
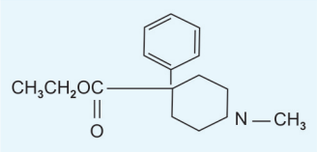

Fig. 14.24: Meperidine

Meperidine is 1/10 as potent as analgesic than morphine. It appears to cause more euphoria, but less nausea and vomiting than the equipotent dose of morphine. Miosis and corneal anaesthesia may follow the topical use of this drug. In common with other opioids, meperidine decreases the rate of gastric emptying. This drug appears to cause less marked increase in the bile duct pressure and less depression of the intestinal activity (and therefore constipation) than equipotent doses of morphine. This drug is less responsible for increase in the ureteric tone. It may increase the amplitude of contractions of the pregnant uterus.

The important differences between the meperidine and morphine are:

(i) Meperidine has dose to dose 1/10 analgesic potency of morphine.
(ii) After IM injection of mepridine, the onset of action is more rapid. But the duration of action is shorter (2 to 3 hours) than morphine.
(iii) It does not effectively supress the cough.
(iv) Spasmodic action on smooth muscles by mepridine is less marked. So miosis, constipation, urinary retentions etc. caused by meperidine are less prominent than morphine. Liability to induce biliary spasm by meperidine is low.
(v) As mepiridine is equally sedative and euphoriant like morphine, so it has similar abuse potential.
(vi) The degree of respiratory depression produced by meperidine at equianalgesic doses is equivalent to morphine.
(vii) It causes less histamine release. So, it is more safer in asthamatics than morphine.
(viii) It has also local anaesthetic actions. Corneal anaesthesia may seen after systemic administration.

It is absorbed by all routes, but absorption may be erratic after intramuscular injection. The adult oral dose of meperidine is 50 to 150 mg at 4 hours interval. The

corresponding dose of meperidine by the IM route is 25 to 150 mg and by intravenous route is 25 to 100 mg. Meperidine may also be administered via the epidural route and a dose of 25 mg is usually employed. The drug acts within 15 minutes when administered orally and within 10 minutes when administered intramuscularly. The duration of action is 2 to 4 hour. The bioavailability of meperidine when administered orally is only 40 to 70%. It is due to the significant fast pass metabolism of it by liver. The drug has a bioavailability of 100% when administered intramuscularly.

Meperidine is 50% protein bound in the plasma. The drug crosses the placenta and the mean cord blood concentration at delivery is 70 to 90% of the maternal blood concentration.

Meperidine is mainly metabolised in liver. It is hydrolysed to meperidinic acid which in turn is conjugated. Meperidine is also N-demethylated to normeperidine which may then be hydrolysed to normeperidinic acid and subsequently conjugated. This conjugated meperidinic and normeperidinic acid is excreted through bile and kidney. Normeperidine may accumulate in the presence of renal or hepatic failure. It has 50% analgesic potency of the parent compound and marked convulsant properties. Meperidine also appears to be effective in the treatment of post anaesthetic shivering.

Severe reactions may follow after the administration of meperidine to a patient, being treated with MAO inhibitors. The reactions are delirium, hyperthermia, hypo or hypertension, rigidity, convulsion, coma and death. This reaction is due to the blockade of neuronal reuptake of serotonin by meperidine and the resultant serotonergic over activity at the synaptic level. So, meperidine and its congener (diphenoxylate, loperamide), dextromethorphan and tamadol should not be used in patient taking MAOI. However, similar interaction wtih other currently used opioids have not been observed clinically.

Promethazine enhances the meperidine induced sedation. Amphetamine enhance the analgesic property of meperidine while counter acts its sedation effect.

Tramadol

Tramadol is a synthetic codeine analogue with dual mechanism of action. It is a weak μ-receptor agonist and to lesser extent δ and κ-receptor agonist. Part of its analgesic effect is produced by the inhibition of reuptake of norepinephrine and serotonin. So, inhibition of pain perception partly involves the activation of descending serotonergic and noradrenaergic pathways. Tramadol as analgesic is 1/5 to 1/10 as potent as morphine and can be given by various parentral routes. So, in the treatment of mild to moderate pain it is effective. But, for the treatment of severe chronic or acute pain tramadol is less effective. Tramadol has no clinically significant cardiovascular effects after IV administration. Respiratory rate, minute volume and P_aCO_2 remain essentially unchanged following IV administration of therapeurtic doses of this drug. It has no demonstrable effect on the bile duct and sphincter activity. The tramadol is 20% protein bound in the plasma and 80% of the administered dose of it crosses the placenta. The bioavailability of tramadol following oral administration is 70 to 100%.

The primary O-demethylated metabolite of tramadol is 2 to 4 times as potent as the parent drug and may account for part of its analgesic effect. The tramadol is supplied as racemic mixture. The (+) enantiomer binds to the μ-receptor and also inhibits the serotonin uptake. While the (–) enantiomer only inhibits the norepinephrine uptake and stimulates the adrenergic receptor.

The recommended dose of tramadol ranges from 50 to100 mg after every 4 to 6 hours interval, with maximum daily dose of 400 mg through all the routes of administration. The paediatric dose of tramadol is 1 to 2 mg/Kg at 4 to 6 hours interval. This compound undergoes hepatic metabolism and renal excretion with elimination half-life of 6 hours. It is less respiratory depressant compared with equianalgesic dose of morphine and the degree of constipation is less than that which is seen after the equivalent dose of codeine.

Its abuse potential is unclear. It can cause seizure by reducing the seizure threshold. Because of its inhibitory effect on serotonin uptake, tramadol should not be used in patient taking MAOI. The use of tramadol is not recommended in patients with end stage renal failure. The dosage interval of tramadol should be increased to 12 hours in patients with renal or hepatic failure. The drug is not licensed for intraoperative use as it may enhance intraoperative recall during N_2O anaesthesia. Tramadol appears to be effective in the treatment of postoperative shivering. It can be slowly removed by haemodialysis.

Fentanyl and its Congeners (Sufentanil, Alfentanil, Remifentanil)

Fentanyl

Fentanyl is a synthetic amine opioid and is structurally related to the phenyl piperidine nucleus. It is a pure μ-receptor agonist and 100 times more potent than morphine as an analgesic in an equivalent doses (Fig. 14.25).

The mechanism of action of fentanyl is same as that of morphine and meperidine. The adult dose of fentanyl for premedication by the intramuscular route is 50 to 100 μg. For the induction or supplementation of general anaesthesia an intravenous dose of 1 to 100 μg/kg may be used. Fentanyl may also be administered via the epidural

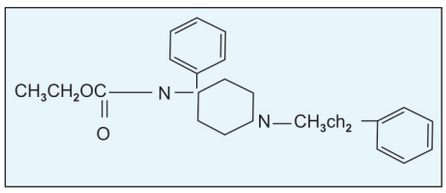

Fig 14.25: Fentanyl

or spinal route and a dose of 25 to 50 µg is usually employed. The drug acts within 2 to 5 minutes when administered intravenously. A small dose of fentanyl has a duration of action of 30 to 60 minutes. Whereas high doses (> 50 µg/Kg) may be effective for 4 to 6 hours.

It has rapid onset and rapid termination of action after a small bolus dose and has relative CV stability. Recovery from analgesic effect of fentanyl is very fast. However, with large dose or after prolonged infusion, the action is prolonged and recovery is delayed like long acting opioids. All the effects of fentanyl are like pure µ-receptor agonist such as morphine. Muscle rigidity such as chest wall rigidity (wooden chest phenomenon) is also common after IV bolus doses of fentanyl and its congeners. This muscle rigidity is centrally mediated and may be an effect of the drug on µ-receptors, located on GABA-nergic interneurones. Rigidity can be mitigated by slower administration (avoiding bolus) or by pretreatment with nonopioid anaesthetics such as IV inducing agents, e.g thiopentone, propofol, etc. or by muscle relaxants. High dose of fentanyl also can cause neuroexcitation.

The most significant cardiovascular effect of fentanyl is bradycardia which is of vagal in origin. Cardiac output, mean arterial pressure, systemic and pulmonary vascular resistance and pulmunary capillary wedge pressure are unaffected or decreased by the administration of fentanyl. It also obtunds the cardiovascular responses to laryngoscopy and intubation (Table 14.19).

Fentanyl is a potent respiratory depressant opioid causing decrease in both the respiratory rate and tidal volume. It also diminishes the ventilatory response to hypoxia or hypercarbia. The drug is also a potent antitussive agent. It causes minimal release of histamine. Bronchospasm is thus rarely precipitated by the drug.

Fentanyl though is 100 times more potent as an analgesic than morphine, but has little hypnotic or sedative activity. Miosis is produced as a result of stimulation of the Edinger Westphal nucleus. There have been several reports of seizure like motor activity, occuring in patients who receives fentanyl. However, no epileptic like spike wave patterns are demonstrable on EEG after the use of fentanyl.

Fentanyl decreases the gastrointestinal motility and decreases the gastric acid secretion. It also doubles the CBD pressure by causing spasm of the sphincter of Oddi. The drug increases the tone of ureters, detrusor muscle of bladder and vesicular sphincter. High doses of fentanyl will obtund the metabolic stress response to intubation and surgery. Unlike morphine, fentanyl does not increase the activity of ADH. Like other opioids fentanyl also decreases the apparent MAC value of co-administered volatile anaesthetic agents and increases the effect of nondepolarising muscle relaxants. The drug is pharmaceutically incompatible with thiopentone. So, they should not be mixed in the same syringe. It is unknown whether fentanyl is removed by hemodialysis or not.

As fentanyl is highly lipid soluble, so it rapidly crosses the blood-brain barrier and an equilibrium between the plasma and CSF concentration is rapidly approximated within 5 minutes. Then the concentration of fentanyl in plasma and CSF rapidly decline due to redistribution of it from low volume but highly perfused group of tissues (brain) to other high volume but less perfused group of tissues such as muscle and fat. The short duraion of action of a single dose of fentanyl is due to this quick distribution and redistribution to other tissues from brain tissues, rather than quick metabolism and elimination of it through liver and kidney. So this is like thiopentone, propofol and ketamine. When saturation and equilibrium of the high volume but less well perfused tisues occurs, then duration of fentanyl's effect prolongs and elimination half-life reaches to 3 to 4 hours.

Therefore, after higher doses or prolonged infusions fentanyl becomes a long

Table 14.19: Doses of commonly used opioids in different routes

Drugs	*Use*	*Route*	*Doses*
Morphine	Premedication	im	0.04 - 0.25 mg/Kg
	Intraoperative	iv	0.2 - 1mg/Kg
	Post-operative	im	0.04 - 0.25 mg/Kg
		iv	0.02 - 0.1 mg/Kg
Meperidine	Premedication	im	0.5 - 1.5 mg/Kg
	Intraoperative	iv	1 - 2 mg/Kg
	Post-operative	im	0.5 - 1.5 mg/Kg
		iv	0.2 - 0.5 mg/Kg
Fentanyl	Intraoperative	iv	1- 100 µg/Kg
	Post-operative	iv	0.5 - 2 µg/Kg
Sufentanil	Intraoperative	iv	0.2 - 30 µg/Kg
Alfentanil	Intraoperative	iv	5 - 100 µg/Kg
	Maintenance	iv	0.5 - 3 µg/Kg/min
Remifentanil	Intraoperative (loading dose)	iv	1 µg/Kg
	Maintenance	iv	0.5 - 10 µg/Kg/min

Opioids have large therapeutic window. This is indicated by wide range of doses of opioids. The doses of opioids also depends on other anaesthetics which are administered simultaneously. During IV infusion of it, tolerance develops rapidly, usually within 2 to 3 hours and infusion rates should be increased gradually. For obese patients, the doses of opioids should be calculated according to their lean body weight or ideal body weight but not on total body weight.

acting opioid. Fentanyl is absorbed orally, but bioavailability by this route is only 33%. The drug is 90% protein bound in the plasma. Fentanyl undergoes both the hepatic metabolism and renal excretion. It appears to be metabolised primarily by N-dealkylation to norfentanyl with subsequent hydroxylation of this. The parent compound is metabolised to hydroxypropionyl derivatives. The drug may also undergo hydroxylation and amide hydrolysis in liver. Some entero hepatic circulation of the drug may also occur. The 10% of an administered dose of fentanyl is excreted in the urine. The elimination half-life of fentanyl is 1.5 to 6 hours.

Sufentanil

All the pharmacokinetic and pharmacodynamic properties of sufentanil is similar to that of fentanyl, except it is 10 times more potent than fentanyl (i.e 1000 time more potent than morphine). The chemical structure of sufentanil is similar to that of fentanyl and is related to phenylpiperidine nucleus. The pharmacokinetic properties of sufentanil are also adequately described by a three compartmental model like fentanyl. After IV injection, the first-pass pulmonary extraction, retention and release of sufentanil are also similar to those of fentanyl (Fig. 14.26).

The intravenous dose of suphentanil is 0.5 to 50 µg/Kg. The dose via the epidural route is 10 to 100 µg. The optimal postoperative dose of sufentanil is 30 to 50 µg. When administered intravenously, the drug acts within 1 to 6 minutes and the duration of effect is 0·5 to 8 hours. Though the drug is normally administered intravenously, it is 20% absorbed when

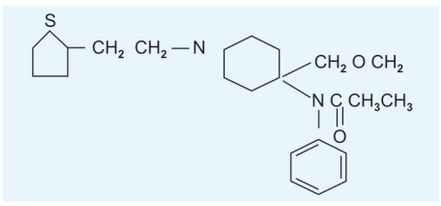

Fig. 14.26: Sufentanil

administered transdermally. Sufentanil is 92% protein bound in the plasma, predominantly to α-1 acid glycoprotein. It is twice as lipid soluble as fentanyl. The major metabolic pathway of sufentanil include N-dealkylation, oxidative O-demethylation and aromatic hydroxylation. Major metabolites of sufentanil include N-phenyl propanamide. The 60% of an administered dose of sufentanil appears in the urine and 10% in the bile. The elimination half-life of sufentanil is 119 to 175 minutes.

Like other opioids, sufentanil also decreases the MAC value of the co-administered volatile anaesthetic agents by 60 to 70%. The drug should be used with caution in the presence of renal or hepatic failure, although the kinetics appear to be unaltered.

Remifentanil (G 187084 B) and alfentanil

They are also synthetic pure µ opioid receptor agonist, related to phenylpiperdine nucleus. The pharmacological properties of these two opioids are same as fentanyl, except few differences. These compounds have very rapid onset and predictable termination of effects. The potency of remifentanil is equal to fentanyl but 20 to 30 times greater than that of alfentanil. Analgesic effect of both of these compounds occur within 1 to 1.5 minutes after IV administration. Alfentanil is metabolised in liver and elimination half-life is 1to 2 hours. Remifentanil is unique in that it is metabolised by plasma esterase. So, elemination of remifentanil from body is independent of the hepatic metabolism and renal excretion and the elimination half-life of it is only 8 to 20 minutes. Therefore, there is no prolongation of effect of remifentanil after repeated doses or prolonged infusion. After 3 to 5 hours of infusion of remifentanil, recovery of respiratory function can be seen within 3 to 5 minutes. While full recovery from all the effects of remifentanil occur within 15 minutes. The major metabolite of remifentanil i.e. remifentanil acid which is 2000 to 4000 times less potent than the parent compound and is excreted through kidney. Remifentanil is ideally suited for short surgical procedure where rapid recovery is the goal. It is also very useful in longer procedure where rapid emergence from anaesthesia is important such as neurosurgery.

However, due to short duration of action, remifentanil alone is a poor choice for post-operative analgesia. It is generaly given by continuous intravenous infusion, because its short duration of action make bolus administration impractical.

Alfentanil can be used intraspinally. But remifentanil is not being used intraspinally, because glycine used in the commercial preparation as preservative can cause temporary motor paralysis.

Individual Opioid with Both Agonistic and Antagonistic Activity

The opioids with both agonistic and antagonistic property are usually produced by alkylation of the piperidine nitrogen and addtion of a three carbon side chain such as propyl, allyl or methylallyl to the structure of morphine. Buprenorphin is a partial agonist at the µ-receptor but antagonist at the κ-receptor. The other compounds are µ-antagonists and full or partail agonists at the κ-receptors. Agonists and antagonistic opioids are less prone to abuse, because they cause less euphoria and are associated with less drug seeking behaviour and physical dependence.

Pentazocine

It is a benzomorphan derivative of morphine and have both agonistic action on κ-receptor and weak antagonistic action on µ-receptor. So, it is an agonistic and antagonistic opioid.

CNS effect of pentazocine is like morphine, including analgesia, sedation and respiratory depression. It is ½ to ¼ as potent as morphine. The analgesic action of pentazocine is due to its agonistic action

on κ-receptor. Higher doses of it (60 to 90 mg) elicit dysphoric and psychotomimetic effect. The possible mechanism for this side effect caused by pentazocine is the activation of supraspinal κ-receptor by it which can be reversed by naloxone. Ceiling to both the analgesia and respiratory depression effect occur after administration of 30 to 70 mg of pentazocine.

Pentazocine depresses the myocardial contractility, but causes ↑BP, ↑HR, ↑SVR, ↑pulmonary artery pressure, ↑left ventricular end diastolic pressure and ↑cardiac work load (left ventricular work index). It also increases the blood catecholamine level. All these changes show that pentazocine increases the myocardial O_2 demand and may precipitate the myocardial ischaemia. Pentazocine appears to cause less *nausea* and vomiting and less marked rise in biliary tract pressure than an equivalent dose of morphine. The drug decreases both the gastric and small intestinal motility.

Though pentazocine has weak antagonistic action on μ-receptor, but it does not antagonise the respiratory depression effect produced by morphine. But, when pentazocine is given in patient dependent on morphine or other μ-receptor agonist, then it may precipitate withdrawl or reduce its analgesic effect.

However, the potentiality for abuse of pentazocine is less than that of morphine, but prolonged use can lead to physical dependence on it. The drug is also well absorbed when administered orally. Orally the bioavailability of pentazocine is only 20%. It is due to the significant hepatic first-pass metabolism of it. The adult oral dose of pentazocine is 50 to 100 mg given at 3 to 4 hours interval. The corresponding parenteral dose of it is 30 to 60 mg at 3 to 4 hours interval. The drug is irritant when injected intramuscularly or subcutaneously. The pentazocine acts within 2 to 3 minutes when administered intravenously and within 20 minutes when administered intramuscularly. The duration of action of this dose of pentazocine is 3 to 4 hours. Metabolism of pentazocine occurs in the liver by oxidation and glucuronidation. However, 60% of the administered dose of it is excreted though the urine within 24 hours. Among this 2 to 10% remains unchanged. The elimination half-life of pentazocin is 2 hours and can be removed by hemodialysis (Table 14.20).

Buprenorphine

It is a semisynthetic, highly lipophilic opioid which is derived from thebaine. It is a partial μ-receptor agonist, but dissociates very slowly from the later leading to prolonged analgesia. Buprenorphin substitutes for morphin at the low level of dependence on later, but precipitate withdrawal in highly dependent subject. Thus it reflects its partial agonistic action at the μ-receptor. Being a partial agonist, buprenorphine like other agonist-antagonistic group may antagonise the effects of morphine and cause symptoms of abstinence in patient who is receiving pure μ-agonist (morphine like drug) for several weaks. Thus, it restricts its usefulness if other μ-agonists are used. Buprenorphine also appears to have a high affinity for κ-receptors which are antagonistic in nature.

The structure of buprenorphine is similar to morphine but is 33 times more potent than it. Its high lipophilicity and high receptor affinity causes its receptor's association and dissociation action very slow. So, it possesses much longer half-life which is near about 160 minutes (fentanyl half-life is 6 minutes). Hence, plasma level of buprenorphine does not correspond to the CNS effect. Buprenorphine's onset of action is slow. Its peak action may not occur untill 3 hours. Its duration of action is also prolonged (≤ 10 hours). Metabolism of it occurs in the liver with biliary excretion of most of its metabolites such as buprenorphine-3-glucuronide, nor-buprenorphine and buprenorphne which are less potent and have lower affinities for the μ-receptor. Thus, most of the drug is excreted through faeces.

Buprenorphine produces analgesia and other CNS effects like morphine. It has minimal cardiovascular effects. The heart rate may decrease by upto 25% and the systolic blood pressure may fall by 10%, following the administration of it. Buprenorphine produces respiratory depression and has antitussive effects, similar to that produced by morphine. The respiratory depressant effects of buprenorphin is not completely reversed by even larger doses of naloxone. This is probably because of more tight binding of buprenorphine with opioid receptors. Doxapram, however, will do so. Severe respiratory depression has occured when BDZ have been coadministered with buprenorphine. It may cause the release of tryptase and histamine from the lung parenchymal mast cells and may increase pulmonary vascular resistance. It also produces miosis and decrease cerebral glucose metabolism by upto 30%.

It is well absorbed by most of the routes. The recommended analgesic dose of buprenorphin is 0.3 to 0.4 mg by oral, IM, IV or sublingual route for premedication, as the analgesic component in balanced anaesthesia and for postoperative pain control. The drug is also effective when

Table 14.20: Haemodynamic effects of opioid agonist - antagonist compared with morphine

Drug	*Cardiac workload*	*Blood pressure*	*Heart rate*	*Pulmonary artery pressure*
Morphine	↓	↓	↓	↓
Pentazocine	↑	↑	↑	↑
Buprenorphine	↓	↓	↓	↓
Butorphanol	↑	↑	=	↑

administered by the epidural route and a dose of 0.3 mg has been recommended for this. The drug is well absorbed when administered orally, but undergoes a significant first-pass liver metabolism. Therefore, the sublingual route is preferred than oral when parenteral route is not used. The bioavailability of buprenorphine is 40 to 90% when administered intramuscularly and 44 to 94% when administered sublingually. It is not removed by haemodialysis. Opioid withdrawal symptoms develop slowly (5 to 10 days) after buprenorphine is discontinued following long term administration.

Butorphanol

Chemically it is a morphine congener with profile of action similar to that of pentazocine. Like pentazocine it is agonist at κ-receptor which is responsible for its analgesic effect, but more potent than pentazocine (2 mg butorphanol = 30 mg pentazocine). Its activity at μ-receptor is either antagonistic or partially agonistic. However, the antagonistic property of butorphanol at μ-receptor are weak and do not usually interfere with the use of other opioid agonist in anaesthesia. It is 5 to 8 times as potent as morphine.

In healthy subject, the butorphanol produce no or minimal CVS changes. But, in cardiac diseased patient the butorphanol causes changes similar to that produced by pentazocine. It causes ↑cardiac index, ↑left ventricular end-diastolic pressure, ↑pulmonary artery pressure. So, the butorphanol is not useful in patient with CCF or at increased risk for myocardial ischaemia or history of previous MI. The major side effects of butorphanol are drowsiness, weakness, sweating, nausea and CNS stimulation. While the incidence of psychotomimetic side effects (quantitatively) of butorphanol is lower than that of equianalgesic dose of pentazocine, but they are qualitatively similar.

Butorphanol is subject to less abuse and has less addictive potential. It is only available in parenteral form. The recommended dose of butorphanol is 1 to 4 mg IM or 0.5 to 2 mg IV.

Opioid Antagonists

The antagonists of opioid receptors (specific or non specific) are the important armours for scientific research of opioids and its receptors. In early 1950, nalorphine and levallorphan was evaluated as opioid antagonist for clinical use, though they have agonistic action. But later they were discarded due to the high incidence of side effects. Then, in 1960, naloxone was introduced and had established its efficacy as an antagonist for opioid induced respiratory depression.

Classification of agonist – antagonist opioids

i. Not used as analgesic
   Nalorphin, Levallorphan
ii. Used as analgesic
   Pentazocine, Nalbuphine
iii. Partial/weak agonists
   Buprenorphine, Butorphanol
iv. Pure antagonist
   Naloxone, Naltrexone

Naloxone (Fig. 14.27)

Slight minor changes in the structure of an opioid molecule can convert its agonistic action into an antagonistic action on opioid receptors. The most common example of such a substitution is N-methyl group which is a typical for μ-receptor agonist. So, such substitution transforms morphine to nalorphine; lavorphanol to levallorphan and oxymorphone to naloxone or naltrexone. Some of these substituted opioid congeners are completely competitive antagonist at μ-receptor, but agonist at κ-receptor. So, they can be used as agonist-antagonistic opioid. Hence, these nalorphine, levallorphan and nalbuphine, etc, can also be used as analgesics like pentazocine, butorphanol and buprenorphin, because though they are antagonistic at μ-receptor, but are agonistic at κ-receptor. However, some of the substituted opioid congeners have antagonistic action on all the opioid receptors without any agonistic action on any opioid receptor. These are naloxone, naltrexone, etc. Later specific opioid receptor antagonists were developed which are not congener of opioids for example, nalmefen which is pure μ-receptor antagonist. Norbinaltorphimine and naltrindole is specific κ and δ-receptor antagonist, respectively.

Thus, naloxone chemically is a substituted oxymorphone derivatives. Its mode of action is a competitive antagonist at μ, κ and δ receptors. Naloxone itself produce no effects. It means it has no intrinsic effects like morphin when it combines with opioid receptors independently or if opioids with μ-receptor agonistic action is not administered previously. If opioid is used previously, then naloxone rescue the respiratory depression effect of opioids and in addition, it can reduce or reverse the opioid induced analgesia, nausea, vomitting, pruritus, urinary retention, rigidity, biliary spasm, etc. Hence, these drugs may precipitate the acute withdrawl symptoms in opiate addicts. The mechanism of action is that it blocks all the opioid receptors and prevents the manifestation of actions of opioid agonist, those work through these receptors.

In shock and certain form of stress when the endogenous opioid system is activated, then the opioid antagonist naloxone also have visible consequences. It attenuates the hypotension associated with shock of diverse origin including that caused by anaphylaxis, endotoxin, hypovolaemia, etc. Naloxone also apparently acts to antagonise the actions of endogenous opioids that are mobilised by pain,

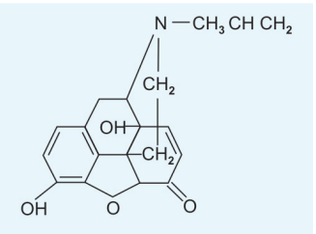

Fig 14.27: Naloxone

stress and that are involved in the regulation of blood pressure by CNS.

However, high dose of naloxone (12 mg) alone have intrinsic agonistic effect. But this is of little clinical significance. Dose of naloxone in excess of 0·3 mg/Kg show increased systolic blood pressure.

Endogenous opioid peptides usually participate in the regulation of pituitary secretion by exerting tonic inhibitory effects on the release of certain hypothalamic hormones. Thus, administration of naloxone by removing this inhibition increases the secretion of corticotrophine releasing factor and elevates the plasma concentration of ACTH. Thus, the elevated ACTH increase the plasma concentration of cortisol and catecholamines.

Naloxone can also be administered through IV, IM or subcutaneous route. But the drug should be administered intravenously in small incremental doses, until the desired end point of reversal of respiratory depression without reversal of analgesia is reached. This is because at different blood level naloxone anatgnise the different actions of morphine. Small dose (0·4 to 0·8 mg) of naloxone given 1M or IV does not reverse the μ-receptor mediated analgesic effects of opioids. But it reverses only the respiratory depression effect and so respiratory rate increases within 1 to 2 minutes. Higher dose of naloxone is needed to antagonise the respiratory depression effect of buprenorphine. Sedative effect of opioid is also reversed and blood pressure, if depressed, returns to normal. If IV access is not available, then naloxone in dose similar to that given by IV is effectively absorbed after intratracheal administration. Naloxone also reverses the psychotomimetic and dysphoric effects of agonist-antagonistic agents such as pentazocine. But for this much higher doses are required.

Opioids decrease the sympathetic outflow through their action on CNS (brain and spinal cord). α-adrenergic agonist (clonidine) and opioids perform this through their action on the preganlionic sympathetic neurons. Opioid antagonists block this action of opioids and increase sympathetic outflow. This explain clonidine's effectiveness in blocking haemodynamic stimulation following naloxone.

Side effects like increased HR, BP and more serious complication like pulmonary oedema may follow the administration of naloxone due to this sympathetic stimulation. So, opioid reversal by naloxone should be avoided in patient in whom the increased HR and BP could be detrimental. Patient with coronary artery disease could be adversely affected by naloxone, because of this sympathetic stimulation. Opioid reversal by naloxone may be hazardous in patient with pheochromocytoma.

The onset of action of naloxone after IV administration is 1 to 2 minutes and duration of effect is about 30 to 60 minutes. Although naloxone is rapidly absorbed through GI tract (91%), it is almost completely metabolised by liver before reaching the systemic circulation (only 2%) and so it must be administered parenterally. It is mainly metabolised by glucuronidation.

Recurrence of respiratory depression after administration of naloxone is due to its short half-life and as well as reuptake of opioid by μ-receptor from peripheral compartmental tissues. So, renarcotisation occurs more frequently after the use of naloxone during reversal of the longer acting opioids such as morphine.

Naloxone acts through μ, δ and κ-receptor, but has greatest affinity on μ-receptor, through which anti-respiratory depression and antianalgesic action is mediated. It is unlikely that analgesia is always spared. But, careful titration by naloxone often restore adequate spontaneous ventilation with out reversal of analgesia.

The other probable conditions where naloxone can be used are :

i. Hemorrhagic shock.
ii. Septic shock.
iii. Post anaesthetic apnoea in infants where opioid is not used.
iv. Primary apnoea and periodic breathing associated with hypoxia.
v. In the treatment of alcoholism (alcohol interacts with many neurotransmitters and endogenous opioid system in the brain. Mesolimbic dopamine system is mainly affected and the links between alcohol and opioid system play an important role in alcohol addiction).
vi. To reverse the effects of some non-opioid CNS depressants (BDZ and barbiturates → opioid – GABA receptor interactions).
vii. To ameliorate the neurological deficit in spinal cord and brain trauma.
viii. To reduce the obesity and clonidine overdose.
ix. To diagnose the suspected opioid overdose.

Naloxone may also partially antagonise the ketamine and N_2O induced analgesia.

Sometimes naloxone enhances the analgesia and morphine requirements is significantly less in patient receiving it. Proposed possible mechanism for this paradoxical effect of naloxone is the enhanced release of endogenous opioids by it and up regulation of opioid receptors.

Naltrexone

It is a μ , δ and κ-receptor antagonist. It differs from naloxone by:

i. Naltrexone is longer acting,
ii. Its half-life is 8 to 12 hours,
iii. It can be used by oral route.

Naltrexone is not subjected to much first-pass hepatic metabolism as naloxone. So, its duration of action approaches 24 hours after moderate oral dose.

Oral naltrexone in the dose of 5 to 10 mg reduces the severity and frequency of respiratory depression, pruritus, nausea and vomiting assocated with morphine without diminishing analgesia. Like naloxone, naltrexone also stimulate CVS.

It is mainly used for the treatment of opium addiction and alcoholisms due to its longer acting and effectiveness by oral route.

Nalmefene

Its structure is similar to naloxone and naltrexone, but has greater affinity to μ than δ and κ-receptor. It is long acting both after oral and parenteral administration. Bioavailability after oral administration is 50%. Plasma half-life varies from 3 to 8 hours. It produces little intrinsic effect when administered by itself without previous adminstration of opioids.

Interaction Between Inhaled Anaesthetic and Opioid

During N_2O administration cardiovascular function is usually preserved. But N_2O-opioid combination cause ↓CO, ↓HR, ↓BP and ↑SVR, ↑PVR, and ↑coronary vascular resistance, resulting in impaired coronary blood flow. Deterioration of cardiac function with N_2O-opioid combination is due to increase in after load (↑SVR and ↑PVR). This deterioration is not evident during routine monitoring of BP due to elevated SVR.

Analgesia produced by N_2O is mediated partly by opiodergic system and cause infra-additive interaction between N_2O and opioid. So the advent of short acting IV anaesthetics (e.g. propofol) and volatile anaesthetics with blood-gas partition coefficient equal to that of N_2O (e.g sevoflorane) has recently decreased the popularity of N_2O in balanced anaesthesia. Except halothane, combination of low concentration of other volatile anaesthetics and opioid is beneficial for compromised ventricular function. New volatile anaesthetics such as isoflurane, desflurance, sevoflurane cause only little myocardial depression.

Low concentration of isoflurane and high dose of sufentanil is very effective and safe to treat the intraoperative hypertension without producing myocardial depression and with out decreasing CO in coronary artery surgery. Halothane plus opioid anaesthesia to control hypertension produce ↓BP and ↓CO which exacerbate regional myocardial hypoperfusion and increase the lactate production. Some potent newer inhaled anaesthetics (isoflurane, desflurane) increase sympathetic nervous system activity, but this can be attenuated by opioid.

Interaction Between Sedative – Hypnotic and Opioid

BDZ is the ideal agent to combine with opioids. This combination acts as synergistic fashion (supra additive) and potentiate to reduce the dose of opioid. The BDZ and opioid combination preserve ventricular function but reduce B.P, SVR, CI, HR due to sympathetic depression and venodilatation. So, in patient with poor ventricular function this drug regime may be hazardous. Fluid loading can attenuate decrease in BP, ventricular filling and CO.

Barbiturates, droperiol, ketamine, etomidate and propofol are some of the other sedative-hypnotics which can be combined with opioid. Hypotension after barbiturate-opioid combination is due to venodilation causing decreased cardiac filling and myocardial depression due to decreased sympathetic nervous activity.

Propofol and opioid combination has the same effect like BDZ and opioid combination. Together they provide unconsciousness and block the responses to noxious stimuli, whereas neither drug alone reliably does the both. Propofol + fentanyl or sufentanil anaesthesia provide acceptable condition for coronary artery by pass surgery. Sometimes, mean arterial pressure can derease to a levels that may jeopardize coronary perfusion. MAP and HR can decrease upto 35% and 16% respectively.

Etomidate and ketamine can be combined with opioid without loss of cardiovascular stability in cardiac surgery. Etomidate and fentanyl combination cause less hypotension than propofol-fentanyl combination.

15 Inhalational Anaesthetic Agents

INTRODUCTION AND HISTORY

In the ancient times the main anchors of analgesia and anaesthesia during surgery, especially before 1800, were the oral opium, laudanum (an opium derivative), mandragora (a juice from 'mandrake' plant) and the liberal use of alcohol. Then, Anton Mesmer had given much importance to the psychological preparation of the patient and he introduced mesmerism in Europe, as a mode of anaesthesia in surgery. This was between 1750 and 1800. At that time, many literatures was also full of references of many wondrous sleeping potions, ranging from Snow White's apple to the mandrake plant used by Shakespeare's Cleopatra. But, the modern inhalational anaesthesia was dawned by the introduction of inhalational anaesthetic agents, such as N_2O in 1844, ether in 1846 and chloroform in 1847.

Around 1628, William Harvey had first discovered the circulation. He also first observed the difference in colour between the pulmonary venous and pulmonary arterial blood. But, he was unable to draw any firm conclusion, regarding the functions of lungs and the cause of difference in colour between the pulmonary venous and arterial blood. Then, in-between 1660 and 1670, Robert Boyle and Robert Hooke understood that some component of air is absorbed by the lungs and is responsible for that difference of colour between the blood of pulmonary vein and artery. After that, Harvey had discovered the different components circulating in blood and developed an intravenous technique for therapeutic purposes. At that time, the basic scientific work on respiration by Priestly, Lavoiser and Laplace had also led to the possibility of use of different breathing gases and vapours for therapeutic reasons (Fig. 15.1).

When Priestley was in Birmingham, he experimented with many gases for therapeutic purposes. During this period his friend, Pearson had recommended the inhalation of ether for the recovery of different lung diseases. Then in the period between 1780 and 1800, Thomas Beddoes, a physician and a chemist of Oxford and a friend of this group of scientists, founded a Pneumatic Institution in Bristol for the study of this pneumatic therapy for the treatment of different diseases of patients. Among the gases that Beddos had used for therapy of the patients were oxygen, CO_2, water gas (mixture of H_2, CO, CO_2) and hydrogen. But Chaussier had first used O_2 in medicine in 1780 for neonatal asphyxia. In 1798, Beddos and Humphry Davy met each other, while they were on a holiday in Cornwall. There, Beddos invited Davy to be the superintendent of this Pneumatic Institution in Bristol. Davy was only 19 years old then. Here, Davy undertook a series of experiments on the effects of breathing of N_2O. Once he had a severe inflammation of his gum with acute pain. During an experiment with this pain, he breathed three large doses of N_2O. The pain was diminished and then Davy had suggested the probable use of N_2O as analgesic with definite advantages during surgical operations. This was the first experiment and suggestion in 1800 by Davy that surgical analgesia might be achieved by inhalation of N_2O. So, inhalational anaesthesia can be dated back to that very suggestion with dawn of modern inhalational anaesthesia where many modern volatile anaesthetics were delivered with sophisticated electronic vapourisers. Davy also realized the pulmonary blood flow. He also suggested that cardiac output and pulmonary blood flow could be measured by estimating the rate at which N_2O is taken up by the lungs. During that period to assist the work of Davy, Sir James Watt also made a special N_2O container. But, after few years due to some unknown reason Davy or his contemporaries did not further pursue the idea of deliberately inhaling N_2O to produce surgical analgesia (Fig. 15.2).

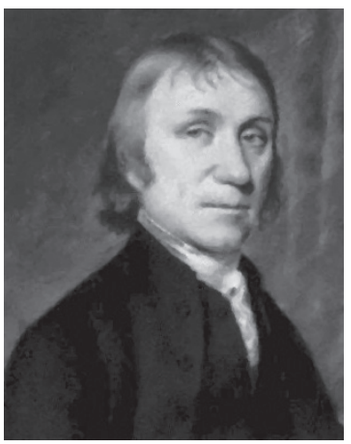

Fig. 15.1: Joseph Priestley

After that Davy's work was known to many and influenced Colton after 44 years. Surprisingly, at that time gases and

Fig. 15.2: Humphrey Davy

vapours were not only breathed in with the hope that they might cure various diseases, but were also inhaled for pure entertainment and amusement purposes. So, Davy also named N_2O as the 'laughing gas'. As this form of entertainment did not seem to cause any long-term harmful effects, so it was widespread in certain rich social circles in Europe. During that period similar use of ether vapour, named as 'ether frolics' was also wide-spread in America. We get the description of such entertainments using laughing gas and ether frolics in the works of great poets, like Samuel Taylor and Robert Southey.

In 1824, the first deliberate use of inhaled gas to produce anaesthesia was performed by Hickman on an animal for surgical operation. He used CO_2 for anaesthesia. But, his experiment and contribution in medical science was not recognized by the medical body at that time. Thus, it was he who introduced the concept of anaesthesia, using an inhaled substance. The first recorded general anaesthesia administered by inhalation of gases in humans was in 1842 by Long and Clarke, using ether. Then, on 16th October 1846, Morton first successfully demonstrated publicly ether anaesthesia at Massachusetts General Hospital. The

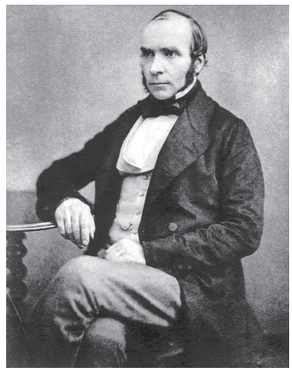

Fig. 15.3: John Snow

operation was the removal of a vascular tumour from just below the mandible and was held at place in what is now called the 'Ether Dome' at Massachuset's General Hospital. The patient who gave the informed consent for operation was a young man named Edward Gilbert Abbott, a printer and journalist and Mr Warren was the surgeon.

Then, in 1847, Pierre Flourens, a Paris physiologist suggested that ether gradually affected the higher cerebral centres, the cerebellum, the spinal cord and finally the medulla oblongata where the cardiovascular and respiratory centres are situated as anaesthesia is gradually deepened. Flourens had also previously demonstrated that the cardiovascular and respiratory centres were located in the medulla.

After that, John Snow, an eminent physician of London also became interested in ether, soon after its introduction. Even before Gudell, he described the five stages of ether anaesthesia in his publication in 1847. According to him the first three stages were of light anaesthesia. The fourth stage is comprised of what we call as the surgical anaesthesia (Fig. 15.3) and in fifth, respiration would become progressively shallow and eventually stopped. Snow quickly realised that the method of administration of ether was faulty. So, he developed many apparatuses for delivering ether to the patient with different known concentration in an attempt to increase the safety. At that time,

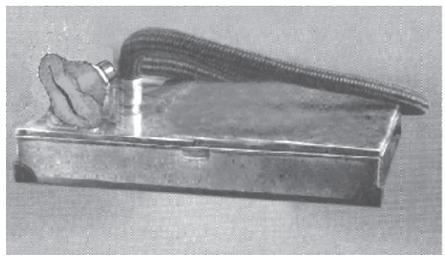

Fig. 15.4: Snow's inhaler

in 1847, two deaths associated with ether anaesthesia were reported. The first was a young woman at Grantham of Lincs and the second was a 52 year old man at Essex in Colchester Hospital. Snow's inventory work was stimulated further by these first report of deaths. Then, Snow investigated many other potential volatile agents for inhalational anaesthesia instead of ether such as benzene, bromoforms, ethyl bromide, ethyl nitrate and amylene in the last 10 years of his life from 1848 to 1858. During this time, in 1857, two patients had also died, while he was administering amylene to the patients. Then, he was the first to suggest that there was an inverse relationship between the lipid solubility and potency of the inhalational anaesthetic agents. During that period, around 1850, many different types of apparatus were also developed to improve the vaporisation of ether. It was also tried by preventing the cooling of liquid ether which occurs when it is evaporated. Many scientists also tried to prevent the dilution of ether vapour which occurred with air during administration of it (Fig. 15.4).

Chloroform was first identified in 1831. But, in 1847 the anaesthetic properties of chloroform in animals were first described by Pierre Flourens. It was first used on humans at St. Bartholomew's Hospital of London by Dr Lawrence under the name of 'chloric ether' in the spring of 1847. But, the use of chloroform in clinical practice was first made in vogue by Simpson. Then it was popularised by his two assistants who experimented with chloroform by inhaling it themselves in Simpson's

house. Simpson then read a report in Edinburgh Medical Society and described chloroform as a new anaesthetic agent which could be used as a substitute for sulphuric ether in surgery and midwifery. Gradually, after 1847, due to the works of Simpson and Snow chloroform became a favoured anaesthetic agent in Britain than ether. Simpson who had worked more on chloroform also had been impressed by ether, but was trying to overcome the disadvantages of ether associated with its administration. He had also been trying for inhalational anaesthesia with other organic volatile agents before chloroform. Then, he finally considered that chloroform had major advantages over ether (Fig. 15.5).

Snow, who had worked more on ether, later also abandoned ether and accepted chloroform as better agent. But, he recognised the dangers of chloroform, if the vapour was too strong. To overcome this danger, Snow invented an instrument by which a fixed percentage of chloroform could (Table 15.1) be delivered. Then within a few months, chloroform displaced ether and became the most popular anaesthetic agent in Britain. On 28th January of 1848, just little more than two months after the introduction of chloroform, first death due to chloroform was reported. The patient was a 15 years old boy named Hannah Greener of New Castle. The anaesthesia was given for a minor operation by Dr. Meggison. Then, Snow gave 5000 anaesthesia by chloroform with only one death. So, he recommended not to use chloroform

Fig. 15.5: Young Simpson

Table 15.1: The advantages of chloroform over ether (as thought by Simpson)

1. Less volume was needed and it was therefore cheaper.
2. It was more pleasant for the patient and induction was quicker.

in concentration more than 4% in an air-mixture. Then, due to toxicity chloroform gradually lost its favour in England (Table 15.2).

Ether did not regain much popularity in Britain until B Jeffries came from America and advocated ether as being much safer than chloroform, in 1872. Then, two years later in 1874 Clover introduced his gas-ether sequence. After that ether became accepted as safe agent for all-purpose anaesthesia.

The major war in which inhalational anaesthetics were used first was the Crimean War in the period of 1850. Even after the introduction of ether for anaesthesia in surgery by Morton, surgeries were still being rampantly performed without any form of anaesthesia in European teaching hospitals. At that time, different countries had also adopted one of these two anaesthetic agents − ether or chloroform and different methods of their administeration. Thus, chloroform was very popular and was used more frequently in Scotland, greater part of Europe and South America. While ether was favourite in England and North America. At that time, there was also much controversy regarding which was the more safer of the two (Table 15.3).

Then, a committee was set up in 1864 which drew attention to the dangers of chloroform. But, the committee also considered ether to be impractical, because it provided a lengthy induction and a prolonged excitatory phase. This commitee

Table 15.2: The toxicities for which chloroform lost it popularity

1. Gradual fall of BP with deepening of anaesthesia,
2. Sudden cardiac arrest during light anaesthesia, due to ventricular fibrillation or vagal inhibition.

also recommended the use of a mixture of ether and chloroform or the use of chloroform for induction and then switching over to ether for maintenance. Then, ACE mixture (alcohol, chloroform and ether in the ratio of 1:2:3) was introduced in anaesthesia practice and gained considerable acceptance. This also opened the door for other important new concepts and the committee suggested that different anaesthetic agents may be needed for different types and stages of an operation, because there was no single perfect universal agent.

Clover worked intensively both on chloroform and ether, in 1862. He invented a chloroform inhaler which enabled the anaesthetists for accurate measurement and administration of a desired percentage of a mixture of air and chloroform to reduce the risks. This took the form of a large bag which was slung over the back of an anaesthetist and contained a mixture of 45% of chloroform vapour with air. So, Clover was selected in the committee which investigated chloroform extensively and he realized its danger. So, he abandoned chloroform and set to work to make

Table 15.3: The advantages and disadvantages of ether vapour over chloroform

Advantages

1. A relative lack of toxicity, especially in light planes of anaesthesia,
2. Excellent muscle relaxation, without severe respiratory depression,
3. Lack of cardiac depression, even if overdose produced respiratory depression,
4. Relatively non-toxic products of metabolism (alcohol, acetaldehyde and acetic acid),
5. Little tendency to cause dysrhythmias.

Disadvantages

1. The risk of explosion and fire, although explosions have never been described during the administration of ether and air mixture, even when diathermy has been used.
2. Stimulation of the secretion of mucus.
3. Post-operative nausea and vomiting.
4. A slow induction and recovery due to its high solubility in blood.

the administration of ether simpler, easier and accurate. He later worked on inducing anaesthesia with nitrous oxide before adding ether. In 1877, Clover invented his portable regulating ether inhaler which made ether more popular at the expense of chloroform. Another Clover's achievements was his teaching that ether could safely be given over long periods with the desired and adequate depth of anaesthesia. By 1870 in this way ether had largely won the game. Then, the two agents N_2O and ether remained the mainstays of inhalational anaesthesia for the next 80 years (up to 1950) (Fig. 15.6).

