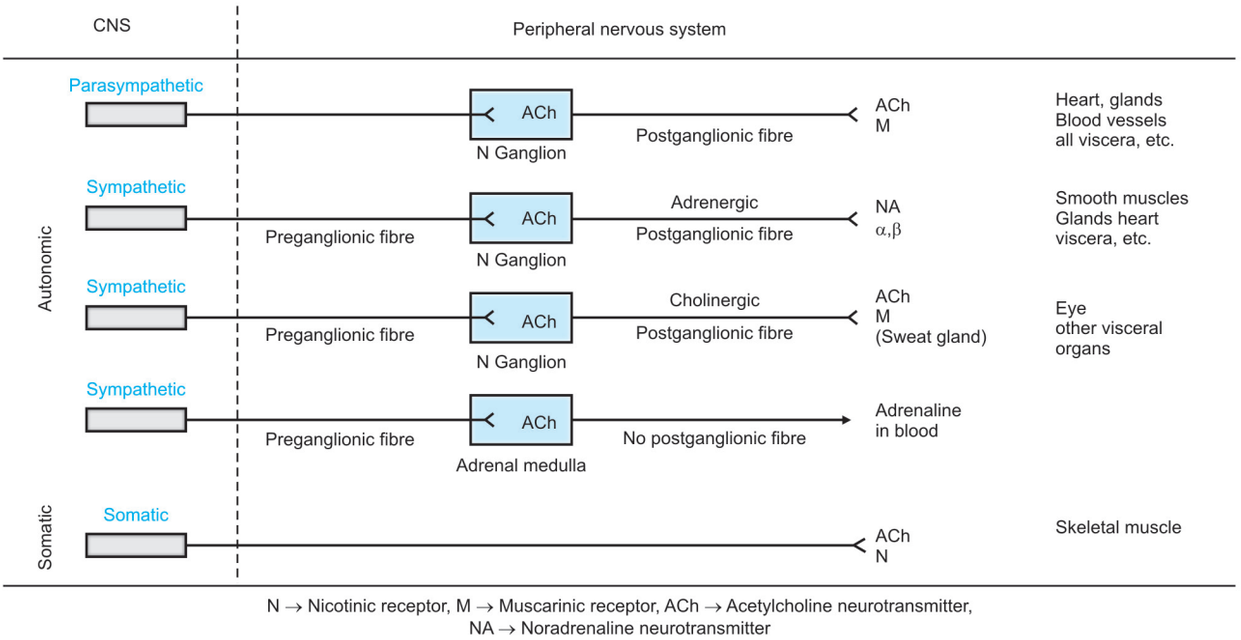

Fig. 11.2: The general outlay of different part of autonomic and somatic nervous system

PERIPHERAL PARTS OF THE ANS

Like the somatic nerves, the peripheral autonomic nerves also has the afferent and efferent fibres.

Autonomic Afferents

Except some local axonal reflexes, most of the visceral autonomic reflexes are mediated through the afferent fibres, the centre of autonomic nerves in cerebrospinal axis (brain and spinal cord) and the effarent fibres. The afferent fibres running from the visceral structures to the spinal cord form the first link of autonomic reflex arc. These autonomic afferent fibres are non-myelinated and are carried to the cerebrospinal axis by the autonomic visceral nerves, such as: vagus, pelvic, splanchnic or other autonomic nerves through which also efferent autonomic fibres come out. For example, most of the fibres (4/5) of vagus nerve are afferent or sensory and rest (1/4) of it are efferent or motor. Many autonomic afferent fibres such as from the blood vessels, skeletal muscles, and certain other integumental structures are also carried through their respective somatic spinal nerves instead of any separate autonomic visceral nerves.

As most of the autonomic visceral nerves carry the non-myelinated autonomic afferent fibres, the cell bodies of these afferent fibres are located in the dorsal or posterior root ganglia of the spinal nerves in vertebral canal, at the spinal level and the sensory autonomic ganglia of cranial nerves, e.g. nodose ganglion of vagus within skull at the cranial level. They transmit different afferent impulses from visceral such as pain, pressure, stretching, etc. which are responsible for the cardiovascular, respiratory and other visceral reflexes. For sympathetic reflexes the dendrites of the neurons of dorsal root ganglion collect impulses from the periphery, and then run through the visceral nerve, sympathetic chain, ganglia (without making any synapse) white ramus and spinal nerve to end in the cell body of dorsal root ganglia. After that the axons of the cell body of dorsal ganglion transmit impulses to the lateral horn cells or the dorsal horn cells of spinal cord.

The neurotransmitter responsible for transmission of these affarent autonomic sensory impulses are not properly known. However, the substances P (neuroactive peptide) is present in abundance in the afferent autonomic sensory fibres of dorsal root ganglia and the dorsal horn cells of spinal cord like the somatic sensory fibre. So, this peptide is considered as the leading candidate among the transmitters that passes the visceral nociceptive stimuli from the periphery to the spinal cord or brain through ANS. Other neuroactive peptides which are also responsible for transmission of autonomic sensory impulses are somatostatin, vasoactive intestinal polypeptide (VIP), and cholecystokinin. Enkephalins, present in the interneuron of dorsal horn cells of the spinal cord (within the area termed the sustantia gelatinosa) also have the visceral antinociceptive effects. It inhibits the release of substance P and diminishes the activity of cells that project from the spinal cord to the higher centres of ANS in CNS. The excitatory amino acids, such as: glutamate and aspartate (which act through the NMDA receptor) also play a major role in the transmission of sensory

responses (both autonomic and somatic) in the spinal cord.

Autonomic Efferents

The efferent or motor pathway of ANS is also functionally divided into the sympathetic and parasympathetic systems. Most of the viscera receives both the sympathetic and parasympathetic innervation and functionally they are antagonistic to each other. However, the level of activity of an innervated internal organ at a given moment is the algebraic sum of the sympathetic and parasympathetic activity during that period. Despite the conventional concept of antagonism between these two divisions of ANS, their activities on specific structure may also be either discrete and independent, or integrated and interdependent. For example, the effects of sympathetic and parasympathetic stimulation on the heart and the iris show a pattern of functional antagonism in controlling the HR and the pupillary aperture. But, their actions on the male sexual organs are complementary to each other and are integrated to promote the whole sexual function. On the otherhand, most of the blood vessels, spleen, sweat glands and hair follicles receive only the sympathetic innervation, while the ciliary muscles, gastric and pancreatic glands, receive only the parasympathetic innervation.

The neurotransmitter for all the efferent preganglionic autonomic fibres (both sympathetic and parasympathetic), all the postganglionic efferent parasympathetic fibres and only few postganglionic efferent sympathetic fibres is ACh (acetylcholine). So, they are called cholinergic fibres. Whereas the neurotransmitter for majority of the efferent postganglionic sympathetic fibres is norepinephrine (NE). So, they are called the adrenergic fibres.

SYMPATHETIC NERVOUS SYSTEM

The activation of sympathetic nervous system elicits reaction what is traditionally called the 'fight or flight' response. It includes: the redistribution of blood flow from the nonvital structure such as skin, different splanchnic regions and skeletal muscles to the vital organs, increased cardiac function, sweating, salivation, pupillary dilatation, etc. Under normal circumstances, the sympathetic system is continuously active and the degree of its activity varies from moment to moment and from organ to organ. The adjustments of body to a constantly changing enviornment are usually accomplished by the sympathetic part of the ANS. Under the circumstances of stress, the lack of sympathetic function becomes evident by the fall of HR, BP, body temperature, etc, and cannot be regulated. Other examples of lack of the effect of sympathetic nervous system are that the concentration of glucose in the blood doesnot rise when it is needed and compensatory responses to haemorrhage, hypoxia, excitement, exercise, etc. are lacking.

The outflow or efferent of sympathetic nervous system takes place only from the thoracolumbar region of spinal cord. It extends from the first thoracic to the 2nd or 3rd lumbar segment of spinal cord. The cell bodies of this spinal component of central part of sympathetic nervous system lie in the lateral horns of the grey matter of the spinal cord (the intermediolateral columns).

The nerve fibres arising from these cell bodies of the lateral horns of the spinal cord extend peripherally to three types of ganglion.

i. paravertebral ganglia, grouped as paired sympathetic chain,
ii. collateral or prevertebral unpaired ganglia,
iii. terminal ganglia near the target organs. (Table 11.2).

The effarent sympathetic nerve fibres first pass out as axons of the lateral horn cells of the spinal cord, and then run through the anterior root of spinal nerves. These preganglionic effarent sympathetic fibres are thinly medulated and β type. So, they are looked white. Then, they leave the spinal nerve in the form of a branch, called the white ramus communicans and enter the ganglion of sympathetic chain. Now, they may end in the corresponding ganglion to create postganglionic fibre or may simply run through the sympathetic chain to other ganglia situated above or below in the same sympathetic chain and there they create the postganglionic fibres. The efferent postganglionic sympathetic fibres which arise from the ganglion of sympathetic chain are non-medulated. Hence, they are looked grey. They run back from the ganglion to join again with the spinal nerve in the form of another branch, called the grey ramous communicans and

Table 11.2: Some differences between the parasympathetic and sympathetic nervous system

	Parasympathetic	*Sympathetic*
Origin	Cranio-sacral outflow (III, VII, IX, X cranial nerves and S_2-S_4 spinal segment)	Dorso or thoraco-lumbar outflow (T_1 to L_2 / L_3 spinal segment).
Ganglia	Situated on or close to the organ supplied.	Situated away from the organs supplied
Pre: Post ganglionic fibre ratio	1:2 to 1:3 (except in enteric plexus)	1:10 to 1:100
Postganglionic fibre	Short	Long
Neurotransmitter at target level	Acetylcholine (ACh)	Noradrenaline (most), ACh (sweat gland, pilomotor, adrenal medula).
Stability of neurotransmitter	ACh - rapidly destroyed and have very local action	NA is stable, diffuses and have actions over wider area.
Important function	Conservation of energy (anabolic)	In stress and emergency (catabolic).

then are ultimately distributed along all the spinal nerves throughout the whole body such as to the pilomotor, pseudomotor (sweat gland), blood vessels, skin and to the other organs of extremities which are not controlled by the somatic nervous system. It is to be noted that all the spinal nerves, extending from the first cervical to the coccygeal vertebral segment, possess gray rami communicans which carry the postganglionic sympathetic fibres and arises from all the ganglia of sympathetic chain and supply the whole body except visceras. But only the thoracic and upper 2 or 3 lumbar spinal nerves have the white rami communicans, which carry the preganglionic fibres to the sympathetic chain arising from 1st thoracic to 2nd or 3rd lumbar spinal segments.

Some preganglionic sympathetic fibres arise directly from the paravertebral ganglia of the sympathetic chain without making any synapses there and run to the prevertebral or collateral ganglion. From there collateral ganglia post-ganglionic sympathetic fibres arise and innervate the visceral structures of the thorax, abdomen, and pelvis. The prevertebral or collateral ganglion supplying the thoracic, abdominal and pelvic viscera contain cell bodies from where the postganglionic fibres arise. They receive preganglionic fibres from the T_5 - T_{12} thoracic segments of the spinal cord directly through the sympathetic chain without making synapses there. Many of the upper thoracic sympathetic fibres arising from the paravertebral ganglia of sympathetic chain form terminal plexuses, such as: the cardiac, oesophageal and pulmonary plexuses and supply these organs. The sympathetic distribution to the head and neck is through the cervical sympathetic chain and its three ganglia. All the postganglionic sympathetic fibres from this cervical chain arise from the cell bodies located in these three cervical ganglia. But, all the preganglionic sympathetic fibres supplying head and neck arise from the lateral horn cells of the upper thoracic segments of the spinal cord, as there are no sympathetic fibres that leave the CNS above the first thoracic level.

Sympathetic Ganglia

There are three types of sympathetic ganglia. These are:

i. Paravertebral ganglia forming the sympathetic chain,
ii. Unpaired prevertebral or collateral ganglia,
iii. Terminal ganglia.

Paravertebral Ganglia

They are about 22 pairs in numbers, (3 cervical, 11 thoracic, 4 lumbar, 4 sacral, and 1 coccygeal) lying on both the sides of the vertebral bodies and are connected with one another by the nerve fibres in the form of a chain which is called the paravertebral sympathetic chain. It extends from the base of the skull to the front of the coccyx. These ganglia are also connected to the spinal nerves by white and grey rami communicans. The white rami are only restricted to the segments of the thoracolumbar outflow, because they carry only the preganglionic myelinated sympathetic fibres that exit from the spinal cord through the anterior spinal roots, arising from the lateral horn cells. The grey rami arises from all the ganglia and carry the postganglionic fibres back to the corresponding spinal nerves for distribution to the sweat glands, pilomotor muscles, blood vessels, joints, skeletal muscles of the trunk and limbs and the skin of whole body. Therefore, as a rule, there should be one ganglion for each spinal or vertebral segment of spinal cord. But, they show a tendency to coalesce at the cervical, sacral and coccygeal region. For instance, the eight cervical ganglia in the neck is fused to form three ganglia, such as: the superior, middle and inferior cervical ganglia. In the thoracic region there are twelve ganglia on each side. The first thoracic ganglion in man sometimes fuses with the inferior cervical ganglion, forming the stellate ganglion. In the lumbar region there are usually four and in the sacral region there are about 4 to 5 ganglia. In the coccygeal region the terminal portions of the two sympathetic chains fuse together and form a single ganglion in front of the coccyx which is called the coccygeal ganglion.

Unpaired Prevertebral or Collateral Ganglia

They lie in the thorax, abdomen and pelvis in close relation to the aorta and its big branches, and supply postganglionic sympathetic fibres to the visceras. These are the coeliac, superior mesenteric, aorticorenal and inferior mesenteric ganglion. The preganglionic sympathetic fibres to the coeliac ganglion are supplied by the lateral horn cells of T_5 - T_{12} spinal segments. The coeliac ganglion innervate the liver, spleen, kidney, pancreas, small bowel and the proximal colon. The preganglionic sympathetic (Fig. 11.3) fibres after arising from the T_5 to T_{12} spinal segments bypass the chain of the paravertebral sympathetic ganglion, without making synapses there and form the greater splanchnic nerve (containing only the preganglionic fibres). It ends in coeliac ganglion and make synapses there. Then, the postganglionic fibres from the coeliac ganglion innervate all the above mentioned visceras forming plexuses over them. Some preganglionic fibres of the splanchnic nerves do not synapse in the coeliac ganglion and innervate the adrenal medulla directly.

The preganglionic fibres arising from the lateral horn cells of the T_{10} to T_{11} segment of the spinal cord may bypass the chain of the paravertebral sympathetic ganglion and form the lesser splanchnic nerve. It ends in the aorticorenal ganglion which is considered as the the lower detached part of the coeliac ganglion. The least splanchnic nerve arises from the lateral horn cells of the 12th thoracic segment of the spinal cord and join the renal plexus. Then it ends in a small ganglia from where the postganglionic sympathetic fibres arise and supply the kidney and the ureter.

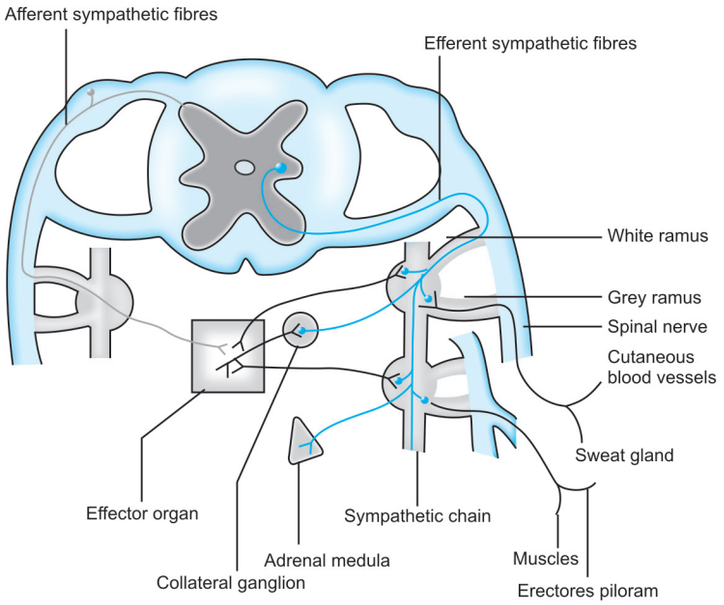

Fig. 11.3: The principles of peripheral distribution of motor and sensory components of sympathetic nervous system. Blue lines are preganglionic sympathetic fibres. Red lines are postganglionic sympathetic fibres. Green lines are sensory sympathetic fibres

The superior mesenteric ganglion innervates the distal colon, and the inferior mesenteric ganglia innervates the rectum, bladder and genitalia.

Terminal Ganglia

They are situated in close relation to the organs which are supplied by them. They are few in number and include ganglia connected with the urinary bladder, rectum and some ganglia in the region of the neck. The adrenal medulla and other chromaffin tissues are homologous to the sympathetic ganglias. This is because all of them are derived embryologically from the neural crest cells. But the adrenal medulla differs from sympathetic ganglia in that the principal catecholamine that is released from adrenal medulla is epinephrine (adrenaline). Whereas, norepinephrine or noradrenaline is the prinicipal catecholamine of other sympathetic ganglion and is also released from the postganglionic sympathetic nerve endings.

The characteristics of sympathetic outflow or efferents are:

i As the sympathetic ganglions are close to the CNS, so the preganglionic fibres are short and postganglionic fibres are long.

ii. The sympathetic efferent distribution is diffuse in character and the response is not confined to the organs supplied by the segments from which they originate. Thus, this allows a more dramatic and widespread response with diffuse discharge from the sympathetic system.

iii. Sympathetic fibres pass through multiple ganglia before it finally synapses with a postganglionic neuron or fibre.

iv. Sympathetic system has an system of amplification. This is because a preganglionic terminal fibre synapses more than twenty postganglionic cells in one ganglion, and thus a large number of postganglionic neurons arise from a single preganglionic neuron. In addition, synaptic innervation overlaps with each other, so that one ganglion cell may be supplied by several preganglionic fibres.

In contrast, the parasympathetic system has its ganglia very near to or within the organs which are innervated by them. Thus, the parasympathetic distribution is much more localised, limited and circumscribed in its influences. In most organs, the relationship or ratio between the number of preganglionic and postganglionic parasympathetic fibres is 1:2 (i.e. there is localized and least amplification) with exception that the ratio of preganglionic vagal fibres to the postganglionic cells in the Auerbach's plexus has been estimated to be about 1:8000.

The cell bodies of the somatic motor neurons lie in the ventral horn of the grey matter of spinal cord. The axon from this somatic motor neuron passes through the ventral root of the spinal nerve. It then passes through the somatic spinal nerves and reaches the muscles where it divides into many terminal branches and each of which innervates a single muscle fibre. Thus, more than 100 muscle fibres of a muscle may be supplied by one motor neuron to form a motor unit. At each neuromuscular junction the axonal terminals of each nerve fibre loses its myelin sheath and forms a terminal arborization that lies opposite to a specialized surface area on the muscle cell membrane, called the 'motor end plate'. Mitochondria and synaptic vesicles containing neurotransmitters are concentrated at the nerve terminal near the end plate. Through trophic influences of the nerve, the nuclei of a skeletal muscle cell, lying in close proximity to a synapse, acquire the capacity to activate the specific genes which synthesise the synapse-localised specific proteins or receptor proteins. Thus, nicotinic receptors are synthesised at the motor end plate.

PARASYMPATHETIC NERVOUS SYSTEM

Elimination of the parasympathetic nervous system is not incompatible with life. This is because it discharges only localised and discrete functions which are not essential for life. Like the sympathetic system, this system is not concerned with the stress and emergency conditions. It mainly governs those activities of our body which are more associated with the digestive and

genitourinary functions. The function of parasympathetic nervous system is concerned primarily with the conservation of energy and maintenance of organ functions, during the periods of minimal activity. This system reduces the HR and BP, stimulates the G1 movement and secretion, helps in the absorption of nutrients, protects retina from excessive light, and empties the urinary bladder, and rectum, etc. Still, however many parasympathetic responses are protective in nature.

Parasympathetic outflow or efferent (motor) takes place through the cranial (midbrain and medulla) and the sacral nerves only. The cell bodies for the cranial outflow of the parasympathetic nervous system lie in the nuclei of cranial nerves, such as: III (midbrain), VII, IX and X (medulla) cranial nerves. Whereas the cell bodies for sacral outflow of parasympathetic system lie in the lateral horn cells of sacral segment of the spinal cord. Like sympathetic system the presence of peripheral ganglion is also a characteristic feature of the parasympathetic system. But unlike the sympathetic system, the ganglia of parasympathetic system lie in or near the viscera, except the meckel's ganglion which are situated at a distance from the supplying viscera. and the otic ganglion. Hence, the parasympathetic nervous system exerts a more localised action than the sympathetic nervous system.

Parasympathetic Outflow or Efferent

1. Cranial outflow

The cranial outflow of parasympathetic nervous system takes place through four cranial nerves — oculomotor III, facial VII, glossopharyngeal IX and vagus X nerves.

(i) Oculomotor nerve or cranial nerve III

The parasympathetic fibres of oculomotor nerve arise from the cranial part of oculomotor nucleus (Edinger-Westful nucleus). They come out of the cranium through the oculomotor nerve and relay in the ciliary ganglion, from where the postganglionic parasympathetic fibres arise and pass through the short ciliary nerve to supply the ciliary muscles and sphincter pupillae.

(ii) Facial nerve or cranial nerve VII

The parasympathetic portions of facial nerve arise from the dorsal nucleus (superior salivary or lacrimatory nucleus) and pass out in the following two ways:

a. One group of fibres passes through the greater superficial petrosal nerve to the sphenopalatine ganglion (Meckel's ganglion), from where the postganglionic parasympathetic fibres arise and supply the lacrimal glands, plain muscles, blood vessels and glands of the palate and nasopharynx.
b. Another group of fibres passes through the chorda tympani nerve to join the lingual nerve. Then, at the floor of the mouth the fibres separate from the lingual nerve to end in the ganglia, such as; sublingual and submaxillary ganglion, close to the sublingual and submaxillary glands. Postganglionic parasympathetic fibres arise from these ganglia and supply the secretory and vasodilator fibres to these glands. (Afferent taste fibres from the ant 2/3rd of tongue also ends in this dorsal nucleus forming a reflex arc for salivation. Hence, its name is superior salivary nucleus).

(iii) Glossopharyngeal nerve or cranial nerve IX

Preganglionic parasympathetic portion of this nerve arises from the dorsal nucleus (inferior salivery nucleus). Then, it passes along the tympanic nerve and the lesser superficial petrosal nerve to the otic ganglion. Here, the postganglionic parasympathetic fibres arise which pass along the auriculotemporal nerve and supply the secretory and vasodilator fibres to the parotid gland. (Taste fibres from the posterior 1/3 of tongue end in this nucleus and form a reflex arc for salivation. Hence, the name of this nucleus is inferior salivary nucleus).

(iv) Vagus nerve or cranial nerve X

The vagus is the most important parasympathetic nerve. It is widely distributed and carries the parasympathetic fibres practically to every corner of the body. The preganglionic fibres in vagus arise from the dorsal nucleus situated in the medulla and run through this nerve. Then the fibres supplying the individual organs pass out of the vagus trunk separately to end in the ganglia in or near that viscera, from where the post ganglionic parasympathetic fibres arise and supply that viscera, as mentioned below. The vagus nerve in addition, also carries a far greater number of parasympathetic afferent fibres (but apparently no pain fibres) from the viscera to the medulla. The cell bodies of these fibres lie in the nodose ganglion.

a. **Heart:** Preganglionic efferent parasympathetic fibres of the vagus reach the heart near the SA and the AV node. Postganglionic parasympathetic fibres arise from the ganglionic cells near the SA and AV nodes, and supply inhibitory fibres to the junctional tissues, cardiac muscles and the dilator fibres of the coronary vessels.
b. **Lungs:** Vagus supplies the constrictor fibres to the bronchial muscles.
c. **GI tract:** Vagus supplies the GI tract from the oesophagus to the caecum. Preganglionic parasympathetic vagal fibres reach the tract at the Auerbach and Meissner's plexuses. Postganglionic parasympathetic fibres arise from the Auerbach's plexus and Meissner's plexus. Fibres from the former plexus supply the muscle coats to stimulate the intestinal movements and to inhibit the sphincters. Fibres from the latter plexus supply the vasodilator and secretomotor fibres to the glands and mucosa.
d. Pancreas: Parasympathetic vagus fibres supply the secretory fibres to the pancreatic alveoli, as well as to the Islets of Langerhans.

e. **Gallbladder:** Action of the vagus on the gall bladder is reverse of the sympathetic fibres.
f. **Liver and kidney:** Parasympathetic vagus has no appreciable effect.

2. Sacral Outflow

The sacral outflow of the parasympathetic nervous system consists of axons that arise from the lateral horn cells of the 2nd, 3rd and 4th sacral segments of the spinal cord. After that, it proceeds as preganglionic fibres through the corresponding anterior roots and the trunk of spinal nerves. Then, they come out of the spinal nerves and unite to form a single nerve, on each side, called the nervi erigentes (preganglionic). After that they relay in the hypogastric ganglia (parasympathetic terminal ganglia) from where the postganglionic parasympathetic fibres arise to supply the urinary bladder, prostate and the whole of the large intestine, except caecum.

Actions of the nerves of the sacral outflow are:

i. Movement of GI tract is stimulated and sphincters are inhibited (reverse of sympathetic).
ii. Also supplies dilator fibres to the blood vessels of external genitalia. This vasodilation is an important factor for causing erection of penis (hence the name nervi erigentes).

3. Spinal Parasympathetic

Posterior spinal nerve roots contain certain parasympathetic fibres, which on stimulation produce vasodilatation. These fibres are said to be parasympathetic due to their action. But, unlike that of the other vasodilator parasympathetic fibres, their actions are not abolished by atropine. These fibres are known as antodormic vasodilator fibres, as their impulses pass out against the general afferent impulses of the posterior nerve roots, and extend up to the posterior root ganglion. Local stimulation by irritants, applied to the skin, produces vasodilatation through these fibres. This is known (Fig 11.4) as the axon reflex. The vasodilatation is produced due to the liberation of ACh at the nerve endings.

CONCLUSION

Though the actions of the sympathetic and the parasympathetic nervous system are antagonistic in nature, but it is not always true. Because, it depends upon: (i) the efficacy of the neurotransmitters, released by either of the system, (ii) the area of innervation and (iii) the relative density of supply of these two nervous systems on a particular area. For example, the sympathetic stimulation markedly enhances the peripheral vascular resistance, but it is not altered appreciably by the activity of the parasympathetic system. The explanation is like that generally most of the vessels involved in the control of blood pressure are innervated only by the sympathetic nerve fibres and these fibres are continuously active. Whereas the parasympathetic nerve fibres which serve the blood vessels are normally restricted to small areas of the body and vasodilatation in these areas does not contribute appreciably to the fall of systemic blood pressure. So, to decrease the blood pressure, it is more significant to paralyse the continuous sympathetic activity, rather than to stimulate the parasympathetic activity (Table 11.3).

The motor or efferent fibres of autonomic nervous system is again traditionally classified into cholinergic and adrenergic nervous systems on the basis of chemical neurotransmitters through which they work. The postganglionic efferent autonomic nerves containing the ACh as their neurotransmitter at their effective site is called the cholinergic nerves and the nerves containing norepinephrine (NE) and epinephrine (EPI) as their neuro transmitter at their effective site is called the adrenergic nerves.

The cholinergic receptors are protein in nature and are situated on the cell membrane. They react with ACh or any other cholinomimetic (like ACh) drugs to cause

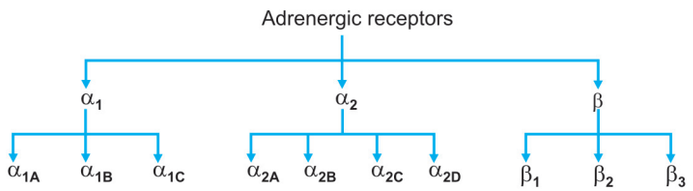

Fig.11.4: Adrenergic receptors

Table 11.3: Cholinergic and adrenergic nerves

The cholinergic nerves include:

1. All the motor nerves that innervate the skeletal muscles.
2. All the postganglionic parasympathetic neurons. So parasympathetic system is also called the cholinergic system.
3. All the preganglionic parasympathetic and sympathetic neurons.
4. Some postganglionic sympathetic neurons supplying the sweat glands and certain blood vessels.
5. Preganglionic sympathetic neurons that arise from the greater splanchnic nerve and innervate directly the adrenal medulla.
6. Some central cholinergic neurons.

The adrenergic nerves include:

1. Postganglionic sympathetic neurons.
2. Some interneurons.
3. Certain central neurons.

the cell to respond. Two types of cholinergic receptors are recognised—muscarinic and nicotinic. The muscarinic receptors are the G-protein coupled receptor in nature (discussed below) and the nicotinic receptors are the ligand or cation channel molecules with gates. (Ligand is an organic molecule that donates the necessary electrons to form the coordinate covalent bonds with metalllic ions. Also, the ligand is an ion or molecule that reacts with another molecule to form a complex).

The cholinergic agonists are agents or drugs that act on the cholinergic receptors like ACh. These drugs are also called the cholinomimetic drugs. The cholinergic antagonists are the agents or drugs that bind with the cholinergic receptors and block the access of ACh or other cholinergic agonist to the ACh-receptors and prevents their actions. These drugs are also called the anticholinergic or cholinergic blocking or cholinolytic drugs.

The adrenergic receptors are also protein in nature and situated on the cell membrane. They react with adrenergic agonists and cause the cell to respond. Adrenergic receptors have been classified into α and β receptors, which are further subclassified into α_1, α_2 and β_1, β_2 receptors. Among all these the α_2 receptors are primarily located on the presynaptic membrane and are inhibitory in nature. The α_1 and β_2 receptors are primarily located on the surface of smooth muscle cells of different organs. The β_1 receptor is primarily located on the cardiac tissue. Drugs mimicking the action of NE are called the sympathomimetic drugs and drugs inhibiting the effects of NE are called the sympatholytic drugs.

Due to the advent of molecular biology, α_1 receptor is again subclassified into α_1A , α_1B , α_1C and α_2 receptor is again subdivided into α_2A , α_2B , α_2C, α_2D and β receptor is subdivided into β_1 , β_2 , β_3 receptor. But, such subclassification is only for scientific analysis and research. The adrenergic drugs currently available for clinical use are still classified as the traditional pattern – α_1 , α_2 and β_1, β_2 agonist or antagoist.

RECEPTORS (FIG. 11.5)

The receptors are macromolecules and protein in nature. However, chemically they may be the nucleic acid in nature. Large number of receptor proteins have been identified, cloned, studied and their primary sequence of amino acids (AA) have also been worked out. Each receptor has two parts—intramembranous and extramembranous and is made up of several non-identical units. Each unit again has polar and no-polar portions. The non-polar portion of the amino acid (AA) sequence of the receptor protein is buried in the cell membrane and the polar portion tends to come out in the aqueous medium on both sides of the cell membrane. The small molecules of agonist or antagonistic agent bind to the outer polar site of the receptor molecule and are capable of tripping the balance of the electrical charges by altering their distribution.

Thus, this tripping of balance of the electrical charge brings out the conformational changes at the inner polar site of receptor, and initiates the binding of the G proteins with the receptor at innerside of the cell membrane. This is the mechanism of action of the G protein coupled receptor such as all the adrenergic receptors and cholinergic muscarinic receptors. On the otherhand, binding of agonist and antagonist or ligand at the outer polar site of some receptors bring about changes in its quarternary structure and the relative aligment of their subunits which results in opening of a centrally located cation channel. This is the mechanism of action of some receptors with intrinsic cation channel such as cholinergic nicotinic receptor. Thus, the receptors subserve two essential functions. These are:

i. Recognition and binding of some specific molecules which are called the ligand or agonist-antagonistic agent at outside on the specific binding domain of the receptor and its activation (receptor).

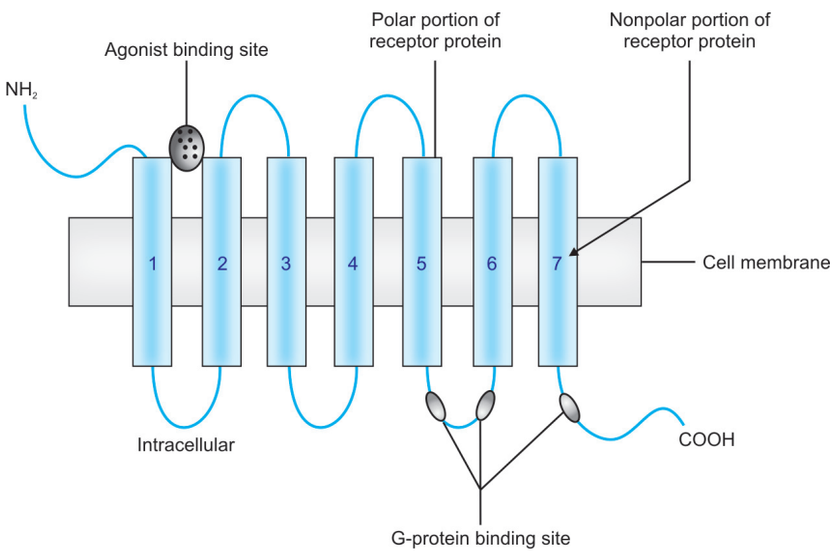

Fig. 11.5: Type of receptor which is coupled with G-protein. Each receptor consists of 7 cylinders, each of which represent a membrane spanning helical segment of amino acids. The cylinders are connected by 3 loops on each side of the membrane. The amino terminus of the receptor lies on the extracellular surface. The carboxy terminus lies on the cytoplasmic side. The approximate location of the agonist and the G-protein binding sites on the receptor are shown in the diagram

Table 11.4: A number of G-proteins have been described. They are distinguished by their α-subunits. The important G-proteins and the effector's chemical through which they act are tabled above. The other G-proteins which are not tabled above are Gn, Gk, G_{13}, Gt, etc.

G-protein	*Effector system or second messanger*
Gs	Adenylyl cyclase ↑, Ca^{2+} channel ↑
Gi	Adenylyl cyclase ↓ , K^+ channel ↑
Go	Ca^{2+} channel ↓
Gq	Phospholipase C ↑

ii. Transduction of the outside signal into the response of cell through a highly complex multi-step process (Table 11.4).

According to the type of receptor activation and its transduction into functional responses within the cell, the responses can be grouped into 5 major categories. These are agonistic, partial agonistic, antagonistic, partial inverse agonistic and inverse agonistic. Receptors falling in one category of function have also been found to possess considerable structural homology and may be considered to belong to one family. According to the mechanism of action, the receptors are broadly classified into two families: the receptors coupled with or acting through the G-protein and the receptors coupled with or acting through the ion channel.

Receptors Coupled with or Act through G-proteins (Table 11.5)

These form a large family of receptors which are situated on the cell membrane. It includes adrenergic receptors (α_1 α_2 β_1 β_2), cholinergic muscarinic receptors (M_1 M_2 M_3), dopamine receptors (D_1 D_2), adenosine rceptors (A_1 A_2), GABA - B receptors, opioid - α , κ , δ receptors and others. They act through one or more GTP-activated proteins for response of the cell. So, they are called the G-protein coupled receptors. All such receptors which act through the G-protein have a common pattern of structural organization. These receptor molecules have 2 to 7 membrane spanning helical structures which are made up of a specific sequence of amino acids and connected with each other by 3 extracellular and 3 intracellular loops. The final amino terminal ($-NH_2$) of the amino acid chain lies on the extracellular surface and the final carboxy terminus (−COOH) of the amino acid chain lies on the cytoplasmic site. The agonist binding site of the receptor is located somewhere between the helics on the external surface. Whereas, the G-protein binding site of receptor is located at the cytosolic segments of the receptor (Fig. 11.6).

Table 11.5: Receptors coupled with or Act through G-proteins

Receptor	*G protein*
β - adrenergic	Gs, Gi , Go , Gn , Gq
Muscarinic	Gi , Gs, Gk
α_2 - adrenergic	Gi , Gs , Gn , Go
GABA - B	Gi , Go , Gk
Dopamine D_2	Gi , Go , G_{13}
5 - HT	Gi , Gq , Gs , Gk , Gt

The G-protein which bind with the intracellular portion of receptor is composed of α, β and γ subunits. A number of G-proteins, distinguished by their α-subunits, also have been described. These are: Gs, Gi, Ge, Gq, etc. Different receptors act through different G-proteins and different G-proteins again next act through different effectors substances or pathways. These effector substances or pathways are called the second messengers (first messengers are agonist and antagonists or ligands) and they produce according to their nature either stimulatory or inhibitory responses in the cell. The effector pathways or second messengers through which the G-proteins act are: adenyl cyclase (AC), phospholipase -C (PLC) and channel regulation protein. This channel regulation protein should not be confused with the ACh receptors (or nicotinic receptor) and Na^+ channel protein, which are actually the receptor with intrinsic ion channel (discussed later) and present at the motor end plates or other sites.

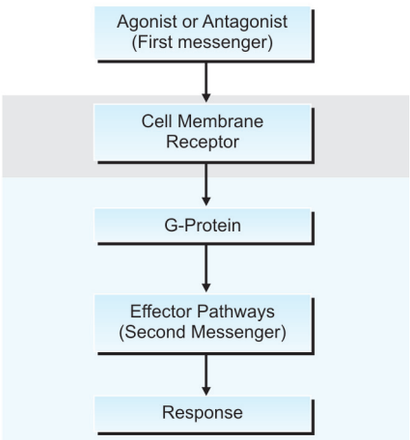

Fig 11.6: Inside the cell

Effector substances (Second messenger)

(i) Adenyl Cyclase (AC)

When an agonist binds with a receptor at the outside of the cell membrane, then the receptor makes a coupling with the G-protein at the inside of the cell membrane, and activates it. Subsequently activated G-protein causes activation of AC (effector pathway)→ it results in intracellular accumulation of cAMP → causes phosphorylation or activation of protein kinase (PK_A) → causes alteration of functions of many enzymes, ion channels, carrier proteins, etc. This is manifested as many cellular functions such as increased contractility, impulse generation, relaxation of smooth muscles, glycogenolysis, lipolysis, hormone synthesis, etc. For example, when epinephrine acts on the β-receptor situated on the cardiac muscle cell membrane, then it activates the Gs protein within the cell which in turn stimulates the adenyl cyclase (AC), a type of effector pathway or second messenger. The reverse occurs when the AC is inhibited by the inhibitory Gi protein (Gi is inhibitory and Gs is stimulatory G-protein), which is activated by the receptor when an antagonist acts on the receptor and stimulates it. As for example, action of acetylcholine (ACh) on muscarinic M2 receptor (located in the myocardial cell membrane) activates an inhibitory G-protein (Gi) inside the cell. Subsequently, the activated inhibitory

G-protein (Gi) opposes the activation of adenyl cyclase (AC) and inhibits the accumulation of cAMP. Thus ACh produces inhibitory responses in the cell. Receptors which act through the G-protein (Gs or Gi) and adenyl cyclase pathways are: adrenergic β (↑), adrenergic α_2 (↓), muscarinic M_2 (↓), dopamine D_1 (↑), dopamine D_2 (↑), adenosine A_2 (↑), adenosine A_1 (↑), etc. (Table 11.6).

(ii) Phospholipase - C (PLC)

Coupling of G-protein (Gs) with the receptor at inside of the cell membrane, after binding of the agonist with the receptor at outside of the cell membrane causes activation of an another effector pathway (second messanger) which is called the phospholipase - C (PLC). This causes hydrolysis of phosphatidyl inositol 4, 5 bisphosphate (P1P2, a membrane phospholipid) → causes generation of inosital triphosphate (IP3) and diacylglycerol (DAG) → results in mobilization of Ca^{2+} from the intracellular depots by IP3 and DAG → activates protein kinase C (PKC) → ↑ Ca^{2+} and activated PKC mediates all the cellular functions i.e. contraction, secretion, transmitter release, neuronal excitibilty etc. Like adenyl cyclase (AC), PLC can also be inhibited by the inhibitory G-protein (Gi) when the opposite responses would be expected. Receptors which act through the G-protein (Gs or Gı) and phospholipase C pathways are adrenergic α_1 and muscarinic M_1, M_3 receptors (Fig. 11.7).

(iii) Channel regulation protein

Coupling of receptors with G-proteins on the inner side of the cell membrane, due to the binding of agonists with receptors on the outside of the cell membrane causes opening or closing of other different ionic channels. These are protein in nature and are specific for Ca^{2+}, K^+, Na^+ ions. These are situated on the cell membrane and cause depolarization or hyperpolarization of the cell membrane. Gs-protein opens Na^+ and Ca^{2+} channels on the myocardial and skeletal muscle cell membrane. So, these are stimulatory in nature. On the otherhand, Gi and Go open the K^+ channels in the heart and smooth muscles and close the neuronal Ca^{2+} channels. Opening of K^+ channel causes hyperploarization of cell. So, these are inhibitory in nature. Closing of Ca^{2+} channel is also inhibitory in nature. Physiological responses like positive or negative inotropic effects, chronotropic effects, transmitter release, smooth muscle relaxation or contraction, etc., also occur through this mechanism (previously mentioned other mechanisms also take part). Examples of these categories of receptors are adrenergic β_1 (Ca^{2+}↑), dopamine D_2 (Ca^{2+}↓), Adrenergic α_2 (K^+↑).

Muscarinic - M_2
Adenosin - A_1

Receptors with Intrinsic Ion Channels

These receptors do not act through the G-protein present within the cell and the second messenger effector system such as AC, PLC, channel regulation protein, etc. But these receptor molecules, present in the cell membrane are composed of 5 subunits (2α + β + γ + δ) and enclose a cylindrical ion channel for the passage of

ions such as Na^+, K^+, Ca^{2+}, Cl^-, etc. All the subunits of this type of receptor generally have four membrane spanning domains and the amino acid (AA) chain traverses the full width of the membrane six times in each domain. The subunits of the receptor are arranged around the centre channel like a rosette and the α-subunit usually bears the agonist and antagonist binding sites.

Normally, these receptors with intrinsic ion channel at the centre remains closed. But when the agonist molecules bind to the α-subunit of the receptor, then all the other subunits move apart, opening the central pore of the channel and allow the passage of partially hydrated Na^+ ion and other cation. Anions are prevented from passing through the channel, because it is lined with positive charges. Receptors such as: nicotinic cholinergic (at motor end plate), GABA-A, glycine, NMDA, 5 HT3, etc. fall in this catagory. In these type of receptors agonists directly operate the ion channels through their binding site situated within the receptor, without the help of a second messenger or coupling with G-protein. The onset and offset of responses through this class of receptors is the fastest than the receptors which act through G protein.

ADRENERGIC RECEPTORS

The chemical structure, classification, subclassification and mechanism of action of different types of adrenergic receptors are already described previously with other receptors. The remaining aspect of individual adrenergic receptors are discussed here.

(i) α_1 Receptor

Location and responses of α_1 receptors are as follows:

i. Arteriole's smooth muscle : Coronary arteries → constriction, Skin and mucosa → constriction, skeletal muscles → constriction, cerebral vessels → constriction, pulmonary vessels → constriction, abdominal viscera → constriction, renal vessels → constriction.
ii. Veins**:** Constriction.
iii. Heart: No α receptors.
iv. Lung: Bronchial smooth muscles - no α receptor
Bronchial gland - decreased secretion
v. Eye: Radial muscle of iris - mydriasis
Lacrimal gland - ↑ secretion
vi. Stomach & intestine : Motility-decrease Sphincter - contraction
vii. Bladder: Detrusor- no α receptor
viii. Ureter: Motility increase
ix. Uterus: Pregnant - contraction
x. Smooth muscle of prostate and bladder neck: Contraction and obstruction.
xi. Male sex organ: Ejaculation
xii. Spleen capsule: Contraction
xiii. Skin-Pilomotor: Contraction
xiv. Sweat gland: Secretion (Table 11.7).

Agonists of α_1 receptor are methoxamine and phenylephrine and its antagonist is prazocin. Prazocin is a selective α_1 antagonist. So, its use in benign prostatic hypertrophy avoids postural hypotension and other deleterious effects that occur with other less specific α_1-antagonists.

(ii) α_2 receptor

The α_2 receptors are found in the CNS, peripheral nervous system and in the variety of other organs which include platelets, liver, pancreas, kidney and the eye etc. The predominant α_2 receptor which is found at the human spinal cord was identified as the α_{2A} subtype.

The α_2 receptors can be presynaptic or postsynaptic, but predominantly they are presynaptic. The presynaptic α_2 receptor may act either as a heteroreceptor or a autoreceptor (An autoreceptor is a presynaptic receptor that reacts with the neurotransmitter which is released from its own presynaptic nerve terminal, providing a feedback regulation. A heteroreceptor is a presynaptic receptor that responds to substances other than the neurotransmitter, released from that specific nerve terminal).

Among the many presynaptic receptors that have been identified, the α_2 receptor is of the greatest clinical importance. Presynaptic α_2 receptor regulates the release of NE and ATP through a negative feedback mechanism from its own presynaptic nerve terminal. Stimulation of α_2 receptor on the presynaptic membrane by the released NE from that nerve terminal inhibits the subsequent release of NE. Clonidine is a prototype of α_2 agonist. Then by stimulating the presynaptic α_2 receptor, it inhibits the release of NE and produces hypotensin. The action of clonidine in relief of pain by stimulation of α_2 receptor is discussed in elsewhere. Highly densed α_2 receptors are found in the cortex and medulla. Stimulation of these α_2 receptors at this level is responsible for the bradycardia and hyotensive action of α_2 agonist. Presynaptic α_2 receptors and cholinergic receptors inhibit the release of NE, whereas the presynpatic β-receptors stimulate the release of NE.

Table 11.7: Differences between α_1 and α_2 receptor

	α_1	α_2
Location	Post junctional	Prejunctional Postjunctional (at few sites)
Function	Vascular smooth muscle - contraction Gut smooth muscle relax Gland - secretion	↓Transmitter release ↓Synaptic outflow Vasoconstriction
Selective agonist	Methoxamine, phenylephrine	Clonidine Dexmedetomidine
Selective antagonist	Prazosin	Yohimbine
Nonselective antagonist	Phentolamine Phenoxybenzamine	Phentolamine Phenoxybenzamine

Location and responses of α_2 receptors at other sites are:

i. Coronary artery — Constriction
ii. Artery of skin and mucosa — Constriction
iii. Renal artery — Constriction
iv. Veins — Constriction
v. Intestine — Decreased motility and secretion

(iii) β receptors

Like the α-receptors, β-receptors are also the member of a superfamily of all the receptor which acts through coupling with G protein. They have seven helics of amino acids which are woven through the cell membrane. These transmembrane domains are labelled by numbers from M1 to M7. Antagonists have the specific binding sites on the receptor, whereas the agonists are more diffusely attached to the hydrophobic membrane spanning domains of it. The extracellular portion of the receptor ends as an amino group. A carboxyl group occupies the intracelular terminus and it is here where the phosphorylation or activation of receptors occurs. At these cytoplasmic domains, interaction of receptor with G-proteins occur. The β-receptors have the structural and functonal similarities with the cholinergic muscarinic and adrenergic α-receptors, but not with the cholinergic nicotinic receptors (Table 11.8).

β-receptors are subdivided into β_1, β_2, β_3 (as already discussed). All of them increase cAMP through activation of the G-protein and adenylate cyclase effector pathway. Traditionally, the β_1 receptors are thought to be concentrated more on the cardiac tissue and β_2 receptors on cardiac, vascular, bronchial and other smooth muscles. This model of distribution of β_1 and β_2 receptor is still useful for the pharmacological manipulation them by the specific drugs. But, the role of β_2 receptors is more important during heart failure than normal cardiac function. The β_2 receptor population in the ventricles and atria are 15% and 30% of the total β receptors, respectively. These β_2 receptors play an important role in compensation during cardiac failure and help to maintain the responses to catecholamine stimulation. β_1 receptors are down-regulated during chronic catecholamine stimulation and CHF. But the β_2 receptor population remains unaffected till the endstage of congestive cardiac failure. In additon to positive inotropic effects, β_2 receptors in human atria participate in the regulation of heart rate. Thus, β_2 agonism may have a significant effect on cardiac contractility and rate.

Location and responses of β_1 and β_2 receptors:

i. *Heart:* SA node (β_1, β_2) - ↑heart rate; Atria (β_1, β_2) -↑contractility, ↑conduction velocity; A.V node (β_1, β_2) - ↑automaticity, ↑conduction velocity. HIS-Purkinje system (β_1, β_2) - ↑automaticity, ↑conduction velocity; Vent-tricles (β_1, β_2) - ↑contractility, ↑conduction velocity, ↑automaticity, ↑ idioventricular pacemaker.
ii. *Arterioles:* Coronary (β_2) - dilatation; skeletal muscle (β_2) - dilatation; Pulmonary (β_2) - dilatation; Abdominal viscera (β_2) - dilatation; Renal (β_1, β_2) - dilatation.
iii. *Veins* (β_2): Dilatation
iv. *Lung, tracheal and bronchial smooth muscle* (β_2): Relaxation
v. *G I* (β_1, β_2): Decreased motility
vi. *Gall bladder* (β_2) : Relaxation
vii. *Detrusor* (β_2): Relaxation
viii. *Uterus* (β_2): Relaxation
ix. *Spleen capsule* (β_2): Relaxation
x. *Skeletal muscle* (β_2): Increased contractility, glucogenolysis.
xi. *Liver* (β_2): Glycogenolysis, gluconeogenesis
xii. *Islet* (β_2): ↑ Secretion
xiii. *Fat cells* (β_2): Inhibition of lipolysis

Table 11.8: Difference between adrenergic β_1 , β_2 , β_3 receptors

	β_1	β_2	β_3
Location	Heart, kidney	Heart, bronchi, blood vessels, uterus, intestine, eye, urinary tract, gall bladder etc.	Adipose tissue
Specific agonist	Dobutamine	Salbutamol, Terbutaline	Under research
Specific antagonist	Metoprolol, Atenolol	Butoxamine, α-methyl propranolol	Under research
NE	Strong action	No or very weak action	Strong action
EPI	Strong action	Strong action	Weak action

(iv) Dopamine Receptor (DA)

Dopamine is an intermediate product during biosynthesis of norepinephrine (NE) and epinephrine (EPI). It acts through five dopamine receptors. Among them DA_1 and DA_2 receptors are the most prominent. Dopamine also acts on α and β receptors.

DA_1 receptors are post-synaptic and are located at renal, mesenteric and vascular smooth muscles. It mediates the vasodilatation response. DA_2 receptors are presynaptic and inhibits the release of NE. DA_2 receptors are also located in the brain, which mediate nausea and vomiting. The antiemetic action of droperidal and metoclopramide acts through these DA_2 receptors.

SUMMARY

After the attachment of adrenergic agonists to the adrenergic receptors, the extracellular signal is transformed into an intracellular signal by coupling of a stimulated α_1, α_2, β_1, β_2 adrenergic receptor with the G-proteins. This signal transformation is known as the signal transduction. Each class of adrenergic receptor couples to a different type of G-protein which in turn is linked to different types of effector pathway or second messengers such as adenyl cyclase (AC), phospholipase C, etc. Thus, α_1 receptor is linked to Gq protein and in turn is linked to activation of

phospholipase C. Contrarily the α_2 receptor is linked to Gi protein and is responsible for the inhibition of adenyl cyclase. β-receptor is linked to Gs protein and in turn is linked to stimulation of adenyl cyclase. ACh receptor is linked to Gi protein and in turn is linked to inhibition of the effector system, named adenyl cyclase.

G-protein has three subunits − α, β and γ. The α-subunit is most variable and determines the type of activity (Table 11.9) of G-proteins. According to the variety of α-subunit, G-protein may be of stimulatory (Gs), inhibitory (Gi) or inactive (Go) and Gq. The α-subunit may split off from the mother molecule of G protein and behave independently, whereas β and γ subunit may remain together. In the resting state, G-protein is attached to guanosine diphosphate (GDP). When the G-protein is activated through the receptor, then it leads to displacement of GDP by GTP. GTP is attached with α-subunit of the activated G-protein. Then G-protein splits up simultaneously into two parts, consisting of α-GTP and the β–γ subunit. The released α-subunit of G-protein with the GTP then binds to the second messenger molecule, such as: the adenyl cyclase and activates it and then converts its attached GTP to GDP. Therefore, GDP returns to its resting state and is detached from the α-subunit of G protein. Then the α-subunit rejoins again with the β-γ subunit and reconstructs the G-protein, waiting at the inner surface of the cell membrane with the receptor for further activation (Fig. 11.8).

Both β_1 and β_2 receptor stimulation by an agonist activates the G-protein which in turn enhances or activates the AC. Activated AC increases the intracellular concentration of cAMP. Thus, increased intracellular cAMP concentration activates the protein kinase, which then further phosphorylates or activates many other other target proteins. Thus, target phosphorylation elicits a variety of cellular responses and complete the path between the receptor and the effector response.

Table 11.9: Responses of effector organs due to to adrenergic and cholinergic nerve impulses

Organ	*Receptor*	*Adrenergic response*	*Cholinergic response*
HEART			
SA node	β_1 , β_2	↑ Heart rate	↓ Heart rate
Atria	β_1 , β_2	↑ Contractility, ↑ conductivity	↓ Contractility / conductivity
AV node	β_1 , β_2	↑Automaticity, ↑ conductivity	↓Conduction - AV block
Purkinje system	β_1 , β_2	↑ Automaticity, ↑ conductivity	Little effect
Ventricle	β_1 , β_2	↑Contractility	Little effect
		↑ Conduction velocity	Little effect
		↑ Automaticity	Little effect
		↑ Idioventricular pacemaker	Little effect
ARTERIOLES			
Coronary	α_1, α_2	Constriction +	Dilatation
	β_2	Dilatation + +	–
Skin and mucosa	α_1, α_2	Constriction + + +	Dilatation
Skeletal muscle	α_1, α_2	Constriction + +	Dilatation
	β_2	Dilatation + +	–
Cerebral	α_1	Constriction +	Dilatation
Pulmonary	α_1	Constriction + +	Dilatation
	β_2	Dilatation +	–
Abdominal viscera	α_1	Constriction + + +	–
	β_2	Dilatation +	No effect
Renal	α_1, α_2	Constriction + + +	–
	β_1, β_2	Dilatation +	No effect
VEIN			
Systemic	α_1, α_2	Constriction + +	No effect
	β_2	Dilatation + +	–
LUNG			
Bronchial muscle	β_2	Relaxation +	Contraction + +
	α_1	↑ Secretion	Secretion + +
Bronchial gland	β_2	↓ Secretion	–
INTESTINE			
Motility / tone	α_1 , α_2 , β_2	Decrease +	Increase + + +
Sphincter	α_1	Contraction +	Relaxation +
Gland secretion	α_2	Decrease +	Increase + + +
Gall bladder and bile duct	β_2	Relaxation	Contraction +
EYE			
Iris (radial muscle)	α_1	contraction	No effect
Iris (sphincter muscle)	–	No effect	Myosis (contraction) + + +
Ciliary muscle	β_2	Relaxation	Contraction for near vision +
Lacrimal gland	α	Secretion +	Secretion + + +
URINARY BLADDER			
Detrusor	β_2	Relaxation	Contraction + + +
Trigone, sphincter	α_1	Contraction ++	Relaxation + +
URETER			
Motility, tone	α_1	Increase	No effect
Uterus	α_1	Contraction	Variable
	β_2	Relaxation	–
Sex organs (male)	α_1	Ejaculation	Erection + + +

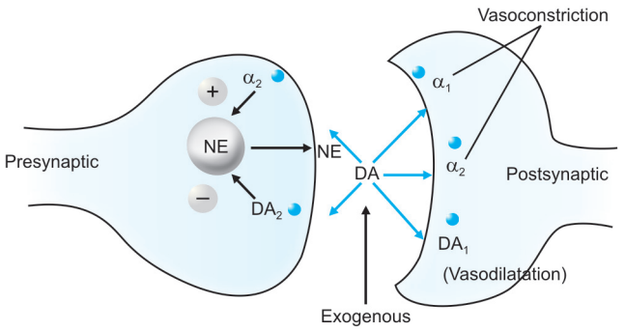

Fig. 11.8: Schematic representation of α_1, α_2 and DA_1 receptors on the postsynaptic membrane and α_2, DA_2 receptor on the presynaptic membrane. When dopamine is administered exogenously, then activation of DA_1 receptor on the postsynaptic membrane causes vasodilatation. While activation of DA2 receptor on the presynaptic membrane causes inhibition of NE release. Large doses of dopamine also activaes α_1 and α_2 receptor on postsynaptic membrane and cause vasoconstriction. It also activares the α_2 receptor on the presynaptic membrane and inhibit the release of NE. NE is released from the presynaptic sympathetic terminal and acts on α_1 and α_2 receptor on the postsynaptic membrane, causing vasoconstriction

G-protein and effectors system (i.e. adenyl cyclase, phospholipase-C, etc.).

The negative inotropic action of halothane and other volatile anaesthetic agents is mediated through the inhibitory G-protein (Gi) and ↓ cAMP concentration. Other possible mechanisms of negative inotropic effects of halothane are: attenuation of the release of neurotransmitter from the peripheral sympathetic neuron, blockage of calcium channel in the heart and thus alteration of the calcium fluxes from sarcoplasmic reticulum and reduction of the cardiac contraction. Hence, it proves that the negative inotropic effect of inhalational anaesthetics occurs at several sites.

Stimulation of α_1 receptor results in inhibition of the adenyl cyclase and this inhibition is mediated by the Gi protein (Fig. 11.9).

Actually, the α_1 receptor acts through the G-protein but activates phospholipase C in the inner surface of the cell membrane. Activated phospholipase C, then, increases the hydrolysis of phospho-inosotol diphosphate (P1P2) to triphosphate and diacylglycerol (DAG). These two compounds, then, mobilize the intracellular calcium stores from the sarcoplasmic reticulum and causes in marked increase in intracellular calcium ion concentration. This calcium then binds to calmodulin (calcium sensitive intracellular protein) which subsequently activates the myosin light chain kinase. This myosin light chain kinase then phosphorylates the myosin light chain and facilitates the interaction between the actin and myosin, resulting in muscular contraction. In other cells, calmodulin stimulates other kinases resulting in other cellular effects.

The myocardial cells respond according to the receptors and the agonist or antagonist(the first messenger) i.e NE, EPI, dopamine, ACh, etc which act on the receptor (Table 11.10). The two opposing effects, i.e. inhibition or stimulation depends on the type of the receptor,

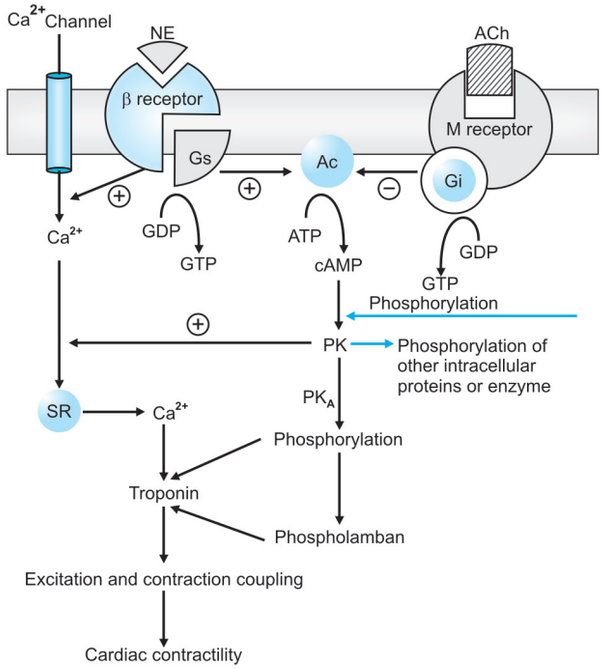

Fig. 11.9: NE binds to β-adrenergic receptors on the outer surface of the cell membrane and induces some conformational changes within the receptor. This permits attachment of the receptor with Gs protein (stimulatory G-protein) and activation of it. Now, the activated Gs protein binds with GTP and its active subunit is dissociated. Activated Gs now activates the enzyme AC (adenylyl cyclase), located on the cytoplasmic side of the membrane. Then, activated AC hydrolyses ATP to cAMP. Now, cAMP phosphorylates and activates the protein kinase (PK_A). The activated PK_A then phosphorylates many functional proteins including troponin and phospholamban. Phospholamban and troponin interact with Ca^{2+}, resulting in increased force of contraction. Intracellular Ca^{2+} is made available by direct entry from outside as well as from the intracellular stores. Direct entry of Ca^{2+} from outside is through Ca^{2+} channel situated on the cell membrane, which is again facilitated by Gs protein and phosphorylation of PK. Action of ACh on the muscarinic receptor (M) activates the inhibitory G-protein (Gi), which opposes the activation of AC by Gs protein

Table 11.10: The difference of adrenergic responses mediated through α and β receptor

	α-actions		*β-actions*
1.	Constriction of arterioles and veins→ rise in BP (α_1 and α_2 action, α_1 action predominates)	1.	Dilatation of arterioles and veins → fall of BP (β_2 action)
2.	Little action on heart	2.	Cardiac stimulation (β_1 and β_2, but β_1 action predominates → cause ↑heart rate, ↑force of contraction and ↑conduction velocity.
3.	On bronchous – no α action	3.	Bronchodilatation (β_2)
4.	Contraction of radial muscle of iris→ mydriasis (α_1 action)	4.	No effect on iris and ciliary muscle
5.	Decreased aqueous secretion	5.	Enhanced aqueous secretion
6.	Intestinal relaxation (α_1 , α_2) contraction of sphincters (α_1)	6.	Intestinal relaxation (β_2 action)
7.	Bladder trigone – contraction (α_1) and sphincter spasm	7.	Detrusor – relaxation (β_2)
8.	Uterous – contraction (α_1)	8.	Uterous – relaxation (β_2)
9.	Insulin secretion – inhibited (α_2)	9.	Insulin secretion - increased (mild) Glucagon secretion – increased (β_2)
10.	Liver – no action	10.	Liver → glycogenolysis (β_2) → hyperglycaemia Muscle → glycogenolysis (β_2) → hyperlactacidemia Fat → lipolysis (β_2) → increased FFA
11.	Male sex organs – ejaculation	11.	Sex organ → no action
12.	Smooth muscle of prostate and bladder neck → contraction with obstruction (α_1)	12.	No effect

UP AND DOWN REGULATION OF β-RECEPTORS

The number of postsynaptic β-adrenergic receptors are not fixed at the site of action. However, the number of receptors change continuously and significantly, matching with the amount of adrenergic agonists and antagonists which are releases in the synaptic cleft. It is found that 30 minutes after denervation or blockade by an antagonist, there is an increased number of receptors. This is called the 'up-regulation' and is the explanation for the sudden rebound phenomenon of tachycardia, ischaemia and increased incidence of MI, after sudden discontinuation of β-blocker, e.g. atenolol, propranolol, metoprolol, etc.

Reversely, if the receptors are continuously or tonically exposed to an agonist, then the responses wane rapidly, despite continuous exposure to adrenergic agonists. This is due to the reduction of number of receptors or the reduction of sensitivity of the receptors to agonists. This phenomenon is called the 'desensitization'. There are three underlying mechanism for desensitization: uncoupling (phosphorylation), sequestration and down regulation.

Uncoupling

It is found that when an agonist continuously binds with a receptor, then it promotes the phosphorylation of the receptor's serine residues near the intracellular carboxy terminus of it. This allows it to bind with a protein, called β-arrestine, which hinders its (receptor) interaction with the Gs protein or coupling, causing desensitization by blocking the signal transduction.

Sequestration

This is a well described, but poorly understood process. It does not apear to be related to the phosphorylation. It is reversible if the agonist stimulaton ceases, with the receptor being returned to the cell surface.

Down-Regulation

It is just opposite to the up regulation. Here, destruction of the receptor is increased or synthesis of the receptor is decreased due to continuous exposure of the receptor to an agonist. It is a slow process than uncoupling and sequestration, and refractoriness develops over weeks and months and receeds slowly. CHF is the most important example of down regulation.

Another example of up-and down-regulation of β-adrenergic receptors is the disease of thyroid gland. The activity of thyroid gland influences the receptor density, with hyperthyroidism decreasing the density and hypothyroidism increasing the density.

CHOLINERGIC RECEPTORS

The receptors on which ACh or agents whose actions are like ACh act are called the cholinergic receptors and these agents are called the cholinergic agonists. There are two types of cholinergic receptors—muscarinic and nicotinic.

ACh has no specificity for these two types of cholinergic receptors, but these two types of receptors structurally and functionally are of distinct classes and have significantly different responses to ACh. Lately, specific agonist to the individual cholinergic receptor has emerged with a definite structure—activity relationship. Chemically, all the cholinergic agonists are of quarternary ammonium compound and have an atom which is capable of forming a hydrogen bond with the

cholinergic receptor through an unshared pair of electrons. The distance between the two (i.e. the ammonium group and the atom) determines whether the agonism is muscarinic or nicotinic. When the distance is 4.4 Å then the agonist has muscarinic action and when the distance is 5.9 Å then the agonist has nicotinic action.

(i) Muscarinic Cholinergic Receptors

These receptors belong to the superfamily of G-protein coupled receptors. Therefore, it also consists of 7 helical membrane spanning hydrophobic amino acid segments, where aminoterminus ($-NH_2$) lies outside the cell and carboxy terminus (−COOH) lies inside the cell. They have a greater similarity or homology to the α and β-adrenergic receptors than to the nicotinic cholinergic receptors. These cholinergic receptors are selectively stimulated by a chemical substance named muscarine. So, they are called as the muscarinic receptors. It can be blocked by atropine. These muscarinic receptors are located in many visceral organs, such as: heart, blood vessels, eye, smooth muscles, glands, CNS, ganglion, etc.

These muscarinic receptors are also present on the presynaptic membrane of post ganglionic cholinergic nerve endings. Activation of these presynaptic muscarinic receptor inhibits the further release of ACh. This is also one of the mechanism of action of α_2-adrenergic agonist which acts on the prejunctional cholinergic receptors to decrease ACh release with some clinical relevance. Similar one also have been demonstrated on adrenergic terminals, activation of which inhibits the NA release. All the blood vessels have muscarinic receptors located on the endothelial cells, though most of them lack cholinergic innervation. Activation of these endothelial muscarinic receptors release EDRF (endothelium derived relaxing factor) which diffuses in the smooth muscle and cause relaxation with vascular dilatation.

Muscarinic receptors have been divided into 5 subtypes and named as M1 to M5 on the basis of their primary structural variability which includes a huge cytoplasmic loop situated between the fifth and sixth membrane spanning domains. Out of these, the first three receptors (M1, M2, M3) have been clearly functionally defined, while the responses indicated through M4 and M5 receptor subtypes are not well defined. Most organs have more than one subtype of receptor, but usually one subtype predominates in a given tissue. The M1 receptors are primarily a neuronal receptor, located on the ganglion cells and central neurons; specially in the cortex, hippocampus and corpus striatum (though all subtypes of muscarinic receptors are present in the CNS). It also plays a major role in mediating gastric secretion and relaxation of lower oesophageal sphincter on vagal stimulation. Cardiac muscarinic receptors are predomintly of M2 subtype, while smooth muscle and glandular ones are of M3 subtype. Therefore, M2 and M3 subtype receptors together mediate most of the well recognised muscarinic actions.

As described previously, the muscarinic receptors are the G-protein coupled receptors. The M1 and M3 (and probably M5) subtypes function through the Gq/11 type of G protein and activate the membrane bound phospholipase C (second messenger), generating inositol triphosphate (IP3) and diacylglycerol (DAG). Actually, stimulation of phospholipase C causes the immediate hydrolysis of phosphotidylinositol polyphosphates, which are the components of the plasma membrane, and form inositol triphosphates. This in turn releases the Ca^{2+} intracellularly from the ER, and causes the contraction of (Table 11.11) smooth muscle of GI tract and glandular secretion. The M2 (and probably M4) receptor subtype functions through the Gi and Go type of G protein. It inhibits the membrane bound AC (adenyl cyclase) which in turn opens the K^+ channels, causing hyperpolarization and suppression of the activity of voltage gated Ca^{2+} channels. Thus it causes reduced pacemker activity of SA node, slowing of the conduction and decreasing of the force of contraction of heart.

The responses of the muscarinic receptor to its agonists and antagonists are slower. They may be excitatory or inhibitory. However, they are not necessarily linked to the changes in ion permeability, like nicotinic receptor.

(ii) Nicotinic Cholinergic Receptors

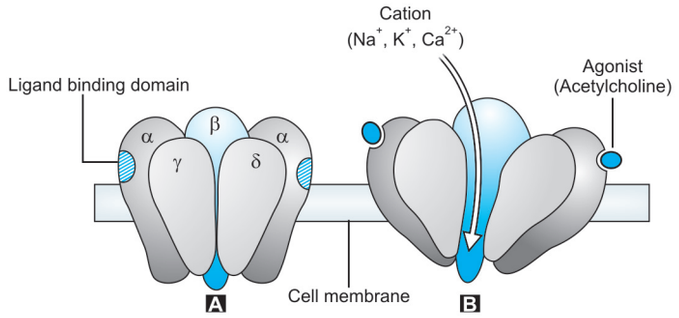
These receptors belong to the superfamily of ion gated channel (i.e. ion channel

Table 11.11: Site of cholinergic transmission and type of receptors involved

Site	***Type of receptor***	***Specific agonist***	***Specific antagonist***
All postganglionic parasympathetic nerve endings	Muscarinic	Muscarine	Atropine
Inside the ganglia (both sympathetic and parasympathetic)	Nicotinic (N_n)	Nicotine DMPP (selective)	Hexamethonium
Few postganglionic sympathetic (sweat gland, some blood vessels, nerve endings)	Muscarinic	Muscarine	Atropine
Adrenal medulla	Nicotinic (N_n)	Nicotine DMPP (selective)	Hexamethonium
Skeletal muscle : motor endplate	Nicotinic (N_n)	Nicotine PTMA (selective)	Curare
CNS (cortex, basal ganglia, spinal cord, other sites)	Both muscarinic and nicotinic	Muscarine Nicotine	Atropine Curare

DMPP = Dimethyl phenyl piperazinium, PTMA = Phenyl trimethyl ammonium ACH is agonist to both muscarinic and nicotinic receptors

through the receptor with gates) and are selectively activated by nicotin. So, they are called the nicotinic receptors. Nicotinic receptors are located only at the motor endplates in the neuromuscular junctions and in the peripheral autonomic ganglion. Those which are located in the motor endplates can be blocked selectively by tubocurarine, decamethonium (ten carbon atom structure) or other nondepolarizing muscle relaxant. But, those which are located at the autonomic ganglion can be blocked selectively by hexamethonium (six carbon atom structure), which has no effect at the motor endplates (Figs 11.10A and B).



Figs 11.10A and B: This is a schematic representation of a receptor with an intrinsic ion channel. An example of this type of receptor is the nicotinic receptor.
A. shows a closed nicotinic cholinergic receptor. This molecule is composed of 5 subunits such as: 2α , β, γ and δ subunits, enclosing a cylindrical ion channel.
B. shows, when two molecules of ACh bind to the two α-subunits of a nicotinic receptor, then, all the subunits of the receptor move apart.This opens the central pore of the receptor and allows the passage of cation. Anions are blocked from passing through the channel by the positive charges lining it. In other cases K^+, Ca^{2+} ions move through the channel, depending on its ion selectivity

The nicotinic receptors or ion gated channels are pentameric membrane proteins in structure, which form the passage for non-selective cations among these the most important cation is Na^+. There are two α-subunits and one each of β, ε and δ subunit in each nicotinic receptor. The α-subunit represents the binding site for both agonists (ACh, nicotin, etc.) and antagonists (curarins and decamethonium). At birth, γ subunit occupies the position of ε (epsilon) subunit, which is normally present in an adult receptor. But, within the first two weeks of life, this γ subunit is replaced by ε subunit. This change in subunit converts the receptor from one, with low conductance and a relatively long duration of opening of channel to a receptor with a high conductance but a brief duration of opening of channel.

Therefore, there are important structural and functional differences of nicotinic receptors during their developments in life. But, it is important to mention that the important drug binding subunit or α-subunit remains constantly present in the receptor throughout the life. Again, there are eight subtypes of the α-subunit which are named as α_2-α_9 and three subtypes of the β-subunit which are named as β_2-β_4. Although, not all the combinations of α and β subunits are functional, but the number of permutations and combinations of these subtypes of α and β subunit that yield (Fig. 11.11). many functional receptors is sufficiently large to produce a pharmacological variation and classifications of all these receptor subtypes. On the basis of location and selective action of agonist and antagonist, two subtypes of nicotinic receptor such as N_M and N_N (previously labelled as N_1 and N_2) are also recognised. N_m receptors are present at the skeletal muscle's endplates and mediate the skeletal muscle contraction. Whereas the N_N receptors are present at the autonomic ganglion (sympathetic and parasympathetic), adrenal medulla (embryologically derived from the same site as ganglionic cells), spinal cord and certain areas of the brain. The difference between the N_M and N_N receptor is that the pentamer of N_N receptor consists only of α and β subunits and constitutes the primary pathway for transmission in a ganglion.

These 5 subunits (2α, β, ε, δ) of a nicotinic receptor surround a channel through which the cations like Na^+ and Ca^{2+} may enter or K^+ may exit the cell. So, it is called the ion channel. For the channel to open, both the α-subunit should be occupied by agonists, such as ACh. Occupation of one α-subunit by ACh will not open the channel. Thus, if one α-subunit is occupied by ACh and the other is empty, then the channel remains closed with no flow of ions, no change in electrical potential and no muscular contraction. On the otherhand if one site is occupied by ACh and another site by an antagonist, such as: pancuronium, then the channel will also remain closed and no contraction of muscle. Similarly, if both sites are occupied by pancuronium the channel also remains closed. From this discussion it is clear that for the action of agonist (ACh) two molecules are needed which bind with the two α-subunit of nicotinic receptor. But for the action of antagonist (nondepolarising muscle relaxant) only one molecule is sufficient which bind with one α-subsunit of nicotinic receptor.

The response of nicotinic or ion-channel receptor to ACh is instantaneous, but usually lasts for few miliseconds only. This

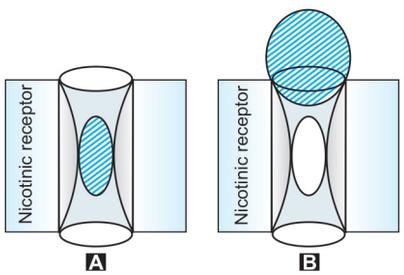


Fig. 11.11: A→Open channel block, B→Closed channel block

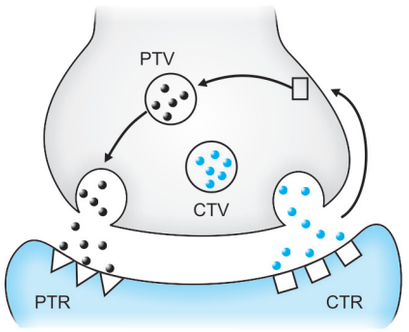
is because ACh is rapidly destroyed by true acetylcholinesterase present in the synaptic cleft. This ultrashort acting response of a nicotinic N_M receptor to ACh gives the motor endplate a greater flexibility to neural stimulation. This contributes profoundly not only to the viability of an organism or animal, but also to its ability to control its own body movements precisely.

In addition to the binding of α-subunit by ACh or its antagonist, there are another two types of channel block—open and closed. With open-channel block (first type), a drug enters the channel, after it is opened by ACh. But, the drug molecule cannot travel all the way through the channel. Entering the opened channel the drug molecule temporarily binds at some point within the wall of the channel. Thus, it blocks the ionic flow through the channel and prevents depolarization and muscular contraction. So, intensity of this type of neuromuscular block depends upon (Table 11.12) the degree of previous opening of the channel and the total activity of the system. Thus, this open type of channel block of nicotinic receptor is termed as 'use dependent'. This type of open channel block is driven by the difference of electrical potential across the membrane, and the charge which is inherent to the molecular structure of the drug, responsible for the block. So, the duration of this type of open channel block is partially dependent on the identity of the drug molecule. In closed-channel block (second type), the drug molecule stay at the mouth of the already closed channel and block it and thus prevents ion flow. Channel opening is not required and this type of block is, therefore, not use dependent. As this type of closed channel block is not due to drugs binding at the ACh binding site by competitive antagonism, so the classic agents that inhibit cholinesterase are ineffective to prevent this type of block and fell to initiate the contraction of muscle (Fig. 11.12).

In the motor endplate or on the postsynaptic membrane of the ganglia, the nicotinic receptors are present only opposite to the presynaptic area and are absent on the rest of the muscle cell membrane. The usual density of nicotinic receptors at a motor end plate is 10000/sq μm and is the centre of accomplishing successful neuromuscular transmission. A number of intracellular (utrophin, syntrophin) and extracellular (agrin, laminin, dystroglycan) proteins have been identified, those direct and help in the formation of the nicotinic receptors in the motor endplate and on the postsynaptic membrane in the ganglia within hours of the presynaptic terminals reaching the myocyte (muscle cell) or the postsynaptic neurons during the development of motor endplate or ganglion in intrauterine life. Only the postsynaptic areas of the cell membrane is depolarised by ACh and generates an action potential which next spreads along the whole cell membrane of myocyte from the synaptic point, resulting in the contraction of muscles or transmission of the impulses by the neurons through ganglion.

The action of ACh on the nicotinic receptor can be prolonged by its repeated doses, or by anticholinesterase, or by long acting cholinomimetic agents, such as succinylcholine. In such circumstances, the initial depolarisation and propagation of impulse along the cell membrane of a muscle fibre, which is seen as fasciculation, is quickly followed by a blockade of transmission and muscular relaxation. This clinical effect is due to the Na^+ channels which are present on the cell membrane of the myocyte just around the postsynaptic or motor endplate area. In normal circumstances, after the first impulse of



PTR : Primary transmitter receptor,
PTV : Primary transmitter vesicle,
CTR : Cotransmitter receptor,
CTV : Cotransmitter vesicle

Fig.11.12: This is a schematic diagram of transmission by cotransmitter. Cotransmitter is stored in the prejunctional nerve terminal like the primary transmitter, but in a separate vesicle. Sometimes, the cotransmitter is stored in the same vesicle with the primary transmitter. Nerve impulses coming to the nerve terminal release both the transmitters at the same time, but from the separate vescicles specific for each or from the same vesicle containing both. After release, acting on the cotransmitter receptor, the cotransmitter modifies the responsiveness or the effects of primary transmitter. Sometimes it even substitutes it. Cotransmitter may also act on the prejunctional receptors and modulate the release of the primary transmitter

Table 11.12: Differences of subtypes of nicotinic receptors

	NM nicotinic receptor	*NN nicotinic receptor*
Location and function	Neuromuscular junction → contraction of muscle	Autonomic ganglia → Transmission of impulse through ganglia. Adrenal medulla → Release of catecholamines, CNS → site specific excitation and inhibition
Nature	Has intrinsic ion channel, Pentamer of 2α , β , δ and ε or γ subunits	Has intrinsic ion channel Pentamer of only α and β subunits
Transducer mechanism	Passage of cation (Na^+ , K^+)	Passage of cation (Na^+, K^+, Ca^{2+})
Agonist	Nicotine	Nicotine
Antagonist	Tubocurarine and other muscle relaxants	Trimethaphan and hexamethonium.

depolarisation these Na^+ channel at the perisynaptic area gets time for rest During this rest period they become repolarized and become ready to transmit the next impulse for next muscular contraction. But, when ACh is used repeatedly or its concentration is increased at the motor endplate by anticholinesterases or when succinylcholine is used, whose action is much longer than ACh, then the perisynaptic Na^+ channels remain continuously in depolarised state and do not get time for recovery or repolarization before further transmission of impulse. Thus, it block the subsequent transmission of impulses which are continuously generated at the motor endplate by succinylcholine or anticholinesterase or repeated doses of ACh and produce molecular paralysis. This is discussed more elaborately in chapter 7.

TRANSMISSION OF IMPULSES

New Concept

For many years ACh, dopamine NE GABA, histamine, etc. were considered as the only neurotransmitters for transmission of impulses. But, recently many other compounds have also been identified as neurotransmitters. They are: purines (ATP, adenosine); peptides (vasoactive intestinal peptide or VIP, neuropeptide - Y or NPY; substance-P or SP, enkephalins, somatostatin etc.); 5-HT, calcitonin gene related peptide (CGRP) and many other small molecules such as NO, etc. Furthermore, a peculiar non-adrenergic and noncholinergic transmission has also been demonstrated in the autonomic innervation of gut, vas deferens, urinary tract, salivary glands and certain blood vessels where nerve stimulation is able to evoke responses, even in the presence of total adrenergic and cholinergic blockade (Fact file-I).

Before the recognition of the newer transmitters, 'one neurone - one transmitter' model was the accepted theory. But it has now become apparent that this classical model was an over-simplification. Many peripheral and central neurons have been shown now to release more than one active substance when stimulated, i.e. more than one neurotransmitter may be co-localised in the same nerve terminal and synaptic transmission may be mediated by the release of more than one neurotransmitter.

The most common combination of neurotransmitters in nerves are NE, ATP and NPY in the sympathetic nervous system and ACh, VIP in the parasympathetic nervous system and SP, CGRP, ATP in the sensorimotor nerves. These newer transmitters are called the co-transmitters and the transmission caused by them is called the co-transmission. The co-transmitter is stored in the same neuron, but in distinct synaptic vesicles and at distinct locations. On being released by the presynaptic nerve impulse, these cotransmitter may serve to regulate the presynaptic release of the primary neurotransmitter and / or postsynaptic sensitivity to it (neuromodulator role). The co-transmitter may also serve as an alternative transmitter in its own right.

FACT FILE - I

The diameter of each vesicle or quanta is 300 µm and each vesicle contains 10,000 molecules of ACh (the range of which varies from 1000 to over 50,000 per vesicles). The difference between the central cholinergic transmission and the cholinergic transmission in the neuromuscular junction is that very few vesicles are present in the presynaptic terminal in CNS and these vesicles look clear under the electron microscope.

Release of contents of one vesicle causes opening or stimulation of 2000 receptors situated on the postsynaptic membrane and produce a miniature potential of 0.5 mV. Upon activation of the receptor by ACh, its intrinsic channel opens for about 1 millisecond. During this brief period of interval, about 50,000 Na+ ions traverse the channel through this opened receptor. Thus, each channel that is opened results in depolarization of 0.00022 mV. When impulses arrive at the presynaptic nerve terminal, then 100 to 300 vesicles or quantas release their contents and bring about changes in the normal resting membrane potential of the post synaptic membrane above the threshold level. This is called the excitatory post synaptic potential (EPSP) which is about +50 to +100 mV.

In case of many, but not all there is evidence that NE and ATP act as co-transmitters. Being released by the same nerve, they act on α_1-adrenoreceptors and P_2-purinoreceptors respectively to produce vasoconstriction. The first component of contraction appear to be mediated by the voltage dependent P_2 calcium channels and ATP, while the sustained later part of the contraction is mediated by NE through the receptor, operated by α_1 calcium channels.

Neuromodulation also modify the process of neurotransmission. Such neuromodulators may be the circulating neurohormones, local agents or neurotransmitter substances, which are released from the same nerve or form other nerves nearby. Neuromodulation can occur either prejunctionally by decreasing or increasing the release of the amount of neurotransmitter from presynaptic membrane or post-junctionally by altering the effect of neurotransmitter on postsynaptic membrane. In all the known examples where both pre-and postjunctional neuromodulation occur, they act in concert, either to alternate or augment the effective transmission.

Examples

NPY neurotransmitter is localised with NE and ATP transmitters at nerve endings. After release, it acts as a neuromodulator – prejunctionally it inhibits the release of NE from the nerve terminal and postjunctionally it enhances the action of NE. In spleen, skeletal muscles, cerebral vessels, coronary vasculature etc, NPY has direct vasoconstrictive actions. In heart and brain, NPY is used by the local intrinsic neuron as the principal transmitter to cause vasoconstriction. Actually, the release of the type of neurotransmitter depends on the frequency of stimulation or nerve impulse.

ACh and VIP neurotransmitters coexist in the parasympathetic nerve endings of many organs. They are stored in separate vesicles and are released differently at different stimulation frequencies. They both

modulate transmission by acting on pre and post-junctional site.

Steps of Transmission

Before discussion of this part of the chapter, we will have to define two terms : conduction of impulse and transmission of impulse. The term 'conduction' is defined as the passage of an impulse along an axon to the synapse. And the term 'transmission' is defined as the passage of an impulse across a synaptic junction, between an axon and a muscle fibre or between two axons. Thus, the term transmission includes the release of transmitter and the action of transmitter on the postjunctional membrane.

Conduction of impulse to synapse

At the resting state of a cell, the transmembrane or resting membrane potential (RMP) varies between –70 mV to –90 mV. This is due to the high negativity inside of the cell and high positivity outside of the cell. It is established and maintained by the high intracellular concentration and high cell membrane permeability of K^+ ion, coupled with low permeability and active extrusion of Na^+ ion from inside of the cell in exchange of K^+ which enter the cell by the Na^+- K^+ ATPase pump. On arrival of an electrical impulse or stimulus the voltage sensitive Na^+-channel on the cell membrane is activated and the channel is opened. Thus, there is a sudden increase in conductance of Na^+ into the cell through the cell membrane and a positive overshoot of the transmembrane potential, resulting in depolarization to occur. Therefore, inside of the cell becomes 20 mV positive or + 20 mV and outside of the cell becomes negative which are opposite to the resting state of the cell. After this depolarization, rapid inactivation of the Na^+ channel and opening of the K^+ channel occurs. This permits K^+ ions to move out of the cell and thus repolarization occurs. This means inside of the cell again becomes −ve like the resting membrane potential (with the extrusions of K^+), which had become +ve due to the entry of Na^+ during depolarization. Then, after repolarization in the refractory period, ionic distribution which is now reversed by Na^+ remaining inside the cell and K^+ remaining outside of the cell is normalised by the activation of Na^+-K^+ ATPase pump, involving an adenosine triphosphatase (ATPase). This Na^+-K^+ ATPase pump is activated by Na^+ at the inner and by K^+ at the outer surface of the membrane. Now Na^+ goes out and K^+ comes into the cell. Thus the action potential (AP), which is generated by depolarization and repolarization sets up a local circuit of current and activates the ionic channels at the next excitable part of the axonal cell membrane or next node of Ranvier in a myelinated fibre and is propagated without any decrement. Although not important in axonal conduction, but Ca^{2+} channels in other tissues (e.g heart) also contribute to the action potential by prolonging the depolarization by its inward movement. This influx of Ca^{2+} also serves as a stimulus to initiate the other multiple intracellular events, such as: muscular contraction, secretion, etc.

Release of transmitter

Different neurotransmitters such as excitatory or inhibitory are stored at the presynaptic nerve endings in different synaptic vesicles. The non-peptide neurotransmitters (ACh, NE, etc) are largely synthesized at the terminal regions of the axons and is stored there in multiple synaptic vesicles. Peptide neurotransmitters (SP, ATP, NPY, etc) are found in large dense core vesicles which are transported down the axon from their site of synthesis in the cell body. After their formation, the vesicles are clustered at nerve terminals in some particular discrete areas underlying the presynaptic plasma membrane, termed the 'active zone'. These active zones often are aligned with the tips of the postsynaptic fold. After the impulse reaches the nerve endings, the vesicles move and fuse with the presynaptic axonal membrane. Then all the contents of the vesicles are extruded into the synaptic cleft. This fusion and fluidization of the vesicular and axonal cell membrane is promoted by the impulse itself and by the entry of Ca^{2+} ion into the nerve ending. A number of proteins like synaptotagmin, synaptobrevin, neurexin, syntaxin, etc, are also located on the vesicular and axonal membranes which participate in this fusion and fluidisation of the vesicular and axonal membrane, resulting in extrusion of tranmitters. This is called exocystosis.

This exocystosis or the release of neurotransmitters in the synaptic cleft is also modulated by the neurotransmitter itself or some cotransmitter, through the activation of some specific receptors located on the prejunctional membrane. For example, the release of NE is inhibited by NE itself and by some other cotransmitter such as dopamine, adenosine, etc, acting on the presynaptic α_2 receptors and dopamine receptor, respectively. While isoprenaline acting on the presynaptic β_2 receptor increases the NE release. Similarly α_2 and muscarinic receptor agonists acting on the presynaptic and other α_2 and muscarinic receptors inhibit the release of ACh at the autonomic neuroeffector site, but not in the ganglia and the skeletal muscles. Stimulation of the presynaptic nicotinic receptors also enhance the release of nerve transmitters in the motor neurons. Adenosine, dopamine, glutamate, GABA, PGS (prostaglandins), enkephalins, etc, have also been shown to influence the release of various neurotransmitters.

Action of transmitters on postjunctional membrane

The released neurotransmitter diffuses across the synaptic cleft and combines with the specific receptors on the postjunctional membrane. Depending on its nature, the neurotransmitters induce an excitatory postsynaptic potential (EPSP) or an inhibitory postsynaptic potential (IPSP).

a. EPSP

In this type of action potential (AP) there is an increase in the permeability of Na^+ ions and occasionally Ca^{2+} ions inside the

cell, causing depolarisation which is followed by efflux of K^+, causing repolarisation. This results in excitatory AP and propagation of impulse.

b. IPSP

In this type of action potential, there is no increase in the permeability of Na+, but there is only an increase in the permeability of smaller ions such as K^+ and Cl^-. So that K^+ moves out and Cl^- moves into the cell, resulting in hyperpolariston of the cell. The normal electrical potential difference across the cell membrane is called the polarized state of the cell where inside of the cell is negative and outside of the cell is positive. Hyperpolarisation means inside of the cell becomes more negative, which is normally present during the resting condition of a cell. This is called IPSP. The changes in some special channel permeability that cause this type of potential change i.e. hyperpolarisation are specifically regulated by some specialised postjunctional receptors and some specific neurotransmitters acting on it. The ligand-gated protein channels which belong to a large superfamily usually include the nicotonic receptor, glutamate receptor, certain serotonin ($5\text{-}HT_3$) receptor purine receptors, etc. They conduct primarily the Na^+ permeability and cause depolarisation. So, they are excitatory in nature. On the otherhand, the GABA and glycine receptors which conduct Cl^- permiability cause hyperpolarisation and are inhibitory in nature.

Without any impulse in the resting state, there is continuous and spontaneous slow release of some isolated quanta of transmitters at the synaptic cleft. This produces a minimal electrical response or action potential below the threshold level at the post-junctional membrane which is called the miniature endplate potential (MEPP). This is associated with the minimum maintenance of physiological responsiveness of the effector organ. Thus a slow level of continuous electrical activity within the motor unit of skeletal muscle is very important and is needed since the skeletal muscle lacks the inherent tone.

Post-junctional activity

MEPP cannot generate action potential above the threshold level like EPSP, which is needed to generate a propagated postjunctional AP resulting in nerve impulse (in neuron), contraction (in muscles), secretion (in glands) and other cellular activities. But multiple MEPP work together to form a clinically effective action potential resulting in EPSP. An IPSP stabilises the postjunctional membrane and resists the depolarising stimuli. Whether a propagated impulse or some other response will occur, it depends on the summation of all the excitatory and inhibitory potential.

Termination of action of neurotransmitter

Following the attachment with the receptor, the transmitter is either locally degraded (e.g ACh) or is taken back into the prejunctional neurone by active uptake (e.g NE) or diffuses away into the extracellular space and enters the circulation. The rate of termination of the transmitter's actions governs the rate at which responses can be transmitted across the junction. The termination of the action of only amino acid neurotransmitters result from their active transport into the neurons and the surrounding glia cells. Peptide neurotransmitters are hydrolysed by various peptidases and also dissipated by diffusion.

Neurotransmitters

Adrenergic Neurotransmitters

The adrenergic (more precisely called the noradrenergic) neurotransmitter is mainly related to the postganglionic sympathetic nerve endings. There are three structurally closely related endogenous adrenergic neurotransmitters. These are noradrenaline, adrenaline and dopamine.

i. Noradrenaline (NA) or norepinephrine (NE)

It naturally acts as neurotransmitter in certain areas of brain and at all the postganglionic sympathetic nerve endings except the sweat glands, hair follicles and some sympatheitc vasodilator fibres where the acetylcholine acts as a neurotransmitter.

ii. Adrenaline or Epinephrine (EPI)

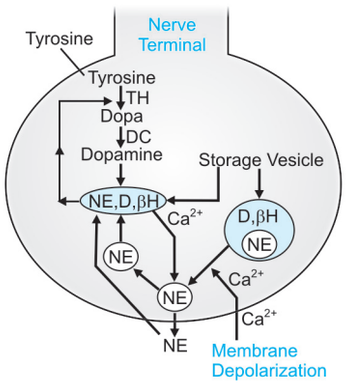
It is mainly secreted from the terminal end of presynaptic neuron in adrenal medulla. Because it acts as the sympathetic ganglia where only the preganglionic fibres end, but no postganglionic fibres exit from it. Adrenaline may have some role as neurotransmitter in some places of brain also.

iii. Dopamine (DA)

It is normally the major neurotransmitter in the basal ganglia, limbic system, CTZ, anterior pituitary of the CNS and in some places of peripheral nervous system.

Synthesis of adrenergic neurotransmitter or catecholamines (CA)

Primarily the adrenergic neurotransmitter such as dopamine, NE, and EPI are synthesised from tyrosine. It is actively transported to the postganglionic sympathetic nerve endings directly from the circulation. Tyrosine is first synthesised from phenylalanine in the liver with the help of an enzyme named phenylanine hydroxylase. It is also available directly from the diet. In phenylketoneuric patients, there is lack of phenylalanine hydroxylase enzyme. So, in these patients tyrosine is not synthesized in the liver. Tyrosine is available for these patients only from diet. The enzymes that participate in the formation of NE from tyrosine at the nerve ending are synthesized in the cell bodies (Fig. 11.13) of the neurons and are then transported along the axons to their nerve terminals. In the nerve endings, as a first step, tyrosine after entering from the circulation is converted to dihydroxy phenylalanine (DOPA) by the enzyme named tyroxine hydroxylase (TH).



TH : Tyrosine hydroxylase, DOPA : Dihydroxy phenylalanine,
DC : DOPadecarboxylase, DβH : Dopamine β-hydroxylase,
NE : Norepinephrine.

Fig. 11.13: The synthesis, release and reuptake of NE at sympathetic nerve terminal

This is a rate-controlling step for the biosynthesis of NE. Because tyrosine hydroxylase is activated following stimulation of the adrenergic nerves. This enzyme is activated by cyclic AMP-dependent or Ca^{2+}-Calmodulin dependent protein kinase C. Thus, this activation or phosphorylation of TH catalysed by protein kinase C may be associated with increased tyrosine hydroxylase activity. This is an important acute mechanism for increasing the catecholamine synthesis in response to increased nerve stimulation. On the otherhand high levels of NE inhibit TH and low levels stimulate this enzyme. During sympathetic stimulation, an increased supply of tyrosine will also increase the synthesis of NE. Chronic stress can also elevate the TH levels by stimulating the synthesis of new enzyme. When the TH level is reduced quantitatively, it may reduce NE synthesis significantly and may account for the changes in wakefulness of an individual. Inhibition of TH by α-methyl-P-tyrosine results in depletion of catecholamines. Thus, this also can be used in pheochromocytoma before surgery, and also in the inoperable cases (Fig. 11.14).

In the next step, DOPA is converted to dopamine by the enzyme, called the DOPA decarboxylase. In the course of synthesis of adrenergic neurotransmitter, the hydroxylation of tyrosine to DOPA and the decarboxylation of DOPA to dopamine, takes place in the cytoplasm of the nerve terminal. About half of the dopamine formed in the cytoplasm is then actively transported into the dopamine-β-hydroxylase (DβH) enzyme containing storage vesicle. In the storage vesicle the dopamine is converted to norepinephrine (NE) by the enzyme, named dopamine-β-hydroxylase (DβH). The remaining dopamine in the cytoplasm is metabolised to homovanillic acid (HVA).

In Parkinson's disease, the central dopaminergic functions are altered. So, administeration of DOPA can improve the dopaminergic function in the brain. This is because DOPA, but not the dopamine, crosses the blood brain-barrier. Dopamine can act as a neurotransmitter in some cells. But in most adrenergic neurons, dopamine

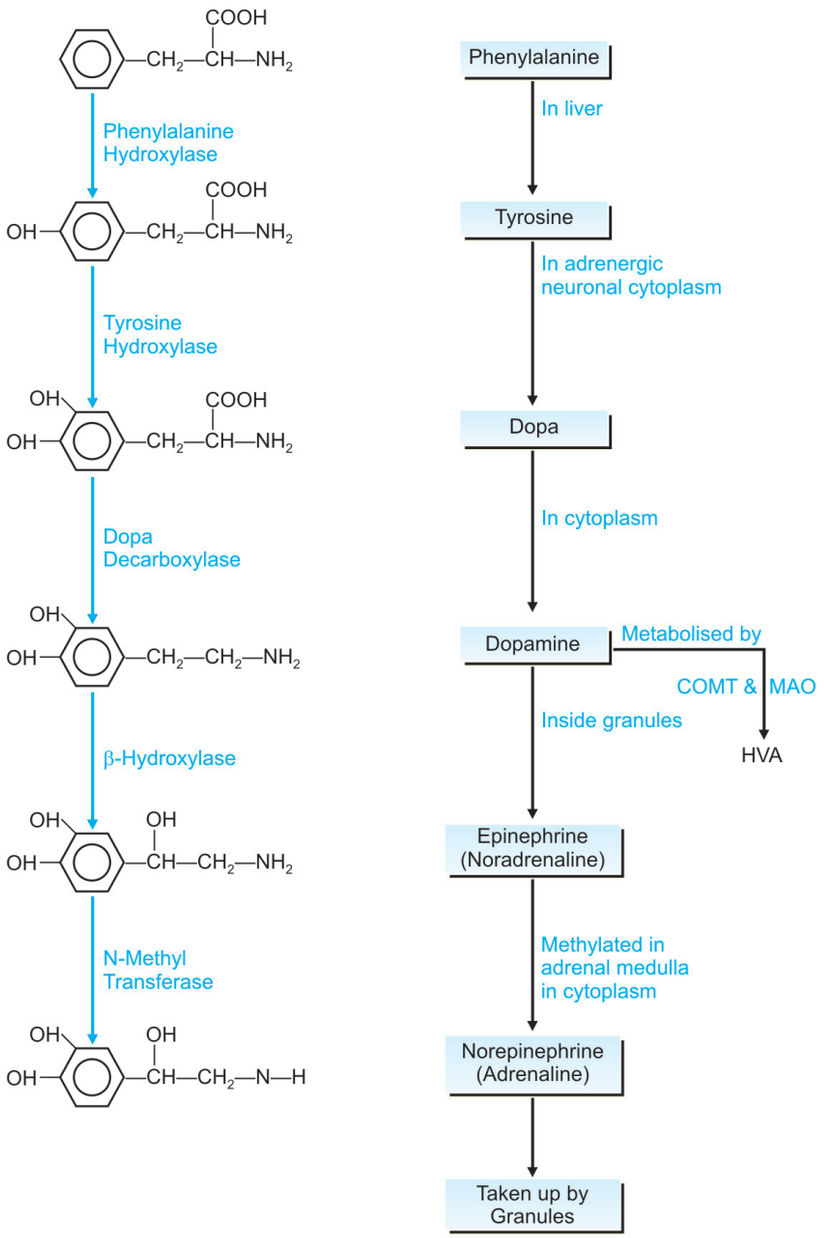


Fig 11.14: Biosynthesis of N_2

is catabolised quickly by the enzyme monoamine oxidase (MAO), found in the mitochondria.

The enzyme DOPA decarboxylase is nonspecific and can also act on some closely related substances. For example, this enzyme can form 5HT from hydroxytryptophan and α-methyl dopamine from α-methyl DOPA. The latter, i.e. α-methyl dopamine may function as a false neurotransmitter and is used in the treatment of hypertension.

In the adrenal medulla, in some discrete regions of the brain and in certain ganglia there is an additonal enzyme, named phenylethanolamine N-methyltransferase (PNMT). This enzyme methylates about 85% of the NE to EPI. Glucocorticoids from the adrenal cortex, passing through the adrenal medulla, can activate this system, so that the stress induced steroid release can cause the increased level of EPI production from adrenal medulla. In adrenal medulla, NE is stored as chromaffin granules in the vesicles. These vesicles also contain extremely high concentration of ascorbic acid, ATP and some other specific proteins, such as : chromograffins, the enzyme DBH and peptides including enkephalin and neuropeptide Y. In sympathetic nerve terminal under electron microscope two types of storage vesicles are found: (i) large dense core vesicles corresponding to chromaffin granules and (ii) small dense core vesicles containing NE, ATP and membrane bound dopamine-β-hydroxylase (DBH) enzyme.

Storage of catecholamines

After synthesis of NE or EPI it is stored in the synaptic vesicles as granules at the adrenergic nerve terminal. The vesicular membrane actively takes up the dopamine from the cytoplasm. Then the final step of synthesis and storage of NE takes place inside the vesicles. The vesicles also contain calcium, varieties of peptides or proteins, and ATP which looks under electron microscope as granules. The proteins of synaptic vesicles can be classified functionally into two classes. One class consists of transport proteins that provide the channels and pumps and are needed for uptake and storage of neurotransmitters. Another class consists of proteins that are involved in the direction of movement and the docking reactions of the synaptic vesicular membrane with the presynaptic membrane.

The NE is stored in the vesicle as a complex with ATP (in ratio of 4:1), and is absorbed on the surface of a protein, called the chromograffin granules. In the adrenal medulla, the NE thus formed within the vesicles and absorbed on the chromaffin granules again diffuses out into the cytoplasm of the cell where it is methylated and EPI is formed. EPI so formed, is again taken up by a separate set of vesicles.

Functionally there are two types of vesicles at the nerve terminal : recycling population of synaptic vesicles that are used normally, and a reserve population of synaptic vesicles that is mobilised only on extensive stimulation during emergency. Transmitters that are newly synthesised or newly taken up from synaptic cleft are preferentially incorporated into the recycling vesicles and are released during the normal stimulation of nerve. Sympathomimetic drugs that mimic adrenergic neurotransmitter are also taken up presynaptically and are stored in the recycling vesicles. Among the reserve population of vesicles, only 10% stays in the readily releasable condition. But, only 1% out of this 10% readily releasable reserve population is released during each depolarisation which implies a significant functional reserve.

Release of catecholamines

The release of contents of synaptic vesicles into the synaptic cleft is called exocytosis. When an AP reaches the nerve terminal, then the presynaptic plasma membrane depolarizes and the voltage gated calcium channels situated on it open at the active zone. As a result, the intracellular Ca^{2+} concentration increases and triggers the docking, fusion and fluidization of the vesicular and presynaptic membrane, causing pouring out of all the vesicular contents, such as NE, EPI, ATP, DBH, chromograffin granules, etc, in the synaptic cleft. In addition, the vesicles which contain peptides like enkephalin, neuropeptides-Y, etc., as cotransmitters are also simultaneously released. The release of this vesicular content is modulated by many presynaptic receptors, of which α_2-inhibitory control is dominant. Many chemical compounds, such as angiotensin II, prostacyclin, histamine, etc. may also potentiate the release of transmitters. While ACh (acetylcholine), prostaglandin E, etc. inhibit this release. Tyramine (a sympathomimetic amines) induces the release of NE. But, it is done by displacing the NE from the nerve ending binding sites and by exchange diffusion, utilizing amine carrier of uptake-I. This process is not called exocytosis and does not require Ca^{2+} (Fig. 11.15).

In adrenal medulla, the chromaffin cells synthesize and stores the NE or EPI and their preferential release depends on the nature of the stimulus. Nicotinic agonists or depolarizing agents cause the preferential release of NE, whereas histamine predominantly elicites the release of EPI. Protein kinase C plays an important role in regulating the secretion of catecholamines from NE containing chromaffin cells.

Uptake of catecholamines after its release

There are two very efficient mechanisms by which NE and other catecholamines is recaptured after its release from the nerve terminal. Released NE and other catecholamines is rapidly reuptaken by nerve terminals (uptake-1) or reuptaken by non neural tissues (uptake-2) (Fig. 11.16).

Uptake - 1

This is first and most important step for the inactivation of the released NE. The half-life of NE in its biophase (i.e. in the extracellular space in close proximity to the receptor after combination with it) is very short. The majority of the released NE is transported back into the nerve ending for

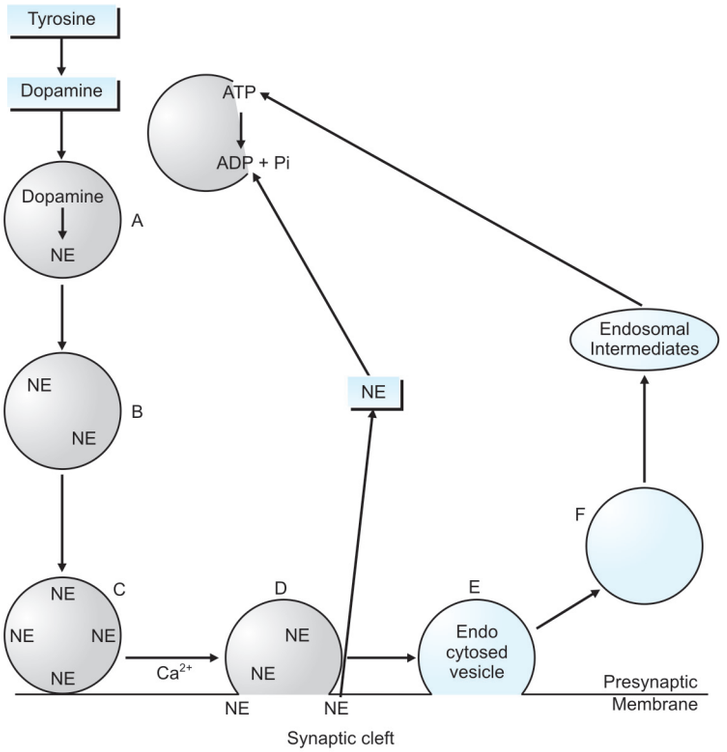

Fig. 11.15:
Stage A : Synthesis or active transport of NT (neurotransmitter) such as norepinephrine (NE) in synaptic vesicles.
Stage B : Movement of the vesicle with NT towards synaptic membrane.
Stage C : Docking of the vesicle at the active zone.
Stage D : Ca^{2+} influx after depolarization triggers exocytosis of vesicle and release of NT.
Stage E : Empty vesicle is endocytosed.
Stage F : Recycling, empty vesicle

the reuse by an active amine pump (transporter), which is present at the presynaptic neural membrane. This active amine pump is a large hetero-oligomeric molecular complex, containing eight or nine different subunits. This amine transport system across the axoplasmic membrane is Na^+ dependent and can be blocked selectively by a number of drugs, including cocaine and the tricyclic antidepressants, such as impramine. Thus, they cause an enhanced response to catecholamines, as the more NE is available to the receptors on the post synaptic membrane. Cocaine and tricyclic antidepressants also block the reuptake of NE in the vesicle from the axoplasm.

A number of other highly specific transport system have also been identified for the reuptake of dopamine, norepinephrine, serotonin and a variety of other amino acid neurotransmitters. These transport or reuptake system may be viewed as targets for many specific drugs, which are used in clinical practice, such as cocaine (block dopamine transport or reuptake), fluoxetin (block serotonin transport or reuptake), etc. Then, NE is driven from axoplasm into the vesicle by the electrochemical proton gradient across the membrane of the synaptic vesicle. After reuptake in the axoplasm of the nerve terminal, a small amount of NE which is not taken up by the vesicle is deaminated by MAO enzyme. There are several organ specific forms of this enzyme. After reuptake or new synthesis, some vesicular NE constantly leaks out into the axoplasm and is recaptured or metabolized by this mechanism. This reuptake of NE into the vesicle from axoplasm is inhibited by reserpine.

This reuptake of NE in the nerve terminal and then in the vesicle is not always specific for that neurotransmitter. So, some compounds that are similar to NE in structure may also enter the nerve terminal and vesicle, causing depletion of the actual neurotransmitter. These structurally similar compounds are called the false or pseudotransmitters and have great clinical importance in the management of hypertension.

The integrity of this uptake-1 system varies from tissue to tissue. As for example, reuptake of NE is lowest or minimum in the peripheral blood vessels (where the rate of new NE synthesis is highest). Conversely, the highest rate of reuptake of NE is found in cardiac tissues with less rate of synthesis of NE. Thus, those drugs that inhibit the biosynthesis of NE (e.g. α-methyl dopa) have more effects on blood vessels and blood pressure. While those that affect the reuptake of NE (e.g. cocaine, desipramine and its congeners, such as guanethidine and many H_1 antihistaminics) have more influences on the cardiac rate and rhythm.

When NE passes through the pulmonary circulation then 25% of the circulating NE is removed by the lung tissues, while EPI and dopamine passes unchanged. However, the functional significance of this removal of NE by the pulmonary vasculature is not known. This effect may also account for some of the differences which is clinically observed in the right sided versus left sided infusions of vasopressors. Pulmonary hypertension also accounts for diminition of NE uptake.

Uptake - 2

After release in the synaptic cleft, the inactivation of NE also occurs by its uptake through other tissue cells, enzymatic breakdown in synaptic deft and diffusion in the interstitial fluid followed by absorbtion by vasculature. This process of uptake 2 of catecholamine is ubiquitous and is present in glial, hepatic, myocardial and other tissues. This has no physiological

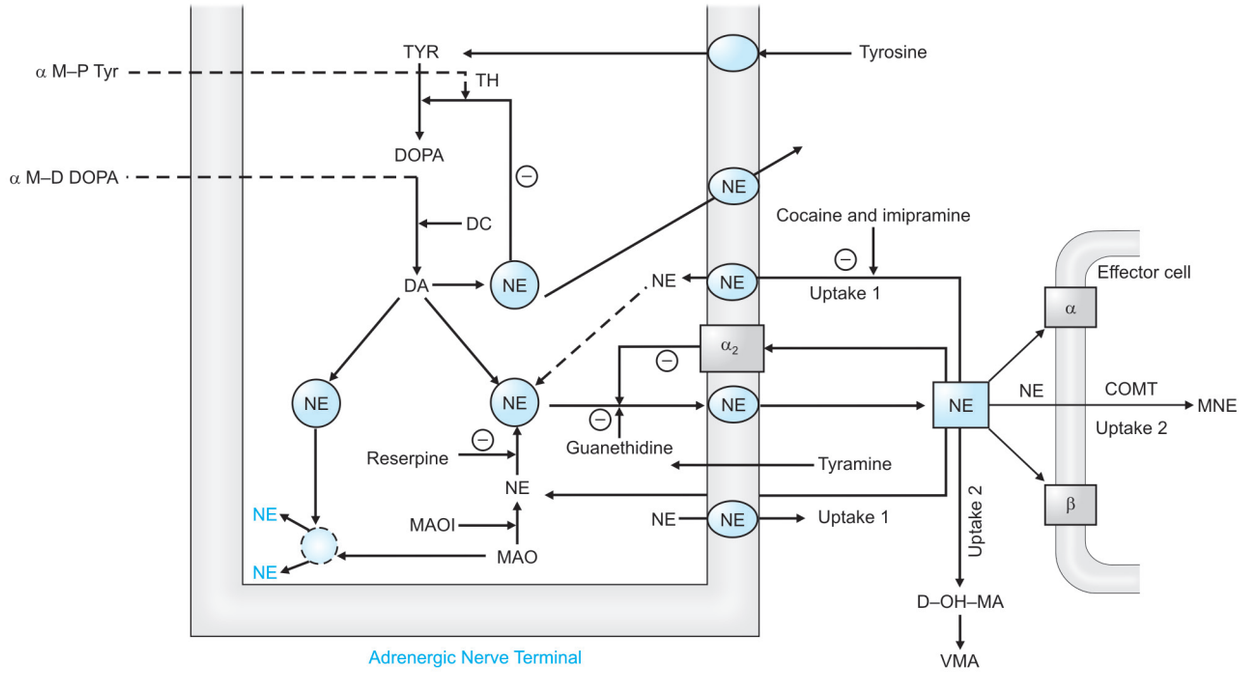

Fig. 11.16: Schematic representation of adrenergic neurotransmission and its modification by drugs. TYR→ Tyrosine, α M-P-Tyr→α methyl-P-tyrosine, α M-DOPA→ α methyl DOPA, D-OH-MA→ Dihydroxy mandelic acid, MNE→ Metanorepinephrine, VMA→ Vanillyl mandelic acid, DA→ Dopamine

or pharmacological importance. It is not inhibited by uptake-1 inhibitors (cocaine, imipramine, fluoxetine etc).

Metabolism of catecholamines

The pathways of metabolism of catecholamines are depicted in the diagram. During storage, release and reuptake of catecholamines at the nerve endings, a small amount always escapes and enters the circulation. In the circulation, NE is metabolised by the mono-amino-oxidase (MAO) and catecholamine-o-methyl-transferase (COMT) enzyme very rapdily. So, inhibition of MAO by MAOI greatly increases the sympathetic function. The metabolism of catecholamine also occurs in the liver and kidney. EPI liberated from adrenal medulla is also metabolised by the same pathway. The final product of both NE and EPI metabolism is 3 methoxy 4 hydroxy mandelic acid or vanilyl mandelic acid (VMA) which are excreted through the urine. The other major metabolites excreted through the urine are 3-methyoxy-4-hydroxy phenylglycol, along with some normetanephrine and metanephrine. These metabolites are mostly conjugated with glucoronic acid or sulphate before excretion through urine. Only 25 to 50 µg of NE and 2 to 5 µg of EPI are excreted in the free form in 24 hours urine. However, metabolism by MAO and COMT in the circulation doesnot play an important role in terminating the action of catecholamines liberated at the nerve terminal. Very quick reuptake of NE and EPI from the synaptic cleft and store in the vesicles, and little metabolism (Fig. 11.17) by the two catabolic enzymes account for the efficient clearance of catecholamines liberated at the nerve terminal. Due to this rapid clearance of catecholamines (NE and EPI) from the circulation by MAO and COMT the half-life of most of the biogenic amines or NE and EPI in plasma is very short which is less than 1 minute. So the very short half-life of these catecholamines necessitates their administeration by infusion. Another consequence of short half-life of these catecholamines is that their production in the body can not be measured by their plasma level, rather by the measurement of the metabolic products of these catecholamines. For example, the screening of NE producing pheochromocytoma is done by frequently measuring the plasma or urine level of VMA but not the plasma level of NE.

Cholinergic Neurotransmitters

Acetylcholine (ACh) is the cholinergic neurohumoral transmitter and occupy the major portion of the autonomic as well as the somatic synapses. The sites of synthesis of this cholinergic neurotransmitter and the description of its rceptors are discussed before. So here, we will discuss only the mechanism of synthesis, storage and inactivation of ACh.

Synthesis of acetylcholine (ACh)

Acetylcholine is synthesised intraneurally from choline (the source of which is described below) and acetyl CoA (formed

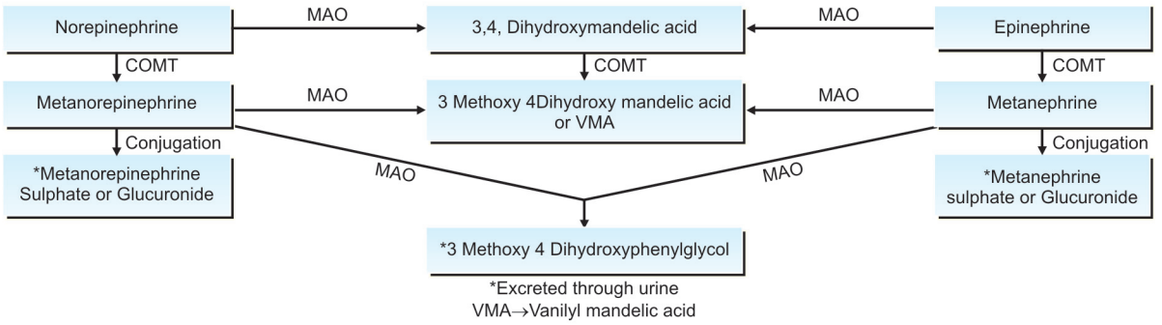

Fig 11.17 : Metabolism of catecholamines

during metabolism of glucose, fat and amino acid) by the enzyme, named choline acetyl transferase (ChAT) situated in the mitochondria. ChAT, like other protein constituents of the neuron, is synthesised within the perikaryon (cell body of the neuron) and then it is transported along the length of the axon to its terminal. Axon terminals also contain a large number of mitochondria, where acetyl CoA is synthesized from metabolism of glucose, fat and protein.

The sources of choline which is another component of ACh includes:

i. Dietary choline – a type of phospholipid.
ii. Hepatic synthesis of phosphatidylcholine from dietary precursors, such as: ethanolamines
iii Choline, released by hydrolysis from previously synthesised ACh.

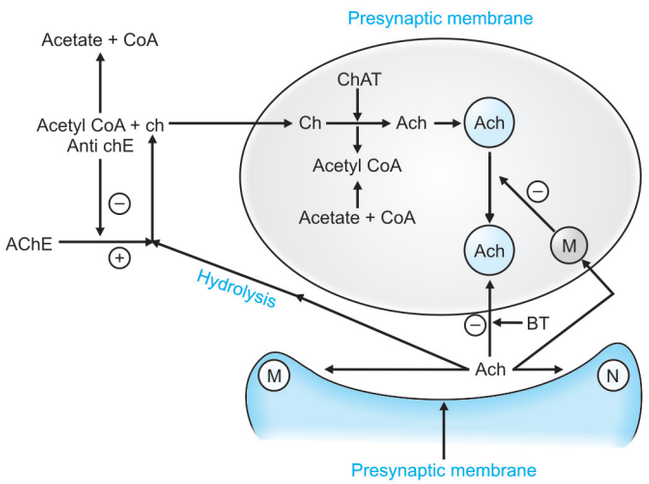
Among these three sources, the hepatic source for choline is the major and most important. After synthesis in the liver, the choline is transported as phospholipid to the nerve terminal through circulation and is actively taken up by the high affinity transport system situated on the neuroaxonal membrane. This hepatic synthesis appears to be largely responsible for determining the ACh levels at the nerve terminals. The level of circulating choline in blood also affects the amount of ACh released from nerve terminals, particularly when the rapid firing takes place at the cholinergic motor neurons. There is also some evidence that the availability of a precursor for the synthesis of ACh may limit the cholinergic activity.

It is found that despite the presence of high density of the choline acetyl transferase enzyme (ChAT) in the brain tissues, choline itself is not produced there, but is transported from the outsources. So, research is going on to develop the choline analogues to enhance the neural transmission in the brain and to treat the Alzheimer's disease.

Choline, after entering into the nerve cell, binds with the acetyl coenzyme A, present within the cell on the surface of the enzyme named choline acetyl transferase (ChAT). This enzyme facilitates the condensation of choline with the acetyl group of acetyl CoA. Thus, acetylcholine and CoA is produced. After synthesis, ACh is rapidly packed in the vesicles for immediate release during proper stimulation. ChAT enzyme also catalyzes the reaction in a reverse direction between the acetylcholine and CoA producing choline and acetyl CoA, but at a much slower rate than the forward direction (Fig. 11.18).

Storage and release of acetylcholine

After synthesis, ACh is rapidly packed in synaptic vesicles at the nerve terminals which are called the quanta. It has been calculated that a single motor nerve terminal contains near about 3,00,000 vesicles or quanta. In addition, an uncertain but possibly a significant amount of ACh is also present in the extravesicular cytoplasm. When the action potential reaches the nerve ending, then ACh is released from



ACh: Acetylcholine, Ch: Choline, ChAT: Choline acetyl transferase, AChE: Acetylcholine esterase, Anti-chE: Anticholine esterase, M: Muscarinic receptor, N: Nicotinic receptor, BT: Botulinus toxin, H: Chemicolinium.

Fig. 11.18: Cholinergic neuronal transmission

the vesicle in the synaptic cleft by the same mechanism as adrenergic neurotransmitters, but at the fixed presynaptic release sites (active zone) which are located opposite to the shoulders of the folding of postjunctional membrane. First quantas or vesicles containing ACh move toward these specific release sites or active zone of the presynaptic membrane which is influnced by the influx of Ca^{2+} like adrenergic transmission and fuse with the presynaptic membrane. Then, fluidization of the vesicular and synaptic membranes occur and throw out their contents in the synaptic cleft and on the post synaptic membrane receptors.

Inactivation of acetylcholine

After release in the synaptic cleft, ACh is rapidly broken down by hydrolysis into choline and acetate, but neither of these metabolites have significant pharmacological actions. This hydrolysis of ACh is catalysed by an enzyme called cholinesterase. There are two most important type of cholinesterases, present in the body. These are tissue cholinesterase or true cholinesterase and butyryl or pseudocholinesterase.

The tissue or true acetylcholinesterase is a postsynaptic membrane bound enzyme which is present at all the cholinergic synapses and destroys the ACh neurotransmitter, after it is released from the presynaptic membrane. It is called the 'true choline esterase' or 'tissue choline esterase', because it does not circulate in the plasma. It is also found in tissues that are not innervated by nerves e.g., erythrocytes. But, here its function is not exactly known.

Butyryl cholinesterase is also called the 'plasma choline esterase' or 'pseudo cholinesterase' and is found in plasma. It is synthesised in the liver and circulates in the blood. Its function in plasma in a normal healthy person is not known and the individuals who are genetically incapable of synthesising these enzymes are normal in all other regards. Only its importance lies in the destruction of some cholinergic drugs, e.g. succinylcholine which is used as a muscle relaxant during anaesthesia and is not destroyed by tissue cholinesterase or true choline esterase.

The molecule of true or pseudo cholinesterase has two areas: an anionic site which carries a strong negative charge and an esteric site which contain electrophilic amino acids. ACh molecule has a positive charge at the quarternary nitrogen atom. During hydrolysis, the positive charge of ACh is attracted by the negative charged site of the enzyme and is attached there. Then, an electrophilic attack on the molecule of ACh occurs and the acetate link is transferred from the choline to the amino acid site of the enzyme. After that the choline which is attached to the negatively charged anionic site of cholinesterase enzyme drifts away, leaving only the acetylated cholinesterase enzyme. The acetate link on the acetylated cholinesterase enzyme is subsequently attacked and broken down by a hydroxyl group forming water. After that the acetate also drifts away from the cholinesterase enzyme and the regenerated free enzyme becomes again ready to interact with another molecule of ACh.

Inhibition of the cholinesterase enzyme prevents the destruction of ACh in cholinergic synapses, and subsequently prolongs its action (muscarinic and nicotinic) in all the cholinergic systems.

Characteristics of cholinergic transmission at various sites

Characteristics of cholinergic transmission are not the same in different tissues. There are marked differences of cholinergic transmission at various sites. The examples are:

a. Skeletal muscle

Attachment of ACh with the nicotinic cholinergic receptor situated at the postjunctional endplate membrane causes marked increase in the permeability of Na^+ cations, through it due to opening of receptor channels. This results in localised depolarisation within the endplate (EPP) which triggers the muscle action potential and contraction.

b. Cholinergic autonomic nerve endings

Here, the ACh as first messenger acts through the muscarinic receptor and causes stimulation or inhibition of autonomic effector cells (smooth muscles and glands) by acting through the muscarinic receptor → G protein → effector system or second messenger complex, such as adenylcyclose and phospholipase-C. In contrast to skeletal muscles, all the cardiac and smooth muscles have their own intrinsic electrical activity. Here, the cholinergic transmission only modulates the cardiac and smooth muscle's intrinsic electrical activity, but does not initiate any new impulse or action potential. In intestinal smooth muscles the site of pacemaker activity continuously changes. But, in the heart spontaneous depolarisation normally arises from the SA node. Under pathological conditions, when SA node activity is depressed, then a new pacemaker activity can arise from any part of the conduction system as all of them have the intrinsic electrical activity. In basal conditions, individual muscle cells of the SA node show waves of depolarization. Cholinergic transmission causes inhibition of this spontaneous depolarization of the SA node by causing hyperpolarization of the cell membrane. These effects are, at least in part, due to the selective increase in the permeability of K^+.

c. Autonomic ganglia

The primary pathway of the cholinergic transmission in the autonomic ganglia is similar to that of neuromuscular junction of the skeletal muscles, i.e. through nicotinic receptors. Several secondary transmitters or modulators either enhance or diminish the sensitivity of postsynaptic membrane of the ganglionic cells to ACh. But, this sensitivity appears to be related to the membrane potential of the postsynaptic nerve's cell body or its dendritic branches.

d. Action of ACh on presynaptic sites

Action of ACh neurotransmitters on presynaptic cholinergic receptors appear to be present on sympathetic vasoconstrictor or adrenergic nerves. Activation of these presynaptic cholinergic receptors by ACh causes inhibition of further release of NE and produces vasodilatation. But, practically cholinergic innervation of the blood vessels is limited. So, clinical dilatation of blood vessels in response to the administration of ACh involves a separate mechanism which includes presynaptic inhibition of NE release. The vasodilator effect of ACh requires an intact layer of endothelium in the blood vessels. Activation of the presynaptic muscarinic ACh receptors results in the liberation of special vasodilator substances, called the endothelium derived relaxing factor (EDRF) or nitric oxide from the endothelium. It diffuses from the endothelium to the adjoining smooth muscle cells and causes relaxation with dilatation of blood vessels.

CATECHOLAMINES (CAS) (Fig. 11.19)

The parent structure of all the sympathomimetic agents is β-phenyl-ethyl amine which includes a benzene ring and an ethylamine side chain. When the 3rd and 4th position of this compound or benzene ring is substituted by a hydroxyl group (−OH), then this benzene ring is called the catechol ring and the β-phenyl-ethyl amine is called the dihydroxy phenylethylamine which is known as catecholamines. The catecholamines which are found naturally in the body are called endogenous catecholamines. They are NE, EPI and dopamine. Synthetic sympathomimetic agents, like isoproterenol, dobutamine, etc, also have the similar structure like endogenous catecholamines. So, they are called the non-endogenous catecholamines. There are other sympathomimetic agents whose structures are not like catecholamines. They are called non-catecholamine sympathomimetic agents. Some examples of this type of drugs are: metoproterenol, albuterol, terbutaline, methoxamine, phenylephrine, mephenteramine, metaraminol, etc.

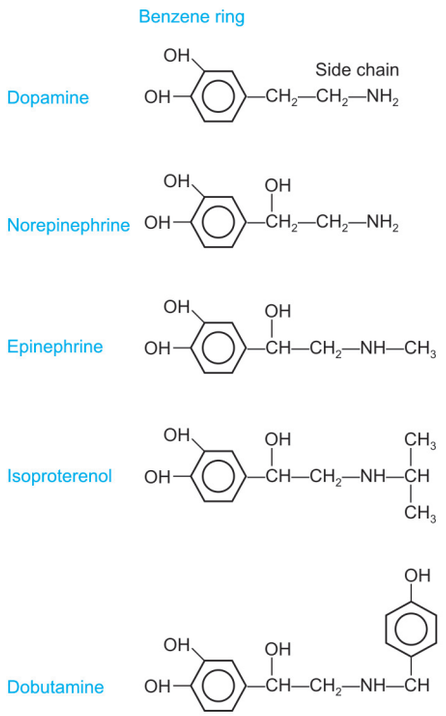


Fig. 11.19: Structures of some common catecholamines. The catechol nucleus is formed by a benzene ring with two adjacent hydroxyl groups

Due to the hydroxyl group, sympathomimetic agents of catecholamine group are quickly metabolised by COMT. But the absence of −OH group in non-catecholamine sympathetic agents increases their oral effectiveness and duration of action, as they are not metabolised by the COMT. They are primarily metabolised by MAO.

Non-catecholamine sympathetic agents that have a substituted α-carbon have a longer duration of action. This is because they are not metabolised by either COMT or MAO.

Endogenous Catecholamines

One Epinephrine (adrenaline)

The effects of an endogenous catecholamine such as epinephrine (EPI) on target organs are complex, as it is a potent stimulant of both α_1, α_2 and β_1, β_2 adrenergic receptors. Its particular and prominent actions are found on the heart than the vascular and other smooth muscles, although the occurrance of sweating, piloerection and mydriasis produced by EPI depend on the physiological state of the subject. The most potential therapeutic effects of EPI include its positive inotropic effects (β_1), positive chronotropic effects (β_1), enhanced conduction in the heart (β_1), smooth muscle relaxation in the vascular and bronchial tree (β_2) and peripheral vasoconstriction of the resistance vessels (α_1). Various effects of EPI at different sites are

a. Blood pressure

EPI is one of the most potent vasopressor agent. On rapid intravenous injection, BP rises rapidly which is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure.

The mechanism of rise of BP due to epinephrine are:

i. Positive inotropic action — direct myocardial stimulation that increases the force of ventricular contraction.
ii. Positive chronotropic action— increase in heart rate.
iii. Constriction of vascular smooth muscles, particularly precapillary resistance vessels of the skin, muscle, mucosa, kidney, and veins.

Initially HR increases, but later it slows down markedly which is proportional to the height of the rise of blood pressure. This is due to the compensatory vagal discharge.

On small doses of 0·1 µg/Kg through IV route EPI reduces the blood pressure, and this is due to only β_2 receptor stimulant effect of EPI. But in higher doses there is a biphasic response (initially rises then falls). In higher doses this biphasic response is due to the greater sensitivity of epinephrine to β_2-receptors at high doses which

causes vasodilation than the α_1-receptor effect which cause vasoconstriction. The effects of EPI in doses as large as 0.5 to 1.5 mg through IV route (or 10 to 30 µg per minute) are: rise in systolic BP due to increased cardiac contractile force and a rise in the cardiac output. But, the diastolic BP decreases due to the decrease in peripheral resistance, owing to the dominant action on β_2-receptors, causing vasodilatation than α_1-receptors of resistance vessels, causing vasoconstriction. Heart rate, stroke volume, CO, left ventricular work load are all increased as a result of its direct cardiac stimulant effect and increased venous return to the heart. At higher doses, the effects of EPI on the peripheral resistance and diastolic pressure depends on the ratio between the α and β responses on the various vascular beds.

b. Vascular effects

The site of action of EPI on the vascular beds is at the smaller arterioles and precapillary sphincters, but various vascular beds react differently. EPI markedly decreases the cutaneous blood flow. However, in therapeutic doses, the blood flow to the skeletal muscle increases with EPI. This is due to its powerful and predominant vasodilating β_2-receptor action (β_1 is situated on the heart). But it is particularly counter balanced by the vasoconstrictory α-receptor action (both α_1 and α_2). In such situations, if a α-adrenergic antagonist is given, then the vasodilatation effect of β_2-receptor predominates and SVR decreases, resulting in acute fall of mean blood pressure. Reversely, EPI increases blood pressure considerably if the vasodilatation β_2-receptor action is blocked by some non-selective β-blocker.

c. Cerebral blood flow

The adrenergic receptors present on the cerebral vascular bed is predominantly α_1 (vasoconstrictor). So, the therapeutic doses of EPI causes cerebral vasoconstriction. This is due to the direct effect of EPI on cerebral vessels. But, clinically the main effect of EPI on cerebral circulation is conducted through the changes in systemic BP and not through these receptors. Again, the cerebral self or local autoregulatory mechanism tends to limit the increase in cerebral blood flow, caused by increase in BP (Table 11.13).

d. Renal effects

Kidney has both the α_1, α_2 and β_1, β_2 adrenergic receptors. Here, the vasoconstrictor effect of α-receptor predominates much more over the vasodilatatoin action of the β-receptor. So, the doses of EPI which cause little effect on mean arterial pressure, cause the tremendous decrease (40%) in the renal blood flow due to a consistent increase in renal vascular resistance by the predominant $\alpha_1$action. In spite of this, GFR is slightly altered and filtration fraction is consistently increased. Its cause is discussed in details in the renal chapter. Urine volume may be increased, decreased or unchanged. Due to the direct effect of EPI on β_1-receptor of juxtaglomerular apparatus, renin secretion is also increased.

e. Pulmonary effects

Pulmonary vasculature contains both the α_1 (vasoconstriction) and β_2 (slight vasodilatation) receptors. Due to the predominant α_1 action of EPI on pulmonary vasculature, arterial and venous pulmonary pressure is raised. Still, clinically the redistribution of blood from pulmonary circulation to systemic circulation does not occur. Rather, redistribution of blood from the systemic to the pulmonary circulation occurs and this is due to the strong vasoconstriction action of more powerful musculature of the systemic great veins. Therefore, the total effect is an increase in the pulmonary vascular pressure. Thus, by the same mechanism epinephrine in higher concentration may precipitate pulmonary

Table 11.13: Comparison of effects of NE and EPI (Intravenous infusion)

Response	*NE (norepinephrine)*	*EPI (epinephrine)*

oedema by elevating the pulmonary capillary filtration pressure.

f. Coronary circulation

Coronary vessels contain α_1, α_2 and β_2 receptors. Here, the vasodilatation action of β_2 receptors predominate over the vasoconstriction action of α receptors. So, coronary blood flow is increased by it or by cardiac sympathetic stimulation. Another mechanism of increased coronary blood flow by EPI is the elevated aortic blood pressure caused by it. Epinephrine increases the strength of myocardial contraction (β_1 action) and O_2 consumption which also dilates the coronary vessels by their local metabolic effects. This local metabolic dilatation effect of EPI on coronary arteries is mediated by adenosine, released from the cardiac myocytes due to hypoxia. Therefore, all these effects tend to overcome the direct coronary vasoconstriction effect of EPI that results from the activation of α receptor in coronary vessels.

g. Cardiac effects

Heart muscles contain predominantly β_1 receptors. But, β_2 and α receptors are also present in minimum concentration. Therefore, EPI is a powerful cardiac stimulant and acts mainly through the β_1 receptors. It increases the heart rate and often the sinus rhythm is altered. All the effects of EPI on cardiac tissue are largely secondary to this increase in heart rate. Because, when the HR is increased, the duration of action potential is consistently shortened and the refractory period is correspondingly decreased. The increased heart rate by epinephrine is due to the acceleration of the slow diastolic depolarisation phase or phase 4 of action potential and also due to the increased rate of the rise of transmembrane potential to the threshold level, at which point the action potential is triggered. The amplitude of AP and the maximal rate of the rise of depolarisation (phase 0) are also increased. Cardiac systole becomes shorter and powerful. CO increases. The work load of heart and O_2 consumption is also markedly increased by EPI. But, the cardiac efficiency which is determined by the work load relative to O_2 consumption decreases. EPI also increases the excitability and automaticity in the specialized tissues of heart. This is also due to the acceleration of the slow diastolic depolarisation phase of action potential. However, these changes in automaticity usually do not occur in the atrial and ventricular muscle fibres. These occur only in the cells of SA node.

Altered pacemaker activity due to increased automaticity by the exogenous EPI is rarely seen with conventional dose. But, ventricular extrasystole, tachycardia or even ventricular fibrillation may be precipitated by the release of small amount of endogenous epinephrine, when the heart has been sensitized by certain anaesthetic agents or in case of MI.

EPI shortens the refractory period of AV nodal tissue and decreases the grade of AV block, which usually occurs by the effect of many diseases, drugs and vagal stimulation.

Supraventricular arrhythmias may occur from the combination of action of epinephrine and cholinergic stimulation, if these two events occur at the same time due to any reason. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in the EPI induced ventricular arrhythmias. So, various drugs (e.g. atropine) that block the vagal effect confer some protection against EPI induced ventricular arry thmias. The action of EPI in enhancing cardiac automaticity, and causing arrhythmias are effectively antagonised by β-adrenergic receptor antagonist.

h. Bronchial smooth muscle

Epinephrine has a powerful bronchodilating effect. This is particularly occurred when EPI is administered during the acute exacerbation phase of bronchial asthma due to allergic response to various drugs and autacoids. In such situations, EPI has a striking therapeutic effect as a physiological antagonistic agent to the substances that cause bronchoconstriction. The beneficial effect of EPI in asthma also arises from the inhibition of the antigen-induced release of inflammatory mediators from mast cells, and to a lesser extent from the diminution of the bronchial secretions and congestion within the mucosa. The inhibition of bronchial smooth muscle constriction by EPI which is induced by mast cell secretion (release of inflammatory mediators) is mediated through the stimulation of β_2-adrenergic receptors and the effects on bronchial mucosa (reduction of congestion) are mediated through the stimulation of α receptors.

i. Urinary bladder

The detrusor muscle of the bladder is relaxed as a result of the activation of β-receptors by EPI. This causes retention of urine. Again, α agonistic activity of epinephrine results in contraction of the trigonal and sphincteric smooth muscles, causing hesitancy and retention of urine. Activation of the smooth muscle contraction in prostate by EPI also promotes the urinary retention (α-receptor effect).

j. Effects on uterus

The response of EPI on uterine muscle varies with the species, phases of sexual cycles, state of gestation and doses of the drug given. During the last month of pregnancy and parturition, epinephrine inhibits the uterine tone and reduces the contraction which is mediated through its β_2-receptor agonistic action. So, β_2-selective agonists (ritodrine, terbutaline) have been commonly used to delay the premature labour by relaxing the uterine musculature.

k. GI

The effects of EPI on the smooth muscles of vascular system has more physiological

importance than their effect on the smooth muscles of GI tract. In general, GI smooth muscle is relaxed by EPI and this effect is due to the activation of both α and β adrenergic receptors. Tone, frequency and amplitude of intestinal contraction are all reduced. The stomach is usually relaxed, but the pyloric and ileocaecal junction are contracted. However, these effects of EPI on gastrointestinal system depend on the pre-existing tone of the muscles. If the tone is already high, then EPI causes relaxation of the smooth muscle and vice versa.

l. CNS effects

As epinephrine (EPI) is a polar compound, so it usually does not cross the blood brain barrier and enters the CNS. Thus, it is not a powerful CNS stimulant. Hence, restlessness, headache, tremor, apprehension, etc, produced by EPI are all due to the secondary effects of it on CVS, skeletal muscular system and its intermediary metabolites. It is not due to the direct effect of epinephrine on CNS. Though EPI does not enter the CNS, but some other sympathomimetic drugs can readily cross the blood brain-barrier and may produce the symptoms.

m. Metabolic effects

EPI increases the concentration of glucose and lactate in blood. It inhibits the secretion of insulin by its α_2-receptor action and stimulates the secretion of insulin by its β_2-receptor activation, both of which are contradictory. But, the predominant effect of epinephrine on insulin secretion is inhibition and rise of blood glucose concentration. Glucagon secretion is enhanced by the action of EPI on β-receptors, present on the α-cells of pancreatic islets. This also causes the increased concentration of glucose in blood. The effect of EPI to stimulate glycogenolysis in most of the tissues involves β-receptor stimulation.

EPI raises the concentration of free fatty acids in blood by stimulating the β-receptors in the adipocytes. This result is due to the activation of triglyceride lipase in the adipocytes which accelerates the breakdown of triglycerides to form the free fatty acids and glycerol. The plasma renin activity is also increased by epinephrine (β_1 effect). The serum K^+ concentration transiently rises (due to release from the liver), following the administeration of epinephrine. Later, a more prolonged decrease in K^+ concentration follows. Epinephrine administeration increases the basal metabolic rate by 20 to 30% So, in combination with the cutaneous vasoconstriction that the drug produces, pyrexia may result due to this increased metabolism.

n. Effects on secretary glands

In most of the secretary glands of GI tract, EPI inhibits the secretion. This is partly due to the reduced blood flow in gland, caused by vasoconstriction and partly due to the direct action of EPI on α and β receptors situated on the gland. On the lacrimal glands, it stimulates the lacrimation (α-receptor action) but causes scanty mucous secretion from the salivary glands. Sweating and pilomotor activity (α_1-receptor) is minimal after systemic administeration of epinephrine.

o. Effects on eye

Mydriasis occurs during the systemic administeration of EPI. It is due to the contraction of the radial muscles of iris (α_1 action). But, it does not occur when the EPI is instilled in the conjunctival sac, because it penetrates the cornea poorly. Epinephrine also lowers the intraocular pressure, especially in the wide-angle glucoma. However, the mechanism of this effect is not clear. But, both the reduced production of aquous humour due to vasoconstriction and the enhanced outflow due to mydriasis are the probable causes.

p. Skeletal muscle

Directly EPI does not excite the contraction of skeletal muscle. But, indirectly it facilitates the neuromuscular transmission. In ANS the stimulation of presynaptic α-receptor by epinephrine causes inhibition of the release of ACh. In contrast, stimulation of α-receptor by EPI at the somatic motor neurone causes a more rapid increase in transmitter release. The greater physiological and clinical importance of EPI on skeletal muscle is its selective β_2 agonistic activity which causes physiological tremor. This is due to the β receptor mediated enhancement of discharge from the muscle spindle.

Absorption, fate and excretion: EPI is not effective by oral administration. This is because it is rapidly metabolised in the GI mucosa during absorption by COMT and MAO enzymes which are present there and in the liver when circulates through the portal circulation. Because of its local vasoconstriction effect, the absorption of epinephrine from the subcutaneous tissues is also very slow. But after intramuscular injection absorption of EPI is more rapid. In emergencies, EPI is always used by IV route. When EPI is used by inhalation or through a nebulizer, then its action is largely restricted locally to the respiratory tract. However, arrhythmia may also occur, if a large amount of EPI is used through this route.

Epinephrine (EPI) is metabolised and inactivated by COMT and MAO enzyme which are present in all the body tissues, plasma and liver. The liver is rich in both the enzymes and is particularly important in this regard.

Administration and preparations: Epinephrine is unstable in alkaline solutions. So, it is always prepared in an acidic medium. It should always be protected from the air and light. Because, in air and light, the EPI is oxidised to adrenochrome which then turns from pink to brown due to the formation of its polymers.

EPI is used in different clinical conditions and through different routes, such as subcutaneous (most common), IV (during emergencies), inhalation and topical

(specific). So, a variety of formulation of EPI with different strength and concentration are available in market for use through different routes. The epinephrine injection which are available in different strengths are : 1:100 (10 mg/ml), 1:1000 (1 mg/ml), 1:10000 (0·1 mg/ml), 1:100000 (10 µg/ml) and 1:200000 (5 µg/ml). The patients vary tremedously in their response to catecholamines. Therefore, a patient's response should be carefully titrated with the dose of EPI when used through any route. During administration of EPI, appropriate measures should be taken to monitor the renal, cerebral and myocardial perfusion which is more important than a rigid adherence to the theoretical dosing scheme. An infusion rate of 1 to 2 µg/min of EPI predominantly activates the β_2 adrenergic receptors, causing vascular and smooth muscle relaxation. On the otherhand, a rate of 2 to 10 µg/min of EPI infusion activates both the $\beta_1$and β_2 receptors causing an increased heart rate, ↑conduction through the AV node and ↑contractility of the heart. Dose of EPI in excess of 10 µg/min by infusion causes marked α-stimulation with resultant generalised vasoconstriction and ↑BP.

EPI is a potent renal vasoconstrictor, acting directly through the stimulation of α-receptor and indirectly by the stimulation of the release of renin. So, to avoid the renal ischaemia dopamine in renal dose is frequently combined with the IV doses of epinephrine. The usual subcutaneous therapeutic dose of EPI in an adult is 0.3 to 0.5 mg. However, absorption of subcutaneous EPI is extremely slow. This is due to the intense local subcutaneous vasoconstriction. The effect of very large subcutaneous doses of epinephrine such as 0.5 to 1.5 mg, is roughly equivalent to an intravenous infusion in the dose of 10-30 µg/min which can result in life-threatening ventricular arrhythmias, hypertension and cerebral haemorrhage.

The normal dose of epinephrine by IV infusion during management of hypotension or shock is 0.01 to 0.1 µg/kg/min which is titrated according to the response. In emergency, the IV route for administration of EPI is preferred and the drug is used very slowly and very cautiously by diluting the solution. The IV dose is seldom exceeds 0.25 mg, except in cardiac arrest when the large doses can be used (3 to 5 mg or more) according to the response. In very emergency conditions such as asystole, VF, EMD and anaphylactic shock the recommended dose of epinephrine is 0.5 to 1 mg/70 Kg IV. The aim of this higher dose of EPI is to maintain the myocardial and cerebral perfusion by increasing the mean arterial pressure through intense peripheral vasoconstriction. However, more higher doses of EPI greater than 0.1 mg/Kg also have been studied during resuscitation of cardiac arrest, but does not appear to improve the rate of survival in adults. This higher dose of EPI is used only when the usual doses fail to respond. The endotracheal doses of EPI in emergency situations, when IV route is not available, should be at least double of the IV dose and is diluted in 10 ml of normal saline solution in adult patients. This is because epinephrine is well absorbed from the tracheal mucosa. 1% (1:100) formulation of EPI is only used for inhalation and should never be used for parenteral route. This is because inadvertent IV injection of 1:100 solution can be fatal. Inhaled EPI constricts oedematous mucosa and may be used in the treatment of severe croup and traumatic airway oedema. For inhalation, 1% solution of epinephrine is diluted with water or saline in 1:4 ratio and nebulized. This treatment can be repeated every 2 hours, with effects lasting for 30 to 60 minutes.