After experiment with chloroform and ether, amylene was also used successfully for inhalational anaesthesia by Snow. But, it was quickly abandoned following two deaths. Then, came ethyl chloride for its rapid action and the relative freedom from side effects. But, ethyl chloride in its active pure chemical form was difficult to obtain as it was highly volatile. Again, at that time there was no such technically improved vapouriser for the use of ethyl chloride. So, ethyl chloride was introduced as local anaesthetic spray, especially for dentistry, rather than general inhalational anaesthesia. In 1894, this local use of ethyl chloride by dental surgeons resulted in accidental general anaesthesia. Thus, the apparent ease for use of ethyl chloride led some surgeons to adopt it for GA. The first death associated with the use of ethyl chloride was reported in 1899. Then gradually, the dangers of ethyl chloride soon became apparent, as general anaesthetic agent over the chloroform and ether. So, several anaesthetists used ethyl chloride just for induction of anaesthesia and then changed over to ether or chloroform for maintenance.

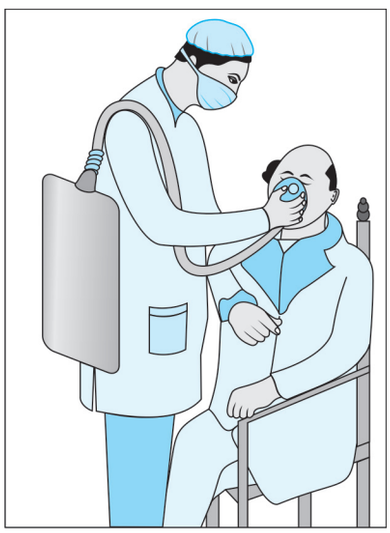

Fig. 15.6: Joseph Clover monitoring the patients pulse while giving anaesthesia by chloroform vapour from a bag

Towards the end of the nineteenth century after a rush of innovation, the development in anaesthesia became dramatic. At that time, antiseptic methods were also developed in the surgical fields which was parallel to the development of anaesthesia. The combination of this development of antisepsis in surgery and the development of anaesthsia gradually allowed the development of prolonged and delicate surgery that could not have been possible before the beginning of 20th century or the end of 19th century. But, during that period still it was very difficult to convince a surgeon that anaesthesia required its own specialist. It required someone who was perfectly skilled to select the anaesthetic agents and apparatus which are most suitable for that patient according to his physical conditions and the proposed operation. However, though late, still this realization came first from Britain, followed by America and much later from the different parts of the Europe. Then from 1800's to 1900's there were many significant changes in inhalational anaesthesia. But, it was more a period of consolidation.

At the end of the 19th century, two German pharmacologists, named Meyer and Overton suggested that the potency of inhalational anaesthetic agents increase with their lipid solubility. This hypothesis was based on the assumption that anaesthetic agents act on the brain which is rich in lipids. In 1922, the fifth edition of Hewitt's book was published which helped to uphold the standard of British anaesthesia. The influence of this book was wide spread. Hewitt emphasized in his book that N_2O anaesthesia was possible without hypoxia. He also suggested that chloroform was especially dangerous during induction. During that time, ether and chloroform were still the main anaesthetic agents, but ethyl chloride and N_2O were often used for induction. During this period Simpson's open-drop method for ether administration was most popular, though in 1917 the first Boyle's machine had already appeared. From this time onwards, the speed of progress in anaesthesia was very fast and was continued to do so. Before 1930's the anaesthetists administered the mixture of only volatile anaesthetic agents as balanced anaesthesia which produced unconsciousness, muscle relaxation and analgesia. This balanced method of anaesthesia by mixture of gases had reduced the amount of a particular toxic drugs and also reduced the hazards of anaesthesia.

However the actual concept of balanced anaesthesia had started in 1911 by George Crile. He taught that 'psychic stimuli' must be obliterated by light general anaesthesia with volatile anaesthetic agents while the noxious stimuli due to surgery must be blocked by local anaesthesia. In 1926, Lundy of the Mayo's Clinic had first introduced the term 'balanced anaesthesia' by combination of premedication, regional analgesia and general anaesthesia, using one or more volatile anaesthetic agents, so that pain relief was obtained by judicious mixing of agents and techniques. While anaesthesia was first divided into three basic components such as narcosis, analgesia and relaxation by Rees and Gray of Liverpool. Gray named these components of GA as the 'triad' of narcosis, reflex supression and relaxation (Table 15.4).

In the early part of 1930's, there were also certain important innovations in anaesthesia. During that period, blind nasotracheal intubation only under the

Table 15.4: Important innovations in anaesthesia in early 1930

1. The popularization of endotracheal intubation by Magill and Rowbotham.
2. The appearance of bromethol, divinyl ether, cyclopropane, trichloroethylene.
3. The induction of anaesthesia by intravenous barbiturates.

volatile anaesthetic agents was increasingly used. But there was difficulty in obtaining good relaxation of the jaw and larynx with ether only. So, controlled respiration with muscle relaxation was used with cyclopropane during that period. Thus, when Griffth at Montreal first used curare in 1942, to deal with hypoventilation and apnoea by controlled ventilation, then it was already well established and so IPPV became a routine procedure.

The two World Wars had greatly influenced and changed the scenario of both surgery and anaesthesia. The doctors had learnt a lot during their army tenure and had practised those anaesthetic procedures during their later civilian life. That led to the massive development in anaesthesia speciality. Then technical improvements in anaesthesia and academic recognition of it was followed gradually. In 1935, in London, the first examination for Diploma in Anaesthesia was held successfully.

In 1917, Haldane had first popularised the modern medical use of oxygen. In 1995 Helium was first isolated by a British chemist and Nobel prize winner, named Sir W. Ramsay. The respiratory stimulating effect of CO_2 was first shown by Herman and Escher in 1870. This was followed by recommended use of 5% CO_2 in anaesthesia by Haggard and Henderson in 1921. However, then many fatal accidents had occured with accidental overdosage of CO_2. So, Waters pointed out that the ill effects of inadequate ventilation were not due to hypoxia, but due to the excess of CO_2, in 1920's. When Waters started to use cyclopropane, he extensively developed a CO_2 absorption system, though CO_2 absorption during anaesthesia was pioneered by John Snow.

In the first half of the twentieth century, a number of other volatile anaesthetic agents also enjoyed immense popularity. These included ethylene, acetylene, premixed O_2 and N_2O (or entonox) trichloroethylene, cyclopropane, methyl-n-propyl ether, ethyl vinyl ether, etc. Ethylene was more potent than N_2O and had shorter induction period. Therefore, more oxygen could be used with it than N_2O which was the main disadvantage of the use of latter. But, the main disadvantage of ethylene was that this gas was highly inflammable. During that period it was used mainly in USA and 20 massive explosions were reported. So, ethylene was abandoned and paved the way for acetylene.

Characteristics of acetylene were similar to ethylene. There was rapid induction and recovery by acetylene, and also there was possibility of administering O_2 upto 50% with it. It was used mainly in Germany and USA. It was also highly inflammable and multiple explosions were reported.

Then, in 1945 premixed N_2O and O_2 (80:20) in a cylinder at a pressure of 700 lb/in^2 was used in USA. Later, it was found that at room temperature and at a pressure of 2000 lb/in^2 certain proportions of N_2O in O_2 remains as a gaseous phase due to the solvent action of O_2 at this pressure. This is called the Poynting effect. Tunstall had described this phenomenon making the point that upto 75% of N_2O remains in gaseous phase with O_2 under this condition. He also first reported the clinical use of mixture of 50% N_2O and 50% O_2 contained in one cylinder for the relief of pain during childbirth. Cooling of such a mixture produces liquid N_2O at the bottom of the cylinder. This remains liquid even when the cylinder is rewarmed. In these circumstances, if the cylinder is used, it will first deliver the gas mixture with high O_2 content and later with high N_2O content. So delivery of constant mixture of N_2O and O_2 from the cylinder can only be assured either by preventing cooling or by inverting the cylinder many times after rewarming if cooling occurs. Thus, entonox (50:50 mixture of N_2O and O_2) was prepared and sold commercially (Fig. 15.7).

The trichloroethylene had long been used in the industries both as a fat solvent and for dry cleaning. Its poisonous properties had also long been recognized and this poisonous property was used especially to produce numbness and anaesthesia along the distribution of fifth cranial nerve to relieve trigeminal neuralgia. But, its general anaesthetic properties was described in 1911 and 1933. Then, it was used to anaesthetize 300 patients in 1935. If trichloroethylene was used in

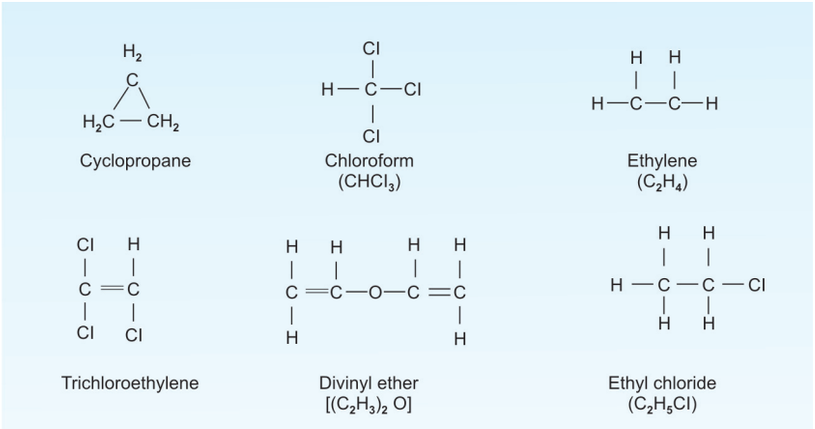

Fig. 15.7: Commercial anaesthetic agents

a closed circuit with sodalime, then toxic substances were formed. The most important toxic product of trichloroethylene in a closed circuit with sodalime is dichloroacetelene which is a very potent nerve poison and produced paralysis of the cranial nerves or even death. Also, it was decomposed into phosgene at a temperature above 125°C during cautery, and had caused death of many patients. But, cardiovascular stability provided by trichloroethylene was good, although dysrhythmias are seen. The heart was sensitized to adrenaline by trichloroethylene. It had an excellent analgesic property and was used in both surgery and in obstetrics, but was abandoned after the 1st half of twentieth century.

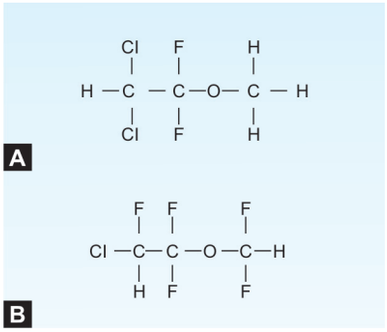
Cyclopropane was first synthesized in 1882, but nobody knew its anaesthetic property. Its anaesthetic property was first discovered in 1929. It was stored in orange cylinders as a liquid at a pressure of 5 bars without requiring any reducing valves during delivery. It was highly explosive and inflammable (Table 15.5).

Though, it had a powerful respiratory depressant effect, and also produced ventricular dysrhythmias with some deaths from ventricular fibrillation, still it was used for many years in the practice of inhalational anaesthesia since its introduction due to some advantages which are tabled. High incidence of PONV was common after anaesthesia with cyclopropane. Some anaesthetists found it immensly useful for very old, ill and shocked patients as it provides a strong haemodynamic stability. It was also popular for induction in children, till the 1980's (Figs 15.8A and B).

In 1950, Kety and Eger described the pharmacodynamics of inhalational anaesthetic agents, and determined the rate at which the arterial partial pressure of a volatile anaesthetic agent approached that of the inspired concentration of gas. During that period, occurence of diffusion hypoxia during emergence from N_2O anaesthesia was also described by Fink.

Table 15.5: Advantages of cyclopropane

1. Very rapid induction,
2. Cardiac output and arterial pressure are well maintained, even in very ill patients.



Figs 15.8A and B: (A) Methoxyflurane (B) Enflurane

Booth and Bixby, in 1932, observed that the greatest potential of an inhalational anaesthetic agent lay within its organic fluoride compound. This is because the substitution of fluoride ion for other halogenions in the compound reduced the boiling point, increased the stability and generally reduced the toxicity of the gases. Then, a large number of fluorinated volatile anaesthetic compounds were produced over the next 20 years. At last it culminated in 1950 with the development of fluroxene and then in 1952 with the synthesis of halothane, the first of the truly modern inhalational anaesthetic agents.

Then the first great jump-forwards in modern anaesthesia was the introduction of halothane into clinical practice with calibrated vapourisers in 1956. Then, the progress in the field of anaesthesia depended mainly on the pharmaceutical companies, developing the various inhalational anaesthetic agents. In 1960 methoxyflurane arrived. It had good analgesic properties, but had an unpleasant smell. It was non-inflammable and non-explosive. It had no reaction with sodalime. However, a significant amount of methoxyflurane was metabolised to fluoride which was toxic to the kidneys and caused high output renal failure. So, methoxyflurane was abandoned after its introduction.

Then came enflurane, in 1963, in USA. After that, isoflurane entered into the anaesthetic arena. It was a fluorinated methyl ethyl ether which was originally synthesised in 1965, but was first used in clinical anaesthesia in 1971. Then sevoflurane was first synthesised in the late 1960's at Baxter Travenol laboratory and was first used experimentally on animals in 1971 in North America. The first published record of its use in humans came out in the year of 1981. Then, the results of phase I trial of this drug on six healthy adults were published. It had two drawbacks. The metabolism of sevoflurane resulted in the production of potentially significant level of fluoride ions. And, it had also been found to be chemically unstable in the presence of sodalime. So, Baxter company decided not to develop this drug commercially. Then it had contracted with a Japanese pharmaceutical firm. There more extensive experiments were being done. After that, it was approved for clinical use in Japan in 1990 and eventually became the most popular inhalational anaesthetic agent there. Its success in Japan was subsequently followed by its introduction in Europe. But, the potential toxic degradation products of sevoflurane delayed its release in USA, until 1994.

Then came desflurane. It was first synthesized by Dr Ross Terrell who had also developed isoflurane and enflurane. But, due to its physical properties and some technical difficulties the subsequent research of desflurane was delayed. Later, a safer process of synthesis of desflurane was developed, and the result of the phase I trial was published in 1990. Subsequently it was approved for clinical use in USA in 1992 (Fig. 15.9).

Fig. 15.9: Nitrous oxide

NITROUS OXIDE

History

N_2O was first prepared by Priestley in 1772. But, Humphry Davy first demonstrated its anaesthetic properties in 1800. At that time Davy was only 21 years old. However, from 1800 to 1844 it was absent from the anaesthetic practice, though the exact reason behind this is still not known. Then, on 10th December in 1844, Gardner Colton (Fig. 15.10) again demonstrated the anaesthetic property of N_2O in front of a big audience at Hartford. He was a lecturer in chemistry. Horace Wells (Fig. 15.11), a dentist, was among the audience. He was very much impressed by seeing the anaesthetic property of N_2O. So, this demonstration was again repeated on himself in the next day privately. In this demonstration, a local druggist's shop assistant, named Samuel Cooley banged the shin bone of Mr Wells and made it bleed, while he was under the effect of N_2O.

Then, Wells after recovery stated that he had experienced no pain. He also commented that N_2O could be used for tooth extraction painlessly. During this time, Mr Wells's wisdom tooth was producing trouble. So, he requested Mr Colton to extract it and try the N_2O gas on him during the dental surgery. So on 11th December in 1844, this experiment with N_2O was carried out, again where Colton was the anaesthesiologist, John M Rigg was the dental surgeon and Wells was the patient. It was also a big success, when Mr Wells had recovered from the anaesthetic effect of N_2O. Then he declared it as the new era of dental medical science. So, he asked for some N_2O from Colton and in the next day he used it on one of his patients for extraction of tooth. This procedure was also painless. By the middle of January, in 1845, Wells then performed 15 successful cases of painless extraction of tooth at his clinic. Next, Wells tried to demonstrate this technique at Massachusetts General Hospital in front of big audience. But, the patient complained of pain and Wells was dubbed as a fraud. The low lipid solubility of N_2O was the cause of this failure and it may be the cause of his suicide, at the age of 33 years.

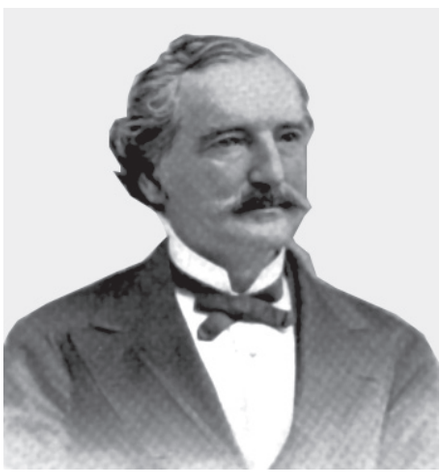


Fig. 15.10: Gardner Colton

Fig. 15.11: Horace Wells

These series of events antedates the first public demonstration of ether as an anaesthetic agent by only 21 months. So, at that time the introduction of both ether and N_2O delayed the full appreciation of the analgesic effects of the latter. Again, 20 years later Colton reintroduced it in dental practice.

So after a temporary period of its eclipse by ether, N_2O was reintroduced in anaesthesia practice and was widely used from 1867 onwards. By 1868 the gas was first available in London as a compressed gas in metal cylinders. Two years later, it was available as liquid nitrous oxide in metal cylinders. Then a reducing valve was attached in 1873 to the cylinder. During this period, the main difficulty was in the technique of administration of N_2O in its pure form as asphyxia was inseparable by this use. This difficulty was first overcome by Edmund Andrew, who in 1868 used N_2O with 20% O_2 for prolonged anaesthesia, avoiding asphyxia. Then in 1868, Clover first proved that N_2O had true anaesthetic properties. Subsequently, in 1876, he first introduced the N_2O-ether sequence in anaesthesia. N_2O is the only gas which has continued its use from the era of chloroform till the present day. In view of the large number of volatile anaesthetic compounds that have been used as anaesthetics and whose use has been discontinued after shorter or longer periods, it is remarkable that the use of N_2O still continues. More patients have been anaesthetized with N_2O than with any other inhalational agent and at present it still continues to be the most widely used agent than any other volatile anaesthetic.

Chemistry

Except xenon, nitrous oxide is the only inorganic compound which has been used to produce analgesia and general anaesthesia. This is not due to the some unusual pharmacological property of N_2O, but is due to the consequence of its degree of solubility in blood and lipid, and due to its chemical stability in the body. The structure of a molecule of N_2O is linear and asymmetrical, having a significant resonance feature: $N \equiv N =$.

Although biochemically N_2O is stable, but it is a thermodynamically unstable and is an endothermic compound. Because, it supports combustion by decomposing itself into its elements such as N_2 and oxygen. But a temperature above 450°C is required to initiate this reaction.

$$2\ N_2O \rightarrow 2N_2 + O_2 + 163\ kJ$$

Preparation

In laboratory, N_2O is prepared by allowing the reaction between iron and nitric acid. In this reaction nitric oxide is produced first which is then reduced to N_2O by excess iron.

$$Fe + 2NO \rightarrow N_2O + FeO$$

Commercially, it is produced by heating ammonium nitrate between 245°C to 270°C.

$$NH_4NO_3 \rightarrow N_2O + H_2O + 58.4\ kJ$$

The major part of the world's supply of N_2O gas is usually obtained by this method. In older plants, this was performed by heating solid ammonium nitrate. But, now in more modern plants an aqueous solution of 83% ammonium nitrate is being used. This is available as byproduct, during large scale manufacturing of ammonia.

Accurate temperature control during this process is essential. Because this reaction is exothermic and above 270°C the level of impurities increase. Again above 290°C, this reaction becomes very explosive. So, the control of accurate temperature is necessary. Serious explosions may also occur in a nitrous oxide manufacturing plant, if the temperature goes out of control. In the older type of plants where solid ammonium nitrate was used, the retort in which the exothermic reaction is occurred had to be externally cooled by ice-water. But, in newer plants, where ammonium nitrate solution is used, temperature control is done by the addition of more solution.

During the preparation of N_2O by heating NH_4NO_3 other higher components of nitrogen, such as ammonia, nitric acid, N_2, NO, and NO_2 are also produced. But, by different processes, adopted by different companies, N_2O is separated, dried and purified from this mixture. Then, pure N_2O is compressed to liquid form and filled in cylinders. However, during purification, a great care should be taken so that the content of higher oxide of nitrogen mixed with N_2O should not exceed 1vpm (volume per million). Greater care is also taken to prevent moisture from being included in the gas cylinder. Because water tends to freeze within the pipeline of anaesthetic machine as the N_2O passes through the reducing valves when the cylinder is turned on, and may lead to the obstruction of gas flow. About nine-tenths of a full cylinder is filled with the liquid form of N_2O. Nitrous oxide is stored and supplied in cylinders for anaesthetic purpose under a pressure of 5000 kPa at 20°C. A full N_2O cylinder at room temperature contains liquid N_2O. For this reason, cylinder should be kept upright when it is in use. When the cylinder is turned on and the gaseous portion above the liquid leaves the cylinder, then the liquid N_2O starts to vaporise. The pressure gauze on the N_2O cylinder cannot indicate the total content of liquid N_2O, until all the liquid is exhausted and cylinder is filled only by N_2O gas. Nevertheless, they do warn about the failure of gas flow when all the liquid is exhausted. For vaporisation of N_2O, during its flow from the cylinder, latent heat is obtained from the metal cylinder. So it rapidly cools, and water vapour of air outside the cylinder freezes on the cylinder forming a layer of ice.

Physical Properties

N_2O is a non irritating, odourless and colourless gas. Its molecular weight is 44. It is neither inflammable and nor explosive. Specific gravity of N_2O is 1.527 (air =1). At 50 atmospheric pressure and at 28°C, N_2O becomes a clear and colourless liquid with a boiling point of –89°C. It is stable in soda lime. Its partition coefficient at 37°C are : oil / water 3·2, water / gas 0·435, oli / gas 1·4, blood / gas 0·468. The critical temperature of N_2O is 36°C and the critical pressure of it is 72 bar. Its MAC value is 105.

Importance of N_2O as Anaesthetic Agent

This is remarkable that N_2O has stood the test for a long time since its inception as an anaesthetic agent. The other volatile anaesthetic agent which also stood the test of time with a contemporary history is only the diethyl ether. But, since the introduction of halothane, in 1950, ether has been of little use in Europe, and recently its production has also been stopped (Table 15.6).

Therefore, it is expected that N_2O would still have the considerable virtues as an inhalational anaesthetic agent which are tabled.

The speed of onset and the recovery from anaesthesia of any volatile anaesthetic agent is regulated by its blood solubility. The lower the blood solubility, the faster is the onset and recovery. The blood-gas partition coefficient of N_2O is only 0.46. This is the lowest for any inhalational agent that are currently used. This lowest blood-gas solubility of N_2O has another advantage. This makes it easier to control the depth of anaesthesia. Because any slight change in the inspired concentration of N_2O rapidly results in the change of its partial pressure in the blood and the brain, due to this less blood gas solubility of it. Thus, lightening and deepening of anaesthesia is quickly achieved, which is parallel to the partial pressure of this agent in the blood and the brain. So, after a few breaths the alveolar concentration of N_2O becomes equivalent to the inspired concentration of it, and the alveolar concentration or a partial pressure of N_2O (which is parallel to the partial pressure of the agent in blood and brain) reflects the depth of anaesthesia (Fig. 15.12).

So, now from the above discussion it is clear that the low blood gas solubility of

Table 15.6: Virtues of N_2O as an anaesthetic agent

1.	Have no irritant properties,
2.	Have good analgesic property,
3.	No metabolism in the body,
4.	Minimal adverse effects,
5.	Have advantages when used with other volatile agents,
6.	Low blood solubility,
7.	Accuracy of administration.

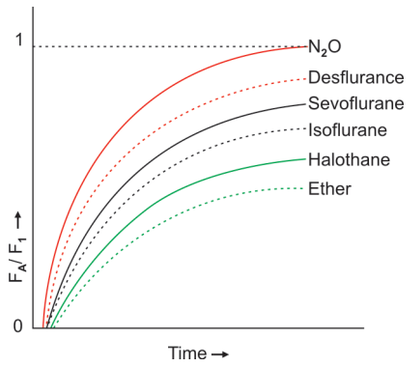

Fig. 15.12: FA /FI ratio of different volatile anaesthetic agents. In case of N_2O the alveolar fractional concentration (FA) rises rapidly and reaches the value of inspired fractional concentration (FI) quickly. Thus, the FA/FI ratio reaches to the value of 1 most rapidly with least soluble agent such as N_2O

any inhalational agent is a great asset for it. But, low blood – gas solubility is also associated with a low fat solubility, which indicates that the agent is of low anaesthetic potency. Because, it is known that anaesthetic potency of any volatile agent depends on its fat solubility. This is the disadvantage of N_2O or any such agent, and is the reason for the high MAC value of N_2O which is 104.

Impurities

During manufacturing of N_2O the main impurity in it is the higher oxide of nitrogen, i.e. NO_2. In addition to nitrogen dioxide (NO_2), atleast seven other oxides of nitrogen are also known to be present in it. But among these impurities those of importance as contaminants are – nitric oxide and nitrogen trioxide. This is because nitric oxide (NO) combines with air to form an even more toxic, nitrogen dioxide, which remains in equilibrium in the mixture and this point of equilibrium depends on the temperature of the mixture. The European and US standards for maximum permissible limit of NO and NO_2 in the medical preparation of N_2O is 5 ppm. The higher oxides of nitrogen in N_2O can be detected by smell at a concentration above 5 ppm. The consequences of inhaling higher oxides of nitrogen in concentrations above 50 ppm are: reflex inhibition of breathing, laryngospasm, cyanosis, methaemoglobinaemia, and pulmonary oedema. An insidious feature of these manifestations is the pulmonary damage, which may not become apparent until the development of pulmonary oedema and this usually occurs many hours later. If the patient does not die immediately, then chronic chemical pneumonities may follow with the resultant pulmonary fibrosis. Hypotension may be marked and results from the effect of nitrates on the vascular smooth muscles. Other impurities in N_2O, except the higher oxides of nitrogen are : ammonia, carbon monoxide and chlorine. So, after production scrubbing of N_2O with permanganate solution, sulphuric acid solution and water is important to remove all these impurities.

Pharmacological Actions

N_2O is very rapidly absorbed from alveoli into the blood if only remains in plasma as dissolved state. 100 ml of plasma can carry 45 ml of N_2O. It does not combine with Hb, nor does it undergo any chemical combination within the body tissue. It remains in blood just as physical solution. So, elimination of N_2O from body is as speedy as absorption through the lungs. It is 15 times more soluble in plasma than N_2, and 100 times more so than O_2. As far as anaesthetic action is concerned, N_2O is a weak anaesthetic agent. To produce a surgical anaesthesia (stage III) only with N_2O, a plasma partial pressure of 760 mm of Hg of N_2O is required. However 80% N_2O in mixture with O_2 at normal atmospheric pressure produces a partial pressure of only 600 mm of Hg in blood. So, surgical anaesthesia cannot be produced without hypoxia when N_2O is used alone. Only a 50:50 mixture of N_2O and O_2 at 2 atmospheric pressure can rapidly produce this surgical anaesthesia with complete saturation of arterial blood by O_2. Whereas, the same concentration of N_2O at 1 atmospheric pressure does not produce the loss of consciousness in a patient. So, in modern anaesthetic practice, N_2O alone at sea level is no longer used as the sole induction agent. But when accompanied by 33% O_2, it is used as an important supplement and carrier for other volatile anaesthetic agents.

1. Effects on CVS

N_2O is not a potent anaesthetic agent. It is also surprising that its adverse effects on CVS were overlooked, until the recent years. On the normal heart, the effect of N_2O is little and is entirely obscured by the sympathetic stimulation with concomitant rise in plasma noradrenaline concentration which is an important pharmacological action of N_2O. If there is no sympathetic stimulation or it is prevented then it reduces the cardiac output which is suggestive of its cardiac depression effect. It also causes the fall in heart rate and the decreases in limb blood flow. So, it is said that N_2O has a negative inotropic and chronotropic effect on heart and at the same time produces α–adrenoreceptor stimulation on the peripheral circulation which neutralises the depressive action on heart.

Inspite of this cardiac depression by N_2O, the normal arterial pressure appears to be maintained. This is because of the increased peripheral resistance by concomitant sympathetic stimulation by N_2O. It is also suggested that the depressant effect of N_2O on the heart is marked by the cardiac depressant effect of other anaesthetic agent, when they are used concomitantly. This N_2O induced myocardial depression may be offset by the concomitant increase in the sympathetic nervous system tone caused by it. 70 % N_2O decreases myocardial contractility to approximately the same extent as 1 MAC isoflurane. The negative inotropic action of N_2O may be more pronounced in the presence of pre-existing LV dysfunction. N_2O also produces LV diastolic dysfunction in a patient undergoing coronary artery bypass graft surgery. The N_2O induced depression of myocardial

contractibility is related to the decrease in Ca^{++} availability to the contractile element of myocardial tissue. But, it does not affect the myofibril sensitivity to Ca^{++} or in the Ca^{++} uptake and its release from the SR (sarcoplasmic reticulum).

N_2O increases the venous tone and decreases the venous capacitance. It modestly increases the pulmonary artery pressure and PVR. But in a normal patient this pulmonary artery pressure and pulmonary vascular resistance are not significantly affected by N_2O. When pulmonary hypertension is already present, then N_2O causes a marked increase in the mean pulmonary artery pressure and the pulmonary vascular resistance (PVR). Thus, the combined effects of enhanced venous return; elevated pulmonary vascular resistance and depressed myocardial contractile function, probably contribute to the increase in CVP during N_2O anaesthesia. Such an increase in PVR may adversely enhance the R to L atrial or ventricular shunt (if they are present) and compromises the arterial oxygenation in a patient with congenital heart disease. So, in such circumstances the use of N_2O is inadvisable.

The addition of N_2O to halothane lowers the threshold value in which halothane-induced arrhythmia occurs. This results from the combination of both the sympathetic nervous system stimulation by N_2O and myocardial sensitization by halothane. As the N_2O activates the sympathetic nervous system, it also causes the capillary dilation, diaphoresis, ↑SVR, and increased central blood volume. These findings suggest that the N_2O induced direct myocardial depression is partially offset by sympathetic nervous system stimulation, and may be partially responsible for the relative stability of hemodynamics during N_2O anaesthesia. The sympathomimetic action of N_2O on heart normally exceeds its direct depressant effect. The administration of drugs that tend to block this sympathetic stimulation, such as narcotics may reveal the underlying cardiac depressant action of N_2O. For this reason, the addition of N_2O to high-dose narcotic anaesthesia (to reduce the risk of awareness) has been found to cause depression of the cardiac function, which is not seen when either drug is given alone. However, this effect of N_2O is only of importance when cardiac performance is compromised by some cardiac disease. Thus, it is safe to conclude that in such conditions where there is need of strong sympathetic stimulation, such as hypovalaemia, then N_2O is considered as a cardio-depressant. Again in more complex situations its cardiac effects are not always predictable. This is because of an uncertain balance between its direct depressant and indirect stimulant action.

2. Effects on the respiratory system

Nitrous oxide is pleasant to inhale. Its pharmacokinetic properties make it very useful to act as supplement to other volatile anaesthetic agents, particularly during inhalational induction. This is done by increasing the uptake and reducing the MAC value of other volatile or inhalational anaesthetic agents. When given alone, N_2O has a minimal effect on ventilation. Like other inhalational agents, N_2O also increases the respiratory rate and decreases the tidal volume. However, this increase in respiratory rate is sufficient enough to compensate for the decrease in tidal volume. So that, despite the unfavourable change in the ratio of dead space to tidal volume during N_2O anaesthesia, alveolar ventilation is well maintained and $PaCO_2$ does not rise. This remains true even upto 2 MAC value of nitrous oxide, when the respiratory rate has been found to be two to three times greater than the normal value. N_2O does not alter the ventilatory responses to the changes in $PaCO_2$, but it significantly reduces the ventilatory response to hypoxia.

3. Effects on the CNS

When N_2O is used alone, it produces a significant increase in both CBF and ICP in normal, head injury and brain tumour patients. If N_2O is added to any volatile anaesthetic agent, there is also a significant rise in CBF and ICP. However, the interesting finding is that when the intravenous anaesthetic agents are administered in conjunction with N_2O, then these effects of N_2O on CNS may be greatly attenuated. N_2O also increases the cerebral metabolism. When the N_2O is used during neurosurgery, it should be kept in mind that it may diffuse into any air pockets, left within the skull following the closure of wound and may later increase the intracranial pressure. Despite all these potential disadvantages, the use of N_2O in patients undergoing neurosurgery remains an established and accepted practice (Table 15.7).

4. Analgesic properties

From the first observations of Humphry Davy it has been demonstrated that even when N_2O is inhaled at subanaesthetic concentrations, it has a strong analgesic action. The analgesic effect of 30% nitrous oxide has been found to be equivalent to that produced by 10 mg of morphine subcutaneously. So, the 50:50 nitrous oxide and oxygen mixture (Entonox) is widely used all over the world to alleviate labour pain and to facilitate minor surgical procedures. But it has a very weak anaesthetic property. Anaesthesia is likely to be inadequate when N_2O is used alone as a sole anaesthetic agent.

It is unclear why some inhalational anaesthetic agents have an analgesic effect at subanaesthetic concentrations and others do not. However, in the case of N_2O

Table 15.7: Advantages when N_2O is used in combination with a second volatile anaesthetic agent

1. It reduces the MAC of second agent.
2. It also reduces the amount of second agent required for effect.
3. It also increases the uptake and elimination of second volatile agent by second gas effect.
4. It increases the rate of induction and recovery.

(not other agents) there is evidence that the analgesic effect or at least a part of it is brought about by an interaction of N_2O with the opiate receptor. The chief evidence in support of this view is that the partial but significant reversal of analgesia produced by nitrous oxide is possible by naloxone. Also depletion of endogenous opiate stores may play a part in the acute tolerance to N_2O (Table 15.8).

However, the naloxone neither reverses the effect of anaesthesia, nor increases the MAC value of N_2O. In case of N_2O, although analgesia is partially reversed, but the ED_{50} of nitrous oxide as assessed by loss of righting reflex in mice (= MAC) is unaffected by naloxone. It is, therefore evident that the effect of anaesthesia is separable from analgesia in the case of N_2O.

Not only the naloxone does not affect the anaesthetic effect produced by other inhalational agent, but it also does not affect the analgesia produced by such volatile anaesthetic agents, other than N_2O. This shows the further evidence of the existence of other non-opiate pain control systems. It also suggests that the opiate receptor – endorphin system – is not directly involved in the mechanism of general anaesthesia.

Table 15.8: Adverse effects of N_2O

Harmful effects which have been clearly demonstrated

1. Adverse circulating effects,
2. Diffusion in close (compliant or noncompliant) spaces,
3. Oxidation of vitamin B_{12} causing :
   a. Abnormalities in haemopoietic system
   b. Abnormalities in nervous system

Harmful effects which are insignificant

1. Impaired wound healing,
2. Impaired leucocyte function,
3. Malignant hyperpyrexia,
4. Postoperative nausea and vomiting,
5. Teratogenicity,
6. Carcinogenicity,
7. Mutagenicity.

Metabolism of N_2O

N_2O is metabolised very minimally in the body. Hence, metabolites of N_2O in the liver has been detected, though in very low concentration. So, it can be concluded that with the probable exception to xenon, nitrous oxide is least metabolised in our body among all the anaesthetic agents.

The two small loci, responsible for the N_2O metabolism have been identified in the body. One is the reduction of this gas to nitrogen by bacteria, which is present in the gut. This has been estimated to be about 0.004% of the total quantity of N_2O taken by the body. It has also been shown that during this reduction of N_2O, free intermediate radicals may be formed. These compounds are potentially harmful, but there is no evidence of any toxic effects, resulting from these compounds due to their very low concentrations. Some bacteria in the gut may also synthesise N_2O themselves.

The other identified metabolic process of N_2O is the interaction between N_2O and vitamin B_{12}. The amount of gas taking part in this reaction is also too small to be of any significance. Interestingly, the reduction of nitrous oxide by intestinal bacteria may result, atleast in part, from the same chemical reactions in the body, since these organisms synthesise vitamin B_{12}.

Toxicity

N_2O has no direct toxic activity. However, its long term use can indirectly produce some hematological, neurological and gestational defects.

1. Haematological toxicity

Use of N_2O for a long period may cause pancytopenia (aplastic anaemia) and megaloblastic anaemia. Mild depression of bone marrow seen after exposure to N_2O for 6 hours may become severe after 24 hours of exposure. The mechanism of this response is probably due to the N_2O induced inactivation of Vit. B_{12}, which leads to an impaired synthesis of methionine and deoxythymidine, and also an impaired folate metabolism. However, all these are very essential factors for normal haemopoiesis.

2. Neurological toxicity

These have been found after long-term unintentional inhalation of N_2O by anaesthesiologist, OT assistant and habitual abuser. Neurological toxicity appears in the form of motor and / or sensory incoordination and / or reflex defects. This effects are due to the demyelination of posterior column, lateral spinothalamic tract and spinocerebellar tract of spinal cord. However, the mechanism of this toxicity is like the hematological toxicity, i.e, inactivation of Vit. B_{12}. The failure to synthesis S-adenosyl-methionine from methioxine and ATP leads to failure of methylation of basic protein in the myelin sheath.

3. Gestational toxicity

Increased incidence of gestational defects, abortion, foetal death etc., are found among OT personel who continuously inhales N_2O for prolonged period. Mechanism is similar to that of the hematological and neurological effects − inactivation of vit. B_{12}.

Interaction between N_2O and Vitamin B_{12}

The introduction of long-term IPPV by a ventilator, after 1952, facilitated the use of N_2O for long term sedation. Then several workers described granulocytopenia in cases where N_2O had been used continuously for several days. On long term administeration of N_2O, even at low concentration, leucopenia will occur after about 3 days which may develop into agranulocytosis in 5 to 7 days. However, if the patient does not succumb due to his or her primary illness, then the recovery of bone marrow from its depression effects of N_2O occurs within 4 to 5 days, after withdrawal of the N_2O. In such circumstances

the treatment with vitamin B_{12} was found to have no result.

In 1968, a paper was published describing the interactions between N_2O and vitamin B_{12}. Then in 1978, it was established that giving N_2O for 24 hours affects the DNA synthesis. Shortly after this, it was shown that the selective inhibition of synthesis of vitamin B_{12} by N_2O in due to inhibition of the action of an enzyme named methionine synthetase which is responsible for DNA synthesis. Thus it affects the DNA synthesis (Fig. 15.13).

Vitamin B_{12} is a cobalamine. The function of cobalt in the structure of vitamin B_{12} can be compared with that of the iron in Hb. The oxidation of cobalt in the vitamin B_{12} by N_2O is analogus to the oxidation of Fe in Hb by any chemical oxidizing agents to form methaemoglobin. In the case of cobalt, the N_2O converts the monovalent cobalamine to bivalent cobalamine, in which form it can no longer function as a methyl carrier. Methionine is a sulphur containing essential amino acid. It is available from food and also by metabolism of homocysteine. Folate which is also of dietary origin, is necessary for this conversion.

The enzyme methionine synthetase together with vitamin B_{12}, transfers the methyl group from methyl-tetrahydrofolate to homocysteine, and converts the later to methionine. At the same time, by losing its methyl group, methyl-tetrahydrofolate becomes simply tetrahydrofolate. Following this transmethylation, methionine and tetrahydrofolate take part in several reactions and result in the formation of deoxythymidine from deoxyuridine. Deoxythymidine is an essential component of synthesis of DNA. 90% of the deoxythymidine, incorporated into DNA, comes from the metabolism of deoxyuridine. Thus, inhibition of DNA synthesis by N_2O is thought to cause the hematological and the neurological toxicity effects of N_2O. The neurological effects may result from the depletion of methionine.

The duration of exposure of N_2O which is required to produce significant bone marrow depression is very clearly important. In man this time course is slower. No inactivation of methionine synthetase activity in human placenta was found, following N_2O administeration for upto 30 minutes during caesarean section. Presumably, this duration of exposure is inadequate. The intermittent exposure to N_2O such as Entonox during physiotherapy has been found to produce megaloblastic bone marrow.

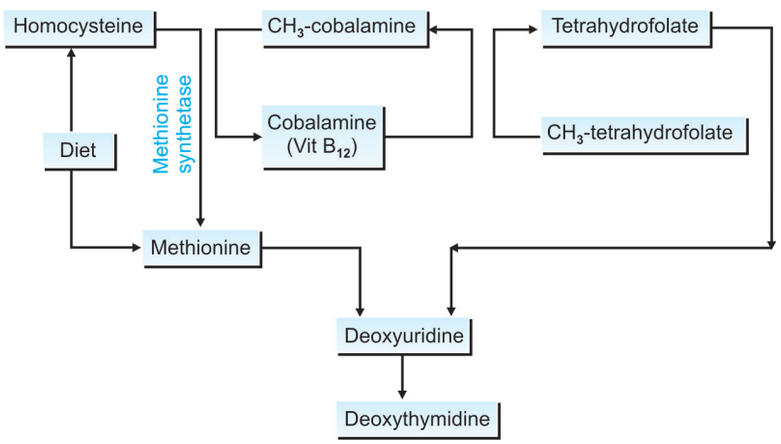

Fig. 15.13: The mechanism of synthesis of methionine from homocysteine with the help of vit B_{12} and folic acid

It is clearly important to discover the extent upto which the biochemical lesions produced by N_2O can be prevented or reversed by restoring the levels of deficient metabolites by folinic acid (5-formyl tetrahydrofolate, leucovorin, citrovorum factor etc). These compounds are freely available. They are used in chemotherapy as an antidote to folic acid antagonists, such as methotrexate. They are converted to methylene tetrahydrofolate and thus restores the metabolic pathway which leads to DNA synthesis. It is also seen that the two parenteral doses of 20 mg folinic acid, prevents the development of an abnormal deoxyuridine suppression test and megaloblastic changes in the bone marrow in 8 out of 10 patients, ventilated for 36 hours with 50% N_2O. It is also seen that in patients, subjected to N_2O anaesthesia for upto 12 hours, the abnormal deoxyuridine suppression test is corrected almost to the normal limit within 2 hour of giving of 15 mg folinic acid.

In addition to the impairment of DNA synthesis, a clinical feature of N_2O toxicity is vitamin B_{12} deficiency. This N_2O induced B_{12} deficiency is characterised by inability to synthesize myelin, causing a neuropathy. This usually develops insidiously in peripheral nerves and gradually progresses to involve the posterior and lateral columns of the spinal cord. But, it may be concluded that neuropathy is unlikely to be developed during clinical use of N_2O within the normal dose range in normal subjects.

The evidences regarding the effects of N_2O on chemotaxis, phagocytosis and wound healing are not entirely consistent. But, it seems likely that the stress metabolic responses due to surgery and anaesthesia on wound healing are more important than the effects of N_2O itself on it. The N_2O does not have any direct negative effect on wound healing.

Multiple reports have failed to show any carcinogenic potential of N_2O. The teratogenicity or other effects of N_2O on

the reproductive process is also less clear. The only agreed positive finding regarding the teratogenicity of N_2O is an increase in the rate of spontaneous abortion among the personnel who are exposed to N_2O for long duration. However, oocyte retrieval was carried out under N_2O anaesthesia, without any ill effects. Also no effect of N_2O on human spermatozoa and IVF success rate was found.

It is generally considered that N_2O is a weak triggering agent for malignant hyperpyrexia. So it is best to avoid its use, if it is suspected that the patient is susceptible.

N_2O and PONV

It is generally accepted that the use of agents that have sympathomimetic effects, such as cyclopropane or trichloroethylene results in more postoperative nausea or vomiting than the use of agents that lack such effects. For this reason and also due to the effects on middle ear (that is already described) it has been suspected that nitrous oxide might produce increased incidence of postoperative nausea and vomiting.

Methods of Administration of N_2O

1. By intermittent flow

This method of delivery of N_2O by intermittent flow is important for economy of the gas. For intermittent flow the two techniques are adopted. In the first technique a demand valve is commonly used where N_2O and O_2 coming from separate sources are combined in variable concentration in a mixing chamber and this is situated on the high pressure side of the demand valve. The characteristic of this demand valve is that it will deliver a flow of gas at low pressure, but upto the peak inspiratory flow rate in response to the slight negative pressure developed by the patient's own inspiratory effort. Since, as this type of valve is capable of delivering gas flows equal to that of the peak inspiratory flow rate, so no reservoir bag is needed. Sometimes a low resistance vapouriser, such as Goldman's, vapouriser may be placed between the valve and the patient if anaesthetist wants to use volatile anaesthetic agents to anaesthetise his patients. Such an assembly may be classified as an intermittent flow machine and these are commonly used for dental anaesthesia.

The second technique depends on the premixed cylinder, containing N_2O and O_2 under pressure with a demand valve which allows the gas to flow to the patient only during inspiration. In room temperature and at a certain pressure (2000 lbs/sq in) some N_2O remains in gaseous phase (25% in liquid form and 75% in gaseous) with O_2 due to the solvent action of later. This solvent action of O_2 is called the Poynting effect. In a premixed N_2O and O_2 cylinder with 50:50 proportion (Entonox) under pressure of 15000 kPa at 20°C, N_2O remains fully in gaseous phase (no liquid) due to this Poynting effect. Without O_2 it is not possible to keep this N_2O in gaseous phase under pressure. But, cooling of this cylinder to – 6°C causes part of the N_2O to become liquid, allowing a higher concentration of O_2 to be delivered first and exhausted. Then the cylinder will deliver a higher concentration of N_2O later and will cause hypoxia. Rewarming only can then help. So, delivery of a constant mixture of N_2O and O_2 from the cylinder can only be assured either by preventing cooling or should cooling occur, by briskly inverting the cylinder several times after rewarming.

2. By continuous flow

The continuous flow of N_2O is supplied from the Boyel's anaesthetic machine through a open, semi-closed (frequently used) or completely closed system. The semi closed technique is frequently used with CO_2 absorber to make the gas flow economical. The completely closed system with CO_2 absorber is not indicated when N_2O is used. Because, it is extremely difficult to ensure adequate oxygenation of the patient, if N_2O is used in a completely closed system. However, the development of an accurate oxymeter with a high and low alarm and also a digital display of FiO_2 has brought the completely closed circuit for N_2O delivery into the realms of clinical anaesthesia. In the absence of such sophisticated instruments the only safe way of the use of N_2O by continuous flow is to maintain a spontaneous respiration and to stop using N_2O once the system is completely closed.