Adverse effects and contraindications: EPI causes more or less serious adverse effects. Less serious, but common adverse effects of epinephrine are transient restlessness, palpitation, anxiety, tremors, throbbing headache, etc. On the otherhand, more serious, but less frequent adverse effects are cerebral haemorrhage, angina, cardiac arrhythmias, etc, and all these are due to the large doses of EPI. The use of EPI is contraindicated in hypertensive, hyperthyroid and angina patients. It should be given cautiously during halothane anaesthesia and to patients who are receiving non-selective β-blockers. This is because its unopposed actions on the vascular α_1-adrenergic receptor may lead to severe hypertension. Halothane is known to sensitize the heart to catecholamines (CAS). So, the dose of epinephrine should be limited to 1 µg/Kg/30 min in the presence of halothane and to 3 µg/Kg/30 min in the presence of isoflurane and sevoflurane. CAS decreases the refractory period and thus renders the heart more susceptible to arrhythmias. Preexisting use of α_1- blockade can cause the paradoxical phenomenon of EPI reversal, because as the β_2-vasodilating effects are unmasked.

Therapeutic uses: EPI has limited therapeutic uses. But its major use is to provide a rapid relief during hypersensitivity reactions including anaphylaxis, arising from drugs and other allergens. Its cardiac effects may be of use in restoring the cardiac rhythm in patients with cardiac arrest. Other therapeutic uses of EPI are with local anaesthetics or as topical haemostatic agents, or for inhalation in the treatment of postintubation or infectious croup (Table 11.14).

When used with local anaesthetics or applied locally on the mucosal surface to stop bleeding, then the α receptor-mediated vasoconstrictive effect of EPI decreases bleeding in that area and slows the vascular uptake of local anaesthetic agents. Thus, it decreases the peak serum level of the local anaesthetic agent and prolonges its duration of action. Several studies have shown that elevation in the plasma levels of EPI after local application is relatively modest, but substantially less than the levels, seen during the physiological stress.

Table 11.14: A general protocol for management of suspected anaphylaxis

1. Suspected drugs likely to cause anaphylaxis should be stopped immediately.
2. 100% O_2 should be given with maintenance of airway.
3. Feet should be elevated with the patient lying flat.
4. Epinephrine should be used immediately. The recommended dose is 50 to 100 μg (0.05 to 0.1 ml of 1:1000 solution) IV over 1 minute, for hypotension with titration for further doses, as required.

   In patients with severe cardiovascular collapse, 0.5 to 1 mg (0.5 to 1 ml of 1:1000) may be required intravenously, in divided doses by titration. This should be given at a rate of 0·1 mg/min, stopping when a response has been obtained.

   Alternatively, epinephrine may be given IM in a dose of 0.5 to 1 mg (0.5 to 1 ml 1:1000) and may be repeated every 10 minutes according to the arterial pressure and pulse, until improvement occurs.
5. Intravascular volume expansion with crystalloid or colloid should be started immediately.
6. As a secondary measure, corticosteroids (100 to 300 mg hydrocortisone IV) and antihistamines (chlorpheniramine 10 to 20 mg by slow IV) are also given.
7. Catecholamine infusion is started:

   Epinephrine - 0.05 to 0.1 μg/Kg/min

   Norepinephrine - 0.05 to 0.1 μg/Kg/min
8. Sodium bicarbonate can be considered for acidosis (0.5 to 1 m.mol/Kg IV)
9. Bronchodilators may be required, if there is bronchospasm.

Management of patient with suspected anaphylaxis:

As soon as an anaphylaxis is suspected in a patient, it should be controlled by the following basic steps, which are given in table 11.14

2. Norepinephrine

Norepinephrine (NE) differs structurally from the epinephrine (EPI) by lacking the methyl substitution in amino group and is the major neurotransmitter among all the postganglionic adrenergic nerve endings. Normally, in adrenal medulla NE constitutes about 10 to 20% of the total catecholamine content. But, in pheochromocytoma, NE constitutes about 97% of the total catecholamine content in the adrenal medulla. This is due to the lack of enzyme, named N-methyl transferase.

Like EPI, the NE is also a direct adrenergic agonist, stimulating both the α and β receptors on the effector cells. But, the action of NE depends mainly on the ratio of its effectiveness on the α and β receptors. It is usually used for its potent α-agonism. NE is a potent agonist of α-receptors and has a relatively lesser action on β-receptors (than EPI). So, the peripheral or systemic vascular resistance is tremendously raised, due to the constriction of resistance vessels (α_1-action > β_2-action). This results in the elevation of systolic (β_1-action on heart, though less potent) and diastolic blood pressure (α_1-action on resistance vessel). Thus, pulse pressure is also increased. Cardiac output is unchanged or decreased (due to increase in systemic vascular resistance). Compensatory vagal reflex activity due to increased mean arterial pressure slows down the heart rate (↓HR). The increased systemic vascular resistance causes reduction of blood flow in the kidneys, mesenteric vessels, liver and other splanchnic areas. Coronary blood flow is increased due to the local coronary vasodilatation (here β-action predominantes over the α-action) and also due to the elevated aortic pressure. Patients with Prinzmetal's variant angina may be supersensitive to the α-adrenergic vasoconstrictor effects of NE. Unlike EPI, small doses of NE do not cause vasodilatation (in low doses, β-action of EPI predominates over α-action and the vessels dilate and cause reduction in BP) and does not reduce the blood pressure. The α-adrenergic blocking agents, therefore, abolish the pressor effects of the NE, but donot cause significant hypotension in low doses.

Other effects of NE, such as on bronchial muscles, mast cells, mucosa, eye, uterus, etc. are like EPI, but are not prominent in human beings. This is because, these are observed only when much larger doses of NE are given than EPI. So, NE is mainly considered as a pressor agent and is not considered as an effective 'hormone' like epinephrine.

Like epinephrine, NE is also not effective when given orally. It is also poorly absorbed through the subcutaneous route. It is rapidly metabolised in the body by COMT and MAO enzymes like EPI. Therefore, due to its short half-life of 2·5 minutes, a continuous infusion of NE is recommended. With less than 2 μg/min of infusion dose, the β stimulation effect of NE predominates. While with the usual infusion rate of more than 3 μg/min, peripheral vasoconstriction is elicitated from α stimulation of NE. Small amount of metabolites of NE are normally found in urine. But, in pheochromocytoma the concentration of metabolites of NE in urine is greatly increased.

The complications and contraindications of NE are similar to those of EPI. There is typical greater elevation of blood pressure by NE than EPI. The excessive doses can cause severe hypertension. So, careful monitoring of (Table 11.15) blood pressure is generally indicated during systemic administration of this agent. Blood pressure must be determined frequently during infusion and particularly during the adjustment of rate of infusion. Reduced blood flow to the organs such as the kidney and intestines impose a constant danger to these organs during the use of NE. So to ameliorate these renal effects, low dose of dopamine infusion also can be added to NE infusion. Pulmonary vascular resistance may be increased, so NE should be used with caution in patients with pulmonary hypertension. During IV infusion of NE, extravasation of drug can cause necrosis and sloughing of the tissues.

Like EPI, the NE has also limited therapeutic use. Like other sympathomimetic

Table 11.15: Dose dependent actions of adrenergic agents

Drug	*Receptor*	*Dose of infusion*
Norepinephrine	α_1 , β_1 , > β_2	4 to 10 μg/Kg/min (but much higher doses have been used in clinical practice)
Epinephrine	β_2 $\beta_1 + \beta_2$ α_1 Cardiac arrest	1 to 3 μg/Kg/min 2 to 10 μg/Kg/min > 10 μg/Kg/min 0.5 to 1 mg IV (bolus)
Dobutamine	$\beta_1 > \beta_2$, α_1	3 to 10 μg/Kg/min (but much higher doses have been used in clinical practice)
Dopamine	DA β α	1 to 3 μg/Kg/min 3 to 10 μg/Kg/min > 10 μg/Kg/min (or even higher doses)
Isoproterenol	$\beta_1 > \beta_2$	1 to 10 μg/min
Amrinone	Increase cAMP by PDE inhibition	0·75 mg/Kg/loading dose over 2 to 3 min, followed by 5 to 10 g/Kg/min infusion

amines, it is mainly used in shock to elevate the blood pressure. In the treatment of hypotension, the dose of NE is titrated to the desired pressure response.

Dose

2 to 4 μg/min by IV infusion.

3. Dopamine

It has been discussed in details in the chapter of heart failure.

ADRENERGIC AGONISTS

These include endogenous and exogenous catecholamines and non-catecholamine sympathetic amines. Among these endogenous catecholamines are discussed before. Here we will discuss only exogenous catecholamines and moncatecholamines which are adrenergic agoinst.

β-Adrenergic Agonists

The β-adrenergic agonists play a major role in the treatment of heart block and bronchoconstriction such as in patients with asthma or COPD. At first, for many years epinephrine was used as a bronchodilator. Later, ephedrine was introduced in 1924 as a bronchodilator. It has action on both α and β-receptors, but the action of ephedrine on β-receptors is more prominant than the α receptors. Then isoproterenol, a selective β-receptor agonist (both β_1 and β_2), without any α-adrenergic activity was developed in 1940. The recent development of β_2-selective adrenergic agonist with minimum β_1 cardiovascular effect and lack of α-adrenergic activity has changed the total scenario of management of asthma. But till now no selective β_1 agonist has been developed to control the cardiac problems. The drugs which are used as specific β_2 agonistic effect, but still in these group of drugs β_1 effect is greater than β_2 effect.

The specific β_1-adrenergic agonists are used to stimulate the rate and force of cardiac contraction. The chronotropic effect of specific β_1-adrenergic agonist is useful in the emergency treatment of arrhythmias, such as torsades-de-pointes, bradycardia, heart block etc. Whereas, the inotropic effect of specific β_1-adrenergic agonist is useful when it is desirable to augment the myocardial contractility.

(i) Isoproterenol

It is a potent nonselective β-adrenergic agonist with very low affinity or almost no action on α-receptors. It has powerful effects on both the β-receptors (β_1 and β_2), but its β_1-effect is significantly stronger than its β_2-adrenergic effects. The intravenous infusion of isoproterenol due to its prominent β_2-stimulating action relaxes the vascular smooth muscles (β_2-receptor dilates and α_1-receptor constricts the vascular smooth muscles), primarily of the skeletal muscles but also of the renal and mesenteric vascular beds, and lowers the SVR. So, diastolic pressure falls. But, systolic pressure is increased due to the positive inotropic and chronotropic effects of it (β_1 stimulating action). CO is increased due to the positive chronotropic and inotropic actions, coupled with decreased SVR. Large doses of isoproterenol may lead to palpitation, sinus tachycardia and more often serious arrhythmias. This is due to the strong β_1 effect of it. So, due to the development of other safe inotropes, its popularity has gradually declined, because of this side effects like tachycardia and serious arrhythmias. Isoproterenol helps in asthma, not only by bronchial smooth muscle relaxation (β_2-action), but also by inhibiting the antigen induced release of histamine and other mediators due to inflammation. But for many years in the treatment of bronchial asthma, isoproterenal has been replaced by other β_2-selective adrenergic agonists which cause lesser cardiac side effects.

During emergencies, isoproterenol is usually used parenterally by the IV route (infusion rates at 0.5 to 10 μg/min for adults) to increase the heart rate in patients suffering from severe bradycardia on heart block, particularly in anticipation with implantation of cardiac pacemaker or in patients with ventricular arrhythmia like torsades-de-pointes. In the past, it has been used in the treatment of bradycardia or heart block which is resistant to atropine. But, now it is no longer a part of the Advanced Life Support Protocol. It is readily absorbed when given by other parenteral routes, for example, as an aerosol, subcutaneous injection, etc. It is metabolised primarily in the liver and other tissues by COMT. Isoproterenol is a relatively poor substrate for MAO and is not taken up by the sympathetic nerve terminals to the same extent as NE and EPI. The duration of action of isoproterenol is, therefore, longer than that of EPI, but is still brief.

(ii) Dobutamine

It has been discussed in details in the heart failure chapter, along with dopamine.

β_2-Selective Adrenergic Agonist

As already discussed, nonselective β-adrenergic agonist, used in the treatment of asthma, also causes stimulation of β_1-adrenergic receptors in the heart. So, the drugs with preferential affinity for β_2-receptors than β_1-receptors have been developed. However, this selectivity is not absolute and at higher doses this preferentiality for β_2 than β_1 receptors becomes blurred. In addition, β_2-receptor stimulation in the SA node causes tachycardia.

The other aim to increase the usefulness of a selective β_2-receptor agonist in the treatment of asthma by modifying the structure of it is to lower the rates of metabolism of this drug and thus prolonging the therapeutic benefits and enhancing the oral bioavailability of it. This can be done by placing hydroxyl group at position 3 and 5 or substituting another moiety for the hydroxyl group at position 3 of phenyl ring of the β agonist. Thus this results in drugs, such as metaproterenol, terbutaline and albuterol (salbutamol) etc and these are not substrates for COMT. Thus, the addition of a bulky structure to the amino group of catecholamine increases the β_2 selectivity, decreases the affinity for α-receptor, and protects it against metabolism by COMT.

The another strategy for enhancing the preferential β_2 receptor activity of these drugs is to administer them by inhalation. This activates only the β_2 receptor in the airways and causes less systemic drug concentration. Thus, the less systemic drug concentration of the β_2 agonist prevents the activation of cardiac β_1 receptors and skeletal muscle β_2 receptor (stimulation of β_2 receptor of skeletal muscle causes tremor and limits the oral therapy). The β_2 adrenergic agonists given by aerosol have very rapid thrapeutic actions, generally within minutes (except salmeterol which has a delayed onset of action). Response to aerosol therapy depends on the technique of delivery of drugs to the distal airways which in turn depends on the size of the particles of the drug in aerosol, inspiratory flow rates, tidal volume, breath holding time and air way diameter. Only about 10% of the inhaled dose actually enters the lungs. Much of the remainder is swallowed and ultimately is absorbed through the stomach. Successful therapy by inhalation of β_2 adrenergic agonist requires each patient to be master regarding the inhalation technique of drug administeration. Whereas, particularly the children and elders fail to use the optimum technique. So, in these patients, spacer devices enhance the efficacy of inhalation therapy.

Other than the activation of pulmonary β_2 receptors and decrease of airway resistance, the selective β_2 adrenergic agonists have other major therapeutic effects in asthma, such as suppression of the release of leukotrienes and histamine from the mast cells in lung tissues, enhancement of mucociliary function, decreased microvascular permeability and inhibition of phospholipase A_2. It is becoming increasingly clear that airway inflammation is directly involved in airway hyper-responsiveness. So, the use of antiinflammatory drugs, such as inhaled steroids may also have primary importance.

The adverse effects of selective β_2 adrenergic agonists are due to the additional excessive side activation of β_1 adrenergic receptors. Hence, in patients at risk of underlying cardiovascular diseases this adverse effect can be reduced by administering the drug by inhalation, rather than orally or through other parenteral routes. Susceptibility to arrhythmia caused by these selective β_2 agonistic agents is due to the direct cardiac stimulation by β_1 or by β_2 induced hyperkalaemia. Skeletal muscle tremor (β_2 effect) is a relatively common adverse effect of β_2 selective adrenergic agonist. However, tolerance generally develops to this effect, but it is not clear whether this tolerance is due to the desensitization of β_2 receptors on skeletal muscles or adaptation in CNS. Tachycardia is another common adverse effects of β_2 adrenergic agonists and is primarily due to the β_1 receptor stimulation of the heart. It is still uncertain, to what extent the increase in heart rate is due to the activation of cardiac β_1 receptor or is due to the reflex effect that stems from the β_2 receptor mediated peripheral vasodilatation. However, during severe asthmatic attack, the HR may actually decrease during therapy with β_2 adrenergic agonist and it is due to the improvement of pulmonary function with consequent reduction of endogenous cardiac sympathetic stimulation. In patients with cardiac diseases, β_2 adrenergic agonists rarely cause significant arrhythmias or myocardial ischaemia. But, patients with underlying coronary artery disease or pre-existing arrhythmias are at greater risk. The risk of adverse cardiaovascular effects also increases in patients who are receiving other sympathomimetic drugs or MAO inhibitors.

Long term systemic administeration of β_2 adrenergic agonists, leads to down regulation of β_2 receptor and decreases its pharmacological responses. Chronic use of these drugs may also increase the airway hyperactivity. However, it appears that the tolerance to the pulmonary effect of these drugs is not a major clinical problem for majority of the asthmatic patients who do not exceed the recommended dosage of the β_2 adrenergic agonist and when given by inhalation.

When given parenterally, the selective β_2 adrenergic agonists may increase the concentration of plasma glucose, lactate and free fatty acids. Plasma K^+ concentration is increased and it may be especially important in patients with cardiac disease, particularly those taking cardiac glycosides and diuretics. Therefore, hyperglycemia may be worsened by these drugs and higher doses of insulin may be required. All these adverse effects of selective β_2 agonists are far less likely with the inhalation route, than with the oral or other parenteral routes.

Examples of some β_2 selective adrenergic agonists are metaproterenol (orciprenaline), albuterol (salbutamol), feneterol, formoterol, salmeterol, isoetharine, terbutaline, etc.

(i) Metoproterenol

Though metaproterenol is a selective β_2 adrenergic agonist, but less selective than terbutaline and albuterol (salbutamol). It is resistant to methylation by COMT. So, it is absorbed in the active form after oral administeration. Effects occur within minute of inhalation of metaproterenol and persists for several hours. However, after oral administration the onset of action is slower and its effects last for 3 to 4 hours.

(ii) Albuterol (Salbutamol)

It is also a selective β_2 adrenergic agonist and all the pharmacological actions of it are similar to terbutaline. It may be administered by inhalation or orally. When administered by inhalation, it produces significant bronchodilatation effect within 15 minutes and action lasts for 3 to 4 hours. The CVS effects of salbutamol is considerably weaker than those of isoproterenol, when the equivalent doses that produce comparable bronchodilatation are administered by inhalation.

(iii) Terbutaline

It is also a β_2 selective adrenergic agonist and is not a substrate for methylation by COMT. It can be administered orally or by inhalation or by parenteral (subcutaneous) routes. Effects are very rapid after inhalation or subcutaneous injection. After inhalation, the action of terbutaline persists for 3 to 6 hours. With oral administration, the onset of action is delayed by 1 to 2 hours.

α_1 Selective Adrenergic Agonists

The action of α_1 adrenergic receptors are predominant on vascular smooth muscles (though both α_1 and α_2 are present) and activation of both α_1 and α_2 receptors causes vasoconstriction, causing increased systemic vascular resistance (SVR) and increased BP. So, α_1 adrenergic agonists are useful in the treatment of hypotension and shock, and where peripheral vasoconstriction is needed, as in the treatment of hypotension in spnial anaesthesia. Phenylephrine and methoxamine are directly acting selective α_1 agonists. Whereas, mephenteramine and metaraminol are both the directly and indirectly acting selective α_1 adrenergic agonists. The indirect action means, a portion of the effect of the drug is mediated through the release of endogenous norepinephrine.

(i) Methoxamine

It is a selective, directly acting α_1 adrenergic agonist and increases the SVR and BP. It has no action on β adrenergic receptors and does not cause cardiac stimulation. The increase in BP is associated with reflex sinus bradycardia. This is because of the activation of vagal reflexes. Atropine can counteract this bradycardia. Methoxamine is administered through IV in the treatment of hypotension and shock.

(ii) Phenylephrine

It is also a directly acting selective α_1 adrenergic agonist. But, at very high concentrations, it may also activate the β receptors. The pharmacological actions of phenylephrine are similar to those of methoxamine and are used by intravenous infusion to raise BP. When given intravenously, phenylephrine has a rapid onset and relatively short duration of action (5 to 10 minutes). It may be given by bolus doses of 40 to 100 µg or by infusion at a starting rate of 10 to 20 µg/minute. Phenylephrine is also used as a mydriatic, nasal decongestant, and with local anaesthetics.

(iii) Mephentermine

It acts by both directly and indirectly stimulating the α_1 and β_1 receptors. Direct stimulation means, mephentermine produces both cardiac stimulation and vasoconstriction by directly activating α_1 (predominant) and β_1 (lesser extent) adrenergic receptors. Indirect stimulation means it acts by releasing endogenous norepinephrine (NE). It enhances the cardiac contraction and increases CO. Both the systolic (due to enhanced cardiac contraction and CO) and diastolic blood pressure (due to peripheral vascular constriction and increase in SVR) increases. The ultimate increase or decrease in CO depends on the increase in afterload and preload caused by mephentermine. If SVR increases tremendously, then CO may fall. In haemorrhagic shock naturally there is an increase in SVR and in the force of cardiac contraction due to the release of large amount of endogenous CAS. But still the CO falls and this is due to the severe reduction of preload (Table 11.16), reflecting severe hypotension. In spinal anaesthesia, there is reduction of SVR (afterload) which may increase the CO. On the otherhand, reduction of venous return (preload) may decrease the CO. But, the ultimate reflection of hypotension in spinal anaesthesia is due to ↓SVR, ↓preload and ↓CO. If the reduction of BP is not much below the level of 20% of MAP, then in such situations there is a definite increase in CO due to ↓SVR only (after load). But this small

Table 11.16: Adrenergic agonists and their receptors

Epinephrine (EPI)	α_1 , α_2 , β_1 , β_2 (no β_3 action or weak)
Norepinephrine (EPI)	α_1 , α_2 , β_1 , β_3 (no β_2 action or weak)
Isoprenaline	β_1 , β_2 , β_3 (no α action)
Dopamine	D , β_1 , α_1 (Dopamine receptor-D, predominates)
Dobutamine	α_1 , β_1 , β_2 (β_1 predominates)
Salbutamol	β_1 , β_2 (β_2 predominates)
Methoxamine	α_1 , β_1 (α_1 predominates)
Phenylephrine	α_1
Mephentermine	α_1 , β_1 (α_1 predominates)
Metaraminol	α_1 , β_1 (α predominates over β)

fall of BP is due to the slight reduction of preload, which is not upto that extent causing reduction of CO and severe hypotension. So, mephentermine is used to prevent hypotension which frequently accompanies spinal anaesthesia, in titrable doses to keep the BP at the preoperative level or within 20 to 25% of MAP.

The direct positive chronotropic effect of mephentermine on heart is generally counter balanced by the indirect vagal stimulation due to the rise in mean BP. So, the change in HR is variable, depending on the degree of vagal tone which again depends on BP. All the adverse effects of mephentermine are related to excessive rise of BP causing LVF, pulmonary oedema, etc, and arrhythmia (β_1 effect). Mephentermine is not a substrate for either MAO or COMT. So, it is orally active with longer duration of action (2 to 6 hours). It can cross the blood brain-barrier partially and so produce excitatory CNS effects at higher doses. During the treatment of hypotension the dose of mephentermine is usually titrated according to the fall of BP. It is presented as 15 mg in 1 ml amp or 3 mg/ml in 10 ml vial. Mephentermine is now used mainly to prevent and treat hypotension due to spinal anaesthesia.

(iv) Metaraminol

Metaraminol is a synthetic sympathomimetic amine. Like mephentermine, it is also a direct and indirect acting adrenergic agent that has agonistic effects on both α and β adrenoreceptors, although the α agonistic activity predominates. So, its main action is peripheral vasoconstriction.

Metaraminol causes a sustained increase in systolic and diastolic blood pressure, due to the increase in SVR and CO. But, the increase or decrease of CO depends on the elevation of SVR and preload. It also increases the pulmonary vascular resistance. Like mephentermine a reflex bradycardia also occurs with rise of BP. Like epinephrine the coronary blood flow is increased by metaraminol by an indirect mechanism.

It causes a slight decrease in respiratory rate and an increase in tidal volume. The cerebral blood flow is decreased by the administration of metaraminol. The renal blood flow is also decreased by it due to the renal vasoconstriction. The drug causes contraction of the pregnant uterus.

Metaraminol increases the glycogenolysis and inhibits the release of insulin, leading to hyperglycaemia. Lipolysis is similarly increased by it. The drug may also increase the O_2 consumption and body temperature.

Like mephentermine, metaraminol also causes CNS stimulation and produces headache, dizziness, tremor, nausea and vomiting. Rapid and large increae in blood pressure, resulting in LVF and cardiac arrest have also been reported after the administration of metaraminol.

Metaraminol is mainly used by intravenous infusion, diluted in saline or dextrose and the dose should be titrated according to the response. Bolus doses of 0.5 to 5 mg of metaraminol may be administered intravenously, but with extreme caution. Its onset of effect after IV administration occurs within 1 to 2 minutes, with maximum effect at 10 minutes and lasts for 20 to 60 minutes. The corresponding IM or SC dose of metaraminol for the prevention of hypotension is 2 to 10 mg.

Metaraminol is used as an adjunct for the treatment of: (i) hypotension occuring during general or spinal anaesthesia and (ii) for the management of hypotension, occurring during cardio-pulmonary bypass.

α_2- Selective Adrenergic Agonists

Many blood vessels contain α_2 receptors that promote vasoconstriction on stimulation. So, clonidine as a selective α_2 adrenergic agonist was initially developed as a vasoconstricting nasal decongestant. But, later it was found that clonidine, reduces the blood pressure by activating the presynaptic α_2 adrenergic receptors present in the CNS which controls the CVS. Such central presynaptic α_2 adrenergic receptor activation supressses the outflow of sympathetic nervous system activity from the brain. Therefore, there is a contradiction between the peripheral action of clonidine, causing hypertension and its central action, causing hypotension. But, the ultimate or resultant effect of clonidine depends on the predominancy of the site of action of the drug. As for example, when the clonidine is given intravenously, then there is acute rise in BP. This is due to the predominant activation of α_2 receptors in peripheral vascular smooth muscles. After IV administration, transient vasoconstriction and hypertension caused by clonidine is followed by hypotension which results from the decreased central outflow of impulse from central sympathetic nervous system. However, this hypertensive response of clonidine that follows parenteral administration is not seen when the drug is given orally.

(i) Clonidine

When clonidine was first synthesized in 1960, it was used to produce vasoconstriction (as a nasal decongestant) that was mediated through the stimulation of local peripheral α_2 adrenergic receptors on vascular system. But, later when clonidine was used, it was found that clonidine can cause hypotension, sedation, analgesia and bradycardia. Then, it was postulated that this action of clonidine is mediated through the central presynaptic α_2 adrenergic receptors.

The probable mechanisms of hypotension and analgesic effect of clonidine are:

i. Activation of the presynaptic α_2 receptors by clonidine in the lower brain stem region decreases the discharge from sympathetic preganglion fibres in the splanchnic nerve, as well as in the postganglionic fibres of the cardiac nerves.
ii. Clonidine also stimulates the parasympathetic outflow and this may contribute to the slowing of heart rate.
iii. Some of the antihypertensive effects of clonidine may also be mediated by activation of the presynaptic α_2 receptors

that suppress the release of norepinephrine from the preganglionic nerve endings.

iv. α_2 receptors are also located on the primary afferent terminals (peripheral and spinal) of the neurons of the superficial laminae of the spinal cord, and within several brain stem nuclei which are responsible for analgesia. This explains the analgesic effect of the α_2 receptor ago nist, clonidine.

v. Similar to a local anaesthetic agent, α_2 adrenergic agonists have also been found to produce the dose dependent blockade of conduction in nerve fibres, particularly of the C fibres than A-δ fibres. This can explain the local anaesthetic property of clonidine.

vi. Additionally, clonidine hyperpolarizes some neurons of the dorsal horn and renders them less resposive to afferent impulses. Thus, it can produce analgesia.

vii. Neuro-axial administeration of clonidine directly inhibits the sympathetic preganglionic neurons in the spinal cord. So, local anaesthetic agents when is combined with α_2 adrenergic agonists can increase the degree of sympatholysis, resulting in severe hypotension.

viii. Similar to opioids, clonidine also decreases the afferent noxious inputs through its interaction with the specific receptors in the spinal cord which are G-protein coupled. Like opioids, clonidine also reduces the substance P and the excitatory amino acids, which are released by peripheral nerves stimulation at noxious intensities.

Clonidine is well absorbed after oral administration. Bioavailability is 100% through the oral route. Peak effect of clonidine is observed within 1 to 3 hours after oral administeration and duration or half-life is 12 hours.

The major adverse effects of clonidine are dry mouth and sedation. Sexual dysfunction may occur. Marked bradycardia and hypotension is observed in some patients.

The major therapeutic use of clonidine is in the treatment of hypertension. Now, clonidine is useful in selected patients receiving anaesthesia, because it decreases the requirement of anaesthetics agents and increases the haemodynamic stability. Other potential benefits of clonidine in anaesthesia include preoperative sedation, anxiolysis, drying of secretions and analgesia.

(ii) Methyldopa

Methyldopa is also a selective α_2 adrenergic agonist and its antihypertensive action is exerted through its central action like clonidine which is by inhibiting the adrenergic neuronal outflow from the brain stem. Actually the methyldopa is a prodrug and an analog to DOPA. It is metabolized by decarboxylase in the adrenergic neuron to α-methyl-dopamine which is then converted to α-methyl norepinephrine. After that this α-methyl norepinephrine (which is called false neurotransmitter) is stored in the vesicles at the adrenergic nerve endings and acts as a false adrenergic neurotransmitter, replacing or substituting the true norepinephrine. Thus, when the adrenergic neuron discharges its neurotransmitter, then α-methyl norepinephrine is released instead of NE. As a vasoconstrictor (peripheral $\alpha_2$adrenergic agonistic action) α-methyl norepinephrine is as potent as NE (but NE has both α and β agonistic action). But, α-methyl norepinephrine acts in the brain to inhibit the adrenergic vasoconstrictive outflow and this central effect, which predominates than the peripheral effect, is principally responsible for its antihypertensive action.

Methyldopa reduces the peripheral vascular resistance (afterload) and preload. Thus, the increase or decrease of cardiac output depends on the intensity of reduction of afterload and preload. If afterload reduction is more than preload (younger patients with uncomplicated essential hypertension) CO increases. Alternatively, if preload reduction is more than afterload (as in older patients), then CO falls with a reduction in the stroke volume. Symptomatic orthostatic hypotension is less common with methyldopa than other antihypertensive agents which act on peripheral adrenergic receptors or autonomic ganglia. This is because methyldopa does not block baroreceptor mediated vasoconstriction. For this reason, it is well tolerated during surgical anaesthesia. Any severe hypotension produced by methyldopa can only be reversed by volume expansion, but not by a peripheral α-adrenergic agonist. This is because methyldopa does not block the peripheral α-receptors. In hypotension, like spinal anaesthesia where adrenergic neurons are blocked, peripheral α-adrenergic agonists are antidotes. But this is not possible in hypotension produced by methyldopa.

Renal blood flow and renal function is maintained during treatment with methyldopa. Plasma concentration of NE falls in association with the reduction of arterial pressure during treatment with methyldopa and this reflects the decrease in sympathetic tone, discharged from the CNS. In contrast, the reduction of BP by vasodilators is associated with the increased concentration of NE in plasma. Renin secretion is reduced, but this is not the major effect and is not responsible for the hypotensive effect of methyldopa.

In the brain, methyldopa acts on the α_2 adrenergic rceptors and inhibits the centres that are responsible for wakefulness and alertness. Thus, it produces sedation, drowsiness and depression. The medullary centres that control salivation are also inhibited by α_2-adrenergic receptors, and so methyldopa produces dryness of mouth. Other CNS effects of methyldopa include reduction in libido, parkinsonian signs, hyperprolactinemia and gynecomastia.

Methyldopa is absorbed actively through the GI tract by amino acid transport system, when administered orally. Its transport into the CNS is also an active process. So in spite of rapid absorption, the peak action of methyldopa is delayed by about 6 to 8 hours, even after an IV administration. This is due to the time taken by methyldopa to convert to its

active metabolites, α-methyl norepinephrine. The duration of action of a single dose of methyldopa usually lasts for about 24 hours.

Methyldopa is an active antihypertensive agent, but is not usually used as the first line of treatment. This is because of its frequent side effects, such as hepatotoxicity and haemolytic anaemia (Coomb's test becomes positive and that is due to the autoantibodies directed agonist - the Rh locus on erythrocytes). Therefore, methyldopa is reserved for patients in whom it may have a special value. For example, it is the preferred drug for treatment of hypertension during pregnancy which is based on its effectiveness and safety for both the mother and foetus.

Other Selective α_2 Adrenergic Agonist

(i) Apraclonidine

It reduces the formation of aqueous humour and is usually used topically to reduce the intraocular pressure.

(ii) Guanfacine

It is a more selective α_2 agonist than clonidine and has less side effects. Its mechanism of action is same as clonidine and is used in the treatment of hypertension.

(iii) Guanabenz

It is also selective α_2 adrenergic agonist. Its mechanism of action and therapeutic effects are similar to that of clonidine and guanfacine.

(iv) Tizanidine

It is also a selective α_2 adrenergic agonist, and is used as a muscle relaxant in the treatment of spasticity, associated with cerebral and spinal disorders.

(v) Brimonidine

Being a α_2 agonist, it is used topically to lower the intraocular pressure in patients with ocular hypertension or open angle glaucoma.

Miscellaneous Adrenergic Agonists

Ephidrine

It is both the α and β adrenergic receptor agonist (direct action) and also enhances the release of endogenous NE from the sympathetic neurons (indirect action). By its α action it increases the systemic vascular resistance (SVR) and BP, and by its β action it increases HR and CO. Ephedrine increases the coronary blood flow. It is a respiratory stimulant and also causes bronchodilatation. It is a potent CNS stimulant. Like amphetamine, it increases the cerebral blood flow. Mydriasis occurs after topical use. Ephedrine constricts renal blood vessels and may lead to a decrease in both the renal blood flow and GFR. It is not metabolised by MAO or COMT. So, it is also effective after oral administeration and this effect lasts for many hours. Ephedrine is excreted through the urine, largely as an unchanged form.

Previously, ephedrine was used in (i) Stokes, Adams attack, (ii) as a CNS stimulant in narcolepsy and depressive states, (iii) as bronchodilator in bronchial asthma, (iv) in urinary incontinence, etc. But now-a-days, ephedrine is replaced by more specific drugs for each disorder. Recently, ephedrine has only been used to treat hypotension occurring with spinal anaesthesia.

Untoward effects of ephedrine include the risk of hypertension, particularly after parenteral administeration or with higher than recommended oral dose. The parenteral dose of ephedrine is 3 to 30 mg which is titrated according to the response.

Other miscellaneous adrenergic agonists

Other miscellaneous adrenergic agonists are: amphetamine, methyl amphetamine and methyl phenidate.

Several sympathomimetic drugs, used primarily as a vasoconstrictor of nasal mucous membrane, when used topically are: propyl hexedrine, naphazoline HCl, tetra hydroxoline HCl, oxymetazoline HCl and xylometazoline HCl.

Phenylephrine, pseudoephedrine and phenylpropanolamine are the sympathomimetic drugs that have been used as oral preparation for the relief of nasal congestion.

USES OF SYMPATHOMIMETIC AGENTS IN HYPOTENSION AND SHOCK

Drugs with predominant α adrenergic activity can be used to raise BP in patients with decreased SVR, due to failure of sympathetic nervous system, such as: spinal anaesthesia, overdose of antihypertensive medications, etc. However, slight hypotension is not an indication for treatment by these agents, if there is adequate perfusion of vital organs, such as : brain, kidney, heart and lungs. But, in patients with spinal anaesthesia, where there is severe or total failure of the sympathetic nervous system, use of vasopressor drugs to increase SVR and to maintain perfusion in the vital organs is indicated. A number of sympathomimetic agents have been used for this purpose. But, the ideal agents would cause arterial constriction, with relatively little arteriolar constriction (the primary side for systemic vascular resistance), which would not increase the afterload and will not reduce CO, although will maintain the BP. However, no such ideal agent is currently available. Only midodrine shows promise in treating hypotension with this idea.

In other forms of shock, such as: haemorrhage, loss of fluid, etc, where the sympathetic nervous system does not fail, but the accompanying fall in BP generally leads to marked activation of the sympathetic nervous system. This in turn, causes increased peripheral vasoconstriction and ↑SVR and also an increase in the rate and force of cardiac contraction. In the initial stage of shock, this mechanism tries to maintain BP and cerebral blood flow, but blood flow to the kidneys, skin and other organs may be decreased, leading to impaired production of urine and metabolic

acidosis. But, later when the SVR tremendously increases and the preload severely falls, due to more haemorrhage and loss of fluid, then CO drastically reduces, causing more hypotension. Thus a vicious cycle is set up.

So, the initial therapy of shock involves basic life support and a specific therapy, such as: fluid or blood for hypovolaemic shock, antibiotics for septic shock, emergency cardiac catheterisation or surgical revascularisation or even angioplasty for cardiogenic shock. Mechanical left ventricular assisting devices, such as: the intra-aortic balloon pump (IABP) also may be important in maintaining CO and coronary perfusion in critically ill patients. In the setting of severely impaired CO, failing blood pressure leads to intense discharge of sympathetic outflow (provided the sympathetic system is not blocked) and vasoconstriction. This may further decrease CO, as the damaged heart pumps against a higher peripheral systemic resistance or the afterload. In such situations, medical intervention is designed to optimise the CO by manipulation of the cardiac filling pressure (preload), myocardial contractility (pump) and peripheral vascular systemic resistance (afterload).

Preload may be increased by administeration of IV fluid or reducing the dose of diuretics and nitrates (nitrates reduce the preload by dilating the venous side of the vascular system). If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities of BP and flow. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic agonist may be used in an attempt to increase myocardial contractility or to modify the peripheral vascular resistance. In general terms, β adrenergic agonist increases the HR and the force of contraction, α adrenergic agonist increases the SVR and dopamine (in renal doses) promotes dilatation of renal and splanchnic vascular beds, in addition to activating β and α adrenergic receptors (in higher doses).

A number of sympathetic amines have been used to increase the force of cardiac contraction. But, some of these drugs have disadvantages. For example, isoproterenol is a powerful chronotropic agent and can greatly increase the myocardial O_2 demand. NE intensifies peripheral vasoconstriction and EPI increases the heart rate and may predispose the heart to dangerous arrhythmias. Dopamine is an inotropic agent that causes less increases in heart rate and promotes renal arterial dilatation. When dopamine is given in higher doses (>10 to 20 μg/Kg/min), it activates the α adrenergic receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions to increase the myocardial contractility with little increase in HR and peripheral resistance.

In most forms of shock, except few, where there is vasodilatation (e.g. spinal anaesthesia, septicaemia, anaphylaxis), there is intense reflex vasoconstriction. In such situations, the use of α adrenergic agonists may further compromise blood flow to the vital organs, such as: kidneys, brain, heart, guts, etc. as well as adversely increase the work of the heart. Indeed, in such situations, vasodilating drugs such as nitroprusside are more likely to improve blood flow in vital organs and decrease cardiac work by decreasing the afterload, if a minimally adequate blood pressure is maintained.

ADRENERGIC RECEPTOR ANTAGONISTS

α - Adrenergic Receptor Antagonist

Endogenous catecholamines (CAS), exogenous catecholamines and other non-catecholamine sympathomimetic or adrenergic agents mediate their actions through both the α and β or only through α and β receptor. Among these, the α_1 receptor mediated actions are confined only to the arterial and venous smooth muscle contraction.

Whereas the α_2 receptor mediated actions are:

i. Suppression of central sympathetic outflow.
ii. Increment of vagal tone.
iii. Facilitation of platelet aggregation.
iv. Inhibition of release of NE and ACh from presynaptic nerve endings.
v. Regulation of metabolic effects, including suppression of insulin secretion, inhibition of lipolysis, etc.
vi. Contraction of smooth muscles of some arteries and veins.

So, the α-adrenergic receptor antagonists have a wide range of pharmacological actions and every agent has different affinity for both the α_1 and α_2 receptors. For example, prazosin as a α receptor antagonist has greater affinity for α_1 than α_2 receptors. Whereas yohimbine is a selective α_2 antagonist and phentolamine has the same affinity for both receptors. α-receptor antagonists are also heterogenous in nature, because they vary widely in structure.

α_1 - Adrenergic receptor antagonist

Clinically, the most important effect of α_1 the receptor antagonist is observed in the cardiovascular system. Blockade of α_1 receptor causes vasodilatation and decrease in BP with decrease in SVR. This fall of blood pressure is more marked in upright than in supine position and in hypovolaemia. This fall in BP by α_1 receptor antagonist is usually counteracted by rise in HR and CO by reflex baroreceptor mechanism. There is also fluid retention during the use of α_1 adrenergic receptor antagonist.

The interaction between a α_1 receptor antagonist and a sympathomimetic amine (which sometimes occur in clinical practice) depends on the adrenergic agonist that is administered. For example: (i) Pressor response of phenylephrine can be completely suppressed by α_1 receptor

antagonist. (ii) Action of NE can be incompletely blocked by a α_1 receptor antagonist, because of residual stimulation of cardiac β_1 receptor by NE. (iii) Pressure response of EPI can be transformed to hypotension effects by the concomitant use of a α_1 receptor antagonist. This is because of the residual stimulation of β_2 receptors by EPI on the vasculature with resultant vasodilatation and hypotension.

α_1 receptor antagonist also inhibits the smooth muscle contraction of trigone, bladder sphincter and prostate, leading to decreased resistance to urinary outflow. Recent evidence suggests that there are two types of α_1 receptors such as α_{1A} and α_{1B}. Among these α_{1A} receptors are important in mediating catecholamines-induced prostatic smooth muscle contraction which can be inhibited by a specific α_{1A} receptor blocker, such as tamsulosin. Although, theoretically some α_1 receptors promote bronchial smooth muscle contraction, but the importance of α_1 receptor antagonist in asthma is minimal.

α_2 - Adrenergic receptor antagonist

α_2 receptors have an important role in the regulation of the activity of sympathetic nervous system, both peripherally and centrally. Activation of the presynaptic α_2 receptors inhibits the release of NE from the sympathetic nerve endings. Thus block of presynaptic α_2 receptors withdraw this inhibition and causes increased release of NE from the nerve endings, leading to activation of both α and β receptors in the heart and contraction of the peripheral vascular smooth muscles, with consequent rise in BP and SVR. Whereas the activation of presynaptic α_2 receptors in pontomedullary region of CNS inhibits sympathetic outflow and causes fall in BP. α_2 antagonist thus reverses this action and increases the sympathetic outflow and BP. Thus, on one side, the α_2 receptor antagonist increases the sympathetic outflow by acting peripherally on the receptors at presynaptic membrane and acting centrally at pontomedullary region. Thus, it increases the BP. On the otherside, α_2 antagonist directly blocks the peripheral vascular α_2 receptor which causes vasoconstriction and thus produces vasodilatation with decrease in BP.

Some α - Adrenergic Antagonists and their Therapeutic Uses

(i) Phenoxybenzamine

It irreversibly blocks both the α_1 and α_2 receptors (irreversible because furthur restoration of cellular responsiveness to α adrenergic agonists probably requires the synthesis of new receptors) and causes progressive lowering of BP and SVR. It is predominantly an arterial vasodilator. Thus, it increases the HR and CO (upto a certain level of fall of blood pressure) and this is due to reflex baroreceptor stimulation. During the use of phenoxybenzamine, pressor response of exogenously administered CAS is impaired and hypotensive response to EPI occurs. This is because of the unopposed β adrenergic receptor mediated vasodilatation by EPI. In normotensive subjects, BP in supine position is little affected by phenoxybenzamine. But, there is a marked fall in BP in standing position (orthostatic hypotension) and this is because of the antagonism of α receptor mediated compensatory vasoconstriction which is essential for maintaining BP in standing condition. In addition, the normal ability of a patient to respond to hypovolaemia and to anaesthesia induced vasodilatation is impaired by phenoxybenzamine, causing severe hypotension. The drug also increases the rate of peripheral turn over of NE. This is because the amount of NE that is released per nerve stimulation is increased by the blockade of presynaptic α_2 receptor. Phenoxy benzamine inhibits CAS induced cardiac arrhythmias. It also causes a shift of fluid from the interstitial to vascular compartment and it is due to vasodilatation of pre- and post-capillary resistance vessels.

The major clinical use of phenoxybenzamine is in the treatment of pheochromocytoma. A vast majority of pheochromocytomas are treated surgically. But this drug is used frequently to treat the patient where surgery is contraindicated or to prepare the patient for operation preoperatively. Initially phenoxybenzamine is started in the dose of 10 mg twice daily for 1 to 3 weeks before operation. Then, the dose is gradually increased till the desired lower level of BP is achieved. But the therapy by phenoxy benzamine may be limited by postural hypotension. The usual total daily dose of phenoxybenzamine in patient with pheochromocytoma is 40 to 120 mg which is given in two or three divided doses. The corresponding dose of phenoxy benzamine by intravenous infusion (diluted in dextrose or saline) over 1 hour is 10 to 40 mg. After the intravenous administration, the drug acts within 1 hour and has a duration of action for 3 to 4 days. Some anaesthesiologists donot routinely use phenoxybenzamine preoperatively for the preparation of patient before pheochromocytoma surgery. In patients with inoperable and malignant pheochromocytoma prolonged treatment with phenoxybenzamine may be necessary. Another approach for management of pheochromocytoma, particularly with a malignant disease, is administration of metyrosine. It is a competitive inhibitor of tyrosine hydroxylase which is the rate limiting enzyme in the synthesis of catecholamines. β adrenergic receptor antagonists or β blockers are also used to treat pheochromocytoma, but only after the administeration of an α receptor antagonist.

Phenoxybenzamine is the first α receptor antagonist which was also used previously for the treatment of benign hypertrophy of prostate (BHP). The mechanism of action of phenoxybenzamine in the treatment of BHP is the blockade of α receptors, situated on the smooth muscle of prostate and bladder base. Thus, it decreases the obstructive symptoms and decreases the need to urinate at night (α

receptor is responsible for the spasm of bladder trigone, bladder neck and prostate muscle, causing urinary obstruction). However, terazocine and other related drugs are safer and more preferred than phenoxybenzamine, as they are more specific α_1 adrenergic antagonists for this disorder.

The major side effects of phenoxybenzamine is postural hypotension which is accompanied by reflex tachycardia. Hypotension produced by α-antagonist may be severe, if there is hypovolaemia and there is history of concomitant use of vasodilator drugs.

(ii) Phentolamine and Tolazoline

Like phenoxybenzamine, phentolamine is also a competitive α adrenergic antagonist and have same affinity for both the α_1 and α_2 receptors. It also causes the blockade of 5 HT receptors and causes the release of histamine from mast cells. Tolazoline has similar function like phentolamine, but is less potent. Phentolamine and tolazoline both increase the G1 motility which can be antagonised by atropine.

Phentolamine can be used for a short-term basis to control hypertension in pheochromocytoma. Infusion of phentolamine may be used, but very cautiously. The adult IM dose of phentolamine for the control of paroxysmal hypertension is 5 to 10 mg. The drug may also be administered by IV infusion (diluted in dextrose or saline) at the rate of 0·1 to 0·2 mg/min.

(iii) Prazosin and related drugs

(a) Prazosin

It is also a potent selective α_1 adrenergic antagonist, with thousand fold greater affinity for α_1 receptor than α_2. But among the subtypes of α_1 receptors (α_{1A}, α_{1B}, α_{1D}) it has same affinity to all.

The pharmacological effects of prazosin are due to the result of blockade of α_1 receptors in arterioles and veins, leading to ↓ BP, ↓ SVR and ↓ preload. However, like other vasodilating drugs, it doesnot reflexly increase the HR at the clinical level. Again, it does not block the presynaptic α_2 receptor. Hence, it does not promote the release of NE from presynaptic sympathetic nerve endings in the heart. As the prasocin decreases preload more than afterload, so it does not increase CO (in contrast to vasodilators, such as hydralazine that have minimal dilatory effect on the veins). It also acts in the CNS and suppresses the central sympathetic outflow.

Prazosin is well absorbed when given orally with bioavailability of about 50 to 70%. Peak serum concentration through the oral route is generally reached within 1 to 3 hours after administeration.The plasma half-life of prazosin is 2 to 3 hours and the the duration of action is typically 7 to 10 hours. For the treatment of hypertension, prazosin is started initially in smaller doses such as 1 mg at bedtime, so that the patient is recumbent for at least several hours after its administration. Thus, it reduces the risk of syncopal reaction due to hypotension that may follow the first dose of prazosin. Then the dose is titrated upwards, depending on the blood pressure. The maximum effect of prazosin is generally observed with the total daily dose of 20 mg in patient with severe hypertension. For the treatment of benign prostatic hypertrophy (BPH), prazosin in the dose of 1 to 5 mg twice daily is usually used.

(b) Terazosin

It is structurally an analog of prazosin, but less potent than it. Like prazosin it is highly selective to α_1 receptors than α_2, with no discrimination among α_{1A}, α_{1B}, α_{1D} receptors regarding affinity. The oral bioavailability of terazosin is 90% and half life of elimination is approximately 12 hours with duration of action of 18 hours. The drug is taken as once daily dose to treat the hypertension and BPH. An initial first dose of 1 mg of terazosin is recommended. Then the doses are titrated upwards gradually, depending on the therapeutic responses. Terazosin in the dose of 10 mg/day may be required for maximal effect in BPH.

β-Adrenergic Receptor Antagonists

It has been discussed in the hypertension chapter.

CHOLINERGIC RECEPTOR (MUSCARINIC AND NICOTINIC) AGONIST AND ANTAGONIST

The cholinergic receptor agonists are the drugs or agents that act like ACh on both the cholinergic receptors, i.e. muscarinic and nicotinic. ACh is the endogenous cholinergic neurotransmitter which acts on both the muscarinic and nicotinic receptors. But there are other agents which also act selectively only on the muscarinic or the nicotinic receptors. So, they are called as the selective muscarinic or nicotinic receptor agonists, respectively.

Nonspecific Cholinergic Agonist

Acetylcholine (ACh)

It is an endogenous cholinergic neurotransmitter. It acts at all the cholinergic synapses in the central and peripheral nervous system of the body. Its actions are mediated through both the muscarinic and nicotinic receptors. Muscarinic receptors in the peripheral nervous system are primarily found on all the cells that are innervated by the preganglionic autonomic (sympathetic and parasympathetic) nerve fibre except the ganglionic cells, the postganglionic parasympathetic nerves and some postganglionic sympathetic fibres that supply the sweat gland, hair follicle and erector piloris. Muscarinic receptors are also present in the CNS and on certain other cells such as endothelial cells of blood vessels that receive little or no cholinergic innervation. Certain centres of the brain, such as hippocampus, cortex, thalamus, etc. also have a high density of muscarinic receptors. Nicotinic cholinergic receptors are only found at the

neuromuscular junctions, causing skeletal muscle contraction and at the peripheral autonomic ganglia (sympathetic and parasympathetic) including the adrenal medulla, because adrenal medulla itself is an autonomic ganglia.

As ACh acts on both the muscarinic and nicotinic receptors, so its pharmacological actions can also be divided into muscarinic and nicotinic actions.

(i) Muscarinic actions

It is due to the stimulatory action on muscarinic receptors. Muscarinic actions include actions on the heart, blood vessels, smooth muscles, glands, eye, viscera, mucous membrane, etc., where muscarinic receptors are abundantly present. Whereas, nicotinic actions include only actions on the skeletal muscles and autonomic ganglia where nicotinic receptors are only present.

(a) CVS

The main muscarinic effects of ACh on the CVS are vasodilatation, ↓ HR, ↓ conduction in heart, ↓ contractility of the cardiac muscle etc. ACh is not given systemically for any therapeutic indication. But, its importance lies within the mechanism of action of many cardiac glycosides, antiarrhythmic drugs, many other agents and following afferent stimulus from the viscera, during surgical intervention. IV small dose of ACh causes reduction of BP due to vasodilatation and there is reflex tachycardia due to reduction of BP. A relatively higher dose of ACh causes bradycardia and ↓ conduction in the cardiac tissues. However, IV large dose of ACh causes ↑ BP, specially after administration of atropine, which block the muscarinic receptors. This is caused by stimulation of the adrenal medulla and sympathetic ganglia by ACh which release CAS into circulation from adrenal medulla and at postganglionic sympathetic nerve endings (nicotinic actions).

ACh causes dilatation of both the pulmonary and coronary vasculature. This dilatation of coronary blood vessel is caused by the baroreceptor and chemoreceptor mediated reflex or by the release of NO. However, neither the parasympathetic vasodilator, nor the sympathetic vasoconstrictor fibre plays a major role in the regulation of coronary blood flow. It is effected by the local O_2 tension and local autoregulatory metabolic factors, such as: adenosine that determines the blood flow through coronary vessels. Though, most of the blood vessels do not receive cholinergic innervation, still the vasodilatation of it is mediated in response to ACh by the presence of muscarinic receptors on the endothelial cells, primarily of M_3 subtypes. When these receptors are stimulated by ACh, the endothelial cells release endothelium dependent releasing factor (EDRF) or nitric oxide, which diffuses to the adjacent smooth muscles and causes them to relax. Vasodilatation may also arise secondarily from the inhibition of release of NE from the adrenergic nerve ending by ACh.

Cholinergic parasympathetic fibres are extensively distributed in the SA node, AV node, atrial muscle, bundle of HIS, right and left bundle branch, and specialized conducting tissue of the heart, like purkinje fibres. The cholinergic innervation to ventricular myocardium is sparse. ACh acts on the cardiac tissues directly by stimulating the parasympathetic activity and indirectly by inhibiting the effects of adrenergic activity. The inhibition of adrenergic activity by ACh depends on the present level of sympathetic drive on the heart. Inhibition of this adrenergic drive by ACh, results partly from the inhibition of cyclic AMP formation and partly from the reduction in L-type Ca^{2+} channel activity. In SA node, the pacemaker activity of the SA nodal cells is caused by the presence of spontaneous diastolic depolarization phase or phase 4. At a critical level (i.e at the level of threshold potential), this spontaneous slow diastolic depolarization automatically initiates an action potential and a full cardiac cycle. ACh slows the heart rate by decreasing this rate of spontaneous diastolic depolarization and by increasing the repolarizing current (i.e., resting membrane potential become more negative) of SA nodal cells and thus delaying the attainment of threshold potential from RMP and delaying the cardiac cycle.

ACh also causes reduction of the force of contractility of cardiac muscles, slows conduction in conducting tissues and increases the refractory period. The decrement in AV nodal conduction is usually responsible for the complete heart block, that may be observed when large quantities of cholinergic agonists are administered systemically. With an increase in the vagal tone, (which acts through ACh neurotransmitter) such as: produced by digitalis glycosides, the increased refractory period of the AV node and the bundle of HIS can contribute to the reduction in frequency, with which the aberrant atrial impulses are transmitted to the ventricle and thus decreases ventricular rate during atrial flutter and fibrillation.

(b) Gastrointestinal, urinary tract and other smooth muscles

Smooth muscles of most of the organs are contracted by ACh as they are rich in muscarinic receptors. Thus, the tone and peristalsis of GI tract is increased and the sphincter relaxes, causing abdominal cramps and evacuation of bowel by ACh. Bronchial smooth muscles also contract by ACh, causing attack of bronchial asthma. Peristalsis of the ureter is increased. The detrusor muscles of urinary bladder contract, while the bladder trigone and sphincter relaxes by ACh, causing voiding of bladder.

(c) Glands

Secretion from all the cholinergically innervated glands is increased by ACh, causing salivation, sweating, lacrymation, etc. Tracheobronchial and gastric secretion is also increased by ACh. The secretion of pancreatic and intestinal glands also increases, but is not so marked. Secretion of milk and bile is not affected by ACh.

(d) Eye

Contraction of the constrictor muscle of iris by ACh causes miosis (constriction of the pupil). Contraction of ciliary muscles also cause loss of accommodation, increased outflow facility and reduction in intraocular tension.

(e) C N S

Naturally occurring cholinomimetic alkaloids such as pilocarpine, muscarine and aerocholin, etc. can cross the blood brain-barrier and evoke a characteristic cortical arousal and CNS stimulating response, which are similar to that produced by the injection of anticholinesterase agents. The arousal response of all of these three drugs can be reduced or blocked by atropine and related agents. But, choline esters e.g ACh, being a quarternary compound, does not cross the blood brain-barrier and does not produce any CNS symptoms.

(ii) Nicotinic actions

This is due to the stimulatory actions of nicotinic receptors. The nicotinic receptors are present in all the autonomic ganglia (both sympathetic and parasympathetic) and at the neuromuscular junctions of skeletal muscle.

i. **Autonomic ganglia:** Nicotinic receptors which are situated in both the sympathetic and parasympathetic (autonomic) ganglia can be stimulated by ACh, but only in higher doses. Higher dose of ACh, after IV atropine (to block the muscarinic action of ACh) causes ↑BP and tachycardia. This is called the nicotinic actions.
ii. **Skeletal muscle:** ACh causes contractions of skeletal muscles through the nicotinic receptor.

Nonspecific Cholinergic Antagonist

There is no such nonspecific single agent which blocks the action of ACh on both the muscarinic and nicotinic cholinergic receptor. All they are either muscarinic receptor or nicotinic receptor blocker. The specific muscarinic receptor antagonists and specific nicotinic receptor antagonists are discussed later.

Specific Muscarinic Receptor Agonists

The specific muscarinic receptor agonists can be divided into two groups:

i Some synthetic cholin esters → such as: methacholine, carbochol, bethanechol, etc.
ii. Naturally occurring cholinomimetic alkaloids → such as : pilocarpine, muscarine, arecoline etc.

Therapeutic uses of muscarinic agonist: Among the above mentioned muscarinic agonists, very few are used therapeutically. These are:

(i) Pilocarpine

Pilocarpine is obtained from the leaves of pilocarpus microphyllus and some other species of plants. It has prominent muscarinic actions and also stimulates the ganglia mainly through the ganglionic nicotinic receptors. It causes marked increase in sweating, salivation and other secretions as well. The cardiovascular effects of pilocarpine are complex. Small doses generally cause a fall in BP. But higher doses elicit a rise in BP and tachycardia, which is probably due to ganglionic stimulation (through the nicotinic receptos). Due to its high systemic toxicity, it is only used in ophthalmic medicine in the topical form. Applied to the eye, it penetrates the cornea and promptly causes miosis and ciliary muscle contraction. Thus, it reduces the intraocular pressure. So, the strength of 0.5 to 4% solution of pilocarpine is used in the treatment of glaucoma. It is usually better tolerated than anticholinesterase agents which by inhibiting the cholinesterase enzyme increases the level of ACh and produce the muscarinic actions. Pilocarpine is also used in the treatment of xerostomia following head and neck radiation and in Sjogren's syndrome by increasing the secretion from salivary and lacrimal glands.

(ii) Bethanechol

As bethanechol stimulates the smooth muscle contraction of the GI tract, so it is used in certain cases of postoperative abdominal distension, gastric atony or gastroparesis, in certain cases of congenital megacolon, adynamic ileus, etc. But, due to its many side effects prokinetic agents like metoclopramide (due to its combined cholinergic agonist and dopamine antagonist activity) and serotonin antagonist like ondansetron, have largely replaced bethanechol in the management of the previously mentioned disorders.

Bethanechol is also used in the treatment of urinary retention and inadequate emptying of the bladder, when organic obstruction is absent. The α adrenergic receptor antagonist are also useful in reducing the outlet resistance at the internal sphincter of urinary bladder.

Specific Muscarinic Receptor Antagonists (Anticholinergic Agents)

Specific muscarinic receptor antagonists only prevent the muscarinic action of ACh or other agonists by blocking their action only on the muscarinic receptors which are present at the neuroeffector sites of smooth muscles, cardiac muscles, glands, eye and CNS. These specific muscarinic receptor antagonists cannot block the action of ACh at the nicotinic receptor sites. In CNS the cholinergic transmission occurs both by the muscarinic and nicotinic receptors. These CNS muscarinic actions can also be blocked by specific muscarinic antagonists. Therefore, at high toxic doses muscarinic receptor antagonist causes CNS stimulation followed by depression. But, the anticholinergic agents that are quarternary compounds cannot penetrate the blood brain-barrier and have no effect on CNS.

Though the specific nicotinic receptor antagonists block the nicotinic actions of ACh which are mediated through the nicotinic receptors, but they are generally

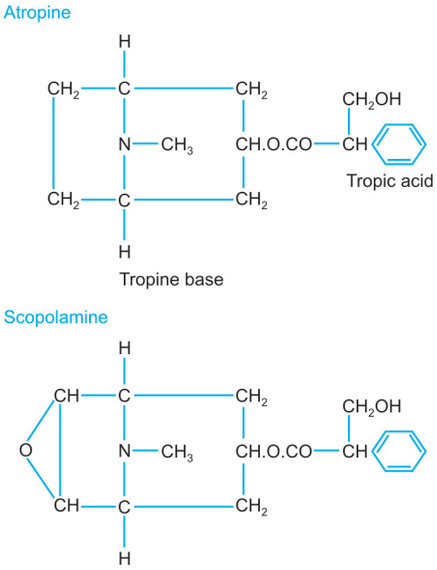

Fig. 11.20: Structure of anticholinergic agents

referred to as the ganglion blockers and neuromuscular blocking agents. However, they are usually not called as the anticholinergic agents. Anticholinergic agents are those which can block only the muscarinic receptors. All anticholinergic agents are competitive antagonists to ACh. (Fig 11.20).

Classification of anticholinergic agents

1. Natural alkaloids - Atropine, Hyoscine (scopolamine)
2. Semisynthetic derivatives - Homatropine, Ipratropium, atropine methonitrate
3. Synthetic derivatives -
   a. Specific antisecretory and antispasmodics
   b. Specific mydriatics - cyclopentolate, tropicamide
      i. Tertiary amines - Dicyclomine, pirenzepine, atropine (also available naturally)
      ii. Quaternary compound - glycopyrrolate, propanthelin, oxyphenonium, clidinium
   c. Specific antiparkinsonian - Benzhexol, procyclidine, benztropine.

In addition, many other drugs, such as: tricyclic antidepressants, phenothiazines, antihistaminics, etc. also possess significant antimuscarinic or anticholinergic actions.

Atropine

Naturally, atropine and its related alkaloids are obtained from many plants such as: Atropa Belladona (which means deadly nightshade), Atropa Acuminata, Hyascyamus Niger and Datura Stramonium (Datura) etc. The name Atropa Belladona represents a paradox. Because the term 'Atropos' comes from the oldest name of 'Three Fades', who cut the thread of life (i.e death) and the term 'Belladona' is derived from a type of practice of beauticians of the Venetian court who put the extract of these plants in their eyes to impart them a 'lustre'. For many centuries the belladona preparations were also known to ancient Hindus. In the Roman Empire and in the medieval ages, this deadly nightshade shrub (Atropa Belladona) was also frequently used to produce obscure or darkness and prolonged poisoning. During the ancient times in India the roots and leaves of some weeds, named Jimson weed which also contained atropine alkaloids, were burnt and this smoke was inhaled to treat asthma. British Colonist observed this and introduced the belladona alkaloids in western medicine as early as 1780 to treat asthma. From this idea ipratropium is used now as inhalation to treat the acute asthma. Then, Dr Mein in 1831 first isolated atropine in pure form and in 1867, Dr Bezold first showed that atropine blocked the cardiac effects of vagal stimulation.

Chemically, atropine is the ester of an organic aromatic 'tropic' acid and an organic aromatic 'tropine' base. Semisynthetic atropine ester, named homatropine is an ester of tropine base and mandelic acid. Its quarternary derivatives are obtained by adding a second methyl group to the nitrogen atom of this ester. The tropine base and tropic acid itself is devoid of any antimuscarinic activity. So, formation of an ester is essential for antimuscarinic activites. The presence of free OH group at the acyl portion of this ester is also important for antimuscarinic activity of atropine. When given parenterally, quarternary derivatives are more potent than their parent ester compounds on both the muscarinic receptors and the nicotinic receptors (ganglionic blocking activities). But, these quarternary derivatives lack the CNS activity, because they cannot cross the blood brain-barrier. Conversion of nitrogen from a tertiary group to a quarternary group also increases the blocking action at the nicotinic receptors.

Mechanism of action

Atropine blocks the muscarinic effect of ACh by competing with it at the binding site of muscarinic receptors. So, it is called the competitive antagonist. The binding site of atropine (competitive antagonist) and ACh on the receptor is situated in the cleft which is formed by the seven transmembrane helices of the muscarinic receptor. An aspartic acid which is present at the N-terminal portion of the third transmembrane helix of all the five muscarinic receptor subtypes is believed to form an ionic bond with the cationic quarternary nitrogen atom of ACh and the tertiary or quarternary nitrogen atom of the antagonist. However, atropine does not interfere with the synthesis or release of ACh at the cholinergic nerve endings. It has no intrinsic ACh like activity. So, atropine and its receptor combination does not produce any muscarinic response like ACh. As the antagonism between ACh and atropine is of the competitive type, so the direction of action depends on the relative concentration of the two at the muscarinic neuroeffector site, and the action can be reversed by increasing the concentration of atropine or ACh.

The dose of atropine required to produce the antimuscarinic or anticholinergic action by the blockade of muscarinic receptor varies from organ to organ. Salivary secretion is extremely sensitive

to the blockade by atropine, while the smooth muscle of GI tract, eye and the heart are less affected. In the CNS, cholinergic transmission at the subcortical and cortical level is predominantly muscarinic and can be blocked by atropine.

Pharmacological properties of atropine

(i) CNS

Atropine has almost no detectable effect on CNS in doses which are used clinically. In this dose it produces the peripheral effects only. At therapeutic doses (0.5 to 1 mg), atropine causes only mild stimulation of the medulla (including vagal, respiratory and vasomotor centres) and higher cerebral centres. But with higher toxic doses, atropine can produce sever cortical excitation, restlessness, disorientation, hallucination and delirium. With still higher doses, this stimulation of CNS is followed by depression, leading to circulatory collapse, respiratory failure and coma. Belladona alkaloids and other related muscarinic receptor antagonists are also used to suppress the tremor and rigidity of Parkinsonism by blocking the relative muscarinic cholinergic overactivity in the basal ganglia. Muscarinic receptor antagonists are also used to treat the extrapyramidal symptoms that commonly occur as side effects, after the antipsychotic drug therapy. Atropine also depresses the vestibular excitation which works through the muscarinic cholinergic pathway and thus exerts an antimotion sickness property.

(ii) CVS

The most prominent effect of atropine on CVS is tachycardia. It is due to the blocking of vagal action, mediated by the muscarinic M_2 receptors on the SA node. Sometimes, initial transient bradycardia often occurs before tachycardia. There are no accompanying changes in the blood pressure or CO by atropine. This is because the cholinergic impulses are not involved in the maintenance of vascular smooth muscle tone and BP.

The influence of atropine on the HR is most noticeable in healthy young adults in whom vagal tone is highest. Contrary in infancy and old age, even large doses of atropine may fail to produce tachycardia. This is because in this age group vagus has minimum action on the heart. Atropine often produces cardiac arrhythmias, but without any significant cardiovascular symptoms.

Many vagus nerve mediated reflexes, such as bradycardia or asystole, caused by oculo-cardiac reflex, anal stretching, peritoneal reflexes, etc, can be abolished by atropine. Atropine shortens the functional refractory period of the AV node and facilitates the AV conduction provided it is caused by the increased vagal tone. Thus, in some 1st and 2nd degree heart block caused by increased vagal tone atropine may lessen the degree of block. In some patients with complete heart block, the idioventricular rate may be increased by atropine. Occassionaly, in therapeutic doses atropine causes cutaneous vasodilatation and flushing. This may be a compensatory reaction, permitting loss of heat to balance the atropine induced rise in temperature due to inhibition of sweating.

(iii) Glands

Atropine markedly decreases the salivary, tracheo-bronchial, lacrymal and other secretions of body by blocking the muscarinic M_3 receptors which are responsible for these secretions. Atropine also inhibits the activity of the sweat glands innervated by the sympathetic cholinergic fibres because if acts as an anticholinergic agent. Thus, skin, mouth and eyes become dry; talking and swallowing may become difficult. Cephalic and fasting phase of gastric secretion is also markedly reduced, but the intestinal phase is partially inhibited by atropine. As both the HCO_3^- and H^+ secretion is blocked, so the pH of gastric secretion does not increase, i.e. does not becomes more alkaline. The secretion of mucin and proteolytic enzymes in stomach are more directly under the control of the vagus nerve than the acid secreting cells. So, atropine inhibits the secretion of mucin and the enzyme more than the acid in stomach. Intestinal and pancreatic secretions are not significantly reduced by atropine. Bile secretion is not under cholinergic control, so is not affected by atropine.

(iv) Smooth muscles

All the visceral smooth muscles that receive the parasympathetic or cholinergic motor innervation are relaxed and the sphincters are contracted by atropine. This is mediated by the muscarinic M_3 receptor blockade caused by atropine, because parasympathetic nerves enhance both the tone and motility of the GI tract and relaxes the sphincters acting through M_3 receptor. However, peristalsis of GI tract is only incompletely suppressed. This is because the intestine has a complex system of intramural local nerve plexuses that regulate the motility, and is not completely dependent on parasympathetic or cholinergic control. It is also regulated by some local reflexes, and other neurotransmitters (5 HT, enkephalin, etc) and hormones. Impulses from the CNS through vagus only modulate these intrinsic reflexes of intestine.

In a normal subject and in a patient with GI disease, atropine produces prolonged inhibitory effect on the motor activity of the stomach, duodenum, jejunum, ileum and colon. This inhibitory effect of atropine on the GI tract is characterised by a reduction in tone, amplitude and frequency of peristaltic contractions, resulting in relief from spasm and causing constipation. However, relatively large doses of atropine are needed to produce such inhibition.

In regulating the bronchomotor tone the parasympathetic neurons plays a major role. Vagal fibres make synapses and activate the nicotinic receptors of the parasympathetic ganglia, located in the wall of the airway. Short postganglionic parasympathetic fibres

come out from this ganglion and release ACh which acts on the M_3 muscarinic receptors in the airway smooth muscles. The submucosal glands are also innervated by these postganglionic parasympathetic neurons and have predominantly M_3 receptors. So, vagal stimulation causes airway smooth muscle contraction and increased tracheo-bronchial secretion. Thus, atropine causes bronchodilatation and reduces the airway resistance, especially in COPD and asthma patients by inhibiting this vagal cholinergic activity. Inflammatory mediators like histamine, prostaglandins, kinins, etc, also increase the vagal activity in addition to their direct actions on the bronchial muscles and glands, causing bronchoconstriction and increased airway resistance. Atropine also partially blocks their action by antagonizing the reflex vagal component and forms the basis of the use of anticholinergic agents, along with β-adrenergic agonists in the treatment of bronchial asthma. Thus, with the introduction of inhaled ipratropium (semisynthetic anticholinergic agent), anticholinergic therapy in COPD and asthma has been revived.

Atropine by its anticholinergic activity also decreases the normal tone and amplitude of contraction of the ureter and bladder. So, urinary retention may occur in older males, especially with prostatic hypertrophy during the use of anticholinergic agent.

Atropine also exerts mild antispasmodic action on the gall bladder and bile ducts. But, this effect is not usually sufficient to prevent the marked spasm and increased biliary duct pressure, induced by opioids. In such circumstances the nitrates are more effective than atropine.

(v) Eye

The muscarinic receptor antagonists or the anticholinergic agents block the responses of cholinergic neurotransmitter such as acetylcholine on the sphincter pupillae muscle of iris and the ciliary muscle of lens, which are responsible for constriction of the pupil and accommodation of vision. Thus, atropine dilates the pupil (mydriasis) and paralyses the accommodation reaction (cycloplegia). The wide dilatation of pupil causes photophobia. Due to blockade of the ciliary muscle the lens become fixed for far vision and the near objects become blurred. This is called the paralysis of accommodation or cycloplegia.

Thus, the topical instillation of atropine causes mydriasis, loss of light reflex, cycloplegia, photophobia and blurring of near vision, lasting for 7 to 10 days. The IOP (intraocular pressure) tends to rise, specially in narrow angle glaucoma by atropine. However, all these effects are caused by topical application of if and the conventional systemic dose of atropine produces minor ocular effects. Muscarinic receptor antagonists such as atropine, used as a mydriatic differs from the sympathomimetic agents, such as epinephrine. The latter causes only pupillary dilatation without loss of accommodation. Because sympathomimetic agents act only on the dilator muscle of pupillae and have no action on the accommodating ciliary muscle of lens.

Absorption rate and excretion

All the anticholinergic agents, such as the natural belladona alkaloids, the semisynthetic derivatives and the tertiary synthetic derivatives are well absorbed rapidly from the GI tract. But, the quarternary synthetic derivatives are poorly absorbed orally and their effects on the CNS are lacking. This is because these agents do not cross the blood brain-barrier. The half-life of atropine on parenteral administration is approximately 4 hours. Half of the dose of atropine is metabolised in the liver and the remainder is excreted unchanged through the urine.

Atropine Substitutes

Many semisynthetic and large number of synthetic derivatives of belladona alkaloids have been introduced in clinical practice, with the aim of producing more selective antimuscarinic actions. These synthetic derivatives are again classified as : quarternary compounds, tertiary compounds, mydriatics and antiparkinsonians.

Quarternary Anticholinergic Agents

The characteristics of quarternary anticholinergic compounds are:

i Poor oral absorption.

ii. Do not produce CNS and ocular effects after parenteral or oral administeration due to poor penetration in the brain and eye.

iii. Have higher nicotinic blocking property which may even occur at clinical doses, causing postural hypotension and impotence.

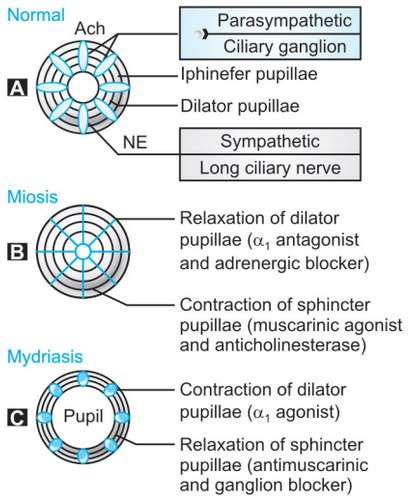
iv. At higher doses neuromuscular blockade may also occur due to the blocking of nicotinic receptor at motor endplate.

The following are the quarternary anticholinergic agents:

i. **Hyoscine butylbromide** − used as antispasmodic.

ii. **Atropine methonitrate** − used for abdominal colics and hyperacidity. As an aerosol, it is also used in bronchial asthma.

iii. **Ipratropium bromide** − It is used in the treatment of bronchial asthma by inhalation.Ipratropium bromide acts on the muscarinic receptors, located mainly on the large central airways (in contrast, sympathomimetics such as β_2 agonist act primarily on the peripheral bronchioles). The increased parasympathetic tone is the major reversible factor in (Fig. 11.21) chronic obstructive pulmonary disease (COPD). Therefore, it is more effective in COPD than in acute bronchial asthma. Another desirable feature of ipratropium is that in contrast to atropine, it does not depress the mucociliary clearance of bronchial epithelium. It has a gradual onset and late peak (60 to 90 minutes) bronchodilating action in comparison to inhaled sympathomimetics. So, it is more suitable for regular prophylactic use, rather than for rapid symptomatic relief during an acute attack.



Figs 11.21A to C: Autonomic control of pupil
A: Normal pupil, B: Miotic pupil, C: Mydriatic pupil

iv. **Tiotropium bromide** − It is a congener of Ipratropium with high bronchial selectivity in action.

v. **Propantheline** − used for the treatment of gastric ulcer by reducing the gastric secretion.

vi. **Oxyphenonium** − used for the treatment of peptic ulcer by reducing the gastric secretion.

vii. **Clidinium** − with diazepam it is used as antispasmodic in nervous dyspepsia, irritable colon, etc.

viii. **Pipenzolate** − used for infantile colics.

ix. **Isopropamide** − used in hyperacidity, nervous dyspepsia, irritable bowel syndrome, etc.

x. **Glycopyrrolate** − It is a potent and rapidly acting antimuscarinic agent, lacking central and ocular effects. Otherwise, all its clinical actions are like atropine. The dose of glycopyrrolate to control the muscarinic effects of neostigmine is 10 to 15 µg/Kg.

Tertiary Anticholinergic Agents

i. **Synthetic atropine** - already discussed

ii. **Dicyclomine** - Due to direct smooth muscle relaxation effect, it is used as an antispasmodic.

iii. **Pirenzepine** - It selectively blocks the M_1 muscarinic receptors and inhibits the gastric secretion, without producing typical atropine like side effects which are due to blockade of M_2 and M_3 receptor. The exact location of M_1 receptors through which pirenzepine exerts its antisecretory action is not definite. The more likely site of action of pirenzepine is the intramural plexuses and ganglionic cells, rather than the parietal cells.

Mydriatics

i. Homatropine - It is 10 times less potent than atropine and peak onset of action is 40 to 60 minutes. Mydriasis caused by homatrophine lasts for 1 to 3 days, while accommodation recovers in 1 to 2 days.

ii. Cyclopentolate - It is a potent and rapidly acting mydriatic agent. Mydriasis and cycloplegia occur in 30 to 60 minutes and lasts for a day.

iii. Tropicamide - It has the quickest (20 to 40 minutes) and briefest (3 to 6 hours) action.

Nicotinic Receptor Agonists and Antagonists

As described before, the nicotinic receptors are rosette-like pentameric structures enclosing a cation (Na^+) channel. Activation of this receptor causes opening of this channel and rapid flow of cations such as Na^+, resulting in depolarization and action potential of the membrane. These receptors are activated by nicotine (so it is such named) and blocked by tubocurarine or hexamethonium. Nicotinic receptors are classified into Nn and Nm (previously as N_1 and N_2) on the basis of their location and selective agonist and antagonist.

(i) N_M nicotinic receptor

They are located at the endplate of skeletal muscle and are activated by ACh, but selectively by phenyl trimethyl ammonium (PTMA). They are antagonised by tubocurarine and other non-depolarizing muscle relaxants. These receptors mediate skeletal muscle contractions.

(ii) N_N nicotinic receptor

They are present in the sympathetic and parasympathetic ganglionic cells, in adrenal medullary cells (as adrenal medulla is derived embryologically from same site as the ganglionic cells), in the spinal cord and in certain areas of brain. They are also stimulated by ACh but are selectively stimulated by dimethyl phenyl piperazinium (DMPP) and blocked by hexamethonium. They constitute the primary pathway of transmission in ganglia.

12 Preoperative Evaluation and Preparation

INTRODUCTION

The diversity and versatality of the subject of anaesthesia makes proper preoperative evaluation of each patient a major issue. This is because, a single anaesthetic procedure cannot meet all the various demands, of all the patients. The ultimate need of preoperative assessment, in patients about to undergo anaesthesia care, is to reduce morbidity and mortality, to improve the quality of anaesthesia, to optimise the patient's health and to return the patient to normal functioning, as early as possible. So, an anaesthesia programme should be made, keeping in mind the specific patients physiological status, psychological built-up, past and present medical conditions, previous surgical history, present complaints, drug allergy and intolerance, anaesthetic experiences of the past, and of course the planned surgical procedure. We should remember that improper and inadequate preoperative evaluation, is one of the major causes of all anaesthetic complications. So, every time surgery is planned in a patient, he should be evaluated thoroughly in the pre-anaesthetic clinic by an anaesthesiologist preferably, treated for any existing medical pathology and his health should be optimised, that is he should be made fit for anaesthesia.

PREOPERATIVE ASSESSMENT

Preoperative assessment is traditionally done by arranging a meeting between the patient and the anaesthesiologist. This facilitaties certain important purposes, and helps to make the patient comfortable, by rendering a healty patient – doctor relationship.

The Goals Achieved by Preoperative Assessment

1. It helps to know the medical history and the psychological make-up of the patient, to assess any known or unknown underlying pathology, to determine the required laboratory tests and specialized consultations, for optimising the patient's health. This decreases hospital stay and unnecessary delay in scheduling of surgery.
2. It helps the anaesthesiologist to select the proper anaesthesia care or programme for the operation planned, by understanding the patient's mental make-up and the medical history.
3. In this age of information technology, a preoperative meeting between the patient and the anaesthesiologist, helps inform and educate the patient about the anaesthesia services rendered, perioperative care and postoperative pain management. Patient education also helps reduce the patients anxiety, allay his fears and makes recovery faster and better.
4. It helps maintain a more optimal health of the patient by managing preexisting medical pathologies efficiently. Detection and treatment of conditions like respiratory tract infection, diabetes mellitus, congestive cardiac failure, etc. prior to delivery of anaesthesia, by proper and meticulous preoperative assessment, improves the quality of anaesthesia and optimises the health of the patient, thus reducing perioperative morbidity and mortality. The presence and severity of underlying medical problems may require consultation with specialists, for obtaining an optimal medical condition, before anaesthesia is actually delivered. The specialist's help can also be extended for better perioperative care.
5. It facilitates better perioperative care management and even helps make it less costly, by proper planning.
6. It helps obtain an informed consent from the patient, in the true sense, for all medicolegal purposes.

Routine Preoperative Anaesthetic Assessment

1. History

a. Name, age, sex, weight
b. Present complaints
c. Past medical history
d. Treatment history
   – Medicines being used currently.
   – Medicines that had been used in the past
   – Drug allergy and intolerance
e. Social history
   – History of addiction and habits, drugs, alcohol, tobacco, etc.
f. Non-specific factors
   – Obstetric history in females, pain history, etc.
g. Family history

– For malignant hyperpyrexia, porphyria, cholinesterase abnormality, etc.

h. History of previous surgery and anaesthesia

2. History to have an overall review of all systems

a. Respiratory system – History of smoking, bronchitis, common cold, asthma, chronic cough, etc.
b. Cardiovascular system – History of hypertension, palpitation, chest pain, syncope, dyspnoea, etc.
c. Gastrointestinal system
d. Genitourinary system
e. Musculoskeletal system
f. Neurology
g. Haematology
h. Endocrinology
i. Orthopaedics
j. Dermatology
k. Psychiatry

3. Physical examination of the patient

a. General condition – Pallor, cyanosis, jaundice, oedema, consciousness, aptitude, co-operativeness, activity level, etc.
b. Vital signs – Arterial blood pressure in both hands, examination of peripheral pulses, jugular and carotid pulsations, etc.
c. Airway – Neck mobility, jawbone size, tongue size etc., for intubation
d. Pulmonary evaluation – Auscultation for rhonchi, wheeze, crepts, or other sounds of lung pathology
e. Cardiovascular evaluation – Auscultation for murmurs, thrust, gallop and other adventitious sounds
f. Extremities – Oedema, clubbing, varicosity of veins, etc.
g. Neurological examination – Peripheral neuropathy, tremor, convulsion, seizure, etc.

4. Laboratory investigations

5. ASA Classification

History Taking

History taking is the most vital part of preoperative evaluation. It helps to establish all known past and present medical problems of the patients, plan the anaesthetic program, laboratory tests and post operative managenent efficiently. The medication history often reveals significant drug allergies, (rash, dyspnoea), drug interaction and drug intolerance (GIT problems). Even herbal medicines cause drug interactions, like garlic, often used to reduce blood pressure and cholesterol level, inhibits platelet aggregration and should be discontinued seven days prior to surgery. Ginseng, a root, is often used as an antistress factor is known to produce hypoglycemia and inhibition of coagulation cascade, and should be discontinued seven days prior to surgery. Meticulous history to review the various systems and their pathologies, if present, is one of the best tools for optimal assessment of a patient, along with optimal choice of laboratory investigations required and subsequently the perfect choice of anaesthesia care. Preoperative interview helps bring out important information and gives the anaesthesiologist enough time to motivate a patient for a healthy lifestyle, like maintaining blood pressure and blood sugar, reducing or even quitting smoking, if required, etc. This naturally improves the quality of the anaesthesia service and helps reduce morbidity and moratlity, due to anaesthesia (Table 12.1).

Table 12.1: The rule of three for history taking

1. The three aspects of acute history that effects preoperative evaluation of a patient waiting for anaesthesia are:
   - History of present health problems
   - Tolerance to exercise
   - How long ago the patient had visited his pirmary care physician
2. The three aspects of chronic history that effects preoperative evaluation of a patient waiting for anaesthesia are :
   - Medicines being used currently and allergy, if any, to any medicine
   - Family history
   - Social history
   - History of past illness
3. The three features of clinical examination are:
   - Vital signs of the patient
   - Pulmonary assessment
   - Cardiovascular evaluation

Laboratory investigation

Preoperative laboratory testing and its results had so far been the primary source of information of a patient's vital characteristics. But now, they are considerd ineffective as screening devices. The tests are considered useful only when the anaesthesiologist changes the anaesthesia plan according to the laboratory test results, for the benefit of the patient, and helps to optimise the health of the patients. But, it is not always true that the results of the laboratory tests are necessarily adjuvants to the patient's medical history and physical examination, for meticulous preoperative assessment.

Preoperative test with borderline or false-positive results can merely distract the anaesthesiologist's attention and cause no benefit at all. The anaesthesiologist may then pursue and treat this borderline or false-positive cases unnecessarily, causing unwanted delay in scheduling of surgery and also making the procedure expensive. Thus, unindicated routine laboratory testing can decrease the overall quality of anaesthesia care, by causing sheer confusion and is often harmful for the patients. So laboratory tests should only be implemented in patients, in whom it may decrease health hazards, mortality and morbidity due to anaesthesia. Extra-testing hardly provides medicolegal protection to the anaesthesiologist. When too many tests are ordered, the anaesthesiologist often tends to overlook the slightly positive or borderline cases, and that poses greater medicolegal risk to the doctor. Only those patients who actually suffer from a disease may benefit from the test specific for the disease (Table 12.2).

Table 12.2: Routine preoperative laboratory investigations

1.	Full blood count
	All male patients above 50 yrs of age
	All female patients
	All major surgical procedures
	Whenever pallor is detected clinically
2.	Routine urine examination (for sugar, blood, protein)
	All patients
3.	ECG (an ECG tracing is valid for a year, if there is no recent history of cardiac pathology)
	All patients above 50 years of age
	All patients with cardiac diseases, hypertension, chronic pulmonary diseases
4.	Blood glucose (FBS, PPBS)
	All patients with diabetes mellitus
	All patients with glycosuria
5.	Urea,creatinine electrolytes
	All patients more than 60 years of age
	All major surgical procedures
	All patients with diabetes mellitus
	All patients taking diuretic drugs
	All patients with renal diseases
6.	Blood coagulation tests
	All patients with bleeding tendencies
	All major surgeries
7.	Chest X-Ray
	All patients of acute cardiac diseases
	All patients of acute pulmonary diseases
	Chronic-on-acute cardiac or pulmonary diseases
	Malignant diseases
	Suspection of pulmonary tuberculosis
8.	Pregnancy test
	All female patients in the reproductive age

ASA classification

The ASA (American Association of Anaesthetists) in 2002, had set up a set of guidelines to be followed by anaesthesiologists during routine preoperative evaluation.

This helped the anaesthesiologists to do a meticulous and justified preoperative assessment, of a patient waiting for anaesthesia and surgery. It was not mandatory to follow these guidelines, but they were there to help the anaesthesiogists, whenever they were in a dilemna to take decisions.

The guidelines were :

1. In patients undergoing minimally invasive surgery, the anaesthesiologists opinion, based on the history and physical examination, should be considered more important than the results of the laboratory tests.
2. In patients undergoing surgery other than the minimally invasive ones, or if patient is not presently healthy, preoperative evaluation should always occur one day prior to the day of surgery.
3. Certain laboratory tests to be done as routine procedures in most invasive surgeries (Table 12.2).
4. Pregnancy test to be done in all female patients of the reproductive age group. (Table 12.3).

Table 12.3: ASA classification of patients waiting for surgery

Grade 1:	Normal, healthy patients, no pre-existing medical pathology, other than the disease for which surgery is planned.
Grade 2:	Patients with mild systemic disease, without any functional handicap.
Grade 3:	Patients with severe systemic disease, with functional handicap.
Grade 4:	Patients with severe life-threatening systemic disease.
Grade 5:	Moribund patients who would die without the surgery.
Grade 6:	Brain-dead patients who are being operated for removal of organs, for donor purposes.
Grade E:	Emergancy procedures - here the physical status is followed by E, e.g. -3E.

THE ANAESTHETIC PLAN

The choice of the final anaesthetic plan should be safe, comfortable for the patient, suit the competence and experience of the anasthesilogist, and of course depend on the type of surgery and the convenience of the surgeon. A detailed and meticulous preoperative evaluation enables the anaesthesiologist to draw an anaesthetic plan and discuss it in details with the patient. This helps assure quality anaesthesia service, reduce the patients anxiety and fear and reduce mortality and morbidity (Table 12.4).

Special care, if required	
Complication management	

PREANAESTHETIC PREPARATION

Routine preanaesthetic preparation is a must for every patient ready to undergo anaesthesia and surgery.

Fasting

It is an important event during the postoperative preparation of a patient, for surgery or anaesthesia. Aspiration of gastric contents into the lungs, is associated with high morbidity and mortality. Some very common causes for regurgitation of gastric contents and subsequent pulmonary aspiration are: pregnancy, obesity, full stomach, difficult airway, emergency surgery without proper preoperative medication, etc. Even 20 to 30 ml of gastric content

aspirated, can cause severe irreversible pulmonary damage. So, one of our main aims during preoperative preparation of a patient is to decrease the volume of gastric content, so that regurgitation is prevented (Table 12.5).

Gastric emptying time may be delayed due to metabolic disorders (diabetes mellitus or renal failure), head injury, pyloric stenosis, opiods, trauma, etc. Whereas, pregnancy and obesity increases the intra-abdominal pressure and causes passive regurgitation.

Antacids (not the particulate ones), like sodium citrate solution, given shortly before induction of anaesthesia, neutralises the acid in the stomach, but is not at all preferred by most anaesthesiologists as it increases the volume of gastric contents, causing further complications. Proton-pump inhibition and H_2 blockers decrease acid secretion in the stomach and are very effective. Gastric motility increasing agents, like metoclopramide, are very effective, especially in trauma patients being put up for emergency operation, more by the intravenous route than orally. Ranitidine may also be used routinely, especially in pregnant patients (Table 12.6).

Premedication

A preoperative interview between the doctor and the patient, thorough explanation of all planned and anticipated procedures and support-cum-compassion of the anaesthetic team, are not always enough to allay the fears and concern of the patient, and reduce all the unwanted stress factors. Certain drugs are often used to treat anxious patients preoperatively. Preoperative medication helps the anaesthesiologist to travel a comfortable road during the course of anaesthesia, and decreases morbidity and mortality to a great extent.

Special care should be taken to select the drugs for premedication of each patient individually, depending on the history and clinical examination of the patient, the surgery planned and the anaesthetic programme decided.

Table 12.5: Routine preanaesthetic preparation

1.	Patient education and psychological support, regarding all procedures planned.
2.	Sedation to be given the previous night, for a restful sleep.
3.	Fasting.
4.	Evacuation of the urinary bladder.
5.	Removal of false teeth and eyes, artificial limbs, contact lenses, jewelleries, nail varnish, etc.
6.	Loose OT dress to be worn.
7.	Identification tag to be put on the patient.
8.	Signature on the informed consent.
9.	Premedication.
10.	All resuscitative measures to be started, like intravenous line, noninvasive monitoring, etc.
11.	Documentation: Preoperative notes.

Metoclopramide

It is essentially a prokinetic drug, that is, it increases the gastroduodenal motility and hastens gastric emptying. Though it is structurally similar to procainamide, its pharmacological properties are absolutely different from procainamide. Metoclopramide is now widely used as an antiemetic.

It relaxes the pylorus and the first part of the duodenum, and thus hastens gastric emptying. It increases the lower oesophageal sphincter tone (LES), and prevents gastro-oesophageal reflux.It also increases intestinal peristalsis but has no action on gastric secretion.It has certain antidopaminergic actions, prolactin-secretion inducing action, and blocking of vomiting induced by narcotics. So, it is considered to be a relatively selective D_2 antagonist and its antiemetic action is due to D_2 antagonism in the CTZ. Peripherally, it has cholinomimetic actions, i.e, it increases acetylcholine release from the myenteric neurones.This inturn promotes gastroduodenal peristalsis, speeds up gastric emptying and increases the LES tone. Metoclopramide also blocks the $5HT_3$ receptors present in the CTZ and the vagal efferents in the GIT, but only in higher doses.

Metoclopramide is absorbed very rapidly when given orally, crosses the blood-brain barrier and the placental (Fact file- I) barrier, and is secreted in the breast milk.Its half life is 4-6 hours. It is partly conjugated in the liver and is excreted through the urine. It speeds up absorption of drugs like aspirin and diazepam, reduces the absorption of digoxin and decreases the effects of levadopa, by blocking the DA receptors in the basal ganglion.

Metoclopramide is well tolerated but certain extrapyramidal symptoms like dizziness, sedation, muscle dystonias and

Table 12.6: ASA guidelines for preoperative fasting in healthy patients presenting for elective surgeries

Clear liquid	Water, clear tea, fruit juice without pulp	2 hours
Breast milk		4 hours
Infant formula milk		4-6 hours
Animal milk	Cow, goat, buffalo	6 hours
Light meal	Toast	8 hours
Solid meal	Fish, chicken (high fat or protein content)	8 hours

FACT FILE- I

A good premedicant should:

- Help decrease the patients anxiety and stress.
- Decrease the secretion of the respiratory tract.
- Decrease salivary secretion.
- Decrease undesirable vagal reflexes.
- Reduce intraoperative awareness of the patient.
- Facilitate smooth recovery from anaesthesia.
- Reduce postoperative nausea and vomiting.
- Reduce postoperative restlessness of the patient.
- Reduce postoperative pain.
- Be safe for the patient.
- Protect the patient from the toxic effects of anaesthetics.
- Keep the patient optimised.

diarrhoea are not uncommom. Galactorrhoea, gynaecomastia and parkinsonism may occur, when the drug is used continuously for a long time.The dose is 10 mg orally, IM or IV.

It is an effective antiemetic agent for many types of vomiting like drug induced, postoperative, radiation sickness, chemotherapy-induced, migraine, etc.It is not very effective in motion sickness, and should be used very cautiously in pregnancy, as the safety factor is still not very well defined. It should also be used cautiously in lactating mothers, since it is secreted in the breast milk. It is the most effective gastrokinetic agent used to accelerate gastric emptying, especially when general anaesthesia has to be given in a patient posted for emergency surgery, when he has taken solid food less than 4 to 5 hours ago.

Ondansetron

This is a $5HT_3$ antagonist, first developed to control intense nausea and vomiting induced by chemotherapy or radiotherapy, in patients undergoing treatment for cancer. But, later it was found to be equally effective in controlling postoperative nausea and vomiting. Ondansetron blocks both the peripheral origin in the gut and the central pathway in the CTZ, of the emetogenic reflex. But neither does it reduce motion sickness induced nausea and vomiting, nor does it block the dopaminergic receptors. Unlike procainamide, it does not have any prokinetic action in the GIT. It blocks the $5HT_3$ receptors, thus inhibiting the action of 5HT in the GIT as well as in the CTZ. Thus, it is useful in combating the multifactorial origin of postoperative nausea and vomiting (Table 12.7).

Due to first pass metabolism, bioavailability of ondansetron after oral intake is about 60-70 %. CYP1A2, 2D6 and 3A can hydroxylate ondansetron. Drug interactions are rare. It is secreted through the urine and faeces as metabolites. The half life of ondansetron is 2-5 hours and duration of action is 4-10 hours. Side effects are rare. Dose to control postoperative nausea and vomiting is 4-8 mg IV and may be repeated after 4 hours.

[The other drugs have been discussed in the relevant chapters].

Informed Consent

All conscious, educated, competent patients have the right to either give or withhold consent for their treatment, or even a physical examination. A competent person is an adult, who is intelligent enough to understand his problems, remember the information given to him, and weigh out the risk – benefit ratio rationally, to make a decision regarding his treatment. No other peson can interfere with the decisions of such a competent person. To get the consent of the patient, all details of the anaesthetic procedures with its alternatives and complications should be discussed, so that the intelligent and competent person can understand and choose the best procedure for his treatment. A thorough discussion of the benefits versus the risks, often helps the patient choose the best option. All theoritical risks need not be detailed, instead the common and realistic ones should be explained. Life threatening complications,

Table 12.7: Some commonly used preoperative drugs

Drugs			*Route*	*Dose*
Drugs increasing gastric pH		Ranitidine	Oral	150 to 300 mg previous night and 2 hours before surgery
		Omeprazole	IM / IV	50 mg 2 hours before surgery
		Sodium citrate solution	Oral	40 mg previous night and 2 hours before surgery
			IV	40 mg slow IV over 40 minutes
			Oral	30 ml 10 minutes before surgery
Sedatives	BDZ	Temazepam	Oral	10 to 30 mg
		Lormetazepam	Oral	0.5 to 1.5 mg
		Lorazepam	Oral	1 to 2.5 mg
		Midazolam	Oral	0.2 to 0.5 mg
			IM	2 to 10 mg
	Non BDZ	Zopiclone	Oral	3.75 to 7.5 mg
Antiemetics		Metoclopramide	Oral/IM/IV	10 mg
		Ondansetron	IV	4 to 8 mg before surgery
Analgesics	Opioids	Morphine	IM/SC	10 to 15 mg
		Pethidine	IM	50 to 100 mg
	NSAID	Diclofenac	Oral/PR	50 to 100 mg
	Others	Paracetamol	Oral/PR	1 mg
Anticholinergics		Atropine	IM/IV	0.6 to 2 mg
		Glycopyrrolate	IM/IV	0.1 to 0.3 mg
Anxiolytics		Diazepam	Oral	5 to 10 mg

if likely, should always be innumerated. This often helps the patient and his guardian to accept the inevitable and prepares them mentally, allay their concern and anxiety to some extent.

Competent young adults over the age of 16 years can give their own consent, regarding their treatment. Competent children even below the age of 16 years, can give their own consent, especially if they can weigh out the risk – benefit ratio appreciably. If a competent child refuses treatment, the consent of the parents enables the doctor to proceed with all lifesaving procedures. The consent of the parents is enough to start treatment in patients below the age of 18 years, who are not competent. Verbal consent may be accepted in life-threatning and emergency conditions, but written ones are always preferred for medicolegal purposes. When the child or even the parent refuses treatment in an emergency and life-threatning condition, a court order may be sought to continue with the necessary treatment legally. Unconscious adults may be given essential treatment without consent, but it is always better to discuss the procedures with his guardian. Patients hospitalised with mental disorders may be treated without consent for his mental problems, but never for his associated physical ailments. But ECT always requires the consent of the patient or his guardian.

Restricted consent

Some competent patients may give consent for the treatment in general, but refuse cetain aspects of the treatment, e.g, blood transfusion. This is called restricted consent. The risks and the benefits of the procedures should be discussed in details with the patient, always in presence of a witness. All details of the patients restrictions and refusals should be noted in the consent form, duly signed by the patient and the witness. But in the end, the desire of a competent patient should be honoured.

Any procedure performed without a proper consent can lead to medicolegal assault of the anaesthesiologist. Treatment without consent is allowed only in dire emergencies or in life saving procedures.

Documentation

Maintenance of pre, intra and post operative anaesthesia record is of utmost importance in present day scenario.It helps to monitor the patient intraoperatively, deal with postoperative complications if any, and is the best document for all medicolegal purposes. Thus proper documentation ensures quality service.

Preanaesthetic record

A preanaesthetic record maintenance is absolutely mandatory nowadays. It should contain all the information about the preoperative evaluation of the patient by the anaesthesiologist and his team, including medical history, treatment history, laboratory test results, ASA classification of the patient and advice of the specialist, if required, for optimising the health of the patient. It should have the detailed anaesthetic plan, with all the alternatives clearly stated. All common and probable complications should be mentioned. It should also contain an informed anaesthesia consent, duly signed by the patient or his guardian.This record may be handwritten, narrative or printed forms may also be filled up with all the details.

Intraoperative record

This is a useful intraoperative monitor and assures quality anaesthesia service.It also helps to guide future anesthesia care. Hence this document should be accurate and precise.

It should include the following:

(i) Checking of the anaesthesia machine and other instruments, required to provide quality aneasthesia delivery and service, often referred to as the 'cockpit drill'.

(ii) Final evaluation of the patient before the induction of anaesthesia.

(iii) Checking for the duly signed anaesthesia consent, newer laboratory results, if any, and specialists advice for optimising the health of the patient, if required.

(iv) All information about the important and vital anaesthesia procedures like intubation, positioning of the patient, attachment of all invasive and noninvasive monitors, ryle's tube placement, etc.

(v) Details of intraoperative fluid management and blood product transfusion.

(vi) Details of all drugs administered with their dosage used and time of administeration.

(vii) Details of findings of all intraoperative monitoring and assistance.

(viii) All vital signs recorded every 5 minutes, if possible graphically.

(ix) Timing of all vital events lke intubation, excision, extubation, etc.

(x) Complications, if any, and how they were managed.

(xi) The patients condition during extubation and recovery from anaesthesia.

Postoperative record

The anaesthesiologist should always accompany the patient to the post anaesthesia care unit (PACU), and look after the patient till all the vital signs become normal and the patient is considered stable.He should give a detailed discharge note before the patient leaves the PACU, including the pain management procedures and the general condition of the patient during discharge from the PACU. Only then does the responsibility of the anaesthesiologist end.

CONCLUSION

The primary goal of an anaesthesiologist is to deliver quality anaesthesia service to the patient, decreasing morbidity and mortality in the process and most important, returning the patient to

his normal stable status as soon and as efficiently as possible. This whole procedure is a team work. A balanced harmony between the anaesthesiologist, surgeon, internist and specialist, ensures the best possible outcome. For the anaesthesiologist, the show is the longest, starting from meticulous preoperative evaluation and ending with the discharge of the patient from the post anaesthesia care unit (PACU), and hence the job is the toughest. Thus, preoperative evaluation and meticulous and thoughtful patient preparation, facilitates achieving the most sought after goals, improves quality care and reduces the cost of treatment. Perhaps the most productive and enjoyable part of clinical anaesthesia practice is interaction with the patient during preoperatiuve evaluation in the preanaesthetic clinic (PAC). Inefficient and inadequate preoperative assessment is nowadays the main reason for medicolegal assault against anaesthesiologists.

13 Local Anaesthetic Agents

HISTORY

The local anaesthetics (LA) are drugs or agents which temporarely prevent or cause the reversible loss of generation of impulses from any part of a neuron or temporarely stop the conduction of impulses through the nerve fibres when they come in contact with it, but without causing any structural damage. The term 'Local Anaesthesia' is restricted to the technique of infiltration of local tissue with a local anaesthetic agent, where only the nerve endings supplying that particular tissue is blocked. Whereas, the term 'Regional Anaesthesia' signifies the temporary block of conduction of impulses through a specific nerve or a group of nerves, supplying a particular region of the body like hands, legs, face, etc. Before the days of LA agents, in the sixteenth and seventeenth centuries, Ambrose Pare (French Surgeon) obtained the effect of local anaesthesia by producing direct mechanical compression on the nerve trunks. Then other European and American surgeons also followed this procedure of Ambrose during this time for local anaesthesia. For many centuries, the leaves of an indigenous shrub called Erythroxylum Coca was chewed by the people of Peru and Bolivia of South America as a CNS stimulant and appetizer. During this chewing they were used to feel numbness of their oral mucous membrane. But, at that period this associated numbness (the local anaesthetic effect) of their oral mucous membrane was not given much importance by them. They also never knew that these effects were primarily due to the local anaesthetic effect caused by principal alkaloid, named cocaine present in the leaves of these shrubs. However, it was first understood and this alkaloid was isolated by Neimann in 1860. Then, the physiological or local anaesthetic effects of cocaine were studied in details by Sigmund Frend in 1880. But he did not publish it. In 1884, when S. Frend was visiting his fiancé, his colleague Carl Koller took the opportunity and in his absence Carl Koller first declared and introduced the local anaesthetic properties of cocaine in an Opthalmological Congress. Thus he himself took all the credit of discovery of cocaine immediately. Then he performed an impressive series of experiments on himself and his colleagues, using the suspension of cocaine powder in distilled water. After that this news of Koller's work spread rapidly all over the world and subsequently cocaine solution was injected locally or applied topically by a wide variety of practitioners for local anaesthesia in both Europe and America. But the high systemic toxicity and addictive properties of cocaine had engineered the search for a better substitute of it. Thus, procaine came in 1905, which was synthesised first by Einhorn in 1904. It was less toxic than cocaine, but unfortunately it was quite unreliable and had a very short duration of action. Then, gradually many other non-promising LA drugs came and phased out. Such as, in 1930, dibucaine and tetracaine arrived which despite being much longer acting, still proved to be toxic in large volumes. Furthermore, these compounds, being esters like their predecessors were unstable at high temperature and thus could not be autoclaved. The another great disadvantage of these ester group of LA agents was that their metabolites had frequently caused allergic reaction which was sometimes very serious.

The next great milestone in local anaesthesia was the introduction of lignocaine in 1943. It was first synthesised by two scientists named Lofgren and Lundqvist in the laboratory of Astra. However, the beauty of lignocaine is that it was not an ester compound like their predecessors. Therefore, this drug was stable at high temperature and less toxic. It did not have such metabolites that could be implicated for allergic reactions. Hence, during that period it became the first prototype of a new class of local anaesthetic agents, called the amides. However, it is still now the most widely used local anaesthetic agent all over the world. Subsequently, the late 1950's saw the appearance of mepivacaine and prilocaine. In 1963, the introduction of bupivacaine in clinical practice was the begining of an era of long acting local anaesthetic agents in anaesthesia which are amides. But, the potential more cardiotoxicity of bupivacaine than lignocaine had provided the impetus for the development of ropivacaine which is the newest lesser cardiotoxic but long acting amide local anaesthetic agent. It became available by 1997 in most of the countries.

Other than LA agents, the local anaesthetic action can also be produced by

many other compounds such as some tertiary amines, certain alcohols and few other drugs such as propanol, antihistamines, quinidine, chlorpromazine etc. But, they are not used for this purpose because of their local irritation and other undesired prominent systemic effects. Local anaesthesia can also be produced by deep cooling, as for example by application of ice, CO_2 snow, ethylchloride spray, etc. on the surgical site.

CHEMISTRY (FIG. 13.1)

All the local anaesthetic agents bear the suffix – "caine". Structurally, they have two groups : a lipophilic aromatic group and a hydrophilic amine group. This amine group may be a secondary or a tertiary amine. An intermediate chain (alkyl or acyl) links these two groups through an ester or amide linkage. On the basis of this linkage local anaesthetics are classified into two broad groups.

When the linkage chain is an ester (−COO−), then they are called the ester local anaesthetics (esters of aromatic acids with amino alcohols). The examples of ester local anaesthetics are : cocaine, procaine, chloroprocaine, amethocaine, etc. Esters are unstable in solution and can not be autoclaved, because of their relatively unstable ester-linkage. They are also too short acting, because of their rapid metabolism (Fig. 13.2).

When the linkage chain is an amide (−NHCO−), then they are called the amide local anaesthetics. These amide local anaesthetics are again of two types : amides of aromatic acid with aliphatic diamines (aminoalkyl amides) and amides of amino acids with aromatic amines (aminoacyl amides). The examples of aminoalkyl amides are: cinchocaine and procainamide. The examples of aminoacyl amides are: lignocaine, prilocaine, mepivacaine, bupivacaine, etidocaine, ropivacaine, dibucaine, etc. Among all the amide local anaesthetics, only the hydrophilic amine group in prilocaine is a secondary amine. Otherwise all others have tertiary amines.

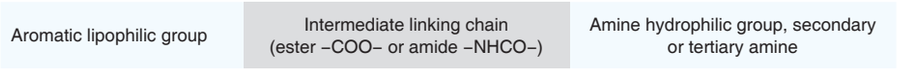

Fig. 13.1: Linkage of an anaesthetics

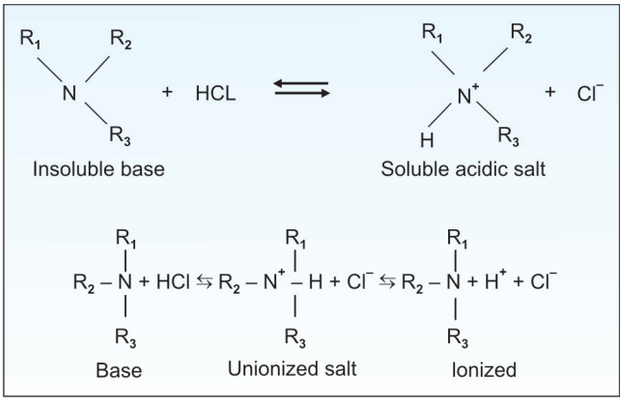

Fig. 13.2: Chemistry of an anaesthetics

The amine group in the structure of a amide local anaesthetic molecule confers it the property of an insoluble weak base (or proton acceptor). Thus it can combine with an acid to form a water soluble acid salt. This water soluble acid salt remains in more ionised form in commercially available water solution of it (as soluble in water) than its alkaline salt, which is not soluble in water and is usually stable.

All the local anaesthetic drugs, except ropivacaine are of racemic mixtures. However, only ropivacaine is unique, in that, it is available in a pure chiral form. This is important, because all the racemic mixtures have more toxicities and variable potencies, when compared to its chiral form. So, one of the major advantages of ropivacaine, in clinical use, is its less systemic toxicity than any other local anaesthetic agents, but with similar duration of action.

Features of Amide Local Anaesthetics in Comparison to Ester LA's

i. The amide groups of LA agents produce more intense and long lasting local anaesthesia than the ester group of local anaesthetic agents.
ii. The amide group of LA agents bind to α_1 acid glycoprotein and albumin in plasma.
iii. The amide group of LA agents are not hydrolyzed by plasma esterases like ester group of LA agents.
iv. The amide group of LA agent very rarely cause hypersensitivity reactions, than the ester group of LA and has no cross – sensitivity with ester group of LA.

Carbonated Local Anaesthetics

From the previous discussion, we already come to know that the original amide group of LA agents are insoluble weak base. So, the commercial preparations of these drugs are produced as soluble acidic (mainly hydrochloride by reacting with HCl) salts, with pH values ranging between 3 to 7. It is also clear from the previous discussion that in the solution of lower pH (i.e. in acidic situations), the drugs remain mainly in the ionised form, the ion of which can not penetrate or diffuse the nerve cell membrane easily. On the other hand, we also come to know that only the unionized form of molecule of LA agent penetrates or diffuse the nerve cell membrane easily and for its action from the inner side of the cell membrane of axon, it further undergoes intracellular

ionization. Thus, the unionised molecule of the LA agent helps in penetration through the nerve cell membrane, and for its action this unionised form of LA agent ionises first in the cell cytoplasm and then this ionised form acts at the inner side of the Na^+ channel which is situated on the cell membrane. The inner side of Na^+ channel which is situated on the cell membrane is the principal site of action of the LA agent. So, one would easily predict that due to more ionization of acid salt in the acidic solutions of LA agents it will have less penetrable form of LA molecule (i.e. unionised LA molecule). So, acidic hydrochloride preparation of LA agent will less penetrate the cell membrane and its intracellular concentration will be less. Hence, the acidic solution of LA agents would take a longer time for the onset of action, produce less intense block and have an increased incidence of missed block. Therefore, it can be predicted that alkalinization of the local anaesthetic solutions with $NaHCO_3$ (which is called carbonated local anaesthetic) prior to its injection will result in better action than its acidic solution, in respect of the onset, duration and density of action. This is because (Fig. 13.3) in alkaline carbonated form the LA agent remains more in the cell membrane-penetrable unionized form. But the main problem of this alkalisation of LA agent is that the formation of original molecule of LA agent by adding $NaHCO_3$ are weak base and are so insoluble in water solution of it.

A number of factors contribute to an enhanced effect of the carbonated LA agent, over its hydrochloride form. These are:

i. When the pH of the solution is more alkaline, then there is an increased concentration of uncharged or unionized base form of the LA agent which can easily penetrate the cell membrane.

ii. CO_2 diffuses rapidly to the interior of the cell membrane. Within the cell the CO_2 lowers the intracellular pH by forming H_2CO_3 and increases the ionization of the local anaesthetic agent. Intracellular ionisaton of the LA agent helps in two ways:

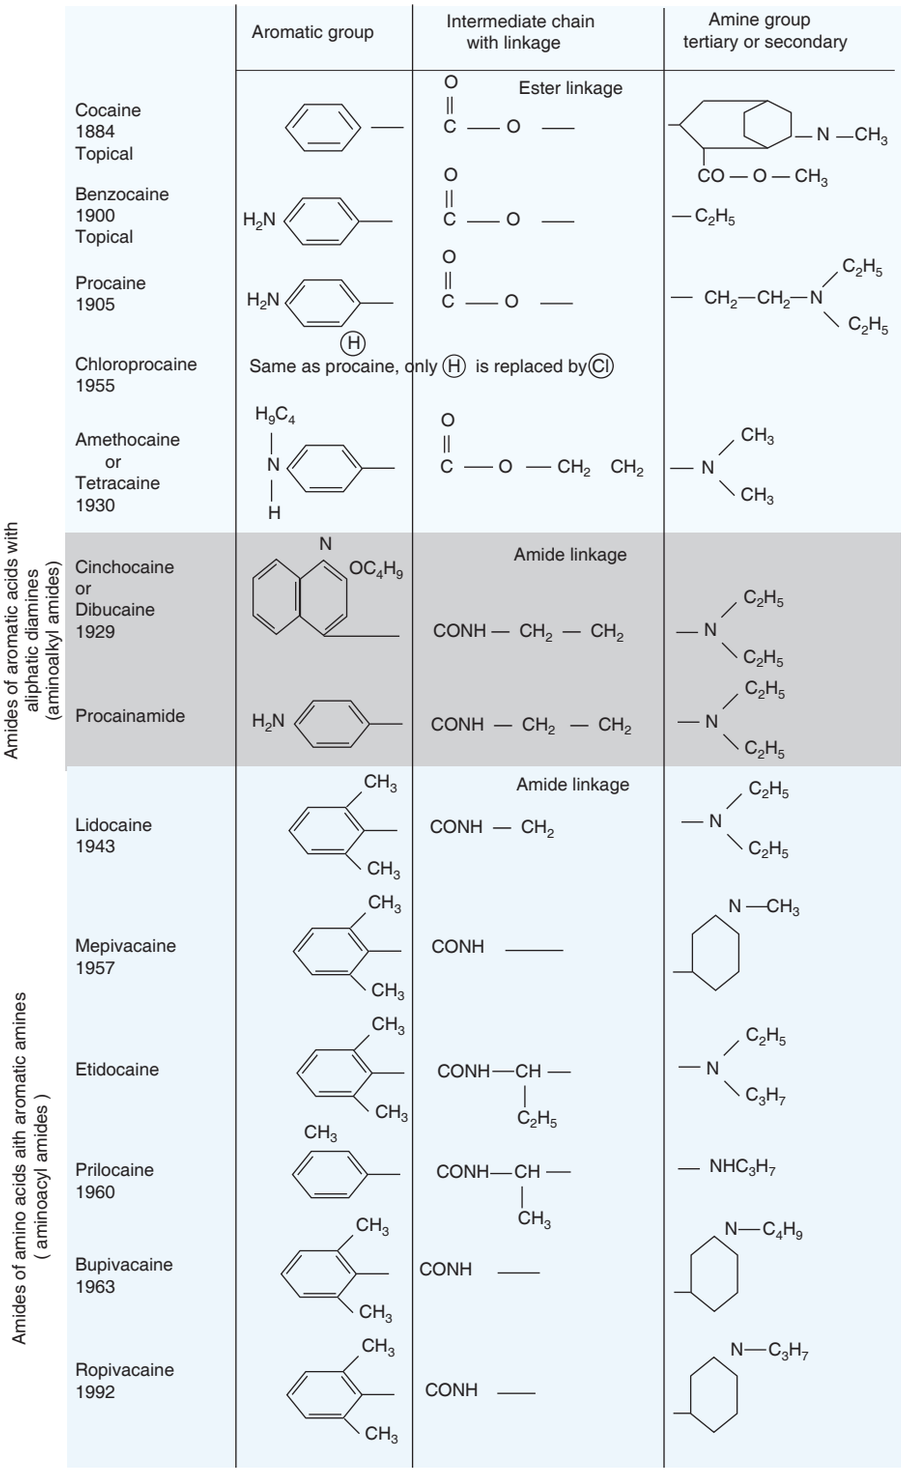

Fig. 13.3: Structures of various anaesthetics

a. release of more cations after intracellular ionization of LA agent enhances the nerve blocking activity and
b. reduction of the unionized base inside the cell increases the gradient of this form of the local anaesthetic agent and helps for further diffusion of this form into the cell.

Carbonated lignocaine is also superior to its hydrochloride form for epidural block in respect to the speed of onset, reduction in the incidence of missed segment and increased incidence of deep motor block.

Compounds with more lipophilic nature are obtained by increasing the size of the alkyl substitutes. These agents are more potent and produce long lasting effects than their less lipophilic congeners. For example, etidocaine has 3 more carbon atoms than lignocaine in the amine end of the molecule and is four times more potent and five times more long lasting.

CLASSIFICATION OF LA AGENTS

Local anaesthetic (LA) agents can be classified under different headings as follows :

A. Injectable

i. Low potency and short duration of action – cocaine, procaine and chloroprocaine.
ii. Intermediate potency and medium duration of action – lignocaine, prilocaine, mepivacaine.
iii. High potency and long duration of action – tetracaine, bupivacaine, ropivacaine, dibucaine, etidocaine.

B. Surface anaesthetic

i. Soluble – cocaine, lidocaine, tetracaine (amethocaine).
ii. Insoluble – Benzocaine, oxethazaine and butylamino benzoate (butamben).

C. Chemistry

i. Ester – cocaine, amethocaine (tetracaine), benzocaine, butamben, chloroprocaine, procaine.
ii. Amide – prilocaine, lidocaine, mepivacine, bupivacaine, etidocaine, ropivacaine.

As the amide group of local anaesthetic agents are structurally base, so it combines with acids to make a water soluble acidic salt which is stable and can be autoclaved. Otherwise, amide group of local anaesthetic agent itself being a base is not water soluble and is only soluble in relatively lipophilic organic solvents. So, for convenience most of the LA drugs are marketed as its soluble acidic hydrochloride salts. On the other hand, ester linked local anaesthetic agents are unstable in solution and can not be autoclaved. Ester linked local anaesthetic agents are degraded in plasma by hydrolysis, except cocaine and their metabolites are more prone to produce anaphylactoid reaction. Cocaine is metabolized predominantly by hepatic carbonyl esterase. P-aminobenzoic acid (PABA) is one of the important metabolites of all the ester type compounds that can induce anaphylactoid or allergic reactions. But amides are degraded by oxidative dealkylation in liver and hence anaphylactoid reactions are extremely rare (Fig. 13.4).

The lipophilic or lipid-soluble unionised form of amide LA agent (base or unprotonated) is the active form which can penetrate the nerve cell membrane. This unionised form of amide LA agent after entering the cell membrane is ionized and acts at the intracellular pole of Na channel to exert their LA action. In a marketed acidic solution of amide LA agent the unionized and ionised form of the LA compound remain in certain ratio. The equilibrium of ratio between the unionised and ionised portions of a particular local anaesthetic agent depends on the pKa value of that particular drug. The pKa value is the pH at which the unionised & ionised forms of the local anaesthetic agent remain in 50:50 proportion. Most of the local anaesthetics in clinical use are weak bases with pKa values varying between 7.5 and 9.5 (mainly around 8). The higher the pKa value of the drug, the stronger is its action as a base. Therefore, little of it will be available in the unionised (more will be ionised) form at normal body pH. As for example, pKa value of lignocaine is 7.86. So, at a tissue pH of 7.8, lignocaine will have unionized and ionized forms in the ratio 50:50. But at a pH of 7.4, only 25% of lignocaine will remain in the active unionised form and the rest 75% will remain in the nonactive ionized form. In an inflammed tissue, the pH is more acidic. So, the percentage of the active unionized form of LA agent will be lesser and the anaesthetic effect will be also low in the same concentration or dose for a given drug. The pKa value of procaine is 9. So, at pH 9 the unionised & ionised forms of the drug are at the proportion of 50:50. But at pH 7.4, only 25% of procaine remains in the unionised active and penetrable to cell form, and rest is in the ionized form. As, it is the unionized, lipid soluble moiety of a LA agent that can penetrate most rapidly the lipid rich barriers protecting the axon, so one would easily predict that procaine would penetrate the body tissues slowly at normal body pH. Thus the clinical utility of procaine is confined primarily to the circumstances in which the large lipid barriers are not encountered, such as during direct topical anaesthesia of the cornea or conjunctiva and spinal anaesthesia.

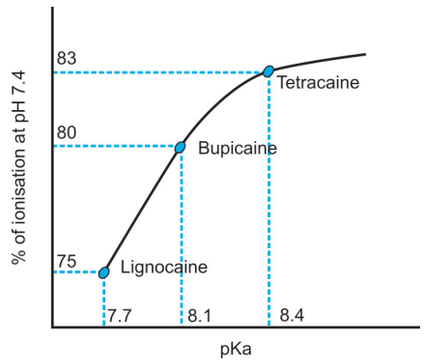

Fig. 13.4: This schematic diagram shows the percentage of charged ion of different local anaesthetic agents with different pKa value at pH 7.4

After injection in the tissue, the drug first moves from the site of injection to the area which is immediately outside the target nerve. This movement is through the subcutaneous or other tissues. The factors governing this first stage of journey of a local anaesthetic agent from the site of injection to the site of action at nerve fibre are: the concentration gradient, the mass or volume of the drug, the degree of ionisation and the solubility of the LA agent. Concentration gradient at the site of injection and the total mass depend on the volume and concentration of the drug injected. Greater concentration and bigger volume of injected drugs will cause a rapid increase in the therapeutic concentration of the drug at the nerve site. According to the theory of drug diffusion, larger size of the drug molecule has more difficulty in moving rapidly through the extracellular space. In fact, the speed of drug movement is more closely related to the square root of the size of the molecule. The molecular weight of all the local anaesthetic agents usually vary between 236 to 250 Da. Therefore, this factor plays a little role in the difference, regarding the speed of onset of the block among the LA drugs.

According to the previous discussion, it is found that at physiological pH most of the LA agents exist in a protonated or ionised form, while a much smaller portion exists as unprotonated or unionized form. Consequently, the sodium channel which is responsible for the cellular action potential is a protein in nature and is embedded in the lipid rich cell membrane. It is the inner intracellular pole of the Na^+ channel which is the site of action of the local anaesthetic agent. Unprotonated local anaesthetics are lipophilic in nature. Therefore, these molecules move easily and rapidly through the cell membrane (but not through the Na^+ channel) to arrive inside the cell. Subsequently, this unprotonated or unionised form then becomes protonated or ionized inside the cell and traverses through the water and electrolyte rich cytoplasm of the cell to attach to the inner side of the Na^+ channel. This protonated or ionised or cationic form of the local anaesthetic agent is responsible for most of the nerve blocking or Na^+ channel blocking effect, which acts from the interior of the cell membrane. Whereas, unprotonated, or unionized or the base form of local anaesthetic agent is responsible for penetration of the nerve fibre for its lipid solubility. Thus the unionised form is more important and active form than the ionised form.

Once attached to the intracellular part of the sodium channel, it appears that the local anaesthetic molecule can act on any one of the functional states of Na^+ channel. However, the local anaesthetic inhibits only the active sodium channels more strongly than the inactive sodium channels. Actually, the sodium channels pass through a cycle of different stages. This corresponds to the different functional states depending on the different phases of the action potential. The ability of a local anaesthetic molecule to bind with any given form of sodium channel is said to be the function of the position of that sodium channel in its cycle of action potential. It is also a dynamic process that channels are rapidly occupied and unoccupied by LA agents during a single action potential.

The pH of a tissue into which local anaesthetic is injected also directs the drug activity by altering the relative percentage of uncharged or unionised (unprotonated) and charged or ionized (protonated) molecule of the agent according to its pKa value. The uptake of drug by tissues largely results from the lipophilic absorption. So, as more of the drug will be lipophilic the more of the drug will be absorbed. Alkaline tissues alter the drug activity by matching the tissue pH with the drug pKa values and thereby favouring the unionised base for its absorption. The tissues also alter the effect of the drug by limiting the diffusion of the local anaesthetic agent from the site of injection. The tendency of the drug to be protonated (ionized) also depends on many other environmental factors, such as: temperature and medium surrounding the drug.

When pH of a local anaesthetic solution is lowered by addition of adrenaline, sodium metabisulphide (antioxidant), glucose, etc. then the tissue pH becomes more acidic (this is because buffering effect of local tissue is low) and availability of unionised form will be less. Thus, the power of penetration and intracellular concentration of LA agent decreases which in turn decreases the intracellular ionised form and hence the blocking action of the Na^+ channel from inside of the cell membrane. The mucous membrane also has minimal buffer reserve and so needs higher concentration of drugs for topical anaesthesia. The pH of all marketed plain solutions of LA agents varies from 4.4 (etidocaine) to 6.3 (lignocaine).

ANATOMY OF NEURON

The term 'Neuron' means nerve cell which consists of body and its processes such as dendrites and axon. They vary in shapes and sizes in different parts of the body. For example, its diameter varies from 5 µm (in cerebellum) to 120 µm (at the anterior horn cells of the spinal cord) and the length of axons also vary from a few micromillimeter to about 90 cm.

Within the cell body of neuron there is cytoplasm (axoplasm) and nucleus. The cytoplasm of the cell body is again differentiated into two parts such as under the cell membrane a superficial gel layer and a relatively fluid core. The outer gel layer of cytoplasm has a contractile property. This contractile property of the outer gel layer results in a continuous flow of axoplasm from the cell body to the periphery into the axon and dendrites. A large vesicular nucleus with a single prominent nucleolus is seen in every cell body of the neuron. In the cell body adjacent to the nucleus there is often seen a large granule, representing sex chromatin. In the cytoplasm of the cell

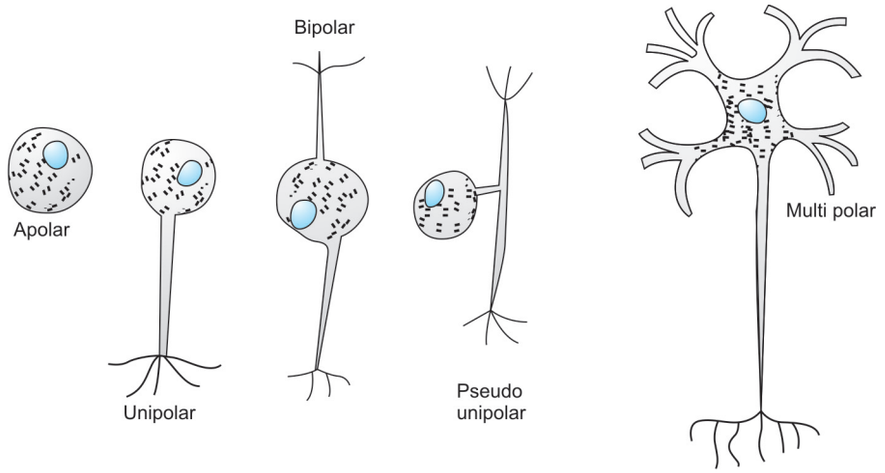

Fig. 13.5: Basic morphological features of different types of neurons

body near the nucleus there are also found many Nissel granules, numerous rod like mitochondrias, golgi apparatus and some fine long filaments called the neurofibrils. The neurofibrils and mitochondrias can enter into the axons from cell body, but the Nissel granules are not found in axon (Fig. 13.5).

Nissel granules are actually the endoplasmic reticulum and the granules covering them are called the RNP (Ribose Nucleo Protein). RNP are one of the most striking morphological features of the neuron and it indicates intense protein production with high activity. In dendrite the Nissel granules are rod shaped. In motor neurons they are coarse and flocculent, while in sensory neurons they are almost dust-like. Fatigue, poisons and sectioning of the axon cause Nissel granules to disintegrate into fine dust and eventually disappear.

Dendrites are the processes that carry impulses towards the nerve cell body from outside. They are generally shorter than the axon and contain many branches with Nissel granules. The number of dendrites of a cell body varies from nil to numerous. But as a rule they are multiple, relatively short, and follow a specific branching pattern (Fig. 13.6).

According to the number of processes, the neurons can be classified in the following:

i. Apolar neurons – They have no processes.
ii. Unipolar neurons – All developing neuroblasts pass through this stage when they have only one process, called the axon. In the adult humans such true unipolar neurons are not commonly seen. They are only found in the mesencephalic nucleus of the 5th cranial nerve.
iii. Bipolar neurons – Typically these neurons are spindle shaped, possessing a axon at one pole and a dendrite at the other. Neurons, developing from neuroblasts pass through this stage. In adults they are usually found in the retina, vestibular ganglion, spiral ganglion of cochlea and olfactory neuroepithelium.
iv. Pseudounipolar neurons – Such typical bipolar neurons are found in all the spinal ganglia and in the ganglia of the cranial nerves, other than the 8th. In this type of neuron, there is a single process with T-shaped divisions. One branch of the T is a dendrite coming from the periphery and the other is the axon, extending centrally.
v. Multipolar neurons – These neurons have most varied forms. They are Purkinje cells of the cerebellar cortex, pyramidal cells of the motor cortex, small neurons of the spinal nucleus of the trigeminal nerve, motor neurons of the ventral horn of the spinal cord, etc. Usually the shape of these neurons depends mainly on the number and position of the dendrites.

Axon is the process of a nerve cell body which carries impulses away from it. The term nerve fibre usually refers to the bundle of axons. The axon arises from that part of the nerve cell body, which is called the axon hillock. Axon contains no nissel granules. The number of axon of a cell body of a neuron is single but constant. If a neuron has only one process, then it will be the axon. The axis cylinder of an axon contains cytoplasm which is called axoplasma. It is a semifluid substance and is essential for nutrition and growth of the nerve fibre. The axon also contains many neurofibrils and mitochondria within its axoplasm and ends in numerous terminal buttons, called the telodendria (Figs 13.7A and B).

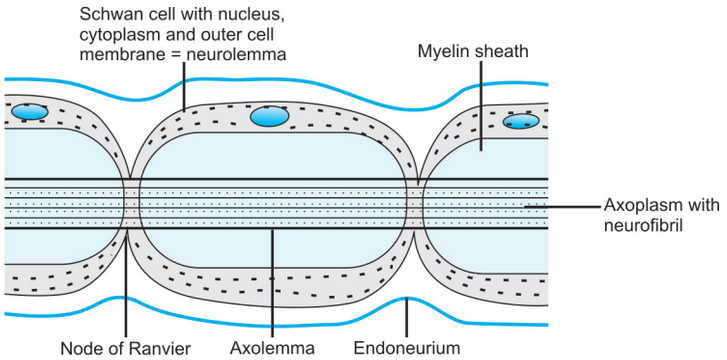

Fig. 13.6: Longitudinal section of a myelinated peripheral nerve

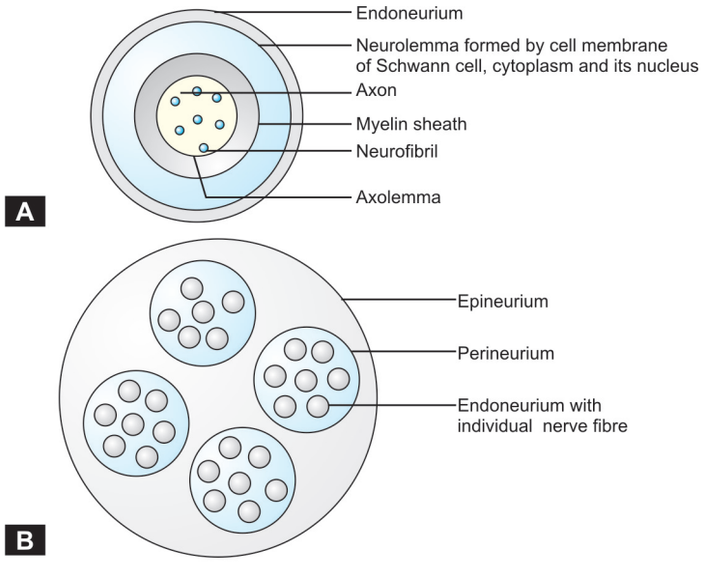

Figs 13.7A and B: Organisation of a trunk of peripheral nerve: (A) Cross section of a single nerve fibre, (B) Cross section of a nerve trunk

So long as the nerve fibre or axon remains within the grey matter of the central nervous system, it remains naked. Then as soon as it enters the white matter of the CNS, it gets the first covering, called the myelin sheath (white). After that when it comes out of the central nervous system, it receives a second covering called the neurilemma. When the nerve fibre terminates at the periphery on a target cell, then the neurilemma sheath is lost first, and next the myelin sheath. Lastly the axis cylinder of the axon ends as a naked process with out any coverings. Each motor nerve fibre at its termination breaks up into about 150 branches and each of these branches ends on a separate muscle cell or fibre. One motor nerve fibre or axon with all the muscle fibres that it supplies constitute one motor unit. Each motor unit is controlled by one motor nerve cell of the CNS. In the central nervous system the nerve fibres do not contain any neurilemma sheath. Myelination in CNS does not takes place by Schwann cells. It is occured by oligodendroglia cells which surround the axon in CNS and form the myelin sheath. Schwann cells take part in the formation of myelin sheath in the periphery. Like the peripheral nerves, the nerve fibres of the CNS also possesses the nodes of Ranvier, but these are not so obvious as in peripheral nerves.

Medullated (or Myelinated) Nerve Fibre and Myelinogenesis

In a myelinated nerve fibre, the central core is the axon. The outer cell membrane of the axon, which is called the axolema is here the actual impulse conducting membrane. The axon is filled with a viscus intracellular fluid, called the axoplasm. In a myelinated nerve fibre the axolema is surrounded by a sheath of lipid material, which is known as the myelin sheath. The myelin sheath is present in all the thick somatic nerve fibres, but not over the postganglionic autonomic nerve fibres. The somatic nerve fibres of 1μ diameter or less are not medullated. All the preganglionic autonomic fibres are also medullated. The myelin sheath is again lined by a delicate membrane which is known as the neurilemma sheath. However, this is nothing but the last turn of the Schwann cell and is formed during the formation of myelin sheath. In the last turn of the Schwann cell, there is a nucleus which is located near the most outer membrane of the Schwan cell. Thus the most outer Schwann cell membrane, nucleus and the irregular cytoplasmic strands inside the Schwann cell membrane constitute the Schwann cell sheath of neurilemma in all the matured nerve fibres.

In a medullated nerve, the myelinogenesis is caused by the depostion of myelin sheath around the axon by the Schwann cells. The axon is first enveloped completely by a Schwann cell. The Schwann cell then gives several turns around the axon by many concentric layers of cytoplasm and its cell membrane. Then the cytoplasm disappears from the concentric layers, leaving only the cell membrane of the Schwann cells, wrapping one on another. Thus, the compact myelin sheath consists only of several concentric layers of the Schwann cell membrane. Only the outer turn of the Schwann cell persists as the sheath of neurilemma with some cytoplasm, nucleus and the outer cell membranes. This myelin sheath acts as an insulator and prevents the flow of almost all the ions across the axolema. The myelin sheath is not continuous all over the whole axon, but is interrupted regularly at an interval by the nodes of Ranvier. In the nodes of Ranvier the myelin sheath is absent and the outer turn of the Schwann cell membrane (neurilemma) is dipped inwards over the axon. In comparison with the myelin sheath, the axolema and neurilemma in this region of the nodes of Ranvier are highly permeable to ions and takes part in the conduction of impulse alony the axon.

In case of unmyelinated nerve fibres, the axons are also buried within the Schwann cells. Here, the axons are enclosed by a Schwann cell, but it does not spin a myelin sheath around them. Non-myelinated nerves are abound in the CNS and in the dorsal nerve root. Myelination in CNS occurs by different process. Here the cell is oligodendroglia but not the Schwann cells which takes part in the process of myelination.

Thus, a medullated nerve fibre consists of the following structures from within outwards:

i. A central core of axon with semifluid axoplasm, which flows from the cell body of the neuron to the periphery. If the axon is sectioned, the axoplasm pours from the cut ends. The axoplasm contains numerous fibril like structure called neurofibril and mitochondria. The axolema (the cell membrane of the axon) separates the axoplasm from the surroundings structures.
ii. The axon is surrounded by a myelin sheath, which is interrupted regularly at the nodes of Ranvier.
iii. The neurilemma represents the outer most cell membrane of the Schwann cell and under it lies a thin layer of Schwann cell cytoplasm with its peripheral nucleus.
iv. At the most periphery outside the neurilemma sheath a single Schwann cell and a single axon is wrapped by a layer of permeable connective tissue, called the endoneurium. Several of these units are further bundled together within a sheath of squamous cells, known as the perineurium. This layer is more resistant than the endoneurium to the passages of chemical molecules. The perineural bundles can be seen with the naked eye. These multiple perineural bundles are packed by an another outermost connective tissue covering and constitutes a nerve. This outermost connective tissue covering of a nerve is called the epineurium. This layer protects the nerve from the external damage. It is more permeable than the perineurium and contains the nerve's blood vessels.

ACTION POTENTIAL AND TRANSMISSION OF IMPULSES

Action Potential

Action Potential (AP) is the sequence of changes of intracellular and extracellular electrical charges which accompanies the passage of an impulse along the cell membrane. This is the mechanism by which the nerve cells transmit the electrical signals. A typical cell membrane is a molecular lipid bilayer which is composed of phospholipids and cholesterol in the ratio of about 5:1. This lipid bilayer of cell membrane also contains many proteins which are absorbed on the surface or embedded in it. These proteins are known as the receptors or ion channels and are used for intracellular communication. The lipid bilayer character of (Fig. 13.8) the cell membrane is arranged in such a fashion that the long hydrophobic fatty acid tails of the phospholipid molecules that lie in the centre of the membrane and the polar hydrophilic head groups of the phospholipid molecules project in the cytoplasm or in the interstitial space.

In the resting state of the axon the outer surface of the cell membrane is positively charged and the inner surface of the cell membrane is negatively charged. So that, at rest, between the inside and outside of the cell membrane there is a difference of electrical potential which is about –70 mV. However normally this range varies between –60 to –90 mV. This difference in electrical potential at rest is known as the resting membrane potential (RMP) and this is necessary for the cell membrane to receive and transmit the impulses in the form of action potential. In order to maintain this resting electrical potential or polarized state, the nerve cell must resist their natural tendency to neutralize this difference in electrical potential by opposing the diffusion of ions across the cell membrane according to their concentration gradient. So, this diffusion is opposed and the polarized state or the concentration gradient of ions is maintained by an ATP energized Na^+ and K^+ membrane pumps which actively push Na^+ out of the cell and K^+ into the cell. For every $3Na^+$ is pushed out, $2K^+$ is pushed in.

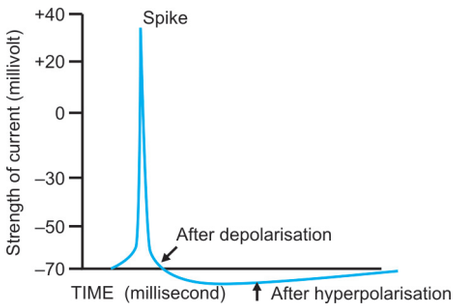

Fig. 13.8: Complete action potential. The first manifestation of action potential is depolarisation of membrane,i.e. influx of Na^+. After an initial –40 mv depolarisation, the rate of depolarisation increases. The point where this change of rate occurs is called the threshold or firing level. After the threlevel, the depolarisation level overshoots and crosses the iso-potential (or zero potential), to reach +40 mv. Then the membrane potential reverses and falls rapidly towards wards the resting level. This is called 'repolarisation'. When the repolarisation is 70% completed, the rate of change decreases,and the tracing approaches the resting level more slowly. The sharp rise and rapid fall of membrane potential is called the 'spike'. The slower fall at the end of repolarisation is called 'after-depolarisation'. After reaching the resting level, the membrane potential slightly moves in the hyperpolarising direction, to form a small but prolonged 'after-hyperpolarisation' state

In the resting state, the Na^+ concentration at outside of the cell membrane is higher than that of the inside of the cell membrane. Again, K^+ concentration at inside of the cell membrane is higher than that of the outside of the cell membrane. On the other hand, K^+ can penetrate through the cell membrane at the resting state, but not the Na^+. Positivity at outside of the cell membrane which is due to higher Na^+ concentration and other reasons also cause the K^+ to be pushed inside the nerve cell, producing higher K^+ concentration inside the cell. The axoplasm (cytoplasm of the axon) is also rich in proteins and organic acids, which are negatively charged and are too large to pass through the membrane (Fig. 13.9).

These are also responsible for the negativity of the inside of the cell in the resting state. Not all the ions are equally important for the maintenance of resting membrane potential. But each ion contributes to the aggregate potential

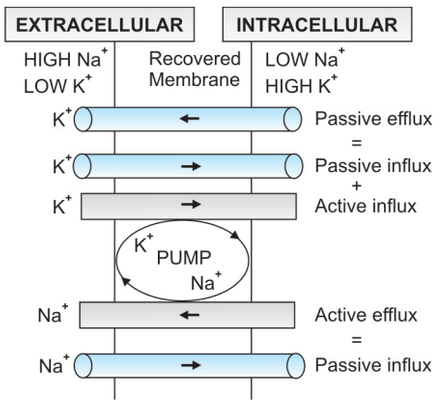

Fig. 13.9: Sodium pump is required to expell Na^+ from the interior of the nerve axon so that the internal Na^+ concentration is held to about 7% that of external fluid. At the same time pump drives K^+ uphill from a lower external concentration to about 28 times higher internal concentration

difference across the cell membrane which is based on the ratio of their concentration gradient between inside and outside of the cell and also based on the permeability of the cell membrane to that particular ion. The Na^+-K^+ pumps which are straddled in the cell membrane and require high energy phosphate (ATP) for their action are only responsible for maintaining Na^+ and K^+ gradient across the cell membrane at resting state. This gradient is again responsible for the influx of Na^+ into the cell and movement of K^+ out of the cell, during action potential. If this gradient is not maintained, then action potential is not possible.

In the resting state, the nerve fibre remains in a polarised state and the resting membrane potential lies around −70 mV. The inside of the nerve cell is negative and the outside of the nerve cell is positive. The permeability of Na^+ through the cell membrane is increased only when the stimulus reaches the cell membrane. It is the first event of the action potential. It has been postulated that in the resting state the calcium ions (Ca^{++}) remain bound to the protein surfaces of the membrane pores. It does not allow the Na^+ to permeate through these resting pores. During excitation this Ca^{++} is dislodged from its binding sites, and the permeability of Na^+ inside the cell is increased. With the entry of Na^+ inside the cell, the membrane potential gradually decreases. However, when the potential difference across the cell membrane comes to a critical or threshold level (approximately –40 mV for most cells), then there is a sudden and spontaneous increase in Na^+ permeability and Na^+ enters inside the cell membrane. Thus, the depolarisation starts with the onset of increase in Na^+ permeability of the cell membrane. This tremendous increase in Na^+ conductance during this period is known as activation of membrane. During depolarisation, this change in transmembrane potential is accompanied by a further increase in Na^+ permeability with the creation of a positive feedback loop by which the influx of Na^+ facilitates further Na^+ influx.

Thus, due to influx of Na^+ during depolarisation the reversal of potential across the cell membrane is occurred with the development of positivity inside of the cell membrane and negativity outside of the cell membrane. With the increase of positivity inside of the cell, further entry of Na^+ is prevented and calcium begins to bind with the proteins of the membrane pores. So, at the end of depolarisation, as soon as the transmembrane potential attains the voltage of approximately +50 mV, then Na^+ influx stops. In that situation, the cell attains an unstable condition because both the Na^+ and K^+ one inside of the cell with reverse potential (positivity inside the cell and negativity outside the cell). But this unstable condition cannot be allowed to continue indefinitely. So, at this point a less rapid, but more sustained change in the permeability of the cell membrane to K^+ occurs and this is beginning of repolarisation. With the beginning of repolarisation K^+ flows along its concentration gradient from inside to outside of the cell taking +ve charges with it. Thus the loss of +ve ions from inside of the cell causes a fall in the electrical potential of the axoplasm and reach the normal resting negative (– ve) value. But, indeed the change in K^+ permeability is sustained for a sufficient time and this is for the net potential difference across the cell membrane to reach −75 mV which is some what below the resting membrane potential (–70 mV). This hyperpolarisation, combined with the inactive sodium ion channel is responsible for the brief refractory period that each segment of a neuron requires following generation of an action potential.

In this hyperpolarization phase, though the resting membrane potential (i.e. negativity inside the cell and positivity outside the cell) is achieved, but the resting ionic status is not established (Na^+ inside and K^+ outside the cell). So, the resting ionic status is achieved now by the active Na^+-K^+ pump-mechanism and Na^+ begins to come out of the cell. Increased concentration of Na^+ outside the cell now causes the K^+ to diffuse back into the interior of the nerve cell.

Thus, the action potential cycle is completed with the establishment of a normal electrical potential status and normal ionic status. Now Na^+ and K^+ pumps maintain this concentration gradient of Na^+ and K^+ across the cell membrane.

Transmission of Impulses

The impulses are actually the propagated waves of depolarisation caused by the continuous coupling between the excited and the nonexcited regions of the cell membrane. It has already been discussed earlier that a resting nerve fibre remains in a polarised state with positive charges lined up along the outside of the cell membrane and negative charges along the inside of the cell membrane. Then as soon as the nerve fibre is excited at any point, then the polarity is changed at that point and for a brief period it is actually maintained at that point. However, this reversed polarity of cell membrane at that point of stimulation is due to the increased inward permeability of Na^+ through the membrane. Thus, a small area of depolarisation develops at

the point of excitation. Then a local circuit current flows between the depolarised area of membrane and the adjacent resting polarised area of the membrane. Thus an ionic current entering the axon through the excited depolarised region, flows down the axoplasm and exits through the surrounding resting membrane, causing depolarisation of the adjacent resting regions. Thus, positive current flows inward through the depolarised membrane and outward through the resting membrane and in this way a small circuit of current or a wave of depolarisation is completed which as a impulse travels in all directions along the entire length of the nerve fibre. Though, this local circuit current or the wave of depolarisation spreads away from the excited zone in both directions, but the regions behind the impulse having just been depolarised is absolutely refractory. So, the impulse propagation is unidirectional. After the wave of depolarisation, a repolarisation wave first occurs at the point of stimulus, a few ten-thousandths of a second later than the depolarisaton wave and spreads progressively along the membrane, following the similar directions as the depolarisation wave had spread previously. This type of conduction is observed in the non-medullated nerve fibres (Fig. 13.10).