In a completely closed circuit, if low gas flow (e.g. 1 lit flow of 75:25 N_2O/O_2) is used, then it will not render the patient unconscious, even after 10 minutes of breathing this mixture. This is because, the volume of air in lungs and the apparatus dead space is great enough and leads to the dilution of inspired N_2O to a level which is insufficient for narcosis. So, a high flow (e.g. 8 litres) of N_2O and O_2 gas mixture is used first. Then, when the consciousness is lost within a few minutes as the apparatus dead space is rapidly flushed out, it is switched over to a low flow technique. So, if low flow and a completely closed N_2O technique is to be used, it should always be started with a high flow for few minutes before reducing to low flow. Once, on a low flow and the circuit is completely closed, then we will have to keep in mind that the inspired O_2 concentration is not at the same level for certain constant flow, like in the beginning. Because, during every inspiration, O_2 will be taken up from the alveoli into the blood, while the N_2O will not be taken up (when body is completely saturated with N_2O). So, the O_2 concentration in the alveoli will gradually fall and N_2O concentration will gradually increase. This emphasizes the paramount importance of using an O_2 analyzer in the completely closed circle system, when a low flow of N_2O and O_2 mixture is being administered in the circuit. Provided that the concentration of O_2 in the inspired mixture does not fall below 25% and the total minute volume is adequate, then this technique can safely be used. It is best not

to use an inspired mixture containing less than 33% of O_2.

Diffusion of N_2O into Closed Space

The diffusion is defined as the physical process of intermingling of molecules, when the different gases and liquids are kept in close contact. This process results from the random movement of the molecules, present in the gases and the liquids. This is called the Brownian movement.

The factors which regulates the rate of diffusion are:

i. The concentration gradient or partial pressure of gases,
ii. The molecular size,
iii. The solubility of gases in the liquid when the passage of gas through liquid is involved.

Fick's law dictates that the rate of diffusion is directly proportional to the concentration or the gradient of partial pressure of the gases.

Graham's law dictates that the rate of diffusion of gases of identical partial pressure through some membranes is inversely proportional to the square root of their molecular weight. Therefore, a difference in gas density has only a small effect on the rate of diffusion. Finally, where the transfer of gas across the blood or water film is involved, the rate of diffusion is proportional to the solubility of the gas in that liquid. This is the principal factor for regulating the rate of diffusion of gases into or out of the spaces within the body, which can be seen from the Table 15.9.

The body is normally in equilibrium with the atmospheric nitrogen. So the N_2 present in the air of any closed cavity within the body will contain approximately the same concentration of N_2 as in the atmosphere. But, if the subject breathes a nitrogen-free gas mixture, containing 60 to 70% N_2O and 30 to 40% O_2, then it can be seen from the table that N_2O will diffuse into such spaces 25 times faster than the rate at which N_2 can diffuse out. But if the space is compliant, such as the gut, then there will be an increase in volume without an increase in pressure. But, If the space has rigid walls and is non-compliant, such as the middle ear, then there will be a rise in pressure without an increase in volume. Some cavities, e.g. the pneumothorax will fall between these two clearly defined cases, where there is both an increase in volume and an increase in pressure. Such an increase in volume and pressure may take place at the expense of other tissues, namely the lungs and mediastinal structures in the case of the pneumothorax.

Table 15.9: Diffusion of gases

Gas	*Density relative to O_2*	*Diffusion capacity relative to O_2*	*Water solubility relative to O_2*
O_2	1	1	1
N_2O	1·37	14	16·3
N_2	0.88	0.55	0.5

There are some sites within the body where the air filled cavities are normally present (such as the middle ear, sinus, etc.) or where air has been accidentally pushed or injected, (such as pneumothorax) or deliberately introduced (such as air encephalogram) and they cause an increase in volume and/or pressure, following the administration of N_2O. If the administration of N_2O is continued for a long time, then all the nitrogen of the body will diffuse out of the space, and the pressure and / or volume after having risen to a peak will return to normal. This is because, all the nitrogen would be replaced by the nitrous oxide and an equilibrium will be reached. Also, when the N_2O is withdrawn and air breathing is started, then the process goes into a reverse order and a subatmospheric pressure is created for a while in any cavity, until all the nitrogen diffuses back into the cavity. This low pressure phase during recovery is only seen in the case of the noncompliant middle ear (Table 15.10).

Table 15.10: Types of air filled cavities in our body

Non compliant
a. Nasal sinuses
b. Middle ear
c. Vitreous cavity
d. Intercranial – subdural, cisternal
Compliant
a. Stomach and gut
b. Pneumoperitoneum
c. Pneumothorax
d. Air embolus
e. Surgical emphysema

Stomach and gut

Under normal situations the volume of gas in the gut is not large enough. So, little to moderate increase in its volume due to diffusion of N_2O into the gut is not important in the absence of obstruction. But, when the intestinal obstruction is present, then the volume of gas within the lumen of intestine may be much greater and then even a little expansion of it by N_2O could cause problems. Imagining that no nitrogen is absorbed through the gut, so the theoretical increase in the volume of the gut that could result from the breathing of 66% nitrous oxide is almost 200%.

The effects of nitrous oxide on the motility of postoperative bowel have been extensively investigated. It is found that any excess of gas (N_2O) is absorbed long before the peristalsis of gut is re-established. So, the use of N_2O does not delay the return of gastrointestinal function or motility in patients undergoing bowel surgery.

Pneumoperitoneum

The gas which is most commonly introduced in the peritoneal cavity during laparoscopy surgery is CO_2. However N_2O anaesthesia does not produce any problem during this CO_2 pneumoperitoneum, because (i) N_2O and CO_2 have similar diffusing capacity, and (ii) the abdominal cavity is always vented out through some leak.

Pneumothorax

When GA is maintained by continuous flow of N_2O, then the risk of accumulation of N_2O in the cavity of pneumothorax,

producing tension pneumothorax has long been investigated. The similar risk is also applied when the sub-pleural blebs or lung cysts are present. Such cavities are non-communicating or communicate with airways only through a very narrow orifice, which becomes vulvular when there is an increase in the volume of cavity. But during breathing air, the volume of these cavities do not increase and do not cause any problem. However, the volume increases in the pneumothorax or in the subpleural blebs when N_2O is breathed in. It is found experimentally that during breathing of 70% N_2O, the volume of a pneumothorax is doubled in 15 minutes and tripled in 35 minutes.

Surgical emphysema

During maintenance of GA by N_2O, if surgical emphysema is produced, then air bubbles in the subcutaneous tissue will be expanded by N_2O, diffusing within it. But, problems have not been reported from this phenomenon, perhaps because even extensive surgical emphysema is not life-threatening.

Air embolism

It is predicted that during N_2O anaesthesia N_2O would enter and enlarge the venous air emboli, which may occur during neurosurgery and also open-heart surgery. In such situations, stopping the administration of N_2O should produce a rapid decrease in the size of such air bubbles.

Middle ear and nasal sinuses

The skull cavities such as the middle ear, frontal sinus, maxillary sinus, etc. are normally vented to the atmosphere via the eustachian tube or the various other ostia. These may be blocked by inflammatory processes or other lesions previously. Then, the pressure changes in these cavities following diffusion of N_2O during maintenance of GA by continues flow of N_2O may be expected. The nasal sinuses remain to be investigated. But, in the case of middle ear, the effects have been observed which is attributable to both the raised pressure during nitrous oxide administration and sub-atmospheric negative pressure, after its removal. These effects include: (i) rupture of the drum, (ii) graft displacement, (iii) stapes displacement, (iv) hematotympanum, and (v) temporary or permanent hearing loss. Low pressure in the middle ear after N_2O administration is particularly common in children. This is probably because the Eustachian tube is compliant and it collapses when ear pressure is sub-atmospheric. Thus, fails to maintain equilibrium of pressure on both sides.

Pneumoencephalos

The presence of air pockets or air bubbles any where within the brain or within the rigid skull raises the possibility of harmful pressure changes, due to diffusion of N_2O into these cavities if NO_2 is administered during GA. This is called tension pneumoencephalos. It is very common after posterior cranial fossa surgery, particularly in the sitting position. This condition is also found, if air is injected into the ventricle for radiological investigations, which is followed by general anaesthesia with N_2O. Intermittent drainage or aspiration of CSF from the ventricle during surgery via a shunt or ventriculostomy is also associated with this type of complication.

The eye

During surgery for retinal detachment, some ophthalmic surgeons may often inject gas bubbles into the vitreous cavity to tamponade the retina in place. So, it is desirable that this gas bubble remains in place for several days. For this purpose sulphur hexafloride (SF_6) and perfluroprofen (C_3F_8) gas have been used. They have very low blood-gas solubility. So, they are very slowly absorbed by the blood. A bubble of 40% SF_6 and 60% air maintains a constant volume for several days. But, if N_2O is given for maintenance of anaesthesia in such cases, then a considerable rise in intraocular pressure may occur due to diffusion of N_2O into this $C3F_8$ or SF_6 gas bubble. So, it is recommended that N_2O should be discontinued 20 minutes before the injection of the gas into vitreous cavity. However, practically the rise in intraocular pressure is not much, if N_2O is withdrawn simultaneously as the gas is injected.

Cuffs and Balloons and N_2O

The cuffs of endotracheal tube, balloons of Swan-Ganz catheters, and other balloons and cuffs which are used in anaesthesia are all permeable to N_2O gas. When these balloons and cuffs are in situ and filled with air, then they are subjected to pressure and/or volume changes in the same way, as other gas-filled cavities in the body during N_2O anaesthesia. These changes are clearly a complex one and many variables determine the rate of change of volume and pressure in these cuffs or balloons. These variables include the permeability of the material of the balloons or cuffs to N_2O, elasticity, contents of the cuff, its initial volume and pressure, the inspired N_2O concentration, temperature, etc.

Although sore throat is a common after effect of intubation, but serious problems do not commonly occur as a result of increased cuff pressure after routine N_2O anaesthesia. However, it is clearly undesirable to expose the tracheal mucosa to unnecessary pressure. Thus, care must be taken to inflate the endotracheal tube cuff to not more than the sealing pressure. We should also remember that the pressure may go on rising which need certain adjustments accordingly after every interval of 3 hours. The suggestions to minimise the pressure changes in cuffs include: inflating the cuff with the inspired gas mixture, (such as, with N_2O and air) or perhaps best of all with water and saline. Recently, several constant pressure inflating devices also have been developed.

Second Gas Effect of N_2O

When a high concentration of N_2O is given with O_2 and other accompanying

volatile anaesthetic agents, then N_2O quickly replaces the nitrogen, which was previously present in the alveoli. Then, though N_2O has a low blood-gas solubility compared to other volatile agents, still it is more soluble in blood than nitrogen. So, the volume of N_2O taken up by the blood is greater than the volume of nitrogen entering the alveoli from the blood. Therefore, the alveoli get smaller and the fractional concentration of the second volatile anaesthetic agent in the alveoli increases. This phenomenon is called the 'second gas effect'. After absorption of the N_2O in the blood, although the volume of N_2O in the alveoli decreases, but the concentration does not diminish to the previous level, because the volume of the alveoli also decreases.

At the end of anaesthesia, the opposite phenomenon occurs. Supply of the N_2O is stopped and the patient is allowed to breath air. At that time, N_2O diffuses back into the alveoli from the blood more rapidly, than the rate at which blood can take up nitrogen from the alveoli (as patient is breathing air). So, the concentration of N_2O in the alveoli increases with the volume of the alveoli. This increase in volume of the alveoli will cause a relative reduction of the concentration of the second volatile anaesthetic agent, which in turn will help in recovery.

Diffusion Hypoxia or Fink Effect

While a patient is breathing N_2O mixed with O_2 during anaesthesia, then a relatively large amount of this gas will replace the less soluble N_2 which is already present in the body tissues and fluids during breathing of air. Again, at the end of anaesthesia when the patient starts breathing air, then the alveoli soon become filled with N_2 and O_2 from air. But, there is still an appreciable quantity of N_2O dissolved in the blood and body tissues. Although N_2O is always referred to as an insoluble anaesthetic agent, it is 34 times more soluble than N_2. It means blood can carry much more N_2O than N_2. So, during the first few minutes after the end of anaesthesia, when the patient starts breathing in room air, then large quantities of N_2O leave the body tissue and enter into the alveoli and N_2 (now being breathed with air) diffuses from the alveoli back into the tissues. As the solubility of N_2O is much greater than that of N_2, so a relatively small amount of N_2 passes from the alveoli to the blood and tissues, but much larger amount of N_2O passes back from the tissues and blood to the alveoli. This mass movement of N_2O into the alveoli causes dilution of the alveolar O_2 concentration and reduces its tension. This is called the diffusion hypoxia or Fink effect. Normally in an alveoli, when the patient breathes in room air, then O_2 concentration is 14%. But, under these conditions, this O_2 concentration may drop to as low as 10% and result in a severe degree of hypoxia, which may be dangerous for elderly and critically ill patients. Clinically, diffusion hypoxia is only significant for N_2O anaesthesia, because N_2O is the only anaesthetic agent which is used in high concentrations and this diffusion hypoxia usually persists for about 10 minutes after the sttopage of flow of N_2O. However, it is of little significance in healthy patients and can be prevented by giving 100% O_2 for 5 minutes in the immediate postoperative period.

DIETHYL ETHER $(C_2H_5)_2O$ (FIG. 15.14)

History

It is commonly called as ether and was first prepared by Valerius Cordus in 1540. But, at that time it was not used as an anaesthetic agent and during this period it was called as the 'Sweet Oil of Vitriol'. Then, Sigmund August, a German chemist, botanist and physician, named it as ether. Previously, instead of being used as an anaesthetic agent, the vapour of it was being mostly used as a drug of amusement together with N_2O in both America and Europe. However, analgesic effects of ether were accidentally discovered in 1833 by an unknown chemist. He wiped freely the face of his wife with ether during her prolonged labour. Then, he observed that her distress passed away. So, he understood that ether had analgesic property. After that, ether was probably first used for clinical anaesthesia by Clarke, an anaesthetist, in January 1842 when a dentist named Elijah Pope extracted a tooth from his patient, named Miss Hobbie. But, this was not published by Clarke and did not attract attention during that period.

Crawford Williamson Long (Fig. 15.15), a general practitioner in Jefferson, Georgia was used to inhale ether frequently for amusement. Like Mr Wells, he also noted that he could acquire painless trauma on his body while under the influence of ether without remembering it later on. He applied this experience to remove one or two cysts from the back of his patient's neck, after administering ether from a towel. Thus, he used ether over the next few years for minor surgeries. But, even he did not publish his results.

During the period of 1843, Green Morton (Fig. 15.16), a specialist in dental

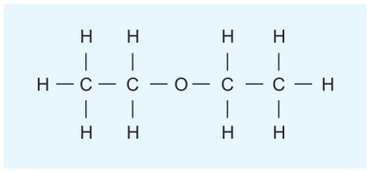

Fig. 15.14: Diethyl ether

Fig. 15.15: Crawford Long

Fig. 15.16: Green Morton

prosthetic works, had moved from Hartford to Boston and had set up his dental practice there. He had observed both Well's demonstration of N_2O and his failure at the Massachusetts General Hospital in 1845. He had also observed ether's anaesthetic effect on his patients, when they breathed the vapour of ether which was applied as a liquid to deaden the painful tooth sockets. Subsequently, Morton tried ether on himself, a dog and his two young assistants. But fortunately all were successful experiments. Then, Morton also gained further experience of anaesthesia from the administeration of ether in 50 cases of anaesthesia for a surgeon named Henry Jacob Bigelow, who was then a professor of Materia Medica. Morton then approached John Warren who was a senior surgeon of Massachusetts General Hospital for an opportunity to make a public demonstration of ether anaesthesia. However, this was arranged within two days and on 16th October in 1846 Morton successfully demonstrated the anaesthetic properties of ether publicly on a patient, named Gilbert Abott for removal of a congenital vascular malformation from the floor of the mouth under the tongue. It was operated by the surgeon, named JC Warren. The operation took place in what is now known as the 'Ether Dome' at Massachusetts General Hospital (Fig. 15.17).

Williamson Long also discovered the anaesthetic property of ether, even before

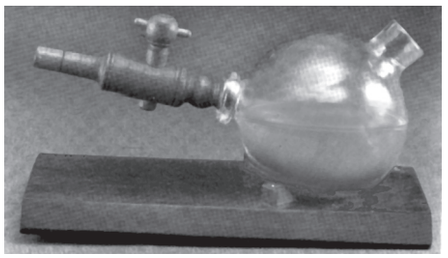

Fig. 15.17: Morton's inhaler

Morton. But he did not demostrate this in public. So, when Long reported his work in1849, Morton's fame was already well established. In science, ironically the recognition for the new discovery goes to the man who demonstrates, publishes and convinces the world first, but not to the man in whom the idea came first. Hence, as Morton convinced the world regarding the advantages of ether anaesthesia though late, so he bagged the crown.

Preparation

Ether is prepared by the reaction between ethyl alcohol and sulphuric acid at 140°C.

$C_2H_5OH + H_2SO_4 \rightarrow C_2H_5HSO_4 + H_2O$

$C_2H_5HSO_4 + C_2H_5OH \rightarrow (C_2H_5)_2O + H_2SO_4$

Physical Properties

It is a colourless, volatile liquid, with a very characteristic pungent smell. At room temperature (20°C) its vapour pressure is 425 mm of Hg. This vapour pressure helps to calculate the inspired concentration of ether, delivered to the patient by the bubble-through type of vapouriser (copper Kettle or Vernitrol). But this vapour pressure is not helpful for a blow-over type of vapouriser (Boyel's ether bottle) to calculate the inspired concentration of ether. If Boyle's ether bottle is converted to the bubble – through type of vapouriser by dipping the plunger into the liquid of ether, then also the constant change of temperature of the ether liquid due to the latent heat of vaporisation makes the calculation of the inspired concentration of ether difficult. On the other hand, in a copper kettle the temperature of ether is kept constant. Cooling of the Boyle's ether bottle due to the latent heat of vaporisation and freezing of the moisture outside the glass is prevented in a Oxford Vapouriser Mark II, where ether bottle is surrounded by a chemical crystal with a melting point more than ether and it helps ether to vaporise constantly. So, the ether vapour in Oxford vapouriser remain under pressure and emits spontaneously and continuously at a set concentration.

Ether and its vapour is highly inflammable and ignite at 154°C. Low concentration of ether vapour burns itself with a clear blue flame and at higher concentrations it explodes. Ether vapour is 2.5 times heavier than air and spreads like an invisible blanket over the floor. So, a spark from any electric point near the floor can ignite this ether blanket, causing a cold blue-like flame which is invisible in daylight. The zone of inflammability of ether vapour is usually confined to 25 cm around the exhalatory valve. So, if diathermy is kept outside this area and an efficient gas exhaust system is maintained in the OT, then there is little risk of explosion (Table 15.11).

The decomposition of ether is favoured by air, light and heat and it is prevented by copper and hydroquinone. So, ether is always kept in a dark, airtight bottle in a cool place. The main impurities due to decomposition of ether are: acetic aldehyde, ether peroxide, alcohol, sulphuric acid, SO_2, mercaptans, ethyl ester, etc. The systemic effects (toxicity) due to these impurities of ether in man are doubtful. The probable problems due to these impurities of ether on human body are gastric irritation (due to peroxide) and tachycardia with hypotension (due to mercaptans). During ether anaesthesia, the presence of mercaptans can be suspected, if the patient's expired air has a peculiar fishy odour.

Pharmacological Properties

Ether's blood/gas solubility coefficient is 12·1. So, it indicates that ether is highly

Table 15.11: Characteristic features of various anaesthesia

Agent	*Molecular Weight*	*Boiling Point (°C)*	*Vapour Pressure at 20°C (mm of Hg)*	*Blood-Gas Solubility*	*Oil-Gas Solubility*	*MAC*	*Metabolism*
Nitrous oxide (N_2O)	44	–88	–	0.42	1.4	105	0
Diethyl ether (C_2H_5-O-C_2H_5)	74	36.5	440	12.1	65	1.92	4
Halothane ($CF_3CHClBr$)	197.4	50.2	243.3	2.5	224	0.75	20
Isoflurane (CHF_2-O-$CHClCF_3$)	184.5	48.5	250	1.4	99	1.15	0.2
Sevoflurane (CF_3-CHO-CH_2F-CF_3)	200.5	58.5	160	1.69	50	2	4
Desflurane (CHF_2-O-CHF-CHF_2)	168	22.8	664	0.42	19	6	0.02
Xenon (Xe)	131.3	–107	–	0.11	–	71	0

absorbable in blood. Therefore, as it is constantly being removed from the alveoli by dissolving in plasma and without increasing its tension in plasma due to the high blood solubility, it takes a longer time to raise the plasma and alveolar tension. On the other hand, alveolar and plasma tension of any anaesthetic agent is synonymous with brain tension. So, induction of anaesthesia by ether will be slow (15 to 20 minutes) and may take a longer time to achieve deep anaesthesia than other volatile anaesthetic agents whose blood/gas solubility coefficient is very less. Similarly, recovery from ether anaesthesia will also be slow. The oil/gas solubility of ether is only 65, indicating that it is less potent than halothane and other volatile agents (halothane's oil/gas solubility 224). This is because potency of any volatile anaesthetic agent depends on its lipid solubility i.e. oil/gas solubility coefficient.

90% of inspired ether is excreted unchanged through the lungs. Rest is metabolised or excreted through the skin, body secretions and urine. About 4% of inhaled ether is metabolised in the liver to acetaldehyde and ethanol. Like phenobarbitone, ether is also a powerful inducing agent of hepatic microsomal enzymes. So, its prolonged exposure increases the rate of metabolism of other drugs in liver. Ether is an irritant to the mucosa of respiratory tract and increases the bronchial secretion. It also stimulates the vagal afferent fibres in bronchial tree, leading to an increased depth and rate of respiration. Ether itself is a bronchodilator. It does not affect the surfactant production. So, it does not reduce the surface tension of alveoli and does not help in the formation of atelectasis. Respiratory rate increases during ether anaesthesia, till a very deep level is achieved when the paralytic action supervenes with steady decline of minute volume, leading to apnoea. So, $PaCO_2$ level does not rise, till a very deep level of anaesthesia is reached with ether. Thus, in spontaneous respiration during ether anaesthesia, controlled or assisted ventilation is not needed till a very deep level is reached. Ether minimally depresses the ventilation than the other inhalational anaesthetic agents. It diminishes the ventilatory response to inhaled CO_2 at an anaesthetic depth at which $PaCO_2$ is maintained at normal levels. The action of ether on CVS is explained by an increased sympathetic activity caused by it. Ether anaesthesia produces a small alteration in BP and pulse rate. Very rarely it leads to cardiac irregularities, because it does not sensitize the myocardium to adrenaline. With a very deep anaesthesia, CVS is also depressed by ether. This is due to reduced catecholamine secretion from the exhausted sympathetic system and at this situation it should be used very cautiously with β-blocking agents.

Ether causes skeletal muscle relaxation by: depressing the CNS, affecting the motor end plate and affecting the muscle itself similar to tubocurarine. Ether is secreted through the saliva and passes to the stomach. It also stimulates the vomiting centre in medulla and is responsible for higher incidences of PONV. Smooth muscle motility of the intestine is depressed during ether anaesthesia. As ether stimulates the sympathetic activity, it leads to an increased release of catecholamines. So, glycogen is mobilized from both the liver and the muscles and a marked rise in blood sugar follows, due to the endogenous catecholamine-induced glycolysis. Ether reduces the tone of gravid uterus, even in slight concentration.

Clinical Uses

Ether is associated with lowest death rate in a properly conducted anaesthesia and lowest incidence of liver damage. Still it is gradually going out of vogue, because it does not attenuate the intubation induced sympathetic over activity, pungent odour, increased secretion, delayed induction and recovery, etc. It alone produces all the three major components of anaesthesia such as sedation, analgesia, and depression of reflexes. So, though modern anaesthetic techniques go far beyond this maxim, ether still remains the popular and most effective means of anaesthesia in many underdeveloped countries, mainly at rural area.

Guedel's Classification of Ether Anaesthesia

As the depth of ether anaesthesia increases, then gradually the respiratory pattern changes, more and more reflexes become suppressed and characteristic changes in the size of the pupil occur. So, in 1920

these slow progression of changes made it possible for Guedel to divide these various alterations in reflex activity during deepening of anaesthesia into four stages, after an exhaustive study of open-drop ether anaesthesia (Fig. 15.18).

GA by ether causes an irregular or a regular depression of the CNS in a descending order, i.e. higher functions are lost first and progressively the lower areas of the brain are involved. But, in the spinal cord lower segments are affected somewhat earlier than the higher segments. The vital centres located in the medulla are paralysed at last, as the depth of anaesthesia increases. However, these clear cut stages of anaesthesia are not seen nowadays with the use of muscle relaxants, faster acting inhalational anaesthetic agents, premedications and employment of many drugs together. These precise sequence of events also differs somewhat with other inhalational anaesthetics than ether. However, as still ether continues to

Fig. 15.18: Guedel

be widely used in India and so descriptions of these stages still serve us to define the level such as the light and deep anaesthesia (Fig. 15.19).

Stage I or stage of analgesia

It starts from the begining of inhalation of ether to the loss of consciousness. Pain is progressively abolished during this stage. Thus, it is named so. But the patient remains conscious or semiconscious. He can hear, see and feel a dream like state. The reflexes and respiration remain normal. Though some minor operations can be carried out during this stage, but it is rather difficult to maintain this stage. So its use is limited to very short procedures only.

Stage II or stage of delirium

It extends from the loss of consciousness to the beginning of regular respiration. Apparent excitement with irregular respiration is seen in this stage. The patient may shout, struggle or hold his breath. Muscle tone increases. Jaws are remained tightly closed. Breathing is jerky and vomiting, involuntary micturition or defaecation may occur. Heart rate and BP may rise and pupils may dilate due to the sympathetic stimulation. No stimulus should be applied or no operative procedure should be carried out during this stage. This stage can be cut short by rapid induction and premedication. However, this stage is

Stage		Respiration		BP	Sk muscle tone	Ocular movement	Pupil size	Reflexes				Heart rate	Uses
		Thor	Abd					Eyelid	Pharyngeal	Corneal reflex	Light reflexes		
I Analgesia				++	++	Normal						++	Delivery and minor surgery
II Delirium				++++	++++							++++	Nil
III	1			+++	+++	Roving eyeball		No eyelid reflex	No pharyngeal reflex	No corneal reflex	No light reflex	+++	Most of the surgical operations
	2			++	++							++	
	3			+	+	Fixed eyes						+	Occasionally reached
	4			+	+							+	Never attempted
IV Medullary paralysis		No respiration or very shallow		Pressure not record able	Fully relaxed		Non reacting fully dialated	No reflexes				No heart rate is recordable or severe bardycardia	Coma or death

Fig. 15.19: Stages of general anaesthesia

inconspicuous in modern anaesthesia due to the use of IV anaesthetic agents, muscle relaxants, very rapidly acting anaesthetic agents, etc.

Stage III or surgical anaesthesia

This stage extends from the onset of regular respiration to the cessation of spontaneous breathing. This has been again divided into four planes which are well distinguished as:

i. *Plane I* − moving eye balls. This plane ends when the eyes become fixed.
ii. *Plane II* − loss of corneal or laryngeal reflexes.
iii. *Plane III* − pupil starts dilating and light reflex is lost.
iv. *Plane IV* − intercostal paralysis, shallow abdominal respiration and dilated pupils.

In this stage as the level of anaesthesia passes on to the deeper planes progressively, so the muscle tone decreases, BP falls, pulse becomes weak and the heart rate increases. After that respiration gradually decreases in depth and later on in frequency.

Stage IV or stage of medullary paralysis

It extends from the cessation of breathing to the failure of circulation and death. In this stage pupil is widely dilated, muscles are totally paralysed, pulse is imperceptible and BP is very low to non-recordable.

However many of the above mentioned features described in different stages of ether anaesthesia may be masked by the use of atropine (pupil and heart rate), narcotics (respiration and pupil), muscle relaxant etc. So, during the use of many inhalational anaesthetic agents to determine the stages of anaesthesia, an anaesthetist may have to depend on several other observations.

i. If eyelash reflex is present and the patient is making swallowing movements, then stage II has not been reached.
ii. If incision of skin causes a reflex increase in respiratory rate and rise in BP or insertion of the endotracheal tube is resisted and induces coughing, vomiting, laryngospasm or tears appear in the eye during operation, then these indicate that the level of anaesthesia is in light plane.
iii. Fall of BP, HR and RR with cardiac and respiratory depression are the signs of deep plane of anaesthesia.

Now, modern multidrug anaesthetic technique is used in anaesthesia where combination of different drugs, each with more or less its distinct action is choised. It avoids the unnecessary depression of other parts of the body which is not under the area of action of that agent which occur occasionally, when a single agent with large doses is used. This type of multidrug anaesthesia is called the control or balanced anaesthesia, utilizing more than one agent to offset the disadvantage of another. Now, we choose a mixture of drugs that best fits with the anticipated needs of that operation.

Method of Administration of Ether

Ether can be administered mainly by three methods such as open, semiclosed and closed with CO_2 absorption. The open technique is used by a Schimmelbusch mask and ether is dropped from a Bellany Gardner dropper bottle. As the patient inspires only the mixture of air (which contains only 20% O_2) and ether vapour, so in this mixture the exact inspired O_2 concentration (FiO_2) falls which cannot be calculated accurately. Hence, extra O_2 supply by a catheter is mandatory to rise the FiO_2 > 33%. Patient inhales air and anaesthetic ether (ether vapour) mixture which is at low temperature. So, the respiratory tree is called upon to perform heavy task to raise the temperature of air – ether mixture to 37°C and also to saturate it with water vapour. It has also been estimated that there is heat loss of about 300 calories / minute from the patient, using ether (Fig. 15.20).

In a semiclosed technique, ether is used by blowing the mixture of N_2O and O_2 gas over it or bubbling through it, that is contained in a glass bottle vapouriser. The

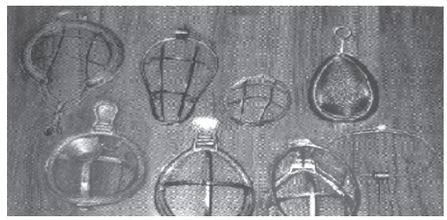

Fig. 15.20: Schimmelbusch masks

example of this technique is ether anaesthesia by Boyel's machine using Boyel's ether bottle vaporizer. Safety of this technique lies in the fact that, as vaporisation of ether increases, the temperature of the liquid and the bottle falls which in turn slows the rate of vaporisation from the bottle. Therefore, the control knob set to deliver a certain concentration of ether vapour, cannot perform this job. This is because after sometime, with the control knob still in the same position, there is reduction in the vapour concentration of ether due to the cooling of anaesthetic agent and bottle. In a circle system, higher concentration of ether is built-up very quickly (only if vapouriser is within the circuit), because the whole volume of expired gas passes through the ether bottle and vaporisation is assisted by heat, both from the patient and the canister (Fig. 15.21).

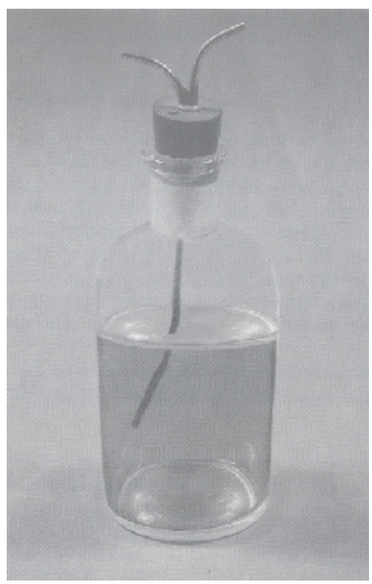

Fig. 15.21: Bellamy Gardner dropper bottle of ether

EMO vapouriser

Basically this is a draw-over or blow-over type of vapouriser, which is used to vaporise the ether. To deliver a required concentration of ether, the ether bottle is kept in a water bath which acts as a heat buffer and allows the delivery of a fixed concentration of anaesthetic vapour, set by the dial. This discussion is only for hitorical interest.

HALOTHANE

(2-bromo 2-chloro 1,1,1 trifluoroethane) (Fig. 15.22).

CW Suckling had first synthesized halothane in the laboratory of Imperial Chemical Industries at Manchester, in 1951. Then, Raventos studied its pharmacological properties in the succeeding years. After that, it was first used clinically in 1956 by Johnstone at Manchester and that was followed by Bryce-Smith and O'Brien at Oxford.

Physical Properties

Halothane is a colourless, non-inflammable, potent anaesthetic liquid with a sweet smell. Its commercial preparations contain 0.01% thymol for stability. Boiling point of halothane is 50.2°C and it does not react with soda lime. It decomposes to HCl, HBr, free chlorine, free bromine and phosgene gas, when exposed to bright light for several days. So, presence of thymol prevents this decomposition. It is suitable for vaporisation in a bubble-through vapouriser (copper kettle) or temperature and flow compensated vapouriser (flutec vapouriser).

If water vapour is present in the halothane vapour, then it can attack some metals like aluminum, brass and lead. But, copper and chromium is not attacked by halothane

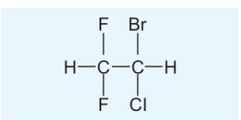

Fig. 15.22: Halothane

vapour. So, the previous metals are not used to build the halothane vapourisers. Halothane is readily soluble in rubber, but less so in polythene. Significant rubber solubility and the large amount of rubber used in anaesthetic delivery systems make the uptake of halothane by rubber very significant. The concentration of vapour of halothane in an anaesthetic gas mixture can be estimated by gas chromatography or by infrared analyser or by ultra-violet light analyser.

Pharmacology

The MAC value of halothane is 0.8. Its blood gas solubility co-efficient is 2.3 (N_2O is 0.46, Ether is 12.1, Isofluorane is 1.4, Sevoflurane is 0.69). So, the solubility of halothane in blood is of a medium range. Thus, as it is relatively insoluble (in relation to ether) in blood, so it is not taken up very rapidly from the alveoli. This means that alveolar concentration and tension of halothane can soon approach its inspired concentration and tension very rapidly. On the other hand, alveolar concentration and tension is virtually synonymous with the brain concentration and tension of volatile anaesthetic agent. So, a high concentration and tension of halothane is rapidly achieved in the brain. This means the induction of anaesthesia by halothane is relatively rapid in comparison to ether. During the first few minutes of halothane anaesthesia most of it goes to the heart, brain, liver, kidney, and later comes to an equilibrium with these tissues. After that, muscles tend to remove their quota from the circulation and take a few hours to come to an equilibrium. Then one of the principal reason for prolonged uptake of halothane by the body is the remarkable capacity of the human fat to absorb it due to its high solubility coefficient in fat (60 for halothane, 1 for N_2O). So, the fat is capable of removing almost all the halothane, received in the circulation. In this manner the body continues for almost indefinite pleriod to keep removing halothane vapour from the lungs. In fact, a complete equilibrium between the inspired and alveolar concentration of halothane is probably never reached, because a small amount of it is continuously lost through the skin.

Metabolism

Twelve percent of inspired halothane is metabolized in the body by liver through the oxidation and dehalogenation mechanism forming trifluoroacetic acid, bromide radicals and chloride radicals which are excreted through the urine. Then, the remaining part of inhaled halothane is expired through the lungs.

Pharmacological Actions

1. Effects on CVS

Halothane is a potent volatile anaesthetic agent. It reduces the myocardial contractile force, stroke volume, cardiac output and the heart rate by its direct –ve chronotopic action on the SA node and by its direct –ve inotropic action on the myocardium. Thus, during holothane anaesthesia BP goes down without any change in SVR. 2 MAC of halothane results in 50% decrease in blood pressure and cardiac output. As halothane attenuates baroreceptor reflexes, so HR does not change with the fall in BP that is normally expected in response to hypotension. At 1.1% end tidal concentration of halothane, the baroreceptor reflex is completely inhibited but SVR is very slightly affected. However, atropine can reverse this bradycardia, induced by halothane, but not the arterial hypotension or cardiac output. Thus, it indicates that hypotension during halothane anaesthesia is due to the direct myocardial depression effect and not due to bradycardia (Table 15.12).

The major cause of arterial hypotension during halothane anaesthesia is the fall in cardiac output, due to depression of the myocardial contractility. During halothane anaesthesia the limbs remain warm and dry with prominent peripheral superficial

Table 15.12: Mechanism of actions of hypotension due to halothane

1. It gradually blocks the action of noradrenaline at the effector sites in heart, CNS and peripheral tissues.
2. It gradually reduces the secretion and activity of nor adrenaline at the sympathetic nerve endings, in the myocardium.
3. It sensitises the parasympathetic nerve endings, leading to bradycardia.

veins, suggesting vasodilatation of both arteriolar and venular component of vascular tree. But, this does not cause reduction in SVR and hypotension. Plasma catecholamine levels are not raised during halothane anaesthesia. Decreased catecholamine level during halothane anaesthesia is due to the diminished release of adrenaline and noradrenaline from the adrenal medulla and the sympathetic nerve endings. Marked reduction of the coronary vascular resistance also occurs by halothane. So, although halothane is a coronary vasodilator, but coronary blood flow decreases. It is due to the drop in systemic arterial pressure. However, adequate myocardial perfusion is still usually maintained, as its oxygen demand also drops.

Arrhythmia and halothane

Most of the changes in cardiac rate and rhythm which occur during halothane anaesthesia may be explained on the basis of altered autonomic balance, i.e. preponderance of either vagal or sympathetic activity induced by halothane. The vagal stimulation produced by halothane causes slowing of sinus rate. If the SA node is sufficiently depressed, then the role of pacemaker activity of SA node may be taken over by the AV node. There may also be some independent activation of atria or ventricles, while intense vagal stimulation may lead to partial or complete SA block, bundle branch block, or even asystole. The relative sympathetic stimulation induced by halothane also causes sinus tachycardia or occasional ventricular extrasystole, although the actual plasma catecholamine level does not increase. When this relative sympathetic activation caused (Table 15.13) by halothane becomes more profound, then multifocal ventricular extrasystoles, ventricular tachycardia and VF may occur.

It has also long been known that the general anaesthetic agents which have a hydrocarbon structure in some form sensitize the myocardium to the effects of catecholamines. So like other hydrocarbons, halothane also sensitises the myocardium to the effects of catecholamines though the actual level of catecholamines does not increase. However, the manner by which halothane produces this effect (arrhythmia) is not clear, but it would seem that a reduction of HR and increase of ventricular automaticity plays an important role.

The halothane anaesthesia is accompanied with the shifting of pacemaker site, from the SA node to AV node. It is probable that these changes are mainly due to the increased vagal activity and can often be counter balanced by the action of atropine. It is believed that some form of re-entry mechanism is also likely the cause for production of halothane-induced arrhythmia. The respiratory depression and retention of CO_2 during halothane anaesthesia also may give rise to bigeminal rhythm, multifocal ventricular extrasystoles and VT. The higher degree of hypercarbia is required to provoke ventricular extrasystoles and their incidence is not related to the concentration of the inspired halothane. The correction of respiratory acidosis will often abolish these ventricular irregularities, even though the concentration of halothane is unaltered.

It is essential that the changes in heart rate and rhythm during halothane anaesthesia should not be treated indiscriminately with atropine. Because random abolition of any restraining vagal tone,

may accentuate the severity of arrythmia and may even induce VF. It has long been suggested that if ventilation is adequate and the concentration and total dose of adrenaline is kept within prescribed limits, then SC injection of adrenaline may safely be given during halothane anaesthesia. It has been found that ED_{50} (the dose producing a positive response in 50% of patients) of epinephrine that produces arrhythmia during halothane anaesthesia is 2.5 µg/kg. So, it is considered that a maximum dose of 10 ml of 1:100000 epinephrine for 10 minutes period is safe. In the vast majority of patients, the incidence of arrhythmia can also be diminished, if isoflurane is substituted for halothane. The endogenous catecholamines are an important factor for the causation of arrhythmia, when their concentration is elevated during light anaesthesia by surgical stimulation. In such circumstances, the absorption of even a small amount of exogenous adrenaline which is injected may have serious consequences. It is, therefore, best to avoid the use of adrenaline for external sources during light halothane anaesthesia.

The mechanism of action of halothane on cardiac contraction

Halothane, like other inhaled anaesthetic agents, depresses the cardiac contraction by decreasing the free intracellular Ca^{2+} level by:

i. Interfering with the Ca^{2+} movement through the sarcolemma and by decreasing the release and availability of Ca^{2+} from the sarcoplasmic reticulum.
ii. Altering the sensitivity of the regulatory and contractile proteins to the available Ca^{2+}. The order of potency of inhalational anaesthetic agents regarding myocardial depression is halothane > enflurane > isoflurane > N_2O.

Halothane and pulmonary vascular resistance (PVR)

In the absence of underlying pathology, halothane have little affect on the pulmonary blood flow and pulmonary arterial pressure. However halothane in general decreases PVR and increases the left atrial pressure.

Halothane and hypoxic pulmonary vasoconstrictive response (HPV)

The mechanism by which halothane interferes the HPV response remains still a mystery. The possible theories are:

i. Halothane acts by interfering with the action of local vasoactive metabolic substances, responsible for vasoconstriction.
ii. Direct relaxing effect of halothane on vascular smooth muscles, counteracting the locally or systemically mediated vasoconstrictive response.
iii. Interfering with the Ca^{++} uptake by the cells of vascular smooth muscle.

Halothane and baroreceptors

Due to baroceceptor reflexes the changes in blood pressure result in an alteration in the peripheral vascular resistance, heart rate, venous tone and CO. Halothane (like other anaesthetics) depresses this baroreceptor reflex. So, hypovolaemic or CVS compromised patients are less able to compensate the hypotension, when they are anaesthetised by halothane. Another importance of this baroreceptor attenuation is that the clinical signs of hypovolemia or reduced CO are masked under halothane anaesthesia. So, sophisticated monitoring is required during halothane anaesthesia, specially when there is associated hypotension.

2. Effects on the respiratory system

Halothane is a non-irritating respiratory depressant and progressively decreases the tidal volume, rather than the rate of respiration. Actually, halothane increases the rate of respiration. But still the minute volume is reduced and this is due to the relatively much reduction of tidal volume. Halothane used in clinical practice produces bronchodilatation and this is probably not mediated through the β_2-adrenoreceptor stimulation. This is proved by the fact that this bronchodilating action of halothane is not inhibited by propanolol or β-adrenergic blocking agents. Halothane attenuates the airway reflexes and relaxes the bronchial smooth muscles by inhibiting the intracellular mobilization of Ca^{2+} within these bronchial smooth muscle cells.

Halothane is the most potent bronchodilator of all the available volatile anaesthetic agents. There may even be a decrease in the effective alveolar ventilation. It has no effect on the synthesis of surfactant of the lungs. In unstimulated airway, the resting muscle tone is minimal, so the bronchodilating properties of halothane is also nil (during normal condition). Only during bronchoconstriction, bronchodilating property of halothane is well demonstrated. Systemic administration of halothane via a bypass pump, does not cause bronchodilatation which suggests that halothane acts directly on the airway musculature and/or through the local reflex arc, rather than via the centrally controlled reflex pathways.

Halothane does not inhibit the release of histamine from the mast cells, causing bronchoconstriction. So, histamine level is not affected. Patients, resistant to other bronchodilators, promptly respond to halothane.

Halothane and mucociliary function of the respiratory tract

All the halothane like inhaled anaesthetic agents diminish the rate of mucous clearance by diminishing the ciliary movement and also by altering the quality and quantity of mucous production. Halothane anaesthesia decreases the mucous velocity by 7.7 mm/min. So no mucus movement seen after 90 minutes of halothane anaesthesia. So, prolonged anaesthesia could lead to the pooling of mucous which results in atelectasis and infection. Patients with a greater risk are those who are susceptible to excessive mucous production such as asthma, bronchitis, RT infection, cystic fibrosis, etc. So, the patients of COPD who

are anaesthetised by regional block, show less incidence of respiratory failure, than those who are undergone general anaesthesia with voltile anaesthetic agent.

Halothane and ventilatory response to CO_2

Measuring of minute ventilation in response to varying levels of $PaCO_2$, is a common method of measuring the effects of anaesthetic drugs on ventilatory drive caused by $PaCO_2$. Compensatory changes in ventilation secondary to alteration in $PaCO_2$ are believed to be mediated chiefly via chemoreceptors located in the medulla. In normal subjects, there is increase in ventilation by approximately 3 litre/minute for every mm of Hg increase of $PaCO_2$. It indicates a high gain from the central chemoreceptors in response to the variation in $PaCO_2$. All inhaled anaesthetic agents including halothane generally depress this CO_2 response curve. At sedating concentrations, halothane has little effect on this response curve. But, 1 MAC halothane has a profound depressant effect. At 2.5 MAC halothane level, there is no increase in ventilation in response to any altered blood CO_2 level. The slope of the ventilatory response curve during halothane anaesthesia usually returns towards normal after 6 hours of anaesthesia.

N_2O is a relatively weak inhaled anaesthetic and does not depress the ventilatory drive or response to CO_2, even at a concentration of 50%.

Halothane and ventilatory response to hypoxaemia

Increased ventilation in response to progressively lowered PaO_2 is also mediated entirely by the peripheral chemoreceptors. Ventilatory response curve to hypoxaemia is hyperbolic. This hyperbolic response curve rises most sharply at a PaO_2 of approximately 40 mm of Hg. At 1MAC level of halothane, significant depression of ventilatory responsiveness to hypoxia is observed. Synergistic effect of hypoxia and hypercarbia on ventilation is also profoundly attenuated by halothane. Peripheral chemoreceptors are remarkably sensitive to the depression effect of halothane. Patients with chronic respiratory failure, in whom the level of $PaCO_2$ may represent an important determinant of minute ventilation, may be drastically affected.

3. Effects on the cerebral blood flow and intracranial tension

Halothane decreases the cerebral vascular resistance by dilating the cerebral vessels. Thus it increases the cerebral blood flow, provided the systemic BP is maintained. Hence intracranial and CSF pressure increases, especially in a case of space occupying intracranial lesion. So, headache may occur following halothane anaesthesia. Cerebral blood flow is further increased by the addition of N_2O, because autoregulation of the cerebral blood flow is completely absolished by halothane. The net effect on ICP and cerebral perfusion pressure depends on the systemic blood pressure and brain compliance. CSF production is decreased by 30% by halothane. This increase in ICP and cerebral blood flow by halothane, can be prevented by hypocapnia. But, if there is any intracranial lesion, then this rise of ICP by mixture of halothane, N_2O and O_2 cannot be prevented by hypocapnia or hyperventilation. Halothane also reduces the cerebral O_2 consumption by 25%, with greatest reduction at an inhaled concentration between 0.5 to 0.8%. There is little further change in cerebral O_2 consumption with a further increase in halothane concentration, until the toxic levels are reached.

4. Effects on the GI tract

Halothane inhibits the motility of the stomach, jejunum, small intestine and colon like other inhalational anaesthetic agents.

5. Effects on the skeletal muscle

Halothane has direct neuromuscular blocking action and also potentiates the action of other neuromuscular blocking agents. Thus, halothane produces moderate skeletal muscle relaxation with increasing depth of anaesthesia. It is postulated that the post junctional membrane is the structure which is most sensitive to the neuromuscular blocking effects of halothane (Table 15.14A).

Shivering

Shivering is sometimes observed during the early post operative period after halothane anaesthesia. This is probably due to the vasodilatory action of drug and cool environment of operation theatre. This shivering and the muscle spasticity which occurs during emergence particularly from the halothane anaesthesia also occur with other halogenated volatile agents and is often referred to as the 'halothane shakes'. Due to this shivering, oxygen consumption and incidence of hypoxaemia are markedly increased. Its incidence may be as high as 80%. Patients are commonly hypothermic due to the cutaneous vasodilatation by halothane and the chilled OT enviornment. Thus, there is significant heat loss during anaesthesia, as the thermoregulatory response is also impaired by halothane. So, shivering is a normal physiological response during recovery (when muscle relaxation is gradually

Table 15.14A: Mechanism of action of relaxation of bronchial smooth muscles by halothane in asthma

1. Direct dilatation of the bronchial smooth muscles, involving increased cyclic AMP.
2. Blocking the effects of various bronchoconstricting mediators, by reducing the free Ca^{++} in the cytoplasm and suppressing the influx of Ca^{++} across the cell membrane. This action is also common to vascular smooth muscles for relaxation and cardiac muscles for depression by halothane.
3. Bronchodilation of halothane is not caused by β_2 stimulation.
4. Attenuation of centrally mediated bronchoconstricting reflexes by increasing the depth of anaesthesia (depresses the airway reflexes), which occurs in light anaesthesia.

withdrawn). However, this is not the complete explanation. There is also some central and spinal effects of halothane which may cause altered muscular activity during the emergence from halothane anaesthesia, producing shivering. A number of agents have been experimented to reduce this shivering, such as opiates, magnesium sulphate, muscle relaxants and clonidine, etc. But among these, meperidine is the most effective in reducing such shivering.

6. Effects on the uterus

Halothane relaxes the uterine muscles. It is due to the stimulation of uterine adrenergic β_2-receptors. But, uterine contraction is recovered twice as quickly as ether when halothane is stopped. So, it is not so liable to produce PPH as has been stated before. It readily crosses the placental barrier.

7. Effects on the liver

It is the most controversial issue. Although, no consistent abnormal histological pattern of liver parenchyma after exposure to halothane has emerged in the National Halothane Study, still it is appeared that some cases exhibited a lesion which simulate the fatal viral and drug-induced forms of hepatitis after exposure to halothane. It is more often than those associated with administration of other inhalational anaesthetic agents. It is written in details later in the chapter of 'liver diseases and anaesthesia'.

Clinical Use

Due to a high vapour pressure(243.3 mm of Hg at 20°C), low boiling point (50.2°C), high lipid gas solubility (224) and low blood gas solubility halothane can be regarded as a potent anaesthetic agent. So, a low concentration such as 0.4% halothane is capable of maintaining unconsciousness. Thus, it is widely used in anaesthesia for all types of surgeries, including general, ENT, orthopaedic, paediatric, neuro, etc. The reduction of blood pressure by halothane is used as an advantage in major surgeries. Halothane is also used to reduce the blood loss and to control the intubation-induced hypertension. It has a low incidence of postoperative nausea and vomiting (PONV). During abdominal surgery, if halothane is combined with muscle relaxant, then a very good relaxation is achieved without restoring to high concentration of halothane which prolongs the recovery.

Method of Vapourisation

High cost of halothane demands reasonable economy during its use. So, it cannot be used by open-mask method, pouring drop by drop on the Schimmelbusch mask. Halothane is used in a copper kettle (bubble through) vapouriser with a flow of 100 ml O_2 through the vapouriser at the room temperature. When this is added to 5 litres of N_2O : O_2 gas mixture, we get an inspired concentration of 1% halothane. Similarly 200 ml of O_2 will give 2% halothane concentration.

But, now a days halothane is used by a flutec vapouriser. It is temperature and flow compensated. It receives part of the inspired gas enroute to the patient and adds the predicted amount of halothane concentration to the gas mixture. It is now the most sophisticated and satisfactory vapouriser for halothane administration (Fig. 15.23).

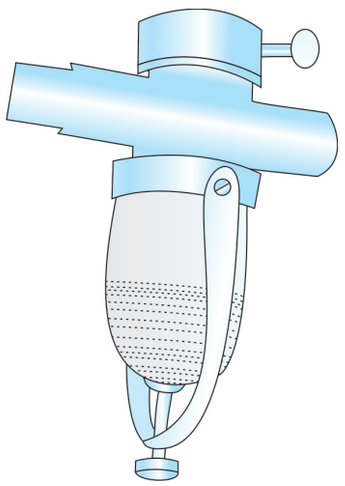

Fig. 15.23: Goldman's halothane vapouriser

A small, convenient, inexpensive Goldman vapouriser, which delivers a maximum of 2.3 volume % of halothane, is generally used in developing countries. It is not temperature or flow compensated.

ISOFLURANE (FIG. 15.24)

Chemically, isoflurane is a methyl-ethyl-ether and is an isomer of enflurane.

Physical Properties

It is a clear, colourless and non-inflammable liquid. Specific gravity of isoflurane is 1.52 at 25°C. Its boiling point is 48.5°C and vapour pressure is 250 mm of Hg (like halothane) at room temperature (20°C). It is non-corrosive and does not attack the metal, which are commonly used in the construction of anaesthetic apparatus and vapourisers. It has three fluorine atoms on the terminal ethyl carbon which makes it resistant to chemical and biological degradation. It is stable in warm soda lime and ultraviolet radiation. It can also be stored without any preservative at room temperature. Though, it is stable in sodalime, but like enflurane and desflurane it contains some moiety. So, it may undergo some degradation when exposed to sodalime or baralyme, resulting in the production of carbon monoxide, although not to the same degree as enflurane or desflurane.

Isoflurane has very pungent smell like ether. The pungent odour of isoflurane limits its speed of induction, due to coughing, breath holding, laryngospasm, etc. But, the low blood-gas solubility coefficient of isoflurane indicates its rapid induction like halothane. However, premedication, use of intravenous inducing agents, or

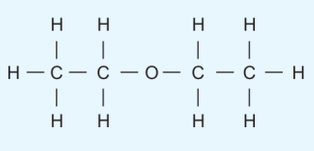

Fig. 15.24: Diethylether

step-by-step increase in the inspired concentration of isoflurane can overcome this problem. Low blood/gas solubility coefficient of isoflurane (isoflurane 1.4, halothane 2.3) suggests a swift induction and emergence from anaesthesia, compared to halothane. It takes only 4 minutes to reach a F_A/F_1 (ratio of the alveolar concentration to the inspired concentration) ratio of 0.5, compared to the 30 minutes required by halothane.

Greater chemical stability of isoflurane is reflected by its lesser metabolism in the body tissues(0.2%). This may in turn reduce the likelyhood of its toxicity due to low level of its metabolites. The rate of metabolism of isoflurane is considerably less (less than 1/5th of halothane) and near about 95% is excreted unchanged through the exhaled air. The metabolism of isoflurane is occurred in liver by oxidation through the hepatic cytochrome P_{450} system, with the production of inorganic fluoride and trifluoroacetic acid (TFA).

Pharmacology

The MAC value for isoflurane is 1·3. It decreases to 1 in elderly patients and decreases further to 0.6, when N_2O is used with it. For example, the addition of 70% N_2O roughly halves the MAC value of isoflurane, which further can be reduced by opioid analgesics. Premedicant drugs also reduce the requirement of isoflurane and its MAC value. Its oil/gas solubility coefficient is 98, which is much lower than that of halothane (halothane is 224). This suggests isoflurane is a weaker anaesthetic agent than halothane. Its vapour pressure is 250 mm of Hg at room temperature (halothane's vapour pressure 243 mm of Hg) and thus allows the delivery of desired concentration of isoflurane from the same vapouriser which is usually used for halothane. But, for obvious reasons this practice is not encouraged. Isoflurane is absorbed in the plastics and rubber used in the anaesthetic circuits, although not to the same extent as halothane.

Action on the respiratory system

Isoflurane is a potent respiratory depressant and this effect is more than halothane. For this reason, there is lack of increase in respiratory rate when a high concentration of isoflurane vapour is inhaled. This is in contrast to halothane, sevoflurane and desflurane anaesthesia where respiratory rate increases. However at a lower concentration of isoflurane respiratory rate is increased but the tidal volume is decreased with the net reduction of minute ventilation. Ventilatory responses to hypercarbia, progressively and linearly approaches to zero at about 2 MAC value of isoflurane. Ventilatory response to hypoxia disappears at 1 MAC concentration of isoflurane. So, reduction of the ventilatory response to hypercarbia and hypoxia may lead to a grossly impaired ventilation and gas exchange. Isoflurane produces a small drop in the total lung compliance and FRC. Bronchodilating effect of isoflurane is as good as halothane. As isoflurane is quite irritating (due to its etheral odour) to the airway, so it is not particularly suitable for inhalational induction of anaesthesia.

Action on the CVS

Isoflurane is less myocardial depressant than halothane, even upto the concentration of 2MAC value. But, the arterial blood pressure and peripheral vascular resistance (SVR) are much reduced in a dose related manner by isoflurane than halothane. It is due to the direct relaxation of vascular smooth muscles produced by isoflurane. However, cardiac output is maintained close to the control value by isoflurane. This well maintained cardiac output with isoflurane and sevoflurane is accompanied by or due to the dose related decrease in SVR by them. Whereas we have seen that there is little change in SVR, but a greater decrease in the cardiac output due to greater depression of the cardiac contractility with increasing doses of halothane. Thus, in contrast to isoflurane and sevoflurane, halothane lowers BP by reducing the myocardial contractility and cardiac output but not reducing the SVR. For this reason, deep isoflurane anaesthesia has been suggested as an appropriate technique for controlled hypotension (being preferable to halothane, in which hypotension is accompanied by decreased cardiac output and hence decreased perfusion).

Isoflurane depresses the baroreceptor function, but very less quantitatively than the other inhaled anaesthetics. This less depressed responsiveness of the baroreceptors probably better maintains the cardiac output in the face of hypovolaemia. So, there is wide margin of cardiovascular safety with isoflurane than with halothane. Isoflurane increases the HR in response to a lowered BP and maintains the cardiac output. This is because, the baroreceptor reflexes are relatively preserved. The isoflurane induced tachycardia is more pronounced in paediatric patients or in the presence of a vagolytic agent. This CVS stimulation and tachycardia by isoflurane may result from the sympathetic stimulation. It is achieved by the activation of tracheopulmonary and systemic adrenoreceptors by isoflurane, and can be attenuated by pretreatment with β_1-adrenoreceptor antagonist, α_1-adrenoreceptor antagonist or opioids.

Isoflurane is also a coronary vasodilator. Ventricular work and myocardial oxygen consumption are reduced by isoflurane. Thereby, it improves the oxygen supply-demand ratio of myocardial tissue. The coronary vasodilatation, produced by isoflurane, is mediated through the ATP-gated potassium channel (K_{ATP}). In the presence of adequate O_2, where intracellular level of ATP is high, these channels open and causes hyperpolarization. In turn this hyperpolarization reduces the cellular acitivity. Therefore, in vascular smooth muscles the muscle tone is reduced and blood flow is increased in the coronary vessels (also in other vessels). In myocardial cells activation of these channels

results in a reduced action potential duration, reduced calcium entry and a reduction in the myocardial contractility. But, this is very insignificant. Thus this helps to protect the myocardial cells from the effects of ischaemia. Although, isoflurane causes some slowing of the myocardial conduction, but it is less than halothane. So, cardiac rhythm is more stable during isoflurane anaesthesia.

Isoflurane preserves the regulation of autonomic nervous system on circulation to a greater extent than other volatile anaesthetic agents. During halothane anaesthesia there is a dose-related increase in the right arterial pressure and it is as a result of the direct negative inotropic action of halothane on the heart. Whereas, the pronounced venodilating properties of isoflurane and sevoflurane cause less increase in the right arterial pressure than halothane.

So, there appears to be a wide margin of cardiovascular safety with isoflurane. Cardiac index (ratio of doses producing circulatory arrest versus MAC) of isoflurane is 5.7, which is significantly higher than halothane which is only about 3. Isoflurane does not affect the cardiac rhythm and so dysrhythmia following injection of adrenaline is less likely with isoflurane than with halothane. This is a major advantage of isoflurane over halothane in plastic surgery, where there is a widespread use of adrenaline. The doses of epinephrine required to produce arrhythmia in patients receiving isoflurane is three times greater than the dose required in patients receiving halothane.

In normal doses and concentration, as isoflurane does not evoke sympathetic activity, so β_1-adrenoreceptor blocking agents are unlikely necessary. The vast majority of disorders of ventricular rhythm during isoflurane anaesthesia usually disappears when the concentration of inspired isoflurane is reduced and ventilation is improved. The use of β_1-adrenoreceptor blocking compounds should be reserved for the intractable tachyarrhythmias which is liable to progress to ventricular fibrillation. But, these drugs are contraindicated in the management of disorders of heart, arising from excessive vagal activity.

Isoflurane tries to maintain the myocardial contractility near normal and does not sensitize the heart to adrenaline. But, it maintains CVP very well. During isoflurane anaesthesia, the BP falls due to decrease in the systemic vascular resistance, but not due to myocardial depression and HR increases. It maintains the peripheral blood flow and tissue perfusion very well. Ventricular work is reduced due to reduction of after load. Pulmonary artery and wedge pressure remains normal.

Action on the CNS

Isoflurane produces a dose dependent depression of CNS activity. Concentration of isoflurane above 0.25 MAC produces amnesia. It does not promote convulsive activity. Cerebral metabolism is decreased which may lead to decrease in the cerebral blood flow. This property is very helpful in conditions where there is elevated intracranial pressure. Isoflurane does not increase the CBF in normocapnic patients, provided the mean arterial pressure does not increase. If MAP is allowed to fall, then ICP and CBF are both reduced. The increase in ICP, if occurs with isoflurane, is easier to reverse with hypocapnea than with halothane. Isoflurane with hypocapnea does not increase ICP associated with intracranial mass.

Neuromuscular effects

Isoflurane produces adequate muscle relaxation. It also enhances the action of suxamethonium. The neuromuscular effect of isoflurane is dose-related, but is more pronounced than that observed with halothane. Shivering also occurs during emergence from isoflurane anaesthesia like halothane, due to thermoregulatory response to hypothermia. But this can be suppressed with meperidine.

Effects on the uterus

As isoflurane relaxes the muscles of uterus in a dose-related manner and increases bleeding, so it is not recommended in obstetrical anaesthesia.

Metabolism and Toxicity

Isoflurane is physicochemically very stable which is reflected by its resistance to biodegradation. So, 95% of the administered dose of isoflurane is excreted unchanged in the exhaled air. Only less than 0.2% of the administered isoflurane (much less than halothane) is metabolised in liver and is excreted as urinary metabolites. Thus, the near absence of metabolism of isoflurane implies that the possibility of liver and kidney toxicity by the metabolites of isoflurane is remote. The main metabolities of isoflurane metabolism are trifluoroacetic acid and inorganic fluoride ions. The peak serum inorganic fluoride level after prolonged isoflurane anaesthesia was found to be only 4.4 μmol/lit, a concentration which renders the possibility of nephrotoxicity very little or almost nil. At a comparable anaesthetic exposure, there is ten times more production of fluoride ions with methoxyflurane which is known for nephrotoxicity. Production of trifluoroacetic acid, responsible for hepatoxicity, is also ten times less during isoflurane anaesthesia than during comparable exposure to halothane.

The Ames test which is widely accepted as a test for the mutagenicity and carcinogenicity for both the mother drug and its metabolites is negative for isoflurane, but positive for halothane and its metabolites.

Indications for Use of Isoflurane

The use of isoflurane is clearly of benefit in circumstances where:

i. The disturbance of cardiac rhythm is very likely.
ii. The neurosurgical patients who are known to have raised intracranial pressure.

iii. The patient presents with pre-existing renal and liver diseases.
iv. The patient who needs frequent exposure to an inhalational anaesthetic.

It is less useful, if an increase in the heart rate is not desirable, but would be deleterious in the presence of multivessel coronary artery diseases.

SEVOFLURANE

(1,1,1,3,3,3 hexafluro-2-fluromethoxypropane) Chemically, it is a halogenated (fluorine only) methyl-propyl-ether. As it does not contain any chlorine or bromine atom, so like halothane, isoflurane and desflurane it has no effect on the ozone layer of environment. The first report of this agent appeared in 1970. It has no asymmetrical carbon atom, so has no optical isomer. In this respect, sevoflurane is unique among all the currently available inhaled anaesthetics (Fig. 15.25A).

Physical Properties

Molecular weight of sevoflurane is 200.1(Da) and boiling point is 58.5°C. Its vapour pressure at 20°C is 160 mm of Hg. So, it can be administered by using a conventional temperature and flow compensated vapouriser. Rubber/gas partition coefficient of sevoflurane is 31(halothane 120, isoflurane 62). So, it is less soluble in rubber and plastic which are present in the anaesthetic circuits than halothane and isoflurane. The MAC value of sevoflurane with O_2 is 2 and with 70% N_2O is 0.8. The MAC value of sevoflurane also decreases with increase in age, like other inhalational agents. So, in neonates the MAC value of sevoflurane is 3.3, while in adults it is only 1.48. The MAC value of sevoflurane is also reduced with narcotics and hypnotics. No preservative is needed for sevoflurane for keeping it in bottles (in halothane, thymol is used as the preservative). Most of the administered sevoflurane is excreted unchanged by exhaled air through lungs and only 3 to 5% is recovered as metabolites (Table 15.14B).

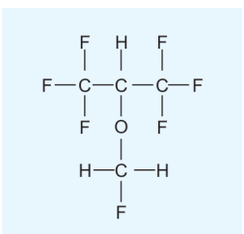

Fig. 15.25A: Sevoflurane

Blood/gas partition coefficient of sevoflurane is 0.6, which is substantially lower than other inhalational anaesthetic agents. So, the alveolar anaesthetic concentration of sevoflurane is very rapidly achieved which results in fast induction. Within 5 minutes, after the start of induction of anaesthesia, the F_A/F_I (ratio of the alveolar concentration to the inspired concentration) value for sevoflurane is 0.5, which is reached by halothane only after 30 minutes. This F_A/F_I ratio of sevoflurane is same as isoflurane, which indicates very quick induction of anaesthesia by it. However, sevoflurane blood-gas solubility, unlike that of halothane and isoflurane, does not alter with age. Sevoflurane has also lower distribution coefficient than other agents. So, elimination of it is very quick. Hence, it may prove ideal for outpatient anaesthesia due to its fast recovery. Sevoflurane is nonirritant to the upper airway. So, it is very suitable as an inducing agent for children. It is non inflammable.

Table 15. 14B: Effect of age on MAC of sevoflurane

Age (years)	*Sevoflurane with O_2*	*Sevoflurane with N_2O and O_2*
< 3	2.5-3.5	2
3-5	2.5	NA
5-10	2.5	NA
10-25	2.5	1.4
25-35	2.2	1.2
40	2	1.1
50	1.8	0.95
60	1.6	0.85
80	1.4	0.7

NA = Not applicable

Sevoflurane breaks down with sodalime. Metabolism of sevoflurane occurs in the liver by the cytochrome P_{450} system. It is broken down into inorganic fluoride ions and the organic fluoride compounds, such as hexafluoroisopropanol (HFIP). HFIP is conjugated with glucoronic acid to form HFIP glucuronide, which is then excreted through the bile and kidneys. There is no evidence of hepatic and renal toxicity associated with HFIP.

Pharmacological Actions

CVS effects

Sevoflurane has effects on the CVS which is similar to that of isoflurane, but it may cause less marked changes in the heart rate. That is, unlike isoflurane which cause tachycardia, sevoflurane causes minimal tachycardia or none. It causes decrease in the pulmonary arterial pressure and systemic arterial pressure, where decrease in diastolic pressure is more than systolic. This is due to the vascular smooth muscle relaxation and reduction of SVR, but not due to the much reduction of cardiac contractility and cardiac output, like halothane. It causes dose-related minimal decrease in myocardial contractility and cardiac output. Renal and hepatic blood flow is well maintained. Sevoflurane does not sensitise the myocardium to catecholamines.

Respiratory effects

Sevoflurane has no irritant effect on the airway like ether and isoflurane, and is very pleasant to inhale. So, these two qualities (nonirritant and pleasant smell) along with its low blood/gas solubility coefficient make the sevoflurane a very suitable agent for inhalational induction in children, infant and neonate. It is the least respiratory tract irritant among all the currently available inhalational anaesthetic agents. But, for induction it is less potent than halothane (MAC value of sevoflurane is 2, whereas MAC value of halothane is 0.75). This can be overcome

by using initially a higher inspired concentration of sevoflurane which is very well tolerated.

Like other halogenated volatile ether anaesthetics, sevoflurane is also a respiratory depressant. Tidal volume is reduced and respiratory rate is increased. But this increased respiratory rate cannot compensate the reduction in tidal volume. Thus it causes reduction of the minute volume. Both, ventilatory response to CO_2 (more than halothane) and hypoxia (30 to 40%) is depressed by sevoflurane. Sevoflurane also reduces the protective hypoxic pulmonary vasoconstriction reflexes in a dose-dependent manner. But, there is no change in the arterial O_2 concentration, when sevoflurane or isoflurane is used in anaesthesia during one-lung ventilation. Sevoflurane is also an effective bronchodilator, but is not as effective as halothane.

CNS effects

Sevoflurane may cause less cerebral vasodilatation than isoflurane. But the other effects of it on CNS are similar to isoflurane. Sevoflurane causes minimal increase in CBF in normocapnia, like isoflurane. Both sevoflurane and isoflurane reduce the cerebral metabolic rate. Cerebral perfusion pressure (CPP) is better maintained by sevoflurane, than isoflurane. Sevoflurane, like isoflurane causes a slight increase in ICP in normocapnic patients. The cerebrovascular response to CO_2 and cerebral autoregulation are both preserved under sevoflurane anaesthesia.

Metabolism and Toxicity

Sevoflurane is less significantly metabolised than halothane (but more than isoflurane and desflurane) by defluorination in liver and the plasma fluoride and HFIP concentration reaches a level of 15 to 25 μ mol/litre after 1 MAC exposure of the drug for 1 hour. But, it is much less than the nephrotoxic level. Approximately 3 to 5% of the inhaled dose of sevoflurane undergoes biotransformation in the liver. But this is 1/4 than that of halothane and 20 to 25 times more than that of isoflurane and desflurane. After prolonged anaesthetic exposure (13 to 14 hours) 5 out of 10 patients exceed the serum fluoride concentration more than 50 μ mol/litre (Fig. 15.25B).

This is a level which was previously thought to be nephrotoxic. But, still there have been no reports of renal failure. In vitro, sevoflurane undergoes extensive metabolism. But clinically (in vivo) it is not a problem, because it is very less soluble in blood. When sevoflurane is exposed to baralyme or sodalime, it breaks into methanol, formaldehyde, carbon monoxide, compund A and compound B. Both of these compounds are hepatotoxic and nephrotoxic. But, still there is no evidence of long term serious renal or hepatic injury after exposure to sevoflurane with baralyme or sodalime. Of the halogenated anaesthetic agents which are currently in widespread use, the sevoflurane is the only one which is not metabolised to trifluoroacetic acid (TFA), implicated in hepatotoxicity. Sevoflurane can also be degraded to hydrogen fluoride. This is due to the metal or environmental impurities which are present in manufacturing equipments. This hydrogen fluoride may produce an acid burn, when it comes in contact with the respiratory mucosa.

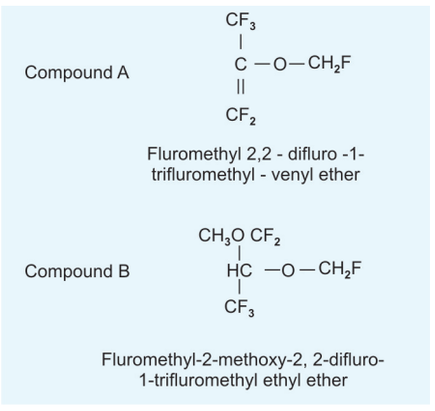

Fig. 15.25B: Sevoflurane compounds A and B

Potential Indications for Use of Sevoflurane

Sevoflurane has a definite place in paediatric anaesthesia practice for inhalational induction and maintenance. Though induction and recovery from sevoflurane is quick like isoflurane and has no pungent smell, so there is a definite advantage of sevoflurane over isoflurane. Sevoflurane offers good haemodynamic stability (like isoflurane) than halothane. As sevoflurane does not contain any chloride ion, so it is environment friendly. Although seveoflurane has fewer side effects than halothane, but there are some concerns about its hepatotoxicity (like halothane). There is also some concern about the renal toxicity of compound A, formed as a result of degradation of sevoflurane by CO_2 absorbers. But, this is not proved to be of any clinical problem.

DESFLURANE (FIG. 15.26)

After the appearance of sevoflurane in 1971, hundreds and hundreds of halogenated volatile anaesthetics agents were synthesized and analysed. Then, desflurane came in this effort. Initially, several factors had delayed the development of desflurane. These were: (i) the potentially hazardous process of utilizing only fluorine in the synthesis of desflurane (in desflurane there is no chlorine or bromine ion), and (ii) the peculiar vapour pressure of desflurane which is very close to the atmospheric pressure at room temperature. This is because the boiling point of desflurane is 22.8°C which is near about to the room temperature. So it starts to boil in the normal room condition. This precludes the use of conventional vapourisers for its administration. Later, a safer

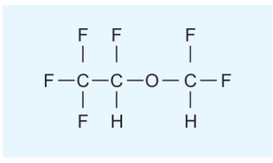

Fig. 15.26: Desflurane

process of synthesising desflurane was developed and there after the Aladin cassette vapouriser was invented for administration. Then, desflurane was subsequently approved for clinical use in USA in 1992. Desflurane is a halogenated (fluorine only) methyl-ethyl-ether. Structurally, it differs from isoflurane by the substitution of chlorine by fluorine on the α-ethylcarbon. The desflurane exists in different optical isomers and the drug for clinical use is a racemic mixture.

Physical Properties

The desflurane has very pungent odour. So, it makes desflurane very irritating and unpleasant to inhale like isoflurane.The molecular weight of desflurane is 168, boiling point is 22.8°C and vapour pressure at 20°C is 664 mm of Hg. Low boiling point of desflurane which is near about to the room temperature indicates that it cannot be administered by using a standard vapouriser. The MAC value of desflurane varies, depending on the stimulus and other co-agents used. It also decreases with age. MAC value of desflurane with O_2 is 6 to 9 and with 70% N_2O is 2.5 to 3.5. The blood/gas partition coefficient of desflurane is 0.42. It needs no preservative for storing and is stable in alkali, ultraviolet light and metal. Only 0.02% of the inhaled drug is recovered, as its metabolites. Desflurane has the lowest blood and other tissue partition coefficient, compared to other inhaled anaesthetics. So, it is unique as an agent for very fast induction and recovery than other inhalation anaesthetic agents. But, unfortunately, as it is an irritant to the upper respiratory tract and causes cough, breath holding, laryngospasm, etc. so induction by desflurane is automatically slowed. Hence, it is not the drug of choice for induction.

Desflurane is relatively less potent than other agents. It is extremely stable and is presented as a clear liquid in amber bottles without preservatives. Its physical properties (i.e, boiling point is around room temperature) donot allow its use by a standard vapouriser. So, special Tec-6 vapouriser is needed for its use. Like sevoflurane, as it is entirely fluorinated, so ozone depletion of the enviornment is minimal. Thus, it is environment friendly. Both sodalime and baralyme can degrade it with the production of carbon monoxide.

Pharmacological Action

CVS effects

The effect of desflurane on CVS is same as that of isoflurane. It causes the reduction of systemic vascular resistance, mean arterial pressure and increase in HR. The decrease in MAP by desflurane is due to the decrease in SVR, but not due to the much reduction of cardiac contractility like halothane. Therefore, there is a very small change in cardiac output. The arrhythmogenic potency of desflurane is like isoflurane. The decrease of SVR by desflurane is due to the peripheral vasodilatation. However the cardiac index remains unchanged or increased. The hepatic blood flow is maintained by desflurane. When desflurane is used for maintenance of anaesthesia there is no change in renal blood flow at concentrations upto 2 MAC. Desflurane is a direct coronary vasodilator. But, the potential improvement in coronary blood flow due to coronary vasodilation is offset by the tachycardia caused by desflurane and also by the fall of coronary perfusion pressure, resulting from peripheral vasodilatation caused by desflurane and hypotension. Like isoflurane, use of desflurane is associated with rapid increase in HR. But this can be reduced by small doses of opioids, esmolol, clonidine and N_2O. Desflurane does not sensitise the myocardium to epinephrine. It can slow the atrioventricular conduction or induce the junctional bradycardia.

Respiratory effects

Like other inhaled anaesthetic agents the ventilatory response of desflurane is accompanied by an increase in respiratory rate and decrease in tidal volume. But, ultimately there is reduction in the minute volume and an increase in $PaCO_2$. However, desflurane does not significantly reduce the minute ventilation, until a concentration of it greater than 1.6 MAC has been used. Thus, at higher concentrations of desflurane respiratory rate decreases, but less than halothane. At more higher concentrations, the respiratory depression effect of desflurane is similar to that of isoflurane and sevoflurane. Ventilatory response to CO_2 is also reduced. Intrapulmonary shunt fraction and the physiological dead space are also increased. Induction by desflurane is associated with coughing, salivation and laryngospasm due to its very pungent odour. This outweighs the benefit of its direct bronchodilating action and rapid induction. And, it is postulated that this causes early sympathetic stimulation. Thus, desflurane is unsuitable for inhalational induction, both for children and adults.

CNS effects

Desflurane decreases the cerebro vascular resistance. Thus, it increases the cerebral blood flow and intracranial pressure. But, it also decreases the cerebral O_2 requirement. Desflurane increases the CSF pressure to a greater extent than isoflurane. In a comparative study, carried out on patients with intracranial mass, 1 MAC desflurane or isoflurane was given. Then, it was observed that ICP increased progressively in the desflurane group, even with hypocapnia. Whereas there was no increase in ICP in the isoflurane group.

Of the commonly employed volatile agent, the order of cerebral vasodilating potency is as follows:

Halothane >> Enflurane > Isoflurane = Sevoflurane = Desflurane

Desflurane causes increased CSF production, under condition of ↑ICP and even in hypocapnia. To date, no clear advantage has been seen for any given inhalation agent over another in neurosurgical anaesthesia. But, the very rapid recovery

characteristic of desflurane may offer a definitive advantage for its use in neurosurgical patients in whom rapid postoperative neurological assessment is desirable. An EEG change caused by desflurane is comparable with that of isoflurane, but no epileptic form of activity is seen.

Effects on muscle

Like other inhaled anaesthetic agents, desflurane depresses the neuromuscular function and augments the action of both non-depolarizing and depolarizing muscle relaxants. Thus, it can provide sufficient muscle relaxation to allow tracheal intubation.

Metabolism and Toxicity

Desflurane has a very low blood-gas and blood-tissue solubility. So, it is very stable and undergoes minimal metabolism in body. These are the properties of desflurane that should favour its low systemic toxicity. However, still a very small amount of desflurane is metabolised with the production of difluoroacetic acid, which may interact with the hepatic proteins and may induce an immune response in susceptible patients. But, after a same concentration and same hour of exposure of desflurane, the concentration of toxic metabolites is 10 folds less than the levels, seen after exposure to isoflurane. So, its potential to cause organ toxicity is very negligible or nil. There is no evidence of renal toxicity with desflurane, even after prolonged exposure. Desflurane may trigger malignant hyperthermia. So, it is prudent not to use desflurane in susceptible patients.

Magnitude of carbon monoxide production in sodalime or baralyme absorber from greatest to least is :

Desflurane >> Enflurane > Isoflurane >>Halothane = Sevoflurane

Indications for Use of Desflurane

The recovery from desflurane anesthesia is more rapid and complete than following recovery from either propofol, isoflurane or sevoflurane-maintained anaesthesia. This suggests that it is very suitable for day-case anaesthesia. Insolubility of desflurane makes it eminently suitable for use in low-flow, closed circuit anaesthesia delivery systems. The lack of effect on the atmospheric ozone layer layer also makes desflurane environmental friendly. Though desflurane is metabolised in fraction to isoflurane, this advantage is theoretical than practical, as the use of isoflurane is not associated with significant incidence of organ toxicity.

XENON

This element was first discovered, in 1898, by W Ramsay and MW Travers. It is present in the atmosphere to the extent of about only one part out of twenty million part. Thus, the concentration of xenon in the atmosphere is only 0·0000087%. Before 1962, it was generally assumed that xenon and other noble inert gases were unable to form compounds with other elements. But, evidence has been mounting in the last few years that xenon and other zero-valency elements can form compounds with other elements. However, xenon is not toxic. But its compounds are highly toxic, because of their strong oxidizing characteristics.

By 1950, studies had proved that there was some hypnotic effect of this noble gas, xenon. Then, in 1951, xenon was first used as an anaesthetic agent by Cullen and Groaa and the patient was a 81 year old man, undergoing orchidectomy. They used 80% concentration of xenon. After that and till now different attempts has been taken to make it feasible to use in clinical practice. But due to different reasons which are described later it was not technically possible. At that time, different isotopes of xenon were also isolated and used in different industries, such as in X-ray tubes for high intensity lights and in many biological experiments such as measurement of cerebral blood flow and lung volumes etc. (Table 15.15).

Atomic number of xenon is 54 and its molecular weight is 131.3. It is a colourless, odourless, non-irritating gas and is four times heavier than air. It is more viscous than nitrogen. It freezes at −111.9°C and boils at −107.1°C It is non-inflammable and does not support combustion. As it is extremely inert, so it does not react with sodalime. It can diffuse readily through rubber. The MAC value of xenon is 71. It indicates that xenon is a more potent anaesthetic agent than N_2O. Therefore, it is possible to use xenon as the sole anaesthetic agent, at least in some patients. Its blood/gas partition coefficient is 0.115 and is lowest among all the available inhalational anaesthetic agents. So, it provides very rapid induction and very rapid emergence from anaesthesia. Its oil/gas partition coefficient is 0.14 to 0.2, which is lower than that of N_2O (0.47).

Xenon is extracted as a side product during air liquefaction (Linde process). Then, the gas is stored in cylinders, similar to those used to store O_2 or N_2O. As xenon only makes up a very small percentage of the atmospheric air, so it is extremely expensive to extract from it. It exerts analgesic effects independent of the α_2-adrenergic and opioid receptors. Although, the most intravenous general

Table 15.15: Advantages and disadvantages of Xenon (Xe) anaesthesia

Advantages

- Inert - has no metabolism,
- Nontoxic,
- Minimal CVS effects,
- Very low blood gas solubility coefficient,
- Very rapid induction and recovery,
- Does not trigger malignant hyperpyrexia,
- Non explosive,
- Environment friendly,

Disadvantages

- Very high cost,
- Low potency (MAC = 71),
- At present no commercially available anaesthetic equipment using xenon.

anaesthetics agents enhance the inhibitory activity of GABA receptors, but the action of xenon on these receptor is also negligible. Xenon potentially inhibits the excitatory NMDA (N-methyl-D-aspartate) receptor channels like ketamine like ketamine and this may account for the xenon's anaesthetic property. Though, xenon has more potent analgesic action than N_2O, but it is not always possible to use xenon as a sole anaesthetic agent. However, less supplementation by intravenous or inhalational anaesthetic agents is needed than N_2O. Like N_2O, xenon has the same potential for diffusion hypoxia during recovery and has the same implications regarding diffusion into gas-filled cavities within the body.

Xenon, being a chemically inert gas, does not enter into any metabolic process of the body, and therefore leaves behind no metabolic products. It is completely excreted through the lungs. Even in high concentrations, xenon is completely nontoxic. Xenon has no or minimal systemic and pulmonary effects. As xenon is odourless, so like N_2O, it is very useful for inhalational induction. Xenon is four times greater in density than that of nitrogen and 3 times denser than that of N_2O. Also it has a higher viscosity than that of both the nitrogen and N_2O. Thus, both the high density and high viscosity property of xenon have significant effects on the pulmonary mechanics, i.e. increasing airway resistance and airway pressure. So, xenon should not be used in patients with respiratory diseases, especially during obstruction of airway. Respiratory rate is slowed by xenon, but there is a compensatory increase in the tidal volume with little change in minute ventilation. It preserves the myocardial contractility in humans. Xenon attenuates the increased plasma epinephrine and cortisol level, associated with the surgical stimulus. It has a very minimal effect on LV systolic and diastolic functions of both the normal and cardiomyopathic heart. In conclusion, we can say that xenon provides good haemodynamic stability with mostly little change in myocardial contractility, SVR, PVR, blood pressure and heart rate (slight reduction of heart rate) than other inhalational anaesthetic agents.

Xenon causes an increase in the CBF and an increase in the ICP, but a reduction of CPP. So, xenon should be used with caution in patients who are at risk from raised ICP. Xenon does not cause malignant hyperthermia. S-100 is a protein that is found in high concentration in the nervous system of vertebratas. Any structural damage of the glia cells cause leakage of this protein S-100 into the extracellular compartment and finally into the serum, where the β-subunit of the protein S-100 can be measured. But, there is no increase in S-100 values during xenon anaesthesia. Thus, it can be concluded that xenon does not impair cerebral integrity.

When exposed to xenon, the patient loses consciousness within a very short period and the patient's state remains stable throughout the anaesthetic procedure. Pain is alleviated. Unlike other commonly used anaesthetic agents, patient's blood pressure does not drop. Patient becomes fully conscious without any side effects within two minutes of completion of the operation and cessation of the supply of xenon. The depth of anaesthesia is also sufficient at a xenon gas concentration of about 55%.

Till now, it is too expensive to use xenon gas in the routine anaesthesia practice. Only when the reuse of the gas within a low-flow, closed circle system becomes true, then the clinical application of xenon will become both possible and economical. At the end of the process of anaesthesia the xenon gas is recollected in a container, compressed and filled again into cylinders. Then it is returned again to the gas supplier to be prepared for reuse. Roughly, 15 to 20 litres of xenon gas is consumed during an operation, lasting for two to three hours. Xenon anaesthesia is mainly used in paediatric and cardiac anaesthesia. It is enviornmental friendly, as it is an atmospheric gas. Now, it is routinely used for anaesthesia in Germany, Netherlands, Sweden and Russia.

ANAESTHETIC DELIVERY SYSTEM OR CIRCUITS

History

The open-drop method of administeration of volatile anaesthetic agents was first introduced by Sir James Y Simson, in 1847, for chloroform. He first used a folded handkerchief as mask on the patient's face on which chloroform was instilled drop by drop. Later it was modified by different persons to ultimately schimmelbushch mask, which is still used now. But the disadvantage of this open-drop method was: (i) an uneven anaesthesia due to variations in concentration of the vapour of anaesthetic agent which was inhaled, (ii) risk of fire, wastefulness, and pollution of the atmosphere, (iii) fall in O_2 concentration under the mask (which could be remedied by giving O_2 under the mask via a small catheter) and (iv) the risk of damage to the eyes and skin of the patient from the direct contact anaesthetic liquid. Then, the administration of ether by a simple inhaler was developed by Morton. In 1846, he used a glass draw-over vapouriser for his public demonstration of general anaesthesia by ether. In 1862, Thomas Skinner, who was a general practitioner and obstetrician of Liverpool first invented a wire frame mask, covered with a domette which could be carried in the top of the hat. After that these masks gained wide acceptance. Then, in 1890 Schimmelbusch, a Berlin surgeon developed a trough shaped rim around this wire frame to prevent the anaesthetic liquid from flowing over directly on the patient's skin of face during open drop method of administration of volatile anaesthetic agent. It was used both for the ether and chloroform. During these first 80 years of general anaesthesia many

millions of patients were managed satisfactorily using this mask and dropping ether or chloroform on this mask (open drop method).

What is now called the anaesthetic mask was originally called the face-piece and was first invented by Cloquet and Sibson? Sibson's original mask was made of mackintosh (waterproof coat) and was lined with silk. Later, it was improved by Snow whose version was made of a thin lead sheet, covered with leather outside and velveteen inside. It was fitted with valves and was used with his newly invented ether inhaler. During that period nasal masks were also developed, instead of face masks for dental anaesthesia. In 1859, Faure of Paris gave chloroform vapour through a rubber tube inserted into one of the nostrils for oral surgery.

The history of anaesthetic machine dates back to 1880 when both the O_2 and N_2O were available as compressed gases in iron bottles for industrial purposes. From this period the development of the basic anaesthetic machine began. In the late nineteenth century, Sir Frederick Hewitt described a machine in which both the O_2 and N_2O from their cylinders was stored in two rubber bags and delivered in variable concentrations to the patient via a stopcock that he designed. Then in 1912, Cotton and Boothby developed a 'N_2O, O_2 and ether apparatus' with compressed gas cylinders where they also incorporated, reducing valves, bubble flowmeters and a bubble-through ether vapouriser. During that period many machines were also developed by many scientists. But the first World War had stimulated the major developments in anaesthetic machine.

In 1912, James Gwathmey of USA developed the first practical anaesthetic machine. Then, in 1917, Henry Boyle modified this American Gwathmey Apparatus and from that period his name became synonymous with this anaesthetic machine. One of Boyle's most important modifications of the Gwathamey Apparatus was the addition of reducing valves. During that time another modification of the Gwathmey's Apparatus was done by Marshall in London. Thus, a major advantage of this Marshall and Boyle's modification over the Gwathmey's Apparatus was the use of Hewitt stopcock to prevent rebreathing.

The original Boyle's machine of 1917 was rebuilt by an engineering firm named Coxeters for commercial use making a company. In its original form it housed two N_2O and two O_2 cylinders in a wooden box. There also was a water-sight flowmeter and an ether vapouriser. It had (Table 15.16) a pressure gauge on the O_2 cylinders and fine adjustment reducing valves. It also had a spirit lamp to warm these cylinders and to prevent the obstruction of gas flow from freezing of water vapour which remained as an impurity in early gas supplied in cylinder. A reservoir bag, a three way stopcock and a facemask completed the apparatus. A portable form of this Boyle's apparatus was also designed for the use of British army in France, and was then popularised very rapidly. However, the modern Boyle's apparatus bears little resemblance to this original model and subsequent modifications were included in the original one (Fig. 15.27).

In the mean time, many developments in anaesthesia had continued between the wars. For example, Jackson in UK introduced a circle system in 1915. Waters in USA developed CO_2 absorption system, in 1924, using granular sodium and calcium hydrate. At this time, watersight feed-meters and bubble bottles were used in industry to indicate the gas flow. In the early 1930's, Coxeter introduced the dry gas flowmeter. The rotameter which is still used today had been first designed by Kuppers in 1908 and was first widely used in the industry for gas and fluid. It was not until 1937, when it was introduced into the anaesthetic machines.

Table 15.16: Modifications of the Boyle's machine

1920 :	Addition of the first Boyle's vaporising bottle to flowmetres.
1926 :	Addition of a 2nd vaporising bottle and bypass controls.
1927 :	Addition of a 3rd watersight flow meter, for CO_2.
1930 :	Addition of a plunger device to the Boyle's vapourising bottle.
1933 :	Dry bobbin type of flowmetre instead of the water sight metre.
1937 :	Rotameters displaced dry bobbin flowmetres.
1952 :	Introduction of the pin-index system.

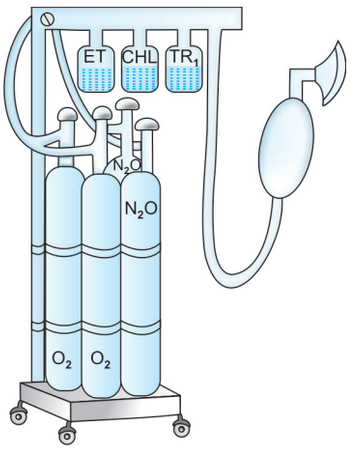

Fig. 15.27: Early Boyle's machine

After that during the next 50 years or more, much of the development of the Boyle's apparatus was focussed on patient's safety and standardization of its design. However, since the early 1990's the introduction of sophisticated electronic monitoring devices in anaesthetic arena has placed a new set of demands on the machine's design.

So, the design of an anaesthetic machine has now changed much for safety and monitoring purposes from its introduction at the end of the last century. However, the modern anaesthetic machine is a highly sophisticated piece of mechanical, pneumatic and electronic engineering tools which is built to maintain good safety standards and incorporate a state of the art monitoring and ventilator system. Now, the anaesthetic machine is called as

an anaesthetic work-station and is a part of a larger system incorporating : decision support, central monitoring and automated anaesthetic record keeping. Now, the most dangerous part of an anaesthetic machine is the operator. Therefore, it is the obligation of the manufacturer to make the new machines absolutely easy to use and also to help the anaesthesiologists to understand how to use them safely.

The Inhalational anaesthetic system has basically two parts:

i. Anaesthetic machine, itself, and
ii. Anaesthetic delivery system or breathing system.

The breathing system is defined as the conduit which is situated between a pressure-reduced and flow-restricted gas source or anaesthetic machine and the patient's airway. The term 'breathing system' is nowadays the preferred term, rather than the former term 'circuit'. Because the flow of gases does not necessarily circulate. Many breathing systems also incorporate the facility of artificially ventilating the patient, a system of humidification and also a facility of connecting the machine to a scavenging system.

Here, we will discuss only the anaesthetic delivery or breathing systems but not the whole anaesthetic machines. The whole anaesthetic machine is discussed in details in Chapter 1. All the anaesthetic delivery systems have some standard common features. These are:

i. Source of O_2 – may be atmospheric or compressed.
ii. Source of anaesthetic gases are compressed cylinders (N_2O) or vapourisers (for volatile anaesthetic agents).
iii. A method of CO_2 elimination – either by venting it to the atmosphere or by chemical absorption.
iv. A reservoir to meet the demand of high peak gas flow during inspiration.
v. A steady inflow of fresh gas both during inspiration and expiration.

The breathing system has three main functions. These are:

i. The supply of O_2 to patient,
ii. The supply of anaesthetic gases and vapours to the patient,
iii. The elimination of CO_2.