However, in the myelinated nerve fibre conduction occurs in a similar pattern as described above. But the myelin sheath is an effective insulator. So, ions cannot pass through the myelin sheath. Therefore, the nodes of Ranvier only allows the ions to penetrate through it more easily. Nodes of Ranvier are 500 times more permeable than unmyelinated fibres. For this reason, the impulse or the wave of depolarisation is transmitted from one node of Ranvier to another, rather than continuously along the entire length of the medullated nerve fibre. Thus, the depolarisation in a myelinated axon jumps from one node of Ranvier to the next. So, this jumping or leaping of depolarisation from one node to another is known as the saltatory (saltare = to dance) conduction of impulse.

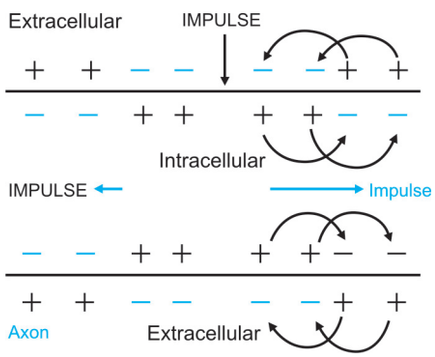

Fig. 13.10: This is a diagrammatic representation of current flowing along the cell membrane of an axon (axolemma), in an unmyelinated nerve fibre

MECHANISM OF ACTION OF LOCAL ANAESTHETICS

The local anaesthetic (LA) agents block the generation or conduction of nerve impulses by decreasing or stopping the entry of Na^+ ions through its channel inside the cell, during the depolarisation phase of AP. As the concentration of the LA agent is increased, then the rate of the rise of depolarisation potential to the threshold level and subsequently the initiation of AP is inhibited, causing slowing or total block of generation and conduction of nerve impulses (Fig. 13.11).

The LA agent acts through binding a site which is situated at the intracellular portion of the voltage sensitive Na^+ channel and raises the threshold value of the channel opening. This binding site of LA agent at the intracellular portion of the Na^+ channel is called the LA receptor. This Na^+ channel is nothing but a special protein through which Na^+ enters the cell, and also called the ion channel. Thus the Na^+ channel fails to open after binding with the LA agent and the Na^+ permeability fails to increase in response to an oncoming impulse or stimulation. The Na^+ channel is situated in the cell membrane with a small portion protruding inside and outside of it. It has an activation gate (A) near its

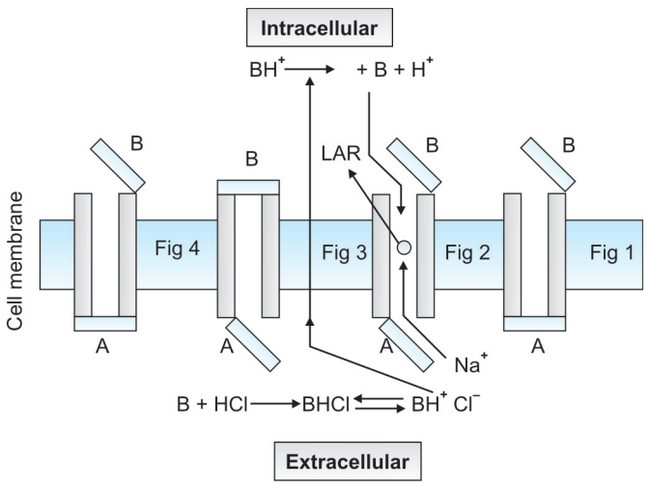

Fig. 13.11: This is a schematic diagram of axonal Na^+ channel in different phases of action. The picture also shows the site and mechanism of action of local anaesthetics. The Na^+ channel has an activation gate (A), near its extracellular mouth and an inactivation gate (B), at the intracellular mouth. In the resting state the activation gate (A) remains closed, while the inactivation gate (B) is open (Fig. 13.1). When the resting membrane potential (RMP, reaches the threshold level and depolarisation shoots up, then the activation gate opens and allows the Na^+ to flow in the cell along the concentration gradient (Fig. 13.2). Within a few milliseconds the inactivation gate closes and the flow of Na^+ stops (Fig. 13.3). After that the Na^+ channel recovers to the resting stage (Fig. 13.4) by opening of the inactivation gate and closing of the activation gate.
B = Insoluble local anaesthetic base, BHCl = Soluble hydrochloride of local anaesthetic (LA) unionized, BH^+ = Ionised form of LA, LAR = Local anaesthetic receptor

extracellular mouth and an inactivation gate (B) at the intracellular mouth. In the resting (Fig. 13.12) state, the activation gate (A) is closed and inactivation gate (B) remains open. During the depolarisation of AP when the threshold level of membrane potential has been reached, then the activation gate opens and allows the Na^+ ions to flow inside the cell, along the concentration gradient. At the resting state, the membrane is normally permeable to K^+ through the K^+ channel, but not permeable to Na^+ through the Na^+ channel. But, during the depolarisation phase of AP the nerve membrane transiently switches its permeability from K^+ selectivity to Na^+ selectivity. After the opening of activation gate within a few milliseconds, the inactivation gate (B) closes and ion flow ceases. But in this phase activation gate is still open. After that the channel recovers to the resting state in a time dependent manner with the closed activation gate (A) and opened inactivation gate (B) (Fig. 13.13).

At a physiological pH, the LA molecule is partly ionised and partly unionised. However the equilibrium between the unionised or unprotonated base form (BH) and the ionized or protonated or cationic form (B) of a LA agent depends on the pKa of it, the pH of the solution, and also the pH of the local tissue. The LA agent traverses the nerve cell membrane in its lipophilic unionised form (BH).

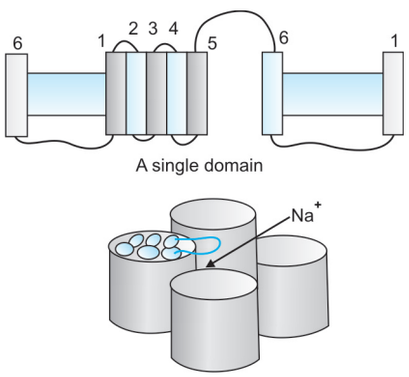

Fig. 13.12: Four domains forming the Na^+ channel

Then it reionises in the axoplasm and its ionised form approaches the LA receptor situates at the intracellular mouth of Na^+ channel. At the receptor the LA agent binds with the Na^+ channel and prevents its opening. It is the cationic or ionised form (B) of the LA agent which primarily binds to the receptor and is responsible for its action. The activated receptor has higher affinity or is more accessible to the LA agent, compared to the resting state of it. Binding of the LA agent to its receptor site stabilizes the Na^+ channel in the inactive state and thus reduces the probability of opening the channel and prevents the influx of Na^+ inside the cell. Thus it prevents the depolarisation part of action potential to initiate and block the conduction of impulses through a nerve fibre. Moreover, the exposure of LA receptor to higher concentration of Ca^{2+} reduces the inactivation of Na^+ channels and lessens the degree of block. Here, the generation of blockade of any conduction of impulses by the LA agent is not due to the hyperpolarisation of cell membrane. Infact, resting membrane potential is also unaltered, because the K^+ channels are not affected. These are blocked only by higher concentrations of the LA agent (Fact file- I).

The cationic form of LA agent is able to approach to its receptor site, only when the channel is opened and binds more avidly.

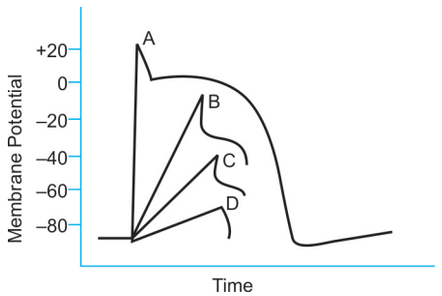

Fig. 13.13: This is the schematic diagram of action potential of different nerves, untreated or treated by LA agents. A=Action potential of a nerve untreated by a local anaesthetic, B,C,D=Show the effects of LA agents on the generation of action potential of a nerve fibre by progressively increasing the concentration

FACT FILE- I

The molecular weight of the neuronal Na^+ channel has been found to be of 300 KDa. Chemically, it is a glycoprotein and is composed of one large (α) and two small (β_1, β_2) subunits. The α-subunit encloses the Na^+ selective pore within its 4 homologous domains (I to IV) where each domain has 6 membranes spanning helical segments (S_1 to S_6) connected alternately by intracellular and extracellular loops. The wall of the pore is formed by the S_5 and S_6 segment of all the four domain, while the short nonhelical loops connecting S_5 - S_6 segments on the extracellular surface fold into the pore and serve as the activation gate. Voltage sensors located in the S_4 segment move vertically on depolarisation and open the activation gate by allosteric conformational change. A few milliseconds later, the short intracellular loop connecting the domains III and IV folds into the inner mouth of the pore, activating the channel. The LA receptor is located in the S_6 segment of domain IV.

Thus, a resting nerve is rather resistant to blockade and blockade develops rapidly when the nerve is stimulated repeatedly. The degree of blockade is also frequently dependent on higher frequency of stimulation. The onset of blockade is primarily related to the pKa value of the LA agents. Those with lower pKa values (7.6 to 7.8), such as lidocaine, mepivacaine, etc., are fast acting, because 30 to 40% of these LA agents remain in the unionized base form at pH 7.4 and it is this form of LA agent which only penetrates the axon membrane. Procaine, tetracaine, bupivacaine have higher pKa value (8.1 to 8.9). Thus only 15% or less of them remain in the unionized form at pH 7.4. So, they are slow acting. However, the chloroprocaine is an exception of it having rapid onset, despite high pKa value.

CLASSIFICATION OF NERVE FIBRES

Nerve fibres have been classified into different types under different headings :

i. Histologically – myelinated and non myelinated.
ii. Functionally – motor (efferent) and sensory (afferent).

iii. Chemically – adrenergic (mainly sympathetic) and cholinergic (mainly parasympathetic).
iv. According to the diameter of fibre and the conduction velocity of impulses.

Classification of Nerve Fibres According to their Diameter and Conduction Velocity

The physiological properties of nerve fibres vary with their diameter and conduction velocity of impulses. Thicker will be the fibre, higher will be the impulse velocity and peak potential, but lower will be the refractory period and the stimulus threshold. Erlanger and Gasser have classified the nerve fibres according to their diameters and conduction velocity into A, B and C. The A fibres are myelinated, somatic, afferent and efferent axons. B fibres are the preganglionic, myelinated, efferent, sympathetic axons. C fibres are the sympathetic and somatic, unmyelinated axons. Again the C fibres are of two types – the s C group and d r C group. The s C group of fibres are efferent, postganglionic sympathetic axons and the d r C group of fibres are the small afferent axons, found in the peripheral nerves and dorsal roots. In a peripheral somatic nerves, both A and C fibres are present.

If a peripheral nerve is stimulated at one end and the impulse is recorded through the oscilloscope at the other end, then a compound action potential formed in this nerve is found to be composed of four different deflections – α, β, γ and δ. These different deflections are due to the corresponding stimulation of different nerve fibres with different conduction velocities within this nerve. The α-deflection is due to the stimulation of nerve fibres, having comparatively larger diameter with higher conduction (Table 13.1) velocity. δ-deflection is due to the stimulation of nerve fibres having lowest diameter and slowest conduction velocity. The B fibres are histologically indistinguishable from small A fibres, but distinguishable principally from A fibres by the absence of negative action potential. The C fibres in a somatic nerve are stimulated only when the threshold stimulus is higher than the stimulus which is used in case of A fibres. Functionally, the C nerve fibres are distinguishable from the A fibres by slow conduction velocity, long spike duration and a high threshold value. The classification of nerve fibres according to their conduction velocity and diameter is already tabulated.

For the clinical blockade of a myelinated nerve fibre a segment or a length of atleast 6 mm (or preferably 10 mm), representing two to three nodes of Ranvier must be exposed to the local anaesthetic agent. Because it will deter the impulses from skipping over the blocked segment by a process which is known as the saltatory conduction. The motor nerves have greater internode distances, than the sensory nerves. This may account for the differential blocked, favouring the affection of more sensory than motor fibres in certain circumstances. Where the length of a nerve fibre available for exposure to local anaesthetic agent is short, then the decision to use a higher concentration of LA agent may be necessary in order to achieve desired effects. Whereas, if longer sections of a nerve is available for action then the contact with LA agent with less concentrations of drug would suffice. However, a certain minimum concentration of the local anaesthetic agent is necessary to block a nerve fibre of a given type. Hence, the clinical emphasis should always be on using the least effective concentration in the smallest volume that produces the desired degree of blockade. Motor and proprioceptive nerve fibres require higher minimum concentration of the LA agent for effective block, than the other modalities such as pain and temperature. Hence, if the achievement of motor akinesia is used as the yard stick for block effectiveness, then pain will never be experienced if there is full motor block. In such situation,

Table 13.1: Classification of nerve fibres

Types of fibre	*Diameter of fibre in μm*	*Velocity of conduction in m/sec*	*Location*	*Sensory function*	*Motor function*
(Myelinated)					
A - α	12 - 20	70 - 120	Afferent and efferent from joints and muscles	Proprioception	Somatic motor
A - β	5 - 12	30 - 70	Afferent and efferent from joints and muscles	Touch, Pressure	Somatic motor
A - γ	3 - 6	15 - 30	Efferent to muscle spindle	No sensory	Motor to muscle spindle
A - δ	2 - 5	12 - 30	Afferent sensory nerves	Pain, temperature and touch	No motor
(Myelinated) B	< 3	3 - 15	Preganglionic sympathetic fibres	–	Various autonomic functions
(Non myelinated) C-dorsal root (d, r, C)	0.4 - 1.2	0.5 - 2	Postganglionic sympathetic fibres	Pain, touch and temperature reflex response	No motors
C - sympathetic (s, C)	0.3 - 1.3	0.7 - 2.3	Afferent sensory nerves	–	Various autonomic functions

touch and tissue movement appreciation (proprioceptive mediation) may be occasionally experienced as pain or discomfort in nervous patients.

POTENCY, DURATION OF ACTION AND SENSITIVITY OF DIFFERENT NERVE FIBRES TO LOCAL ANAESTHETICS

Certain physicochemical conditions control the important biological properties of the local anaesthetic agents. Among these, the protein binding, dissociation ratio and lipid solubility are the most important ones. The affinity for protein (protein binding) is the predominant property that governs the duration of action of LA agents. The agents with high protein affinity occupy the active binding sites of the receptor for a longer period of time and therefore have a prolonged duration of action (e.g. bupivacaine and etidocaine). Drugs with somewhat lesser affinity for protein receptor have an intermediate period of action (e.g. lignocaine and mepivacaine). Whereas, procaine which is poorly protein bound is a short acting LA agent.

The dissociation ratio between the unionised and the ionised form of a LA agent is largely responsible for the speed of onset and the tissue penetration ability of the drugs. Those, being presented in more highly ionized form have inferior properties in this regard.

High potency of a LA agent is associated with high lipid solubility of it. This property also facilitates the solution of a LA agent to enter into the cell through the cell membrane and to reach the nerve fibre (site of action) from the site of injection. So, lipid solubility or hydrophobicity is the prime determining factor for intrinsic anaesthetic potency of LA drugs. After entering the cell, the ionised form of the LA drug is again attached to the hydrophobic LA receptor site of the Na^+ channel which is also related to the potency. But, clinically the correlation between the lipid solubility and potency of the drug is not precise. There is a difference between the in vitro and in vivo results. This difference in result between the in vitro and in vivo studies is related to a number of factors, such as volume of drug, concentration of drug, local vasodilatation or constriction, and tissue redistribution properties etc.

Usually the injected volume and the concentration of LA drug is important in the process of the spread of agent and achieving the adequate concentration of it around the nerves. Concentration of drug around the nerve fibre is also of prime importance in the development of diffusion gradient for nerve penetration. So, though high potency and long duration of action depends primarily on the lipid solubility of the drug, but the action of less lipophilic drugs can be prolonged by increasing the concentration and the volume of it at the injection site or near the nerve fibres. Vasoconstrictive effects of the LA drug also tends to prolong its action by reducing the rate of removal of it from the site of action by vascular absorption. Vasodilator property of the drug has opposite effects. Lignocaine causes greater degree of vasodilatation than prilocaine, causing more rapid vascular uptake and shorter duration of action. So, fewer molecules are available for nerve blockade and has a reduced potency, though lipid solubility of lignocaine is greater than prilocaine. High lipid solubility of etidocaine results in greater uptake of agent by adipose tissue in the epidural space, leaving fewer molecules available for nerve blockade, as compared to bupivacaine.

All the types of nerve fibres are affected by local anaesthetics, but fine and slower conducting nerve fibres are more readily blocked than the thicker and fast conducting fibres. This is because the sensitivity of block is determined by the diameter of the fibre. So, the fine fibres are blocked more easily than the thick fibres. But, these rules do not always hold good. For example, the myelinated preganglionic B fibres are more sensitive than the non-myelinated preganglionic C fibres, though the former is thicker than the latter. The preganglionic myelinated B fibres are most sensitive to all. So, vasodilatation and consequent hypotension is the first effect of spinal anaesthesia than the sensory blockade. Though the thick A fibres are certainly more resistant to local anaesthetic agents, but the fibres within them also differ in the critical length that must be exposed to the LA agent for effective block. Fine fibres have shorter critical length and so is more sensitive to the LA agents. Frequency dependent block also makes the fine sensory fibres more vulnerable to LA agents. This is because they generate high frequency, long lasting action potetial than motor fibres. The fibres subserving pain and temperature (A-δ) are more sensitive than C pain fibres. So, sometimes pathological pain, e.g. impending uterine rupture which is conducted by C fibres may break through an epidural block, which is relieving the physiological pain of labour. This is called the epidural sieve. Sensory A fibres are more sensitive than motor A fibres.

Thus the order of sensitivity of nerve fibres to local anaesthetic agents (starting from most sensitive to less sensitive) are: Pregrianglionic – Pain – Temperature – Touch – Proprioception (pressure) – Motor.

PHARMACOLOGICAL EFFECTS

The pharmacological effects of LA agents are described under three headings : local, regional and systemic.

Local Effects

The block of conduction of impulses through nerve and the relaxation vascular smooth muscle are the two most important local direct effects of local anaesthetic agents.

Regional Effects

Loss of pain, temperature, touch and pressure sensation are the regional effects of local

anaesthetic agents. Loss of motor power and vasomotor tone are also the regional effects of local anaesthetic agents.

Systemic Effects

The LA agent, injected locally is ultimately absorbed by the blood and produces systemic effects. However, this systemic effect depends on the plasma level of this drug. The production of nerve block by systemic administration of a LA agent requires very high doses, rather than local infiltration and is so systemically highly toxic. Hence, it is not used for conduction block of nerves by systemic administration. For example, lethal doses of lignocaine is necessary to block the sensory nerve endings when used systemically. Another example is that the analgesic properties of procaine infusion are due to its action on the CNS, rather than peripheral nerve blocking effect.

The chief systemic toxicities of LA agent are mainly divided into CVS and CNS effects, and this is principally due to its membrane stabilizing property. Therefore, the toxic effects when they occur affect mainly the organs which have excitable membranes such as the brain and myocardium. The incidence of systemic toxicity with local anaesthetic agent when used locally is also related to the total dose of drug given, vascularity of the site of injection, type of drugs used, speed of injection and whether the adrenergic agents have been used as an additive with the LA agent to delay the systemic absorbtion or not. However, in clinical practice the systemic toxicity is most likely to be encountered following the unintentional intravascular injection.

Action on CVS

Infiltration of the LA agent in conventional doses have no significant effect on the CVS. Infiltration in higher doses or inadvertent IV injection of the LA agent cause all the problems. They depress automaticity of SA node and suppress cardiac rhythms. They prolong the action potential of myocardium, increase effective refractory period, slow down conduction through AV node, bundle of His and Purkinje fibres and depress the myocardial force of contraction. All the LA agents reduce cardiac sensitivity to adrenaline.

The local anaesthetic agent such as procaine and procainamide have quinidine like effects. However, procaine is not used as an antiarrhythmic agent for its short duration of action, but procainamide is a classical anti-arrhythmic drug. The electro-physiological properties of the heart muscles are markedly altered by the high plasma concentration of LA agent, and then can itself induce cardiac arrhythmias. Lignocaine is not so cardiotoxic and used clinically as an antiarrhythmic agent. Bupivacaine is more cardiotoxic and may cause ventricular tachycardia, fibrillation or even cardic arrest. Cardiac toxicity of bupivacaine usually does not occur in subconvulsive doses or in the absence of severe electrolyte disturbances or respiratory and metabolic acidosis. Large doses of LA agent may also produce circulatory collapse, as a result of the medullary depression.

Action on Vascular Smooth Muscles

LA agent acts on the smooth muscles of blood vessels through different levels: local, regional and systemic. But the ultimate effect is both complicated and confusing. At the local level procaine is a vasodilator and cocaine is a vasoconstrictor. Mepivacaine is a vasoconstrictor at clinical concentration than prilocaine, lignocaine, bupivacaine in that order. Lignocaine exists in two isomers and the vasoconstrictive effect appears to be vested only on one of the isomers. In case of mepivacaine both the isomers have vasoconstrictive property.

However, at the regional level all the LA agents cause vasodilatation in the area, supplied by the blocked sympathetic fibres. At the systemic level the effects of LA agents on vascular smooth muscle are produced by reflex mechanism or through CNS involvement.

Action on CNS

Cocaine is primarily a CNS stimulant, producing euphoria, excitement, restlessness, tremor, twitching or convulsions. This is due to the inhibition of the inhibitory neurons of central nervous system, as the inhibitory neurons are more susceptible than the excitatory neurons. So, after inhibition of the inhibitory neurons, the excitatory neurons of CNS take an upper hand and produce convulsions. In the 2nd phase with increasing dose of cocaine, when the excitatory neurons are also blocked after the inhibitory neurons, then the total depressive effects of the LA agents become prominent. This is manifested by unconsciousness, respiratory depression, cardiac depression, coma and death. Cardiac depression of LA agents may be the result of medullary depression, other than direct action on myocardium and is compounded by convulsion with associated hypoxia.

Procaine and other LA agents are much less potent. At the safe clinical doses, they produce little or no CNS effect. But, at higher doses or after accidental IV injection it produces CNS stimulation, followed by depression like cocaine.

Lignocaine, on the contrary as CNS effect, causes sedation and higher doses produce excitation, followed by depression. The sedative effect of lignocaine which is observed after epidural administration is well recognized. Hypoxia and acid base disturbances lower the threshold, both to the CNS and to the cardiac toxicity of the LA agent.

Action on Autonomic Nervous System

Cocaine potentiates the action of autonomic sympathetic nervous system by inhibiting the catecholamine uptake at the synaptic level and then produces excitement, tachycardia, hypertension, etc. However, other local anaesthetic agents

block both the cholinergic and adrenergic receptors (but not found in clinical doses).

Hypersensitivity

The true hypersensitivity reaction to modern amide groups of LA agents is very rare. But it is reported and is more common in atopic individuals than the normal population. On the other hand, this term is frequently misused to describe the other adverse reactions of LA agents which is due to the accidental intravenous injection or frank over doses of it. Other modalities of reactions of LA agents which may be mistaken as allergic reactions is vasovagal attacks, which is often found during injection (may be due to fear) in a person with strong vagal activity. Hypersensitivity of LA agent is manifested as local oedema, urticaria, angioneurotic oedema, etc. Anaphylactic reaction is less common than the atopic reaction.

Hypersensitivity reactions to ester group of LA agents is not rare, and is more common than the amide group of LA agents. This is because the para-aminobenzoic acid (PABA) produced by the enzymatic cleavage of it in plasma is the principal metabolic product of the ester linked LA agents and this product is thought to trigger off the allergic reactions in centrain individuals. Amide linked local anaesthetic agents, on the other hand, are broken down in the liver but not in the plasma like the ester type of LA agent, producing PABA. However, as the methyl para-aminobenzoic acid (methylparaben) which is used as a preservative in multidose vials of drug of certain amide linked preparations is related to PABA and may produce hypersensitivity reaction. So, it is better to use preservative free vials, where the history of the problem of allergic reaction exists. There is also a history of cross-sensitivity between the ester group of LA drugs and p-aminobenzoic acid used in sunscreen, cosmetics, different food preservatives, etc. This is because all the benzoic acid esters are highly antigenic.

Absorption

All the local anaesthetic agents are totally absorbed in the systemic circulation after their parentral use through local tissue infiltration. But the systemic absorption of all the local anaesthetic agents after their infiltration in the tissues depends on several factors.

(i) Lipid solubility of the agent

It determines the proportion of the aqueous part of LA agent which is available for rapid removal by blood and the proportion of the lipid soluble part which is taken up by the tissues and thereafter slowly released into the systemic circulation.

(ii) Vascularity of the tissue

The vascularity of local tissues where LA agents are infiltrated also dictates the absorption of the LA agents in the circulation. The more vascular is tissue, the more is the absorption of the drug in the circulation and its systemic effects. This is also altered by the LA agent itself by its vasodilator or vasoconstrictor properties and by the adrenaline added into the LA solution. Absorption of the LA agent through the trachea and inflamed urethra is also as good as IV injection.

(iii) Absorption through various tissues and the GI tract

It is only good for LA agent like procainamide and so it is useful as oral antidysrrhythmic agent. But for lignocaine, after oral administration 70% is metabolized during its single passage through the liver. So, this route is ineffective for lignocaine. A comparison of the blood concentration of LA agents after their absortion following various routes of administeration, reveals that the plasma level of anaesthetic drug is highest after the intercostal blocks, followed by caudal epidural, lumbar epidural, brachial plexus and subcutaneous tissue infiltration in a decreasing order. Thus, use of a fixed dose of LA agent may be toxic in one area, but not in others. For example, 400 mg of lignocaine in intercostal block may easily cause the peak plasma level of 7 µg/ml, which is sufficiently high for CNS toxicity. Whereas, the same dose in brachial plexus block causes peak plasma level of only 3 µg/ml, which is rarely associated with CNS toxicity. Large volumes of diluted solutions of the LA agent cause higher blood level than the same dose in mg in smaller volume. This is because large volume causes larger spread with large surface area for absorption. With same anaesthetic profile lignocaine absorb more quickly than prilocaine, and bupivacaine than etidocaine.

Distribution

After infiltration of a LA agent in the tissues, it is gradually absorbed in the blood. In the blood, LA agent is bound to the plasma protein such as α1-acid glycoprotein but a quantititively more important contribution is also made by the palsma albumin and a small proportion remains free which enters the red cells. Then the LA is very rapidly removed from the blood by the other tissues and it is so rapid that even before proper mixing of the drug in circulation, the removal of LA agents by the other tissues is complete. So, full equilibrium with tissues takes many hours to develop. LA agents readily crosses the blood brain barrier and the placenta. It is distributed throughout all the body tissues, but the relative concentration in different tissues varies. A highly perfused organ shows higher concentration and less perfused organ shows less concentration. The LA agent is rapidly extracted by the lung tissue, so that the whole blood concentration of LA decreases markedly as these agents pass through the pulmonary vasculature. The lung tissue has a lower pH than the plasma and thus favours the transformation of the local anaesthetic into its ionised form.

The highest percentage of the injected dose of LA agent is found in the skeletal muscles. At the tissue level, local anaesthetic agents are also metabolized by

tissue enzymes. This is important for the esters than the amide local anaesthetics, but this has minimal clinical significance. The kinetics of this total process vary from drug to drug. But more prominently, this kinetics vary greatly with the anatomical site of the injection. The relative speed of absorption of LA agent from the site of injection are determined by the vascularity of site, and by the amount of local fat that bind the LA agent and makes its absorption into the blood stream slow. Nevertheless, different drugs given at the same site will also result in different plasma concentrations. Degree of ionization and solubility of an individual drug play some role in this process. Other important factors that play a role in this process are : the total dose of drug in mg, the speed of injection, the presence and absence of additives such as bicarbonate or adrenaline, the presence or absence of concomitant end organ diseases and the effect of surgical lesion on homeostasis. It is very interesting to know that plasma level of local anaesthetic agent does not correlate well with age, body habitus or gender.

Metabolism

LA agents are metabolized in the liver to form more water soluble compounds and so are rapidly excreted through the kidney than other agents. Amide local anaesthetics are mainly metabolised in the liver, whereas the most ester group of LA agents are hydrolysed in the plasma. In liver, the several pathways of metabolism that are mainly involved are: N-dealkylation, hydroxylation, and hydrolysis. Now, most of the local anaesthetics agents are tertiary amines. So N-dealkylation of the tertiary amine (e.g. lignocaine) produces a more water soluble secondary amine and renders it more susceptible to amide hydrolysis, like secondary amine such as prilocaine.

Hydroxylation of the aromatic nucleus of tertiary amine is also believed to occur in the case of lignocaine, mepivacaine, bupivacaine, etc. However, hydroxylation of these agents produce a compound which can be conjugated and so become solely water soluble. Thus, as much as 70% of all the amide LA agents may be broken down during their single passage through the liver. This high first-pass clearance of lignocaine in liver yields mainly the N-dealkylated product such as mono ethylglycine xylidine, which is itself moderately toxic and effective anti dysrrhythmic agent. However, the high clearance rate of lignocaine is markedly reduced in the presence of low cardiac output state. There is a strong relation between the class of local anaesthetic drug and the rate of hepatic metabolism. In addition, a small fraction of the injected dose of the LA agent is excreted unchanged directly through the kidney.

Procainamide (amino alkylamides → diamines) is metabolised more slowly than lignocaine (amino acylamide → tertiary amines) and a larger proportion of it is excreted unchanged through the kidney. Some degradation of amide type of local anaesthetic agent also occurs in tissues other than the liver. Less than 5% unchanged drug is excreted via kidney through the urine. Procaine and amethocaine are hydrolysed by pseudocholinesterase in plasma and compete with suxamethonium. Cocaine is not broken down by cholinesterase.

The water soluble metabolites of LA agents are rapidly excreted through the urine. But the lipid soluble local anaesthetic base, once filtered in the glomerulus are reabsorbed by the renal tube. In an acidic urine, it becomes highly ionized, then tubular reabsorption is inhibited and renal clearence increases.

Toxicity of Local Anaesthetics

The toxicity of LA agent mainly affects the CNS and CVS. The subconvulsive doses does not cause the circulatory depression, but may depress the CNS. However, like other drugs, the toxicity of LA agents is not the mere extension of their therapeutic action but has a distinct mechanism. It depends on the speed of vascular absorption, and trouble starts when the absorption and elimination of the drug does not balance. The occurrence of toxicity of LA agent is not related to the concentration of the solution injected, but rather to the total dose of drug. Similarly the site of injection and its vascularity also affect the speed of absorption of LA agent, as well as its toxicity. The relative overdose for a given plasma concentration in case of very young or old patients is not due to their raised sensitivity. So, widespread field block and excessive surface application should be avoided in such group of patients. The cause of toxicity of LA agents in correctly administered dose is due to gradual accumulation in body due to the continuous or repeated administration of gradual accumulation in body due to the short acting drugs. So, long duration of bupivacaine and rapid elimination of etidocaine has clear advantage for continuous infusion.

CNS Toxicity

Subjective signs

These are: light headedness, dizziness, visual and auditory disturbances such as difficulty in focusing and tinnitus, disorientation and drowsiness.

Objective signs

These are: shivering, twitching, tremor, convulsion, respiratory depression, respiratory arrest, coma and death.

There is an inverse relationship between the intrinsic anaesthetic potency of a LA agent and the doses required to induce CNS toxicity.

An increase in $PaCO_2$ decreases the convulsive threshold level of local anaesthetic agent by approximately 50%. The explanation is like that an elevation of $PaCO_2$ increases the cerebral blood flow a and so more anaesthetic agent is delivered to the brain rapidly. In addition, the diffusion of CO_2 in the neural cell decreases the intracellular pH and thus facilitates the conversion of unionised form of the drug to ionised form within the cell, which only bind with the hydrophobic receptor site of

the intracellular part of Na^+ channel. Thus the cationic or ionized form does not cross the nerve cell membrane, so that ion trapping occurs and increases CNS toxicity.

On the other hand, hypercapnia or acidosis decreases the plasma protein binding capacity of LA agents, and so increases the proportion of free drug available for diffusion into the brain. Seizure and CNS depression again produce hypoventilation and respiratory acidosis, which further exacerbates the CNS toxicity establishing a vicious cycle. So, in local anaesthetic toxicity prompt assisted ventilation correcting acidosis is essential.

Cardiovascular toxicity

The direct cardiac effects of LA agents are:

i. The LA agents decrease the rate of depolarisation in the fast conducting tissues such as Purkinje fibres and ventricular muscles. This reduction in the rate of depolarisation is believed to be due to decrease in the availability of fast Na^+ channel in cardiac cell membrane and myocardial depression.
ii. The duration of action potential and effective refractory (Fact file-II) period is decreased, leading to ventricular tachycardia, fibrillation, ectopics, etc.
iii. The ratio of effective refractory period and duration of action potential is increased.
iv. Bupivacaine depresses the rapid phase of depolarisation to a greater extent than lignocaine.
v. The rate of recovery from the use dependent block is slower in bupivacaine than lignocaine. This slow rate of recovery results in incomplete restoration of some Na^+ channel and less availability of it between two subsequent action potential. In contrast, recovery from lignocaine is complete. The effect of this differential recovery explains the antiarrhythmic properties of lignocaine and arrhythmogenic property of bupivacaine.
vi. The LA agents prolong the conduction time and thus increase the PR interval and the duration of QRS complex.
vii. The Extremely high concentration of local anaesthetic agents depress the spontaneous pacemaker activity in the SA node, causing sinus bradycardia and sinus arrest.
viii. All the LA agents have dose dependent negative inotropic action on cardiac muscles. This negative inotropic effect on myocardium is due to the inhibition of release of Ca^{2+} from the sarcoplasmic reticulum and also inhibition of Na^+ currents.

FACT FILE- II

The cardiac toxicity of the more potent LA agents such as bupivacaine appears to differ from that of lignocaine in the following ways:

i. The CC/CNS ratio, i.e., the ratio of the dose that is required to produce cardiac collapse (or toxicity), and the CNS toxicity is lower for bupivacaine than lignocaine.
ii. Ventricular fibrillation or any other ventricular arryth-mia usually occurs following IV administration of the bupivacaine, but not lignocaine.
iii. Cardiac resuscitation is more resistant following bupivacaine induced cardiac collapse than that of lignocaine.
iv. Pregnant patients are more sensitive to cardiac toxicity of bupivacaine than lignocaine.
v. Cardiac toxicity of bupivacaine is markedly potentiated by acidosis and hypoxia.

Local tissue toxicity

The volume and concentration of LA agent used clinically rarely produce localized nerve damage. But the evidence of local neurotoxicity, caused by LA agents is occasionally seen and depends on the type of agent used (the ester linked may be more neurotoxic than the amide linked anaesthetics), its concentration, the site of injection, osmolarity and pH of the solution, and the presence of other certain additives with it such as vasoconstrictors, antioxidants, preservatives, etc. Electron microscopy studies indicate that the perineuronium, Schwann cells and axons themselves may be damaged due to the neurotoxicity of LA agents. The advanced age and diseased states of the nervous tissue also enhance the susceptibility of LA agents to the neurotoxicity. The neurotoxicity in clinical practice is most commonly seen with spinal anaesthesia. Adrenaline has also been investigated as a possible contributor to the local anaesthetic neurotoxicity. The suspected mechanism is decreased intraneural blood supply due to vasoconstriction by adrenaline. Admixture of LA agent with antioxidant, such as sodium bisulphite, in the presence of a low pH has also been shown to be neurotoxic. So, for a safer and more effective alternative to these commercial solutions, adrenaline may be added to local anaesthetics freshly before use. There are many reports of inadvertent needle penetration of the globe of eyeball during peribulbar or retrobulbar block which is followed by injection of local anaesthetic agent in clinical concentration intraocularly. But, the retina which is a specialized nerve tissue did not undergo toxic changes in these circumstances. Concentration of lignocaine required to produce irreversible conduction blockade and permanent damage of nerve fibre in experimental conditions overlap the concentration which is used clinically, such as 2% lignocaine. But, practically this does not happen. This is because LA agents are not applied clinically directly to the nerve fibre in such concentrations.

So, although the LA is injected clinically at a much higher concentration than their physiological effective range, but they are usually diluted in the tissues during the process of transport from the site of injection to the site of action and hence no harm is produced. If this dilution does not occur then a permanent neural deficit do result. Thus, application of 5% lignocaine in hyperbaric solution, through a narrow intrathecal catheter is associated with high incidence of cauda-equina syndrome. However, anaesthetists should keep in mind that the concentrations of marketed LA solutions are neurotoxic and their dilution in tissue is essential for safe use.

Continuous spinal anaesthesia, using a micro catheter is associated with a high incidence of neurotoxicity, such as

radicular irritation, cauda equina syndrome, etc. Studies suggest that microcatheter facilitates a localized deposition of high concentration of drug which are inadequately dispersed or diluted in the CSF, leading to direct contact of a high concentration of drug around the sacral roots and consequent neurotoxicity.

THE ADJUVANT DRUGS TO AUGMENT THE CLINICAL EFFECTS OF LOCAL ANAESTHETICS

The most commonly used adjuvant drugs with LA agents to increase their efficacy and duration of action are adrenaline, noradrenaline, felypressin, hyaluronidase and sodium bicarbonate.

ADRENALINE

By its α-stimulant action, adrenaline constricts the vessels at the site of injection of LA agents and thus reduces its absorption through the blood. So, the local anaesthetic action is prolonged, the depth of block is increased and the toxicity of drug is reduced. As a whole, the quality and reliability of the block are improved. Adrenaline added to the local anaesthetic solution also provides a marker for inadvertent intravascular injection of it. Other vasoconstrictors, such as norepinephrine, phenylephrine, etc., also have been used with LA agents, but they are not superior than adrenaline in this purpose. The α-adrenergic receptors in spinal cord are also known to activate the endogenous analgesic mechanism and thus adrenaline also increases the depth of analgesic action of LA agents in the central neuraxial block. Therefore, where prolonged block is necessary, the addition of adrenaline with local anaesthetic agents reduces the number of repeated doses of it, and thus delays the onset of chronic toxicity and tachyphylaxis of the LA agents. Particularly, it is very valuable in highly vascular areas, e.g intercostals space, pelvic floor etc., than the less vascular areas e.g. epidural space. So, the aim of use of adrenaline differs from time to time. Sometimes it is to reduce the toxicity and sometimes it is to prolong the effect of LA agent. However, the presence of adrenaline in the LA solution makes the injection more painful. It also increases the chances of subsequent local tissue oedema and necrosis, as well as delays the wound healing by reducing the oxygen supply and enhancing the O_2 consumption in the injected area. Sometimes, the LA agent with adrenaline may raise BP and promote arrhythmia in susceptible individuals. The effect of adrenaline on long acting drugs, such as bupivacaine and etidocaine are less marked. In dentistry, always some form of vasoconstrictor is essential with most LA agents to diminish the bleeding during extraction of teeth. The inclusion of adrenaline in LA solution necessitates addition of antioxidants such as sodium metabisulphite or ascorbic acid. This is because adrenaline is stable in acidic solution only and this is provided by Na metabisulphite or ascorbic acid. But these agents reduce more the pH of LA solution, even less than 4 and increases the toxicity. In Britain, bupivacaine with adrenaline contains fewer additives and the pH is around 4.5 (Fact file- III).

Dose

Adrenaline should not be used in concentration more than 5 µg/ml (1:200000) which causes optimal degree of vasoconstriction. But, in dentistry as the total volume of drug used is small, so a higher concentration of adrenaline, such as 12.5 µg/ml (1:80000) is used. When injected IV accidentally, adrenaline is more dangerous than the local anaesthetic itself. If the total volume of local anaesthetic agent containing 100 to 150 µg of adrenaline is inadvertently injected intravenously, then it produces severe systemic effects such as tachycardia, arrhythmia, ventricular fibrillation, sweating, etc. for a brief duration. But, in a correctly placed block adrenaline is absorbed slowly from the tissue and no systemic effect occurs. Adrenaline is contraindicated in patient (i) taking certain antihypertensive drugs, (ii) taking tricyclic antidepressants, (iii) with thyrotoxicosis, (iv) for digital block, (v) for penile block, etc. Its use may be dangerous in epidural analgesia or anaesthesia for anterior spinal artery syndrome.

FACT FILE- III

Advantages and disadvantages of addition of vasoconstrictors in local anaesthetics may be tabulated as follows:

1. Prolongs the duration of action by decreasing the rate of removal from the site of injection in the circulation.
2. Reduces the systemic toxicity.
3. Increases the dose of the drug.
4. Increases the chances of local tissue oedema and tissue necrosis.
5. Delays wound healing by decreasing the oxygen supply, while increasing its consumption in the affected area.
6. Makes the injection more painful.
7. Increases the blood pressure and chances of arrythmias in susceptible persons.

NORADRENALINE

It is also an α stimulant, but less potent than adrenaline. So, in dentistry for the purpose of vasoconstriction and to reduce bleeding noradrenaline in a high dose such as 20 to 40 µg/ml (1:50000 to 1:25000) may be necessary. But this high doses of noradrenaline produces severe hypertension.

FELYPRESSIN

It is a synthetic polypeptide, related to vasopressin. As a vasoconstrictor it is also suitable agent like adrenaline, but less toxic. For example, it produces no changes in CVS in conditions where adrenaline in the dose of 12.5 is likely to produce tachycardia. With prilocaine it is more effective in prolonging the action of LA agents with less toxicity than adrenaline.

HYALURONIDASE

The enzyme hyaluronidase is frequently added to local anaesthetic agents for

regional opthalmic anaesthesia to promote the spread of drug (LA agents) through the intraorbital tissues. It breaks down collagen bonds and thus allows the anaesthetic solution to spread across the fine septal barriers of connective tissue. This action is accomplished by the reversible hydrolysis of hyaluronic acid which is the cement substance of intercellular connective tissues. However, to maintain the full activity of the product, refrigeration is important. Prolonged exposure of hyaluronidase to room temperature (> 48 hours) results in deterioration of enzyme potency. Autoclaving of solutions also results in destruction of the enzyme strength.

Hyaluronidase is added to the local anaesthetic solution in a concentration of 7.5 to 15 turbidity units/ml. Higher concentrations of it have no added advantage. Prior to its introduction, the volume of local anaesthetic agent injected into the orbital cavity for opthalmic regional anaesthesia was limited. This is due to the raised intraorbital and subsequently intraocular pressure as the LA solution does not spread quickly. Then the greatly improved standards of effective local anaesthesia for opthalmic surgery (especially cataract extraction), without compromising the intraocular pressure was made possible by adding hyaluronidase with the large volumes of LA injection. However, hyaluronidase reduces the duration of anaesthesia. This is because it increases the spread of LA agent and absorption and subsequently increases its absorption through the blood vessels. But, adrenaline reverses that tendency. It has allergic potential and is more myotoxic than enzyme free solutions. However, the use of hyaluronidase enzyme is not a substitute for less precise anatomical knowledge and poor technique for high quality opthalmic regional anaesthesia as it only facilitates the spread of LA injection along the path of least resistance of tissue. So, the LA solution should be placed accurately within the appropriate compartment. Hyaluronidase does not enhance brachial plexus block, nor does it influence the plasma levels of local anaesthetics agents.

Sodium Bi-carbonate

The tissue penetration and onset of action is enhanced by adjusting the pH of local anaesthetic solution towards the unionised base by the addition of small amounts of sodium bicarbonate. For each agent there is a pH at which the amount of unionised molecules (which only penetrate the cell membrane) of LA agent in solution becomes saturated. Increase in pH beyond that point results in the precipitation of the free base after which no further clinical benefit is achieved. Infact, a nuisance factor, such as blockage of needles by free base precipitate creates problems. There are also many literatures which are equivocal about the effectiveness of pH adjustment of LA agents by just mere adding $NaHCO_3$ in LA solution in various clinical circumstances. So many anaesthetists fail to see any benefit in their practice, after pH adjustment of local anaesthetics with sodium bicarbonate. However, alkalinised solutions should be used within 6 hours of their preparation. There is definite lesser pain during injection, when bicarbonate is used with LA agents.

GENERAL CONSIDERATION

Onset of Action

The speed of onset of block by a local anaesthetic agent is the specific property of that individual agent. But it also depends on the concentration of that particular agent. For example, (i) 0.25% bupivacaine has slow onset of action. But increasing the concentration to 0.75% hastens the onset of action. Beyond that concentration limit, the onset of action does not improve further (ii) Chloroprocaine's (pKa 9) onset of action is slow. This is due to the less availability of unionised molecule in normal tissue pH. But its low systemic toxicity allows its use in higher concentration (3%), and thus obviously improves the onset of action. So, in clinical use, 3% chloroprocaine has faster onset of action than 2% lignocaine.

Duration of Action

As we know that the duration of action of LA agents depend on the peripheral vascular effects of that agent, but most LA agents have biphasic effects on the vascular smooth muscles. At a low concentration these agents tend to cause vasoconstriction and at clinical concentrations they cause vasodilatation. Lignocaine is a potent vasodilator than mepivacaine and prilocaine, and has a shorter duration of action than these two. Pial vessels are dilated by bupivacaine, but constricted by ropivacaine.

Differential Sensory and Motor Block

Differential block means sensory block without affecting the motor nerves. This is ensured only with lower concentration of local anaesthetic agents. Bupivacaine and etidocaine profoundly have this property. Bupivacaine in a concentration of 0.125% produces adequate antinoception by affecting only the sensory fibres and without profound inhibition of motor activity. So, bupivacaine is widely used epidurally for obstetric analgesia and for post operative pain management without muscle weakness.

There are two probable explanations for this differential block:

i. The length of nerve fibre which is exposed to LA drug in epidural space can explain clinically the differential block. Because if the drug-exposed region of a nerve fibre is longer, then it yields a block by lower concentration of LA drug which is found in case of sensory nerve fibre. However, this does not explain the functional differential loss from peripheral nerve block.
ii. Selective ability to inhibit Na^+ channels over K^+ channels by lower

concentration of LA agent, which itself can produce a differential block. Because these channels are present in very different proportions in different types of nerves.

Site of Injection

The most rapid onset but shortest duration of action occurs following intrathecal or subcutaneous administration of the LA agent. Longest latency of onset and prolonged duration of action are observed following brachial plexus block. For example, bupivacaine in intrathecal route has onset of action within 5 minutes and duration of action is 3 to 4 hours. But, in brachial plexus block the onset of action of bupivacaine is 20 to 30 minutes and duration of action is ±10 hours.

Explanation

Lack of connective tissue sheath around the spinal nerve and deposition of drug in the immediate vicinity of the cord and the nerve are responsible for this rapid onset of action. But relatively small amount of drug used for intrathecal block is responsible for short duration of action. On the other hand, in brachial plexus block LA agent has to diffuse through various tissue barriers, before reaching the nerve which causes delayed onset of action. This also needs a large volume of drug and this larger dose is responsible for prolonged action.

pH Adjustment of Local Anaesthetic Solution

Addition of $NaHCO_3$ to the LA solution causes rapid onset of action. This is because increase of pH increases the amount of drug in unchanged base form and enhances its diffusion across the cell membrane, resulting in a more rapid onset of action. It happens with bupivacaine also. But till now, there is a controversy about the efficacy of technique of carbonation (just merely adding $NAHCO_3$ in acidic LA solution. I do not believe in this process because if causes precipitation) and pH adjustment of LA agent.

Mixture of Local Anaesthetics

The use of mixture of LA agents has become popular in recent years. The basis of this mixture is to compensate the delayed onset of action of one LA agent by early onset of action of another and also to compensate the shorter duration of action of one LA agent by longer duration of action of another. But recently, confusing results have come to the forefront. For example – a mixure of 3% chloroprocaine and 0.5% bupivacaine was used to produce short latency and prolonged duration in brachial plexus block. But, subsequent studies indicate that duration of epidural anaesthesia produced by this mixture is significantly shorter than bupivacaine alone. However, the clinicians should be cautioned not to use the maximum doses of two LA agents in the mixture, with the mistaken belief that toxicities of these agents are independent.

Pregnancy

Except mechanical factors (dilatation of epidural veins causing decreased epidural space and subsequent greater spread of local anaesthetic agent in pregnancy) increased sensitivity of local anaesthetic agent during pregnancy due to alteration in the hormonal level causes greater intensity of epidural anaesthesia. However, greater spread of epidural anaesthesia (the cause of which is explained above) only occurs during 1st trimester of pregnancy.

Pharmacokinetic Alterations of LA Agent by Patient's Age

Patient's age influences the pharmacological character of LA agent. For example half life of lignocaine, following IV administration is twice in old age than in young adults. Newborn infants have immature hepatic enzyme system and so they experience a prolonged elimination half life of lignocaine and bupivacaine. On this basis, a maximum infusion rate of 0·4 mg/kg/hr for bupivacaine in adults during epidural anaesthesia has been proposed. Whereas during continuous epidural anaesthesia by bupivacaine the rates of infusion for neonates and young infants should not exceed 0.2 mg/kg/hr. Similarly lignocaine infusion in neonates shouldnot exceed 0.8 mg/kg/hr.

Methaemoglobinaemia

Large doses of prilocaine is associated with methaemoglobinaemia. In general, 600 mg of prilocaine is required for development of clinically significant levels of methaemoglobinaemia. This is because metabolism of prilocaine in liver results in formation of O-toludin which is responsible for oxidation of Hb to methaemoglobin. This methaemoglobinaemia is spontaneously reversible or may be treated by IV methylene blue. The effect of methaemoglobin is that the patient appears to be cyanotic, but has normal oxygen saturation level. The effect of methaemoglobin on oxygen carrying capacity is not so important in a healthy adult, but can be significant in infants. So, prilocaine is generally avoided in infants.

SUMMARY

The local anaesthetic agents act by causing selective reversible restriction of permeability of sodium ions with free movement of potassium. Usually the sodium ion is restricted to the extracellular space except when the sodium ion channels are open, allowing diffusion through it. Potassium ion is freely diffusable across the membrane. But it selectively accumulates inside the nerve cell to preserve the electrical neutrality by balancing the cations. In an unexcited state, the electrical potential inside the cell is negative in reference to the outside of the cell. During conduction of impulse (action potential) ion gradients are altered along the nerve cell membrane by opening of the sodium ion channels.

Thus, sodium enters into the cell and increases the intracellular Na^+ concentration. This is called depolarisation of the cell. The Na^+ channels are lipoprotein in nature and are embedded in the cell membrane of nerve fibre along the entire width. The gate that opens and closes these channels is present on the axoplasmic side. The channel is most susceptible to LA agent in an open active state and remains inactive in this open state, preventing further depolarisation.

The changes in configuration of Na^+ channel is voltage dependent.But the LA molecule prevents this voltage shift which activates the Na^+ channel. So, LA molecule stabilizes the Na^+ channel in nonconducting configuration.

The LA molecule also has a minor effect on both potassium and the Ca^{2+} channels, which modulate the action of Na^+ channels. However, the K^+ and Ca^{2+} channel blockade by clinically available LA agents is so low that they do not contribute significantly to the conduction blockade.

The LA molecule in the nonionic form crosses the lipophilic hydrocarbon part of the nerve cell membrane to reach the axoplasmic end of Na^+ channel. In axoplasm the LA molecule becomes active in its ionic state and attach to the hydrophilic LA receptors of the Na^+ channel. This dual requirement of a LA molecule determines the chemical characteristic of local anaesthetic agent. One LA molecule blocks only one Na^+ channel.

When the cell membrane is rapidly depolarised from the resting –70 mv to +20 mV, then there is a rapid increase in the sodium channel permeability. The greater the magnitude of depolarisation, the greater is the permeability. Beyond +20 mV there is no greater increase in sodium conductance. This is because there is a definite number of Na^+ channels in the membrane. Also like the neuromuscular junction the conduction of nerves also have considerable reserve capacity. This is explained by the fact that even when 80 to 90% of the sodium channels are blocked, conductance of nerve impulses continue, although at a slower rate.

Local anaesthetic molecules have an aromatic ring (lipophilic) connected to a tertiary amine (hydrophilic) by a short alkyl chain and a hydrophilic bond (amide or ester). So, LA agents are amines and are called as amino-amides or amino esters. All the LA molecules are amphipathic,i.e., possessing both lipophilic and hydrophilic action at opposite sides of the molecule. They are weak bases and are able to accept proton or H^+ to change into a cationic form at pH below their pKa value. This can be calculated from the following formula:

$$pKa = pH + Log (cation / free\ base)$$

The lipophilic side of the LA molecule provides most of the lipophilic properties of the molecule. Its size restricts the movement of the amine (hydrophilic) group to an axis perpendicular to the aromatic ring. This linear relationship between the amine and aromatic group seems necessary to block the hydrophilic binding site of the receptor by the hydrophilic amine group. This also explains the movement of the amine group towards the receptor, while the aromatic lipophilic group is still embedded in the lipophilic nerve cell membrane.

The intermediate chain of LA molecule allows the reversible action of clinically useful LA agent. Since, without the intermediate chain and amide-ester bond, metabolism would be very difficult and toxicity would be unacceptable. Potency of LA increases as lipid coefficient of these lipophilic bonds increase.

Amines (hydrophilic group) are situated at the side of the molecule. It accepts proton and in cationic state is mostly involved in blockade of Na^+ channel. It is probable that the ionic movement of the hydrophilic group away from the lipophilic side of the molecule orients the amine group into a configuration that fits into the sodium channel receptor.

The lipophilic portion of the LA agent is involved in the molecular passage through the lipid membrane. So this facilitates the penetration of perineurium and as well as the nerve cell membrane. The bigger the lipophilic portion, greater the potency of the LA agent. The equilibrium of dissociation between the ionic and the nonionic forms of the LA molecule occurs inside the nerve cell. The hydrophilic group in the ionic form is the part of the molecule which is involved in entering the Na^+ channel to interrupt the Na^+ conduction. A specific distance is required between these two different groups and this is served by the intermediate chain. If the length is too short or too long, then there is minimal or no local anaesthetic activity.

Between the LA molecule and the receptor at the Na^+ channel a semispecific binding of reversible nature occurs. The speed of entry and exit of the LA molecules in these Na^+ channels is agent specific. The short and intermediate acting LA agents are short-in and short-out of Na^+ channels in character (e.g. lignocaine, procaine, mepivacaine). So, they are of early onset and shorter duration of action. The long acting agents (e.g. bupivacaine) are slow-in and slow-out of the Na^+ channels in character. So, they have a delayed onset and a longer duration of action. The bond between the receptor and the molecule of LA agent is weak in case of closed channels, but strongest and most rapid in open sodium channels.

When the lipophilic butyl group is added to the aromatic ring of procaine, then tetracaine is created which is 40 times more potent than procaine. Thus, 40 times increase in potency confirms that the lipophilic property of the LA molecule is the principle determinant of potency. If the same butyl group is added with a hydrophilic tertiary amine group, then the resultant molecule has a potency lower than procaine. It may be due to that, the hydrophilic region (receptor) near the Na^+ channel orients the hydrophilic amine

group of the LA molecule in that channel. So, the addition of the lipophilic butyl group with the hydrophilic amine group of the LA molecule prevents its orientation in the Na^+ channel and reduces the potency.

Protein binding capacity of LA agent determines the duration of action. Agents with greater protein binding capacity have a greater attraction for receptors and remain binding with the Na^+ channel for a longer period of time, causing longer duration of action, e.g. bupivacaine, etidocaine etc. Agents with poor protein binding capacity such as procaine, chloroprocaine, etc. are readily washed out from the channel causing shorter duration of action.

Regarding the alkalinisation by adding sodium bicarbonate to the LA solution, wherever it is possible without precipitation (because addition of sodium bicarbonate to lignocaine hydrochloride causes precipitation of lignocaine bicarbonate), decreases the latency to onset (has been reported in numerous series). For example, in mepivacaine where the pKa value is 7.6 and pH of commercial preparation is 5.5, then alkalinization is possible without precipitation. This alkalinisation increases the concentration of the unionised which is from less than 0.1% to about 40%. However, in more lipophilic agents like bupivacaine precipitation limits the amount of alkalisation and results are more equivocal.

Regarding toxicity, of LA agents the main determinants of toxicity include the total concentration versus free concentration which is again determined by the protein binding capacity and ionisation. Subarachnoid injection of a LA agent for spinal anaesthesia is associated with its lowest blood level.

Regarding relation between the lipid solubility and toxicity, the CNS toxicity of the LA agent in clinical setting is directly related to the lipid solubility. Penetration of the lipid membrane is a limiting step of CNS toxicity of the LA agent. So, more lipid soluble means more CNS toxic. While highly lipid soluble agents are more potent local anaesthetic agents, but their therapeutic and toxic ratio is narrow and degree of safety is less. Toxic form of a LA agent is the unionic unbound fraction in the blood which is available for penetration of the blood brain barrier. The early signs of CNS toxicity are reported in patients, when the unbound fraction begins to cause ionic changes within the CNS. Intra arterial injection of a small amount of LA agent cause vary rapid onset of massive CNS reaction, because the agent is delivered directly in high concentration to the CNS.

Regarding tissue toxicity, all the LA molecules are directly cytotoxic to nerve cells at some concentration. The balance between the ideal concentration to facilitate conduction block and cause nerve damage determines its therapeutic safety index. In addition to the cytotoxicity of anaesthetic agents itself, various buffers and preservatives added to the LA agents have been found in some cases to be cytotoxic.

Regarding allergy, true allergy to local anaesthetics is rare. The most common allergies are due to the ester agents and their metabolites like para-aminobenzoic acid (PABA). This may be due to ubiquitous presence of this aromatic PABA molecule in food preservatives, pharmaceuticals, cosmetics and in sunscreen lotions. Thus, previous exposure to PABA through these chemical agents may prime the immune system in some individuals for an immunologically mediated response to the metabolites of ester group of local anaesthetic agent.

Regarding the cardiac toxicity the specific CVS depression with highly lipid soluble agents such as bupivacaine and etidocaine is not only associated with their increased lipid solubility, but the specific binding of these agents to the cardiac conduction system also magnifies their cardiac toxicity. Bupivacaine has a quinidine like blocking action on the conduction system of heart. This increases activity in re-entrant pathways and predisposes the heart to the development of ventricular arrhythmia.

INDIVIDUAL DRUGS

Procaine and Procainamide

Procaine is a local anaesthetic agent with poor penetrative power and a short duration of action. This is due to its vasodilator activity and high pK value. This high pK value renders procaine highly ionised at a physiological pH of 7.4. So, after injection it is rapidly absorbed into the circulation and has less penetrative power in the tissues and nerve. Hence it is inactive as a surface anaesthetic. It is less potent than lignocaine and its duration of action is half than that of lignocaine. But, it can be greatly extended by the addition of adrenaline.

It is hydrolised in the plasma by pseudocholinesterase and in the liver to PABA (para-aminobenzoic acid) and di-ethyl aminoethanol.

There are several drug reactions with procaine or procainamide. These are :

i. PABA which is one of the metabolites of this group of LA agents is a potent inhibitor of the bacteriostatic action of the sulphonides.
ii. PABA itself acts as an allergen.
iii. PABA prolongs the effect of suxamethonium by competing for the same enzyme, i.e. pseudocholinesterase which is responsible for termination of action of them by hydrolysis.
iv. Anticholinesterase agents potentiate the toxicity of procaine and procainamide. So, it should not be used in patients suffering from myasthenia gravis.

Procaine and procainamide has antiarrhythmic effects like quinidine. But procaine is replaced by procainamide which too has antiarrhythmic properties and is not broken down by pseudocholinesterase, like procaine. At present, procaine has no indication for use LA or antiarrhythmic agent. It has been replaced by many newer and better drugs.

Lignocaine

It was first synthesised in 1943 by Lofgren in Sweden at the AB Astra laboratory, but was first introduced in clinical practice in 1948. It is of moderate potency and intermediate duration of action which varies with the site of injection, concentration and volume of drug, presence or absence of adrenaline, etc. It causes local vasodilatation which again causes quick absorption of it through the circulation and reduces the duration of action. Repeated injection of lignocaine causes tachyphylaxis. Now, it is one of the most widely used local anaesthetic agent in the world. It works rapidly and reliably to give both motor and sensory blockade. It can be used virtually by any route and is a standard antiarrhythmic agent when given IV without any preservative

Lignocaine is commonly marketed as its hydrochloride salt. But carbonate of lignocaine has remarkable penetration power, rapid onset of action and high incidence of deep motor and sensory blockade. Absorption of lignocaine through mucosal surface is very rapid and gives rise to high blood level. Absorption of it from the inflamed urethra is also as good as IV injection. Iantophoretic system (a needle free drug delivery system) for delivery of lignocaine and epinephrine is also available. But this system is generally used for superficial dermal procedures and provides anaesthesia up to the depth of 10 mm.

As lignocaine stabilises the membrane of damaged and excitable cells, so it is used for the treatment of ventricular ectopic foci. In therapeutic antiarrhythmic doses, it causes no change in the heart rate, does not depress the conduction in Purkinje tissue, does not widen the QRS complex and has no apparent myocardial depression. Instead, improvement in cardiac output and BP is observed when lignocaine is used in the treatment of dysrhythmias. But, it is less useful in supraventricular dysrhythmias. Great value of lignocaine is observed in the acute treatment of ventricular dysrrhythmias after MI and cardiac surgery and this is due to the lack of myocardial depressant effect of it.

Doses

Lignocaine in the concentration of 0.5 to 1% is used for local infiltration anaesthesia. The Maximum dose of lignocaine for infiltration is 4.5 mg/kg without adrenaline, and when adrenaline is used this amount can be increased by one–third. When extensive block with high volume of drug is required, then 0.25% lignocaine with adrenaline should be used. For intravenous regional anaesthesia 40 ml of 0.5% lignocaine without adrenaline is used. 1% lignocaine is sufficient for local nerve block. A concentration of 2% lignocaine with adrenaline (1:80,000 or 12.5 µg/ml) is used in dentistry. 1 to 2% lignocaine with or without adrenaline (1:200,000 or 5 µg/ml) is used in epidural anaesthesia. For surface application 4% lignocaine is used as a liquid or 10% as a spray or 5% as a gel.

For cardiac dysrhythmias, mainly ventricular, lignocaine is used in the dose of 1 mg/kg IV as bolus, then 4 mg/kg for the next 20 minutes which is gradually slowed down to 1 mg/minute as tissues begin to take up lignocaine less rapidly. Such infusion continued for days may give rise to systemic toxicity.

Safe upper limit of the dose of lignocaine for infiltration anaesthesia is of much dispute. Most commonly accepted view is 200 mg plain and 500 mg with adrenaline. But, here there is no mention of body weight and site of injection. Another recommended maximum safe dose of lignocaine is 6 mg/kg, but is possibly lesser for plain solution in vascular areas, while greater with adrenaline in less vascular areas. Toxic symptoms of lignocaine may occur at a plasma level of 3 to 5 µg/ml. Yet such a level is not uncommonly produced after a single shot epidural block using 20 ml of 2% lignocaine without adrenaline.

Lignocaine is metabolised in the liver to mono ethylglycine xylidide and glycine xylidide. The later can be metabolised further to monoethylglycine and xylidide. Both the monoethylglycine xylidide and glycine xylidide retain the local anaesthetic property.

Mepivacaine HCl

Regarding clinical activity and toxicity, mepivacaine is similar to lignocaine. But, it has a lesser inherent vasodilator property. So, duration of action of mepivacaine is 50% longer than lignocaine. The addition of adrenaline also prolongs its action by about 75%. Topically, unlike lignocaine, mepivacaine is not effective.

Bupivacaine

It was first introduced in clinical practice in 1963. Its structure is similar to that of lignocaine, except that the amine containing group is a butyl piperidine. It is 3 to 4 times more potent than lignocaine and longer lasting. Its long duration (Table 13.2) of action and tendency to provide more sensory than motor blockade has made it a popular drug for providing prolonged analgesia during labour or the postoperative pain. Analgesia for post-operative pain usually lasts for 4 hours or more when it is used through epidural route. While caudal administration of bupivacaine usually produces perineal analgesia for 8 hours or more.

When bupivacaine is given by repeated injections, then tachyphylaxis is much less common than that of lignocaine. Thus, safe and effective analgesia can usually be provided indefinitely (for several days) by taking the advantage of catheter and continuous infusions through if by epidural route.

Bupivacaine is more cardiotoxic than equi-effective doses of lignocaine. It causes severe ventricular arrhythmias and myocardial depression, than lignocaine if there is sudden inadvertent IV injection. Lignocaine and bupivacaine both rapidly block cardiac Na^+ channels during systole. But, bupivacaine dissociates from these Na^+ channels much more slowly than

Table 13.2: Physicochemical properties of local anaesthetics

	Procaine	*Lignocaine*	*Mepivacaine*	*Bupivacaine*	*Etidocaine*
Year of introduction	1905	1943	1957	1963	1972
Site of metabolism	Plasma (Ester hydrolysis)	Liver (Amide hydrolysis)	Liver	Liver	Liver
Onset of action	Slow	Fast	Fast	Intermediate	Fast
Duration	Short	Intermediate	Intermediate	Long	Prolonged
Equieffective anaesthetic concen	2% (Slow potency)	1% (Intermediate potency)	1% (Intermediate potency)	0.25% (High potency)	0.5% (High potency)
Protein binding (Duration of action)	6% (short)	65% (Intermediate)	75% (Intermediate)	95% (Long)	95% (Long)
Dissociation constant (pKa)	8.9	7.7	7.6	8.1	7.7
Onset time	Slow onset	Fast onset	Fast onset	Intermediate onset	Fast onset
Tissue penetration	Poor	Good	Good	Intermediate	Good
% base at pH of 7.4	2%	35%	35%	20%	35%
Lipid/water	0.6	2.9	0.8	27.5	14.1
Partition coefficient (Anaesthesia potency)	Low potency	Intermediate potency	Intermediate potency	High potency	High potency
Maximum single dose (plain solution)	800 mg	250 mg	300 mg	150 mg	300 mg
Maximum single dose (with adrenaline)	1000 mg	500 mg	500 mg	250 mg	400 mg

lignocaine during diastole. So, significant number of Na^+ channels remain blocked at the end of diastole with bupivacaine. Thus, this block caused by bupivacaine is cumulative and is responsible for more cardiac toxicity than lignocaine. A part of cardiac toxicity produced by bupivacaine is also mediated through centrally, as it is observed that small quantities of bupivacaine injected in the medulla produce malignant ventricular arrhythmias.

Different doses of bupivacaine in spinal and epidural anaesthesia is discussed in their specific chapters. Bupivacaine crosses the placenta, but very little in amount. So, it has a unique value in obstetrics. It is used extensively for lumbar epidural blockade in the concentration of 0.125 to 0.5%. Bupivacaine in a concentration of 0.125%, usually produces only sensory blockade, without affecting the motor function. So, for painless labour or walking epidural, where motor function is preserved but only analgesia is provided, then 0.125 to 0.25% of bupivacaine is the choice. When the concentration of bupivacaine is gradually increased from 0.125 to 0.25%, then there is gradually lesser chance of failure of sensory blockade, but more chance of motor blockade and vice versa. For a single dose epidural, the maximum safe dose of bupivacaine is 2 mg/kg. To provide prolonged or continuous analgesia, 30 mg bupivacaine at 2 hours interval is sufficient and this dose can be repeated for indefinite period. Maximum safe dose of bupivacaine is 2 to 3 mg/kg without adrenaline for infiltration. When adrenaline is added this amount can be increased by one-third.

Etidocaine HCl

Etidocaine is an engineered modification of lignocaine molecule with high potency and prolonged duration of action. It is mainly used in the Scandinavian countries and USA. Unlike bupivacaine, it has a rapid onset of action. So, because of its fast onset and prolonged action, compared to bupivacaine, etidocaine is in vogue in opthalmological practice. It is used clinically in 0.5%, 1% and 1.5% concentrations for any type of regional and infiltration block. This drug can also be used topically, but is rarely used by this route. It is less potent than bupivacaine in producing sensory block, but is more potent for motor block. So, it is usually recommended where prolonged epidural with high degree of motor blockade is necessary. For this purpose 20 ml of 1% etidocaine with adrenaline (1: 200,000 or 5 µg/ml) is used and the motor blockade lasts for 3 to 5 hours, though the sensory blockade is not always adequate. Hence, for obstetric pain relief etidocaine is less reliable than bupivacaine. This is because no concentration of etidocaine can produce effective sensory blockade without affecting motor block.

Prilocaine

It emerged first in 1960 from the AB Astra laboratory, though it had already been synthesised previously by Lofgren. Chemically it is an amino-amide compound and its pharmacological profile is similar to that of lignocaine. But its penetrative power is very good. It can be used for all types of local blockade in the same concentration like lignocaine. When used in epidural anaesthesia it produces higher incidence of motor blockade and a longer duration of action than lignocaine. However it has lesser vasodilator action

than lignocaine and thus used without any vasoconstrictor. For its increased volume of distribution (high therapeutic index) it is less CNS toxic and so also very suitable for IV regional anaesthesia. Administration of prilocaine gives rise to much lower plasma concentration than an equal dose of lignocaine. This is because of its more rapid metabolism and greater tissue uptake, due to less protein binding. It is only about 2/3 as toxic as lignocaine after a single dose. It is considerably less cumulative.

Prilocaine is unique among all the local anaesthetics for its propensity to cause methaemoglobinaemia. It is due to the metabolism of its aromatic ring to O-toludine in liver which induces methaemoglobinaemia. The development of methaemoglobinaemia after local administration of prilocaine is dependent on the total dose administered which is usually above 8 mg/kg of body weight. In a healthy person it is not a problem and can be treated by methylene blue in the dose of 1 to 2 mg/kg of body weight by infusion. However, methaemoglobinaemia following prilocaine has restricted its use in obstetric anaesthesia. The maximum concentration of methaemoglobin normally occurs between 4 to 6 hours after administration of prilocaine. Then it decreases gradually to the normal value in 24 hours. Though the occurance of methaemoglobinaemia contraindicates the use of prilocaine in many circumstances, but a transient rise in its level occurs in most of the people after its use and is harmless.

Ropivacaine

It is a derivative of bupivacaine and consists of a single enantiomer such as the S-stereoisomer. Whereas, bupivacaine consists of both isomers and lignocaine has no stereosymmetry. Ropivacaine is intrinsically less cardiotoxic. It is cleared more quickly from circulation, if the drug is injected IV erroneously and cardiac resuscitation is easy. An important mechanism for the cardiotoxic action of any local anaesthetic is the very slow reversal of Na^+ channel from the blockade. This is the hallmark of bupivacaine, and such slow Na^+ channel reversal with bupivacaine is associated with the persistent slowing of conduction re-entry circuits, ventricular tachycardia and ventricular fibrillation. The difference between the ropivacaine and bupivacaine is that the negative inotropic potency of ropivacaine is less than that of bupivacaine and the therapeutic index of ropivacaine is greater than that of bupivacaine. Again, ropivacaine is slightly less potent and has a shorter duration of action than bupivacaine and the convulsant dose of ropivacaine is larger than bupivacaine. Cardiotoxic effect of ropivacaine in pregnancy is not greater than in the non-pregnant state which is most advantageous for it. All this makes ropivacaine a significantly safer drug for local and regional anaesthesia in obstetrics. Interestingly, it seems to be even more motor sparing than bupivacaine.

Eutectic Mixture of Prilocaine (2.5%) and Lignocaine (2.5%)

The depth of local anaesthetic action of the mixture of prilocaine and lignocaine in the ratio of 1:1 by weight is in between the topical and infiltration anaesthesia. The efficacy of this combination lies in the fact that the mixture of prilocaine and lignocaine has a melting point less than that of either compound taken alone, i.e. below the room temperature and can exist at room temperature as an oil rather than as crystal, which can penetrate the intact skin. The maximum depth of penetration of this mixture in the skin is 5 mm. Onset of action of this local anaesthetic mixture is 1 hour. It is effective for surgical procedures involving the skin and superficial structures. The components of this local anaesthetic mixture is also absorbed into the systemic circulation. This eutectic mixture of LA agent should not be used on the mucous membrane or abraded skin, as rapid absorption of their component may result in systemic toxicity.