Classification of the Anaesthetic Delivery System

It is not possible to classify the anaesthetic delivery system in a completely logical or water-tight manner. Also, there is no justification in using the two near most similar terms – 'semiclosed' and 'semiopened' for confusion instead of one in a single test book. The term 'semiopen' is most commonly used in North America. Any system may function in different modes, according to the rate of inflow of fresh gas, pattern of ventilation, whether patient is in spontaneous or controlled ventilation and different interchanging position of the entry of the fresh gas, reservoir bag, expiratory valve, etc.

The main classification of the anaesthetic delivery system are:

i. Open or non-rebreathing system.
ii. Semi-closed or semi-opened system, where partial rebreathing may occur as there is no CO_2 absorber, such as Mapleson circuits.
iii. Circle rebreathing system with CO_2 absorption.

The main difference between the semiopen and the semiclosed system is that the semiopen systems are valveless and entrainment of room air can occur. But in modern anaesthesia this should not happen. On the other hand, a semiclosed system can not entrain room air. Because, it uses an APL valve and there is an airtight seal between the breathing system and the patient's face, either through a tight fitting mask or by a connection between the breathing system and an airway device such as an ET tube or LMA. In a semiclosed system the problem of peak inspiratory flow is overcomed by the incorporation of a reservoir bag. The bag collapses during inspiration to compensate the difference between the fresh gas flow (FGF) and the peak inspiratory flow. As long as the FGF is sufficient to replace the loss from the system which occurs through APL valve during expiration, the bag will return to its original full state after expiration.

(i) Open or non-rebreathing system

This system ensures that each breath gets full fresh gas flow and all the expired gas is vented out to the atmosphere. This classification includes:

i. Open drop mask,
ii. Insufflation,
iii. A non-rebreathing valve with or without an inspiratory reservoir bag.

Open drop mask

This is the simplest form of anaesthetic delivery system. If supplementary O_2 is not given under the mask, then some rebreathing does occur from the space under the mask which becomes an extension of the anatomical dead space. Schimmelbusch mask and Gardner ether bottle is the best example of this system.

Insufflation

Insufflation means the blowing of anaesthetic gases across the patient face or any part of the patient's airway. Although it is categorised as a breathing circuit, but actually it is considered as a technique that avoids the direct connection between a breathing circuit and the patient's face or airway. Children often resist the direct placement of facemask or an intravenous line before induction. In such circumstances, insufflation is particularly valuable for induction with inhalation anaesthesia. Insufflation avoids any direct patient contact. Therefore, there is no rebreathing of exhaled gases. But the inspired gas contains unpredictable amounts of volatile anaesthetic agents, entrained with the atmospheric air. Insufflation is also used to maintain the arterial oxygenation during a brief period of apnoea, such as during bronchoscopy and laryngoscopy (by oxyscope). In such situations, instead of blowing

gases across the patient's face, oxygen is directly directed and blowed into the the lungs through a device placed in the trachea. Insufflation is also useful during ophthalmic surgery. In ophthalmic surgery under local anaesthesia accumulation of CO_2 under the head and neck drapings is hazardous. So, insufflation of O_2 and air across the patient's face under the drape at a high flow rate (>10 L/min) avoids this problem.

Non-rebreathing valve

Non-rebreathing valve is a modification of semiclosed system. It prevents rebreathing by allowing the unidirectional flow of all the expired gases to the atmosphere. Thus, it enables the patient to inspire a constant proportion of fresh gas flow from the machine or the air, as there is no mixing of inspired and expired gases. Hence, any moment the anaesthesiologist can tell the exact proportion of gases that the patient is inspiring. The examples of this type of nonrebreathing valves are : frumin valve, ruben valve, demand valve etc.

Frumin valve

It can be used both for spontaneous and controlled ventilation. It is so designed that any sudden rise of pressure in the bag which is filled with fresh gases, like squeezing it during controlled ventilation, closes the expiratory valve and all the gases pass on to the patient. On release of pressure at the end of inspiration the expiratory gases escape fully to the atmosphere through the expiratory valve which open during expiration only. This valve can be used either with a facemask or with the ET tube. Resistance and dead space of this valve are minimal.

Ruben valve

The mechanism of action of this valve is same as that of Frumin valve, but it differs from the latter only by very little dead space. Like the Frumin valve, during inspiration this valve automatically closes in both controlled and assisted ventilation, but opens during expiration only allowing expiratory gases to escape fully to the atmosphere. The main advantage of this valve is the small dead space which is only 9 ml. Resistance is also very low in this valve. If it is used with a continuous gas supply, then an inspiratory reservoir bag must be incorporated into the system to supply the peak inspiratory flow rate and the gas flow into the system must be equal or should exceed the patient's minute volume (Fig. 15.28).

When the patient draws air from the atmosphere (i.e. when compressed gas supply is absent), then no reservoir bag is needed. But the system must have a low resistance to meet the peak inspiratory flow rate. Low resistance vapourisers, such as a EMO vapouriser, may be placed in the circuit to deliver the volatile anaesthetic agent and this constitutes a draw-over anaesthetic apparatus. This type of equipment is very useful in remote areas where compressed gas supply is absent. Useful addition to such a system is an extra inlet to permit O_2 enrichment of the inspired air and a bellows with additional valves to permit manual controlled ventilation when needed. The space between the non-rebreathing valve and the patient constitutes the apparatus dead space and for this reason the valve should be mounted as close to the patient as possible. The valve disc and the spring must be made as light as possible to reduce the resistance. The valve should be specially constructed to prevent the formation of water by condensation of its vapour which is present in the expired air. This is because the presence of water may prevent proper functioning of the valve due to sticking (back flow) and may cause serious accidents.

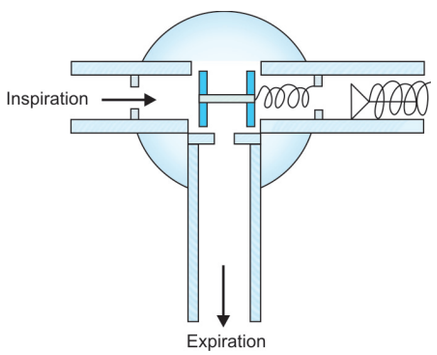

Fig. 15.28: Non-breathing Ruben's valve

Demand valve

This is a valve which is attached to a cylinder of a compressed gas and will deliver the gases at a low pressure up to the peak inspiratory flow rate in response to the slight negative pressure developed by the patient's inspiratory effort. Demand valve is commonly used in connection with the cylinder containing N_2O and O_2 mixture (Entonox). As the valve is capable of delivering gas flows equal to the peak inspiratory flow rate, so no reservoir bag is needed. Such an assemble is classified as an intermittent-flow machine because the valve allows the gas to flow intermittently, corresponding only with the patient's inspiratory effort.

(ii) Semiclosed system

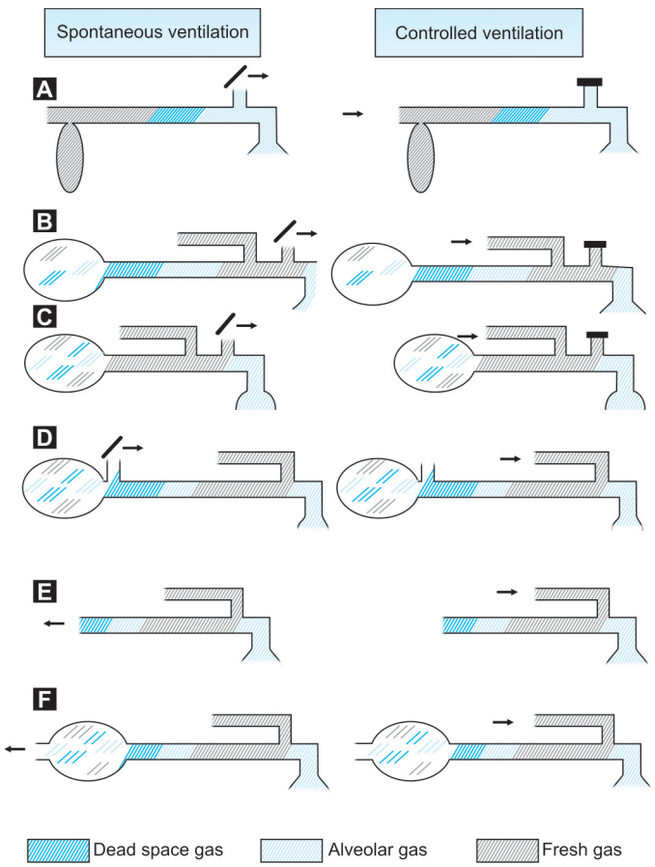
The best example of this breathing system is the series of Mapleson circuit. In 1954, Mapleson described and analyzed the five different types of semiclosed systems or circuits, depending on five different arrangements of the entry site of fresh gas flow, tubing, mask, reservoir bag and expiratory valve to prevent the rebreathing maximally during spontaneous and controlled ventilation. However, in general the elimination of CO_2 depends also on many other factors other than the above mentioned five factors. These are : the fresh gas flow rate, minute volume, tidal volume, the pattern of breathing (spontaneous or controlled), apparatus dead space, resistance of the circuit, the respiratory rate, the I:E ratio, the duration of expiratory pause, the peak inspiratory flow rate, the volume of the reservoir tube and the volume of the breathing bag.

The Mapleson semiclosed circuit is classified as A, B, C, D and E. Willis added an extra F-system to these original classifications. Recently these six types of Mapleson systems were grouped functionally into three. They included the: (i) group A, (ii) group B, C, and (iii) group D, E, F. The Mapleson A has a spring loaded pop-off valve, located near the face mask and the fresh gas flow enters from the opposite end of the system, distal to the reservoir bag. In the B and C groups the spring loaded pop-off valve is located near the face mask, but the fresh gas inlet is located near the patient, close to the APL valve but proximal to the reservoir bag. The reservoir tubing and the breathing bag serve as a blind limb where the fresh gas, dead space gas and alveolar gas can be collected. In the Mapleson D, E and F groups which is also called the T-piece group, the fresh gas enters near the patient end, proximal to the APL valve or an exhalation port, where there is no valve and the excess gas is popped-off at the opposite end of the circuit.

Mapleson – A

It is the most familiar breathing system to anaesthesiologists and is also known as the Magill's circuit. In this circuit the entry of the fresh gas flow is distal to the reservoir bag, opposite to the patient end of the circuit at a distant from the patient. The expiratory valve is near the patient's end. The type of expiratory value which is used in Mapleson circuit is the Heidbrink type. Rebreathing during spontaneous respiration in this circuit can be prevented by a relatively low fresh gas flow than any other Mapleson circuits. During anaesthesia with spontaneous respiration, the Magill's attachment is still the best in an adult for economy in total gas flow and for virtual elimination of rebreathing. During expiration, the first part of the expired gas comes from the anatomical dead space and contains no CO_2. It travels down the corrugated tube towards the reservoir bag and fills it, mixing with the fresh gas coming from the machine. In the next part of expiration when the volume of expired gas from the patient increase, then the pressure in the circuit also rises. Thus, the expiratory valve is lifted up (opening pressure of the Heid brink valve should not be more than 1 to 2 cm of H_2O) and expired gas escapes. Gas escaping at this expiratory part of respiratory cycle is the alveolar gas, containing maximum amount of CO_2. During spontaneous inspiration the fresh gas flushes the dead space gas (which collects in the tubing during first part of expiration) through the tubing towards the patient for rebreathing. But, rebreathing of this dead space gas by the patient poses no problem, as it does not contain any CO_2. If the fresh gas flow is adequate, then the dead space gas during expiration cannot go up to the reservoir bag, but meets with the fresh gas flow at the earlier part of the tube and escapes with the alveolar gas at the end of expiration, pushed by FGF. So, this circuit preferentially eliminates the alveolar gas first, and then the dead space gas later. If the fresh gas flow is gradually reduced, still then rebreathing does not occur, until the fresh gas flow falls below 70% of the minute volume, a figure (Figs 15.29A to F) which is approximately equal to the alveolar ventilation (2 to 4 liters/minute). So, during spontaneous ventilation the recommended fresh gas flow (FGF) rate through the Magill's circuit (Mapleson A) is one times of the minute volume which can prevent the rebreathing of CO_2.

But this Mapleson A circuit is inefficient during controlled ventilation. During controlled or assisted ventilation the



Figs 15.29A to F: Gas disposition at the end of expiration, during both spontaneous and controlled ventilation in Mapleson circuits

resistance of expiratory valve should be increased which will help to ventilate the patient. During expiration of controlled ventilation no venting of gas occurs through valve in the Mapleson A circuit. So, the total expired dead space gas and the alveolar gas are retained in the tubing and the bag. Venting of the gas from the circuit during controlled ventilation occurs only during inspiration by manual compression of the reservoir bag. During squeezing of the reservoir bag the alveolar gas with CO_2 which is retained during expiration in the tube is rebreathed first before the pressure in the system increases enough to force the expiratory valve open. Then this opened expiratory valve causes the dead space gas (without CO_2) with the fresh gas to vent in the last part of the inspiration through the pop-off valve. So adequate CO_2 elimination or prevention of rebreathing during controlled ventilation with Mapleson A system requires a fresh gas flow greater than 20 litre/minute or three times of the minute volume. Hence, in practice, controlled ventilation should be avoided with this system.

Mapleson – B

In this system the fresh gas inlet is near the patient, but just distal to the expiratory valve and proximal to the reservoir bag. But unlike Mapleson A, this system functions similarly both during spontaneous and controlled respiration. During the first part of expiration (both spontaneous and controlled), fresh gas with the dead space gas accumulates in the tube and the bag. Then the expiratory valve opens when the pressure in the circuit increases and a mixture of alveolar with fresh gas is discharged. Some CO_2 containing alveolar gas, dead space gas and fresh gas is also collected in the reservoir tube and the bag. During the next inspiration (in both spontaneous and controlled) patient receives the fresh gas flow from the machine and a mixture of retained dead space gas and alveolar gas from the tubing and reservoir bag. The composition of this inhaled mixture depends on the fresh gas flow rate. In this circuit rebreathing of expired gas (acceptable level of inspired CO_2 is 0.2 to 1%) can be prevented, if the fresh gas flow rate is greater than 2.5 times of the minute ventilation during both spontaneous and controlled ventilation. The amount of FGF needed for proper functioning of this circuit (i.e. prevention of rebreathing of CO_2) greater than D, E and F group of circuit.

Mapleson – C

This system is also known as the Water's circuit. It is also called the Westminister face piece. Arrangement of this system is similar to that of Mapleson B, except that the expiratory or reservoir tube is of large bore and very short. This change reduces the reservoir volume and allows a good mixing of the fresh gases with the exhaled gases. However, this system is less efficient than the Mapleson B system. Because, as there is no tube to maintain the separation of the alveolar and dead space portions of the expired gas, therefore the whole of the expired volume is mixed in the reservoir bag. So, the inspired mixture contains more the expired alveolar gas than the Mapleson B. Thus, a fresh gas flow more than 2.5 times of the minute volume is required to prevent rebreathing. It is, however, a very convenient arrangement for ventilating a patient before intubation or to assist chest physiotherapy in intensive care unit.

Mapleson – D

Actually this circuit looks like a T-piece. The T-piece has three way tubular connection − a patient connection port, a fresh gas port and a port for connection to the corrugated tubing with a reservoir bag and an APL valve for expiration. The Mapleson D system is popular, because the scavenging of excess gases is relatively easy in this circuit and it is the most efficient of all the Mapleson systems during controlled ventilation. For scavenging a large bore tube can be attached to the adjustable pressure limiting (APL) valve. The fresh gas inlet is located near the patient end of the circuit and the pop-off expiratory valve is close to the reservoir bag, i.e., away from the patient end. While in A, B and C Mapleson system the pop-off expiratory valve is situated close to the patient. The length of the expiratory tube is determined by the distance which the anaesthesiologist wants to maintain from the patient, but this length has minimal effects on the ventilation. The sensor or the sampling site for respiratory gas monitor may be placed between the bag and its mount, between the corrugated tubing and the T-piece or between the corrugated tubing and the APL or pop-off valve. In adults, it may be placed between the T-piece and the patient.

During the expiratory phase of spontaneous ventilation first the dead space gas, then alveolar gas and fresh gas, flow subsequently down the expiratory limb. As the pressure increases, the expiratory valve opens and a portion of the gas mixture containing dead space and alveolar gas is expelled. Patient receives a mixture of fresh gas and expired gas from the expiratory limb during next inspiration. The composition of this inspired gas mixture is determined by the rate of fresh gas flow, patient's tidal volume and the duration of expiratory pause. Slow respiratory rate with a long expiratory pause allows the fresh gas to drive out all the expired alveolar gas moving down the expiratory limb. High respiratory rate with a short expiratory pause provides inadequate time to flush out all the alveolar gas and allows rebreathing to occur. Rebreathing in this situation can be prevented by high fresh gas flows.

During the inspiratory phase of controlled ventilation, the alveolar gas and the dead space gas are also forced out of the expiratory valve, instead of the fresh gas like spontaneous ventilation. Therefore, this system also causes less rebreathing than Mapleson A, B and C systems during controlled ventilation. Recommended fresh

gas flow rates during spontaneous ventilation with Mapleson D system is approximately 2.5 times of the minute ventilation. The recommended fresh gas flow-rate for Mapleson D circuit are:

i. 2 to 3 litre/minute for patient weighing less than 10 kg.
ii. 3.5 to 4.5 litre/minute for patient weighing from 10 to 50 kg.
iii. 70 ml/kg/min for patient weighing more than 50 kg. In each of these cases, the recommended tidal volume is 10 to 15 ml / kg and the respiratory rate is 12 to 16 breaths/min.

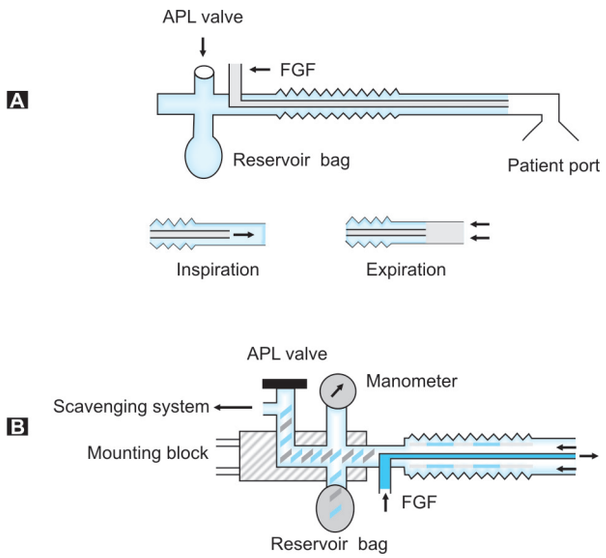
Bain's circuit

It is a modification of the Mapleson D system. It is also called the coaxial circuit, because the fresh gas flows through a narrow inner tube which is situated within the outer corrugated tube used for expiration and delivers fresh gas directly at the patient end of the circuit. The expired gas enters the corrugated outer large bore tube and is vented out through the expiratory APL valve, near the reservoir bag which is situated opposite to the patient end of the circuit. The expiratory gas does not enter the inner narrow tube, carrying the fresh gas because the pressure inside the narrow inner tube is high. The Bain's circuit may be used for both spontaneous and controlled ventilation. Like Mapleson D, to maintain normocarbia and to prevent rebreathing in the Bain's circuit, the fresh gas flow of 2.5 times of the minute volume is needed during spontaneous ventilation. But, only 70ml/kg of fresh gas flow will produce normocarbia in the Bain's circuit during controlled ventilation. Functional analysis of the Bain's circuit during spontaneous and controlled ventilation is like that of the Mapleson D circuit. In spontaneous ventilation during exhalation the expired gas mixes with the fresh gas and moves through the corrugated outer tube towards the bag. After the bag is filled with expired gas, the gas exists via the pop-off or APL valve. Then, during the expiratory pause the fresh gas also flows down the outer corrugated tubing from the narrow inner tubing and pushes the exhaled gas in front of it (Figs 15.30A and B).

In spontaneous ventilation then during inspiration the patient will inhale the fresh gas from the fresh gas inlet, the corrugated outer tubing and the reservoir bag. If the FGF is high, then all the gas which is drawn by patient during inspiration from the corrugated tube and the reservoir bag will also be fresh gas. If the FGF is low, then some exhaled gas which may be present in the outer corrugated tubing and the reservoir bag will be inhaled. So the ventilatory pattern, the FGF rate and the rate of breathing will also help to determine the amount of rebreathing.

In controlled ventilation during expiration the expired gas flows down the corrugated tubing from the patient's end. At the same time, fresh gas flow also enters the corrugated tubing. During the expiratory pause, the fresh gas flow continues and pushes the exhaled gas down the corrugated tubing towards the APL valve and the reservoir bag. During inspiration which is helped by squeezing the bag, the fresh gas and the expired gas from the corrugated tubing, enters the patient. If the fresh gas flow is low, then some exhaled gases may be inhaled from the corrugated tube with the fresh gas from the narrow inner tube. If the FGF is high, then it fills up the whole outer corrugated tube, driving out all the expired gas and the patient inhales only the fresh gas from the inner tube and the outer tube. Prolonging the inspiratory time, increasing the respiratory rate, adding an inspiratory plateau, etc., will increase the rebreathing. Rebreathing also can be decreased by allowing a long expiratory pause, so that the fresh gas can get adequate time to flush out all the exhaled gas from the outer tubing through the APL valve. When the fresh gas flow is high, there is little rebreathing. The $ETCO_2$ is determined mainly by the minute ventilation. The rate of FGF is the main factor controlling the CO_2 elimination. The higher will be the FGF, the lower will be the $ETCO_2$ level.

Bain's circuit (coaxial modification, i.e. tube within tube modification of Mapleson D system) is also available with a metal head and channels drilled



Figs 15.30A and B: Bain's modification of the Mapleson D system. The fresh gas supply tube is inside the corrugated tubing (coaxial version).FGF = Fresh gas flow, APL = Adjustable pressure limiting valve, (A) is the simple Bain's circuit, (B) is the ventilator compatible Bain's circuit permanently mounted on the anaesthetic machine

into it for permanent attachment with an anaesthetic machine. This provides a fixed position of the reservoir bag and the APL valve in relation to the anaesthetic machine. Some metal heads also have a pressure manometer. Mechanically the controlled ventilation can also be achieved by connecting the hose of an anaesthetic ventilator in the place of the reservoir bag and completely closing the APL valve. Excess gas is vented out through the ventilator.

PEEP valves or devices can also be applied with the Bain's system. A bi-directional PEEP device or valve may also be used between the APL valve and the corrugated tubing. This allows PEEP to be administered both during mechanical and manual ventilation. However, some PEEP valves close when a negative pressure is applied. So, spontaneous breathing is impossible, when such a valve is present in the system. The PEEP valve may be applied in the hose pipe leading to the anaesthetic ventilator. In this location it will only be effective during mechanical ventilation. An uni-directional PEEP valve can also be attached at the attachment site of the bag, using special connectors and unidirectional valves. Such an arrangement allows application of PEEP both during mechanical and spontaneous ventilation, but not during manual ventilation (Fig. 15.31).

Advantages of the Bain's circuit are: lightweight, convenient, can easily be sterilized, reusable and easy scavenging of the expired gases. The exhaled gases in the outer corrugated reservoir tube add warmth to the cold inspired gases passing through the narrow inner tube. In a patient weighing less than 40 kg the fresh gas flow should not be reduced below 3 litre/minute, otherwise higher $PaCO_2$ values will result. This is a reflection of the higher metabolic rate in children and infants. Hazards of the Bain's circuit include unrecognized disconnection or kinking of the inner fresh gas tube. So, the outer tube should be transparent for inspection of the inner tube.

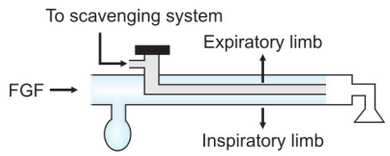


Fig. 15.31: This shows Lack's modification of the Mapleson A system

Another alternative arrangement of coaxial tubing is the Lack's circuit. Here, the fresh gas flows through the outer wide corrugated narrow tube and the expired gas flows down the central narrow inner tube. This central narrow tube runs from the connection at the patient's end to the APL valve at the machine end of the system. This makes it easier to adjust the valve and facilitates the scavenging of excess gas. However, it slightly increases the work of breathing. Actually, this is a modified configuration of Mapleson A (Magill) circuit, where a central inner tube extends from the patient's end to the APL valve. However, the same considerations like Bain circuit will govern the fresh gas flow, which is required to prevent the rebreathing in Lack's circuit. Diameter and length of the tube used in this circuit should be of low-flow resistance. The Lack circuit is suitable for spontaneous respiration and requires a lower fresh gas flow, than the Magill's circuit. The Lack system is also available in both 'dual tube'(or parallel arrangement) or 'tube within a tube'(or coaxial arrangement) arrangements, in which the narrow expiratory limb runs inside the outer wide inspiratory limb. For spontaneous ventilation, the APL or expiratory valve is kept in the fully opened position. Excess gas comes out of it during the later part of expiration. For controlled or manual ventilation, intermittent positive pressure is applied to the bag. Then, the APL valve is tightened accordingly, so that when the bag is pressed, sufficient pressure can be built-up which will be able to inflate the lungs. APL valve opens during inspiration and closes during expiration in controlled ventilation. It is opposite to the spontaneous ventilation.

Humphrey ADE System (Using Mapleson A, D and E Principle)

This is a recently described system or circuit which is available in both the coaxial and noncoaxial form. It is claimed that the Humphery system functions with the efficiency of the Lack's system for spontaneous respiration and of the Bain's system for controlled ventilation. But, it is heavier and less convenient to use. As the name implies, this ADE system works on the principle of Mapleson A, D and E circuits. In the A configuration, it acts similar to the Lack's modification of the Mapleson A system. In the D configuration, its action resembles to that of Bain's modification of the Mapleson D system. It also has a system which allows the APL valve to be bypassed in the D configuration, so that it resembles to the Mapleson E system. It has two levers and their positions determine the functioning of the system. There is a self locking mechanism which prevents the accidental displacement of any lever from their selected position. In the coaxial version, the expiratory limb runs inside the inspiratory limb (Lack system). In the noncoaxial or parallel version the inspiratory and expiratory tubes are held together at the machine end by a metal bridge. The expiratory limb consists of : a long tube which extends from the patient's end to the machine, an APL valve, a valve-bypass outlet and a lever that directs the flow of gases through either the APL valve or the valve bypass outlet. When the liver is kept at a vertical position, then the gases pass through the APL valve. On the other hand, when it is in the horizontal position, then the APL valve is isolated. Hence, gases flow through the valve-bypass outlet, like Mapleson E system. Both the outlets have a 30 mm external diameters for attachment to the scavenging devices. The valve-bypass outlet also has a 22 mm internal diameter for the attachment of a hose leading to a ventilator or a reservoir bag. A

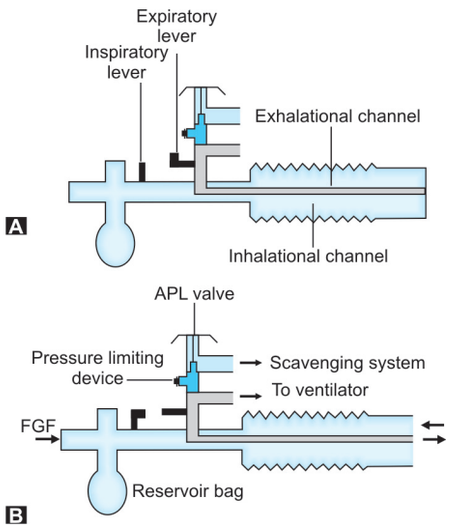
pressure limiting device may be fitted near the APL valve (Figs 15.32A and B).

The inspiratory limb consists of:

i. A fresh gas inlet,
ii. A reservoir bag,
iii. A lever
iv. A length of a corrugated tube that runs to the patient from the machine.

Gases can flow in and out of the bag when the lever is vertical. But, gas flow into the bag is blocked, when the lever is horizontal and thus makes the inspiratory limb a simple tube.

Later, a single lever Humphrey ADE system has also been developed. It is again available in both parallel noncoaxial and coaxial forms. Here, there is a single lever controlled rotating cylinder which passes through the inspiratory and expiratory limbs. When the lever is at an upright position, then the reservoir bag and the APL valve are in the circuit. Thus, the valve-bypass outlet is excluded from the circuit. On the other hand, when the lever is turned down, then the bag and the APL valve are excluded from the system. Thus, the valve-bypass outlet is connected to the system.



Figs 15.32A and B: Humphrey ADE system. The dual lever coaxial version of this system is shown here. (A) A mode ventilation, with vertical levers, (B) D and E mode of ventilation,with horizontal levers

Mapleson – E

The classical example of Mapleson E breathing system is the Ayre's T-piece with a modification of expiratory limb. Phillip Ayre first developed Ayre's T-piece in 1937 for use in paediatric patients, undergoing cleft palate repair and intracranial surgery. Mapleson E is the modification of this Ayre's T-piece with the addition of an expiratory limb. The picture shows the relationship between the fresh gas inlet, patient's end, expiratory limb and the gas exit point. It has minimum dead space, no valves, and exerts very little resistance. The expiratory limb constitutes or acts as reservoir, as there is no reservoir bag in this original Mapleson E system. If the volume of expiratory limb exceeds the tidal volume, then the breathing of room air through it does not occur and thereby prevents the dilution of anaesthetic gases with the room air, which can also occur in the original simple T-piece developed by Philip Ayre. On the other hand, if the volume of expiratory limb is less than the tidal volume of the patient, then the reverse will occur. If fresh gas inflow equals to two and half times of the minute volume of patient, then rebreathing will not occur. The actual length of the expiratory limb is irrelevant, provided it does not cause appreciable resistance to expiration and rebreathing. During expiration of spontaneous ventilation the fresh gas and the exhaled gas flows down the expiratory limb. Then, at the end of the expiration fresh gas accumulates at the patient's end of the expiratory limb. During the next breath, this fresh gas is drawn by the patient, both from the fresh gas inlet and the expiratory limb. The controlled ventilation can be accomplished by intermittent occluding of distal end of the expiratory limb (as there is no bag in this system). Squeezing of the bag attached to the end of expiratory limb (Jackson-Rees modification) can control the ventilation better.

Mapleson – F

This is the most commonly used T-piece system in anaesthesia practice. It is nothing but the Jackson-Rees modification of (Fig. 15.33) Mapleson E system. The Jackson-Rees modification is nothing but the addition of a reservoir bag at the distal end of expiratory limb of the Mapleson E system. The release mechanism is either by an adjustable valve at the distal end of reservoir

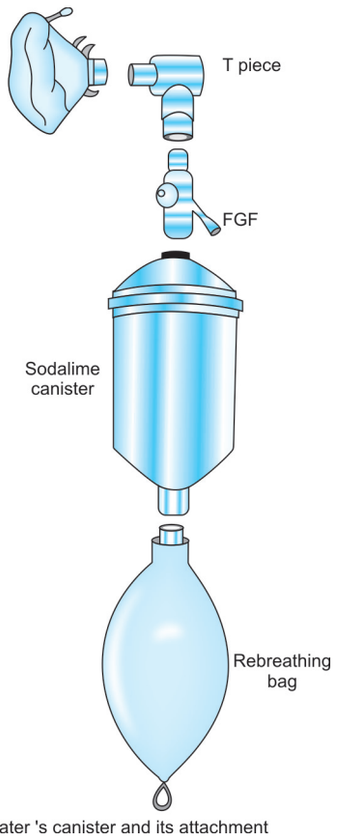


Fig. 15.33: Water's To and Fro T-piece system with carbon dioxide absorption canister which was first introduced in 1923, in clinical anaesthesia practice by Ralph Waters. It is discussed here only for its historical interest. In this system, a canister filled with sodalime was placed between the face mask and the rebreathing bag. Both inspiration and expiration took place through this canister.

This "To and Fro System" had some definite advantages. It was cheap, simple, easy to operate and easy to sterilise. It offered very low resistance and a low gas flow. Heat loss was also low as the exhaled gases were kept warm by the heat generated by a reaction during carbon dioxide absorption. It also helped in the conservation of moisture.

But, it also had some disadvantages. As the canister lay close to the head of the patient (especially a small baby), alkaline dust easily passed on to the patient. Also a heavy canister near the head of the patient was inconvenient

bag, or by an open tail (here lies the difference between Mapleson F and Mapleson E systems). Mechanism of action of this circuit is same as Mapleson D or E. The advantages of this Mapleson F system are : simple construction, inexpensive, minimal resistance and observation of the reservoir bag which allows one to inspect the respiratory excursion and also judge the depth of anaesthesia. Controlled ventilation can also be instituted easily by squeezing the bag if needed. Scavenging system of this circuit is easy. It is accomplished by enclosing the reservoir bag in a plastic chamber.

The disadvantage of this system is the lack of humidification. This problem can be overcome by allowing the fresh gas to pass through an online-heated humidifier. Another disadvantage of the Jackson-Rees modification of Mapleson E system is the need of high fresh gas flow. This system is used mainly in paediatric patients and for transportation of anaesthetized patients.

T-piece system

This is defined as a breathing circuit where the limb through which the fresh gas enters the circuit acts as the vertical limb of T and is placed between the patient's end and the expiratory end of a long tube which acts as the horizontal limb of the T. So, Mapleson A, B and C systems do not come under the T-piece system. But, this functional definition is sometimes confusing as there does not necessarily have a separate limb, leading to the expiratory port. It thus also includes some systems which physically do not look like the T-piece. As the T-piece breathing system is commonly used in paediatric anaesthesia, so resistance is of great importance. Highest resistance occurs at a peak expiratory flow, to which must be added the fresh gas flow.

T-piece system without expiratory limb

Devices of this sort of breathing circuit are mainly used with the endotracheal tube or tracheostomy tube. If the patient breathes spontaneously then no rebreathing occurs, as there is no expiratory limb where the expired gas can accumulate. So, the total amount of expired air is breathed out in the atmosphere. But, when anaesthesia is provided, then to prevent the breathing of room air due to the absence of the expiratory limb, the fresh gas flow must be equal or exceed the peak inspiratory flow rate. This is widely used for resuscitation purposes. If necessary for controlled ventilation, then intermittent occlusion of the expiratory orifice by the operator's finger affords a compact and convenient method of inflating the patient's lungs. But, in such conditions a pressure – relief valve with a water manometer is essential, as the pressure of fresh gas supply is applied directly to the patient's lungs.

Most of the T-pieces have a fresh gas entry port of narrow bore which enters the T-piece at right angles to the main respiratory channel. If high flow of fresh gas enters at an acute angle, within the T-piece then it is found that gases can be entrained in the main tube by the venturi principle. But this results in an impedance of expiration with dangerously high intrapulmonary pressure. This principle is used in a rigid bronchoscope to permit ventilation under general anaesthesia with muscle relaxants. A fine tube, mounted at the eyepiece of a rigid bronchoscope is used for O_2 delivery intermittently. The jet of O_2 entrains air and generates sufficient pressure to inflate the patient's lungs, which deflate as soon as the gas flow through the fine tube is stopped.

Now, at the end of discussion, we can conclude that the relative efficiency of different Mapleson systems with respect to prevention of rebreathing during spontaneous ventilation is like the following:

Mapleson A > D,E,F > B,C

and during controlled ventilation is like the following:

Mapleson D,E,F > B,C > A

The Mapleson A, B and C systems are rarely used now, but D, E and F systems are commonly employed. There is also some confusion regarding the recommendation of FGF in the different breathing systems with multiple variable predictions. So, monitoring of the end tidal CO_2 is the best method of determining the optimal fresh gas flow. But during monitoring it should be noted that the $PaCO_2$ to $ETCO_2$ gradient decreases with rebreathing.

PRESSURE LIMITING PROPERTIES OF THE RUBBER RESERVOIR BAG

The pressure/volume or elastic characteristic of the rubber bag which is commonly used as a reservoir in the anaesthetic circuit, constitutes a useful safeguard against the accidental build-up of dangerously high pressure in the patient's lungs which might occur if an expiratory valve is accidentally occluded. For examples if the gas flows into a BOC 2 litres rubber bag at the rate of 8 litre/minute, then the pressure rises quickly to a peak value of 30 mm of Hg and thereafter falls slightly, until it bursts after reaching a volume of more than 144 litres.

Tubing

Tubing in the anaesthetic system is usually made of corrugated walls, so that it can bend at acute angles without kinking. Regarding size 20 mm is the recommended minimum internal diameter of the tube. It must be sufficiently electrically conductive (by adding carbon to rubber) to prevent static charges to build up during anaesthesia which might produce sparking. Compliance of the tube may become an important factor. If the tube has high compliance, then a larger portion of the ventilator's stroke volume may be lost in the tubing. In patient with a very stiff lung , this may be a great problem.

The advantages of Mapleson system

i. The Mapleson system is most simple and inexpensive. In this system without the APL valve there is no moving

parts. The components of this system are easy to dis-assemble and disinfect or sterilize.

ii. This system has a buffering effect. So, any variation in the minute volume affects the end tidal CO_2 tension less than in a circle system.

iii. Rebreathing will result in retention of heat and moisture. In the coaxial system the inner inspiratory limb is heated by the warm exhaled gas in the large coaxial expiratory tubing.

iv. The resistance of this system is usually with in the recommended ranges at a given fresh gas flows which is usually used in clinical practice. So, the work of breathing during spontaneous ventilation is significantly less with these systems than with the circle system. However, this is not always true. The work of breathing increases, if the APL valve is not oriented properly.

v. These systems are of light-weight and not bulky. So, they are not likely to produce excessive pull on the endot – tracheal tube or cause accidental extubation.

vi. They are easy to position in relation to patient. A long Mapleson D system with an aluminium APL valve may also be used to ventilate a patient undergoing MRI investigation.

The disadvantages of Mapleson system

i. The Mapleson system requires a high gas flow. So, it results in higher costs, increased atmospheric pollution and difficulties in assessment of spontaneous ventilation.

ii. In this system it is difficult to determine the optimum fresh gas flow. On the other hand, it is necessary to change the fresh gas flow matching with respiratory rate from time to time during spontaneous ventilation and also while changing from spontaneous to controlled ventilation or vice versa.

iii. Anything that causes accidentally the fresh gas flow to be low then it presents a hazard, because dangerous rebreathing may occur. This has been reported with unnoticed emptying of the N_2O cylinder, a leak in the humidification device or leak of gas through a loose vapouriser-filler cap.

iv. If extra components, such as respiratory gas monitor, heat exchanger, moisture exchanger, etc, are placed between the fresh gas inlet and the patient, then a tremendous increase of the dead space area will occur. Therefore, this will cause dangerous rebreathing.

v. In the Mapleson A, B and C systems the APL valve is located close to the patient, where it is inaccessible to the user. In addition, scavenging is also difficult from this inaccessible APL valve. This disadvantage can be over – come by using the Lack's modification of Mapleson A circuit.

vi. The Mapleson systems are not suitable for a patient with increased CO_2 load, such as malignant hyperthermia. Because, it may not be possible to increase enough the fresh gas flow to remove the increased CO_2 load.

vii. Mapleson E system is notorious for air dilution. It is also difficult to scavenge the Mapleson E and F systems.

Respiratory Gas Monitoring and the Mapleson Systems

All the Mapleson systems, except the 'A' have the fresh gas inlet near the patient-connection port. This may make it difficult to get a reliable sample of exhaled gases for analysis of respiratory gases for monitoring (Fig. 15.34).

There are four possible sites from where the sampling of gases is done. These are :

i. At the junction of the breathing system and the elbow connector,

ii. At the corner of the elbow connector,

iii. 2 cm distal to the elbow conector,

iv. In the tracheal tube connector.

It is found that if the sampling is carried out at the two sites which are close to the patient, i.e. at the point 3 and point 4 of the table above, then the values are more accurate. Significant errors are noted when the samples are taken from the corner of the elbow connector (site 2). But this occurs only if a high fresh gas flow is used and not in low fresh gas flow. Significant errors are also noted when the sampling is performed at the junction of the breathing system and the elbow connector (site1), even if a low fresh gas flow is used. On the otherhand, a cannula that projects into the airway can be used to improve the sampling. In another study, involving infants and children, sampling at the junction of the tracheal tube and the breathing system resulted in a falsely low end tidal CO_2 values in patients weighing less than 8 kg. The accuracy of measurement can also be improved by inserting a small heat and moisture exchanger, between the breathing system and the tracheal tube connector. But, use of device at this site will result in an increase in dead space and may result in excessive resistance, so that spontaneous respiration cannot be used.

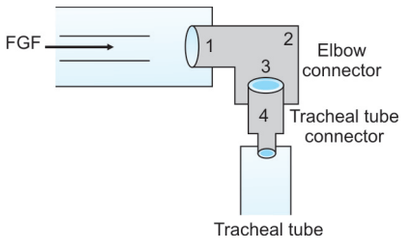

Fig. 15.34: Respiratory gas sampling site in a Mapleson system. Accurate values for expiratory concentration of gases is obtained by sampling at the sites of 3 and 4. Sampling at the site 2 will yield accurate values, only if the fresh gas flow (FGF) is not high. Sampling at the site 1 will yield inaccurate values, even at low fresh gas flows

Circle system

The circle system is the most popular breathing system in anaesthesia practice and is free from most of the drawbacks which are found in the to and fro Mapleson arrangements. It is so named, because its components are arranged in a circular manner. The circle system may be completely closed or semiclosed. The completely closed circle system prevents

rebreathing of CO_2 by the CO_2 absorber, but allows rebreathing of other exhaled gases. The extent of rebreathing of CO_2 in this system depends on the CO_2 absorption power of absorbent, component arrangement and the rate of fresh gas flow (Fig. 15.35).

In a semi closed system the APL valve is partially open and there is no rebreathing of expired gases and requires a very high fresh gas flow. Whereas a completely closed system is one in which the fresh gas flow exactly matches the volume being consumed by the patient. There is complete rebreathing of all other exhaled gases after absorption of CO_2, as all the valves are completely closed.

The circle system consists of seven components:

i. Entry site of fresh gas flow.
ii. Inspiratory and expiratory unidirectional valve.
iii. Inspiratory and expiratory corrugated tube.
iv. Y-piece connector.
v. An overflow or pop-off or damp valve, which is also called the adjustable pressure limiting (APL) valve.
vi. Reservoir bag.
vii. Canister, containing CO_2 absorbent.

Various circle arrangements are possible, depending on the relative position of these seven components. The possibilities

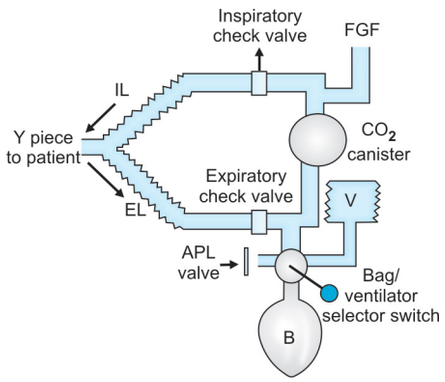

Fig. 15.35: Components of a simple form of circle system. B = Bag, V = Ventilator, FGF = Fresh gas flow, APL = Adjustable pressure limiting valve, IL = Inspiratory limb, EL = Expiratory limb

can also be reduced by considering the best possible arrangements of the 5 main components, such as unidirectional valve, APL valve, reservoir bag, CO_2 absorber and the site of fresh gas entry.

To prevent rebreathing of CO_2, three rules must be followed. They are :

Rule I

Unidirectional valve must be located both in the inspiratory and the expiratory limbs, between the patient and the reservoir bag.

Rule II

Fresh gas inflow cannot enter the circuit between the expiratory valve and the patient. Fresh gas inflow is best placed on the downstream side of the relief valve and after the canister containing CO_2 absorbent. This arrangement conserves the fresh gas which would otherwise be lost through the relief valve. It has been argued that placing the inflow site before the canister would allow the fresh gas to become humidified by the water, which is evolved with absorption of CO_2 by the CO_2 absorbent. However, this water is needed to ensure that the reaction takes place at a maximum rate. If the inlet of fresh gas is placed anywhere on the downstream side of the inspiratory valve, then the fresh gas will become mixed with expiratory gas during expiration and part of it will be ejected. If however, the inlet is placed on the upstream side of the inspiratory valve, then during inspiration any changes in the concentration of the anaesthetic gases are made effective immediately, while during expiration (when inspiratory valve is closed) the fresh gas fills up the reservoir bag. This is the position of maximum economy and efficiency.

Rule III

The over-flow (pop-off) valve cannot be located between the patient and the inspiratory valve, but must be located on the downstream side of the expiratory valve. If these rules are followed, then any arrangement of the other components does not increase the rebreathing of CO_2. The most efficient arrangement of circle system is shown in the picture, and this arrangement conserves the dead space gas and preferentially eliminates the alveolar gas. But, the more practical arrangements, used in all the contemporary anaesthetic machines, are less efficient, because it allows the alveolar and dead space gas to mix before venting. Even, with the fresh gas flow inlet fixed, there are several alternative options for position of the relief valve: (i) in the inspiratory limb, after the reservoir bag, (ii) in the expiratory limb, before the reservoir bag, or (iii) after the expiratory valve (Fig. 15.36).

There are two factors which determine the choice of position of the relief or APL valve. First, although the expired air will be blown-off in any of these three positions, but the closer the valve is to the patient, the more the gas will be pure alveolar air and also depends at the point in the respiratory cycle when the valve opens. Second, if the relief valve is placed before the expiratory valve, there is possibility of ejecting fresh gas, during the inspiratory phase of controlled and assisted ventilation. Thus, combination of these two conditions such as having the relief valve as close to the patient as possible and also on the upstream side of the expiratory valve, can be obtained if the inspiratory valves are a made part of the patient's T-piece. The practical disadvantage of this arrangement is that the

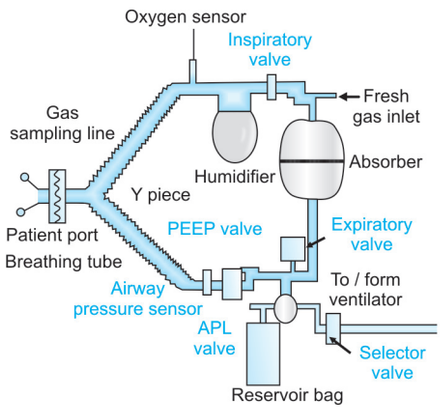

Fig. 15.36: Option for position of relief valve

connection to the patient becomes cumbersome and the operation of the valves may not be reliable, in practice. The alternative arrangement of retaining the relief valve on the T-piece connection to the patient, but moving the inspiratory and expiratory valves back to the anaesthetic machine, is economical only when the respiration is spontaneous. If the relief valve is also moved away from the patient, both alveolar and dead space gas is ejected, but the efficiency of the system is maintained only during controlled ventilation.