LOCAL ANAESTHETICS LARGELY RESTRICTED TO OPHTHALMOLOGICAL USE

Topical Anaesthetics in Ophthalmology

Topical anaesthesia is very essential in ophthalmological practice. It is used for the measurement of intraocular pressure, removal of sutures and foreign bodies, and for other superficial surgeries of the conjunctiva and cornea. Topical anaesthesia is also invaluable in preparing the conjunctiva for subsequent painless transconjunctival injections. Also, like the early part of this century, many cataract surgeries by phaco emulsification technique are now done under topical anaesthesia. The onset of action of all the commonly used local anaesthetic agents as topical drop is 15 to 20 seconds and last for 15 to 20 minutes. Initial stinging sensation of the conjunctiva is the chief side effect of topical anaesthesia especially in paediatric practice. A most useful means of avoiding this stinging sensation is to use 5% proparacaine drops, diluted by a sterile balanced salt solution, prior to the instillation of full strength LA agent. Physiological corneal protective mechanism will be in abeyance in topical anaesthesia (Table 13.3).

So, any rubbing of the eye must be prohibited. Prolonged use of any topical anaesthetic agent may result in corneal toxicity. Healing is delayed and cell division with migration is inhibited by topical anaesthesia. Alteration of lacrimation and tear film instability may also occur. Certain preservatives such as benzalkonium and chlorobutanol which are present in topical anaesthetic agents may be implicated for this effect. Idiosyncratic reactions to any topical anaesthetic agent may also occur. The rate of drug absorption in topical anaesthesia is intermediate between IV and subcutaneous injection and can not be influenced by the addition of adrenaline. Therefore, topically administered LA agents are also capable of attaining clinically significant serum concentrations. Digital occlusion of the lacrimal

Table 13.3: Local anaesthetics commonly used for topical ophthalmic anaesthesia (except cocaine)

Drug	*Concentration (%)*	*Maximum dose*	*Duration (minute)*	*Corneal toxicity*
Cocaine	1 - 4	1 mg/kg (20 drops 4%)	30	+++
Lignocaine	2 - 4	4 mg/kg, (up to 60 drops, 4%)	20	nil to least
Amethocaine (Tetracaine)	0.5	5 mg total (15 drops)	20	++
Proparacaine	0.5	10 mg total (30 drops)	20	+ –
Benoxinate	0.4	4 mg total (upto 15 drops)	20	least

puncta is a useful method of preventing the drugs from entering the nasolacrimal duct and thus gaining access to further mucosal surfaces from which additional absorption can occur. In topical anaesthesia it is also important not to exceed the safe clinical dose. As serious and even fatal reactions do occur with overdosing.

Local Anaesthetics Used Primarily at Mucous Membrane and Skin

Some local anaesthetics are too irritating or too ineffective to be applied on the eye. But they are useful as a topical anaesthetic agent on skin and mucous membrane. Their preparations are effective for the symptomatic relief of anal and genital pruritus, many acute and chronic dermatoses, etc. They are sometimes combined with glucocorticoids or antihistamines. Local anaesthetics used for these purposes are dibucaine, dyclonine hydrochloride and pramoxine hydrochloride.

14 Intravenous Anaesthetics

INTRODUCTION AND HISTORY

At the beginning of 17th century, some far-sighted pioneers conceived the idea of anaesthesia through the intravenous route. But, they lacked the appropriate technology and the suitable agents for intravenous administration. So, the time delay between the pioneer's thought and the advent of appropriate technology for administration of intravenous anaesthesia was about two centuries. After that there was further delay of about five to six decades because the suitable drugs were not invented to make the intravenous anaesthesia popular. Thus, the arrival of hexobarbitone, in 1932, marked the birth of a new age of anaesthesia in which intravenous induction and its supplementation became the norm. However, during this period it results in more comfort to the patient, but not necessarily more safety.

If we go back in the past, we will see that in 1665, for intravenous anaesthesia Johann Sigismund (a German physician) first injected rude opium intravenously to produce unconciousness. Then, Francis Rynd of Dublin, in 1845, used trocar and canuula for IV administration of morphine for the treatment of trigeminal neuralgia. After that, in 1872, Pierre, a professor of physiology of Bordeann, used chloral hydrate intravenously in a patient suffering from tetanus. But, Alexander Wood of Edinburgh was the true founder of intravenous anaesthesia by first using the Ferguson syringe ('syringe' came from Greek word 'syrinx' which means a tube or pipe).

During that period intravenous ether also had been tried on animals by Nilai Ivanovitch of Russia in 1847 for intravenous anaesthesia. This was a year after Morton's use of ether by inhalation. A 2·5 to 5% solution of ether in normal saline or in 5% glucose was used by him. He also used chloroform intravenously on animals in this way.

After that barbituric acid was first synthesised by Adolf Baeyer of Munich in 1864. But its sedative and hypnotic effects were not realised at that time. Then, in Munich, diethyl barbituric acid was also synthetised by Fischer and Von in 1903. At that time, this was known as Veronal. Then phenobarbitone was discovered in 1912 at else where in the world and only oral preparation of it was used. But sommifaine was the first barbiturate to be given intravenously. It was a combination of diethyl and diallyl barbituric acids and was used in France by Bardet in 1924.

During this period, Noel and Souttar also tried paraldehyde intravenously for sedation. Intravenous morphine and hyoscine were also employed by them for 'twilight sleep' in 1916. In 1923, Bumm introduced Pernocton. While 2 years later Zerfas, in USA used sodium amytal intravenously. This was soon followed by intravenous preparation of pentobarbitone or nebutal. Magill was the first person who demonstrate their clinical effects through intravenous route in Britain. Then Johu Silas Lundy of the Mayo Clinic attemped to popularise nembutal in USA in 1931. Inbetween this time Martin Kirschner tried bromethol intravenously in 1929 with moderate success.

Then, the invention of hexobarbiturate was the great breakthrough in the history of intravenous anaesthesia. It was the first drug to make intravenous anaesthesia popular and was first used in 1932 by Helmut. He was a professor of pharmacology at Dusseldorf (German) and director of pharmacology at Beyer. The historical significance of this event also was that it was the first happy partnership between an academic house and a big business house for any invention in medical science. Later, this partnership became a model which had been copied many times for the benefit of mankind. Thus, Helmut was the true father of intravenous anasthesia, though hexobarbitone was first synthetised in 1931 by Kropp and Taub in Elberfeld. It was first used in Great Britain in 1933 by Ronald Jarman.

BARBITURATES

History

Barbituric acid was first synthesised in 1864 by Baeyer which has no hypnotic property. Then, Fisher and Von first synthesised diethylbarbituric acid in 1903 which had hypnotic property. After that in between 1903 to 1932 many barbiturates with hypnotic property came, but they were slow in onset and had a long duration of action. So, they could not be used for IV anaesthesia. Thus, upto 1932 no intravenous drug was getting a strong foothold in anaesthesia. Finally in 1932, synthesis of methylated oxybarbiturate (hexobarbiturate) set the

stage. It had very good hypnotic property with very rapid onset and short duration of action. But, it had much excitatory side effects. Then, in 1934 actual breakthrough was done by the discovery of thiopentone. However, during the first report the proper pharmacokinetic and pharmacodynamic property of this drug was not known. At that time it was thought (wrongly) that the short duration of action of thiopentone is due to its rapid metabolism in the body. Thus, at that time hexobarbitone and thiopentone was used intravenously for induction and maintenance of anaesthesia like ether and chloroform by inhalation. So, overdose of the drug was frequently used due to short action (which was though at that time due to quick metabolism from body) causing many deaths resulting from hypotension. Hence, during that period IV anaesthesia was described as 'an ideal method of euthanasia'. One such example of many deaths by thiopentone is during the treatment of multiple casualties of war by thiopentone at Pearl Harbour. So, at that time it was also thought that though thiopentone has rapid onset and short duration of action, but it was toxic. But, later it was proved that the dose and the method of administration of drug rather than the drug's inherent toxicity caused the adverse outcome. Then Brodie first demonstrated that the effect of thiopentone were quickly terminated not by the rapid metabolism in body, but by the redistribution of the drug from their sites of action to other body tissues. However, in 1960, Price explained that during prolonged and large dose administration of thiopentone as the peripheral distribution site of it approached to saturation and equilibrium, then redistribution from the effector site to the other tissues was less effective and blood concentration rose quickly which ultimately caused CVS collapse and death (Fig. 14.1).

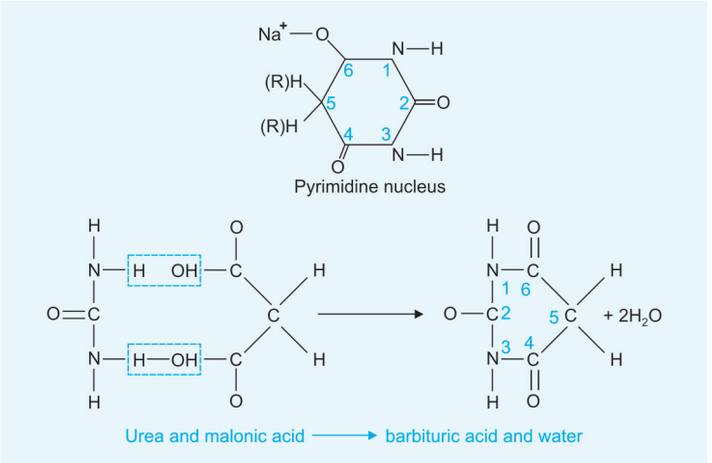

Fig. 14.1: Synthesis of urea and malonic acid

Chemistry

The barbiturates are the salt (usually Na^+) of barbituric acid. It is synthesised from urea and malonic acid. So, it is also called the malonyl urea. Barbituric acid actually has a pyrimidine nucleus. It is termed in North America by using the ending as 'al' (thiopental) and in Britain by using the ending as 'one' (thiopentone). It is available either in Keto or enol form and is acidic in nature due to the presence of H^+ at position 1. However, the Na^+ salt (at position 3) of barbituric acid is water soluble yielding highly alkaline solution. The presence of carboxyl group in the structure of barbituric acid at position 2 is responsible for the acidic character of barbiturates. This is because of the keto-enol tautomerisation, which is also favoured by its location between the two electronegative amido nitrogens. The enol form of barbiturates is favoured in alkaline solution and salts result. Barbiturates in which the oxygen atom at C_2 is replaced by a sulphur atom are called the thiobarbiturates. These are more lipid soluble than the corresponding oxybarbiturates.

Depending on the H, O, S, CH_3 in 1 and 2 position; barbiturates fall into four distinct groups as follows:

Oxybarbiturates (1 = H, 2 = O),
Methylated oxybarbiturates (1= CH_3, 2 = O),
Thiobarbituraes (1 = H, 2 = S),
Methylated thiobarbiturates (1= CH_3, 2 = S) (Fig. 14.2)

The sodium salt of thiopentone (thiobarbiturates) is a pale yellow hygroscopic powder with bitter taste. It is readily soluble in water and alkaline in property. The commercial preparation of thiobarbiturates contain 6 parts of anhydrous Na^+ carbonate.

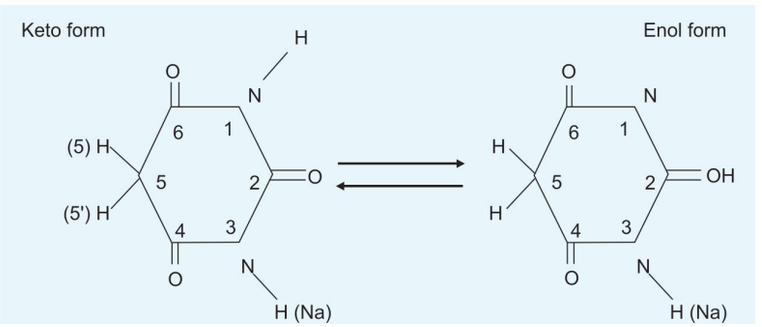

Fig. 14.2: Although, it is more correct to regard the barbituric acid as a pyrimidine derivative, but it is usually depicted in either the keto or enol form. The acidity of barbiturates is due to the hydrogen ion which migrates from the nitrogen of the position 1. In the keto and enol form of the barbituric acid the sites of substitution which are hypnotically active are identified as 1, 2 and 5. In aquous solution it dissociates into hydrogen ion and barbiturate ion. The Na-salts (in the position 3) are water soluble and can be administered parenterally

This prevents the formation of insoluble free barbituric acid from thiopentone by the reaction with atmospheric CO_2 and subsequent precipitation. The aqueous solution of thiobarbiturates is strongly alkaline and the pH of 2·5% thiopentone is about 10.5. The solution of thiobarbiturate (thiopentone) in water may remain stable at room temperature for upto 2 weeks after preparation but should not be used if they become cloudy (Table 14.1).

Structure – Activity – Relationship

The barbituric acid itself originally lacks the central-depressant activity.

i. The hypnotic activity is introduced into the barbituric acid if a side chain consisting of alkyl or aryl group (atleast if one of them is branched) is added at position 5 or 5′ in its structure.
ii. The sleep can not be produced very rapidly (in one arm-brain circulation time) after the IV injection of an effective dose of any oxybarbiturate. So, these have very limited use in clinical anaesthesia and are mainly employed as oral hypnotics and sedatives.
iii. Replacing the O of oxybarbiturates with S at position 2 produces thiobarbiturates which are more lipid soluble, and has more rapid onset and shorter duration of action. Example − Thiobarbiturates (thiopentone and thiamylal) have faster onset and shorter duration of action than oxybarbiturates (pentobarbital and secobarbital).
iv. The increased length of side chain in position 5 increases both the potency and the duration of action of barbiturates. Example, secobarbital and thiamylal is more potent than pentobarbital and thiopentone.
v. Methylation and sulphuration of barbituric acid increases the lipid solubility and the rate of penetration of barbiturates in CNS.
vi. Addition of methyl group at position 1 of oxy barbiturates (oxymethyl barbiturate) not only produce the rapid onset and short duration of action, but also increases the excitatory side effects.
vii. Methylated thiobarbiturates combine the rapidity of the onset of action and the convulsive activity of such severity as to preclude their use in clinical anaesthesia.
viii. Only thiobarbiturates and methylated oxybarbiturates are used in anaesthesia practice.
ix. The sterioisomerism has an important effect on the structure activity relationship of barbiturate. The L-isomer of pento, seco, thio and thiamylal are twice as potent as the D-isomers of it. These barbiturates are markated as racemic mixture. Methohexital has 4-stereoisomer.

Barbiturates are weak acid and in stomach (where pH is 1 or 2) they are practically unionised. Hence in aquous solution they can not be absorbed. So, their rate of absorption through gastric mucosa is related to their lipid solubility which property helps the molecules to pass through the lipid cell membrane gastric mucosal cells. Thus, methylated and thiobarbiturates are very rapidly absorbed by mouth and cause brief period of intense hypnosis when used orally as they are highly lipid soluble.

The approximate potency of the available barbiturate compounds relative to thiopentone is: thiamylal 1.1, thialbarbitone 0.5, thiobutobarbitone 0.7, methohexitone 2.5-3, enibomal 1, hexobarbitone 0.5.

Table 14.1: Classification of barbiturates

Ultra short acting	*Short acting*	*Long acting*
Methohexitone	Secobarbitone	Mephobarbitone
Hexobarbitone	Butobarbitone	Phenobarbitone
Thiopentone	Pentobarbitone	

Mechanism of Action

The barbiturates act throughout the whole CNS. In non anaesthetic doses it preferentially supresses the polysynaptic responses. Facilitation is diminished. Inhibition is enhanced. The site of inhibition of barbiturates in CNS is either the post synaptic area as for example the cortical and cerebellar pyramidal cells, cuneate nucleus, substantia nigra and thalamic relay neurons or the presynaptic area as for example the spinal cord. The enhancement of inhibition of conduction of impulses by barbiturates occurs primarily at the synapses where the neurotransmission is mediated by the inhibitory GABA neurotransmitter, acting through $GABA_A$ receptors (Fig. 14.3).

Barbiturates act mainly through the $GABA_A$ receptor complex at clinical concentration and correlate well with the anaesthetic potency of this agent. GABA is the principal inhibitory neuro transmitter in CNS which also acts through $GABA_A$ receptor. $GABA_A$ receptor has 5 glycoprotein subunit which assemble to form a internal chloride ion channel and have GABA, benzodiazepine and barbiturate binding sites. Activation of this $GABA_A$ receptor by binding with barbiturates at its own site increases the chloride ion conduction through the ion channel and causes hyperpolarisation of the cell membrane of neurone. Thereby it reduces the excitability of the post synptic neuron ($GABA_A$ receptors are referred to as the ligand-gated chloride ion channel) (Fig. 14.4).

Barbiturates enhance or mimic the action of inhibitory neurotransmitter such as GABA. By attaching to their binding site on the $GABA_A$ receptor, barbiturates decreases the rate of dissociation of GABA from their binding site on the receptor and increases the duration of GABA-activated chloride ion channel opening. Thus barbiturates enhance the action of inhibitor neurotransmitter named GABA. However at higher concentration but still in clinical range, barbiturates directly activate

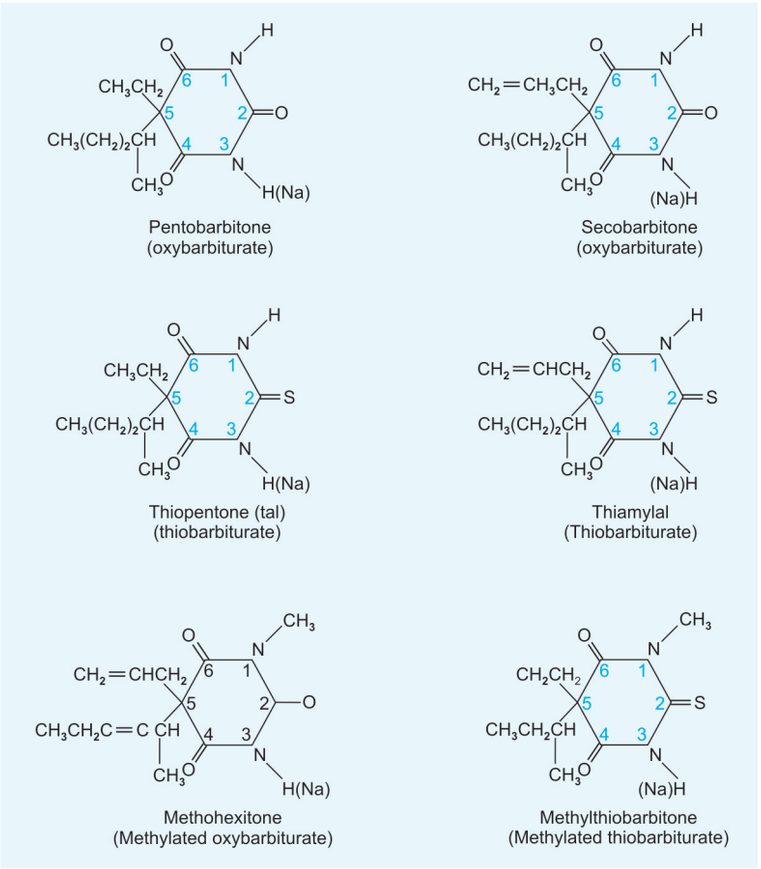

Fig. 14.3: Structure of various barbituric agents

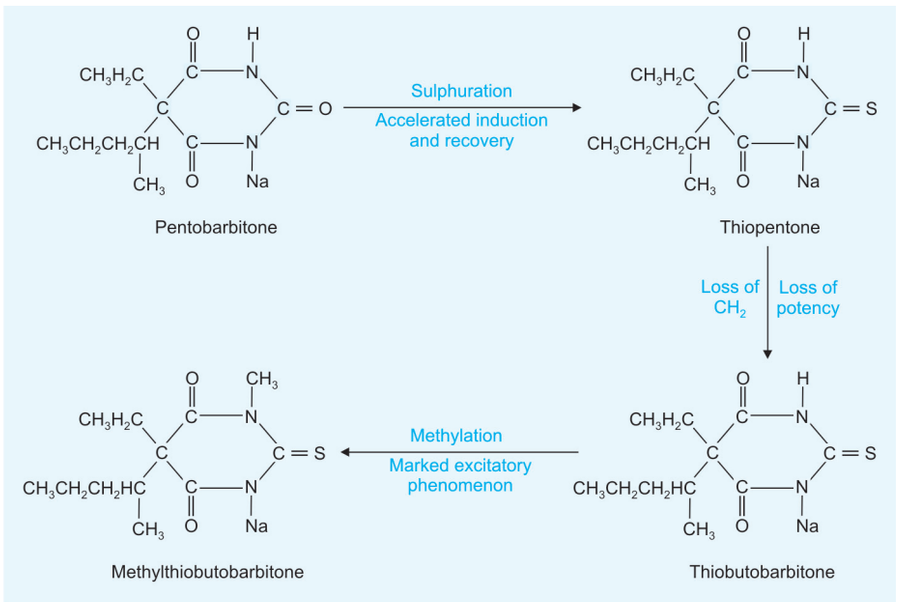

Fig 14.4: Mechanism of action of barbiturate

the chloride an channel after attaching to the barbiturate binding site on the receptor, even in the absence of GABA. This is known as the GABA-mimetic effect of barbiturates. Enhancement of action of GABA by barbiturates is responsible for its sedative and hypnotic effect. But, GABA-mimetic effect of barbiturates at higher concentration is responsible for the barbiturates anaesthesia. The mechanism of the underlying actions of barbiturates on $GABA_A$ receptor appears to be distinct from the action of either GABA or BDZ (benzodiazepine) on the same receptor.

These differences include the following:

i. Although barbiturates enhance the binding of GABA neurotransmitter to $GABA_A$ receptor, they also promote (rather than displace) the binding of BDZ.
ii. Barbiturates potentiate the GABA-induced chloride currents by prolonging the suppression of burst periods, rather than increasing the frequency of suppression of bursts as BDZ do.
iii. Only α and β subunits of $GABA_A$ receptors are required for barbiturates action, but not γ.
iv. Barbiturate's action on the receptor is not affected by the deletion of tyrosine and threonine residue in the β subunits that govern the sensitivity of $GABA_A$ receptor to activation by its agonist GABA (Fig. 14.5).

Except GABA receptor mechanism, there are other proposed mechanism through which barbiturates also act. These are:

i. Barbiturates also act on the glutamate receptors and reduce the glutamate induced depolarisation. Only the AMPA subtypes of glutamate receptor are blocked by barbiturates.
ii. At a higher concentration that produce anaesthesia, barbiturates also supress the high frequency repetitive firing of neuron as the result of direct inhibition of the function of voltage dependent Na^+ channel.

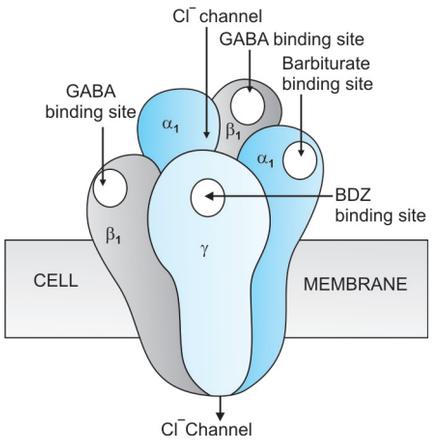

Fig. 14.5: This picture shows the GABA-BDZ-barbiturate receptor complex ($GABA_A$ receptor) with a chloride channel inside it. It is a pentameric protein composed of two α, two β and one γ subunits. There are total two sites for GABA binding on the two β subunits. There is a single binding site each for BDZ and barbiturate on the γ and α subunit, respectively. There is similarity between the $GABA_A$ receptor and the nicotinic acetylcholine receptor

iii. Still at higher concentrations, barbiturates also supress the voltage dependent K^+ channel and its conductances.

In summary, barbiturates activate the inhibitory $GABA_A$ receptors, inhibit the excitatory AMPA receptors and also inhibit the voltage dependent Na^+ and K^+ channel, like local anaesthetic agent. Barbiturates or thiopentone may act in a manner analogus to that of local anaesthetic agents by entering the cell membrane in the unionised form. Then, subsequently it acts from inside of the cell membrane by becoming ionised within the cell cytoplasm and exerting a membrane stabilizing effect by decreasing the Na^+ and K^+ conductance, decreasing the amplitude of the action potential and slowing the rate of conduction of impulse in excitable tissues. In high concentration, barbiturates also depress the enzyme involved in the glucose oxidation which inhibit the formation of ATP and thus depress the Ca^{2+} dependent action potential.

Pharmacokinetics of Thiopentone

Following IV injection of thiopentone, the blood concentration of it rises rapidly. The concentration of thiopentone in highly perfused organ, but with less tissue volume such as brain, heart, kidney, etc, also rises equally rapidly in parallel to its rise in concentration in blood and equilibrate quickly, resulting in induction of anaesthesia.

Thus, the rapid onset of action of thiopentone is due to:

i. the high blood flow to the brain,
ii. the high lipophilicity of the drug,
iii. its low degree of ionisation in blood.

The thiopentone remains as 60% non-ionised diffusible form in blood at pH 7.4. This helps it to diffuse in the brain in increased amount and only this non-ionised fraction of thiopentone crosses the blood-brain barrier. Hyperventilation increases the pH of blood and hence increases the non bound or nonionised fraction of thiopentone. Thus it increases the anaesthetic effect of it. So, thiopentone concentration in CSF reaches a level almost as high as that of the unbound portion of drug in the plasma and is responsible for induction of anaesthsia very rapidly. After that the amount of drug which is present in the blood after the first distribution to brain is distributed rapidly to the next highly perfused but large tissue volume organ such as liver, muscle, spleen, etc. Thus, within few minutes after injection, the blood (central pool) has given up about 90% of the injected dose of thiopentone to the tissues. First the drug is given up by blood to the brain and the patient becomes unconcious. Later the drug is given up by blood to other highly perfused tissues. As a result thiopentone concentration in blood falls rapidly. At that moment, as the concentration of drug in brain tissue is still high than that of the blood, so it diffuses back again in the blood from the tissue of brain and is redistributed to other tissues such as the muscles and fat. Thus, the decrease in brain concentration of thiopentone terminates its effect of induction of anaesthesia and helps in the arousal of patient from sleep. With thiopentone this whole event results in the awakening of patient within 5 to 15 minutes, after a single bolus injection of the usual anaesthetic dose (Fig. 14.6).

Equilibrium with the muscle is not attained untill a quarter of an hour after an IV injection has passed and thereafter, its concentration declines at a higher rate parallel to that of plasma. Despite its higher affinity for thiopentone, adipose tissue which is responsible for final redistribution of drug takes up the drug very slowly because of its poor perfusion. With fat/blood partition coefficent of 11:1, thiopentone will move from blood to fat as long as the conc. in the later is less than 11 times than that of the blood. The maximum deposition of thiopentone in fat occurs after approximately 2.5 hours of IV administration of it. The irreversible removal of thiopentone from the body i.e. elimination clearance by metabolism contributes little to the termination of the anaesthetic effect of the induction dose of it. Thus, in summary it can be concluded that the relatively brief duration of anaesthesia following a bolus induction dose of thiopentone is due to its redistribution from brain to muscle and later to fat tissues, but not due to metabolism in body.

In compartmental pharmacokinetic model, the central volume of distribution (V_C) of thiopentone exceeds the intramuscular space. This indicates that the brain like the intramuscular compartment is also a part of V_C and also explains the rapid onset of action of thiopentone.

When thiopentone is administered in large doses, i.e. by repeated multiple doses

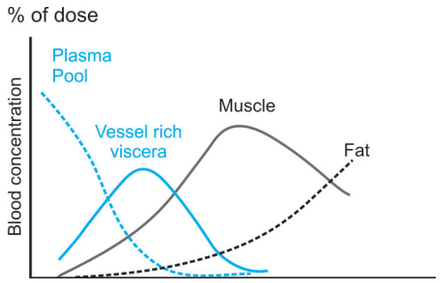

Fig. 14.6: Distribution of thiopentone in different tissues and organs at vious times after its IV injection

or by continuous infusion, then the capacity of lean tissue (muscle) to reduce the plasma concentration of drug by absorption or redistribution in it decreases progressively as the concentration of drug in tissue slowly approaches an equilibrium with the blood concentration. Then after the completion of distribution and redistribution and reaching on equilibrium the termination of the action of drug gradually depends on the slower process of reuptake into adipose tissues from muscle and metabolism in liver, resulting in prolonged drug effect. When thiopentone was administered for 3 to 5 days for cerebral resuscitation, then the redistribution sites (muslce, fat etc) reach equilibrium with the blood concentration and the enzymes responsible for metabolism in liver also soon approach saturation. Then, the recovery depends entirely on the nonlinear drug metabolism process and excretion through kidney and bile which took nearly 5 days. The first pass pulmonary uptake of thiopentone is only 14%.

In hypovolemic (haemorrhagic) shock patient, the anaesthetic dose reqiurement of thiopentone is very less. This is because the fraction of the administered dose removed from the brain tissue by distribution and redistribution to other tissues is very less. This is due to the decreased blood flow to other tissues which is again due to peripheral vasoconstriction for hypotension. In such situation, induction dose of thiopentone should be based on the lean body weight, rather than the total body mass. The usual dose of thiopentone which is based on the total body mass show an increased response in aged, obese and female patients. This is because the lean body mass which represents the principal site for distribution and redistribution represents smaller proportion of total body mass in these patients.

Acute tolerance was seen in thiopentone, i.e. the plasma thiopentone concentration at which the patient awakes is proportional to the initial dose used. The higher the induction dose of thiopentone is used, the lesser sensitive a patient will be to the subsequent doses. On the other hand, when a large amount of thiopentone is given, then the subsequent incremental dose necessary to maintain sleep become gradually less. This is because tissue equilibrium gradually occurs when small doses are required at long intervals. These not only replace the drug which has been detoxicated by metabolism but compensate for the increasing tolerance to metabolism.

The thiopentone is 60 to 80% protein bound in the plasma, predominantly to albumin. However, 40% of the injected dose is sequestreted in red blood cells.

Detoxification and Biotransformation of Thiopentone

10 to 15% of the inducing dose of injected thiopentone is broken down in liver per hour. 30% of the drug may remain in the body for 24 hours, after IV administration of the inducing dose. Liver has important role in the metabolism and also recovery from the excess doses of thiopentone which is rapidly removed from the brain by redistribution. Metabolism (oxidation and reduction) of thiopentone is occured by the cytochrome P_{450} system, situated in the endoplasmic reticulum (ER) of liver cells. Liver is the largest reservoir of ER and removes 50% of thiopentone from hepatic blood. Thus, it also plays a definite role for the short duration of action of the drugs after distribution and with redistribution in different tissues.

The pathways involved in the metabolism of barbiturates in liver are threefold:

(a) Side chain oxidation at C_5 position

Oxidation of radicals at the C_5 position of molecule is the most important step of biotransformation of thiopentone and is responsible for the termination of its biological activity. This oxidation of thiopentone results in the formation of alcohols, ketones, phenols or carboxylic acid which may appear in the urine as such or as conjugates of glucuronic acid.

(b) Oxidative replacement of sulphur at C_2 position

It forms a small quantity of drug's oxyequivalent such as pentobarbitone.

(c) Ring cleavage to form urea and three carbon fragment

Uptake and reuptake of thiopentone by muscle is mainly responsible for the early fall of arterial concentration with a modest (but imprecisely defined) contribution from metabolism in liver and uptake and reuptake by fat. Excretion of thiopentone occurs predominantly in the urine as inactive metabolites. The elimination half-life of thiopentone is 4 to 22 hours and can not be removed by dialysis.

Dosage and Duration of Action of Thiopentone

When thiopentone is injected intravenously, the maximum effect of it is found within about 1 minute. The duration of effect of a single induction dose of thiopentone in 4 to 5 mg/Kg is about 5 to 8 minutes. The induction dose of thiopentone for a healthy adult is 2.5 to 4.5 mg/Kg, for children is 5 to 6 mg/Kg and for infant is 7 to 8 mg/kg. The premedicated geriatric patient may require 30% reduction in dose, as compared with the younger patient. Concomitantly, when the midazolam, opiates, inhalational anaesthetics, ketamine, etc, are given with thiopentone, then it shifts the dose response curve of thiopentone to the left, in proportion to the dose of midazolam, opiates, inhalational agents, etc, which are administered. In hypothermia and circulatory failure state, the circulation time is decreased and the induction time is prolonged. Therefore, much lower doses of barbiturate is needed in such conditions. An acutely inebriated patient by alcohol requires less thiopentone to induce anaesthesia. While chronic alcoholic patients requires a higher dose of thiopentone than normal. This is due to the induction of enzyme, responsible for metabolism of thiopentone in liver. Clinically, there is no difference between

thiopentone and thiamylal in relation to dose, duration of action, potency, incidence of laryngospasm, respiratory depression and cardiotoxicity during induction. On the contrary, the induction dose of methoxital is 1 to 2 mg/Kg of BW. This is because methohexital is 2·5 times more potent than thiopentone.

Recovery

Recovery from anaesthesia produced by thiopentone depends on the total dose of the drug and the other agents which are concomitantly used with it during induction or during premedication to facilitate the induction. If a patient is anaesthetized for 30 minutes by induction dose of thiopentone, i.e. 4 mg/Kg and is maintained by 67% N_2O, 100 µg fentanyl and then a single 100 mg incremental dose of thiopentone, then the patient open his eyes at 3 to 4 minutes interval after N_2O is discontinued. Psychomotor functions will recover completely after 15 to 75 minutes and the psycophysiologic functions will recover completely after 8 hours. However, the abnormal sleep pattern in EEG is found for 12 hours. All these datas recommend not to drive vehicles for 24 hours after thiopentone induced GA.

Complication During Injection of Thiopentone

Pain

The incidence of pain is 1 to 2% when thiopentone is injected into a small vein on the back of the hand or wrist. But there is no incidence of pain when thiopentone is injected into the large veins. If extravasation of thiopentone occurs, then reactions ranging from slight pain, oedema, erythema and soreness to extensive local tissue necrosis can occur depending on the concentration and the total amount of drug injected. Venous sequelae such as thrombosis and phlebitis may not be seen, until few days postoperatively and its incidence is 3 to 4% in patient receiving thiopentone.

Intraarterial injection

If inadvertendly thiopentone in concentration more than 2.5% is injected intra arterially, then intense arterial spasm results, causing immediate excruciating pain spreading distally from the injection site to the hand or fingers. This intense arterial spasm may also cause oedema, hyperesthesia, anaesthesia, motor weakness and even gangrene or loss of tissue. But, sevearity of all these complications depend on the concentraion, dose, total volume and the rate of injection of thiopentone in the artery.

The pathology of these complications following intra-arterial injection of thiopentone is chemical endarteritis induced by high concentration (>2.5%) of it, leading to damage of endothelial, subendothelial and even muscle layer of artery and intra-arterial thrombosis causing gangrene or necrosis. Usually pulse is not felt, but the presence of pulse does not rule out the development of thrombosis. The aim of management of this dangerous complication following intra-arterial injection of thiopentone is to relieve the arterial spasm and to prevent the formation of thrombus, leading to resumption of circulation of blood. These can be achieved by (a) intra-arterial injection of papaverine (40 to 80 mg in normal saline) or 5 to 10 ml of 1% lignocaine which dilute thiopentone and relieve spasm, (b) blocking the sympathetic supply to the upper extirmity by stellate ganglion or brachial plexus block, (c) using heparin intravenously to prevent thrombosis, and (d) by using analgesic and alpha adrenergic antagonists. But, prevention is better than cure. So, as a prophylactic measure to avoid this complication, thiopentone should always be used maximally at a concentration of 2.5%.

Pharmacodynamics of Thiopentone

Effect on CNS

The thiopentone reversibly depresses the activity of all the excitable tissues such as brain, heart, etc. So, it produces a smooth, and rapid induction of anaesthesia. CNS is highly sensitive to thiopentone, but its direct effects on peripheral excitable tissues are weak. The antianxiety property of barbiturates are not equivalent to those exerted by the BDZ, especially with respect to the degree of sedation that is produced by BDZ with equivalent doses. Thus, thiopentone has small therapeutic window. Due to this small therapeutic window of thiopentone, it is not possible to achieve a desired effect regarding sedation like BDZ without evidence of much general depression of the CNS, like general anaesthesia. Thiopentone produces a dose related depression of EEG. By the effect of thiopentone, the wake α-pattern of EEG is replaced by higher amplitude and slower frequency delta and theta waves which gradually progress to burst supression and finally a flat EEG. This flat EEG can be maintained by continuous infusion of thiopentone in the dose of 4 mg/Kg/hour after a loading dose. As there is depression of central neuronal electrical activity so, cerebral O_2 demand which is necessary for and parallel to cerebral electrical activity is also reduced. But, this does not indicate the reduction of cerebral O_2 demand necessary for other cellular metabolic activity which only can be reduced by hypothermia. Along with this there is also parallel reduction of cerebral blood flow and reduction of ICP (provided there is no CO_2 retention following administration of thiopentone). But, the cerebral perfusion pressure is uncompromised, because ICP decreases more than the mean arterial pressure. So, thiopentone is the best drug for neurosurgical anaesthesia.

As there is no analgesic property, so pain perception and its reaction are relatively unimpaired by thiopentone, until the final and very deep stage of anaesthesia is reached. Contrary in small doses the barbiturates increase the reaction to painful stimuli. So, thiopentone has the hyperalgesic effect by subanaesthetic dose. This hyperalgesia or antanalgesia effect of subanaesthetic dose of thiopentone may

result only from the depression effect of barbiturate on some inhibitory system of the brain, (inhibition on inhibition causes excitation). But in full anaesthetic concentration, it inhibits both the inhibitory and excitatory part of the nervous system both at the spinal and cerebral level and thus produce the total depression of CNS instead of excitation.

Effect on CVS

In sedative or hypnotic doses barbiturates do not produce significant or overt cardiovascular depression, except for a slight decrease in BP and HR which occur normally during natural sleep. But, thiopentone is a direct myocardial depressant and depresses the myocardial contractility. However this is less than that of equivalent concentration of any volatile anaesthetic agent. The fall in pH of blood increases this cardiovascular toxicity of barbiturates. However, the mechanism of this myocardial depressant effect of thiopentone is unknown. It is not due to the alteration of Ca^{2+} uptake by cardiac sarcoplasmic reticulum like the halogenated inhalational anaesthetic agents. But the probable explanation is that in addition to depressing Na^{+} channels, they also reduce the function of at least two types of K^{+} channels. However, the direct depression of cardiac contractility occurs only when the large doses of thiopentone which is several times greater than those required to cause general anaesthesia are administered.

Thiopentone produces venodilatation and thus also reduces the preload and cardiac output. Therefore, HR increases via baroreflex mechanism due to the decrease of BP, but cannot compensate this reduced CO. The SVR remains unchanged by thiopentone. But inhigher doses there is also reduction of SVR and much reduction of BP. This is due to the decreased sympathetic tone and dilatation of peripheral resistance vessels. In a normal person, the slow pulse rates are usually quickened (due to fall of BP) and the fast pulse rates are slowed (if it is due to tension and anxiety but not due to shock) by thiopentone during the induction of anaesthesia. The cardiovascular depression is also obtained by partial inhibition of sympathetic transmission by higher doses of thiopentone. This is most evident in patients with congestive heart failure or hypovolemic shock, whose sympathetic reflexes already are operating maximally and in whom the barbiturates can cause an exaggerated fall in blood pressure.

In higher doses the thiopentone itself decreases the sympathetic outflow from CNS, resulting in decreased catecholamines level in blood. But it does not sensitize the heart to catecholamines. So, there is no arrhythmia by thiopentone during induction of anaesthesia, if hypoxia and hypercarbia are avoided.

The thiopentone induced tachycardia caused by hypotension increases myocardial O_2 demand. But, this is meeted by the proportional decrease in coronary vascular resistance and increase in myocardial blood flow (if aortic pressure is maintained) by thiopentone. So, thiopentone should be used cautiously in increased HR, low BP and ↓preload (e.g hypovolaemia, CHF, 1HD, heart block). The hypotensive effect of thiopentone is also exaggerated in patient who receives β-blocker. This is due to the blunted baroreflex, preventing tachycardia.

The IV bolus injection of thiopentone leads to high plasma concentration of drug, suddenly coming into contact with the heart, vasomotor centre and respiratory centre. So, in hypotensive patient with decreased CV reserve, thiopentone may lead to further decrease in venous return (preload), which in turn causes further fall in CO and decreased coronary blood flow. Thus, a vicious cycle can easily be established and may have disastrous effects. So, the IV bolus thiopentone anaesthesia is relatively contraindicated in cardiac patient where rapid hypotensive action is harmful. In contrast, inhalation induction technique has more gradual depressant effect and can be rapidly reversed.

Effect on respiratory system (RS)

Thiopentone reduces both the rate and depth of respiration until apnoea occurs. This depends on the dose and the speed of injection. The stimulatory respiratory response to both the hypercarbia and hypoxia by reflex mechanism mediated by chemoreceptor are depressed by thiopentone. The neurogenic stimulatory drive for respiration is diminished by hypnotic doses of thiopentone, but usually not more than during natural sleep. This neurogenic respiratory drive can essentially be eliminated completely by a dose which is three times greater than that normally used to induce sleep. However, such doses does not supresses the hypoxia drive, but eliminate the chemoreceptor drive by hypercarbia for respiration. At still higher doses powerful hypoxic drive also fails.

Coughing, sneezing, hiccough and laryngospasm may also occur when barbiturates are employed as IV anaesthetic agents. Among these laryngospasm is one of the chief complications of barbiturates anaesthesia. This laryngospasm that sometimes occur is due to the direct effect of thiopentone only on inhibitory system of brain leaving behind the excitatory part in low doses (inhibition on inhibition– described before). The laryngospasm may also be due to insertion of artificial airways, LMA, or ET-tube in a lightly anaesthetised patient. Laryngeal reflexes are less depressed after thiopentone than the equivalent dose of propofol. There is also low incidence of hypersalivation and rarely bronchospasm due to thiopentone. Still thiopentone is safe for asthmatic patient, though do not cause bronchodilation.

Effect on GI tract, kidney and liver

Hypoproteinaemia in patient with liver and renal disease leads to the circulation of greater amount of unbound portion of thiopentone than in normal persons. This causes exaggerated response of thiopentone even with the same dose. In hepatic failure patient the duration of action of

thiopentone is more prolonged in contrast to renal failure patient, where recovery is more rapid. Thiopentone also causes decreased urine output due to decrease in renal blood flow and GFR. This is because thiopentone causes renal vasoconstriction due to sympathetic stimulation from hypotension. So, correction of hypotension by administration of adequate IV fluid, prevents the renal effect of thiopentone from becoming a clinical problem. But, controversy exists, whether there is an increase in secretion of ADH from pituitary in response to thiopentone which may be responsible for decreased urine output.

There is also clinically insignificant increase in blood glucose levels and impairment of GTT after thiopentone anaesthesia.

The incidence of nausea and vomiting after thiopentone anaesthesia is less than that of inhalational anaesthesia. But, the incidence of nausea and vomiting is even lesser after midazolam and propofol than thiopentone.

Peripheral nervous structures

Barbiturates selectively depress the transmission of impulses through autonomic ganglia and reduce the excitation of nicotinic receptor at the motor end plate which is responsible for muscular action. So, at the skeletal neuromuscular junction the blocking effects of nondepolarising muscle relaxants are enhanced during barbiturates anaesthesia. These depressing actions of thiopentone at neuromuscular junction probably result from the inhibition of passage of current through the nicotinic cholinergic receptor.

Miscellaneous actions

Heat loss due to thiopentone induced muscular and cutaneous vasodilatation leads to post-operative shivering. It reduces the plasma cortisol level, but do not supresses the adrenocortical stimulation, during stress and strain of surgery. Thiopentone causes the dose related release of histamine, but it is rarely of clinical significance. After an injection of thiopentone, there may be an anaphylactoid reactions (urticarial rash, hives, oedema, bronchospasm and shock), but the incidence of it is very infrequent. Treatment of this thiopentone induced anaphylactoid reaction include epinephrine, IV fluid, steroid and aminophylline.

Sometimes, thiopentone causes mild muscular excitatory movements, i.e. hypertonicity, tremor, twitching and respiratory excitatory effect including cough and hiccup. This is probably due to the inadequate induction doses of thiopentonewhich evoke excitatory response, because inhibitory areas of brain are the first to be depressed. Atropine and opioids given as premedication prior to thiopentone help to reduce this muscular activity, but phenothiasines and scopolamine, used as premedication, exaggerate it.

Thiopentone does not have the curariform action and does not block the motor impulses directly. Muscular relaxation by thiopentone can be provided through the central nervous system depression. Thiopentone reduces the degree of hyperkalaemia, caused by suxamethonium. The drug causes some depression of intestinal activity and constriction of splanchnic vasculature by sympathetic stimulation due to hypotension.

Obstetric effects

The thiopentone does not depress the uterine tone or contraction. In CS when thiopentone is used in the doses of 6 mg/Kg, then the foetus is not usually depressed during delivery. This is due to the placental factors and redistribution of thiopentone in mother and foetus. The maximum concentration of thiopentone in foetal blood occurs at about 3 minutes after injection, at which time there is an equilibrium between the maternal and foetal blood concentraion. This also explain why umbilical cord blood concentration of thiopentone is half than that of the maternal blood during delivery. If delivery is done within 10 minutes of induction by thiopentone or ketamine, the baby is safe. But, neuro behavioural test of newborn shows better result afer ketamine induction than thiopentone.

Continuous infusions of thiopentone

The continuous infusion of thiopentone for maintenance of hypnosis is not generally used in anaesthesia practice. This is because of the prolonged recovery after completion of infusion of thiopentone. However this can be explained by the context sensitive half time graph (time taken by the drug to decrease to 50% of its plasma concentration) of thiopentone, in relation to other intravenous hypnotic agents used for anaesthesia. This CSHT graph is nothing but the representation of pharmacokinetic property of a particular agent which is discussed before. The successful continuous infusion by thiopentone can be achieved by maintaining blood concentration at the level of 10 to 20 µg/ml during induction, and 5 to 10 µg/ml during maintenance which is obtained by IV administration of 2 to 3 mg/Kg/hour of thiopentone.

Action as anticonvulsants

Barbiturates (thiopentone) and benzodiazepines (diazepam, midazolam, etc) can abruptly stop the seizures in convulsive patient. But, benzodiazepines have largely replaced thiopentone in acute treatment of seizures. This is because, though barbiturates have anti convalsant properties but it (except phenobarbital) possesses a high degree of selectivity and low therapeutic index. Thus, it is not possible by barbiturates to achieve the desired anticonvulsion effect without the evidence of general depression of CNS, like anaesthesia.

Mechnnism of actions of barbiturates as anticonvulsant:

i. Both the barbiturates and the benzodiazepines facilitate the action of inhibitory neurotransmitter named GABA and prolong the hyperpolarisation of post synaptic membrane. Thus, it inhibits the conduction of impulses and stop the convulsions.

ii. Barbiturates alters the postsynaptic membrane conductance of chloride ion and thus antagonise the glutaminergic and cholinergic excitation.
iii. They presynaptically block the Ca^{2+} entry into the nerve terminals and thus diminishes the transmitter release.
iv. They increase the threshold of convulsion in brain by inhibiting the kindling process more effectively.

Action as brain protection

Thiopentone protects the brain by following mechanisms:

i. It decreases the cerebral metabolism (which is only responsible for electrical activity) till the EEG becomes flat, after which no further suppression of metabolism (responsible for other cellular activities other than electrical) occur even with increased dose.
ii. Thiopentone enhances the reversed steal phenomenon in which vasoconstriction in healthy area of brain shunts the blood to the diseased areas. Thus the non healthy tissue of brain becomes less ischaemic.
iii. Thiopentone reduces both the ICP and blood pressure supplying the brain. But, the reduction of ICP is greater than blood pressure. Thus, it maintains the cerebral perfusion pressure. So, arterial hypnotension should be avoided to maintain the adequate cerebral perfusion pressure.
iv. It causes stabilization of the liposomal membrane and free radical scavenging of cell.
v. It attenuates the cerebral oedema, resulting from cranial surgery, head injury or cerebral ischaema. They may decrease the size of infarction and increase the survival rate.

Contraindications of The Use of Thiopentone

There are some occasions where it is necessary to use thiopentone with particular care or some times to avoid it completely. These occasions are:

i. Outpatients who have to leave the hospital alone. After regain of consciousness from thiopentone anaesthesia, there is a stage of euphoria when the patient is not fit to take care or to perform responsible actions by himself. So, driving a car is forbidden for 24 hours following thiopentone anaesthesia.
ii. Children are unsuitable for thiopentone as the sole anaesthetic agent, because they need relatively larger doses to produce a satisfactory depression of all the reflex activity.
iii. When the adequacy of the airway is in doubt, then thiopentone should be used cautiously.
iv. Thiopentone should not be used in patients with the history of hypersensitivity to barbiturates and asthama. Allergic reactions to thiopentone occur especially in persons who tend to have asthma, urticaria, angioedema or similar conditions. Hypersensitivity reactions in this category include localised swellings, particularly of the eyelids, cheeks or lips and erythematous dermatitis.
v. During anaesthesia on patient suffering from cardiac and peripheral circulatory failure the benefit of smooth and pleasent induction by thiopentone should be balanced against the deleterious effect of vasomotor and respiratory depression caused by it. In cardiac disease with fixed and low CO, such as in AS the vasodilation and consequent hypotension caused by thiopentone may lead to cardiac arrests. In shock patient where BP is maintained by sympathetically stimulated vasoconstriction, then vasodilation and depression of sympathetic system by barbiturates can produce fatal effect. However, such conditions are not necessarily absolute contraindication to the use of thiopentone, but should be used very cautiously by experienced person.
vi. Severe uraemia, where small dose of barbiturates produce prolonged effect are the relative contraindication for the use of thiopentone.
vii. Porphyria − In latent stage of this disease any barbiturate may cause an acute exaccerbation of symptoms with porphyrinuria, respiratory paralysis and frequently death. This is because barbiturates enhance porphyrin synthesis. So, the use of thiopentone in a patient with a history of prophyria is absolutely contraindicated.
viii. Untreated adrenocortical insufficiency − This is due to inability of such patient to respond to any form of stress, though thiopentone does not depress the release of adrenocortical steroids itself.
ix. Abnormal severe respiratory depression may follow after the use of thiopentone in dystrophia myotonica.
x. Untreated myxoedematous patient are sensitive to any IV anaesthetic agents. But thiopentone is the most sensitive amongst them.

Porphyrias

The porphyrins are chemical compounds which are formed by the binding of four pyrol rings. The examples of porphyrins are haem and its precursor compounds such as protoporphyrin, protporphyrinogen, coproporphyrinogen, uroporphyrinogen etc. During biosynthesis of heame, multiple steps are involved which are governed by particular enzymes. Deficiency of these enzymes results in increased concentration of that particular precursor of haem (or porphyrins) in blood and urine. This condition is called the porphyrias. Porphyria is classified according to the site of the defected enzyme such as hepatic porphyrias, erythrocyte porphyria, etc.

The acute attack of porphyria is precipitated by various triggering factors which include general anaesthetic agents such as barbiturates, sulphonamides, etc. Acute attack is characterised by abdominal (intermittent) pain, neurological symptoms, psychiatric sympotoms, etc. The diagnosis can be confirmed by examining the urine during

acute attack. The finding of raised aminolaevulinic acid (ALA) and porphobilinogen (PBG) in urine establishes the diagnosis. But, the urine should be protected from light during its collection. However, the concentration of ALA and PBG in urine will be normal in between the attacks.

BENZODIAZEPINE

History

Since antiquity to the begining of 19th century alcoholic beverages and some potions (containing laudanum and various herbals) had been used to induce sleep. Then, in the middle of nineteenth century the first pharmacological agent to be introduced as a sedative and soon, thereafter, as a hypnotic was bromide. After that, as sedative and hypnotic came chloral hydrate (1869) and paraldehyde (1882) which are rarely used now. Then, Fischer and Von Mering introduced barbiturates in the form of barbitone in 1903 and phenobarbitone in 1912. Thus, barbiturates reigned supreme till 1960. Then BDZ had started eroding their position after first discovery of chlordiazepoxide as benzodiazepine in 1957 and have now totally replaced them as sedative and hypnotics in anaesthesia practice.

Then the discovery of partial separation of sedative, hypnotic and anaesthetic properties from anticonvulsant properties which was a characteristic of phenobarbital (have only anticonvulsant properties) had led to the search for agents which have more selective effects on CNS. As a result, phenytoin with relatively nonsedative and high anticonvulsant property was developed in 1930 and then chlorpromazine in 1950 without any anticonvulsant but only with the taming properties was developed.

Introduction of barbiturates in the clinical practice strats the era of intravenous anaesthesia after an initial set back. But, the barbiturates have only hypnotic property. So the search for an ideal intravenous anaesthetic drug which should have hypnotic, amenestic and analgesic property was started. On that searching many drugs were steadily introduced in the clinical anaesthetic practice with varying degree of acceptance. Thus, with increasing number of better drugs and discoveries of superior methods of drugs delivery system, the use of intravenous anaesthesia continues to grow. But, as not a single drug has all the ideal property of anaesthesia, so the future of IV anaesthetic management involves the simultaneous use of several drugs with their specific properties. In 1988, a survey of mortality among 1,00,000 anaesthesia reveals that the practice of combined anaesthetic drug in small doses with their specific property may be safer than the use of only one or two drugs in high doses to extract the all properties which are exerted by many drugs in small doses. This is because a single drug in high doses has many side effects and increases mortality.

In 1955, as the first generation of benzodiazepine chlordiazepoxide was synthesised and in1957 it's hypnotic and sedative effects was first discovered. Then, in 1960 it was released as first orally used benzodiazepine. But, as chlordiazepoxide has no parenteral form, so it was not used for intravenous anaesthesia. After that, as benzodiazepine the diazepam was synthesized in 1959 and was used in anaesthesia through IV route. Then, gradually oxazepam, a metabolite of diazepam was synthesized in 1961 and lorazepam, a substitution of oxazepam was synthesised in 1971. Next major achievement was synthesis of water soluble benzodiazepine, midazolam in 1976. Its water solubility is pH dependent and formulated in a buffered acidic medium (pH 3·5). But it is most lipid soluble *in vivo* than diazepam and lorazepam. After that in 1977 benzodiazepine receptor was described. However, this is better termed as BDZ, GABA and barbiturate receptor complex which is discussed in later paragraph.

Chemistry

The term benzodiazepine is referred to the structure of a molecule that is composed of a benzene ring (A) fused to a seven membered 1-4-diazepine ring (B). However, since all the important benzodiazepines compounds contain a 5-aryl susbstituent ring, so the term has come to mean the 5-aryl-1,4-benzodiazepine. Then, various modifications in the structure of this ring systems have produced different compounds with similar activities. But, the substitutions at various position on these rings affect the potency and mechanism of biotransformation of these compounds. A special benzodiazepine ring, named the imidazole ring of midazolam contributes to its water solubility at low pH. The insolubility of diazepam and lorazepam in water requires propylene glycol for their parenteral preparations which has been associated with venous irritation and pain during injection (Fig. 14.7).

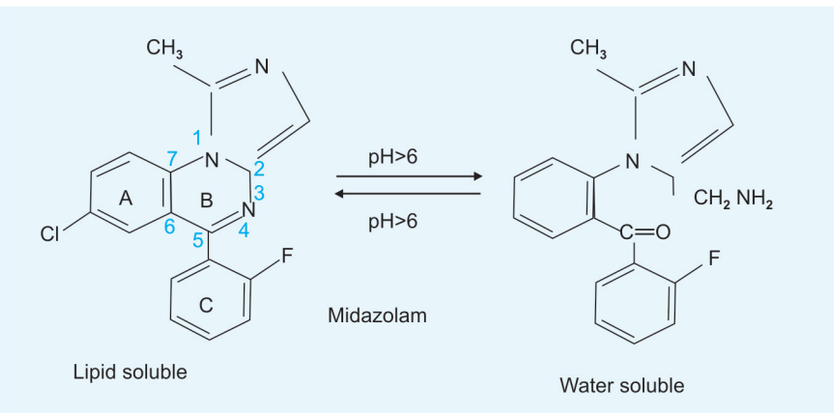

Fig. 14.7: Solubility of midazolam in lipid and water

BDZ – GABA – Barbiturate Receptor Complex or $GABA_A$ Receptor

Benzodiazepines (BDZs) act by occupying the BDZ receptors. Barbiturates and an another inhibitory neurotransmitter, named GABA also act by occupying the respective barbiturate and GABA receptors. But, actually they are not any separate receptor structure. They are truely the binding site of the benzodiazepine, barbiturate and GABA compound on a single large receptor complex, situated on the postsynaptic membrane which is called the BDZ-GABA-barbiturate receptor complex or $GABA_A$ receptor. This large $GABA_A$ receptor complex exerts the action of barbiturates, benzodiazepines and GABA after their binding with this receptor complex at their each specific site and ultimately by promoting and modulating the action of GABA. These large receptor complexes are found in higher concentration at cerebral cortex, cerebellum, olfactory bulb, hippocampus and substantia nigra. In lesser density this large receptor complexes are also found at spinal cord, brain stem and corpus striatum. The barbiturates and benzodiazepines both act through this receptor. But in contrast to the barbiturates, the benzodiazepines selectively inhibit the activity of this receptor in the limbic system, particularly the hippocampus.

GABA receptors are membrane-bound protein structure that can be divided into two major subtypes – $GABA_A$ and $GABA_B$. The $GABA_A$ receptor is composed of 5 subunits that coassemble to form an integral chloride channel. These receptors are responsible for most of the inhibitory neurotransmission in CNS. The BDZ does not act on the $GABA_B$ receptor, but acts only on $GABA_A$ receptor. Unlike the barbiturates, the BDZ do not directly activate the $GABA_A$ receptor, but require inhibitory neurotransmitter GABA to express their own effects, i.e. BDZ only modulates or promotes the effects of inhibitory neurotransmitter GABA. The BDZ modulates the GABA binding site and GABA alters the BDZ binding site in an allosteric fashion (Fig. 14.8).

Each $GABA_A$ receptor complex is believed to consist of a pentamer of homologus subunits. Mainly these subunits are α, β, γ and they coassemble to form a receptor. But, there are other subunits such as δ, ε, π and θ. Again 16 several isoforms of each subunit have also been cloned. These subunits and their isoform composition of the receptor complex may differ at different sites. The multiplicity of these subunits and their isoform generates heterogenesity in $GABA_A$ receptor and is responsible for their pharmacological diversity. The macromolecular complex of this $GABA_A$ receptor and the chloride channels within it also may be the site of action of many general anaesthetics, ethanol and inhaled drugs. The subunits of the $GABA_A$ receptor complex contain various ligand-binding site such as BDZ, GABA and barbiturate. The BDZ binding site is located on the γ subunit and GABA binding site is located on the β subunit of $GABA_A$ receptor complex. With the activation of GABA-BDZ and barbiturate receptor complex, the opening of chloride channel is triggered and hyperpolarization of post synaptic membrane occur. This leads to the resistant of neuronal excitation which is responsible for inhibition of transmission.

The pharmacological spectrum of intrinsic activity of BDZ includes 5 different types – agonist, partial agonist, antagonist, partial inverse agonist and inverse agonist. Antagonist blocks the action of agonist. Whereas the inverse agonist express no action from itself, but causes all the opposite action of agonist. For example an agonist such as midazolam have full positive intrinsic action of benzodiazepine and produce hypnosis, sedation, amnesia etc. Because it alters the configuration the $GABA_A$ receptor complex after binding with the BDZ binding site of this receptor complex which is called as the BDZ receptor. Thus, the binding affinity of GABA neurotransmitter

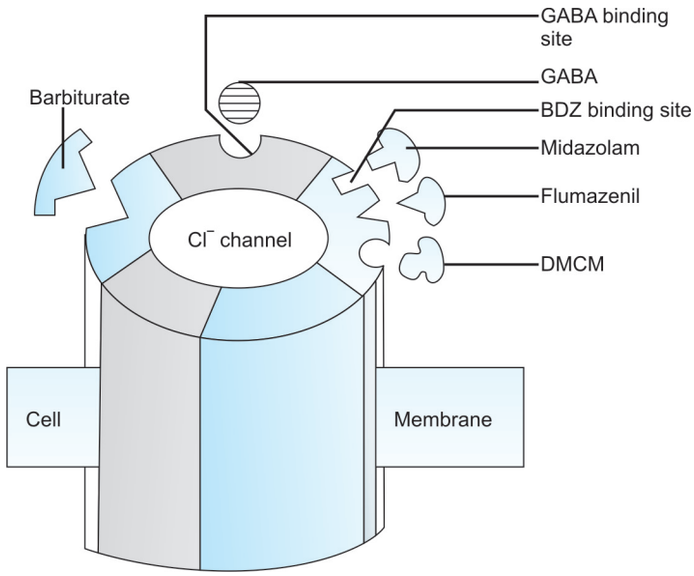

Fig. 14.8: A GABA - BDZ barbiturate receptor complex ($GABA_A$ receptor) with chloride channel. A part of it i.e. the BDZ - binding site (or BDZ-receptor) modulates the action of $GABA_A$ receptor in either direction. The agonist like midazolam facilitates the opening of GABA mediated Cl^- channel in the $GABA_A$ receptor complex and produces all the actions of benzodiazepine. Whereas the inverse agonist like DMCM hinder GABA mediated Cl^- channel opening producing the opposite action of midazolam. Whereas BDZ antagonist flumazenil blocks the action of both midazolam and DMCM. Barbiturate receptor is located in the other part of $GABA_A$ receptor. It also facilitates the action of GABA and is capable of opening the chloride channel directly

to the GABA binding site of GABAA receptor complex is increased and the chloride channel is fully opened. Whereas the antagonists (e.g. flumazenil) occupy the BDZ receptors, i.e. the BDZ binding site of $GABA_A$ receptor complex and have very little intrinsic action expressed by itself after binding with the receptor. Contrary, it blocks all the action of both agonist and inverse agonist by preventing the binding of them with the BDZ receptor (BDZ binding site of GABA receptor complex). Therefore there is no action of BDZ agonist and inverse agonist. In the absence of agonist and inverse agonist, antagonist does not itself cause any $GABA_A$-receptor function. So, they are also called the neutral in function. The inverse agonist has opposite intrinsic activity i.e. produce opposite effect of agonist in the absence of it. It reduces or inhibit the GABA synaptic transmission and since GABA is inhibitory, so the result of inhibition of GABA (inhibition on inhibition) causes CNS stimulation. The potency of these agonist, antagonist and inverse agonist is dictated by its affinity for the BDZ receptor and the duration of effect of these compound is dictated by the rate of clearance of these drugs from receptor. (Table 14.2).

It is still not known how the different effect of benzodiazepine (hypnosis, sedation, anxiolytic, amnesia, anticonvulsant and sleep) are mediated by the same receptor. For this there are two probable theories: (i) different receptor subtypes mediate different action and (ii) different action is due to different blood level of the drug. As for example, the anxiolytic effect of BDZ occurs at 20% GABA receptor occupancy, the sedation is observed with 30 to 50% receptor occupancy and the unconciousness at 60% receptor occupancy.

Table 14.2: The relationship between the different effects of midazolam and its receptor occupancy

Effect	*Receptor occupancy (%)*
Anticonvulsant	20 - 25
Anxiolysis	20 - 30
Slight sedation	30 - 50
Amnesia	
Reduced attention	
Intense sedation	60 - 90
Unconsciousness	
Muscle relaxation	
Anaesthesia	> 95

Different compounds of BDZs differ in their potency and efficiency. This is due to the different chemical structure of each drug which again dictates its particular physicochemical, pharmacokinetics and receptor binding characteristics. For example the order of receptor affinity (thus potency) of three BZD agonist from higher to lower is lorazepam > midazolam > diazepam. So the midazolam is 3 to 4 times and lorazepam is 5 times more potent than diazepam.

Chronic administration of BDZ produces tolerance and causes increased dose requirement. This is due to the down regulation of GABA-BDZ-barbiturate receptor or $GABA_A$ receptor complex. After the cessation of chronic use of BDZ, there is again upregulation of the receptor complex i.e. increased susceptibility to BDZ.

Pharmacokinetic of BDZ

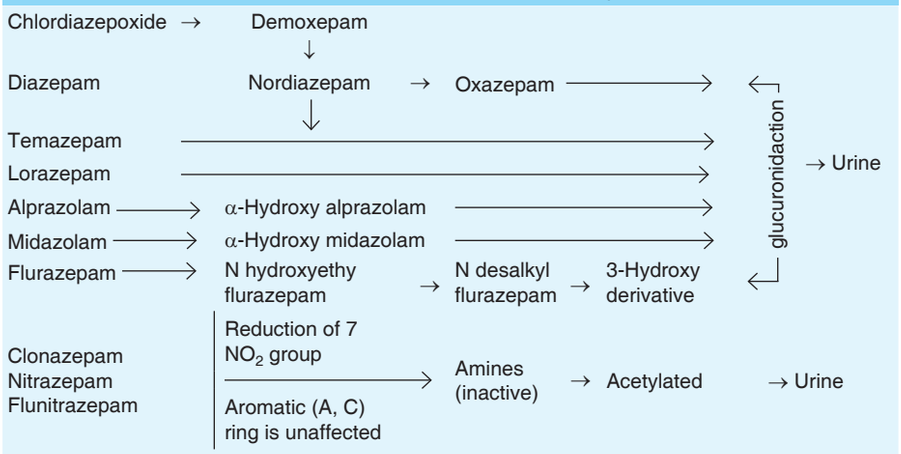
BDZ compounds used in anaesthesia are classified as: (i) long acting with half-life more than 24 hours (lorazepam), (ii) intermediate acting with half-life 6 to 24 hours (diazepam) and (iii) short acting with half-life less than 6 hours (midazolam) according to their plasma clearance. The clearance rate of lorazepam is 0.2 to 0.5 ml/Kg/min, the diazepam is 0.8 to 1.8 ml/Kg/min and midazolam is 6 to 11 ml/Kg/min. So, these drugs have different plasma disappearance curve after their bolus IV administration.

The onset of action of different BDZs depends on their lipid solubility and the duration of action depends on the rate of distribution and redistribution of these BDZ in different compartment of body like thiopentone and metabolism. For example, onset of action of midazolam and diazepam after IV administration is 30 to 60 sec. It is due to their high lipid solubility. But, the onset of action of lorazepam is 60 to 120 sec which is due to its less lipid solubility. The more rapid redistribution from CNS to other body tissues of midazolam and diazepam due to their higher lipid solubility compared to lorazepam also accounts for their shorter duration of action than lorazepam. Thus, the order of three agents according to their early onset and short duration of action is: midazolam < diazepam < lorazepam. Although midazolam is more water soluble and less lipid soluble at low pH, but its imidazole ring closes at physiological pH and causes an increase in its lipid solubility (Table 14.3).

Again, after the prolonged infusion of BDZ when the redistribution site of benzodiazepine becomes saturated and is in equlibrium with the primary site of action, then the blood levels of midazolam will decrease more rapidly than others BZD. It is due to its greater hepatic metabolic clearance rate than others. So, patient will awake faster after midazolam infusion than others. The more lipid soluble member of BZD enters the brain rapidly and have two phases of plasma concentration decay curve like thiopentone. The first decay curve is due to the redistribution and the later decay curve is due to the elimination by metabolism or directly through urine. A relatively shorter duration of action is seen with single dose of any BZD compound that is rapidly redistributed, even though it may have a long elimination half-life ($t_{½}$). So, using the elimination $t_{½}$ alone to predict duration of action may be misleading. However, the plasma $t_{½}$ determine the duration of action of drugs whose elimination is by far the dominant feature or when the drug is given repeatedly or by infusion.

BZDs are metabolised in liver by dealkylation and hydroxylation to many metabolites, some of which are also active. This explains why the effect or the

Table 14.3: Metabolism of benzodiazepine



Red colour = Long acting drugs, Green colour = Intermediate acting drugs, Black colour = Short acting drugs

biological half-life of some drugs may be much longer than the actual plasma t½ of the administered compound. Some BZDs (e.g. diazepam) undergo enterohepatic circulation and is also responsible for their long duration of action. Benzodiazepines are commonly administered orally or intravenously for premedication, sedation, or induction of GA. Midazolam, diazepam and lorazepam are well absorbed from gastrointestinal tract and the peak plasma level is usually achieved within 30 minutes, 1 hour and 2 hours respectively. Midazolam also can be used through intranasal (0.2 to 0.3 mg/Kg), buccal (0.07 mg/Kg) and sublingual (0.1 mg/Kg) route to provide effective preoperative sedation. The intramuscular injection of diazepam is very painful and the action is unreliable due to very erratic absorption of its oily preparation from muscle. In contrast, the midazolam and lorazepam are well absorbed after intramuscular injection with peak levels achieved within 30 and 90 minutes, respectively. However, the induction of general anaesthesia by BDZ only requires IV administration of them.

Metabolism

BDZs and their metabolites which are sometimes more potent than their parent compound bind to plasma protein. This extent of binding of these metabolites with plasma protein correlates strongly well with their lipid solubility and duration of action which ranges from 70% for alprazolam to nearly 99% for diazepam. The concentration of BDZs in CSF is equal to the concentration of free drug in plasma.

The plasma concentration of most of the BDZs exhibits two compartmental model, but three compartmental model appears to be more appropriate for the compounds with highest lipid solubility like midazolam. There is rapid uptake of BDZ by brain after IV administration like barbiturate. This rapid uptake by brain is followed by a phase of redistribution to the less well perfused tissue i.e. muscle. Muscle uptake is followed by again redistribution to fat.

As the metabolites of some BDZs are more active and biotransformed more slowly than their parent compounds, so the duration of action of many BDZs bear little relationship to the actual half-life of elimination of the drug that has been administered. All the BDZs crosses the placental barrier and secreted into breast milk.

BDZs are metabolised extensively in the liver by the enzymes of cytochrome P_{450} family. Some BDZs, such as oxazepam and lorazepam is not metabolised by these enzymes, but is conjugated directly in to the liver. Midazolam is rapidly metabolised by hydroxylation of its methyl group to α-hydroxy midazolam which has appreciable biological activity (elimination half-life 1 hour) and then is conjugated with glucoronic acid in liver.

Diazepam in the first phase is metabolised by the cytochrome P_{450} system in liver to N-desmethyl diazepam (nordiazepam) which is a long acting active metabolites. In the 2nd phase, this nordiazepam is again metabolised to oxazepam which is then conjugated with glucoronic acid and excreted through bile. The half-life of diazepam in plasma is between 1 to 2 days, while that of N-desmethyl diazepam (nordiazepam) is about 60 hours. Half-life of lorazepam in plasma is about 14 hours.

Pharmacodynamics of BDZ

Effects on CNS

The most prominent effects of BDZs on CNS are sedation, hypnosis, decreased anxiety, anterograde amnesia and anticonvulsion activities. The muscle relaxant effect of BDZ is independent to their sedative actions and is due to their action on the spinal cord and brain stem. It affects the activity of neural axis at all the levels, but some structures are affected much greater extent than the others. They are not capable of producing the same degree of neuronal depression at all the centres, as the barbiturates and volatile anaesthetics do.

All the BDZs have very similar pharmacological profiles, but neverthless they differ in selectivity to their different effects. So, the clinical usefulness of individual BDZ varies considerably. BDZs alone do not cause a true general anaesthesia, since awareness usually persist and relaxation which is sufficient to allow surgery can not be achieved by them. During induction of anaesthesia by BDZ with inducing doses, patients are clinically asleep, but EEG changes are not typical to sleep. In a dose related manner the BDZs gradually reduce the cerebral metabolic rate with reduction

of O_2 consumption ($CMRO_2$) and cerebral blood flow (CBF). They increase the seizure threshold and thus inhibit seizure. They have also cerebral protection effect against hypoxia. In this respect midazolam is superior to other BDZs, but is inferior to thiopentone.

BDZs also have the antiemetic effect and lorazepam has the highest result. As they produce anxiolysis, amnesia, sedation and hypnosis gradually, so they should be titrated for this effects and the end point of this titration is sedation or hypnosis. The onset of action is most rapid in midazolam, than diazepam and the last is lorazepam. But recovery with midazolam is faster than diazepam after bolus administration. With all the three BDZs (midazolam, diazepam and lorazepam) there is amnesia, but different level of sedation. Patient is concious and coherent, but amnestic for events and instruction (conscious sedation). With the intravenous preparation the memory loss by BDZs can occur independent of the loss of consciousness. When taken by mouth, it is not possible to demonstrate the amnestic action of BDZs in the absence of drowsiness and the usual small tranquillizing doses (diazepam 5 mg, lorazepam 1 mg) produce no amnesia. There is synergestic action between the midazolam and the regional anaesthesia in respect to ventilation. They do not cause hyperalgesia like the barbiturates.

Anticonvulsant properties

All the benzodiazepines have anticonvulsant properties. Among them midazolam, diazepam, and lorazepam have well defined roles in the management of status epilepticus. This action is due to their ability to enhance the GABA-mediated synaptic inhibition through BDZ-binding site (or benzodiazepine receptor) which is an integral part of the $GABA_A$ receptor.

Effects on CVS

The benzodiazepines display the minimal cardiovascular depressant effects, even at induction doses. The peak hemodynamic effects of BDZs occur within first 10 minutes after their intravenous administration. They all decrease the BP and increase the HR. With midazolam, these effects appear to be secondary to the decrease in peripheral vascular resistance (SVR), but with diazepam these are secondary to the decrease in left ventricular work load and cardiac output. Diazepam increases the coronary blood flow, possibly by increasing the interstitial concentration of adenosine. Accumulation of cardio depressant metabolite may also explain the negative inotropic effects of all the BDZ group of drugs. The predominant hemodynamic changes produced by BDZs are:

i. Reduction of MAP (in midazolam 12 to 26%) due to the decrease in SVR. In this respect midazolam has the highest effect than other BDZs, and is similar to thiopentone. The reduction of SVR for diazepam is upto 0 to 8% and for midazolam it is upto 0 to 18%. Still, they are safe and effective for induction with severe AS (arotic stenosis).
ii. PAP (pulmonary artery pressure) and PVR remains unchanged or slightly reduced. In midazolam both are unchanged, but in diazepam the effect varies between unchanged to minimum reduction.
iii. Right atrial pressure remains unchanged.
iv. Variable response to cardiac index (C1) unchanged in diazepam, 0 to 25% reduction in midazolam.
v. In patient with elevated left ventricular filling pressure, diazepam and midazolam produce NTG like effect by lowering the filling pressure and increaseing the CO.

The mechanism by which BDZs maintain a stable haemodynamic condition is due to the preservation of homeostatic reflex by them. Midazolam or any BDZ can block the stress response due to intubation or surgery. However, addition of N_2O with BDZs has slight synergistic effect to block this response. But addition of opiods with BDZ has supra additive synergistic effect and causes a greater decrease of BP and stress response than when used alone during intubation. However, the mechanism of this synergistic effect is not known, but probably is due to the reduction of sympathetic tone.

BDZs cause coronary vasodialtation which is seen after administration of therapeutic doses.

Effect on respiratory system

The hypnotic doses of BDZs produce minimal effect on respiration in normal subjects, but special care should be taken for children, aged, and alcoholics. It depresses the ventilatory response to hypoxia and CO_2. This depression is usually insignificant, unless the drugs are administered intravenously in large doses or in association with other respiratory depressants. Although the incidence of apnoea may be less common after BZD induction than after barbiturate induction, still sometimes even a small IV doses of diazepam and midazolam have resulted in respiratory arrest. Respiratory arrest or apnoea is more likely to occur during the concomitant presence of opioids. The steep dose response curve of midazolam shows slightly prolonged onset (compared with thiopentone) and high potency of it, necessitating careful titration to avoid over dose and apnoea. So, ventilation must be monitored in all the patients receiving IV benzodiazepines and resuscitation equipment must be immediately available.

The hypnotic doses of BDZs may also worsen the sleep related breathing disorder by adversely affecting the control of upper airway muscles and by decreasing the ventilatory response to CO_2. The latter effect may be sufficient to cause the hypoventilation and hypoxemia in some patients, especially with severe COPD. In some patients with obstructive sleep apnoea (OSA) syndrome, the hypnotic doses of BDZs may decrease the upper airway muscular tone and exaggerate the incidence of apnoeic episodes. Thus, many physicians consider OSA as contraindication for the use of

sedative and hypnotic agents like benzodiazepines. So, during administration of benzodiazepines caution should be exercised in patient who snore regularly. This is because partial airway obstruction may be converted to OSA under the influence of these drugs.

The central respiratory depression produced after administration of BDZs is greater in midazolam than diazepam. The slope of ventilatory response curve to CO_2 for BDZ is flat than normal, and is not shifted to the right like opiods. The peak onset of ventilatory depression effect with midazolam is 3 minutes and remain for about 60 to120 minutes. The faster the drug is given, the quicker the peak depression occur. The combination of opioids with BDZs produce a supra additive respiratory depression effect. Apnoea is common to midazolam than other BDZs and its incidence is similar to thiopentone.

Effects on GI tract

BDZs markedly decrease the nocturnal gastric secretions in human beings.

Induction and Maintenance Dose of BDZs

Among the BDZs, midazolam is the choice for induction of anaesthesia, because for its rapid onset, rapid recovery and lack of venous complications. Induction is complete when there is unresponsiveness to command and loss of eye lash reflex. On the otherhand, the induction with midazolam occurs less rapidly than thiopentone, but amnesia caused by it is more reliable. But the dose, speed of injection, premedication, age, ASA status and many other factors influence the induction time by BDZs. For example, midazolam in the dose of 0·2 mg/Kg induces anaesthesia within 28 sec, if given IV. Whereas diazepam in the dose of 0·5 mg/Kg takes 39 seconds for induction of anaesthesia, if it is given through the same route and in the same speed (Table 14.4).

Table 14.4: Uses and doses of commonly used benzodiazepines (BZD)

Agent	*Use*	*Route*	*Dose (mg/Kg)*
Diazepam	Premedication	Oral	0.2-0.4
	Sedation	IV	0.04-0.3
	Induction	IV	0.3-0.5
Midazolam	Premedication	Oral	0.5
		IM	0.07-0.2
	Sedation	IM	0.07-0.1
	Induction	IV	0.1-0.4
Lorazepam	Premedication	Oral	0.05
	Sedation	IM	0.025-0.05
		IV	0.025-0.05

Due to increased susceptibility to BDZ receptor, the elders need lower doses. In premedicated patient, induction dose of midazolam is reduced to 0.1 to 0.2 mg/Kg. Emergence (defined as oriented to time and pace) in healthy young patient after 10 mg midazolam is 15 minutes. In comparison between midazolam and thiopentone for hypnotic component in balanced anaesthesia, midazolam is superior for this use. This is because of the better amnesia and lesser hemodynamic changes produced by it. Midazolam reduces the opioid requirement than thiopentone. Amnestic period after an induction dose of midazolam is 1to 2 hours. Bolus loading dose of midazolam is 0.05 to 0.15 mg/Kg which maintains plasma level of 50 µg/ml. This is sufficient to keep the patient asleep and amnestic, but arousable at the end of infusion.

INDIVIDUAL BENZODIAZEPINE (BZD) (Fig. 14.9)

Diazepam

Chemically, diazepam is a benzodiazepine derivative. The main actions of it are:

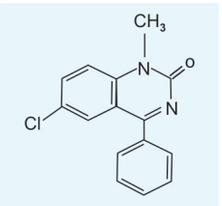


Fig 14.9: Diazepam

hypnosis, sedation, anxiolysis, anterograde amnesia, anticonvulsant and muscular relaxation. Like other BDZs, diazepam is also thought to act via the specific BDZ-receptors, found at synapses throughout the central nervous system, but concentrated especially in the cortex and midbrain. However, the individual receptor cannot directly act. They are closely linked with large complex $GABA_A$ receptos and appear to facilitate the activity of the inhibitory GABA neurotransmitter. The activated $GABA_A$ receptors by diazepam open chloride ion channels which then either hyperpolarize or short circuit the postsynaptic membrane. Thus hyperpolarization of the postsynaptic membrane reduces the action potential and inhibits the transmission of impulses.

The main action of diazepam on cardiovascular system is transient decrease of blood pressure and a slight decrease of cardiac output, but only following its IV administration. The coronary arterial blood flow is increased by diazepam. But this is secondary to the coronary arterial vasodilatation caused by accumulation of adenosine. A decrease in myocardial O_2 consumption has also been reported by it. Large doses of diazepam causes respiratory depression causing decreased tidal volume, respiratory rate, and minute volume. It may also cause apnoea necessitating IPPV. The hypoxic ventilatory drive is depressed to a greater extent than the hypercarbic drive. It is anxiolytic and so decreases the aggression, although sometimes paradoxical excitement may occur. Sedation, hypnosis and anterograde amnesia also occur after the administration of diazepam. The drug also has the anticonvulsant and slight analgesic property and depresses the spinal reflexes.

The toxicity or the side effects of diazepam are nothing but the excessive depression of CNS, including drowsiness, ataxia and headache. Tolerance and dependence to diazepam may occur with prolonged use of it, like other BDZs. So,

acute withdrawl of diazepam in these circumstances may produce insomnia, anxiety, confusion, psychosis or perceptual disturbances. Rashes, GI upset and urinary retention also have been reported as the side effects of it. The commercially available lipid preparation of IV diazepam is highly irritant to vein. So, it produces intense pain during intravenous injection. But its water preparation is not so irritant to do so. However, this preparation is not available commercially.

Diazepam is rapidly absorbed after oral administration. The bioavailability of it by oral route is 90 to 100%. On the otherhand, absorption of diazepam after IM administration of its lipid preparation is slow and erratic. This drug is 99% protein bound in the plasma. Diazepam is converted in the liver to its active metabolites. The major active metabolites of it is desmethyldiazepam (nordiazepam). The other active metabolites of it are oxazepam and temazepam which are further metabolised by glucuronidation. Due to this active metabolites, diazepam is a long acting agent.

Desmethyldiazepam has a half-life of >100 hours. The metabolites of diazepam are excreted through the urine. Diazepam decreases the MAC value of volatile anaesthetic agents and potentiates the action of nondepolarizing muscle relaxants. It is absorbed on the plastic and can not be removed by dialysis. The diazepam is used in anaesthesia for premedication in the dose of 0.2 to 0.5 mg/Kg orally, for sedation in the dose of 0.04 to 0.2 mg/Kg IV and for induction of anaesthesia in the dose of 0.3 to 0.6 mg/Kg IV.

Midazolam

Chemically, it is a water soluble imidazobenzodiazepine compound. Its main actions and mode of action is same as that of diazepam. Midazolam decreases the systolic blood pressure by 5%, diastolic blood pressure by 10% and SVR by 20 to 30%. The heart rate increased by midazolam is 20%. Midazolam in combination with fentanyl obtunds the pressure response during intubation to a greater extend than the thiopentone in combination with fentanyl. It decreases the tidal volume, but this is offset by an increase in the respiratory rate. The minute volume is thus little changed. However, this does not occur with increased dose of midazolam. With increased dose of midazolam, there is reduction of both the tidal volume and respiratory rate with reduction of minute volume. Apnoea occurs in 10 to 70% of patients when midazolam is used as an induction agent with the appropriate dose. The drug impairs the ventilatory response both to the hypercapnia and hypoxia (Fig. 14.10).

The anticonvulsant properties of midazolam in man is like that of other benzodiazepines. The cerebral O_2 consumption and cerebral blood flow are decreased in a dose related manner by midazolam, but a normal relationship is maintained between the two. When administered intrathecally or epiduraly, the drug has antinociceptive effects. A midazolam fentanyl induction sequence is associated with a lower incidence of post-operative vomiting than with a thiopentone-fentanyl sequence. This drug decreases the adrenergic response, but not the cortisol and renin response to stress during intubation and surgery. It causes significant inhibition of phagocytosis and bacteriocidal activity of leucocyte.

The oral dose of midazolam is 0.5 mg/Kg. The intramuscular dose of it is 0.07 to 0.15 mg/Kg. The intravenous dose of midazolam for sedation is 0.07 to 0.1mg/Kg which is titrated according to the response. The endpoint of sedation is drowsiness and slurring of speech, but response to command, however, is maintained. The dose of midazolam for induction of anaesthesia through IV route is 0.1 to 0.4 mg/Kg. The drug may also be administered intrathecally in an adult in the dose of 0.3 to 2 mg or epidurally in a dose of 0.1 to 0.2 mg/Kg. The bioavailability of midazolam when adminstered by the oral route is only 45% and by the intramuscular route is 80 to 100%. It is 96% protein bound in the plasma.

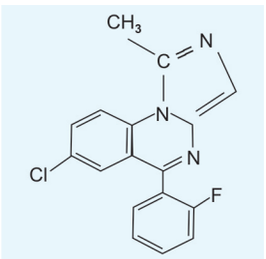

Fig 14.10: Midazolam

The midazolam is virtually completely metabolised in liver to its hydroxylated derivatives which are then conjugated to glucoronide and excreted through the bile and urine. Metabolites of midazolam also bind to the CNS benzodiazepine receptors and are pharmacologically active. Excretion of midazolam also occurs through the urine, predominantly as the hydroxylated derivatives which are formed in the liver. In the absence of renal function it can excrete solely through the bile. So, renal impairment has little effect on the excretion of midazolam. It produce little discomfort at the site of injection. Withdrawl phenomenon may also occur in children after prolonged infusion.

The short duration of action of midazolam is due to its high lipophilicity, rapid redistribution (but less than thiopentone and propofol), high metabolic clearance and rapid rate of eliminatoin. However, this may not be the true after prolonged infusion in intensive care unit. The use of midazolam in premedication decreases the MAC value of volatile anaesthetic agents by approximately 15%. The clinical effects of this drug can be reversed by physostigmine, flumazenil and glycopyrronium.

Lorazepam

Chemically, lorazepam is a lipid soluble hydroxy benzodiazepine compound. Mode of action of it is same as that of diazepam and midazolam. But the only difference is that the prolonged action of lorazepam makes it unsuitable for outpatients. It appears to have no direct cardiac effects. Mild respiratory

depression occurs following the administration of this drug which is of clinical significance only in patients with lung disease, elderly, children and neonates, etc. Like other BDZs, it also produces sedation, anterograde amnesia and anticonvulsant effects. But, the slow rate of onset of action of lorazepam would make it unsuitable, even through intravenous route for the control of status epilepticus, though it could be given as an anticonvulsant. However, clonazepam, another benzodiazepine is recommended as a more specific therapy for the control or prevention of convulsions. This drug has no effect on basal gastric acid secretion. When lorazepam is used as premedication, the circulatory cortisol and glucose levels fall. This is probably secondary to its anxiolytic effect. The prolonged action of lorazepam makes it most dependable agent for minimizing the emergence sequelae which is found, after the use of ketamine in adults. This can be achieved by the IV injection of lorazepam near the end of operation, but not by its premedicant use. So, to be effective lorazepam has to be given in the doses of 2.5 mg IV, but this may delay the complete recovery from anaesthesia (Fig. 14.11).

In adult the oral or sublingual dose of lorazepam is 1 to 4 mg/day in divided doses. For premedication in anaesthesia the lorazepam is used orally in a dose of 0.05 mg/kg. The intravenous or intramuscular dose of it for sedation is (Table 14.5) 0.025 to 0.05 mg/Kg. Intramuscular injection of lorazepam is painful. The bioavailability of this drug is 90% when administered by the oral or IM route. It is 80 to 90% protein bound in the plasma. Lorazepam is less extensively distributed in tissues than diazepam. Thus it has a longer duration of action than diazepam, despite the shorter elimination half-life of it. It is conjugated directly in the liver to glucuronide to form an inactive water soluble metabolite. 80% of an orally administered dose of lorazepam appears in the urine as the glucuronide. The elimination half-life of it is 8 to 25 hours. This is unaffected by renal disease.

The side effects of lorazepam are like that of other BDZs which are drowsiness, sedation, confusion, impaired coordination, etc, in a dose dependent manner. Paradoxial stimulation of CNS has also been reported after lorazepam and occurs more frequently when hyoscine is administered concurrently with it. The tolerance and dependence in lorazepam may occur with prolonged use of it and acute withdrawal in these circumstances may produce insomnia, anxiety, confusion, psychosis and perceptual disturbances.

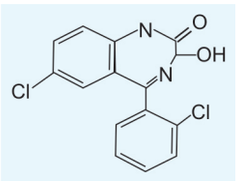

Fig. 14.11: Lorazepam

PHENCYCLIDINE – KETAMINE

Phencyclidine was the first agent among this group of drug. It was first synthesized by Maddox and was introduced in clinical practice by Johnstone in1959. During that period it was a very useful intravenous anaesthetic agent, but had high adverse psychological effect. So, it was withdrawn from the market gradually. Then came the cyclohexamine which was a congener of phencyclidine. It had the same anaesthetic property like phencyclidine, but had less analgesic property and more adverse psyclogical effects. So, it was also abandoned.

Then, ketamine as a derivative of phencyclidine was first synthesisd in 1962 by Stevens and was first used in human being in 1965. However it was released for clinical use in 1970 and is still now the most promising agent among the 200 phencylidine derivatives.

Chemistry

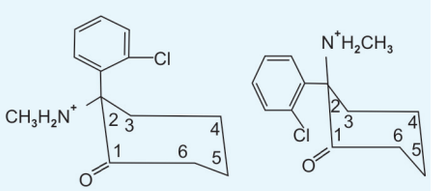
Chemically, ketamine is an aryl-cyclohexylamine compound and is a congener of phencyclidine. It is a partially water soluble white crystaline salt, with pKa value of 7.5. It is highly lipid soluble which is 5 to 10 times greater than that of thiopentone. Ketamine is available commercially as hydrochloride salt (pH 3.5 to 5.5) in concentration of 10 and 50 mg/ml in NaCl solution with benzethenium chloride as preservative. It has two optical isomers and the commercial preparation is a racemic mixture of both the isomer [S (+) and R (−)] in equal amounts, despite the (S) isomer being more potent and having less side effects than the (R) isomer (Fig. 14.12).

Pharmacokinetics

The onset and duration of action of an induction dose of ketamine is also

Table 14.5: Difference in duration of action of diazepam (10 mg) and lorazepam (2 mg)

	Diazepam	*Lorazepam*
Intravenous		
Peak effect	2 - 5 minutes	30 - 40 minute
Duration of sedation	20 - 50 minutes	3 - 6 hours
Amnesia	3 - 30 minutes	½ - 4 hours
Oral		
Onset of action	20 - 40 minutes	40 - 50 minutes
Route differences	Oral more rapid than intramuscular	Intramuscular more rapid than oral



S(+) = Ketamine hydrochloride

R(–) = Ketamine hydrochloride

Fig 14.12: Two stereoisomers of ketamine

determined by the same distribution and redistribution mechanism which is found in other parenteral anaesthetics agents such as thiopentone, propofol, benzodiasepines, etc. Ketamine's pharmacokinetic action have been examined in details after a bolus administration of an anaesthetising (2 to 2.5 mg/Kg), subanaesthetizing (0.25 mg/Kg) and a continuous infusion dose. However regardless of the dose, the ketamine's plasma disappearance can be described by a two compartmental model. The high lipid solubility of ketamine is reflected by its relatively large volume of distribution. The clearance rate of ketamine is also relatively high which accounts for its relatively short elimination half-life of 2 to 3 hours. Ketamine's large volume of distribution and rapid clearance make it suitable for continuous infusion without the drastic lengthening of duration of action, as seen with thiopentone. The protein binding capacity is much lower with ketamine than other parenteral anaesthetic agents. Thus, bolus administration of ketamine results in quick entry of it in CNS and very fast onset of action.

Metabolism

Ketamine is principally metabolised by hepatic microsomal enzyme and the principal metabolic pathway is N-demethylation which form norketamine (metabolite-I). Norketamine is then hydroxylated to hydroxynorketamine (metabolite - II) which is then next conjugated to water soluble glucoronide derivative and excreted through urine and bile. Norketamine is the active metabolites of ketamine and has 20 to 30% activity of its parent compound.

Pharmacodynamics

Effects on CNS

The primary site of action of ketamine is the thalamo-neocortical projection in brain. It depresses the cortex (association area) and thalamus, but simultaneously stimulate the limbic system and hippocampus. Thus, it creates the functional disorganisation between the midbrain, thalamus and cortex.

For ketamine's anaesthetic effect Na^+ channel blockade is not the mechanism of action.But its interaction with the NMDA (N-methyl-O-aspartate) receptor in brain mediate the general anaesthetic and analgesic effect of it. The interaction of ketamine with opioid receptor in brain and spinal cord also account for its analgesic effect. The S (+) enantiomer of ketamine has also been shown to have some opioid μ-receptor activity, accounting for part of its analgesic effect. The inhibition of wide dynamic range (WDR) of neuronal activity in the dorsal horn cells of spinal cord also account for the ketamine's analgesic activity at spinal level.

Cerebral metabolic rate, cerebral O_2 demand, CBF and ICP, etc. are all increased in ketamine anaesthesia. There is also generalised increase in sympathetic nervous system activity due to ketamine and all the above mentioned CNS effect of ketamine is due to this. But thiopentone and BDZ prevent all these responses.

Ketamine produces both dose-related unconsciousness and strong analgesia. During unconsciousness patient remains in cataleptic state, i.e. he is in sleep, but his eyes are opened. So, this anaesthetic state of ketamine is termed as the 'dissociative anaesthesia'. Although ketamine does not produce the classic anaesthetic state, still patients are remained in amnestic and unresponsiveness state to the painful stimuli. Corneal, cough and swallow reflexes are present, but they are not protective. There is amnesia during ketamine anaesthesia but it is less than BDZ. The low molecular weight, pK value near physiological pH and high lipid solubility of ketamine, allow it to cross the blood brain barrier very rapidly. So, the onset of action of ketamine is very rapid which is within 30 sec after IV administration. Lacrimation, salivation, ↑muscletone, purpousless movement of body, dilated pupil, nystagmus, etc. are all very common to ketamine anaesthesia.

The duration of action of 2 mg/Kg IV bolus dose of ketamine is 15 minutes and then full recovery to orientation about the place and time occur within 30 minutes. The plasma level of ketamine of 0.6 to 2 μg/ml is considered as the minimal concentration for GA. The short duration and early termination of effect of ketamine is thought to be due to the redistribution of it from brain (well perfused) to other body tissues (less perfused) like thiopentone and BDZ.

Analgesia due to ketamine occurs considerably at lower blood concentration than GA. This analgesic effect of ketamine also occurs at subanaesthetic dose of 0.25 to 0.5 mg/Kg IV. This analgesia due to ketamine even occurs at plasma level of as low as 0·1 μg/ml.

There are various undesirable psychological reactions during awakening from ketamine anaesthesia which are termed as the emergence reaction or emergence delirium. This emergence delirium of ketamine characterised by hallucination, vivid dreams, or illusions, etc, may sometimes result in serious patient dissatisfaction and can complicate the postoperative management. The incidence of this emergence reaction after ketamine anaesthesia ranges from 5% to 100% and abate within 1st postoperative hour. Though the exact mechanism of this emergence reaction is not known, but it is postulated that the psychic reactions that occur secondary to ketamine anaesthesia during recovery is due to the induced depression of auditory and visual relay nuclei, leading to misperception and /or misinterpretation of auditory and visual stimuli. Many factors affect this emergence reaction of ketamine such as age (less incidence in paediatric group), sex (women are more susceptible than man), dose (larger dose and rapid administration predisposes to higher incidence) and psychological susceptibility of person, etc. BDZs and among them the lorazepam is still the best drug to attenuate this ketamine induced emergence reaction.

The S-enantiomer of ketamine enables quicker recovery than the racemic mixture of

it. This is because lower doses of S-enantiomer is necessary to produce the equianaesthetic effect of the racemic mixture and has 10% faster hepatic clearance rate.

Effects on CVS

Due to increased sympathetic tone during ketamine anaesthesia there is increase in BP, HR, CO, myocardial O_2 consumption and demand. But, this increased myocardial O_2 consumption and demand is fulfilled by ↑CO and ↓ coronary vascular resistance in the normal heart by ketamine, so that the coronary blood flow is appropriate for the increased myocardial O_2 demand and consumption. This hemodynamic change is not related to the dose of ketamine i.e. a very small dose of ketamine also produces the same effect like higher doses. On the other hand, the ketamine induced hemodynamic changes are same in healthy patient and in those with variety of acquired and congenital heart disease (CHD). In patient with CHD, there are no significant changes in direction through shunt after induction with ketamine. Ketamine seems to cause more pronounced increase in PVR than SVR (PVR–pulmonary vascular resistance. SVR – systemic vascular resistance).

Ketamine enhances the sympathetic response by its centrally mediated action. But, the exact mechanism by which ketamine enhances the sympathetic tone is not known. But the probable explanation is that ketamine attenuates the pressure controlling baroreceptor function by effecting the NMDA receptor of the nucleus tractus solitarius of vagus. Directly ketamine is depressent to heart muscle but the centrally mediated sympathetic response of it override this direct response on myocardium. So, the ketamine anaesthesia experiences all the CVS effects which are described above. The sympathetic cardiovascular effects of ketamine are also mediated by the inhibition of both the central and peripheral catecholamine reuptake.

The raised sympathetic response during ketamine anaesthesia can be attenuated in clinical practice by:

i. the use of adrenergic antagonist (both α and β),
ii. the use of vasodilator,
iii. the prior administration of BDZ or thiopentone,
iv. very slow and continuous infusion of ketamine,
v. the use of inhalation anaesthetics.

Effect on RS

The central respiratory drive is minimally affected by ketamine with unaltered response to O_2 and CO_2. But there is transient decrease in minute ventilation due to respiratory depression after a blous dose of it. Seldom, very unusual high dose of ketamine produce apnoea. Usually, O_2 and CO_2 level in blood is maintained at normal level by the conventional dose, if no other sedative is used with ketamine.

By its sympathomimetic action ketamine produces bronchodilatation. In patient with reactive airway disease and bronchospasm, pulmonary compliance is also improved by ketamine. So it is a useful drug to treat the status asthmaticus which is unresponsive to conventional therapy.

Increased salivation caused by ketamine may produce upper airway obstruction and laryngospasm. Although laryngeal, pharyngeal and swallow reflexes are preserved in ketamine anaesthesia, but they are not co-ordinated and not protective. So, there is evidence that silent aspiration can occur during ketamine anaesthesia.

Uses

The poor risk patients with severe cardiovascular and respiratory disorders (except ischaemic heart disease and hypertension) are best suitable for ketamine induction and maintenance of anaesthesia. Hemodynamically compromised patient with hypovolaemia and cardiomyopathy are also the better subject for ketamine anaesthesia, but not the patient suffering from coronary artery disease. Profound analgesia, allowing the use of high inspired O_2 concentration without N_2O and added inhalational anaesthetics and bronchodilatation make the ketamine an excellent agent for induction in asthma patient. However, for extensive trauma or severe septic shock patient, we have to keep in our mind that ketamine has intrinsic myocardial depressant effect and it may be manifested if the sympathetic store is completely depleted in these group of patients before ketamine induction. The cardiac problems which can better be managed by ketamine than thiopentone are temponade, restrictive pericardities, congenital heart disease and especially those in whom the propensity for Right to Left shunt exist. Ketamine is also a very useful drug for patient with the history of potential malignant hyperthermia. It is not arrhythmogenic.

When ketamine is combined with BDZ and fentanyl or sufentanil in continuous infusion, then they attenuate the unwanted tachycardia as well as hypertension caused by ketamine alone and produce very satisfactory condition in cardiac anaesthesia for vulvular disease and IHD. This combination is also associated with minimum hemodynamic changes, perfound analgesia, dependable amnesia, and uneventful convalescence.

Ketamine also can be used for postoperative analgesia in subanaesthetic dose (≤ 1 mg /Kg), when one wishes to avoid narcotics, because of their respiratory depression and when there is also reason to avoid nonsteroidal agents such as ketorolac.

Ketamine is mainly used for short paediatric outdoor procedure, such as cardiac catheterisation, radiation therapy, radiological diagonostic procedure, dressing changes, etc. But, caution is advised during the use of ketamine in patient with elevated PVR. When used as supplementation for regional anaesthesia, ketamine (0.5 mg/Kg IV) combined with diazepam (0.15 mg/Kg IV) is better accepted by patient and not associated with greater side effects as compared with the unsedated patient (Table 14.6).

Table 14.6: Uses and doses of ketamine

Induction of GA	
0.5 - 2 mg/Kg IV	
4 - 6 mg/Kg IM	
3 - 10 mg/Kg oral	
Maintenance of GA	
0.5 - 1 mg/Kg IV (bolus)	With $N_2O + O_2$
10 - 50 µg/Kg/min IV	With $N_2O + O_2$
30-90 µg/Kg/min IV without N_2O	
Sedation and analgesia	
0.2 - 0.8 mg/Kg IV over 3 - 4 minutes	
2 - 4 mg/Kg IM	
10 - 20 µg/Kg/min IV (maintenance)	

Lower doses are used if other drugs such as opioids, BDZ or thiopentone are also given with ketamine.

Doses and Route of Administration

Ketamine can be administered through IV, IM, oral or rectal route. Dose of it depends on the route of adminstration and the desired therapeutic effect. The oral dose of ketamine is 5 to 10 mg/Kg, and the onset of action is 20 to 40 minutes. However the corresponding intravenous dose of it is 1.5 to 2 mg/Kg, administered over a period of 60 seconds. The onset of action of ketamine through IV route occurs within 30 to 60 seconds and the duration of action is 5 to 10 minutes. Through IM route the onset of action of ketamine is about 5 minutes and peak effect is at about 20 minutes. Ketamine may be infused intravenously at the rate of 50 µg/Kg/minute. The drug is also effective when administered extradurally (in an adult the dose is 10 mg) or intrathecally.

Side Effects and Contraindication

The side effects of ketamine are its contraindication for use. These are:

i Intracranial leison, increased ICP, cerebral ischaemia.
ii. IHD due to increased myocardial O_2 consumption and demand.
iii. Open globe injury.
iv. Vascular aneurysm.
v. Psychiatric disease such as schizophrenia.
vi. Eclampsia.
vii. Hypertension.

PROPOFOL

History

In 1970, the extensive search for derivatives of phenol as a substituent of it suddenly resulted in the development of 2, 6, di-isopropyl phenol (commonly named as propofol) which has strong hypnotic properties. Then, the first clinical trial of 2, 6, di-isopropyl phenol as hypnotic in 1977 confirmed the potentiality of it as an anaesthetic inducing agent. Initially, it was prepared in cremophor EL due to its insolubility in water. But, due to the increased incidence of anaphylactoid reaction because of the cremophor EL, the drug was reformulated as an emulsion in soyabean oil and egg white.

Chemistry

Chemically, propofol is a 2, 6-diisopropyl phenol. As it is an alkyl phenol derivative, so it is insoluble in water and remains as liquid oil at room temperature. It is highly lipid soluble. Therefore, the present emulsion formulation of propofol consists of 1% propofol, 10% soyabean oil, 2.25% glycerol and 1.2% purified egg phosphatide, without any preservative. But, disodium EDTA or sodium metabisulfite is added as preservative to inhibit the bacterial growth in USA. Without EDTA or metabisulfite the emulsion preparation of propofol should be used shortly after removal from the sterile packaging. Otherwise, significant bacterial contamination can cause serious infection as there is no preservative. This emulsion preparation of propofol is milky white in appearance and slightly viscous. It is stable at room temperature and is not light sensitive. This emulsion preparation is compatible with 5% dextrose solution.The pH of propofol is 7 and is commercially available as 1% solution (Fig. 14.13).

Pharmacokinetics

Propofol is only available as IV preparation for the induction and/or maintenance of GA. It is also used for conscious

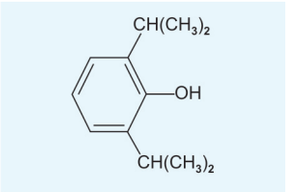


Fig. 14.13: Propofol: It is an alkyl phenol derivative

sedation to deep sedation by continuous IV infusion. The high lipid solubility of it results in an onset of action that is almost as rapid as that of thiopentone. Duration of action after a single equivalent bolus dose of propofol is also similar or even shorter than those of thiopentone. This is due to the rapid decline of plasma concentration of propofol after an IV bolus dose which can be fitted to a typical three compartment model of thiopentone and explain its rapid distribution, redistribution and clearance rate (elimination).

The initial volume of distribution of propofol is 20 to 40 litres and the initial distribution half-life of it is 2 to 8 minutes. Following an IV bolus dose of propofol, the plasma level initially declines rapidly due to redistribution from highly perfused but lower capacity tissue such as brain, heart, etc, to high capacity but lower perfusion sites such as muscle, liver, spleen etc. This initial clearance of propofol from the central compartment by redistribution is rapid (3 to 4 litre/Kg/minute) and is responsible for quick awakening and less hangover from single bolus dose of it. Thus this makes it a better agent for outpatient anaesthesia than the thiopentone and methohexitone (Fig. 14.14).

Propofol's pharmacokinetics may be altered by a variety of factors such as age, gender, weight, other medications, preexisting diseases, etc. A lower induction dose is recommended in elderly patients. This is because of their smaller initial volume of distribution. Women may require a higher dose of propofol than men and appear to awaken faster due to higher volume of distribution. Recovery after multiple doses or infusion of propofol is

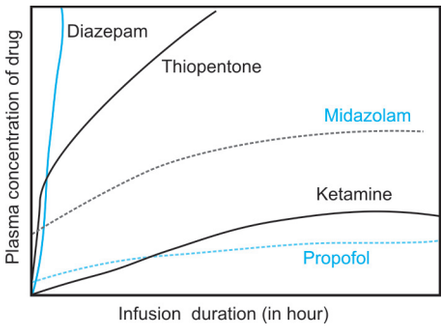

Fig. 14.14: The context sensitive half time or CSHT is the time for the plasma level of the drug to drop 50% after cessation of infusion. This figure shows context sensitive half-time (CSHT) for diazepam, thiopentone, midazolam, ketamine and propofol. The duration of infusion is plotted on the horizontal axis and the drop of plasma level is plotted along the vertical axis. The figure shows that the rapidity with which the drug level in plasma drops is directly related to the properties of that drug and the time of infusion. The longer the drug is infused, the longer is the half-time. It is also noted that the propofol and ketamine have significantly shorter context sensitive half-time (CSHT) than diazepam and thiopentone. So, this makes them suitable for prolonged infusion. The position of midazolam lies between diazepam, thiopentone and ketamine, propofol

much faster than thiopentone. This can be explained by its very high metabolic clearance rate in liver which is about 1.5 to 2.5 litre/minute and 10 times higher than that of thiopentone. This high metabolic clearance rate of propofol exceeds the hepatic blood flow. This also implies the existence of some extrahepatic metabolic clearance site of propofol which is still unknown. But, the lung does not take part as extrahepatic metabolic site of propofol. In liver, propofol is metabolised by conjugation to water soluble glucuronide and sulphates, which are excreted through bile and kidney. Metabolites of propofol are not active one. Although metabolites of propofol are primarily excreted through the urine, but the chronic renal failure does not affect the clearance of the parent drug. The pharmacokinetic of propofol do not appear to be affected by moderate cirrhosis. Use of propofol infusion for long term sedation in children who are critically ill has been associated with cases of lipedemia, metabolic acidosis and death.

Pharmacodynamics

Effect on CNS

The primary action of propofol are hypnosis and sedation, but the exact mechanism of these actions are not known. Probably it acts by enhancing the function of GABA activated chloride channel like benzodiazepine and thiopentone (Table 14.7).

But unlike thiopentone, propofol is not antianlgesic. The onset of hypnosis following IV administration of propofol in the doses of 2.5 mg/Kg is 30 sec (though it depends on the speed of injection) and duration of action (though dose dependent) is 10 to 15 minutes. The onset and duration of action of propofol also depends on the type and dose of premedication. Propofol can also be used in subanaesthetic or subhypnotic dose. Subhypnotic dose of propofol will only produce conscious sedation and amnesia, but no hypnosis or anaesthesia. The infusion of propofol in the dose of 2 mg/Kg/hr is necessary to provide amnesia in unstimulated patients. But, during surgery, higher infusion rate is necessary to prevent the awareness, if propofol is used alone.

The effect of propofol on epileptogenic activity is in controversy. Because the results from studies on the anticonvulsant effects of it are mixed. The propofol induced convulsion is very rare. The EEG amplitude increases when the propofol blood concentration varies between 3 to 8 µg/ml. But when the propofol concentration in blood rises above 8 µg/ml, then the amplitude of EEG decreases rather than increases and there is burst supression. The induction of GA by propofol is occasionally accompanied by excitatory phenomenon such as muscle twitching, spontaneous movement, opisthotonus or hiccup, etc. This is possibly due to the subcortical inhibitory glycine antagonism by propofol. Although these reactions may occasionally mimic tonic-clonic seizure, but actually propofol appears to have predominantly anticonvulsant properties. So, propofol can be successfully used to terminate the status epilepticus and may be safely administered in epileptic patients.

Propofol decreases ICP (30 to 50%) in both normal and in patient with already raised ICP. However, this decrease in ICP is also associated with decrease in cerebral perfusion pressure, both in normal and elevated ICP patient and therefore may not be beneficial. This is due to the much reduction of systemic blood pressure in comparison to the reduction of ICP. So, steps should be taken to support the mean arterial pressure and to elevate the cerebral perfusion pressure (>50 mm of Hg). Propofol also provides cerebral protective effects following ischaemic injury like thiopentone. It also acutely reduces IOP (Intra Ocular Pressure) by 30 to 40% and a small second dose is more effective in preventing the rise of IOP secondary to succinylcholine or ET tube intubation.

The propofol blood concentration (Cp_{50}) needed for loss of response to verbal

Table 14.7: Uses and doses of commonly used drugs for sedation and induction of anaesthesia

Thiopentone (2.5%)	Sedation	IV	0.5 - 1.5 mg/Kg
	Induction	IV	4 - 5 mg/Kg
Propofol (1%)	Sedation (infusion)	IV	25 - 100 µg/Kg/min
	Induction	IV	1 - 2 mg/Kg
	Maintenance	IV	50 - 200 µg/Kg/min
Ketamine	Induction	IV	1 - 2 mg/Kg
Methohexital (1%)	Sedation	IV	0.2 - 0.4 mg/Kg
	Induction	IV	1 - 2 mg/Kg
		Rectal (10%)	25 mg

command is 3.5 µg/ml and to skin incision is 16 µg/ml (propofol alone without narcotics, inhalational agents etc). This propofol Cp_{50} value for skin incision comes down to 2.5 µg/ml, when it is combined with BDZ (as premedication) and 66% N_2O. This value again comes down to 1.7 µg/ml, if narcotic is used in place of BDZ. Awakening from induction usually occurs when the blood concentration of propofol comes down to or below 1.6 µg/ml and orientation comes back when the plasma concentration comes down to 1.2 µg/ml.

Effects on CVS

Prpopofol produces a dose dependent decrease in blood pressure which is significantly greater than that produced by thiopentone. Prpopofol has both the vasodilation (venous and arterial) and myocardial depression effects. This appears to be due to the reduction in sympathetic tone and also due to the direct negative effect on the intracellular Ca^{2+} mobilisation in smooth muscle. Thus, there is decrease in the vascular smooth muscle tone and reduction in preload and afterload. As a result, there is decrease in systolic blood pressure, diastolic blood pressure, and systemic vascular resistance (due to vasodialtion). However, the changes in cardiac output, stroke volume, cardiac index produced by propofol depend on the changes in preload, afterload and SVR. Pulmonary artery pressure and pulmonary wedge pressure are also reduced by propofol.

The HR dose not change significantly with the reduction of BP after an induction dose of propofol. This suggest that propofol either reset or inhibits the baroreflex and thus reduces the tachycardia response to hypotension. Changes in HR and CO are usually transient and insignificant in healthy patients. But, it may be severe enough and lead to asystole, particularly in patients who are at the extreme of age, on negative chronotropic medications, undergoing surgical procedures, associated with ocular cardiac reflex, etc.

When patient is allowed to breath air or air plus O_2 and hypnosis is maintained only by propofol infusion in the dose 50 to100 µg/Kg/min, then SVR, BP, CO, CI are reduced. But, when the same patient is intubated and hypnosis is maintained by N_2O and propofol infusion of same dose, then SVR and BP does not reduce, but CO and CI falls. This is due to the presence of N_2O or surgical stimulus. So, intraoperative BP can not be reduced in intubated hypertensive patient by propofol only.

Infusion of propofol results in significant reduction in both myocardial blood flow and myocardial O_2 consumption. But the global O_2 supply/demand ratio is preserved.

Though the reduction of BP (due to vasodilation) and myocardial depression effect of propofol is blood concentration dependent, but the decrease in BP from propofol during infusion is much less than that seen following an induction bolus dose.

Effects on respiratory system

Propofol's effects on respiratory system is similar to that of barbiturates. So, like barbiturates it depresses the respiration and may produce apnoea. The onset, duration and incidence of apnoea due to propofol depends on the dose, speed of injection and the concomitant use of premedication. The incidence of propofol induced apnoea is greater than any other IV inducing agents and is preceded by marked reduction in tidal volume (40% decrease) and respiratory rate (20% decrease). So, there is unpredictable change in minute ventilation (decreased or increased).

During infusion of propofol the respiratory rate gradually decreases. Then, when the respiratory rate is fixed at lower level and still if concentration of infusion is gradually increased, then there is gradual decrease in tidal volume, but no change in respiratory rate. This is followed by apnoea. Propofol infusion inhibits hypoxic ventilatory drive. Ventilatory response to CO_2 is also decreased. Propofol induces bronchodilatation in patient with chronic obstructive pulmonary disease, although it can cause histamine release. So induction with propofol is sometimes accompanied by a lower incidence of wheezing in asthamatic and nonasthamatic patients, compared to barbiturates and is not contraindicated in asthmatic patients. The propofol induced depression of upper airway reflexes exceeds than that of thiopentone and can prove helpful during intubation or LMA placement in the absence of muscular paralysis by muscle relaxant.

Miscellaneous effects

Like thiopentone, propofol does not potentiate the neuromuscular blockade, produced by muscle relaxant. Propofol does not tigger the malignant hyperpyrexia and so is the anaesthetic of choice in such condition. It does not affect the corticosteroid synthesis or alter the normal response to ACTH stimulation. The incidence of anaphylactoid reaction, following propofol has been reported at about the same low frequency as does the thiopentone. But high percentage of patient who develops anaphylactoid reaction to propofol have the previous history of allergic response. So, the propofol should be used cautiously to the patient who will give the history of multiple drug allergies. It has significant antiemetic property and is a good choice for sedation or anaesthesia in patient who have high risk for nausea and vomiting. Sometimes, postoperative nausea can be treated sucessfully by IV bolus dose of 10 mg propofol. Although, propofol does cross the placental barrier, still it is considered safe for the use in pregnant patient and transiently depresses the activity of newborn as thiopentone (Table 14.8).

Doses

Premedication of patient with opiate and /or BDZ markedly reduces the induction and maintenance dose of propofol. Age also reduces the dose of propofol with or

Table 14.8: Uses and doses of propofol

Induction of general anaesthesia:
1 - 2.5 mg/Kg IV, reduced in patients over 60 years of age
Maintenance of general anaesthesia:
50 - 150 µg/Kg/min IV, reduced if combined with N2O, BDZ or an opiate
Sedation:
20 - 50 µg/Kg/min IV

without premedication. It can also be used successfully for patient controlled sedation (PCS) like patient controlled analgesia (PCA). But in this respect it is better than midazolam and it is due to its rapid onset and offset action. Propofol by its continuous infusion provides a readily titratable level of sedation and rapid recovery once infusion is terminated, irrespective of the duration of infusion.

DROPERIDOL

History

In 1950, Laborit and Hugnenard thought of a new anaesthetic technique which will produce a state of 'artificial hibernation or neurolept'. This new anaesthetic technique was without the need of muscular paralysis and was devoid of CVS and respiratory depression effect. Their concept regarding this technique was to block centrally the autonomic, endocrine and other centres which normally are activated in response to stress during surgery. This central block can be performed selectively by drugs which will produce artificial hibernation, in contrast to the entire depression of CNS which causes general anaesthesia. The first drug which was evolved for this purpose and was used in this concept was 'lytic cocktail'. It was a mixture of meperidine (analgesic), chlorpromazine or promethazine (tranquiliser) and atropine (antisialagogue). It can produce conscious sedation, but not the full GA.

Then, Janssen first synthesised haloperidol (which was the 1st member of butyrophenones group of drugs and the primary neuroleptic component of neuroleptic anaesthesia – NLAN) and phenoperidine (which is the meperidine derivatives). After that in 1959, DeCastro and Mundeleer combined these and used them as a forerunner of NLAN. Then, Janssen synthesised droperidol (a derivative of haloperidol) and fentanyl (phenoperidine congener). So, DeCastro and Mundeleer again used their combination and reported these to be superior than previous combination. Now, droperidol and fentanyl are the currently used combination for neuroleptic anaesthesia (NLAN).

The term 'neuroleptic' is synonymus with the term 'antipsychotic'. Initially this 'neuroleptic' term was used to denote the effect of chlorpromazine and reserpine which reduce the intiative and interest of patient for the external enviornment and as well as decrease the manifestation of emotions. This term 'neuroleptic' is still used now as a synonym for antipsychotic effect. But the more general term 'antipsychotic' is preferred now a days than neuroleptic. Despite their sedation effects, neuroleptic drugs generally are not used to treat anxiety disorders. This is largely because of their autonomic and neurological side effects, which paradoxically include severe anxiety and restlessness.

Mechanism of Action

Like all the antipsychotic drugs, droperidol acts by its potent dopamine D_2 receptor blocking action. Blockade of the dopaminergic projection to the temporal, prefrontal (constituting the limbic system) and mesocortical areas is probably responsible for the antipsychotic action of droperidol. Because dopamine overactivity at limbic system is responsible for the psychiatric condition. Dopaminergic blockade in the basal ganglia also appears to cause the extrapyramidal symptoms of droperidol while that in CTZ is responsible for the antiemetic action of it.

Droperidol like other antipsychiatric drugs also have the α-adrenergic blocking action, weak H_1-antihistamine action and anti-5-HT action.

Pharmacokinetics

The clearance rate of droperidol is 14 ml/kg/min and elimination half-life is 103 to 134 minutes, which indicates its short duration of action. The time course of disappearance of fentanyl and droperidol from plasma is same.

Pharmacodynamics

Effects on CNS

The effects of droperidol on CNS differ in normal and psychotic individuals. In normal individuals it produces indifferences to the surroundings, paucity of thought, psychomotor slowing, emotional quietening, reduction in initiative and tendency to go to sleep from which the subject is easily arousable. The spontaneous movements are minimized, but the slurring of speech, ataxia or motor in coordination does not occur. These have been referred to as the 'neuroleptic syndrome'. Now, there is tendency to use the term 'neuroleptic' to emphasize the more neurological aspects of this syndrome. The neuroleptic agents also have the characteristic neurological effcts including bradykinesia, mild rigidity, tremor and restlessness that resemble Parkinson's disease and is quite different from the sedative action of barbiturates and other similar drugs. These effects are appreciated as unpleasant by most of the normal individuals.

On the otherhand, in psychotic individuals it reduces the irrational behaviour, agitation, aggresiveness and controls the psychotic symptomatology. The disturbed thought and behaviour are gradually normalised and anxiety is relieved. Hyperactivity, hallucinations and delusions are supressed.

It potentiates the action of hypnotics, opioids etc. Performances and intelligence of an individual are relatively unaffected, but vigilance is impaired by droperidol. The medullary respiratory centre and other vital

centres are not affected. It has profound antiemetic action, exerted through CTZ.

Effects on CVS

Droperidol has vasodilating properties and decrease BP. This is due to the α-adrenergic blocking action of it. Directly, it has no action on myocardial contraction. But, it possesses some antiarrhythmic properties like quindine.

Effects on RS

Droperidol has very little effect on RS. So, no significant effect on respiratory rate and tidal volume is found.

Use

Droperidol is used as a component of NLAN. It is also used as antiemetic in the dose of 10 to 20 µg/Kg through IM or IV route. It reduces the incidence of nausea and vomiting upto 50% (Table 14.9).

Droperidol and Fentanyl Combination

In clinical practice of neuroleptic anaesthesia (NLAN), the droperidol and fentanyl combination is used in the ratio of 50:1 (droperidol 2.5 mg/ml and fentanyl 50 µg/ml). In this combination the droperidol produces the hypnotic, sedative and antiemetic effect, while the fentanyl produces the analgesic effect. The action of these two components in their combination are simply additive, but not synergistic. Consciousness returns after NLAN very promptly within 3 to 5 minutes.

Table 14.9: Uses and doses of combination of droperidol and fentanyl in the ratio of 50:1 (droperidol 2.5 mg/ml and fentanyl 50 µg/ml)

Induction of general anaesthesia:
0.1 to 0.15 ml/Kg with N_2O and O_2
Maintenance of general anaesthesia:
Fentanyl 0.02 - 0.05 µg/Kg/min
Sedation and analgesia:
0.5 - 1 ml IV repeated according to the desired effect
1 - 2 ml IM

Due to the presence of fentanyl, this combination produce respiratory depression. This respiratory depression can be antagonised by the administration of a narcotic antagonist. This combination also produce ↓ BP (droperidol effect) and ↓ HR (fentanyl effect – fentanyl induced increased vagal tone). However, there is no reduction in CO, if adequate blood volume is maintained. The combination of droperidol and fentanyl, used as NLAN (neurolept anaesthesia) is very helpful for short outdoor surgeries, diagnostic procedures, sedation during local anaesthesia or conduction anaesthesia. This combination can also be used as inducing agent in GA, performed by N_2O and muscle relaxant in the dose of 0.1 to 0.15 ml/Kg. The components of NLAN can be given separately or as a mixture. When given separately, then droperidol should be given first in the dose of 5 to 10 mg (5 to 15 µg/Kg). This is followed by incremental doses of fentanyl which varies between 50 to 100 µg. These drugs should be used with caution for the possibility of vasodilatation and hypotension. So a test dose of 1 to 2 ml is always recommended before the bolus induction dose. It is also recommended to give 200 to 300 ml of balanced salt solution and correct hypotension prior to induction. The customery dose of this combination for sedation is about 2 to 4 ml in divided doses, titrated to the desired level of sedation. It is very helpful for surgery which are associated with high incidence of post operative nausea and vomiting.

NLAN have several adverse effects such as:

i. *Muscle rigidity:* This is due to the fentanyl which can be treated by muscle relaxant.
ii. *Respiratory depression:* This is due to fentanyl which can be treated by opioids antagonist. But this may reverse the analgesic effect of opiate and precipitate hypertension.
iii. *Hypotension:* This is due to droperidol which can be treated by IV fluid and or α-adrenergic agonist.
iv. *Prolonged somnolence:* This is due to droperidol which is dose related and is reversed by physostigmine (2 mg). Physostigmine is not the specific antagonist of droperidol. Physostigmine clearance is rapid than droperidol, so resedation can occur.
v. *Extrapyramidal symptom:* It is manifested by dyskinesia of face and neck with speech and swallowing difficulties. It is due to droperidol which can be treated by diphenhydramine or benztropine.
vi. Psychological reactions sometimes occur, when used as premedicant and manifested as patient refuses to have surgery.
vii. *Hallucination,* e.g. weightlessness, loss of body image. (viii). Rare complication such as malignant–neuroleptic syndrome.

FLUMAZENIL (Fig. 14.15)

Flumazenil (imidazobenzodiazepine) was first synthesised in 1979 as BDZ – receptor antagonist or blocker. The benzodiazepine agonists have both the affinity for binding with the receptor and ability to produce maximal intrinsic activity such as hypnosis, sedation and amnesia. On the otherhand the antagonists have the same affinity to receptor for binding, but have no ability to produce any intrinsic activity. They just only block the physiological effects of agonist, inverse agonist and other molecules by preventing them to bind with the BDZ receptor. Inverse agonists have also affinity to receptor and have intrinsic activity which are opposite to the physiological effect of agonist. Partial agonists have affinity to receptor and produce submaximal intrinsic activity in the same direction as agonist.

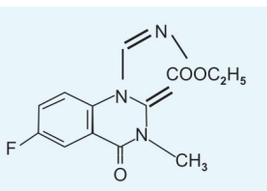

Fig 14.15: Flumazenil

Partial inverse agonists have affinity to receptor and produce submaximal intrinsic activity in the opposite direction to agonist. As flumazenil is the BDZ-receptor antagonist, its structure is similar to that of classical BDZ, except a phenyl group which is replaced by carbonyl group and blocks all the activities of BZDs and its inverse agonists. It was released for clinical use in 1991 (Fig. 14.16).

Flumazenil is a BDZ analogue and forms a complex with BDZ receptor with high affinity, great specificity and block all the effects of benzodiazepine agonist and inverse agonist with the minimal or none intrinsic activity. So, both the electrophysiological and behavioral effects of BDZ (agonist) and DMCM (inverse agonists) are blocked. Hence, it blocks both the depressant effect of BDZ and as well as the stimulant effect of DMCM. The DMCM has stimulant effect, because it is inverse agonist of BDZ receptor. So it produces all the oposite effects of BDZ. It replaces the BDZ agonists at the receptor level in a competitive (competitive antagonist) and concentration dependent manner. Flumazenil like other competitive antagonist does not displace the agonist from the receptor which is already attached. But, rather it occupies the receptor when an agonist dissociates from it and prevents the agonist from further attachment with the receptor. The half-life of a bond between a receptor and antagonist is few seconds and new bonds are then immediately formed. So, it is a dynamic situation where agonist and antagonist continuously compete with each other to occupy the receptor. The proportion of the receptor occupancy by agonist and antagonist obeys the law of mass action, and depends on the affinitly and concentration of the agonists and antagonists. As flumazenil (antagonist) is cleared from the plasma relatively rapidly, so, though it has high affinity to the receptor, the chance of the receptor reoccupied by agonist will increase and the potential for resedation will exist. Low dose of flumazenil in presence of high doses of agonist will only attenuate the deep CNS depression of agonist (unconsciousness and respiratory depression), but without attenuating other agonistic effects which occur at lesser receptor occupancy (drowsiness, amnesia). On the contrary, only the high doses of flumazenil in the presence of low doses of agonist will completely reverse all the effects of BDZ and can precipitate withdrawl symptoms in dependent patient.

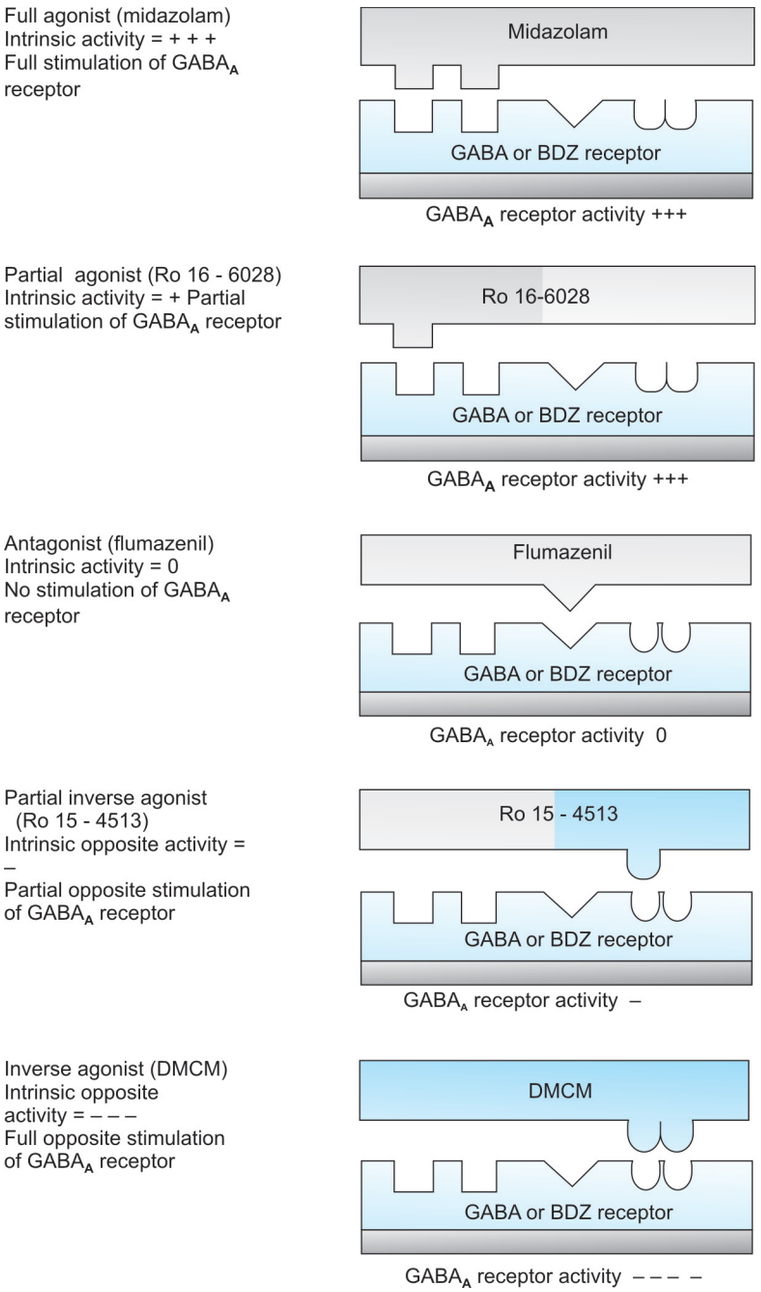

Fig. 14.16: GABA$_A$ receptor activity

Pharmacokinetics

In comparison with BDZ receptor agonists, flumazenil has highest clearance and shortest elimination half-life. The plasma half-life of flumazenil is only 1 hour. This shorter

half-life of it causes the potential risk of resedation due to the still presence of agonist in plasma. So, to avoid this draw back and to maintain a constant therapeutic blood level of antagonist, repeated administration or continuous infusion of flumazenil is required in the rate of 30 to 60 mg/min or 0.5 to 1 µg/Kg/min. Although, it is rapidly absorbed after oral administration, but less than 25% of the drug reaches the systemic circulation as a result of extensive first pass hepatic metabolism or clearance (Fig. 14.17).

Pharmacology

When flumazenil is given alone in the absence of any BDZ, then its intrinsic effects on BDZ receptor are difficult to observe or nil. As previously described, the flumazenil acts by replacing the BDZs from its receptor, so its onset and duration of action are governed by the law of mass action. Onset of action of flumazenil is very rapid and the peak effect reaches within 1 to 3 minutes. It rapidly reverses the unconsciousness, respiratory depression, sedation, amnesia and psycomotor dysfunction produced by the benzodiazepines according to the dose. It has no effect on EEG, cerebral metabolism and has no anticonvulsant properties. But, it reverses the anticonvulsant properties of BDZ. Higher dose of flumazenil is required to reverse the effects of lorazepam than diazepam and this is because of the greater potency of former. The duration of action of flumazenil is determined by its dose, the dose of agonist and the type of agonist. Usually the duration of action of flumazenil is 45 to 90 minutes, after a dose of 3 mg IV. Flumazenil will not reverse the opioid induced respiratory depression. It is completely devoids of cardio vascular effects.

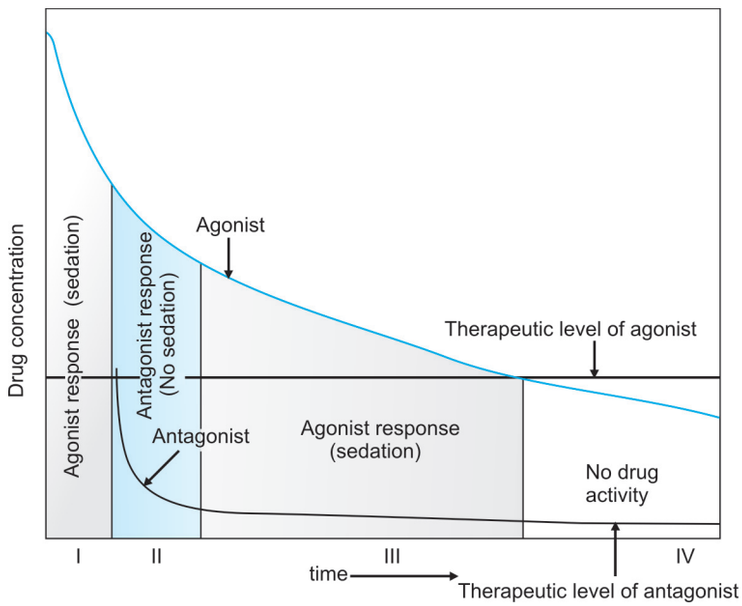

Fig. 14.17: The interaction of duration of action between the short acting antagonist and long acting agonist, causing resedation. The above red curve shows the gradual disappearance of agonist from the blood. The below green curve shows the disappearance of antagonist from blood. This agonist - antagonist interaction is represented by four condition:

I = Full agonistic response or sedation. In this phase antagonist is not administered.

II = Full antagonistic response or awake from sedation. In this phase antagonist is administered and the plasma level of both the agonist and antagonist is above their respective therapeutic level. Patient awake from sedation because antagonist completely block the action of agonist.

III Re-agonist response = resedation. This is because the plasma level of antagonist goes below its therapeutic level, but the plasma level of agonist still remains above its therapeutic level.

IV = No drug effect, with disappearance of both the action of agonist and antagonist. This is because plasma level of both the drugs goes below their respective therapeutic level

Metabolism

Like BDZs, flumazenil is also rapidly taken by the liver from plasma and is metabolised to N-desmethyl flumazenil, N-desmethyl-flumazenil acid and flumazenil acid which are later conjugated to glucoronids and excreted through bile and urine.

Use and Dose

Flumazenil is successfully used to reverse the effect of sedation, respiratory depression and amnesia produced by BDZs during the practice of anaesthesia. The dose of flumazenil varies with the particular BDZ being reversed. The duration of reversal is dependant on both the kinetics of agonist (benzodiazepine) and antagonist (flumazenil). To prevent resedation caused by longer acting BDZs, flumazenil may be administered by continuous infusion. The useful dose of flumazenil is 0.1 to 0.2 mg which is repeated upto total 1 to 3 mg over 1 to 3 minutes. This dose is usually sufficient to abolish the effects of therapeutic doses of benzodiazepines. However, the administration of series of small doses of flumazenil is preferred to a single bolus injection of it.

For diagnostic purpose, the flumazenil may be given in incremental doses of 0.2 to 0.5 mg IV upto 3 mg over 2-10 minutes. If there is no change in sedation, it is unlikely that CNS depression is based solely on BDZ overdose.

Flumazenil is not effective in the treatment of drug overdose by either barbiturates or tricyclic antidepressants. To the contrary, under such circumstances the administration of flumazenil may be associated with the seizures. The risk of seizures is especially high in patients, poisoned with tricyclic antidepressants.

OPIOIDS

History

Opium has been known to mankind for many centuries. It was first mentioned in Eber's papyrus (1500 BC) and in the writing of Theophrastus (300 BC) and Galen

(2nd century AD). On the otherhand, crude opium was available in Asia from two millennium ago before the discovery of modern anaesthesia. It was used throughout the middle ages in Europe as the preparation, named 'laudanum'. Crude opium is a dark brown and resinous material which is obtained from poppy (papaver somniferum) capsule. It contains two types of alkaloids: (i) alkaloid of phenanthrene derivatives–morphine (10%), codeine (5%), thebaine (0.2%), and (ii) alkaloid of benzoisoquinoline derivatives – papaverine (1%), noscapine (6%). Papaverine is devoid of opiate activity, but causes smooth muscle relaxation. Papaveretum is a preparation of crude opium containing the water soluble alkaloids of opium with 50% anhydrous morphine and the remaining 50% is a mixture of papaverine, codeine and thebaine.

Opium eating was a social custom in china. Before 1840, oral opium was the mainstay of analgesia. The first step of success in the introduction of opioids in anaesthesia was the isolation of morphine from opium by Seturner in 1803. It was named 'morphine' after the name of a Greek god of dreams named 'Morpheus'. It was first given hypodermically, using a vaccination lancet in 1836. Then, introduction of syringe and hollow needle in clinical practice by wood in 1853 finally permitted the opioids to be administered in a more precisely measured doses.

Morphin was frequently injected at that time intramuscularly as premedication or as a supplement during the ether and chloroform anaesthesia or as post-operative analgesia. Then in late nineteenth century, high dose of morphine (3 mg/Kg) with scopolamine was used as a complete anaesthetic agent. After that though this technique initially gain popularity, but rapidly fell into disfavour for its high perioperative morbidity and mortality. So, for the next 30 to 40 years anaesthesiologist never used opioid. Later, introduction of thiopentone as IV anaesthetic agent and introduction of concept of balanced anaesthesia led the renewed enthusiasm for the intraoperative use of opioids.

Diamorphine (heroine) was the first synthetic opioid which was synthesised in laboratory, in 1875, and marked the first chemical manipulation of natural opioids for the production of analgesia. Then, papaveretum was prepared, in 1909, as a pharmaceutically standardised preparation of crude opium. It was one of the first opiates to become available as solutions in ampoules.

The next important step in the history of opioid was the development of a completely synthetic opioid, named pethidine in 1939 (meperidine) in Germany. Later, during the World War II methadone was also developed in Germany and was originally named as 'dolfine' in the honour of Adolf Hitler. Then, fentanyl and alfentanyl was produced in 1962. Sufentanil followed soon after this.

Opioid receptors which are peptide in nature were also first discovered in 1979. The term opioid or opiate (which came from the term opium) is used to describe the drugs or chemical compounds that specifically bind to any of the several subtypes of opioid receptor and share the same pharmacological properties of the naturally occurring endogenous opioids. But the term 'narcotic' include the non-opioid compounds also.

Terminology

The word 'opium' is derived from the term 'opos'. This is a Greek word which means juice. So, the opium means drugs which are obtained from the juice of poppy capsule. The term 'opioid' refers broadly to all the compounds which are related to opium. So the 'Opiates' are drugs that derived from opium. The term 'narcotic' is derived from Greek word for sturpor. At one time the term 'narcotic' was referred to any drug that induced sleep and then it became associated with opioids. But now it is often used in legal context to refer the varieties of substances which have abuse or addictive potential (Table 14.10).

Classification

Opioids are usually classified into two groups according to their availability and mode of action.

A. According to their availability

1. *Naturally occurring*

Morphine, Codeine, Papaverine, Thebaine.

2. Semisynthetic

Codeine, heroin, dihydromorphone, thebaine derivative (etorphine, buprenorphine) The semisynthetic products of opioids are obtained from morphine by the following several changes:

i. Esterification of one hydroxyl group of morphine results in codeine (methyl morphine).
ii. Esterification of both the hydroxyl group of morphine results in heroin, (it is diacetylmorphine, made from morphine by acetylation at 3 and 6 position).
iii. Reduction of double bond in the benzene ring of morphine results in hydromorphone.
iv. Thebaine differs from morphine in that both the hydroxyl group of it are methylated and the ring has two double bond. It is an inactive opium derivatives. It is precursor of several clinically used compound such as oxymorphone, oxycodone, naloxone. Etorphine which is a thebaine derivatives, is thousand times more potent than morphine and is used for immobilization and anaesthesia in wild life management (Fig 14.18).

3. Synthetic

i. Morphinan series: Levorphanol, butorphanol.
ii. Diphenylpropylamine series: Methadone.
iii. Benzomorphinan series: Pentazocine.
iv. Phenylpiperidine series: Meperidine, fentanyl, sufentanil, alfentanil.
v. Many of these synthetic opioids are used experimentally for analgesia and

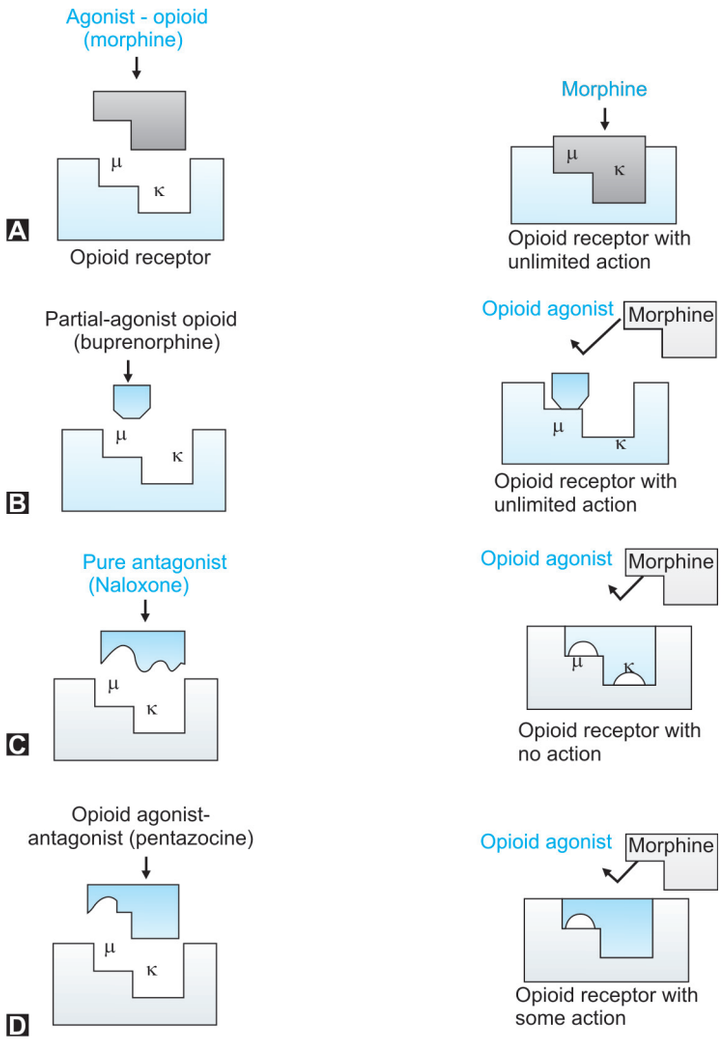

Fig. 14.18A to D: Opioid receptor interactions with agonist, partial agonist, mixed agonist and antagonist and antagoinst at two receptor sites - μ (mu) and κ (kappa).

A. Shows that an pure opioid agonist stimulates both the μ and κ receptor and analgesic action is unlimited.

B. Shows that a partial opioid agonist only combine with the μ-receptor with limited analgesic activity. κ-site remains unoccupied. It also prevents morphine to act.

C. Shows that an opioid antagonist occupies both the μ and κ receptor and prevents the agonist to attach with the receptor. But it has no intrinsic activity.

D. Shows the action of agonist - antagonist opioid which has mixed effect on μ and κ receptor. Analgesia is κ receptor related, while blockade occurs at the μ receptors

anaesthesia. But, only the morphinan, benzomorphinan and phenylpiperidine series are used clinically and play an important role in anaesthesia.

B. According to their mode of action on opioid receptor

i. *Agonist:* Produce full physiological effect in a dose dependent manner, acts on all types of opioid receptors and not blocks (antagonist) any, e.g. morphine, pethidine (meperidine), fentanyl and its congeners.

ii. *Partial or weak agonist:* They does not act on all the types of opioid receptors and thus cannot produce the full spectrum or magnitude of effects, regardless of the dose e.g. buprenorphine, butorphanol.

iii. *Mixed agonist and antagonist:* They acts as an agonist at one type of opioid receptor and as an antagonist (block) at another type of receptor, e.g. pentazocine, nalbuphine.

iv. *Antagonist:* They acts competitively to displace the agonist from the receptor by attaching with it. While it attaches with receptor, elicites no or little effect on its own at clinical dose (intrinsic effect) e.g. nalxone, naltrexone.

Table 14.11: Location of μ and δ receptors

μ receptor	*δ receptor*	*μ and δ*
Cortex (laminae I, IV)	Cortex (laminae II, III, V)	Cortex (lamina IV)
Thalamus	Amygdala	Nucleus ambiguous
Hypothalamus	Olfactory tubercle	Nucleus tractus solitarius
Corpus striatum	Corpus striatum	Vagal fibres
Periaqueductal gray mater	Nucleus accubens	Trigeminal nucleus
Hippocampus	Pontine nuclei	Substantia gelatinosa of spinal cord
Colliculus (Sup and inf)		
Interpeduncular nucleus		
Midbrain		

Opioid Receptor

In 1973, opioid receptors were first conceptualised from the hypothesis that all the opioids act on some macromolecules of the cell membrane which is protein in nature and modulates the pain, mood, hedonic (pleasure related) behaviour, motor behaviour, emeris, pituitary hormone release, GIT motility, etc. But, later this hypothesis was confirmed and these macromolecules were described as opium receptor.

Morphine and other opioids exerts their action by interacting with these opioid receptors. Radio-ligand binding studies have divided these opioid receptor into three types; μ (mu), κ (kappa) and δ (delta) and each has a specific pharmacological profile. However, they also have a distinct pattern of anatomical distribution in brain, spinal cord and peripheral tissues. Three subtypes of each receptor have also been proposed, but have not yet been cloned (Table 14.11).

μ (morphine or mu) receptor

This receptor is named after the drug morphine which is used in the study of this receptor. These μ-opioid receptor manifests high affinity for morphine, pethidine, fentanyl and its congeners. On the other hand, other opioid peptides such as β-endorphin, enkephalins and dynorphins also bind to the μ receptor but with lower affinity. These μ receptors are located both in the brain and spinal cord with highest concentration at the periaqueductal gray region, thalamus, nucleus tractus solitarious, nucleus ambiguous and substantia gelatinosa. Stimulation of these μ-receptors cause analgesia, respiratory depression, euphoria, miosis, reduced G1 motility, physical dependence, etc. The two subtypes of μ receptor have been described. These are μ_1 and μ_2 . Among these the μ_1 has more affinity for morphine. It mediates supraspinal analgesia and is selectively blocked by naloxonazine. Whereas the μ_2 receptor has lower affinity for morphine. It mediates spinal analgesia, respiratory depression and constipation.