Circle system with low gas flow

In a circle system where components are arranged with optimum efficacy, then the expired alveolar gas is preferentially expelled from the circuit. Here, the circle system behaves like the Magill's circuit and rebreathing of CO_2 will not take place until the fresh gas flows falls below the alveolar ventilation. It is found that in the Magill's circuit the minimum fresh gas flow needed to prevent rebreathing in a spontaneously breathing patient is 3 to 4.5 litres/minute. Magill's circuit loses this efficiency when the above calculation is used for controlled ventilation. But, in an optimum arrangement of circle system the preferential elimination of the alveolar gas continues during controlled ventilation also with the same low gas flow which is sufficient to prevent rebreathing in Magill's circuit during spontaneous breathing. During commonly used conditions such as 'closed circuit with leak' and with a fresh gas flow of 4 litres/minute, it is unnecessary to have any sodalime in the canister at all. Under this condition the fresh gas flow takes over the role of the alveolar ventilation in controlling $PaCO_2$ without sodalime, even in controlled ventilation.

When the fresh gas flow is reduced to a level below the alveolar ventilation (or in some other arrangement of components where the system is not optimum) then sodalime is required in the circle system to prevent the rebreathing of CO_2. Without sodalime, when the fresh gas flow falls below the alveolar ventilation, then discrepancy develops between the inspired and delivered O_2 concentration in controlled ventilation. Calculation of the inspired O_2 concentration during the low fresh gas flow (N_2O:O_2 mixture), with considerable accuracy is possible only when a steady state has been achieved. For this reason, monitoring of the inspired O_2 concentration in the circuit is necessary.

Totally closed system

The circle system can also be used in a completely closed manner. After a period of about 10 minutes of breathing with high inflow of fresh gas, which brings about denitrogenation, the expiratory valve can be completely closed and the only fresh gas flow into the system is the patient's basal O_2 requirement together with the anaesthetic agent. Such a system was widely used when cyclopropane was in extensive use and if the O_2 (not N_2O) is the only gas which is flowing, apart from the other liquid anaesthetics. In such circumstances no monitoring is required, except for the usual close observation of the patient.

Advantages of the circle system (Totally closed or partially closed)

1. Reduction of atmospheric pollution

Once the expiratory valve is totally closed, then no anaesthetic gas escapes into the air to pollute the enviornment except a very small percentage which are lost through the different leaks. During totally closed halothane anaesthesia, concentration of halothane in the theatre does not rise above 0.03 ppm. In a partially closed system there is some atmospheric pollution, but this can be prevented by a scavenging system.

2. Economical

In a totally closed system the consumption of any volatile anaesthetic agent and fresh gas flow is very low. For example, the consumption of halothane in an adult patient is about 3.5 ml/hour and the fresh gas flow is about 250 ml O_2/minute. So, it is very economical.

3. Humidification

Intubation bypasses the normal physiological mechanism for humidification of the inspired gas. But, in the circle system with a CO_2 absorber, the inspired gas will be fully saturated with water vapour nearly at a body temperature.

4. Reduction of heat loss

Close circuit conserves the loss of heat of body. Because, the sodalime gets hot during use and thus the circuit actively assists in maintaining the temperature of inspired gas and thus the patient's body temperature.

5. Ease of monitoring

If O_2 is the only fresh gas flow into the completely closed circuit, then the patient's O_2 uptake is easily determined. Then, it is just the flow which is required to keep the volume in the circuit constant. Any change in this rate would be quickly noticed by the volume and movement of the bag. This would give an early warning of the onset of malignant hyperpyrexia. Patient's tidal volume can be assessed more accurately by the observation of the reservoir bag in a totally closed circuit, because there is no high flow of gas to affect the bag's movement.

Disadvantages of the circle system

The major disadvantage of the circle system stems from its complex design. Misconnections, disconnections, obstructions and leaks are the principle problems of this system. Malfunctioning of the valves can also cause serious problems. If the valves stick in an open position, then rebreathing occurs. On the other hand, if the valves are stuck closed, total occlusion of the circuit with high expiratory resistance occurs. In such circumstances, breath stacking and tension pneumothorax can occur.

N_2O in a Totally Closed System

The N_2O agent can be used in a totally closed system, but very cautiously and in a sophisticated manner. It is found that uptake of N_2O by body is about 500 ml/min in the first two minutes. Then, it falls to about 200 ml/min after ½ hour, and 100 ml/min after about an hour. After that, it tends to remain constant at about 50 to 100 ml/hour, due to inevitable losses through the skin and the wound. The complete saturation of body tissues by N_2O takes about 5 hours. At the end of a three hour operation, during which an inspired concentration of 70% N_2O has been used, an average adult will absorb 20 to 26 litres of N_2O, dissolved in his tissues. The fall in uptake of N_2O by the body from a closed circle system will be indicated by a gradual decrease in the inspired O_2 concentration, and the gradual increase in the inspired N_2O concentration in the circuit, which necessitates continuous readjustment of the O_2: N_2O ratio. So, N_2O should never be used in a totally closed circuit, without O_2 and N_2O analyzer.

CARBON DIOXIDE ABSORPTION

History

The idea of CO_2 absorption techniques in anaesthesia by the sodalime or other agents came from the submarine and chemical warfare. It was first applied during World War I, necessitating effective gas masks. Then in 1915, Wilson had patented the new sodalime with increased efficiency. But, CO_2 reabsorption technique in anaesthesia was slow to gain popularity, until the cyclopropane which was then an expensive gas was introduced in this discipline (Table 15.17).

Chemistry

Sodalime and baralyme are the two most important agents which are commonly used for CO_2 absorption in anaesthesia practice. The recently introduced chemical as CO_2 absorbent is calcium hydroxide lime. Of these three agents, the most commonly used is the sodalime. Calcium hydroxide lime consists primarily of $Ca(OH)_2$, $Ca(Cl)_2$ and two other setting agents such as calcium sulfate and polyvinyl pyrolidine. The latter two chemicals enhance the hardness and porosity of the granules of calcium hydroxide lime and increase its efficacy. The most significant advantage of calcium hydroxide lime over the other two agents used for absorption of CO_2 is its lack of sodium and potassium hydroxides as compositions. The absence of these two chemicals in calcium hydroxide lime eliminates the undesirable production of carbon monoxide and the nephrotoxic substance, such as: compound A by the reaction of halogenated anaesthetic agents with it.

Table 15.17: The desirable features of the agents for CO_2 absorption mechanism

1. Lack of toxicity with common anaesthetics,
2. Low resistance,
3. Low cost,
4. Easy handling,
5. High efficacy.

Sodalime consists of 94% $Ca(OH)_2$, 5% NaOH and 1% KOH. But, the precise proportion of these compounds differs for different manufacturers. The composition of best effective, 'high moisture' sodalime is 80% $Ca(OH)_2$, 15% H_2O, 4% NaOH and 1% KOH. Some silica is also added in it to produce the calcium and sodium silicate which makes the product hard and reduces the dust formation. But, the hardness and CO_2 absorption power of any agent varies inversely. In this CO_2 absorbent (soda lime) the NaOH acts as the active component for CO_2 absorption and KOH acts as an activator. In the first step, CO_2 reacts with water to form carbonic acid which then reacts with sodium and potassium hydroxide to form sodium and potassium carbonate. This chemical change requires the presence of some moisture which is provided by the patient's expired gases and at the same time produces heat. The $Ca(OH)_2$ then reacts with Na_2CO_3 and K_2CO_3 to form calcium carbonate and regenerate NaOH or KOH.

$$CO_2 + H_2O \leftrightarrows H_2CO_3$$

$$H_2CO_3 + NaOH \text{ (or KOH)} \rightarrow Na_2CO_3 \text{ (or } K_2CO_3) + H_2O + \text{Heat}$$

$$Na_2CO_3 \text{ (or } K_2CO_3) + Ca(OH)_2 \rightarrow CaCO_3 + 2\ NaOH \text{ (or KOH)}$$

Some CO_2 directly reacts with the $Ca(OH)_2$ to form (Table 15.18) calcium carbonate. But, this reaction is very slow. In the early days it was noted that sodalime could regenerate its efficacy automatically, even after being exhausted. But, the explanation for this regeneration is very complex and is of little clinical importance today. Regeneration is rarely seen nowadays, because of the improved quality of sodalime with less silica and addition of potassium hydroxide.

Water is required in every step of reaction. But, moisture which is provided to sodalime from the patient's expired air does not chemically combine with it. It is probably present as a thin film of NaOH solution on the surface of $Ca(OH)_2$. The sodium and potassium hydroxide is hygroscopic, but calcium hydroxide is not. The moisture threshold of both the sodalime and baralyme for the effective absorption of CO_2 is 10%, and the optimum efficiency of absorption of CO_2 in sodalime is obtained with a hydration of 14% to 19%. When the sodalime is exposed to room air, then it loses its moisture and subsequently efficacy falls rapidly. So, it must be stored properly.

Table 15.18: Specifications of sodalime

Contents	$Ca(OH)_2$	94%
	NaOH	5%
	KOH	1%
Moisture		More than 14%
		Less than 19%
Hardness		Greater than 75
Size of granules		4 to 8 mesh

Baralyme is composed of 80% $Ca(OH)_2$ and 20% $Ba(OH)_2$. It may also contain some KOH. It is more stable than sodalime and does not need any silica binder. But, it is 15% less efficient than sodalime, based on the weight basis. Baralyme contains water as barium hydroxide in the octahydrate form, $Ba(OH)_2\ 8H_2O$, on its surface. So, it may perform better in a dry climate. Because of this, the baralyme is more stable when exposed to dry atmosphere than sodalime. For this reason, baralyme is used to absorb CO_2 in the space capsule, despite it been less efficient than soda lime. The optimum water content for best reaction of baralyme is 11 to14%. The reaction of CO_2 with baralyme differs from sodalime in that more water is liberated during direct reaction of barium hydroxide with carbon dioxide. This CO_2 next reacts with water to form H_2CO_3.

$Ba(OH)_2 + 8H_2O + CO_2 \rightarrow BaCO_3 + 9H_2O$ + Heat

$H_2O + CO_2 \rightarrow H_2CO_3$

Then, by a direct reaction like with KOH and NaOH, Carbonic acid (H_2CO_3) reacts with $Ca(OH)_2$ to form a carbonate.

$H_2CO_3 + Ca(OH)_2 \rightarrow CaCO_3 + H_2O$ + Heat

Like sodalime, baralyme too has no regeneration capability. The granular size of the sodalime or baralyme used in anaesthesia practice varies between 4 and 8 mesh. This is an optimum size at which resistance to airflow is negligible. This is also the optimal size balancing between the resistance and the absorptive capability. The smaller the granules, the more is the surface area available for absorption of CO_2, but the airflow resistance will also increase. The larger the granules, the reverse occurs. Mesh refers to the number of openings per linear inch in a sieve through which the granular particles can pass. A 4 mesh screen means that there are four 0.25 inch openings per linear inch. An 8 mesh screen means that there are eight 0.125 inch openings per linear inch. The hardness number of the granules is 75.

Theoretically, the amount of CO_2 that should be absorbed is 26 litres per 100 gm of absorbent (sodalime or baralyme). However, this is not true in practise because the direct channeling of gas through the granules of the absorbent decreases its efficiency. Thus it actually allows only 10 to 20 litres of CO_2 to be absorbed with an average of only15 litres. The 100 gm of sodalime will absorb about 15 litres of CO_2 before the concentration of CO_2 in exit gas exceeds 1%. From this it can be calculated that 1 kg of soda lime is sufficient for 8 hours. On the other hand the absorptive capacity of calcium hydroxide lime has been reported to be 10 litres of CO_2 per 100 gm of absorbent (Table 15.19).

Indicators

The indicators are the chemical compounds which are used to assess the functional integrity of another channel compound. The pH indicators act on the principle of the changes in pH. The pH indicator which is commonly used for both the soda lime and baralyme to assess their functional integrity is the ethyl violet or triphenylmethane dye. The critical pH value of this indicator is 10.3. It means that above or below this pH level, the colour of this indicator will change. The pH of a fresh absorbent remains above the critical value and the ethyl violet indicator in this CO_2 absorbent exists in a colourless form. Ethyl violet changes from colourless to violet when the pH of the absorbent decreases below 10.3 as a result of CO_2 absorption. In such circumstances, base of the indicator reacts with the carbonic acid which is produced in the absorbent after absorption of CO_2 to form a soluble carbonate which is violet in colour. Indicators are not always reliable for functional status of the absorbent. Fluorescent light can also deactivate the indicator, so that the absorbent appears white even though it is exhausted.

Table 15.19: Different colours of indicators

Indicators	*Soda lime*	
	Fresh	*Exhausted*
Mimosa-Z	Red	White
Phenolphthalein	Colourless	Pink
Clayton yellow	Pink	Yellow
Methyl orange	Orange	Yellow
Ethyl violet	Colourless	Purple (violet)

The final proof of efficacy of a particular sodalime canister's contents can only lie in the periodic testing of the gases flowing through it for the possible presence and percentage of CO_2. Examples of other indicators are: methyl orange, phenolphthalein, clayton yellow, etc.

Canister

It is a container, made up of a transparent plastic to see the (Fig. 15.37) changes of colour of its contents such as sodalime or baralyme with indicators. It is mounted vertically in the machine. The size of the canister is no longer critical and it can be made considerably larger for a longer period of life. But, the optimum size of the canister which is commonly used clinically is 18 cm in height and at least 12 cm in diameter. The capacity of the canister is 2 litres and there is an annular ring which prevents the channeling of gas between soda lime and the canister wall.

The gas flow in the canister is from above downwards and the upper chamber is exhausted first. Once the upper chamber of the canister is exhausted, the lower chamber is placed up and fresh soda lime should be placed in the lower compartment, resulting in a highly efficient use of sodalime. To reduce condensation in the canister and to prevent the sodalime from becoming caked, air spaces are provided at the top and the bottom of the canister. The heat which is produced inside the canister due to the absorption of CO_2 is known as the 'heat of neutralization'. The rise in temperature of up to 60°C have been recorded inside the canister.

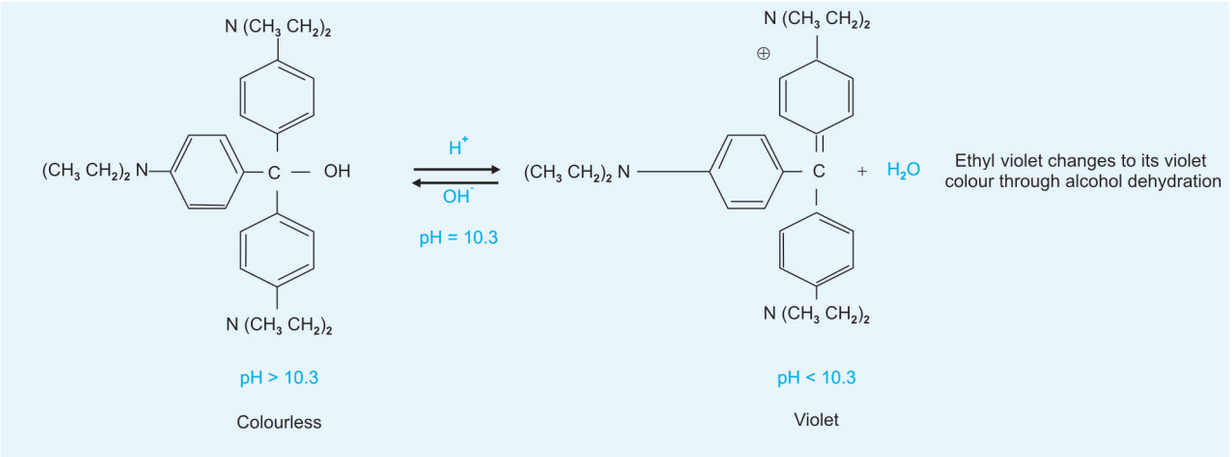

Fig. 15.37: Changes of coloured contents

The production of some heat is a sign that sodalime is functioning efficiently. There is also an overall increase in the weight of the contents of canister which amounts to about 33% when they are completely worn out.

Absorbents and Anaesthetic Agents

There is always some reactions between the CO_2 absorbents and the newer halogenated volatile anaesthetic agents. Halothane, isoflurane, sevoflurane and desflurane are all degraded to some extent by the CO_2 absorbants. But among them, the most extensive degradation occurs with sevoflurane and the degradation product is called 'compound A'. There are some factors which increase this degradation products. These are:

i. Higher concentration of sevoflurane,
ii. Low fresh gas flow,
iii. Higher temperature of the absorbent,
iv. Use of baralyme instead of sodalime,
v. Drying of the absorbent.

The significance of these degradation products is still controversial. The CO_2 absorbents also absorb the volatile anaesthetic of anaesthesia agents. So, they cause slower induction of anaesthesia and later subsequent exposure of the patient to these volatile anaesthetic agents when their use is stopped. Dry absorbents absorb more volatile anaesthetic agents, than the wet one. When volatile anaesthetic agents are used with absorbents, there is more production of carbonmonoxide CO. The concentration of CO increases in the following condition.

i. Increased length of time of use,
ii. Dry absorbents,
iii. Use of baralyme, instead of sodalime,
iv. Concentration of the anaesthetic agent,
v. Higher temperature of the absorbents.

The CO formation is maximum with desflurane which is followed by isoflurane. The amount of CO formed by sevoflurane and halothane is same and very little. Sevoflurane mainly produces 'compound A'. Moisture in the absorbant reduces CO formation. However, the respiratory gas monitors which are used currently cannot detect the CO directly.

Induction and Nitrogen Elimination

The elimination of body N_2 by O_2 during induction is very essential. So, for the first 3 to 5 minutes a high flow of 100% O_2 is necessary. This will reduce the nitrogen concentration in the lungs and breathing system to less than 5%. Fresh 100% O_2 flow can then be reduced. Only the N_2 is dissolved in the tissues, then is diffused back into the alveolar gas. The volume of the dissolved N_2 in an average adult is approximately 1litre and it takes about five hours for the entire body N_2 to be abstracted. In a low flow and semiclosed system, N_2 escapes through the release valve. In a totally closed system, N_2 will accumulate and may constitute as much as 15% of the circuit gas after an hour. However, this is of no consequence, provided N_2O is not given in a totally closed system.

VAPOURISERS

Introduction

Most of the inhalational anaesthetic agents which are used today are liquids at the normal atmospheric pressure and room temperature. So, they must be converted into gas or vapour, before they are used. A vapour is the gaseous phase of a chemical agent that is liquid at room temperature and normal atmospheric pressure. Thus, a vapouriser is an instrument which is developed to change a liquid anaesthetic agent into its vapour or gaseous form and deliver a controlled amount of this vapour or gas to the fresh gas flow. As many as three types of vapourisers are now commonly used and attached to an anaesthetic machine.

Simultaneously, with the development of different types of volatile anaesthetic agents different types of vapourisers also have been evolved. It has initially started from the rudimentary open-mask ether inhalers, and then passes through the EMO

and copper kettle vapouriser to finally reach (Table 15.20) the temperature-compensated, variable-bypass vapourisers. In 1993, with the introduction of desflurane in anaesthesia practice even more sophisticated vapourisers (Tec – 6 and Aladin cassette) were also introduced to handle the unique physical properties of this agent. But, operating principles of every vapouriser depends on the same physical characters of the volatile anaesthetic agents. These physical characters are : vapour pressure, latent heat, specific heat, thermal conductivity.

Physics

Vapour Pressure

When a volatile liquid is kept inside a container closed to the atmosphere, then few molecules of this liquid breaks away from the upper surface of the liquid and enters the space above. Thus, vapour of this liquid is formed. If the temperature of the container is kept constant, then a dynamic equilibrium is developed between the liquid and the vapour phase of this agent at that temperature. In that situation, the number of molecules in the vapour phase of this volatile agent remains constant and the pressure created by the bombardment of the molecules against the wall of container is also constant. Now, the pressure of this vapour is called the 'saturated vapour pressure' at that temperature and pressure. After that, if more heat is applied to the liquid, then the equilibrium is shifted more to wards the vapour phase, so that the more and more molecules enter the vapour phase from the liquid phase of this anaesthetic agent and the vapour pressure rises. On the contrary, if the heat is taken away from the anaesthetic liquid, then more and more molecules enter from the vapour phase into the liquid phase of the agent and vapour pressure falls. This causes a shifting of the equilibrium towards the liquid phase. During delivery of anaesthesia when a carrier gas is passed over a volatile anaesthetic liquid, then the equilibrium shifts to the vapour phase. The vapour pressure of a volatile liquid depends on the temperature and atmospheric pressure and the character of the lquid. So, it is useless to talk about the vapour pressure without mentioning the temperature and pressure. At the boiling point of a liquid, the vapour pressure and the atmospheric pressure is same at that temperature.

Boiling point

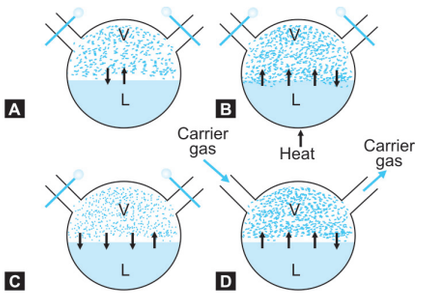
Boiling point of a liquid is defined as the temperature at which its vapour pressure becomes equal to the atmospheric pressure. Or conversely, during gradual increase in temperature of a liquid when the vapour pressure and atmospheric pressure becomes same, then this temperature will be called as the boiling point. The lower the atmospheric pressure, the lower will be the boiling point and higher the atmospheric pressure, the higher will be the boiling point (Figs 15.38A to D).

Concentration of gases

To express the concentration of gases or vapours, two methods are commonly used. These are : partial pressure in mm of Hg or volume in percent (%).

A mixture of many gases in a closed container will exert a total constant pressure on the walls of it. The part of this total pressure which is exerted on the wall of the container by the individual gas in the mixture is called the partial pressure of that gas in this mixture. Hence, the total pressure of the gas mixture is the sum of the partial pressures of each of the constituent gases.

Volume in percent to express the concentration of gas is defined as the number of units of volume of a particular gas in relation to the total 100 units of volume of the total gas mixture. In a mixture of gases each constituent gas exerts a pressure which is directly proportional to its percentage of volume of that gas in the total volume of the mixture. The volume percent expresses the relative ratio of volume of different gases in a gas mixture. Whereas, partial pressure of a gas expresses an absolute value.



Figs 15.38A to D: This figure depicts the changes in vapour pressure, with variations in temperature.
A: shows that the vapour and liquid phases are in equilibrium.
B: shows that the equilibrium shifts towards the vapour phase. Because, heat is applied and more molecules enter from the liquid into the vapour phase.
C: shows that the equilibrium shifts to the liquid phase. Because, cooling of liquid causes more molecules of vapour to enter the liquid and thus reduce the vapour pressure.
D: also shows that the equilibrium shifts to the vapour phase. This is because the carrier gas passes over the liquid. The liquid takes the energy for the molecules to break away and to form vapour. Thus vaporisation gradually removes the molecules from the liquid, which have more energy and the temperature of the liquid falls, as vaporisation proceeds. So, a gradient of temperature will be created between the liquid with the surroundings, and heat will flow from the surroundings to the liquid. This heat is called the heat of vaporisation. It is defined as the number of calories necessary to convert 1 ml of liquid into vapour

Table 15.20: Properties of common volatile anaesthetic agents important for vapourisers

Agent	*Boiling point (0°C)*	*Vapour pressure (mm of Hg)*	*Heat of vapourisation (cal/ml)*	*Specific heat of liquid (cal/ml)*	*MAC in O_2 (%)*
Halothane	50.2	243	65	0.35	0.75
Isoflurane	48.5	238	63	0.35	1.15
Sevoflurane	58.6	157	–	–	2
Desflurane	22.8	669	–	–	6.4

Partial pressure ÷ Total pressure = volumes percent ÷ 100

Although the concentration of a gas or a vapour in a mixture is most commonly expressed as volume in percent, but patient uptake or the depth of anaesthesia are directly related to the partial pressure of the gaseous phase of the agent.

Latent heat

Latent heat of vapourisation is defined as the number of calories required to change 1 gm of liquid into vapour, but without any change in the temperature. This latent heat for vaporisation comes from the liquid itself, or from an outside source. In the absence of outside energy (heat) sources the surrounding air gives the required heat to the anaesthetic liquid for its vapourisation. So, the water vapour in air condenses outside the Boyle's vapourising glass ether bottle and Goldman vapouriser which is not used now in modern anaesthetic machine. Thus, the temperature of the anaesthetic liquid falls and vapourisation is reduced.

Specific heat

The specific heat of a substance is the number of calories required to increase the temperature of 1 gm of a substance by 1°C. The concept of specific heat is important for the design and construction (metal) of vapourisers by the following two ways:

i. It indicates how much heat should be supplied to the liquid to maintain a constant temperature when the heat is lost during vaporisation,
ii. Manufacturers select the metal to build the vapourisers that have a high specific heat. Because it will supply more heat to minimize the temperature changes associated with vaporisation.

Thermal conductivity

The thermal conductivity of a metal is defined as the speed with which the heat flows through this substance. Vapourisers are made of metals of high thermal conductivity which helps to maintain a uniform temperature.

Types of Vapourisers (Table 15.21)

1. Open mask

The basic requirement of all the anaesthetic vapourisers is that they should convert the volatile liquid anaesthetic agents into a continuous flow of anaesthetic vapour of this liquid. Then, it is mixed with air or some other carrier gas under controlled conditions. The simplest form of vapouriser is a gauze pad which is usually fitted on a wire frame. It acts as the wick and a partial reservoir of the volatile anaesthetic liquid. The patient's respiration through the gauze pad, which is soaked with a liquid volatile anaesthetic agent, results in a flow of anaesthetic vapour which is at a saturated vapour pressure level near the gauze. But, it is subsequently diluted as air is entrained passing though the gauze. The temperature of the anaesthetic liquid in the gauze pad will drop below the atmospheric level, because the heat required for vaporisation will be greater than that available from the immediately surrounding air. Some control of the situation can be obtained by controlling the rate at which the anaesthetic liquid is dropped onto the gauze of mask, and the distance between the gauze pad and the patient's face (i.e., the amount of diluting air entrained). It is also fortunate that the main agent administered by open-mask is diethyl ether which does not dramatically depress the respiration (Figs 15.39A and B).

Table 15.21: Classification of different vapourisers

According to method of vapourisation
a. Open drop
b. Bubble through

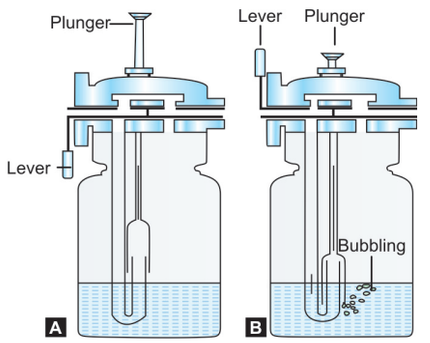
According to the compensation of temperature
a. Thermocompensation
b. Supplied heat

2. Uncalibrated vapourisers

When the use of compressed gas in metal cylinders was introduced into the practice of anaesthesia, then it became possible to contain the liquid anaesthetic agents in a bottle. Then, it also became possible to bubble the gas through the liquid anaesthetic agent, or blow it over its surface for vaporisation. Thus this bottle or container containing liquid anaesthetic agent is called vapouriser. This vapouriser is sometimes also called a plenum vapouriser. Because, gas is being forced into a chamber and plenum is a chamber in which the pressure is greater than outside.

In the Boyle's vapourising glass bottle used for anaesthetic liquid ether, the stream of fresh gas flow directed to the patient is divided into two. The main bypass stream passes straight without coming into contact with the anaesthetic liquid present in the bottle. The second carrier gas stream is passed over the surface or as bubble through the liquid anaesthetic agent kept in a bottle and reunited with the bypass stream. The ratio of the carrier gas to the bypass gas is determined by the position



Figs 15.39A and B: This figure shows uncalibrated vapourisers.
A: The cowl is not fully impinged in the liquid, so it is a Blow-Over type of vapouriser.,
B: The cowl is fully impinged in the liquid, so it is a Bubble-Through type of vapouriser

of the control knob. Again, the position of the plunger, controlled by the anaesthesiologist will determine how closely the stream of the carrier gas will pass over the surface of the liquid anaesthetic (blow-over) agent or whether it actually bubbles through the liquid. In a simple vapourisers of this kind the control of the splitting ratio of the carrier gas by the control knob, is not accurate. It is usually very non linear and there is wide variation between the different instruments. Also, as the latent heat of vaporisation is taken from the liquid anaesthetic agent, so there is also cooling of the liquid which reduces the resulting vapour concentration with passing of time. A number of factors, such as gas flow rate, volume of liquid in the bottle and the atmospheric temperature also influence the rate of vaporisation. So the resulting concentration of anaesthetic vapour received by the patient cannot be predicted with accuracy as it will not match with the indicator's number of control knob. Agitation of the bottle due to any cause will produce a big increase in vapour concentration, even without bubbling. Finally, when the bottle is not used for long time, then the total internal gas space over the volatile anaesthetic liquid becomes filled with the saturated anaesthetic vapour. Then, the initial concentration of the anaesthetic agent when the control lever is first turned on will be unexpectedly dangerously high. This happens particularly when the bottle is surrounded by a warm water bath which is sometimes done to avoid the reduction in anaesthetic concentration, produced by cooling of both the liquid and bottle.

Though, there are considerable draw backs, still the wide spread use of these uncalibrated vapourisers indicate their relative safety. Their safety feature lies in the fact that the anaesthetic vapour concentration falls with time, due to cooling of the anaesthetic liquid. Since, the concentration of vapour they produce is not accurately known, so its anaesthetic effect can only be estimated by noting the volume of anaesthetic liquid being used (vapourised) and close continuous observation of the patient.

The Goldman halothane vapouriser is another type of very simple uncalibrated vapouriser, which is most commonly used today for halothane in less sophinsticated machine and all the physics which is discussed till now should also be applied here. Actually, it was designed for use in an intermittent flow machine. It can also be used inside a circle anaesthetic system. It has a small volume. It offers a low resistance to gas flow, because it was initially intended for use during spontaneous respiration. It is an inefficient vapouriser without temperature compensation. The maximum halothane output of this vapouriser is about 3%. It has also been used successfully in a totally closed anaesthesia circuit.

3. Oxford vapouriser (Fig. 15.40)

This vapouriser is discussed here only for its historical interest. It was developed by Robert Macintosh in collaboration with Morris Motors for use by the Armed Forces in 1940. To increase the concentration of ether vapour the condensation of moisture outside the ether bottle during its vaporisation at the expense of latent heat can be prevented by placing a jacket of warm water around the ether glass bottle. Alternatively, the ether can be kept constantly above its boiling point (36.5°C), so that the ether vapour in the container is under pressure and is trying to escape. Then a fixed amount of ether vapour controlled by a knob is is allowed to come out mixed with the carrier gas to obtain a known percentage of ether vapour which is delivered to the patient. This principle was used in the construction of the Oxford vapourisers. Here ether was surrounded by chemical crystals of calcium chloride with a melting point above that of ether, which was again surrounded by warm water. Once these crystals melted due to the warm water, ether vapour would come out spontaneously (Fig. 15.41).

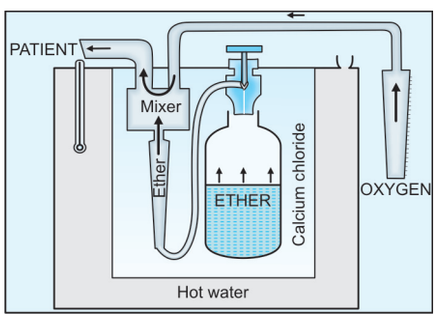


Fig. 15.40: Oxford vapouriser

4. Copper kettle vapouriser

This was commonly used in the past at North America. It is also discussed here for historical interest. In this type of vapouriser an O_2 supply, separate from the main supply, is metered and is passed through a copper vessel (for rapid heat transfer) containing a liquid anaesthetic agent. The gas passes through a fenestrated bronze disc which breaks it up into very fine bubbles. Thus, the gas becomes fully saturated during its passage through the anaesthetic liquid. The temperature of the anaesthetic liquid is measured by a thermometer. From the graph of saturated vapour pressure against this temperature, the concentration of the anaesthetic vapour coming out from the vapouriser can be calculated. Now the volume of gas passing through the vapouriser fully saturated with anaesthetic vabour is known. So, the final concentration of anaesthetic vapour in the mixture reaching the patient can be simply calculated. It may be adjusted finely as required by changing the gas flow rate through the vapouriser. This type of

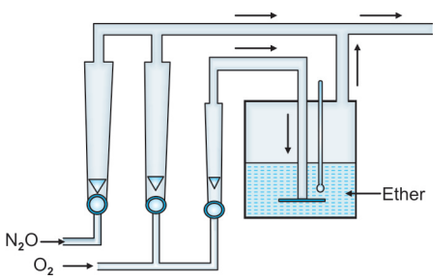

Fig. 15.41: A copper kettle vapouriser

vapouriser is capable of a high degree of accuracy than the simple Boyel's galss bottle vapouriser. The same apparatus may be used for all the types of volatile anaesthetic agents.

5. Draw-over vapourisers

Any vapouriser where the inspired gases is drawn over the surface of a volatile anaesthetic liquid which is kept in a container and offers sufficiently low resistance (1 to 2 cm of H_2O is a satisfactory figure) to gas flow at a normal respiratory flow rate, may be called as a draw-over (Fig. 15.42) vapouriser. The patient inspires air via the vapouriser and expiration is directed to the atmosphere by a nonrebreathing valve. A simple tin can, filled with an anaesthetic liquid may be used as a draw-over vapouriser. A vapouriser which has been specially designed for this purpose is the EMO (Epstein Macintosh Oxford) vapouriser. In this vapouriser ether is used as the anaesthetic agent. In this system a tank of water is used as a heat reservoir and the temperature compensation is made by a bellows filled with ether. It can be combined with an Oxford inflating bellows for intermittent positive pressure ventilation (IPPV). When the plunger is not dipped in the anaesthetic liquid, then the uncalibrated glass bottle vapouriser used in old Boyle's machine also acts as the draw over type of vapouriser.

Draw-over apparatus (Fig. 15.43)

This equipment was developed during the First World War, especially for field use

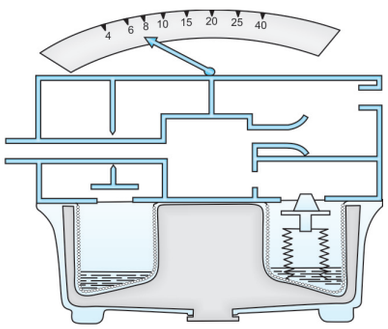

Fig. 15.42: EMO vapouriser

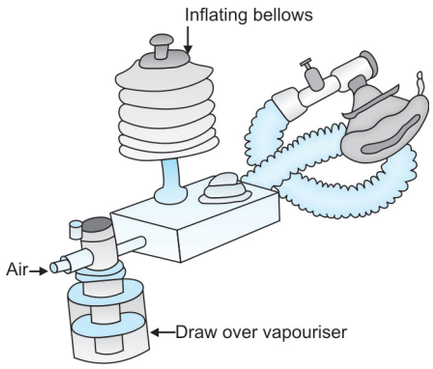

Fig. 15.43: Draw-over apparatus

where nitrous oxide was not available and portability was an important factor. In this apparatus, coffee jars, food tins, or any small cans were used as vapourisers keeping the volatile anaesthetic liquid. The patient who is intubated and under spontaneous ventilation breathed to and fro through this coffee jar used as vapouriser containing ether. Later, it was improvised and a control over the vapour strength coming out from the vapouriser was achieved. This draw-over device had a non rebreathing circuit to direct the expired gas to atmosphere and used ambient air as the carrier gas which enter from other side of the coffee jar (another end of the jar is attached to breathing circuit). Supplemental O_2 could be used, if available.

In its most basic application, air is drawn through a low resistance draw over vapouriser which may be made of a glass bottle or coffee jar, food tins or any small can which was used in First World War. For vaporisation, a suitable low resistance vapouriser, such as the EMO vapouriser may also be placed in the circuit instead of food tins. The device can be fitted with connections and equipments that allow IPPV, as well as CPAP and PEEP with a scavenging system. The N_2O can never be used with draw-over devices. Patients often manifest an oxygen saturation (SpO_2) < 90%. This can be treated with supplemental O_2, attached to a T – piece at the upstream side of the vapouriser. Across the clinical range of tidal volume and respiratory rate, an O_2 flow rate of 1 litre/minute gives an FiO_2 of 30 to 40% or with 4 litre/minute an FiO_2 of 60 to 80%. The greatest advantage of the draw-over system is its simplicity and portability. But the main disadvantage is the absence of a reservoir bag. So, the depth of the tidal volume is not well appreciated during spontaneous ventilation.

6. Variable bypass vapourisers

The variable bypass vapouriser is also called the concentration-calibrated, direct-reading, dial-controlled, automatic – planum, percentage-type and TEC-type (TEC type means Temperature Compensated) vapourisers. The other designation of these variable bypass vapouriser are blow-over, agent-specific and out-of-the breathing circuit vapourisers. Tec 3, Tec 4, Tec 5 and Tec 7 (different model of Ohmeda company) vapourisers are some examples of such vapourisers. They are such named, according to the improvisation of the model by the company. There are also such variable bypass vapourisers of other companies, such as Dragger of North America (vapour 19.1), Sigma and Penlon of UK, etc. However, the model of Tec 3 vapourisers of different companies (Flutec Mark 3, Fortec 3, Enfluratec 3, Sevotec III) are no longer manufactured at present.

The term 'variable bypass' refers to the method of regulating the output of the vapour of volatile anaesthetic agent in different concentration. When the delivered gas after the rotameter flows through the vapouriser's inlet, then the setting of the concentration control dial of vapouriser determines the ratio of flow that goes through the bypass channel without entering the vaporizing chamber that goes through the vaporising chamber. The gas which is channeled through the vaporising chamber flows over the surface of the liquid anaesthetic agent and becomes saturated with the anaesthetic vapour. So, the term 'blow-over' refers to this method of vaporisation (in contrast to the

bubble-through type of vaporisation in Copper Kettle). The term 'temperature-compensated' is applied to this type of vapouriser because every vapouriser is equipped with an automatic temperature compensating device that helps to maintain a constant vapouriser output concentration of volatile anaesthetic agent over a wide range of temperature variation. The mechanism is discussed in Chapter 1 and in this chapter. All these type of vapourisers are agent specific, because all the volatile anaesthetic agents have their own different vapour pressure at certain temperature. So, the control dial controlling the entry of carrier gas in the vaporising chamber and then thus subsequently controlling the concentration of output of anaesthetic agent is marked accordingly. Hence, they are designed to accommodate a single agent and any agent cannot be used in any vapouriser. However desflurane cannot be used by this variable bypass type of vapourisers the cause of which is explained later. These variable bypass vapourisers are usually calibrated using O_2 as the carrier gas. But, even if air is used instead of O_2 then there is no change in output also. On the otherhand, addition of N_2O as a carrier gas results in change of vapouriser output (Fig. 15.44).

These vapourisers are also called the level-compensated vapourisers. Because, one of the sources of variability of output from a simple vapourisers which are not level compensated is the change in the level of the anaesthetic liquid as it is used up. To prevent this variability of output with the change in the level of anaesthetic liquid these level compensated vapourisers use wicks. If the vaporising chamber contains wicks which are constantly wetted by contact with the anaesthetic agent, then not only the vaporisation will be more efficient, but it will also be constant (apart from the temperature effects) until the level of the liquid anaesthetic falls so low that the wicks are no longer wetted. The vapouriser using wicks in this way is described as the level-compensated vapouriser (Fig. 15.45).

The vapour pressure of a particular volatile anaesthetic agent depends on the temperature. For example, at 20°C the vapour pressure of isoflurane is 238 mm of Hg, whereas at 35°C the vapour pressure of isoflurane is 450 mm of Hg (almost double). So, at a fixed dial-setting with variation of temperature, the output of the anaesthetic gas will also vary. So, all the modern vapourisers should be temperature-compensated to keep the outflow constant by regulating the gas entry into the vaporizer. Actually, the temperature compensating devices are bimetallic strips. At an increased temperature this bimetallic strip change its shape and moves in one direction. This movement allows more flow to pass through the bypass chamber, and less flow to pass through the vaporising chamber. On the other hand when the temperature falls due to vaporisation of the liquid anaesthetic, the opposite occurs. Thus, the net effect is a constant vapouriser output. So, vapour pressure at a certain fixed temperature which is a physical principle of individual anaesthetic agents is important for a constant vapouriser output.

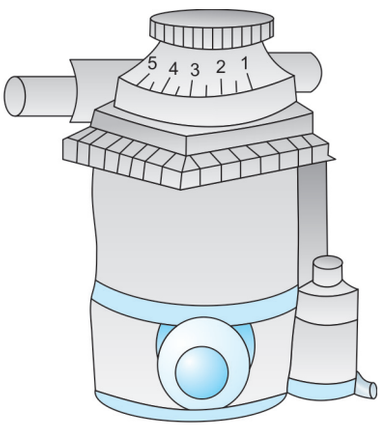

Fig. 15.44: Tec-3 halothane vapouriser

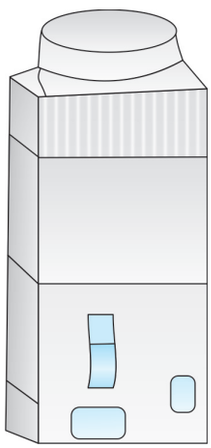

Fig. 15.45: Tec-5 vapouriser specific for isoflurane, halothane and sevoflurane

At 760 mm of Hg pressure (normal atmospheric pressure), the boiling point of desflurane, isoflurane, halothane and sevoflurane are approximately 22.8°C, 48.5°C, 50.2°C and 58.5°C, respectively. Desflurane boils at a temperature that may be encountered at normal room conditions. So, this unique physical characteristic alone mandates a special vapouriser (Tec 6) for desflurane to vaporise and control the delivery of that agent. From the above discussion it is clear that the output of an individual volatile agent depends on its vapour pressure and the temperature. Thus, the resetting dial is graduated accordingly depending on vapour pressure of that agent. So, every vapouriser is agent specific.

Though these variable bypass vapourisers have many advantages, but still they have some limitations. These limitations are: non-compensated for flow-rate, non-compensated for intermittent back pressure and dependent on the carrier gas composition. As these variable bypass vapourisers are not flow-rate compensated so the output variation of the volatile anaesthetic agent is particularly noticeable at the extremes of flow rate. The output from these type of vapourisers is less than the dial setting, when the flow rate is less than 250 ml/min. Similarly, at an extremly high flow rate (15 l/min) the output is also less than the dial setting.

Intermittent back pressure during IPPV or O_2 flushing can cause lower or higher vapouriser output than the dial setting. This phenomenon is called the pumping

effect. The pumping effect is more pronounced at low flow rates, low dial setting, low level of liquid anaesthetic agent in the vaporising chamber, high respiratory rate and high peak inspired pressure. The proposed mechanism for this pumping effect is the retrograde pressure transmission from the patient's circuit to the inside of the vapouriser during the inspiratory phase of positive pressure ventilation, i.e. when the bag is compressed.

However, this pumping effect can be minimized in a number of ways. These include the fitting of a small pressure regulating valve at the vapouriser output and keeping the vaporising chamber as small as possible. The Tec 3 model has a controlling resistance at the outlet of the vaporising chamber, so that the back pressure goes around the bypass and not through the vaporising chamber. In addition, a long inlet pipe to the vaporising chamber prevents vapour from the chamber to get back into the bypass gas stream by this route. This method to prevent the pumping effect is used in the Drager vapouriser.

Vapouriser output is also influenced by the composition of carrier gases that flow through the vapourisers. For example, when the carrier gas is switched over from 100% O_2 to 100% N_2O, then there is a rapid transient decrease in vapouriser output due to slow vaporisation of anaesthetic liquid followed by a slow increase to a new steady state value. This is because other than temperature, atmospheric pressure and character of anaesthetic liquid. The vaporisation of an anaesthetic liquid depends on the composition of gas that blows over it. Most vapourisers are calibrated using O_2 as the carrier gas. Generally, a little change in output occurs if air is substituted for O_2. Addition of N_2O to the carrier gas typically results in both a temporary and a long lasting effect on vapouriser output. The temporary effect is usually a decrease in vapour concentration. The duration of this effect depends on the gas flow rate and the volume of liquid in the vapouriser. The permanent effect may be an increase or decrease, depending on the construction of the vapouriser (Fig. 15.46).

7. TEC 6 Vapouriser

It is a different kind of variable bypass vapouriser and is only used for desflurane for its peculiar physical properties. Boiling point of desflurane is 22.8°C which is around normal room temperature. So, in normal room conditions it may start to boil and remains in a transitional phase between liquid and gas. Thus, its vapour pressure is 3 to 4 times higher than that of the other contemporary volatile anaesthetic agents at 20°C. That is why desflurane cannot be used in contemporary different models of variable bypass vapourisers (Tec 4, Tec 5 and Tec 7; Tec 3 model is obsolete now). Again, normal gaseous flow over desflurane in a traditional vapouriser would vaporise many more volume of desflurane than the dial setting. For example, at normal atmospheric pressure (1 atmosphere) and 20°C, passing over of 100 ml of a carrier gas for 1 min through the vaporising chamber will entrain 735 ml/min of desflurane vapour in comparison to 46 and 47 ml/min of isoflurane and halothane vapour, respectively. This is due to difference in vapour pressure at 20°C of desflurane, isoflurane and halothane which is 669, 240, 244 mm of Hg, respectively. Under the same condition, the amount of bypass flow to dilute the flow which is coming over the anaesthetic fluid and necessary to achieve 1% concentration of an anaesthetic desflurane output is approximately 73L/min compared with 5L/min for isoflurane, halothane and sevoflurane.

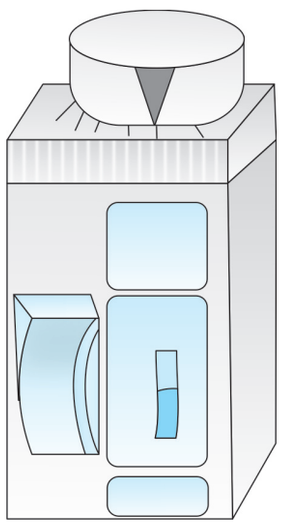

Fig. 15.46: Tec-6 vapouriser (specific for desflurane)

The MAC value of desflurane is 6 to 7 which is 4 to 9 times higher than the commonly used volatile anaesthetic agents. So, the absolute amount of desflurane needed over a given period of time is considerably higher than the other anaesthetic agents. Thus, the supplying of desflurane in higher concentration causes excessive cooling of the vapouriser. So, in the absence of an external heating source, the temperature compensation by using traditional temperature compensated variable bypass vapouriser where simple bimetalic strip is used is almost impossible. Hence, Tec 6 vapouriser requires an external electrical source for heat.