κ (Ketocyclazocine or kappa) receptor

This receptor is named for its high affinity for keto cyclazocine drug which is used for the study of this receptor. Activation of κ-receptor causes mild to moderate analgesia, ceiling respiratory depression, dysphoria, hallucination, miosis, sedation, physical dependence, etc. Two subtypes of κ receptor, such as κ_1 and κ_3 are functionally important. Analgesia caused by κ agonists is primarily spinal and acts though κ_1 receptor. However, κ_3 receptors mediate supraspinal analgesia and is of lower ceiling character (Table 14.12).

δ (Delta) receptor

This receptor has high affinity for enkephalins and is present both in the spinal cord (dorsal horn) and brain (limbic area). Activation of this receptor causes analgesia, respiratory depression, affective

Table 14.12: Nature of interactions of opioid ligands on the three major types of opioid receptors

Opioids	*μ (mu)*	*κ (kappa)*	*δ (delta)*

behaviour, reduced GI motility etc. The δ mediated analgesia is mainly spinal (as δ receptors are present mainly in dorsal horn of spinal cord), but the affective component of supraspinal analgesia appears to involve the δ receptor present in the limbic areas. They are also responsible for dependence. The proconvulsant action is more prominent in δ receptor agonists. Myenteric plexus neurones express high density of δ-receptor which mediate reduced GI motility.

Table 14.13: Action of different types of opioid receptors

μ *(mu receptor)*	κ *(kappa receptor)*	δ *(Delta receptor)*
Analgesia	Analgesia	Analgesia

Miosis	Miosis	
Reduced GI motolity		Reduced GI motolity
Sedation	Sedation	
Physical dependence	Physical dependence	

σ (Sigma) receptor

Now, it is no longer considered an opioid receptor, becuase it is neither activated by morphine, nor blocked by naloxone. However, certain opioids like pentazocine, butorphanol, etc, binds to σ-receptor. Certain effects such as dysphoria, psychotomimetic action, tachycardia, mydriasis, etc, caused by pentazocine like drugs are believed to be mediated by σ-receptor and are not reversed by naloxone (Table 14.13).

Cellular Mechanism of the Action of Receptor

All the three types of opioid receptors (μ, κ, δ) have been cloned and their functions are studied extensively. All these receptors are belongs to the G-protein coupled receptor family. This group of receptors constitutes about 80% of all the known G-protein coupled receptor family in the body which also includes muscarinic, adrenergic, GABA and somatostatin receptors. Amino acid sequence of these opioid receptors is very similar to somatostatin than other receptors. Opioid receptors have three parts – extracellular, transmembrane and intracellular. The amino acid sequence of these three opioid receptors (μ, κ, δ) are 60% identical and greater similarities among them exist in the transmembrane and intracellular part of it. However, the specific amino acid sequence in the extra cellular part of these opioid receptors are the key factor in determining the ligand-specific action.

The opioids modulate the synaptic transmission through opioid receptors by both the presynaptic (indirect) and postsynaptic (direct) facilitatory and inhibitory actions. Inhibitory action is mediated by Gi/Go protein and excitatory effect is mediated by Gs protein. G-protein coupled receptors are situated mostly on the prejunctional neurons. They generally exercise inhibitory modulation by decreasing the release of junctional transmitter. Various monoadrenergic (NA, DA, 5HT), GABA, and glutamate (NMDA) pathways are also intricately involved in opioid actions (Table 14.14).

Opioid receptor-activated G-protein effector system can be divided into two categories – short term effectors acting through K^+ and Ca^{2+} channels and longer term effectors acting through cAMP and adenylcyclase system. All opioid receptors inhibit the opening of Ca^{2+} channel and both the μ and δ receptors also activate the K^+ channel. Thus, the decrease in intracellular Ca^{2+} influx can inhibit the neurotransmitter mobilization with release of it and become a component of the mechanism of opioid induced analgesia. The K^+ channel effect results in hyperpolarization of neuronal membrane and decreases synaptic

Table 14.14: Receptor subtypes and action of various opioids

		Action	
	Receptor subtype	*Agonist*	*Antagonist*
Analgesia			
supraspinal	μ , κ , δ	Analgesic	No effect
spinal	μ , κ , δ	Analgesic	No effect
Respiratory function	μ	Decrease	No effect
GI tract	μ , κ	Decrease motility	No effect
Psychotomimesis	κ	Increase	No effect
Sedation	μ , κ	Increase	No effect
Diuresis	κ	Increase	
Hormone regulation			
Prolactin	μ	Increase	Decrease
Growth Hormone	μ and/or δ	Increase	Decrease
Neurotransmitter release			
Acetylcholine	μ	Inhibit	
Dopamine	μ δ	Inhibit	

transmission. The changes in cAMP may underline the opioid induced modulation of the release of neurotransmitter such as substance P.

Mechanism of Analgesia

The opioids when used systemically act through many higher CNS centres such as amygdala, mesencephalic reticular formation, periaqueductal gray matter (PAG), the rostal ventral medulla, etc. But the role of these higher brain centre, containing opioid receptor in opioid analgesia is still in controversy. Action of opioids at PAG result in impulse that modulate the degree of inhibition, coming from different neuronal pools and contribute in reducing the transmission of nociceptive information from peripheral nerves to the spinal cord. The rostral ventromedial region of medulla also modulates the nociceptive tansmission in the dorsal horn of the spinal cord. Opioid action at PAG controle this region of medulla by direct neural connection. Thus, opioids by systemic administraton activates the total analgesic system in CNS (Fig. 14.19).

Spinal opioid giving through the spinal or epidural route produces analgesia by direct action on the spinal cord only at the level of administration. Subtantia gelatinosa of spinal cord possess dense collection of opiate receptors (μ, κ, δ) and direct application of opioid to these receptors of spinal cord creates intense analgesia by their action at the presynaptic level by reducing the release of substance P. Opioid in the spinal cord also acts on the opioid receptors of dorsal horn cells and inhibits the sharp pain stimulation conducted by the A-δ fibres. At the dorsal horn cells opioids also block the excitatory postsynaptic potential summation and thus inhibit the dull persistent pain sensation, transmitted via the C fibres. This summation is much easier to block before the pain occurs than to treat. This concept explains why preemptive analgesia is more effctive than analgesia after stimulation. Opioids also modulate the pain sensation by preventing the excitatory threshold reduction at the dorsal horn cells.

By some peripheral mechanisms acting outside the CNS, opioids also produce analgesia. In the periphery opioid receptors are located at the nerve terminals of presynaptic affarent neurons and the immune cells, infiltrating the inflamed tissue and produce endogenous opioids for the peripheral receptors. Opioid act on these receptors at the periphery and produce analgesia.

Opioids agonist also produce local anaesthetic like effect on the surface of the excitable cell membrane and reduce pain. Serotonergic pathways may also take part in the opioid mediated analgesia. Some opioids also act through $GABA_A$ receptors like benzodiazepine and barbiturates.

The concentration of opioid receptors and the proportion of its subtypes can change with age and this explains the variation of pain sensitivity with age. Certain opioids can have a duration of action that extends beyond its plasma half-life and it is because of the high affinity of this drug to μ receptor. For example, buprenorphine has very high affinity for μ receptor and very slower dissociation rate from it explains the cause for difficulty in reversing its respiratory depression effects with naloxone.

Other parts of CNS which also contain opioid receptors are basalganglia, limbic area, etc, and they are responsible for the action of endogenous opiates. Cardiosvascular system also contains opioid receptors which are responsible for the receptor mediated opioid's actions in myocrdial ischaemia, shock and other cardiovascular events.

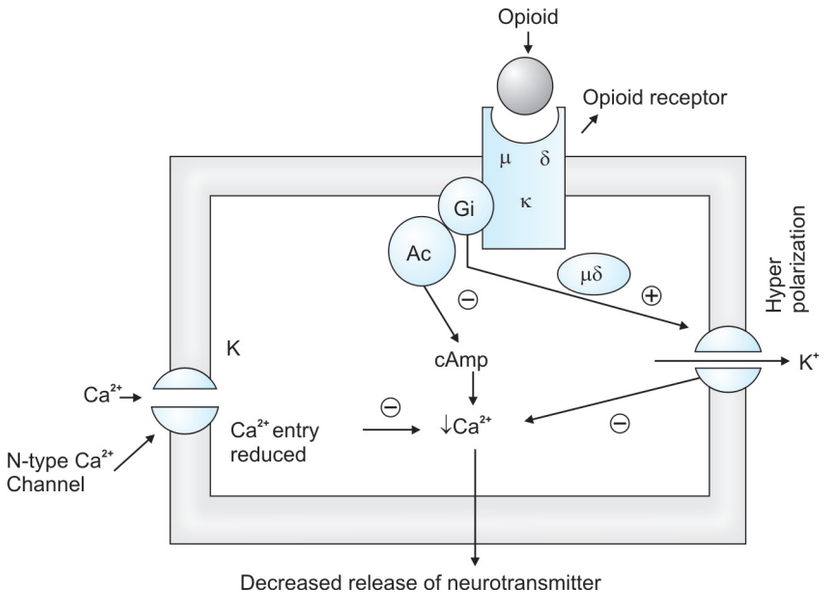

Fig. 14.19: All these 3 types of opioid receptors (μ ,κ § exercise inhibition and decrease the release of junctional neurotransmitter. Various monoaminergic pathways such as NA, DA, 5-HT, GABA, and glutamate (NMDA) pathways are intrically involved in opioid actions. Opioid receptor activation reduces intracellular cAMP formation. It also opens K^+ channel mainly through μ and δ receptors. It also suppresses the voltage gated N type Ca^{2+} channel mainly through κ receptors.These actions result in hyperpolarization and reduced availability of intracellular Ca^{2+}. Thus it causes the decrease in release of neurotransmitter from CNS and myenteric neurons and block pain pathway

Endogenous Opioids

In 1970, a number of peptids were isolated from brain, spinal cord, plasma, GIT, placenta, etc, which also have affinity for opioid receptors (μ, κ and δ) and have morphine like action. So, it was hypothesised that these peptides constitute an

endogenous opiate system which normally modulates the pain perception, mood, hedonic (pleasure related) behaviour, motor behaviour, emeris, pituitary hormone release, GIT motility, diuresis, modulation of respiratory responses to stimuli and drugs, reduction of stress, etc. These endogenous opioid peptides are active in very small amount and there actions can also be blocked by naloxone. Endogenous opioid peptides are classified into 3 different families and each is derived from a distinct large precursor polypeptide. These three families are endorphin family, encephalin family and dynorphin family.

Endorphins (Endorphin family)

There are many endorphins in this family. But, the β-endorphin (β-END) is the most important among all the endorphins in this family. It has 31-amino acids and pro-opio-melanocortin is its precursor. This precursor is cleaved to form ACTH and β-lipotropin (β-LPH). The β-LPH is again cleaved to form β-END. The highest concentration of β-END occur in the pituitary gland, and in the medial, basal, and arcuate regions of the hypothalamus. The presence of β-END in spinal cord is debetable. Outside the CNS, the β-END exists in GIT, placenta, and plasma.

Enkephalins (Enkephalin family)

The most important enkephalins are methionine-enkephalin (met-ENK) and leucine-enkephalin (leu-ENK). They are pentapeptides. Pro-enkephalin is the precursor of met-ENK. The prodynorphin is the precursor of leu-ENK and dynorphin. The enkephalins are widely distributed in many areas of CNS such as amygdala, globuspallidus, striatum, hypothalamus, thalamus, brain stem, dorsal horns, etc, that receive affarent nociceptive information. Enkephalins have also been isolated in the peripheral nervous system such as peripheral ganglia, ANS, adrenal medulla, GIT and as well as plasma. Enkephalins may also elicit analgesia through the modulation of release of substance P from the dorsal horn cells.

Dynorphins (Dorphin family)

The prodynorphins is the precursor of dynorphins and are found in the hypothalamo neurohypophyseal axis. Dynorphin functions primarily as neuromodulators in the CNS by interracting with μ, δ and κ receptor. Dynorphin also appears to be distributed in other areas of CNS which are relevant to nociception such as the periaqueductal grey region, limbic system, thalamus, dorsal horn of spinal cord, etc. Dynorphin is thought to play a more important role for nociception at the spinal cord level (by activation of κ-receptor) than in the brain. It may also control centrally the function of CVS.

A functional interaction occurs between the nociception and the endogenous opioids. The preliminary processing of the afferent nociceptive information first occurs at the dorsal horn cells of spinal cord. Both the dynorphins and enkephalins are active in these areas. The 2nd processing station for nociception reside in the mid-brain, brainstem and thalamus. High concentration of dynorphins, enkephalins and β-endorphin can be found in these areas. Higher brain centre such as limbic system, amygdala, cortex where final processing occur and involved in the affective dimensions of pain contain significant population of neurons where dynorphin, enkepahlin and β-endorphins are found.

Neurophysiological Actions of Opioids

Analgesia

The dull and viseral pain is better relieved than the somatic pain by opioids. The nociceptive pain arising from the periheral receptor is better relieved than the neuretic pain arising from the neural structure due to its damage. Other associated reactions to intense pain such as apprehension, fear, autonomic effects, etc, are also reduced by opioids. Suppression of pain perception by opioids is also selective without effecting other sensation and without producing generalised CNS depression (in contrast to General anaesthetic agents). Perception of pain and reaction to it are both altered, so that pain becomes no longer an unpleasant or distressing element. So, patient tolerates pain better under opioids.

Opioids also act on the substantia gelatinosa of dorsal horn cells and inhibit the release of excitatory neurotransmitter from the primary affarent fibres carrying pain impulse. This action of opioids appears to be exerted through the interneurons which are involved in the gating process of pain impulses. The release of substance P from the primary affarent fibres in the spinal cord and its post synaptic action on the dorsal horn neurons is also inhibited by opioids. The action of opioids at supraspinal sites such as medulla, midbrain, limbic and cortical areas may also alter the processing and interpretation of pain impulses as well as send the inhibitory impulses through descending pathways to the spinal cord. Several aminergic and other neuronal systems also appear to be involved in the action of opioids. Simultaneous action at spinal and supraspinal sites greatly amplifies the analgesic action of opioids.

Sedation

Sedation or hypnosis produced by opioids is different from other sedatives or hypnotics such as benzodiazepine, barbiturates, etc. Drowsiness and indifference to the surroundings as well as to his own body is occurred by opioids without any motor incoordination, ataxia or apparent excitement (contrast to alcohol). Opioids have weaker amnestic effect compared with propofol, barbiturates, midazolam or other benzodiazepines.

Mood and Subjective effects

Opioids relieve anxiety and produce calmness. It causes loss of apprehension, and

lack of initiative. Limbs feel heavy. It causes transient flushing and hot sensation due to the release of histamine. There is mental clouding and inability to concentrate. Patients who are suffering from pain, anxiety and those who are addicted perceive it as a great pleasure. It produces euphoria or dysphoria.

CTZ

Nausea and vomiting can result from opioids. It especially occurs if stomach is full and patient stands or moves about. The mechanism of action of nausea and vomiting produced by opioids is due to sensitisation of CTZ centre by vestibular and other impulses.

Edinger-Westphal Nucleus

Opioids stimulate the EW nucleus or release the cortical inhibition on it and thus produce miosis. No miosis is found by topical application of opioids on conjunctiva.

Other Cortical Areas and Hippocampal Cells

Excitation of CNS by opioids is seen in some individuals. This is due to the stimulation of some cortical areas and hippocampal cells by it. So, opioids have no anticonvulsant action, rather precipitate it. Muscular rigidity is another feature of opioids. The proconvulsant action of opioids also has been ascribed due to the inhibition of release of GABA inhibitory neurotransmitter from the hippocampal interneurones.

EEG Changes

The neurophysiological changes produced by large doses of opioids and inhaled anaesthetics are different. In contrast to gradual burst suppression and ultimate a flat EEG which is found as the effect of inhalational anaesthetics, a ceiling effect is reached by opioids. Once ceiling effect has been reached then subsequent increased dose of opioid does not affect the EEG. Low dose of opioids produce minimal changes in EEG. Higher doses result in high voltage (δ-delta) waves, suggesting a state of consistent with anaesthesia. Transient, isolated (not generalised) sharp waves activity is also seen after large dose of opioids.

Neuro protection effect

Role of opioids in neuroprotection is controversial.

Cerebral blood flow

Opioids decrease (10 to 25%) the cerebral metabolic rate and the intracranial pressure by causing cerebral vasoconstriction.

Neuroexcitatory phenomenon

Opioids cause neuroexcitatory phenomenon ranging from delirium to grandmal seizure like activity. Opioids also cuase other types of neuroexcitation ranging from nystagmus to only flexion or extension of single extremity to repetitive clonic – tonic activity. Initially, on IV injection opioids frequently stimulate coughing, which is of brief duration. This is followed by supression of cough. Meperidine is notorious for its CNS excitability. However, the mechanism of neuroexcitability caused by meperidine is unique which is described below. It is related to its N-demethylation metabolite, named normeperidine, which is twice as likely to cause CNS excitation and convulsion as meperidine and have half the analgesic potency. The CNS adverse effects associated with mepiridine include disorientation, hallucination, tremors, twitching, myoclonus, psychosis and seizures. Treatment of CNS excitability produced by meperidine is supportive and includes cessation of administration of meperidine, substitution with another opioids for analgesia and administration of BDZ for signs and symptoms of CNS irritability. For the treatment of CNS excitability caused by opioids naloxone should be avoided because it can further precipitate seizure by unmasking the excitatory effects when depressant effects are antagonised. Normeperidine has a long elimination half-life (15 to 40 hours) and is excreted via kidney after its hydrolysis to normeperidinic acid which is inactive.

The probable mechanisms for neuroexcitatory phenomenon of opioids are:

i. The opioids cause increase in the glutmate activated current.
ii. The changes in central catecholamine concentration through dopaminergic pathways.
iii. Increase in the release of excitatory neurotransmitter such as met – and leu-enkephalin, which posses epileptogenic properties.
iv. Disinhibition of the pyramidal cells of hippocampus.
v. More recent work suggests that certain excitatory actions of opioids may be related to their coupling to mitogen activated protein kinase cascades (Table 14.15)

If opioids are anaesthetics?

It is a debatable question for many years and still is not resolved. High incidence of awareness during large doses of only opioid anaesthesia highlighted this potential problem. Unconciousness, defined by unresponsiveness to verbal command can be produced with opioids, but is very unpredictable and inconsistant. On the other hand, all the opioids cause reduction

Table 14.15: Factors responsible for intra-operative awareness

1.	No premedication.
2.	Obstetric anaesthesia.
3.	Improper anaesthetic plan.
4.	Escessive use of muscle relaxant.
5.	Inadequate use of analgesic.
6.	Morbidly obese patient.
7.	ASA grade III and IV where less anaesthetic drugs are used.
8.	Prolonged time for intubation.
9.	Cardiac surgery.
10.	Laryngoscopy, bronchoscopy etc.

of MAC value of inhaled anaesthetics. Thus, potency ratio of fentanyl/sufentanyl/alfentanyl/remifentanyl which is based on MAC reduction is approximately 1:12:1/16:1.2. Opioid's analgesic effects reach a ceiling that is subanaesthetic. The exact mechanism of opioids for amnesia and anaesthesia is in doubt. The ability of opioids to produce full analgesia in subanaesthetic concentration and loss of conciousness in higher concentration may be mediated by different mechanism. A dual mechanism for anaesthetic effect of opioids has been proposed in addition to the receptor mediated effects which is responsible for analgesic effects of opioids (Fig. 14.20).

Awareness is defined as the 'spontaneous recall of events occurring during general anaesthesia and surgery'. The conscious recollection of this memory is called the explicit memory. When the patient can not recollect its memory in conscious state this awareness is called the implicit memory. Usually auditory function is left largely intact by opioid and is responsible for awareness during anaesthesia. The overall incidence of intraoperative awareness is 1%. There are also other factors which are responsible for intraoperative awareness. Clinically, intraoperative awreness is monitored by motor and autonomic function. Motor functions during anaesthesia such as eyelid motion, coughing, movements of limbs, facial grimacing, etc are signs of inadequate amnesia. Whereas autonomic functions during anaesthesia such as hypertension, tachycardia, mydriasis, tearing, sweating, salivation, etc, indicate light level of anaesthesia. The monitoring of muscular activity as an indicator of awareness is useful, because muscle movements usually occur before awareness occur. CNS activity also can be meausred by auditory evoked response and EEG. Raw EEG has limited value for awareness monitoring. Bispectral analysis (it is a power spectrum analysis which is a mathemetical technique of EEG transformation) obtain an index number after using processed EEG and correlate well with sedation or anaesthesia by hypnotic or anaesthetic drug, but not by opioids. Opioids does not alter BIS except in high doses.

Muscle rigidity

Opioids often increase muscle tone and produce muscular rigidity. Sometimes this may progress to severe stiffness. The incidence of it may vary from 0 to 100%. In conscious state this rigidity is often manifested as hoarseness of voice. Clinically, the significant opioid induced muscular rigidity begins usually after the patient loses consciousness. Rigidity of the abdominal and/or thoracic muscle (wooden chest syndrome) impair both spontaneous and controlled ventillation in a non-paralysed patient. Rigidity of muscles casuses: ↓ pulmonary compliance, ↓ FRC, ↓ ventilation, hypercarbia, hypoxaemia, etc. It also causes ↑ CVP, ↑ PAP and ↑ PVR etc. Rigidity also causes ↑ ICP and ↑ O_2 consumption. The rigidity and abnormal muscle movement may also occasionally occur during emergence from opioid anaesthesia. This abnormal muscle movement ranges from only flexion or extension of single extremity to multiple tonic-clonic movements.

The precise mechanism for this opioid induced abnormal muscle movement is not known. However, the probable hypothesis are: (i) the alteration of dopamine concentration within the striatum of brain by opioids and (ii) the stimulation of GABA nergic interneurones.

Pruritus

The exact mechanism of opioid induced pruritus is not known. But definitely it is not due to the release of histamine or allergic manifestation by opioids which was previously thought. Because naloxone reverses this pruritus and confirmed the opioid receptor-mediated central mechanism of it. Face, particularly the nose is the commonest site for opioid induced pruritus. Nasal scratching may stimulate ventilation and counter the opioid induced respiratory depression. This may be the mechanism why the nose is the commonest site of pruritus induced by opioids. Pruritus on the nose by spinal opioid may also be due to the opioid triggered neural transmission at a distant site.

Thermoregulation and Shivering

Shivering is a common phenomenon in patients recovering from anaesthesia. Its physiological role is to produce heat. But, its occurence in relation to anaesthesia is inconsistent and is incompletely understood. Neverthless, the post-operative shivering can cuase several undesirable physiological consequences. These are increase in O_2 consumption, incerease in CO_2 production,

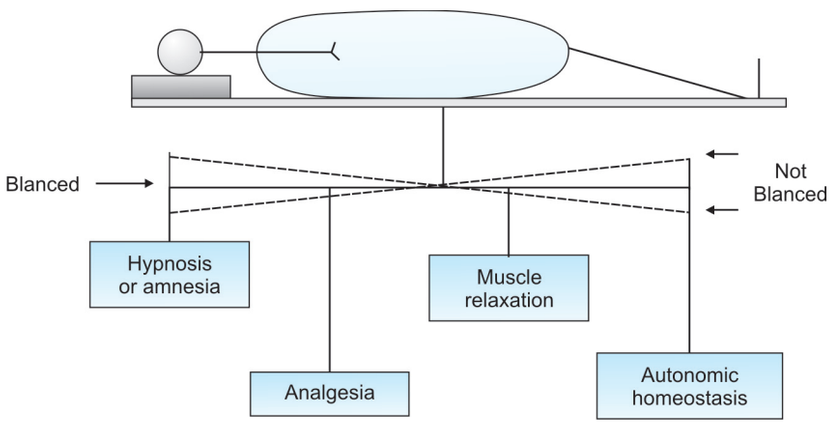

Fig. 14.20: Four components of balanced anaesthesia

↑ minute ventilation, ↑ cardiac output, ↓ mixed venous O_2 saturation and difficulty to measure the O_2 saturation of Hb by pulse oximetry. Opioid ligands and its receptors have a functional role in thermoregulation. For example, μ-receptor stimulation produces hyperthermia. Whereas κ-receptor agonists result in hypothermia. Opioids like inhaled anaesthetics also reduces thermoregulatory threshold and cause shivering.

Meperidine is unique among all the opioids in its ability to effectively terminate or at least attenuate the shivering in approximately 70 to 80 % of patients. Shivering related to blood transfusion can also be controlled with meperidine. Usually 25 to 50 mg slow IV administration of meperidine is effective. However, in the presence of opioid antagonist larger doses of meperidine may be necessary. IV fentanyl, sufentanil and morphine are not as effective as meperidine to reduce the shivering. The cause of this underlying difference and the mechanism for the ability of opioids to attenuate shivering is unclear. Meperidine administered spinally or epidurally is also effective in treating shivering that occurs during epidural anaesthesia.

Respiratory System

All the opioids stimulating μ-receptors cause dose dependent depression of respiration. This is because high concentration of opioid receptors are found in supraspinal respiratory centres such as nucleus solitarius, nucleus retroambigualis and nucleus ambigus. Opioids also depress the respiratory rate through pontine and medullary respiratory centre, because endogenous opioid receptors are also present in high concentration in brain stem nuclei regulating respiration. Opioid induced effects on respiratory rate and pattern include: delays in expiration, long respiratory pause, irregular and/or periodic breathing, apnoea, decreased tidal volume. Prolonged expiratory pause induced by opioid causes greater reduction in respiratory rate than in tidal volume (Fig. 14.21).

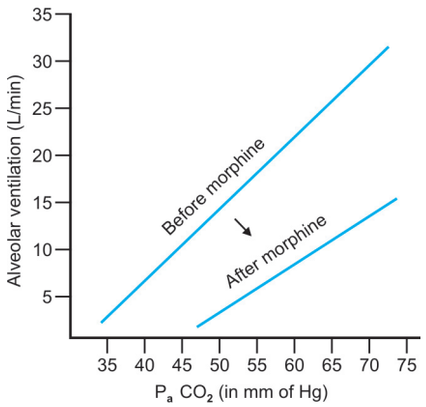

Fig. 14.21: The displacement or shifting of CO_2 curve downward and to the right after use of morphine

The stimulating effect of CO_2 on ventilation is significantly reduced by opioids. Resting PCO_2 in plasma increases and the ventilatory response to CO_2 challenge is blunted, resulting in shift of the CO_2 response curve down ward and to the right. These effects are mediated through the respiratory centres in the brain stem. The apneic threshold, i.e. highest P_aCO_2 at which a patient remains still apneic is elevated. Opioids also decrease the carotid body chemoreceptor and hypoxic ventilatory drive. High doses of opioid can eliminate the spontaneous respiration without producing unconsciousness. So, the patient will still follow the verbal command and often breath when directed to do so. Gender differences may exist in these effects with women demonstrating more respiratory depression.

Opioids decrease the pain and anxiety induced hyperventilation and thus prevent respiratory alkalosis, though large doses of opioids decrease pulmonary compliance and impair ventilation due to its muscular rigidity and respiratory depression effect. On the other hand, the opioid analgesic therapy improves breathing by alleviating the pain and decreasing the voluntary muscle tone related to pain which results in improved dynamic of total respiratory compliance.

Opioids, especially dextromethorphan have centrally mediated antitussive action, but are not necessarily linked to respiratory depression. Again cough may be precipitated after IV bolus opioids. It is due to the stimulation of irritant receptors in tracheal smooth muscle. However this cough is not vagally mediated, because atropine pretreatment does not affect it. Pretreatment with inhaled β-adrenergic agonist significantly reduces this incidence of cough associated with IV opioids injection.

Opioids blunt the somatic and autonomic responses during tracheal intubation by depressing the upper airway and tracheal reflexes. Thus, it allow the patient to tolerate better the ET-tube without coughing and bucking. Hence, on emergence from GA where patient is anaesthetised only with potent inhalational agents and no opioid, routinely cough and buck prior to regaining consciousness. Whereas, when the patient is adequately treated with opioids can awake without such disturbances, even while they are still intubated.

Morphine and meperidine can cause histamine induced bronchospasm in susceptible patients. Although, the opioids can affect the contractile responses of airway smooth muscles, but the clinical significance and relevance of this opioid induced effects on airway resistance remains controversial. Because opioids can also help by avoiding the increases in bronchomotor tone in asthma. Opioids can decrease the airway smooth muscle tone and have long been used in the management of asthma. Fentanyl has antimuscarinic, antihistaminergic and antiserotoninergic actions. So, it may be more effective than morphine in patients with asthma or other bronchospastic diseases.

Certain IV anaesthetics, including opioids, minimally alter the pulmonary function of gas exchange. The minimal impact of opioids on hypoxic pulmonary vasoconstrictic (in contrast to the effect of the potent inhaled anaesthetics), the associated haemodynamic stability, and the stability of bronchomotor tone, all contribute to

the minimal interference with pulmonary gas exchange which is observed after use of opioids and many other IV anaesthetic agents.

Factors affecting the opioid induced respiratory depression

i. Dose: Opioids cause dose dependent respiratory depression and have no ceiling effect.
ii. Sleep: Sleeping patients are more sensitive to opioids and sleep apnoea is an additional risk factor.
iii. Old age: Respiration of aged patient are more sensitive to opioids for depression and its probable causes are decreased clearance, increased elimination half-life, increased brain sensitivity.
iv. Neonates: Neonates are more sensitive to morphine on the basis of weight than adult. Low lipid solubility of morphine limits its penetration to blood brain barriers. But in neonates and infants morphine easily penetrates the brain and this is due to immature blood brain barriers which make the neonats and infants more sensitive to morphine than adult. On the other hand, children are not more sensitive to more lipid soluble opioids (mepridine,fentanyl, sufentanyl) because penetration of these drugs into the brain is not affected by blood brain barrier maturity, but depends on their lipid solubility.
v. Other CNS depressant: Potent inhaled anaesthetics, alcohol, barbiturates, BDZ, etc, potentiate the respiratory depression action of opioids. Exceptions are droperidol, and clonidine.
vi. Pain: Pain counters the respiratory depressant effects of opioids.
vii. Hyperventilation with hypocarbia enhance the activity of opioids. On the other hand hypercarbia has the opposite effect. However, the possible of explanation of this response is increased unionised state of opioid with hypocarbia which facilities its brain penetration and vice versa.

Cardiovascular System

The opioids not only provide analgesia, but also promote stable haemodynamic conditions both in the presence and absence of noxious stimuli. Large doses of opioids, administered as sole primary anaesthetic agent, result in stable hemodynamic situation throughout the operative period. The close association between the distribution of opioid receptor, cardiovascular regulatory centre (N. solitarius, dorsal vagal nucleus, N. ambiguous, parabrachial nucleus) and autonomic regulatory centre in CNS explain the cause of this stable hemodynamic condition by opioids. Endogenous opioid peptides are also associated with the sympathetic and parasympathetic centres in brain which also control the cardiovascular function. Different opioid receptor, occupying the ventrolateral periaqueductal gray region which is the key central site for analgesia, also affects the haemodynamic control.

Activation of μ-opioid receptor suppresses the somato sympathetic reflexes which are transmitted by the unmyelinated C-afferent fibres at the level of spinal cord and modulate them at brain stem. These actions also contribute to the anaesthetic capabilities of opioids. Opioids thus modulate the stress responses by its action on the hypothalamo – pituitary – adrenal axis. Most opioids reduce the sympathetic tone and enhance the vagal tone. Ablation of sympathetic tone can occur by all the modern opioids.

The direct actions of opioids on myocardium are significantly less than other IV and inhalational anaesthetic agents. However the direct effects of different opioids on myocardial contractility is different and controversial. Meperidine has been reported to produce decrease, increase or mixed effects on the myocardial contractlity. On the other hand, morphine has positive inotropic effect. However, most hemodynamic variables including HR, BP, CO, SVR, PVR usually remain unchanged after fentanil, sufentanil and ramefentanil. Morphin reduces both the venous and arterial tone. These changes result in decrease in afterload, venous return and preload. Arterial dilatation is of shorter duration and is of less intensity than venodilatation. This vasodilatation is caused by the release of histamine and is responsible for hypotension. This hypotension again stimulate sympathetic system as a compensatory mechanism. The hypotension produced by opioids can be eliminated or minimised by: volume loading, H_1 and H_2 histamine anatagonists, Trendelenburg position and slow infusion of drugs.

Some reports show that the patients with good left ventricular function become hypertensive more frequently due to opioids than patient with poor left ventricular function during surgery. The explanation of this phenomenon is like that: the patients with good myocardial function could increase cardiac index in response to increase in SVR induced by surgical stimuli. Thus, the patients with limited myocardial reserve could not always maintain CO in the face of ↑SVR. So, their BP does not increase and at times decreases. This rise of BP after opioid, especially during intubation and surgical stimulation has been most often due to the light general anaesthesia which is resulted from the underestimation of opioid dose and faulty timing of drug administration. So opioids should be administered in a fashion which will permit establishment of peak effect before noxious stimuli.

The predominant and usual effect of opioids on the heart rate is to produce bradycardia, resulting from stimulation of central vagus nucleus. The opioid induced bradycardia can be prevented by vagal block with atropine. The blockade of sympathetic chronotropic actions by opioid may also play an important role in opioid induced bradycardia. Meperidine in contrast to other opioids rarely results in bradycardia, but it can cause tachycardia. Tachycardia after meperidine may be due to its structural similarity to atropine or normeperidine or due to its early toxic CNS manifestation.

Opioids depress the cardiac conduction and thus slows the AV nodal conduction, prolongs PR interval, increases AV nodal refractory period, prolongs duration of action potential of Purkinje fibres and prolongs the QT interval. This effect may be related to enhanced Ca^{2+} entry during the plateau phase of action potential or depression of the outward K^+ current during terminal repolarisation of action potential. Clinically the disturbances of cardiac conduction due to opioids are very rare. But they may be more likely to occur in the presence of Ca^{2+} entry or β-adrenergic blocker.

Compared with inhalation anaesthetic agents, the opioids cause better preservation of myocardial function. The hypotension produced by morphine is not due to the myocardial depression like inhalational agents. Opioid receptor stimulation results in reduction of infarction size. High doses of opioids maintain better myocardial perfusion and O_2 supply/demand ratio than inhalational agents.

Morphine and meperidine cause release of histamine which causes sympatho adrenal activation. This is documented by significant increase in plasma epinephrine and norepinephrine level in response to opioids. This hormonal alteration contribute to the cardiovascular changes seen after morphine and include an increase in cardiac index. Decrease in arterial blood pressure and SVR is also due to this histamine effect. Meperidine causes histamine release more frequently than most other opioids, including morphine, fentanyl, sufentanil and remifentanyl. Unlike morphine and mepridine, the fentanyl, sufentanil, remifentanil do not produce increase in plasma histamine and hypotension. Although, the μ-opioid agonist modulate the adrenal secretary response to pain, still the adrenal secretory response to haemorrhage is preserved.

Hormonal Response

Stress response is totally a physiological process that occurs when a patient enounters a significant insult from injury and/or surgery. The main part of this stress response is the neuroendocrine component which works through some centres, situated in the brain and release the corticotropin releasing hormone from para ventricular hypothalamic nucleus and locus caeruleus, responsible for nor epinephrine/autonomic nervous system. During stress or surgical insult hypothalamus secrets trophic hormones which stimulate pituitary to release ACTH, GH, renin, prolaction, ADH etc. Thus, the level of cortisol, catecholamines, glucagon, thyroxine is increased. However, the plasma level of anabolic hormones such as insulin and testosterone are decreased. This increased level of stress hormones during GA and surgery cause haemodynamic instability and periopetrative catabolic metabolism which contribute to operative mortality.

In general, the inhalational anaesthetic agents cannot supress this stress response, but only mask it. But, opioids can do it to certain degree. Only combinations of different anaesthetic agents and technique control the stress response best. Opioids are potent inhibitor of hypothalamus pituitary adrenal axis. It reduces the stress responses by blocking the nociception at different levels of neural axis.

Fentanyl and its congeners are more effective than morphine and meperidine in modifying these hormonal responses to surgery. Increased stress response is detrimental to very ill patient undergoing major procedure. Increased catecholamine increases cardiac risk and increased protein catabolism delay recovery. So, the reduction of stress response by opioids during surgery reduces the morbidity and mortality.

Renal Effects

Morphine and meperidine prevent the release of ADH which occurs in response to stress Thus, the absence of increase in plasma ADH, renin and aldosterone level indicate that opioids most likely preserve or minimally alter the renal function in human subject. Opioids reduce the tone of bladder's smooth muscle, but increase the tone of bladder sphincter, causing retention of urine. Opioids also cause the increased contraction of ureter smooth muscle.

Gastrointestinal Effects

The opioid receptors and the endogenous opioids are found through out the GI tract. So, the opioids produce the wide spread effects on GI tract by supraspinal (vagus nerve mediated), spinal and as well as by peripheral mechanism. Opioids increase the tone and decrease the motility of GI tract and are more likely to have full stomach, regardless of their 'NPM' status. Opioids lower the oesophageal sphincter activity causing relaxation but spasm of pyloric, ileocaecal and anal sphincter. It causes decrease in all GI secretion. Epidural and intrathecal opioids also reduces the GI tract motility. Naloxone reverses the opioid induced delays of gastric emptying.

Opioids induce the spasm of CBD and sphincter of oddi and thus reduce the caliber of CBD and increase the billiary duct pressure. The opioid induced reduction of caliber of CBD is greatest with morphine and is insignificant after fentanyl or sufentanil. This spasm of biliary system can completely be counteracted by naloxone, glucagon, nitrates, theophylline and partially by atropine. The meperidine has dual effect. In lower concentration, it produces the anti muscarinic effect and in higher concentration it produces the biliary spasm. Neither of these respone of meperidine is affected by naloxone.

The little but big problem during perioperative period is the post operative nausea and vomiting which is caused by opioids. Opioids stimulate the centre of CTZ situated in the postrema of medulla and at possibly through δ-receptor. This central action of opioid combined with their action on GI tract promotes nausea and vomiting. There is very little evidence to suggest that any one opioid is constantly

more emetogenic than other. Neverthless, in one particular patient, changing from one opioid to another influence the incidence of associated nausea and vomiting. Factors that increase the incidence of nausea and vomiting are age (paediatric group is more susceptible), sex (females are more prone), obesity, history of motion sickness, anxiety, certain surgical procedures (laparoscopy), opioid premedication, intensity of pain, gastric distension and N_2O. Propofol significantly reduces the incidence of nausea and vomiting.

Nausea and vomiting caused by opioids are of great concern to post-operative patients. So, attempts should always be taken to minimise their occurance. Some efficient antiemetic therapies commonly used in anaesthesia are:

i. Anticholinergic drug such as scopolamine can be given through IM or IV or transdermal patch to reduce the postoperative nausea and vomiting. Glycopyrrolate is ineffective in this respect as it cannot penetrate the blood brain barrier. Atropine is effective to some extent.
ii. Droperidol (0·005 to 0·07 mg/Kg IV) is very effective to reduce the post-operative nausea and vomiting caused by opioids. It acts by its anti dopaminergic action.
iii. Dopamine antagonist such as metoclopramide, is also effective. It acts centrally at CTZ and peripherally at GI tract.
iv. Serotonin antagonist such as ondansetron may be highly effective. But it is associated with low incidence of headache (3%), liver enzyme elevation and high cost benefit ratio.

Obstetric Effects

Morphine and meperidine (not fentanyl, sufentanil, alfentanil) adversely affect IVF (*in vitro* fertilisation) due to their teratogenic potentiality. So, they are not used for this purpose. Parenteral administration of opioids prior to delivery in obstetrics practise remains a commonly used method of analgesia despite the known adverse maternal, fetal and neonatal effects of it and it is due to the arguably superior alternatives other than epidural analgeria. Meperidine (50 mg IV) has been suggested to result in less neonatal depression than morphine. This is because of the immaturity of the foetal blood brain barrier which allows greater than normal brain penetration of the relatively less lipophobic morphine compared with meperidine. Soon after injection, morphine and mepridine rapidly cross the placenta barrier and cause significant blood level in newborn. The elimination half-life of meperidine in newborn can be as long as 23 hours.

Sufentanil is highly bound to plasma protein and thus impedes its placental transfer. Placenta takes up more sufentanil compared with the other opioids and acts as a drug depot. Thus, placental transfer is reduced in case of sufentanil and transfer to the foetus may be least when delivery occurs within 45 minutes of this drug administration.

Meperidine increases the uterine contraction and shorten the labour in a dose dependent fashion which is not reversed by naloxone.

Though, traditionally opioid is not used in GA for caessarean section, but recently patient with severe PIH and CVS problems are induced with newer congener of opioids to promote CVS stability. Maternal effects are deemed beneficial, because naloxone is used for reversal of neonatal respiratory depression. Opioids excrete through breast milk and depress the neonatal neurobehaviour. Newborn of addicted mother exihibits opioids withdrawal symptoms and require appropriate treatment.

Occular Effects

All the opioids prevent the increase in intraocular pressure, associated with succinylcholine and/or tracheal intubation.

Allergic Reaction

The true anaphylactoid reactions to opioids are rare. But most commonly local reaction occur and this may be due to preservatives or histamine release. Naloxone and antihistamins partially attenuate these histamine induced opioid reactions.

Pharmacokinetic

Opioids are weak base and when dissolved in sloution, then they dissociate into protonated or ionised fraction. The relative proportion of these protonated (on ionised) and free base (on nonionised fraction) depends on the pH solution and the pKa value of the agent. Free base or nonionised form is more lipid soluble than the ionised or protonated form. High lipid solubility increases the entry of opioid at the site of action i.e central nervous system and facilitates its rapid onset of action. On the other hand, opioid receptors recognise an opioid molecule in protonated form and the intensity of opioid effect is closely related to the concentration of the ionised portion of the drug in the cell. Thus, the speed of onset and intensity of action is a complex function of lipid solubility and the percentage of ionization which again depends on the tissue pH and pKa value of the drug like the local anaesthetic agent which is discussed in the respective Chapter No. 13.

Opioids are bound to plasma proteins (albumin and α_1-acid glycoprotein) to some extent. Opioid molecules that are bound to plasma protein cannot pass from blood to CNS or any other tissues. Only the unionised and unbound fraction (free base) passes from the blood to tissues where it is ionised and make the concentration gradient which promotes the further diffusion. Hence, the concentration gradient, lipid solubility and the palsma tissue partition coefficient determines the rate at which the opioid diffusion in tissue takes palce. Morphine has low diffusible fraction and is a slow onset opioid. This is because of its low lipid solubility. On the other hand, alfentanil has high diffusable fraction and is a rapid onset opioid. This is because of its high lipid solubility than morphine.

After IV injection, plasma concentration (central compartment) of opioids rise to a peak level within one circulation time like thiopentone and propofol. Thereafter, the plasma concentration of opioids falls very rapidly due to distribution and redistribution of it to the peripheral tissues and later slowly due to metabolism and excretion through the liver and kidney. This is also like barbiturates, propofol and benzodiazepine.

In general opioids are cleared from plasma by biotransformation (conjugation with glucuronic acid) in liver. Kidney also plays a role in conjugation of opioids. Blood and tissue esterase are also responsible for metabolism of remifentanil. Subtle difference of pharmacokinetic of different opioids are also due to its uptake by pulmonary tissue. This is because the rise-time to peak concentration in plasma of an opioids is influenced by the percentage of pulmonary uptake of it. 75% of fentanil is taken up by the lung due to its high lipophilicity and is subsequently released rapidly.

Morphine

The pharmacokinetic of morphine is notably different from its fentanyl congeners. Due to its low lipid solubility, there is little first pass uptake of morphine by the lung. The pKa value of morphine is 8 which is greater than the physiological pH of blood. So, after IV injection only 10 to 20% of morphine remains as unionised form. This property and low lipid solubility limits the ability of morphine to penetrate tissues, particularly the CNS and explain its slow onset of action. But in neonates and infants where the blood brain barrier is not properly build up, morphine has high penetration power in CNS (Table 14.16).

Morphine is principally metabolised in liver by glucuronide conjugation. Kidney is also an important site for extrahepatic metabolism (40%) of morphine. M_3G (morphine 3-glucuronide) is a major metabolite of morphine without any analgesic property. Another metabolite of morphine named M_6G (Morphine 6 glucuronide) accounts for 10% of the total metabolites of morphine. It is more potent analgesic than morphine itself which also acts through μ-receptor.

Bioavailability of orally administered morphine is significantly lower than the pareneral route and is only 20 to 30%. This is due to the hepatic first-pass effect. M_6G is the primary active component when morphine is administered orally due to high hepatic extraction.

Meperidine

Unlike morphine, after IV injection the first-pass uptake of meperidine by the lungs is approximatley 65%. Meperidine's physicochemical properties are not like morphine, but more similar to those of fentanyl congeners. Its pKa value is 8.5. So, it is less unionised (<10%) at physiological pH of blood. Meperidine is more lipid soluble than morphine, but it is more highly bound to plasma protein than morphine, i.e. 70% to α_1-glycoprotein. In contrast to morphine, meperidine binds to plasma albumin in minor extent.

The principal metabolites of meperidine are normeperidine, normepe – ridinic acid and meperidinic acid. All these are produced by N-demethylation and diesterification of meperidine in liver. Only less than 5% meperidine is excreted unchanged through kidney. Normepridine has analgesic and as well as neuroexcitatory property (twice as potent as parent compound in producing seizure). This epileptogenic property of meperidine make its therapeutic index low than that of morphine.

Normeperidine is excreted through kidney and have greater elimination half-life than meperidine. So, repeated administration of meperidine cause accumulation of this toxic metabolites in patient with renal failure and producs seizure.

Fentanyl

A three compartmental model is typically used to describe the pharmacokinetic property of fentanyl, instead of two compartmental model which is used for morphine and meperidine. Like meperidine, after IV injection the first-pass uptake of fentanyl by lungs is 75%. Its pKa value is 8·4. So, like meperidine at physiological pH of blood, unionised diffusible form of fentanyl is <10% and ionised form is >90%. So, diffusible fraction of fentanyl (unionised base) is less. But fentanyl's high lipid solubility increases its large volume of distribution in tissues than morphine and meperidine. Less unionised form explain less availability form of fentanyl for brain tissue and delayed onset of action (than alfentanil). On the other hand, high lipid solubility explain quick transfer of it to the CNS and rapid onset of action. So, the actual onset of action of fentanyl is the resultant effect of this two properties. High lipid solubility of fentanyl also explain more uptake of it by tissue and prolonged action. 80% of injected fentanyl is bound to plasma protein and 40% are taken up by RBC.

Fentanyl is metabolised mainly in the liver by N-dealkylation and hydroxylation. It has high hepatic clearance rate. Norfentanyl, the primary metabolite of

Table 14.16: Physical characteristics of opioids that determine the distribution

Agent	*Protein binding*	*Unionised (diffusible) fraction*	*Lipid solubility*
Morphine	+ +	+ +	+
Meperidine	+ + +	+	+ +
Fentanyl	+ + +	+	+ + + +
Alfentanil	+ + + +	+ + +	+ + +
Sufentanil	+ + +	+ + +	+ + +
Remifentanil	+ + +	+ + +	+ +

fentanyl is detectable in urine for upto 48 hours after single bolus IV administration. It is inactive and has no analgesic or toxic property.

Alfentanil

The unique physicochemical properties of alfentanil is its pKa value which is only 6.5. So, at physiological pH of blood it is mostly (90%) in unionised and diffusible form. But, alfentanil is highly protein bound and is of low lipid soluble. Thus, despite intense protein binding and lower lipid solubility diffusable fraction of alfentanil make its early penetration in CNS. This explains alfentanil's short latency to peak effect (early onset of action) after IV injection. Alfentanil's lower lipid solubility, compared with fentanyl, cause its less amount of uptake by the lipid rich brain tissue. This mechanism explains alfentanil's rapid offset of action.

The volume of distribution of alfentanil is 0.4 to 1 lit/Kg, whereas that of fentanyl is 3 to 6 lit/Kg. This is due to the low lipid solubility of alfentanil than fentanyl and causes less tissue accumulation of this drug. This mechanism is also largely responsible for the short elimination half-life of alfentanil in spite of its lower clearance rate than fentanyl (alfentanil's celarance rate is 4 to 9 ml/Kg and fentanyl's is 10 to 20 ml/min/Kg)

Noralfentanil is the major metabolic product of alfentanil. Other metabolites of alfentanyl metabolism are desmethylalfentanil, desmethyl noralfentanil and others. Any of the metabolites of alfentanil have little or no analgesic activity.

Sufentanil

It is often reported that sufentanil is 5 to 10 times more potent than fentanyl. The pKa value of it at physiological pH is same as that of morphine i.e. 8. Therefore only a small amount (20%) exists in the unionised form. After IV injection, first pass pulmonary extraction and retention of sufentanil in lungs are similar to those of fentanyl. However, this physiochemical property is of little clinical importance to sufentanil. This is because sufentanyl is twice as lipid soluble as fentanyl and is highly protein bound (93%) including α_1-acid glycoprotein. The major metabolic pathways of sufentanyl include N-dealkylation, oxidative N-dealkylation, oxidative O-demethylation and aromatic hydroxylation in liver. Major resultant metabolites of sufentanil include N-phenylpropanamide. Sufentanil is tightly bound to receptor. This property along with the high degree of plasma protein binding capacity and lower volume of distribution, are the probable explanation of sufentanil's shorter elimination half-life and shorter duration of effect as compared to fentanyl, despite the fact that it is highly lipophilic. Infact, after intraoperative infusion of sufentanil for less than 6 to 8 hours of duration, the effects of opioid would dissipate as least as rapidly as those produced by similar infusions of alfentanil.

Remifentanil (G187084B)

Remifentanil is the first ultrashort acting opioid for clinical use as a supplement to GA. The pharmacokinetic properties of remifentanil are best described by three compartmental model like fentanyl and its congeners such as alfentanil and sufentanil. Although, it is chemically related to the fentanyl congeners, but is structurally unique because of its ester linkage. Remifentanil's ester structure contributes its susceptibility to hydrolysis by plasma and tissue – nonspecific esterases, resulting in rapid metabolism of it. Like fentanyl it is not significantly metabolised or sequestreted in the lungs. Its metabolic clearance is several times greater than that of the hepatic blood flow. This explains its widespread extrahepatic metabolism, i.e. in plasma.

Remifentanil is a weak base with pKa value of 7. Its free base is formulated as a solution in glycine. As glycine has been shown to act as an inhibitory neurotransmitter and causes reversible motor weakness when injected intrathecally, so remifentanil is not approved for spinal or epidural use. Remifentanil is highly protein bound (70%), mainly α-acid glycoprotein. In blood, remifentanil is metabolised primarily by enzymes which are present in the erythrocytes. Therefore, it is not a substrate for pseudocholinesterase, and is not influenced by pseudocholinesterase deficiency. The primary metabolic path way of remifentanil is de-esterification to form a carboxylic acid, which have very low analgesic property and is inactive. This metabolite is excreted through urine, though its pharmacokinetic is not appreciably influenced by renal and hepatic failure.

Factors that alter the pharmacokinetics and pharmacodynamics of opioids

Factors that change the pharmacokinetics and pharmacodynamics of opioids are:

Age

Neonates exibit the reduced rate of elimination of opioid. This is due to the immature mechanism for metabolism of opioid resulting in extended elimination half-life of them. At the end of the 1st year this initial extended elimination of opioid quickly is normalised and at the end of 1st decade of life maximum opioid metabolic capacity is achieved (Fig. 14.22).

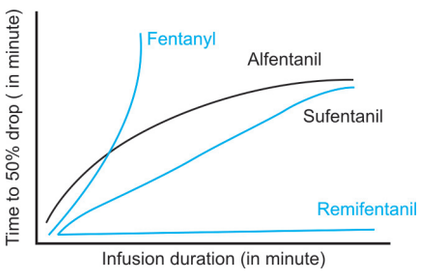

Fig. 14.22: The context sensitive half-time (CSHT) of different opioids. Among all the opioids the time necessary to achieve a 50% decrease in the plasma concentration (CSHT) of remifentanil is very short and is not influenced by the duration of the infusion

However, at the old age, the pharmacokinetic changes play a little role, rather the pharmacodynamic changes which are primarily responsible for the decreased dose requirement of opioid. The small pharmacokinetic change in old age that results in higher peak concentraion after a bolus dose of opioid is due to the low cardiac output and small central volume of distribution.

Weight

Pharmacokinetic parameters of opioids are more closely related to the lean body mass than the total body weight. This is because more than 90% of body's metabolic process is thought to occur in lean tissue. So, the dose regimens should be based on the lean body mass than the total body weight. But, estimation of lean body mass is a cumbersome calculation and total body weight closely relates to lean body mass. So, the dose regime based on total body weight is a clinically acceptable alternative.

Renal failure

Renal failure has major implication on the duration of action of morphine and meperidine. But, renal failure has less marked implication on the duration of action of fentanyl and its congeners.

Patient with renal failure develops very high level of M6G after morphine administration. M6G is μ-agonist with similar or greater potency than morphine. So, there is every chance of life threatening respiratory depression in renal failure patient after administration of morphine. Clinical paharmacology of meperidine is also significantly altered by renal failure. So, morphine and meperidine is not a good choice for renal failure patient. If they are used at all, then dose should be decreased and patient should be carefully monitored.

In contrast to morphine and meperidine, the clinical pahrmacology of fentanyl and its congeners is not grossly altered by renal failure. Decrease in plasma protein binding capacity increases the free fraction of fentanyl and its congeners and subsequently increases their action. Clearance of this fentanyl group of opioids is not affected by renal failure. Because although the metabolites of this group of opiod accumulate in renal failure, but they are inactive and non-toxic.

Pharmacokinetics and pharmacodynamics of remifentanil and sufentanil are unaltered by impaired renal function. But action of alfentanil is increased in renal failure.

Hepatic failure

Even though the liver is the primary responsible organ for metabolism of opioid, but the degree of liver failure that commonly observed in perioperative patient does not have major impact on pahrmacikinetic of most of the opioids, except liver transplantation. The possible explanation of this is the huge metabolic reserve of liver.

There are numerous ways by which liver disease can influence the pharmacokinetics of opioids. These are:

i. Reducing metabolic capacity (cyclochrome P-450 system and conjugation).
ii. Reducing hapatic blood flow.
iii. Reducing plasma protein binding capacity.
iv. Oedema and increasing the total body water – thus increasing the distribution characteristic of drug (volume of distribution).
v. Increasing metabolic capacity by enzymetic induction in early alcoholism.

Because of these numerous mechanism by which the liver disease may alter the pharmacokinetics of opioid, it can be difficult to predict exactly how an individual patient with liver disease will respond to opioid administration.

Pharmacokinetic of morphine is relatively unchanged by liver failure, because substantial amount of metabolism of morphine is done by kidney. On the other hand, the pharmacokinetic of meperidine is altered by liver failure. Like meperidine, alfentanil's pharmacokinetics is also altered by hepatic failure. Fentanyl's pharmacokinetic is not altered by hepatic failure. Remifentanil is perhaps the prototype example of an opioid whose pharmacokinetic is completely unchanged by liver disease.

Anaesthetic Technique

The routine anaesthetic induction is usually achieved by combining a loading dose of fentanyl (2 to 6 μg/Kg) with any sedative or hypnotic such as most commonly thiopentone or propofol and a muscle relaxant. The doses of sedative or hypnotic should be significantly reduced for induction of anaesthesia if opioids are used. Ketamine (0.5 to 2 mg/Kg) provide more haemodynamic stability compared with thiopentone or propofol after fentanyl or other opioids, especially in patient with cardiovascular diseases. Opioids can ameliorate or eliminate the cardiovascular responses to noxious stimuli, and thus control the changes in HR, BP, pulmonary capillary wedge pressure and other aspects of stress response that occur during laryngoscopy, intubation and surgery. Fentanyl and suffentanil should be administered 4 to 6 minutes, and alfentanil and remifentanil should be administered 1 to 2 minutes prior to any stress or stimulation. Once stress response is achieved and catecholamines are released, then opioids are less effective in maintaining haemodynamic stability. Response to laryngoscopy is better controlled with opioid than with esmolol.

After induction the anaesthesia is usually maintained by N_2O with O_2 and low concentration of potent inhalation anaesthetic, plus intermittent boluses (25 to 50 μg every 15 to 30 minutes) or continuous infusion (0·5 to 5 μg/hour/Kg) of fentanyl or other opioids. For short surgical procedures lower doses of fentanyl as bolus or infusion can be used. Premedication by BDZ may reduce the dose of this also supplementation. Propofol infusion may also be used during maintenance as a part of balanced anaesthesia.

Fentanyl plasma concentration of 1 to 2 ng/ml provide analgesia. But, levels of at least 2 to 3 ng/ml is usually required during surgery for adequate analgesia, if the N_2O as only inhaled agent is used. This plasma level can easily be achieved by initial bolus dose of fentanyl as 4 to 8 µg/Kg, followed by continuous infusion of 2 to 4 µg/Kg/Hour. This will often results in adequate plasma levels of 3 to 6 ng/ml.

Excessive doses of fentanyl or other congeners of it may result in postoperative respiratory depression. This is more likely, if fentanyl is given emperically without making titration with pain to some clinical endpoint. Somebody give additional fentanyl in the dose of 1 to 2 µg/Kg during closing of peritoneum to attenuate the hemodynamic response during extubation. But, it may lead to troublesome respiratory depression postoperatively. Another useful clinical approach to attenuate the haemodynamic responses during extubation is to wait for spontaneous ventilation to resume. Then, administer additional titrated dose to 25 to 50 µg of fentanyl to produce respiratory rate to 10 to 12 /min prior to tracheal extubation. Sufentanil, alfentanil, remifentanil are also can be used in place of fentanil.

Continuous Opioid Infusion

The continuous infusions of modern opioids is better alternatives to intermittent bolus technique. It maintains continuously a desired plasma level, a desired drug concentration at effected site and a steady state condition by replacing the drug in plasma that is removed by redistribution and metabolism.

The advantages of continuous infusion of newer opioids such as fentanyl and its congener over intermittent bolus doses are :

i better haemodynamic stability,
ii decreased total dose,
iii decreased side effects,
iv. more rapid recovery of consciousness,
v. less respiratory depression and less need for opioid antagonist,
vi. decreased discharge time.

The dose of continuous infusion of opioid is often reduced gradually to obtain a lower effective plasma concentration level and thus it avoides accumulation, when the redistribution of drug declines and the peripheral compartment comes to an equilibrium with the central compartment after being fully saturated. Computer assisted continuous infusion (computer controlled infusion pump – CCIP) deliver the drugs based on the pharmacokinetic data of a particular agent which feed in the computer. CCIP calculates the necessary infusion rate from the population based pharmacokinetic data of this particular drug to achieve the targated concentration and then CCIP gradually decreases the rate of infusion based on this particular drugs pharmacokinetics. Now CCIP is becoming increasingly popular.

High Dose Only Opioid Based Anaesthesia

The popularity of high dose only opioid based anaesthesia was first established by morphine and it has most commonly been employed in cardiac anaesthesia. But, this popularity of high dose only opioid anaesthesia had been gradually diminished due to several factors.

These include:

i. Lack of significant benefit from very large dose of opioid.
ii. Recent trend towards the 'first track' anaesthesia.
iii. Opioid as sole anaesthetic is not consistently reliable for seduction .
iv. The frequent need to intervene the hypotension caused by high dose opioid based anaesthesia with vasoactive agents.
v. Excessive post-operative respiratory depression.
vi. Intra operative haemodynamic instability, (only by high dose of morphine). So, morphine is not recommended for high dose opioid anaesthesia.

But, now newer opioids are administered in higher doses by continuous infusion with other anaesthetic agent and are still important and effective anaesthetics for patients undergoning cardiac and other extensive operations.

Fentanyl

Many different techniques are used for fentanyl with high doses. Initial bolus injection of fentanyl range from 5 to 75 µg/Kg. But there is little benefit of administering loading bolus doses of fentanyl more than 5 to 30 µg/Kg. These doses will establish plasma fentanyl concentration between 10 to 30 ng/ml, which is sufficient to provide stable hemodynamic condition during induction and intubation. Then continuous infusion in the dose of 0.1 to 1 µg/Kg/min is used for cardiac surgery.

This high dose fentanyl anaesthesia is very effctive and safe for paediatric cardiac surgery also. It reduces the incidence of intraoperative ventricular fibrillation in neonates undergoing cardiac surgery.

Alfentanil

Large doses of alfentanil (150 µg/Kg) may be used with or without thiopentone or propofol for induction of anaesthesia. But, only large doses of alfentanil is not suitable for induction. For cardiac surgery induction and maintenance of anaesthesia with alfentanil (25 to 75 µg/Kg loading dose plus 1 to 2 µg/Kg/min infusion) and propofol (0.25 to 1 mg/Kg bolus plus 80 to 100 µg/Kg/min) is relaible and stable.

Sufentanil

Sufentanil is superior to fentanyl for high dose opioid anaesthesia in cardiac surgery. The advantages are: more rapid induction, better attenuation of intubation reflexes, greater reduction of left ventricular stroke work, more stable haemodynamic condition intraoperatively and post-operatively, early recovery and extubation, and more decrease of BP than equivalent doses of fentanyl.

Dose: For induction sufentanil is used as bolus dose of 2 to 20 µg/Kg or infused over 2 to 10 minutes.

For significant cardiovascular disease etomidate is a better drug combination

with sufentanil. Alternative to etomidate, propofol can be used. Interestingly, sufentanil requirements become triple when midazolam is employed instead of propofol for induction. Etomidate (0.1 to 2 mg/Kg) plus sufentanil (0.5 to 1 µg/Kg) provide excellent haemodynamic stability during induction. Maintenance of anaesthesia by infusion of sufentanil (1 to 2 µg/Kg/H) in a balanced anaeshetic technique, achieves the advantages of an opioid-based anaesthesia and avoids prolonged opioid action post-operatively.

Remifentanil

In high dose opioid anaesthesia the datas regarding remifentanil are insufficient and nothing can be commented. Remifentanil has been employed in cardiac anaesthesia. The pharmacaokinetics of remifentanil were studied in patients undergoing CABG with CPB. The volume of distribution of remifentanil increases by 86% with institution of CPB. The elimination clearance also decreases by 7% for each degree of decrease of temperature below 37°C. So, infusion rate of remifentanil should be changed to maintain a constant plasma remifentanil level. It was shown that the induction with remifentanil (2 µg/Kg) together with propofol and maintenance with remifentanil at the dose of 0.25 to 0.5 µg/Kg/minute provided appropriate anaesthesia for minimally invasive CABG surgery.

Transdermal and Transmucosal Opioid Delivery

These two routes for opioid delivery system have enormous potentialities to improve the analgesic therapy by increasing the patient's compliance, reducing the pain associated with drug delivery, increasing the drug bioavailability, and increasing their analgesic efficacy.

Transdermal

The transdermal opioid delivery technique requires both the high water solubility (for passage through dermis) and high lipid solubility (for passage through corneum) property of the agent. Again the drug should also be of low molecular weight, highly potent (little amount causes clinical effect) and have no skin irritation effect.

At present, fentanyl (but no other opioid) is only available for transdermal delivery system. The advantages of it are no first-pass metabolism by the liver, improved patient's compliance, consistant analgesia, simple noninvasive type of delivery in nature and giving no pain during administration of drug.

After application of transdermal patch, plasma fentanyl level reach the plateau level very slowly extending between 8 to 16 hours and then also falls very slowly after removal of the patch as absorption of the drug which is deposited in the skin still continues. The half-life for decline of fentanyl level after removal of patch is 17 hours.

This transdermal route for administration of fentanyl is very effective for pain management in cancer patient. Faster acting route should be used initially during the acuteness of situation and then to switch over to the transdermal route. This transdermal drug delivery system can also be enhanced by iontophoresis (external electric current). So, patient receiving opioid by iontophoresis requires fewer additional opioid analgesic.

Transmucosal

This route for drug delivery can be achieved through oral, lingual, oropharyngeal, nasopharyngeal, sublingual, rectal or tracheobronchial mucosa (by inhalation). Among them the sublingual route is the most convenient for patients. But increased salivary secretion and subsequent swallowing of this saliva may convert this route to oral and prevent the increased systemic availability of drug due to hepatic fast pass metabolism. But this sublingual route eliminates hepatic first-pass metabolism increasing systemic availability and improves patient's compliance. As mucosa is rich in blood vessels and lymphatics, so absorption of drug will be faster and onset of action will be rapid if drug is administered through this route. This route of administration of drug is usually used for premedication, post operative pain management and treatment of chronic pain. Highly lipid soluble opioids such as buprenorphin, fentanyl and its congeners such as methadone are more effectively absorbed sublingually.

Sublingual buprenorphine

It is a potent, synthetic, mixed agonist and antagonist opioid with long half-life and readily absorbed by sublingual route. When the tablet of buprenorphin is swallowed, then it is almost completely metabolised by liver after absorption due to first pass metabolism. So, it is not used orally. But systemic bioavailability after sublingual route is 50% of that following IV administration. When sublingual buprenorpnin (0.3 mg) is given one hour prior to surgery then it provides a reliable preoperative sedation, intraoperative and post operative analgesia, similar to IM morphin. But as the onset of action is slow (3 hours), so the sublingual buprenorphin is not effective for immediate post-operative pain relief. The percentage of post-operative pain relief by sublingual buprenorphin is 80%, requiring supplementation for more higher success rate (if required).

Transmucosal morphine

Buccal morphine for analgesia is not promising (initial report was promising, but subsequent report disproved it). Low lipid solubility than other opioids make it a bad candidate for this route. In addition, bitter taste of morphine initiates salivation and subsequent swallowing which then become pray to first-pass liver metabolism. Bioavailability of sublingual morphine is 6 times lower than the equivalent dose by IM route.

Transmucosal fentanyl

The oral transmucosal preparation of fentanyl is made of fentanyl citrate which

is incorporated in a sweet lozenge. This is called oral transmucosal fentanyl citrate or OTFC. When consumed, it partly absorbed through oral mucosa and partly swallowed and absorbed through GI tract. But drug bioavailability is greater through oral transmucosal route than GI tract. The recommended dose of transmucosal fentanyl ranges from 5 to 15 μg/Kg depending on the desired degree of sedation and analgesia. Peak plasma concentration after OTFC administration occur at 15 to 30 min and then declines after 1 hour. The speed of onset of analgesia with OTFC is equal to that of IV morphine and elimination half-life is 7 hours which is similar to that of IV route also.

Unlike transdermal route, OTFC does not leave any depot in mucosa after it is removed. As some fraction of OTFC is swallowed and absorb through GI tract, so total systemic bioavailability is only 50% as buprenorphin, but much greater than sublingual morphine. Like systemic fentanyl, OTFC also causes nausea, vomiting and respiratory depression.

Other routes through which opioids can also be administered are intranasal, intratracheal inhalation and rectal.

INDIVIDUAL μ-RECEPTOR AGONIST

Morphine (Fig. 14.23)

Still now morphine is the gold standard μ-receptor agonist among all. So, against this gold standard agonist the potency of other newer opioid analgesic drugs are measured, though individual response may vary dramitically among μ-receptor agonists. As for example, some patients cannot tolerate morphin, but have no problem with equianlagesic dose of methadone. However, the actual underlying mechanism of it is still not known. Chemically, morphine is a phenanthrene alkaloid derivative. It is an agonist on μ, κ and δ receptors. But, its affinity for μ-receptors is much higher than that for the other two receptors. The effects of morphine, therefore, are primarily due to the result of μ-receptors activation. Like other opioids, morphine also appears to extent their effects by decreasing the intracellular Ca^{2+} concentration which in turn increases the K^+ conductance and causes hyperpolarisation of the excitable cell membrane. Thus, the decrease in membrane excitability may decrease both the pre and post synaptic responses (Table 14.17).

Due to difficulties, morphine is not synthesised still now in laboratory and is obtained from opium (extract of unripe seed capsule of poppy plant – papaver somniferum). The milky juice, opium, is dried and powdered to make opium powder which contain number of alkaloids and these alkaloids are divided into two distinct chemical classes, phenanthrenes and benzylisoquinolines. Morphine has minimal effects on the CVS. The predominant effect of morphine on CVS is orthostatic hypotension secondary to the decrease in systemic vascular resistance, at least part of which is mediated by histamin release. The drug may also cause bradycardia when administered in high doses. The principal effect of morphine on respiration is depression with decreased ventilatory reponses to hypoxia and hypercarbia. It also has the potent antitussive action. Bronchoconstriction may occur with the use of high doses of it.

Morphine is a potent analgesic agent and may also cause drowsiness, relief of anxiety and euphoria. Miosis is produced by this drug as a result of stimulation of the Edinger Westphal nucleus in brain. Seizures and muscular rigidity may occur with the use of high doses of morphine. It decreases the gastrointestinal motility and decreases the gastric, biliary and pancriatic secretion. It also increases the common bile duct pressure by causing the spasm of sphincter of oddi. The drug may also cause nausea, vomiting and constipation. The morphine increases the tone of ureters, detrusor muscle of bladder and sphincter. Thus, it may precipitate the urinary retention. Mild diaphoresis and pruritus may result from morphine due to histamine release. Morphine increases the secretion of ADH and may therefore lead to impaired water excretion and hyponatraemia. The drug may cause a transient decrease in adrenal steroid secretion (Table 14.18).

In general, morphine like other opioids are quickly absorbed through stomach and rectal mucosa. However, the more lipophilic newer opioids are absorbed by the nasal and buccal mucosa also. It adequately penetrates the tissue of spinal cord following epidural or intrathecal administration and produce profound analgesia which lasts for about 12 to 24 hours. As, the nature of morphine is more hydrophilic and absorption by the nerve tissue of spinal

Phenanthrene derivatives	*Benzoisoquinoline derivatives*
Morphine (10%)	Papaverine (1%)
Codeine (0.5%)	Noscapine (6%)
Thebaine (0.2%)	
Thebaine, papaverine and noscapine are nonanalgesic.	

Table 14.18: Causes of morphine induced hypotension

i.	Release of histamine.
ii.	Bradycardia due to vagal stimulation.
iii.	Decrease in sympatheitc tone (centrally mediated).
iv.	Arterial and venous dilatation (direct and indirect).
v.	Large doses and rapid administration.
vi.	Sequestration of blood in splanchnic area.

cord is less than the other highly lipophilic agents (fentanyl, sufentanil, etc), so rostral spread of morphin after intrathical administration in CSF is more and this increases the incidence of respiratory depression. In contrast, the highly lipophilic agents such as fentanyl and its congeners produce very localised effects on spinal cord due to their quick absorption in the local nerve tissue and produce more segmental analgesia than morphine. Bioavailability of morphine by oral route is only 25% due to its first-pass metabolism in liver. The shape of the time–effect curve of morphine vary with the different route of administration. Compared with other more lipid soluble opioids such as codiene, heroin, methodone, fentanyl congeners, etc, the morphine crosses the blood-brain barrier at a considerably lower rate and equilibrates very slowly between the plasma and CSF.

About 1/3 of the absorbed morphine is protein bound, predominantly to albumin. It does not persist in tissues 24 hours or tissue concentration remains very low after the last dose.

The major pathways for morphin metabolism is conjugation with glucuronic acid in the liver. The major metabolites are morphine-6-glucuronide (M6G), morphine-3-glucuronide (M3G) and small amount of morphine 3, 6, diglucuronide. Both the M3G and M6G compounds are polar, and cross the blood brain barrier easily to produce significant clinical effects. M6G is responsible for most of the morphine's analgesic activity in patient receiving chronic oral morphine.

Very little morphine is excreted unchanged through urine. It is eliminated by glomerrular filtration primarily as M3G. However, 90% of total excretion takes place during the first day.

Morphine should be used with caution in the presence of hepatic failure. Because, the drug may precipitate hepatic encephalopathy. Similarly, the use of morphine in patients with hypopituitarism may precipitate coma. Like other opioids, it also decreases the apparent MAC value of coadministered volatile agents. Most of the actions of this drug are reversed by naloxane, although the analgesia afforded by the epidural administration of morphine is well preserved after the administration of naloxone. Morphine cannot be removed by haemodialysis or by peritoneal dialysis.

Meperidine

It is a synthetic phenylpiperidine derivative and predominantly μ and κ receptor agonist. It was first synthesised as an atropine substitute, in 1939, and has same actions like anticholinergics. So though chemically unrelated to morphine, still it has many similar actions like it and has been shown to interact with many opioid receptors. Its actions can also be blocked by naloxone. The mechannism of action of mepiridine is same as morphine. It decreases the intracellular Ca^{2+} concentration which in turn increases the K^+ conductance and causes the hyperpolarisation of the excitable cell membrane. Thus, the decrease in membrane excitability by meperidine results in decrease of both pre and post synaptic responses (Fig. 14.24).

Like morphine, meperidine also causes orthostatic hypotension. This is due to the combination of effect of histamine release and α-adrenergic blockade that it produces. The drug also has a mild quinidine like effect and anticholinergic properties (dry mouth, tachycardia, blurred vision etc). Meperidine is a potent respiratory depressant, having a greater effect on tidal volume than on the respiratory rate. It obtunds the ventilatory response to both hypoxia and hypercapnia. It has little antitussive action and chest wall rigidity may occur.