The Tec 6 vapouriser is also flow-compensated. So at a specific dial setting with different fresh gas flow rates, vapouriser output is constant (other variable bypass vapourisers are only temperature-compensated but not flow-compensated Actually the traditional vapourisers are flow compensated in certain limited range such as 250mL/min to 15 L/min). Thus, to conclude we can say that the Tec 6 vapouriser is an electrically heated, temperature and flow compensated, pressurized, electromechanically coupled, dual circuit vapouriser. This is not a blow-over type of vapouriser (other Tecs are all blow-over types).

In Tec 6 vapouriser, two circuits for gas flow are used (dual circuit). One circuit carries the main gas flow (carrier gas) without any bypass chamber. In another circuit there is a container which contains the desflurane in vapour phase. This is done by heating the desflurane electrically and controlling thermostatically at 39°C

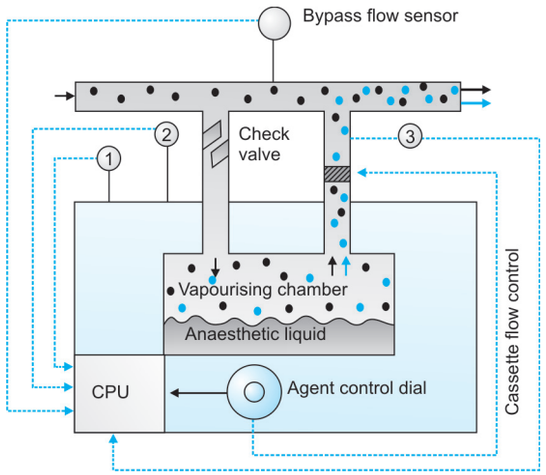

Fig. 15.47: Aladin's cassette vapouriser
1 = Cassette pressure censor,
2 = Cassette temperature censor,
3 = Cassette flow censor,
CPU = Central processing unit.

(a temperature well above the desflurane boiling point). Then the output flow and concentration of desflurane vapour is controlled electronically and is mixed with the main carrier gas flow at the main vapouriser outlet.

8. Aladin cassette vapouriser (Fig. 15.47)

It is a very sophisticated, electronically controlled vapouriser which is designed to deliver five different types of volatile anaesthetic agents, including halothane, enflurane, isoflurane, sevoflurane and desflurane. This type of vapouriser has two main components : a permanent internal control unit or anaesthetic delivery unit (ADU) and an interchangeable Aladin agent cassette unit that contains the volatile anaesthetic liquids

Aladin agent cassettes are colour coded, so that the control unit (ADU component) can identify the specific anaesthetic cassette which is inserted. The heart of the control unit has a electronically regulated flow-control valve, located at the vaporising chamber outlet. This flow-control valve is controlled by a computer (CPU) which receives information from the multiple sources such as agent's concentration control dial located by the side of the CPU, a pressure sensor located inside the vaporising chamber, a temperature sensor located inside the vapourising chamber, a flow measurement unit located in the bypass chamber, a flow measurement unit located at the outlet of the vaporising chamber and a gas analyser regarding the composition of the carrier gas. Using data from all these multiple sources, the CPU is able to precisely regulate the flow control valve to attain the desired vapour concentration of the anaesthetic agent.

Technically, the Aladin cassette vapouriser is a combination of Tec 4, 5 and 7 variable bypass vapourisers, along with the Tec 6 vapouriser and a computer. When desflurane is not used in the Aladin vapouriser, then the carrier gas passes over the anaesthetic liquid in the cassette and the vapouriser works like blow-over type (Tec 4, 5 and 7), but all the parameters are controlled by the computer. On the other-hand, when desflurane is used then Aladin works like a Tec 6 vapouriser, where carrier gas doesnot pass over the anaesthetic liquid. The bypass chamber is cut off from the cassette containing desflurane and the whole unit works as a dual circuit (like Tec 6). One circuit caries the carrier gas and another circuit carries the desflurane anaesthetic vapour from the cassette where like in Tec 6 the desflurane is always kept in a vapour form by a computer controlled electronically heating system at 39°C. The flow and concentration of desflurane is now under the computer control and at the outlet it mixes with the carrier gas.

16 Muscle Relaxants and their Antagonists

HISTORY

- The hint of the presence of these type of drugs such as curare or muscle relaxants first came to the ears of the world, in 1596, when Sir Walter Raleigh mentioned an 'arrow poison' in his book named 'Discovery of the Large, Rich and Beautiful Empire of Guiana'.
- Then 200 years later, in 1812, Sir Benjamin first showed that the life of animals could be maintained by artificial respiration, after they were paralysed or curarised by arrow poison. His source of curare was the bark, leaves, or vines of a tree named Chondrodendron Tomentosum, growing near Amazon. Also before that it had long been used by Amazonian Indians to poison the heads of arrow (arrow poison) for hunting of animals. Later on, they transported this poison to the different parts of the world in bamboo tubes, from where the name tubocurarine (curare in tube) was derived.
- Curare was first brought to the Europe by Charles Waterton. He also described a classic experiment, in which he kept alive a curarised she-ass by artificial ventilation with bellows and a tube introduced through a tracheostomy wound.
- Then, in 1850, the great French physiologist named, Claude Bernard had laid the most important scientific foundation stone. He demonstrated that curare acts by paralysing the myoneural junction. Later, this led to the discovery of concept of motor end-plate.
- During this period, George Harley also showed that curare can be used as an antidote to the convulsion of strychnine poisoning.
- After that, in 1858, a decade after the anaesthetic use of ether, Lewis Albert used curare and artificial verification through a tracheostomy to treat the muscular rigidity of tetanus in Newyork.
- Then, in 1862, curare was first used in American Civil War as chemical weapon.
- After that another foundation stone of anaesthesia was laid in 1864, when physostigmine was isolated from the calabar bean by Sir TR Fraser. But, at that time he was not aware of the anticurare action of physostigmine.
- Then, in 1900, the discovery of anticurare action of physostigmine by Jacob Pal had completed this basic foundation work, on which basis the relaxants are used later clinically in that century. Physostigmine was first used for animal experiment in 1909. Then, in 1912, curare entered the anaesthetic arena and was first used by Aurthur in an effort to reduce the amount of ether, employed for abdominal surgery. At that time the subparalytic doses of curare were used and produces only the relaxation of the abdominal wall, but did not prevent the respiratory movement of diaphragm.
- In 1931, Neostigmine was synthesised.
- In 1934, Dale demonstrated that acetylcholine (ACh) was responsible for the neuromuscular transmission and curare blocks its action.
- In 1935, pure d-tubocurarine was isolated from the crude drug.
- In January 23rd of 1942, at Montreol of Canada, appendisectomy was done under cyclopropane anaesthesia, where d-tubocurarine was first used through IV route, deliberately to give relaxation during surgery. This was a famous day in the history of anaesthesia. During this period the muscle relaxant was used with the idea to provide a greatly relaxed surgical field without the need for large doses of hypnotics and opiate drugs. Thus, the cardiovascular side effects of these anaesthetic agents could be minimised and allowed the very sick patients to get the benefit of surgery.
- The first reported use of curare in routine anaesthesia practice was from Britain in 1945.
- Gallamine was first used in 1948.
- In 1948, decamethonium was also described.
- In 1952, succinylcholine or suxamethonium was first used as muscle relevant and had revolutionised the anaesthesia practice.
- In 1958, alcuronium was first described and used in man.
- In 1967, pancuronium had first come into the anaesthetic arena.
- In 1980, atracurium and vecuronium had further revolutionised the clinical anaesthetic practice.
- The early 1990 had witnessed the introduction of pipercuranium and doxacurium.
- Mivacurium was introduced in 1993 and rocuronium in 1994.

CHEMISTRY OF MUSCLE RELAXANT

According to the chemical structure, most of the muscle relaxants have two positive charged N^+ atoms and so they mimic the quaternary nitrogen (N^+) atom of ACh which acts as the neuromuscular transmitter at the motor end-plate. This is the main reason for the attraction of these molecules of muscle relaxant agents to the cholinergic or acetylcholine receptors at the motor end-plate like acetylcholine. The cholinergic receptors are broadly classified as muscarinic and nicotinic type. In the peripheral nervous system the nicotinic receptors are found postsynaptically at the neuromuscular junction and at the autonomic ganglia. On the other hand muscarinic receptors are found only at the postganglionic parasympathetic nerve endings and some postganglionic sympathetic nerve endings such as sweat gland, erector pile, etc. Muscle relaxants act on the nicotinic receptors only at the neuromuscular junction and autonomic ganglion. Most modern muscle relaxants are specific for these nicotinic receptors with limited effects on other cholinergic receptors, found at the peripheral nervous system, the autonomic ganglia and the parasympathetic effector organs. As all the neuromuscular blocking agents have a quaternary ammonium structure containing nitrogen, so these are maximally ionised at the physiological pH and therefore penetrate the blood brain barrier poorly (Table 16.1).

The two positive charged N^+ atoms of a muscle relaxants are separated by a bridging structure which is lipophilic in nature. This bridging structure is different in size for different muscle relaxants and is the major determinant factor for potency and other pharmacokinetic properties of these group of drugs. Most of the muscle relaxants are highly water soluble. This is due to the positive charge of the molecule and contain various O_2 bearing group. Because of their water solubility, most of the muscle relaxants are easily excreted through urine by glomerular filtration and are generally not reabsorbed through the renal tubules. High water solubility of muscle relaxants also prevents its passage through the lipoid blood brain barrier, placental barrier and lipoid cell membrane of most of the cells, such as, renal tubular cells, hepatocytes, nerve cells, muscle cells, etc. Except few steroidal muscle relaxants, most are not metabolised by the liver due to two reasons: (i) water solubility of muscle relaxants which inhibits its uptake by the hepatocytes and (ii) cytochrome p – 450 oxidative enzyme system in the liver microsome which requires lipophilic substrates for their metabolism. The muscle relaxants used in anaesthesia practice are broadly classified under two heading according to their mode of action. These are: depolarising muscle relaxants and non-depolarising muscle relaxants. Among the depolarising group of muscle relaxants, there are many drugs, but succinylcholine is only and mostly used clinically.

SUCCINYLCHOLINE OR SUXAMETHONIUM (DIACETYLCHOLINE)

Succinylcholine is a quaternary ammonium compound. It is entirely a synthetic product. In contrast to the heavy bulky rigid molecules of non-depolarising muscle relaxants, the structure of this molecule is long, thin and flexible. It is made up of two acetylcholine molecules linked back to back. Like acetylcholine, it also depolarises the postsynaptic membrane. But, its effect on the motor end-plate is more persistant than that of acetylcholine. However, though the action of succinylcholine is like ACh, such as muscular contraction, but the prolonged action of it on the nicotinic receptor at motor end plate produces the muscular paralysis the mechanism of which is discussed in specific chapter. Now, succinylcholine is the only depolarising muscle relaxing agent which is still in clinical use. Though the demise of succinylcholine has been forecasted many times, but it is still widely used in clinical practice because of some unique properties such as earliest (still now) onset and shortest duration of action.

Succinylcholine produces depolarising block which is characterised by:

i. Absence of fade in response to train-of-four and tetanic stimulation (Fig. 16.1).
ii. The absence of post-tetanic facilitation,
iii. Increased intensity of block in the presence of anticholinesterase or cholinesterase inhibitors.

Table 16.1: The cholinergic receptors and its sites and the action of relaxants on it

Receptors	*Location*	*Function*	*Relaxant - interactions*
Nicotinic	Postsynaptic neuromuscular junction	Depolarisation of end-plate – muscle contraction	Succinylcholine – stimulates Non-depolarisation – block
Nicotinic	Presynaptic neuromuscular junction	Helps release of ACh	Succinylcholine – stimulates Non-depolarisers – block
Nicotinic	Autonomic ganglion	Depolarisation of ganglionic cell	Succinylcholine – stimulates Non-depolarser – block
Nicotinic	Postganglionic neurone terminal	Positive feedback for transmitter release	Succinylcholine – stimulates Non-depolariser – block
Muscarinic	SA node of heart	↓ heart rate	Succinylcholine stimulate – ↓ HR Non-depolariser block – ↑ HR
Muscarinic (M_1)	Autonomic ganglionic interneuron cell bodies	Inhibition of depolarisation	Non-depolariser block
Muscarinic (M_2)	Autonomic ganglia: Ganglion cell bodies	Depolarisation	Atropine blocks Non-depolarisers do not act

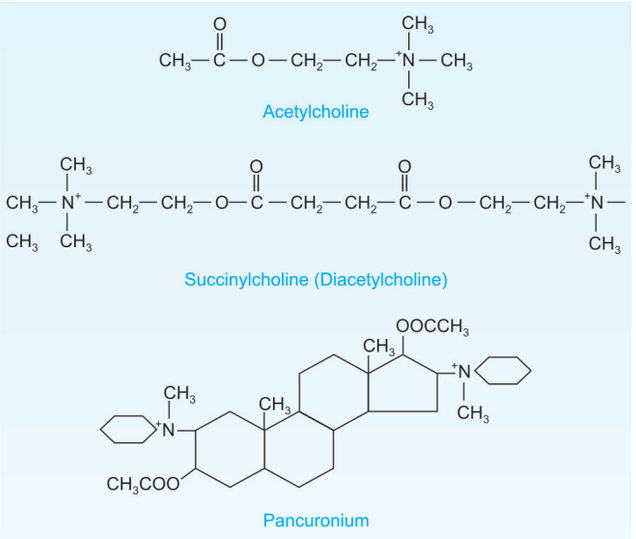

Fig. 16.1: The structural relationship between the acetylcholine, succinylcholine and pancuronium. The succinylcholine is simply a two molecules of acetylcholine, linked through the acetate methyl groups. So, it is called the diacetylcholine. Like acetylcholine, succinylcholine also stimulates the nicotinic cholinergic receptors at the neuromuscular junction, at the ganglionic sites and also on the muscarinic receptors at other autonomic sites. The pancuronium is also made up of acetylcholine like fragments, but properly oriented like a steroid nucleus. But, in contrast the pancuronium and other non-depolarising agents block the nicotinic receptors or inhibit the actions of acetylcholine at the motor end-plate (neuromuscular junction) and autonomic cholinergic sites

Mechanism of Action

Like acetylcholine (ACh) succinylcholine is not metabolised at the motor end-plate by true cholinesterase which are present there. So, the concentration of succinylcholine does not fall as rapidly as ACh in the synaptic cleft. Thus, it causes prolonged depolarisation of the motor end-plate and muscle relaxation, till it swept away from the synaptic cleft. The continuous depolarisation of the motor end-plate by succinylcholine causes muscle relaxation. This is due to the Na^+ channels which are present around the motor end-plate (perijunctional area) and have time sensitive lower gate which opens only during depolarisation for a fixed time period. During the passing of first wave of depolarisation from the motor end-plate to the whole muscle fibre (casing fasciculation) these perijunctional Na^+ channels are also depolarised and time sensitive lower gate opens that allows the passage of Na^+ which is a process of depolarisation. Then it closes after a fixed time period and enters in inactivated state and cannot further reopen until the end-plate repolarizes. The motor end-plate due to prolonged action of succinylcholine do not quickly repolarise after its depolarisation caused by it. Thus, the perijunctional Na^+ channel which make a baricade around the motor end-plate remains in inactive state. Hence, this line of Na^+ channel at the perijunctional area prevents the passage of subsequent impulse which comes through nerve fibre to spread on the surface of muscle fibre and prevents the contraction of it producing paralysis. On the otherhand, the muscle end-plate does not repolarise and continue depolarisation till the succinylcholine is present and thus maintain the muscular relaxation. This is called the 'phase I block'.

If the depolarisation of the muscle end-plate is prolonged further due to repeated injection and large dose of succinylcholine, then the ACh (or nicotinic) receptors at the motor end-plate undergo an ionic and conformational changes that result in 'phase II block' like non-depolarising muscle relaxant, i.e, ion channel in the ACh receptor close permanently with no flow of ions and becomes insensitive to ACh even in the absence of succinylcholine providing prolonged muscular paralysis. On the contrary, the non-depolarising muscle relaxants act on the ACh receptors and does not allow them to open the channel for ion movement from the very beginning and thus produce muscle relaxation. When the molecules of non-depolarising muscle relaxant are moved away from the receptor (nicotine) then ACh again acts on the receptor and resume muscular contraction. The site of action of non-depolarising agents is the ACh binding site of the α-subunit of the nicotinic ACh receptors. However, there are two binding sites of the non-depolarising muscle relaxant on the ACh receptor as there are two α-subunits in one ACh receptor. But, occupancy of only one subunit by non-depolarising agent is sufficient for their action.

This explains the difference in action or the effects of depolarising and non-depolarising muscle relaxing agents in different disease states. For example, during muscle denervation there is decrease in release of ACh. It stimulates the compensatory increase in ACh receptors on the muscle cell membrane. This upregulation of receptor causes an increased sensitivity of muscle to the depolarising agents as more receptors are being depolarized. But, the non-depolarising agents show a resistance in response, as more receptors are needed to be blocked. For another example, in myasthenia gravis there is fewer ACh receptors. This downregulation demonstrates a resistance to the depolarising agents and exaggerated response to the non-depolarising agents.

There are also some agents which act on the ACh (or nicotinic) receptors at the motor end-plate and block these receptors to produce neuromuscular paralysis but not like agonistic (succinylcholine) or antagonistic (non-depolarising) agents. They function by not disturbing the ACh binding sites of the ACh receptors. The example of such agents are: inhalational anaesthetics, local anaesthetics, ketamine, some antibiotics, neostigmine, quinidine, etc. There are

of two types of block of ACh (or nicotinic) receptor through which the above mentioned agents act. These are: close channel blockade and open channel blockade. In close channel blockade the molecules of the agents plug the mouth of ACh receptor channel and prevent the ion movement, whether or not the receptors are activated by ACh. In open channel blockade the neuromuscular blocking agents enter the ACh receptor channel after its opening and plug it preventing ion movement. So, it is use dependent and acts after the ACh activates the receptor and opens the channel. The significance of this channel blockade (closed or opened) is that such neuromuscular block cannot be overcomed by increasing the concentration of ACh by cholinesterase inhibitors. All these are discussed in more details in Chapter 4.

Pharmacokinetics and Pharmacodynamics

Succinylcholine is the only available depolarising muscle relaxing agent which is still used clinically and is very popular, though the popularity is under eclipse now. The popularity of it is due to: (i) very rapid onset of action (30 to 60 seconds), and (ii) short duration of action (5 to 10 minutes for the dose of 1 to 1.5 mg/kg IV). According to the initial bolus dose the duration of action of succinylcholine vary. For example, in dose of 0.5 mg/kg through IV the duration of action is only 3 to 5 minutes, though the onset of action remain same.

It is assumed that the rapid onset of action of succinylcholine is due to the relative large dose that is administered initially. As it is more water soluble and less lipid soluble, so this property prevents the drug to pass easily through the lipoid cell membrane and hence it needs the (Table 16.2) higher doses. After an initial IV bolus doses, a large portion of succinylcholine is rapidly hydrolysed by pseudocholinesterase present in plasma and then a small portion of it is distributed to the motor end-plate in the tissues. This also explains why large doses of succinylcholine is needed initially.

Plasma cholinesterase (pseudocholinesterase) is synthesized in the liver and has a half-life of 5 to 12 days. It hydrolyses or metabolises 70% of a 100 mg bolus dose of succinylcholine within 1 minute. Other drugs metabolised by plasma cholinesterase include mivacurium, cocaine and diamorphine. Only a small fraction of the injected dose of succinylcholine (10 to 15%) reach the neuromuscular junction. As there is no pseudocholinesterase at the motor end-plate, so the neuromuscular blockade by the action of succinylcholine at the neuromuscular junction is terminated only by its diffusion away from the end-plate into the extracellular fluid, where it is metabolised by the pseudocholinesterase. Only the action of acetylcholine is terminated at the motor end-plate by the action of cholinesterase (true) which is present there. Rapid hydrolysis of succinylcholine by pseudocholinesterase (synthesised by liver) in plasma is the cause of brief duration of action of it. Other than plasmacholinesterase the succinylcholine is also metabolised in liver. In the liver succinylcholine is metabolised first to the succinylmonocholine. Much of the succinylmonocholine have weak neuromuscular blocking effect and appear in urine.

The neuromuscular blocked produced by syccinylcholine can be prolonged by

Table 16.2: Drugs which cause the decrease of pseudo (plasma) cholinesterase level

i.	ACh E inhibitors	Neostigmine, pyridostigmine
ii.	Organophosphate use in glaucoma	Echothiophate
iii.	Cancer agent	Cyclophosphamide
iv.	MAOI	Phenozine
v.	β-blocker	Esmolol
vi.	Antiemetic agent	Metoclopramide
vii.	Oral contraceptive	Estrogen, progesterone
viii.	Non-depolarising muscle relaxant	Pancuronium, vecuronium, atracurium, etc.

the reduced quantity of normal or typical pseudocholinesterase enzyme (acquired cause) or by the normal quantity of atypical pseudocholinesterase enzyme (inherited cause). The acquired factors that cause lower typical pseudocholinesterase level in plasma are: liver disease, pregnancy, oral contraceptive pill (due to high oesterogen level), ecothiophate, neostigmine, edrophonium cytotoxic drugs, neoplasia, burns, metoclopromide, bambuterol (a prodrug of terbutaline), malnutrition and elderly, etc. The reduced typical plasma cholinesterase activity can also occur when some drugs which share the same metabolic pathway as succinylcholine (therefore compete with succinylcholine for the cholinesterase enzyme) are administered such as esmolol, MAOI, methotrexate, etc. However, the prolongation of neuromuscular block in these conditions is not very long. Very prolonged block is, however, associated with the presence of silent or atypical genes in homozygous individuals producing atypical pseudocholinesterase enzyme (inherited cause). The neuromuscular block in these cases (atypical enzyme) lasts for several hours, until the succinylcholine is broken down completely by the presence of little amount of normal enzyme (if present any) and eliminated very slowly through urine.

Ranitidine has no effect on pseudocholinesterase level. In a study, it is found that when the pseudocholinesterase level was reduced to 20% of the normal value, then the only duration of apnoea caused by succinylcholine is increased from 3 to 9 minutes.

Atypical Plasma or Pseudo Cholinesterase (Table 16.3)

Though a vast majority of the population possess the normal level of typical plasma or pseudocholine esterase enzyme, but rarely some patients are encountered who are either heterozygous or homozygous for the atypical gene. There are four principal autosomal dominant genes which are associated with

Table 16.3: Different genotype of plasma or (pseudo) cholinesterase

Genotype	*Figure*	*Action*
Usual\ (or typical)	E^u	Normal hydrolysis of succinylcholine
Atypical	E^a	Dibucaine resistant
Atypical	E^f	Fluoride resistant
Atypical	E^S	Complete lack of cholinesterase activity (silent)

Table 16.4: Incidence of Genotype

E^u E^u	Homozygous	95%
E^u E^a	Heterozygous	5%
E^u E^f	Heterozygous	0.5%
E^u E^s	Heterozygous	0.5%
E^a E^a	Homozygous	0.05%
E^a E^f	Heterozygous	0.005%
E^f E^f	Homozygous	0.0003%
E^f E^s	Heterozygous	0.0005%
E^s E^s	Homozygous	0.002%

Table 16.5: Different genotype and dibucaine number

E^u E^u	70-80
E^u E^a	
E^u E^f	50-60

E^a E^a	
E^a E^f	15-30
E^f E^f	
E^f E^s	
E^s E^s	0-5

the normal and atypical plasma or pseudocholinesterase enzyme. But more genes are also described recently. These four principal autosomal genes, responsible for plasma or pseudocholinesterase enzyme (normal and atypical) are designated as : E^u , E^a, E^f , E^s. Among these the only E^u gene is responsible for the typical pseudo or plasma cholinesterase enzyme and the normal hydrolysis of succinylcholine. Over 95% of the whole population have this normal genes and are homozygous who are designated as (E^u, E^u). Whereas the E^a, E^f, E^s genes are responsible for atypical type of pseudocholinesterase enzyme and cannot hydrolyse the succinylcholine or hydrolysis it partially. Normally, the succinylcholine is not resistant to inhibition by dibucaine and in homozygous person (E^u, E^u) the dibucaine number is 70 to 85. This is a method of assessment of the level or activity of typical pseudocholinesterase. The significance of which is discussed in more detail later. The duration of action of succinylcholine will be prolonged, if varieties of atypical genes are present and typical pseudocholinesterase is not produced in normal quantity. The commonest of these variation is the presence of atypical gene E^a in heterozygous form which is present in about 4% of the population. An individual who is heterozygous for this atypical gene (E^u, E^a) may have a slightly prolonged neuromuscular block following a bolus dose of succinylcholine (up to 30 minutes). But if the patient is homozygous (E^a E^a), he will remain paralysed for several hours after administration of succinylcholinne whose prevalence is approximately 1 in 2500 population (Table 16.4).

The atypical pseudocholinesterase produced by them is resistant to dibucaine and dibucaine number is 50 to 60 only. Other atypical genes are fluoride resistant gene (E^f) and silent gene (E^s). Fluoride resistant gene produces atypical pseudo or plasma cholinesterase enzyme which are not resistant to dibucaine, but is resistant to fluoride. Homologous persons with silent gene completely lack the cholinesterase activity. Persons may be homologous or heterologous of these type of genes which are responsible for atypical pseudocholinesterase enzyme with different dibucaine number. These are shown in Table 16.5.

The most variants of atypical pseudocholinesterase are due to the single amino acid substitution or error at or near the active site of the enzyme, e.g. substitution of glycine for aspartic acid at position 70 in atypical dibucaine resistant pseudocholinesterase.

The activity of plasma cholinesterase enzyme can be measured by using the spectrophotometric technique. Phenotype classification is also possible by adding different inhibitors such as dibucaine, sodium fluoride, etc. which cause different enzyme inhibition depending upon the type of enzyme present. Dibucaine inhibits the normal pseudocholinesterase enzyme to a greater extent than the abnormal enzyme. This observation had lead to the development of a test by dibucaine and had made possible to create a number. Dibucaine test examines the amount of inhibition of particular plasma cholinesterase (or pseudocholinesterase) activity by dibucaine. If a specimen has high normal (typical) enzyme content then it will be inhibited to larger extent by dibucaine. This percentage of inhibition can then be expressed as the dibucaine number. For example, if dibucaine inhibits normal enzyme about 80% and only 20% then the dibucaine number is 80 and 20 respectively. Thus, the dibucaine number indicates the genetic makeup of an individual patient with respect to typical pseudocholinesterase level in plasma. It does not measure the concentration of enzyme in plasma and nor does it indicates the efficiency of the enzyme (Table 16.6).

Fluoride test will also reveal a few instances where the samples may show a normal looking dibucaine number, yet an abnormally low fluoride number and prolonged duration of action of succinylcholine. The significance of fluoride test and its number is same as dibucaine. This is due to the some variants of gene which produces such plasma pseudocholinesterase which is inhibited by dibucaine but not by fluoride. Such a situation would be evident in the presence of E^f E^f genotype. The incidence of genotype will play an important part in the number of cases of prolonged response to succinylcholine. If it is accepted that the ensyme formed from E^u E^u genotype can hydrolyze the clinical dose of succinylcholine in about 4 minutes, then E^u E^a and E^u E^f genotype would take 10 to 20 minutes. However in E^a E^a, E^f E^f, E^s E^s genotype more prolonged muscular paresis will persist.

Table 16.6: Relationship between dibucaine number and duration of neuromuscular blockade by succinylcholine

Type of pseudocholinesterase	*Genotype*	*Frequency*	*Dibucaine number*	*Response to succinylcholine*
Typical homozygous	$E^u E^u$	Normal	70 to 80	Normal
Typical heterozygous	$E^u E^a$ $E^u E^f$	1/500	50 to 60	Slightly prolonged
A typical homozygous	$E^a E^a$ $E^s E^f$ $E^s E^s$	1/3000	20 to 30	Markedly prolonged

Doses

Succinylcholine is usually administered intravenously, but it can also be given though IM and SC route. However by IM or SC route, the onset of action of succinylcholine is delayed and duration of action is long lasting. By IV route, the arrival of succinylcholine at any group of muscle is heralded by brief fasciculation which represents this agent's acetylcholine like agonist activity. This usually happens within 30 to 40 seconds, with maximum effect of block occurring in 30 to 60 seconds, following administration of succinylcholine in the dose of 1 mg/kg through IV. This dose represents approximately the three times of ED_{95} value of this agent. The fasciculation following IV administration of succinylcholine is first observed in the eyebrow and in the eyelid group of muscles, passing later to the shoulder girdle and abdominal musculature and finally to the hands and feet. However, this muscle fasciculation is less obvious in deeply anaesthetised patient.

The average single bolus dose of succinylcholine in man is 1 to 1.5 mg/kg by IV with duration of action for only 5 to 10 minutes. For continuous infusion the dose of succinylcholine is 20 to 40 µg/kg/min. Repeated small bolus doses such as 10 mg at small intervals (when effects of relaxation of the previous dose wanes out) can also be used during short surgical procedures which require brief but intense muscle relaxation such as endoscopies, D and C, EUA, etc. When the succinylcholine infusion is used then sometimes methylene blue dye is used as an indicator in the drip. Because, it prevents the confusion between the solution of succinylcholine in bottle and other intravenous fluids. But in modern anaesthesia practice, the availability of short acting non-depolarising muscle relaxants such as mivacurium has decreased the popularity of this continuous infusion technique of succinylcholine. However, to avoid the overdose of succinylcholine by infusion it is essential to monitor the neuromuscular transmission continuously, whenever an infusion of succinylcholine or intermittent repeated bolus doses of it are used.

Adverse Effect

CVS

As succinylcholine is against to acetylcholine, so it stimulates all the cholinergic receptors which are constituted by both the nicotinic and muscarinic types. Action of succinylcholine on the nicotinic receptors of ACh at the neuromuscular junction produces fasciculation and subsequent muscular paralysis. Actions of succinylcholine on the muscarinic receptors of ACh on various tissues vary accordingly. Action of succinylcholine on muscarinic receptors of cardiac tissues produces sinus bradycardia, junctional rhythm, conduction block and ventricular arrhythmias ranging from unifocal premature ventricular contraction to ventricular fibrillation, etc. However, sinus bradycardia is more common after a second dose of succinylcholine and particularly it is found in children. This can be prevented by blocking the vagus or attenuating the muscarinic effect by atropine or by small dose of non-depolarising muscle relaxing drug. The higher incidence of bradycardia and other cardiac complications after a 2nd dose of succinylcholine suggests that hydrolysed product of succinylcholine (succinylmonocholine and choline) may sensitise the heart to the subsequent doses of it. However, bradycardia is not observed when suxamethonium is infused slowly.

Nodal rhythm, caused by succinylcholine is due to the greater activation of the muscarine receptor in the sinus node and thus suppressing the sinus mechanism and allowing the emergence of AV node as pacemaker. It is also common after 2nd dose and can be pervented by atropine or small dose of non-depolarising muscle relaxing agent.

Succinylcholine also induces the ventricular arrhythmias because:

i. It lowers the arrhythmia threshold of the ventricle.
ii. It increases the level of catecholamine and K^+ (due to fasciculation) which also increases the incidence of arrhythmia.
iii. Other associated autonomic stimulation due to intubation, hypoxia, hypercarbia, etc. also increases the incidence of arrhythmia, induced by succinylcholine.
iv. Different anaesthetic drugs such as, halothane (most common) also lower the ventricular threshold level for ectopic beat or increase the arrhythmogenic effect of catecholamines. When this effect of halothane combines with the arrhythmogenic property of succinylcholine, then the incidence of arrhythmia increases many fold. Glycopyrrolate is also effective in preventing the bradycardia and dysarrhythmia, produced by succinylcholine.
v. Other drugs which interact with succinylcholine and predispose ventricular arrhythmias are: digitalis, MAOI, tricyclic antidepressant, exogenous catecholamine, etc.

Hyperkalaemia

The administration of succinylcholine is associated with high rise of plasma K^+

level and it is believed to be due to the K^+ efflux from the muscle fibres during fasciculation. In normal patients this increase in plasma K^+ level is 0.5 m.mol/L and is of little significance. But, this may be significant for patients with pre-existing elevated serum potassium level. Under certain abnormal circumstances this rise of plasma K^+ level is very high and it is due to the spread of ACh receptors (nicotinic receptor) away from the restricted motor end-plate area to the whole outer surface of the muscle cell membrane. So, in these patients succinylcholine acts vigorously by binding with all the receptors and causing excessive fasciculation and tremendous rise of plasma K^+ level. The abnormal circumstances where this type of reaction occurs are: massive burn, massive muscle trauma, lower motor neuron lesion, upper motor neuron lesion, any lesion of the spinal cord, skeletal muscle (Table 16.7) diseases, bed ridden subjects, intra-abdominal infection, renal failure, etc. But, among these both the burn and the massive muscle trauma patients are most susceptible to hyperkalaemia following succinylcholine. This susceptibility to hyperkalaemia present for at least 60 days following burn or trauma or untill adequate healing of the damaged muscle occurs. So, in the above mentioned conditions succinylcholine should not be used, or if used then anaesthetist should be very cautious. Otherwise, subsequent cardiac arrest can occur which is quite refractory to the routine CPR.

Table 16.7: Conditions where succinylcholine causes more hyperkalaemia

- Massive trauma
- Massive burn injury
- Tetanus
- Stroke
- Spinal cord injury (haemiplagia or paraplagia)
- Encephalitis
- Severe Perkinson's disease
- Guillain-Barre syndrome
- Polyneuropathy
- Head injury
- Severe infection or septicaemia
- Prolonged immobilisation of whole body
- Multiple myopathies (Duchenne's dystrophy)
- Haemorrhagic shock with metabolic acidosis

If there is rise of plasma K^+ level due to any renal cause, then the use of succinylcholine is definitely contraindicated. Otherwise, the use of succinylcholine in renal failure is a controversial subject. Because many studies have failed to demonstrate the rise of plasma K^+ level by succinylcholine in renal failure patient. To them, succinylcholine is the muscle relaxants of choice, as it does not depend on the renal excretion. Since, a number of non-depolarising muscle relaxants are now available that depend little or not at all on the kidney for their elimination (e.g. atracurium, mivacurium, vecuronium), so they may be an alternative to succinylcholine as muscle relaxants in patient with renal disease.

Intraocular pressure

Succinylcholine causes tonic contraction of the extraocular muscles and thus increases the intraocular pressure (IOP). But, it has no clinical significance in most of the patients, where globe is not opened. IOP increases within 1 minute of administration of succinylcholine, reaches peak value at an interval of 4 minutes and its duration of action lasts for about 6 minutes. The mechanism of tonic contraction of the extraocular muscles by succinylcholine is discussed in the previous chapter. The use of non-depolarising drugs before the administration of succinylcholine to prevent the rise of IOP is controversial. But, the use of succinylcholine alone is not contraindicated, if the anterior chamber is not opened. Still, there are many studies where succinylcholine has been successfully used in penetrating eye injuries without any loss of global contents. Other than succinylcholine, additional factors such as cough, vomiting, bucking, etc. also raise IOP. So, to prevent a raised IOP the patient should be anaesthetised deeply and should not strain, which can be achieved by an adequate dose of IV anaesthetic drug, deeper level of inhalation anaesthesia, application of topical anaesthesia on trachea, additional muscle relaxants (non-depolarising), etc.

But, in conclusion, we can comment that in open globe eye surgery or lacerated globe injury the succinylcholine should be avoided. However, if for any reason the use of succinylcholine is mandatory for rapid sequence intubation due to full stomach or due to any other causes, then the above mentioned measures should be taken to prevent an increase in IOP.

Intragastric pressure (IGP)

The succinylcholine increases IGP maximum up to 30 cm of H_2O. But the rise of IGP up to 12 cm of H_2O is often normally found following the use of succinylcholine in adult. However, this effect is inconsistant, because many patient even show no rise of IGP after the use of succinylcholine. Again, this effect is insignificant provided the oesophageal sphincter mechanism is properly intact. The increase of IGP by succinylcholine is due to: (i) fasciculation of abdominal muscles, (ii) ACh like effect of succinylcholine which causes vagal stimulation and subsequently increase IGP (4 to 7 cm of H_2O). The increased IGP caused by succinylcholine can be prevented by prior curarisation and atropinisation. Normally, an increase in IGP is not important, as the opening pressure of the lower oespohageal sphincter also subsequently increases due to succinylcholine.

Usually, IGP above than 28 cm of H_2O is necessary to overcome the competence of gastro-oesophageal junction. But, except in few cases, normally this limit does not exceed by succinylcholine. However, only when the normal oblique entry angle of oesophagus into the stomach is altered or distorted due to pregnancy, abdominal distension by ascites or any cause, intestinal obstruction, obesity, hiatus hernia, etc. then the IGP required to cause incompetence of the gastro-oesophageal junction becomes frequently low and is less than

15 cm of H_2O. So, for the above mentioned causes precautionary measure should be taken to prevent regurgitation or the use of appropriate non-depolarising drug should be thinked. Succinylcholine does not increase IGP in infant and children. This is due to minimum or absent of fasciculation in this group of patients.

Muscle pain and fasciculation

The incidence of muscle pain which is most commonly observed as the side effects, following administration of succinylcholine varies from 25 to 89%. It develops mostly in chest wall, upper abdomen, shoulder and back. Sometimes, this muscle pain becomes very debilitating, necessiating analgesics and bedrest. However, it is more common after minor surgeries, in women and in ambulatory patients than the bed ridden patients. It is also more common in young and fit patients and in those who are mobilised early. Extremes of age and pregnancy are seemed to be protective. This muscle pain is due to the fasciculation and it can be substantiated by finding myoglobinaemia and increase in serum creatine phosphokinase (CPK) following the administration of succinylcholine, especially in children anaesthetised with halothane.

The subparalysing dose of non-depolarising muscle relaxant prevents this fasciculation and muscle pain and substantiates this hypothesis. But, the prior treatment with non-depolarising drug, mainly pancuronium, reduces the effectiveness of succinylcholine by about 30% and also cause the prolongation of effect of the depolarising drug by virtue of its anticholinesterase properties. However, due to the reduction of effectiveness a larger dose of succinylcholine (1.5 mg/kg) is then required. Muscle pain can also be reduced by premedication with diazepam, lignocaine, pentothal and bedrest. Raised CPK level due to rupture of muscle cell or fibre associated with muscle pain supports that fasciculation produced by succinylcholine is the cause of muscle pain.

So, it may be a better practice to use a small dose of non-depolarising muscle relaxants, before the administration of succinylcholine due to the following reasons: (i) fasciculation, which is the root of many problems can be prevented, (ii) postoperative whole body muscle pain, elevated IOP and increased IGP − all can be decreased or eliminated, (iii) succinylcholine induced increase in serum creatine phosphokinase (CPK) and myoglobinuria may be better attenuated. The relation between the muscle spasm and malignant hyperthermia is variable.

Masseter spasm

Succinylcholine may cause the spasm of certain group of muscles, especially masseters leading to masseter spasm, while other muscles are flaccid. Probably, this is an exaggerated response of succinylcholine at the neuromuscular junction of certain specific muscles and mainly found in children. Sometimes, this masseter spasm may be severe enough, making the laryngoscopy and intubation difficult. In such cases, the smaller dose of non-depolarising agent is not of much benefit. It is not the diagnostic sign of malignant hyperthermia, because it is not invariably associated with this syndrome, though it has been suggested that this is an early warming sign of the development of malignant hyperthermia.

Intracranial pressure

Succinylcholine transiently increases ICP, though the mechanism and significance of it is unknown.

Malignant hyperpyrexia

Succinylcholine often trrigers the mechanism of malignant hyperpyrexia in susceptible patient who is anaesthetised with halothane. Malignant hyperthermia is a hypermetabolic disorder of skeletal muscles. But, the signs and symptoms of it resemble those of neuroleptic malignant syndrome (NMS), though the pathogenesis is completely different. However, there is no need to avoid the use of succinylcholine in patients with NMS.

Allergic reaction

Of all the drugs used in anaesthesia, the frequency of allergic and/or anaphylactic reactions is probably highest with succinylcholine. If there is a history of previous allergic reactions, then the likelihood of further reaction is very high. Succinylcholine may also give rise to cross-sensitivity with other muscle relaxants in this respect.

Phase II block

It occurs if the ACh (nicotinic) receptors are exposed to succinylcholine either in excess doses or for prolonged period. The phase II block is nothing but like non-depolarising block with some exception. The transition from a depolarising or phase I block to phase II block is gradual and usually occurs after administration of large dose such as 7 to 10 mg/kg of succinylcholine intravenously. The recovery from phase II block is much slower and for it the cholinesterase inhibitor (anticholinesterase) should not be used. If used it may prolong the effects of succinylcholine and phase II block will be more intensed.

Interaction between Succinylcholine, Non-depolarising Muscle Relaxants and Neostigmine

Interaction between the succinylcholine and the non-depolarising muscle relaxants are antagonistic and/or additive, i.e. complex. These complex interactions are:

i. If succinylcholine is given first to facilitate the intubation, then it enhances the depth of block caused by subsequent dose of non-depolarising muscle relaxant and reduces the dose of it. But, there is no effect when the non-depolarising drug is given after the block from succinylcholine has dissipated.
ii. If the non-depolarising agent is given first, then it antagonises the depolarising phase I block produced by subsequent administration of succinylcholine. This

Table 16.8: Difference between phase I and II block by succinylcholine

	Phase I	*Transition*	*Phase II*
Train - of - four (TOF)	No fade	Moderate	Marked fade
TOF ratio	> 0.7	0.4 - 0.7	< 0.4
Tetanic stimulation	No fade	Moderate	Marked fade
Post-tetanic facilitation	No	Moderate	Marked present
Recovery	Rapid	Less rapid	Prolonged
ACh E - inhibitor	Increase (agonist)	Little effect	Decrease (antagonise)
Dose requirement (IV)	1 - 2 mg	3 - 4 mg	> 5 mg

is because, the non-depolarising agents occupy some of the ACh-nicotinic receptor at the motor end-plate and partially prevent the agonistic action of succinylcholine. An exception to this phenomenon is pancuronium. It augments the blockade of succinylcholine by inhibiting the pseudocholine esterase enzyme and increasing the concentration of succinylcholine.

iii. When succinylcholine is used after neostigmine, the duration of succinylcholine action is prolonged. This is due (Table 16.8) to the inhibition of pseudocholinesterase by neostigmine.

iv. If neostigmine (ACh E–inhibitors) is used to antagonise or to recover the phase I block produced by succinylcholine, then it markedly prolongs the effect of succinylcholine. This happens by two mechanism: (a) by inhibiting the acetylcholinesterase (ACh E) they cause the higher acetylcholine concentration at the motor end-plate which intensifies the depolarisation and phase I block. (b) They also reduce the hydrolysis of succinylcholine by inhibiting the pseudo (plasma) cholinesterase and potentiate the phase I block.

Difference between Phase I and Phase II Block

Train-of-four (TOF) is the best guide to detect the transition from phase I to phase II block. It helps to avoid the succinylcholine overdose by detecting the development of phase II block, observing the rate of recovery and assessing the effect of neostigmine on recovery from phase II block. Attempt to antagonise the pahse II block by neostigmine is controversial. If TOF ratio is less than 0.4, administration of neostigmine causes prompt antagonism of phase II block.

NON-DEPOLARISING MUSCLE RELAXANTS

Classification

Classification according to chemical structure

A. Steroidal Compound

Pancuronium, Pipercuronium, Vecuronium, Rocuronium and ORG 9487 (Rapacuronium).

Steroidal compounds have the following characteristics:

i. High potency,

ii. Lack of histamine release,

iii. Exhibits vagolytic property − moderate for pancuronium, slight to moderate for rocuronium, absent in clinical dose for pipercuronium and vecuronium,

iv. Excreted by kidney,

v. Duration of action depends on the balance between the lipophilic and hydrophilic activity of the molecule.

B. Benzylisoquinolinium Compound

d-tubocurarine (dTc), Metocurine, Doxacurium, Atracurium, Cisatracurium (51W89) and Mivacurium.

Benzyl isoquinolinium compound has the following characteristic (Table 16.9):

i. High potency,

ii. Lack of vagolytic effect,

iii. Tendency to release histamine − prominent for d-tubocurarine, moderate for metocurine, slight in atracurium and mivacurium, absent in dexacurium and 51W89 (cisatracurium)

iv. Excreted by kidney − also have unimportant biliary excretion for dTC and doxacurium,

v. Degradation by Hoffmann elimination (atracurium and 51W89) or hydrolysis by pseudocholinesterase (mivacurium) in plasma.

However, the choice of a particular drug during anaesthesia practice depends upon their unique characteristic which is related to their structures. This can be explained

Table 16.9: Summary of pharmacology of non-depolarising muscle relaxants

Drugs	*Chemical structure*	*Primary excretion*	*Histamine release*	*Vagal blockade*	*Autonomic ganglion block*
d-tubocurarine	B	Renal	+ + +	+	+ +
Gallamine	B	Renal	+ +	+ + +	0
Pancuronium	S	Renal	0	+ +	0
Pipercuronium	S	Renal	0	0	0
Vecuronium	S	Biliary	0	0	0
Atracurium	B	Insignificant	+	0	0
Cisatracurium	B	Insignificant	0 / +	0	0
Doxacurium	B	Renal	0	0	0
Mivacurium	B	Insignificant	+	0	0
Rocuronium	S	Biliary	0	+	0
Rapacuronium	S	Biliary	+ +	0	0

B = Benzylisoquinolinium compound, S = Steroid compound

by the fact that steroidal compounds tend to be more vagolytic, whereas the benzylisoquinoline compounds release more histamine. Again because of the same chemical structure allergic history to one group of muscle relaxants may precipitate allergic reactions to other group of muscle relaxants.

Classification according to duration of action

Long acting relaxants

It includes d-tubocurarine (dTC), metocurine, doxacurium, pancuronium, pipercuronium, gallamine and alcuronium. They have slow onset of action and maximum blockade occurs at 3 to 6 minutes, following an intubating dose which is 2 to 3 times of the ED95 dose. The average duration of action of these group of muscle relaxants is 80 to 120 minutes (measured as recovery of twitch response to the 95% of baseline) following an intubating dose. In clinical practice selection of these long acting muscle relaxant depends on their effect on CVS and the duration of surgery. Careful antagonism of residual paralysis at the end of operation is very important when these long acting muscle relaxants are used. All long acting agents are primarily excreted unchanged through urine with little or no-metabolism.

Intermediate acting relaxants

It invites vecuronium, rocuronium, atracurium, cisatracurium, (51W89). The onset of action of this group of drugs occur at 2 to 3 minutes following administration of an intubating dose which is 2 times of ED95 dose and the duration of action is 45 to 75 minutes (90% twitch recovery). The vecuronium and rocuronium have dual excreting pathway (liver and kidney). However, the atacurium and 51W89 have undergone Hoffmann elimination.

Short acting relaxants

It includes only mivacurium and rapacurium (ORG9487). Onset of action of these agents is 2 to 3 minutes following a tracheal intubating dose and clinical duration of action is 12 to 15 minutes. After intravenous administration of these agents 95% twitch recovery occur between 25 and 35 minutes. Mivacurium is destroyed spontaneously in plasma by pseudocholinesterase like succinylcholine, though it is non-depolarising drug. Only 5% is excreted unchanged in urine.

Pharmacokinetics and Pharmacodynamics of Non-depolarising Muscle Relaxants

The non-depolarising muscle relaxing agents act by competitive antagonism with the ACh at nicotinic ACh-receptor on the post-synaptic membrane of neuromuscular junction. The dose response relationship of this group of drug is sigmoid in shape. From the dose-response curve, like any other agent, the potency of any non-depolarising neuromuscular blocking agent also can be estimated (Fig. 16.2).

The potency of any agent is expressed as ED (Effective Dose) value. The effective dose or ED value that results in 50%, 90% or 95% neuromuscular block is termed the ED_{50}, ED_{90} and ED_{95} of muscle relaxant respectively. In general, a dose that is 2 to 3 times of the ED_{95} value is administered for facilitation of tracheal intubation.

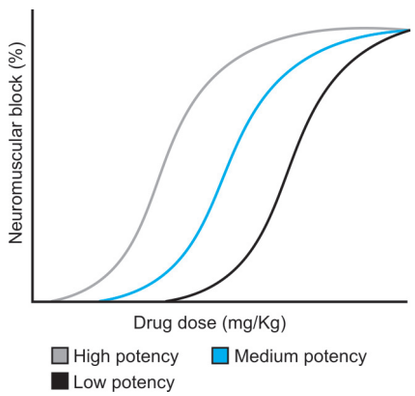

Fig. 16.2: This is a schematic representation of relationship between the dose of muscle relaxant and the percentage of neuromuscular block. A drug of high potency would be represented by pipercuronium, medium potency by atracurium and a low potency by gallamine

Clinically, the onset of neuromuscular block is the time which is taken for a drug to produce a depression of measurable response which is contraction of muscles for a muscle relaxant. During the onset of response, nearly 70% of the receptors must be occupied by the drug. The speed of onset of action of muscle relaxant depends upon the cardiac output, muscle blood flow, the potency, the dose, and some kinetic characteristic (e.g. clearance) of the relaxant. It is now established that drugs with low potency have a more rapid onset of action and potent drugs have slow onset of action. This is because as potency increases less amount of drugs (fewer molecules) are injected and the concentration gradient of the acting drug at the receptor site will be low causing delayed onset of action. For example, doxacurium is the most potent, but has slowest onset of action. Potent muscle relaxants also have high affinity for the receptors. So, their effects wear off very slowly, resulting in long duration of action.

The distribution profile of the currently used non-depolarising muscle relaxants can be described by two or three compartmental models. First, the relaxants are distributed from the central compartment (blood) to the peripheral compartment (tissue). Then, it is followed by one or two elimination phases when the drugs are metabolised in liver and excreted through urine. After IV injection the concentration of muscle relaxant in plasma (central compartment) rises rapidly. After that drug moves into the tissues from the plasma and the concentration of it in blood fall rapidly. When this fall in plasma level go beyond the tissue concentration level, then the drug again returns in the plasma from the tissues. Now plasma concentration depends on two factors: rate of re-entry from tissue and elimination from plasma by metabolism and / or excretion. Ultimately an equilibrium between the tissue and plasma concentration reaches and after that there is slow decrease in concentration of drug in plasma, constituting terminal elimination phase (Fig. 16.3).

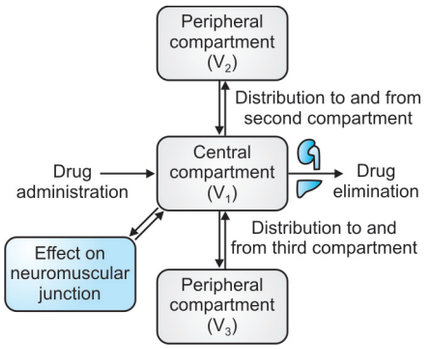

Fig. 16.3: This is a schematic representation of drug distribution into different compartments of body. These compartments are mathematical concepts only. It does not represent the real physiological space. The effect compartment in this case is the neuromuscular junction

After IV injection, the plasma concentration of muscle relaxants fall gradually. But in contrast the neuromuscular block begins to occur and does not recover even after many minutes of the gradual decrease of plasma concentration of muscle relaxant. This discrepency between the plasma concentration and the drug effect is because the action of muscle relaxants is not in the plasma, but at the neuromuscular junction.

The potency of non-depolarising muscle relaxants is increased by prior administration of succinylcholine. But, potency is decreased in patient with burn, injury, neonates and infants than the older children and adults.

Choice of non-depolarising agents for intubation

None of the recently available non-depolarising agent can fulfill the desire condition necessary for intubation, i.e. rapid onset and short duration of action which is provided by succinylcholine. But, succinylcholine is a depolarising agent and has many drawbacks which we do not want. So, there is continuous search for newer and newer non-depolarising agents which would have property like succinylcholine, i.e. quicker onset and short duration of action but should not have the drawback like depolarising agent. However, the onset of action of non-depolarising agent can be quickened by using a priming dose or a larger dose which is 2 to 3 times of ED_{95}.

The idea behind the priming dose is that if 10 to 15% of the recommended intubation dose is adminstered 5 minutes before induction, then it will occupy the enough receptors, so that paralysis will quickly occur when the balance or remaining 85 to 90% of the recommended dose is given after induction and before intubation. The use of this technique enables to perform intubation quickly within 60 to 90 seconds after administration of muscle relaxant. However, it is applicable mainly for short and intermediate acting non depolarising agents. Priming dose occupies usually 20 to 25% of the receptors. So, it does not produce clinically significant paralysis and its symptoms, before induction which requires 75 to 80% receptor occupancy. However, in some patients priming dose produces clinical paralysis manifested by dyspnoea or heavyness of breath, diplopia, muscle weakness, etc. In such instances patient should be reassured or induced quickly (Table 16.10).

ED_{95} is the dose when 95% of the effective block occur. But 2 to 3 times (some body uses 1 to 2 times) of the ED_{95} dose is usually needed for intubation. If the dose is increased more, then the intubation will be more rapid. But it exaccerbates the side effects and prolongs the duration of action. For example, pancuronium in high doses of 0.15 mg/kg (usual dose 0.08 mg/kg) produces an excellent intubating condition within 90 seconds and its irreversible duration of action lasts for more than 60 minutes, but at the cost of pronounced tachycardia and hypertension.

Table 16.10: Priming doses (mg/Kg)

Drugs	*Priming dose*
Atracurium	0.05
51W89	0.01
Rocuronium	None
Mivacurium	0.02
Vecuronium	0.01

It is also important to understand that the different muscle groups vary in their sensitivity to different non-depolarising muscle relaxants. Relaxation of laryngeal muscles are important for intubation. But, it recovers from blockade more quickly than adductor pollicies which is commonly monitored for neuromuscular paralysis.

Doses – the principle

i. The dose of non-depolarising muscle relaxants for tracheal intubation is 2 to 3 times than that of ED_{95} dose.
ii. If the patient has already been intubated, then the dose slightly less than that of ED_{95} dose is needed to produce the surgical relaxation.
iii. The maintenance doses for non-depolarisers ranges from 20 to 30% of the initial bolus dose.
iv. The intermediate and short acting non-depolarising muscle relaxants can be used by continuous infusion to keep the relaxation smooth. It also helps rapidly adjustment of the depth of relaxation according to the surgical needs and prompt recovery at the end.
v. Somebody thought that if the subparalysing dose of a non-depolarising agent is given 2 to 4 minutes before the final 2nd dose for intubation after induction, then the onset of action of this 2nd dose will be accelerated and intubation can be performed within 90 to 120 seconds. This procedure is called the 'priming'. When rapid tracheal intubation is performed by non-depolarising relaxants, then 'priming' is recomended. But long acting drugs are not advised for this priming and rapid intubation (Table 16.11).

Metabolism and elimination of non-depolarising muscle relaxants

The all non-depolarising muscle relaxants contain quaternary nitrogen atoms. So, they are positively charged cation. These characteristic nature conform them with a high (Table 16.12) degree of water solubility and only a slight degree of lipid

Table 16.11: Doses of rapid tracheal intubation in mg/Kg

Drugs	*Intubating dose*	*Clinical duration (minute)*	*Full recovery (minute)*
Atracurium	0.7 - 0.8	45 - 60	60 - 90
51W89	0.2 - 0.25	50 - 70	70 - 100
Rocuronium	0.6 - 1	30 - 60	60 - 120
Vecuronium	0.15 - 0.2	60 - 70	90 - 120
Mivacurium	0.25	15 - 20	20 - 30

Table 16.13: Doses of different nondepolarising agents when they are used by continous infusion

Continuous infusion	*(µg/kg/minute)*
Mivacurium	6 - 8
Atracurium	4 - 12
Cisatracurium (51W89)	1 - 2
Rocuronium	10
Vecuronium	0.8 - 2

solubility. So, this hydrophilic character enables the non-depolarising muscle relaxants to eleminate completely via kidney with no tubular reabsorption. Hence, they depend little or nothing for metabolism in the liver for exit from the body. Therefore, elimination of these drugs depend only on the glomerular filtration and make them long acting in renal disease (Table 16.13).

Effect on CNS

The non-depolarising muscle relaxants can hardly enter into CSF and their clinical significance is not clear. When inadvertently neuromuscular blocking agent is given in CSF (during spinal anaesthesia) then myotonia, autonomic changes, convulsion, etc. have been occurred. However, prolonged administration of rocuronium, atracurium and vecuronium in ICU results in entry of sufficient amount of these drugs in CSF. Laudanosine, a metabolite of atracurium crosses the blood barrier and causes CNS stimulation. In case of cisatracurium which is an isomer of atracurium and 5 times more potent than it, the measured quantities of laudanosine in CSF is 5 times lower than that of atracurium. However, the CNS effect of non-depolarising muscle relaxant due to prolonged use on morbidity and mortality in ICU is unclear.

Paediatric group of patient and muscle relaxant

At birth, the development of neuromuscular unit is immature. It becomes mature at 2 months of age. So, newborns are more sensitve to non-depolarising muscle relaxants than adult and a lower plasma concentration of it can achieve the desired neuromuscular block like adult. But, the dose of non-depolarising muscle relaxant should not be reduced due to its large volume of distribution in neonate and infant. Slower clearance by kidney also contribute to longer elimination half-life of the non-depolarising agents in children. In spite of these, the non-depolarising muscle relaxants can safely be used in neonates and infants.

Atracurium, cisatracurium, vecuronium, rocuronium are commonly used non-depolarising muscle relaxants in children due to their faster onset, intermediate duration of action, and minimum residual paralysis.

The mivacurium can safely be used in children and needs larger doses than adult. However, the duration of action of mivacurium is shorter in children than adult. It is best used by infusion in children for its shorter duration of action and infusion rate should be twice than that of adult.

The status of rocuronium in children is same as that of the adult. Rocuronium in the dose of 0.6 mg/kg has the earliest onset of action (60 to 90 seconds) among all the non-depolarising agents and produces an

Table 16.12: Doses, onset of action, duration of action and potency of different nondepolarsing agents

Drug	*ED_{95} (mg/kg)*	*Intubation dose (mg/kg)*	*Onset of action of intubating dose (min)*	*Duration of action of intubating dose (min)*	*Supplemental dose (mg/kg)*	*Potency*
Long acting						
Tubocurarine	0.5	0.5 - 0.6	1 - 2	30 - 60	0.1 - 0.2	7
Gallamine	3	4 - 6	2 - 3	90 - 120	0.5 - 1	40

Short acting						
Mivacurium	0.08	0.2 - 0.25	2.5 - 3	15 - 20	0.05 - 0.1	1.6
Rapacuronium (ORG9487)	0.75	1.5 - 2	1.5	14 - 20	0.05	–

excellent intubating condition for rapid tracheal intubation than vecuronium and atracurium, both for the adult and children. For rapid sequence intubation (within 30 to 60 seconds) in the presence of full stomach, rocuronium in the high dose of 1.2 to 1.5 mg/kg are also suggested.

The succinylcholine should be discontinued in paediatric group of patient, because of many side effects of it such as rhabdomyolysis, hyperkalaemia, acidosis and even cardiac arrest, particularly in patient with unsuspected muscular dystrophy of Duchenne type.

The antagonism of non-depolarising block in children is similar to adult.

Geriatric group of patients and muscle relaxant

The duration of action of most of the non-depolarising muscle relaxants is prolonged in older group of patients. This is due to many geriatric physiological changes which occur in the body and neuromuscular junction with increasing age.

The physiological changes in geriatric group of patients which affects the action of muscle relaxants are:

i. ↓splanchnic and renal blood flow,
ii. ↓GFR,
iii. ↓hepatic function,
iv. ↓total body water,
v. ↓cardiac reserve.

With increased, age the physiological and anatomical changes of neuromuscular junction which affects the action of muscle relaxants are:

i. ↑junctional cleft,
ii. flatening of folds of the motor end-plate,
iii. ↓concentration of ACh receptors,
iv. ↓ amount of ACh in vesicle.

In old age the sensitivity of nicotinic receptor to the muscle relaxants at myoneural junction is not altered. But, the decreased clearance of each drug from the plasma explain the prolonged duration of action in old age. The decreased clearance of drug in elderly is due to the ↑ volume of distribution. Atracurium and cisatracurium depends on ester hydrolysis and Hoffmann degradation for their clearance. So, the duration of action of atracurium and cisatracurium is not influenced by age.

The plasma cholinesterase activity of older patients is reduced by 26% than the younger ones. So, as mivacurium is metabolised by plasma cholinesterase, its activity is prolonged by 20 to 25% in the aged.

Obesity

The doses of the non-depolarising muscle relaxants should be precisely calculated in obese patient. In obese the dose of a drug would depend on the lean body mass rather than the actual body weight and will be 20% more. The recovery from atracurium does not depend on obesity. The duration of action of rocuronium is prolonged in obese, but the duration of action of pancuronium is unaffected by obesity.

Renal disease

The renal failure prolongs the duration of action of the non-depolarising muscle relaxants by causing decreased elimination of the drug or its metabolites via kidney or by decreasing the activity of enzymes which metabolise the drug. The long acting non-depolarising muscle relaxant such as pancuronium, pipercuronium, doxacurium, gallamine and metacurine are associated with decreased plasma clearance and increased elimination half-life with prolonged duration of action in renal failure. So, because of the prolonged duration of action and availability of intermediate and short acting muscle relaxants which depend much less on the kidney for their elimination, use of long acting drug in renal failure is not recommended now. The duration of action of atracurium is unaffected by renal failure. Vecuronium depends on both the liver and kidney for its excretion. So, its clearance is also reduced and action is prolonged in renal failure patient. In renal failure due to decreased activity of plasma cholinesterase, the duration of action of mivacurium is also prolonged by 50% (10 to 15 minutes). However, the duration of action of rocuronium is not prolonged and is not cumulative in renal failure. As only 16% of the total excretion of cistracurium depends on kidney (77% by Hoffmann degradation), so the renal failure has little impact on the duraton of action of cisatracurium.

Liver disease

Hepatobiliary diseases prolong the duration of action of pancuronium, doxacurium, vecuronium, rocuronium and mivacurium. The relationship between the liver disease and the pharmacokinetics of non-depolarising muscle relaxants is complex. Liver disease is associated with increased volume of distribution and decreased plasma clearance. As a result, there is apparent resistant to the effect of drug and prolonged action. So, the initial dose is increased to reach the desired level of effect in plasma and thus the subsequent recovery is slower. On the other hand, the decreased synthesis of plasma cholinesterase in liver disease causes prolonged action of mivacurium and almost is tripled. But the clearance of atracurium and cisatracurium is little affected by liver disease, and so also their duration of action.

Inhaled anaesthetics

In a dose dependent manner all the inhaled anaesthetic agents potentiate the action of non-depolarising muscle relaxants. But, the extent of potentiation is different for different inhaled anaesthetic agents.

The proposed several mechanisms for augmentation of neuromuscular block by inhaled anaesthetic agents are:

i. The increased blood flow by inhaled anaesthetic agent causes more availability of the injected muscle relaxants at the neuromuscular junction.
ii. Due to depressive action on CNS, the volatile anaesthetic agent itself often produces adequate muscle relaxation. Thus, this augments the action of muscle relaxants, without producing any neuromuscular block by itself.

iii. The decreased sensitivity of the post junctional membrane to depolarisation by inhaled anaesthetic agent.
iv. Some specific effects of inhaled anaesthetic on ACh receptor channel which reduces the average duration of opening of it during activation. The effect of inhaled anaesthetic on non-depolarising blockade is a pharmacodynamic one (i.e. blood concentration of muscle relaxants to produce paralysis is decreased) but not a pharmacokinetic one.

Temperature

Hypothermia invariably lengthens the duration of neuromuscular blockade produced by non-depolarising muscle relaxants.

Antibiotics

Some antibiotics enhance the neuromuscular blockade caused by non-depolarising muscle relaxants. The mechanism of potentiation of neuromuscular blockade by these antibiotic is prejunctional (depression of the evoked release of ACh) or postjunctional or mixed. Calcium is not used for reversal of this neuromuscular blockade caused by antibiotic for two reasons : (i) antagonism produced by calcium is not sustained and (ii) calcium antagonise the antibacterial effect of antibiotics also.

Antibiotics that potentiate the neuromuscular blockade are streptomycin, gentamicin, kanamycin, neomycin, tetracycline, polymycin A and B, lincomycin, clindamycin, etc.

Magnesium

Magnesium sulphate, used in the treatment of pre-eclampsia amd eclampsia, also have the neuromuscular blocking properties and enhances the action of non-depolarising and depolarising muscle relaxing agents. The mechanism of (Table 16.14) actions of magnesium in neuromuscular blockade are:

i. It reduces the amount of ACh, released from the presynaptic membrane at the nerve terminal,
ii. It reduces the depolarising action of ACh on the postjunctional membrane,
iii. It reduces the excitability of muscle fibre,
iv. It reduces the amplitude of motor endplate potential.

Enhancement of succinylcholine blockade by magnesium also involves the same mechanisms. Magnesium also inhibit the action of plasma-cholinesterase.

Local anaesthetic and antiarrhythmic agents

Local anaesthetic agents enhance the effect of neuromuscular block produced by both non-depolarising and depolarising muscle relaxants. So, when the local anaesthetic agent is given as antiarrhythmics in intraoperative or postoperative period then the muscular relaxation effect produced by muscle relaxant is prolonged. It acts by stabilising the postjunctional membrane and thus by blocking the ACh-induced muscular contraction. In addition, procaine inhibits the plasma cholinesterase action and enhances the effect of succinylcholine.

The antiarrhythmic agents (e.g. quindine) also augment the neuromuscular block caused by muscle relaxants. Any drug that influences the conduction of impulse and electrical properties of heart, e.g. β-blocker, Ca^{2+} channel blocker, etc. also influence the ion transport at neuromuscular junction and enhance the action of muscle relaxants. But, in clinical level these interactions are minor.

Antiepileptic agents

Antiepilepitic agents, e.g. phenytoin, carbamazepine, etc. reduce the action of both depolarising and non-depolarising muscle relaxants and accelerate the recovery from muscular paralysis. Patients receiving anticonvulsants are somewhat resistant to the blocking effect of muscle relaxants.

Diuretics

The diuretics in their clinical dose augment the effect of non-depolarising muscle relaxants. They inhibit the production of cyclic AMP → leads to ↓ATP → ↓output of neurotransmitter → ↑blocking effect. Mannitol and other osmotic and tubular diuretics have no effect

Table 16.14: Metabolism and elimination of muscle relaxants

Drug	*Duration*	*Metabolism*	*Elimination by kidney*	*Elimination by liver*
Succinylcholine	Ultrashort	Pseudocholinesterase (99%)	<2% metabolites eliminated in urine	None
Mivacurium	Short	Pseudocholinesterase (90%)	<10% metabolites eliminated in urine	None
Atracurium	Intermediate	Hoffmann elimination and esterase hydrolysis (60 - 90%)	10 - 40% metabolites eliminated in urine	None
51W89 (cisatracurium)	Intermediate	Hoffmann elimination (90%)	10 - 40% metabolites eliminated in urine	–
Rocuronium	Intermediate	None	40% relative excretion by liver and kidney	60%
Vecuronium	Intermediate	Liver (20 - 40%)	40 - 60%	60 - 40%
Pancuronium	Long	Liver (10 - 30%)	85%	15%
Pipercuronium	Long	None	>90%	<10%
Tubocurarine (dTc)	Long	None	80%	20%
Gallamine	Long	None	100%	0

on the non-depolarising muscle relaxants. Because the excretion of relaxants depend primarily on GFR. Mannitol, being an osmotic diuretic, exerts its effect in proximal tubules, so that the water is retained within the tubules, but does not ↑GFR and does not increase the excretion of non-depolarising relaxants.

Interactions between the non-depolarising drugs (change from short to long acting and *vice versa*)

The effects of some non-depolarising muscle relaxants may be potentiated by simultaneous or prior administration of other non-depolarising agents. This usually happens if the combinations of aminosteroidal and benzylisoquinolinium group of muscle relaxants are used together. In modern anaesthetic practice there is no reason to combine the drugs from different group of non-depolarising relaxants. But, sequential administration of long and short acting drugs can be considered. However, the general rule for change over from one non-depolarising agent to another is that 95% of the 1st drug should be cleared. If anybody wants to change from short to long acting drug (for example mivacurium to doxacurium), then the second drug should be given when the TOF response has begun to recover, i.e. two to three twitches are visible. Similarly, if any body wants to change from long to short acting drug for maintenance, then very small dose should be given.

Anaphylactic or allergic reaction

Due to the quarternary structure and previous natural sensitisation to such molecules, muscle relaxants are the most commonly responsible drug for allergic or anaphylactic reaction during anaesthesia. Manifestations of some reactions such as flushing, urticaria, tachycardia and hypotension may sometimes be severe enough and can lead to cardiac arrest. In some patients this reaction is manifested as severe bronchospasm. Succinylcholine is the most commonly implicated agent for allergic reaction, though any muscle relaxant may be responsible. Recently, rocuronium and cistracurium have also been implicated. However, the determination of causative preoperative muscle relaxant for anaphylactic or allergic reaction involves the demonstration of specific antibodies or skin testing by this agent.

Effects on autonomic ganglia and release of histamine

Within the therapeutic dose range, the different non-depolarising muscle relaxing agents differ in their effects on autonomic ganglia. The older agents like tubocurarine has marked ganglion (which also contain nicotinic receptor) blocking effect. Thus, it compromises the ability of sympathetic nervous system to increase the heart rate and the myocardial contractility in response to hypotension and other perioperative stresses. On the other hand, galamine and pancuronium have marked vagal blocking or vagolytic (muscarinic receptor) effect causing tachycardia. All newer (Table 16.15) non-depolarising muscle relaxants such as atracurium, cisatracurium, rocuronium, vecuronium, etc. are devoid of significant ganglion blocking effects in their recommended clinical dose range.

Many non-depolarising agents release histamine from mast cells causing bronchospasm, peripheral vasodilatation, hypotension, skin flushing, urticaria, etc. But, they are insignificant in recommended dose range, except atracurium and mivacurium where this incidence is high.

Other factors that may interfere with the action of muscle relaxants

(i) Acid-base state

Acidosis (respiratory or metabolic) augments the effect of non-depolarising block. So, antagonism of neuromuscular block is difficult in such situation. Administration of narcotics in recovery room to relieve pain may cause hypoventilation and respiratory acidosis → more augmentation of residual block → again more hypoventilation → more acidosis → vicious cycle.

(ii) Electrolyte imbalance

The low extracellular K^+ concentration increases the end-plate resting transmembrane potential (due to higher ratio

Table 16.15: Interactions of depolarising and non-depolarising muscle relaxants with other drugs

Other drugs	*Depolarising muscle relaxant*	*Non-depolarising muscle relaxant*
A. Antibiotics		
Streptomycin, kanamycin, neomycin, polymyxin, colistin aminoglycosides, tetracycline, clindamycin, lincomycin	Potentiation	Potentiation
B. Anticonvulsants		
Carbamazepine, phenytoin, valporate, primidone	Resistant	Resistant
C. Antiarrhythmics		
Ca-channel blocker, quinidine	Potentiation	Potentiation
D. Cholinesterase inhibitors		
Neostigmine, edrophonium, pyridostigmine	Potentiation	Resistant
E. Inhalational anaesthetics		
Halothane, isoflurane, sevoflurane, desflurane	Potentiation	Potentiation
F. Magnesium sulfate	Potentiation	Potentiation
G. Lithium carbonate	Potentiation	Not known
H. Ketamine	Not known	Potentiation
I. Local anaesthetics	Potentiation	Potentiation

of intracellular to extracellular K^+). This hyperpolarisation increase the resistance to depolarisation and neuromuscular transmission. Thus, hypokalaemia enhances the block produced by non-depolarising muscle relaxants. This also diminshes the ability of neostigmine to antagonise the block. Thus, K^+ imbalance due to other diseases also increases the response to muscle relaxants. The severe dehydration also concentrates the muscle relaxants present in the plasma, thereby increases the muscle relaxants activity.

(iii) Myasthenia gravis and muscle relaxants

In myasthenia gravis (autoimmune disease) as there is less number of postjunctional nicotinic receptor, so the patients are more sensitive to non-depolarising muscle relaxants and resistant to succinylcholine. However, not all the muscles are affected in the same way. So, only the short and intermediate acting non-depolarising muscle relaxants should be used in low dose, guided by the monitoring with nerve stimulator. About 1/5 to 1/10th of ED_{95} value should be given initially as test dose to estimate the patient's requirement.

If patients have already received pyridostigmine for the treatment of myasthenia gravis, it should be continued preoperatively. It modifies the response of muscle relaxants as follows: (i) the sensitivity to non-depolarising muscle relaxants will be diminished, (ii) the response to succinylcholine and mivacurium are lengthened, because pyridostigmine inhibit plasma cholinesterase, (iii) the reversal of block is ineffective as ACh E inhibitor already exist in plasma. So, it will probably be safer to allow the spontaneous recovery.

Eaton-Lambert Syndrome (Myasthenic Syndrome)

This syndrome resembles to myasthenia gravis and is associated with carcinoma and motor neuropathy. The patients with this syndrome are usually sensitive to both the non-polarising and depolarising muscle relaxants.

Upper and Lower Motor Neurone Disease

i. The lower motor neurone disease results in resistance to the non-depolarising muscle relaxants. It is because of the proliferation of acetylcholine (or nicotinic) receptors.
ii. In upper motor neuron lesion (hemiplegia and paraplegia) patient is more susceptible to succinylcholine.

(iv) Burns and muscle relaxants

Burn patient show abnormal response to depolarising muscle relaxants. Because after burn there is proliferation of extra junctional ACh (or nicotinic) receptor throughout the surface of the muscle cell membrane. Thus, massive stimulation of these receptors by normal dose of succinylcholine can cause massive release of potassium, producing ventricular tachycardia, ventricular fibrillation or cardiac arrest. So, succinylcholine can safely be administered within first 24 hours following burn injury or 1 to 2 years after the burn, when the skin has healed completely.

Burned patients also show abnormal response to non-depolarising muscle relaxant. Due to increased hepatic and renal clearance and due to hypermetabolic state, burn injury shortened the duration of action of non-depolarising agent. Dose requirement of non-depoalrizing agent is also increased. This resistant is due to the increased population of extrajunctional ACh receptors by burn injury.

INDIVIDUAL NON-DEPOLARISING MUSCLE RELAXANT

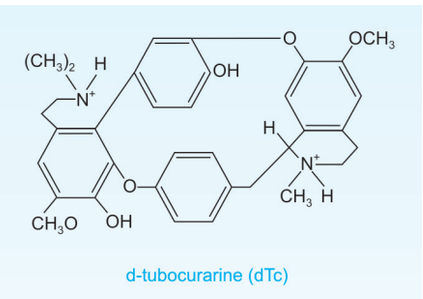
Tubocurarine (dTc)

d-tubocurarine is the first non-depolarising neuromuscular blocking agent found in the arena of anaesthesia. It was clinically first used by Griffith and Jhonson in 1942, at Montreal during an appendisectomy operation. It was first described by King in 1935 as bisquaternary compound. But, the correct formula of it is monoquaternary compound which is described recently. Despite many side effects, it was popular till 1970. But after that pancuronium and other short acting drugs like gallamine take the place of this long acting muscle relaxant. However, now it was only indicated for prolonged operation and where hypotension is desired which is due to the huge release of histamine by it (Fig. 16.4).

The release of histamine is profound by dTc than anyother non-depolarising neuromuscular blocking agent, when it is given in bolus. However, it can be prevented by slow administration, but not by H_1 & H_2 blockers. Histamine release may go up to 10 folds, causing severe hypotension (30 to 50% drop of BP). Though, theoretically it causes anaphylactoid reaction, but clinically is extremely rare, even in atopic individuals. Although, it was widely used in asthma without any adverse effect, still it may produce bronchospasm and should be avoided in these patient.

dTc has profound ganglion blocking effect as ganglion has the nicotinic receptors. But, this side effect is probably beyond the clinical dose range of it. Increase in HR by dTc is uncommon and may be due to the hypotension which is again due to the release of histamine.

As the hypotension by dTc is usually due to the release of histamine, but it also



d-tubocurarine (dTc)

Fig. 16.4: The chemical structure of d-tubocurarine

may be due to very slight ganglion blocking and cardiac depressant effect.

There is no active metabolism of dTc. It is mainly excreted unchanged through the urine. So, kidney is the primary and liver is the 2nd alternative route for elimination of it. In the presence of renal failure, biliary excretion of dTc is increased to provide a satisfactory alternative means of excretion. So, this drug is not indicated when both the renal and hapatic failure are present, at a time.

Clinical Use

dTc is not used now due to discovery of many other safe non-depolarising muscle relaxants. But the prolonged experience on this drug since 1946 has established its safety. It should be avoided in atopic and hypovolaemic patient. It should be avoided or used with caution in those patient in whom a modest fall of BP may endanger the cardiac function. The effective neuromuscular blocking dose of dTc is 0.3 to 0.5 mg/kg IV which provides good muscle relaxation for about 45 to 75 minutes.

Gallamine Triethiodide

Chemically, gallamine is a tribenzene triethiodide compound. In 1947, Bovet and his coworkers had first described the muscle relaxants properties of this synthetic product. It is the 1st synthetic neuromuscular blocking agent used in practice of anaesthesia. But, the effect of this muscle relaxant in man was first described in 1948 (Fig. 16.5).

Like dTc, it is a non-depolarising agent. Triquaternary structure of gallamine confers a strong vagolytic property on it and

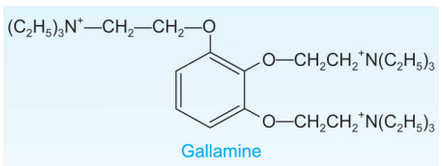


Fig. 16.5: It is a triquaternary ether of gallic acid. Its strong vagolytic property is probably due to the triquaternary structure of it. Gallamine is the only triquaternary compound, available in clinical anaesthesia

the degree of tachycardia goes up to 20 to 60% over the control value. This property of gallamine is useful when it is used in combination with halothane as halothane reduces the HR by stimulating the vagus. This tachycardia caused by gallamine can be accompanied by ↑BP and ↑CO. This may probably be due to increased release of catecholamines. Gallamine causes very little (1/2 to 1/5 quantity of histamine as campared to dTc) release of histamine and less block of autonomic ganglia. Therefore, it does not cause decrease in BP. It crosses the placenta in appreciable concentrations. It is not metabolised in the liver. So, it is entirely excreted by urine as unchanged form and has no biliary excretion. Thus, in the absence of renal function, there is no alternative way of lowering the blood concentration of this drug. The effective neuromuscular blocking dose of gallamine is 4 to 6 mg/kg through IV for intubation and 1 to 1.5 mg per kg of body weight through IV for maintenance of relaxation.

Pancuronium

It was introduced in clinical anaesthesia practice by Baird and Reid in 1964 by the addition of 2-acetylcholine like groups on the rigid nucleus of steroid molecule, at 2 or 3 and 16 or 17 position. Thus, pancuronium is a bisquaternary aminosteroidal non-depolarising muscle relaxing agent which was ultimately introduced in market in 1967. It is 10 times more potent than dTc with an ED_{95} value of about 0.06 mg/kg. High potency, lack of hypotensive effect, and mild to moderate vagolytic property, in contrast to then only available drug, i.e. dTc and gallamine at that time, make pancuronium an instant success in clinical practice. It was the first muscle relaxant introduced in clinical practice which did not have the ganglion blocking or histamine releasing properties, like d-tubocurarine and gallamine but has the long duration of action. So, its administration was ideally suited for longer operation, lasting for 3 to 4 hours and in which prompt extubation is not necessary. It is also suited for operation in which increased HR and BP is desirable as it has no ganglion blocking and histamine releasing property. Pancuronium also causes transient mild depression of pseudocholinesterase enzyme (Fig. 16.6).

CVS effects

Pancuronium stimulates the sympathetic nervous system by inhibiting the reuptake and increasing the release of catecholamines at nerve ending and by the muscarine receptor blockade action. Thus, catecholamines level increases by the use of pancuronium. All this effects results in tachycardia, ↑SVR, ↑CO, ↑after load, etc. So, pancuronium should not be used in patient with coronary artery diseases and myocardial failure. It may be associated with arrhythmias and cardiac ischaemia in susceptible individuals. So, the use of pancuronium is only advantageous in some situations where increase in HR, BP and CO is needed. Two such situations are when high dose of opium is used in cardiac surgery or in shock patients. Hence, the use of pancuronium has been decreased markedly following the introduction of other new short and intermediate acting muscle relaxants. But still it is a popular choice with many anaesthetists for use during cardiac surgery. This is because it tends to counteract the vagal effects which is found in high dose opiate anaesthesia. It causes very little release of histamine.

Metabolism and excretion

85% of the injected dose of pancuronium is cleared unchanged by the kidney and

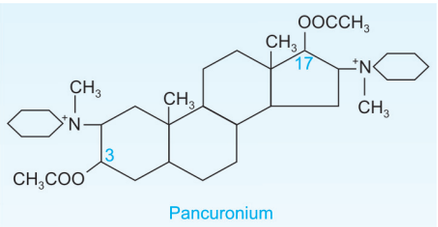

Fig. 16.6: The chemical structure of pancuronium

15% is metabolised in liver to 3-hydroxy or 17-hydroxy or 3,17-hydroxy compound to excrete throuh both kidney or bile. The first and principle metabolite of pancuronium is 3-hydroxy derivative whose potency is half than that of the mother compound. Due to the limited metabolism and limited biliary excretion its action is greatly prolonged in patient with severe renal disorder.

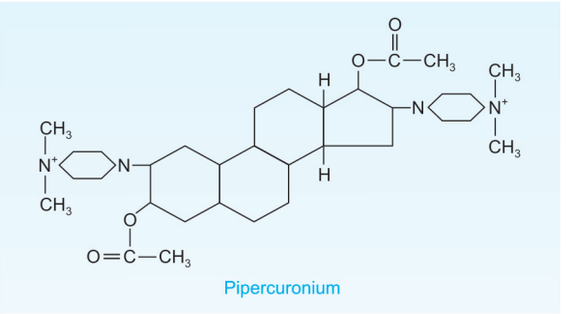

Fig. 16.7: The positive charge of the quaternary nitrogen atom in the pipercuronium molecule is separated by two carbon atoms from the carboxyl group in comparison to pancuronium. This chemical change reduces the vagolytic effect of pipecuronium by 10 times than pancuronium

Dose and clinical use

In clinical practice pancuronium is used in the dose of 0.07 to 0.1 mg/kg through IV (intubating dose) and the duration of action of this dose is 60 to 120 minutes. In this clinical dose (which is 1 to 1.5 times of ED_{95}) intubating condition only reach after 3 to 4 minutes of administration. However, higher doses have more faster onset and much longer duration of action. As pancuronium has the markedly cumulative action, so the top-up maintenance dose, only in the range of 0.01 to 0.015 mg/kg, should be used with duration of action of 30 to 40 minutes. With repeated administration progressive increase in the duration of action of pancuronium occur.

Pipercuronium

Chemically, pipercuronium is an aminosteroid compound. It is a pancuronium derivative, but vagolytic property is 1/10 of that of pancuronium. Pipercuronium is 20 to 30% more potent than pancuronium, but is free from cardiovascular side effects of the latter. Pipercuronium is a long acting drug with duration of action depending on the size of the dose. Spontaneous recovery from pipercuronium is very slow. It is only used when the early extubation is unnecessary and cardiovascular stability is required.

In the clinical dose range, pipercuronium does not release histamine. It has non-vagolytic action and does not block autonomic ganglia. The ED_{95} dose of pipercuronium during balanced anaesthesia is about 0.04 mg/kg. In comparison with pancuronium, increase in HR and cardiac index was observed only when the two times of ED_{95} dose of pipercuronium is administered. Haemodynamic changes are also minimal following pipercuronium up to the doses of 3 times of ED_{95} value (Fig 16.7).

No metabolism of pipercuronium occur in body. So, it is mainly excreted unchanged through the kidney. Liver is possibly a minor secondary pathway for elimination of pipercuronium. Intubating dose of pipercuronium is 0.08 to 0.12 mg/kg with duration of action 60 to 120 minutes. The onset of action of this intubating dose is 2.5 to 4.5 minutes and this dose is 1 to 2 times of ED95 value. The time of onset of neuromuscular block also decreases with increasing the dose. Maintance dose of pipercuronium is 0.005 to 0.01 mg/kg with the duration of action of 30 to 45 minutes. Like all other muscle relaxants renal elimination is also basic to pipercuronium. But the additional process of clearance shorten the duration of effect.

Vecuronium

Chemically, vecuronium is a 2-desmethyl analogue (or 16-monoquaternary derivative) of pancuronium with ED_{95} value of 0.04 to 0.05 mg/kg. However, the stereoisometric relationship of the 3-acetyl group on the molecule of vecuronium makes it structurally dissimilar from the pancuronium. It is more lipid soluble than pancuronium. This is because of the absence of methyl group in the molecule of vecuronium (Fig. 16.8).

The loss of quaternising methyl group at position 2, also destabilises the 3 acetyl group present in the molecule of it. As a result, the vecuronium compound in the form of solution has very short half-life and should be prepared in alkaline buffer solution shortly before its use. But, the powder of it does not need refrigeration. It is the first non-depolarizing agent with intermediate duration of action and the most popular muscle relaxant in clinical practice at present. The reason of popularity of vecuronium are: (i) it helps in more facile tracheal intubation, (ii) it causes easy administration by infusion for maintenance, (iii) it possesses intermediate duration of action, (iv) it has faster and more complete recovery, (v) it causes a remarkable lack of cardiovascular side effect, throughout a wide clinical dose range from one to eight times (0.05 to 0.4 mg/kg). It is more potent than pancuronium, because ED_{90} value of vecuronium

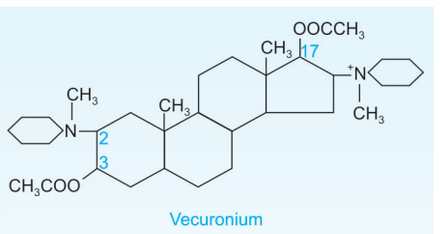

Fig. 16.8: The chemical structure of vecuronium

is 0.03 mg/kg, compared to 0.05 mg/kg for pancuronium.

It has 20 times less vagolytic action than pancuronium. It possesses no ganglion blocking, histamine releasing and cumulative effect. The drug is rapidly cleared from plasma. It has a short α-half-life, compared to pancuronium. However, its β half-life is similar to that of pancuronium (Fig. 16.9).

Vecuronium has two major routes of elimination. These are liver and kidney, and they are of approximately equal importance. 30 to 40% of the injected dose of vecuronium is deacetylated at 3 and 17 position by liver, producing 17-OH vecuronium, 3-OH vecuronium and 3,17-OH vecuronium. But, the major metabolite is 3-OH vecuronium which is as potent as the mother compound and is excreted through both urine and bile. For this reason, the effects of vecuronium are prolonged in patients with hepatic or renal failure. These metabolites may also be responsible for prolonged paralysis, seen after the long term administration of vecuronium in patients in ICU. Because of the lack of cumulative effect, vecuronium can be used as continuous IV infusion and rapid recovery is ensured after infusion has stopped.

Doses

The intubating dose of vecuronium is 0.1 to 0.2 mg/kg through IV route with duration of action of 45 to 90 minutes. It provides acceptable intubating condition within 90 to 120 seconds. However, both the onset and duration of action are dose related. The onset of action of vecuronium can also be accelerated by inducing anaesthesia with a potent volatile agent such as sevoflurane. The maintenance dose of vecuronium is 0.01 to 0.02 mg/kg IV, as intermittent bolus with duration of action only 15 to 30 minutes. The infusion dose of vencuronium is 0.8 to 2 mg/kg/minute.

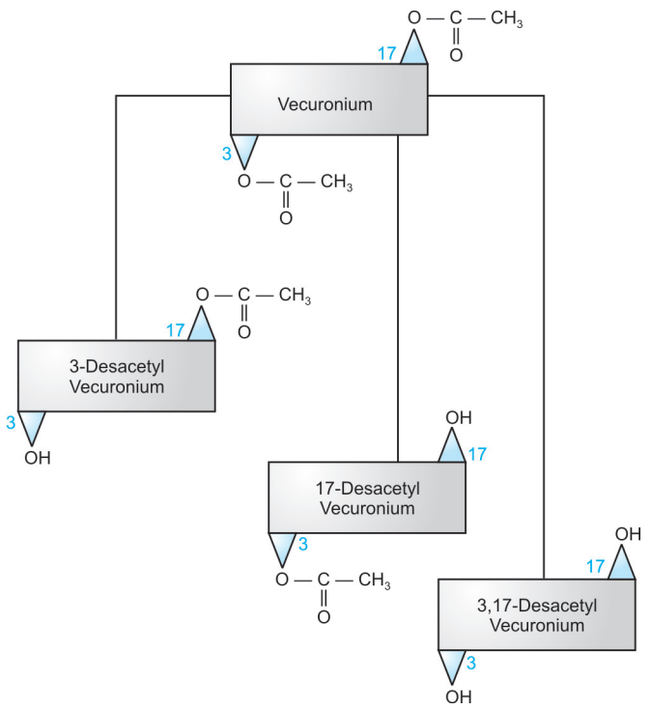

Fig. 16.9: Schematic diagram of metabolism of vecuronium. Metabolism of vecuronium occurs in the liver. About 30-40% is deacetylated at the 3 and 17 position. The major metabolite is 3 – OH vecuronium. Other metabolites are 17 OH vecuronium and 3,17 – OH vecuronium. All these metabolites are excreted in the urine and bile

Because of the safety factor, top-up dose of vecuronium can also be given in multiples of ED_{95} value for maintenance.

Of all the neuromuscular blocking drugs available, vecuronium is the most specific for neuromuscular junction and, therefore, has the least side effect. So, even when used in large doses, it is associated with extremely good cardiovascular stability. There is a wide separation between the vagal and neuromuscular blocking dose (68:1) of vecuronium. It has little sympathetic stimulation activity. Larger doses of vecuronium (1-4 × ED_{95}) can be administered to achieve a faster onset of action and good intubating conditions for rapid sequence intubation.

Atracurium (BW33A)

Like vecuronium, atracurium also has revolutionised the clinical anaesthesia practice due to the same reason.Chemically it is a synthetic bisquaternary benzylisoquinolinium ester and is of intermediate duration of action. It is the first non-depolarising muscle relaxant which is degraded in plasma by spontaneous chemical reaction, called the Hoffmann elimination, but not by the biological process, i.e. metabolism in liver and excretion through urine or bile.

The cardiovascular effects of atracurium are same as that of vecuronium, but it has a strong potential for the release of histamine. However, it is evident only when the higher doses (two times of ED_{95} value) are injected very rapidly. The release of histamine causes ↓BP and facial erythema. But the combined H_1 and H_2 receptor blocker effectively blocks the CVS manifestation of histamine, released by atracurium. The atracurium has no vagolytic action. It also does not block the autonomic ganglia. The pharmacodynamics of atracurium are unchanged with advancing age.

Atracurium is spontaneously degraded by (i) Hoffmann elimination, and (ii) ester hydrolysis. The Hoffmann elimination is

a pure chemical process, where the parent molecule of atracurium is fragmented by itself to laudanosine (a tertiary amine) and a monoquaternary acrylate at the physiological pH and temperature of plasma, i.e. at a pH of 7.4 and a temperature of 37°C. This spontaneous degradation is slowed down by the fall in pH (acidic condition) and temperature (hypothermia). Whereas degradation is accelerated by alkaline pH and rise in temperature of plasma. So, atracurium is stored at 4°C and is buffered to a pH of 3, where it is stable. Atracurium becomes unstable when it is injected in blood-stream and breakdown from itself in blood's normal pH and temperature. The alteration of pH and temperature of blood within its physiological range does not decrease the rate of Hoffmann's elimination of atracurium and does not cause clinically significant increase in the duration of action. Atracurium's duration of action is prolonged markedly by hypothermia. The ester hydrolysis which is a second pathway for degradation of atracurium may be of more importance than was originally thought. The steps of this hydrolysis is shown in figure. Laudanosine which is formed by Hoffmann's degradation is excreted through urine and bile. It can cross the blood brain barrier and enter the CNS. Very high doses of laudanosine can cause CNS excitation. But no clear cut cases have been noted in human (Fig. 16.10).

The duration of action of atracurium is not prolonged by the absence of hepatic and renal pathways for excretion. So, it is the relaxants of choice for patient with renal and hepatic failure. 90% atracurium is destroyed in plasma. Only 10% drug is excreted unchanged through urine. (Fig 16.11).

Doses

The intubating dose of atracurium is 0.5 to 0.6 mg/kg, with duration of action only 30 to 45 minutes. Actually, the ED_{95} value of atracurium is approximately 0.2 mg/kg and the onset of action of this ED_{95} value is 3 to 5 minutes. So, this onset of action can be reduced by increasing the intubating dose from 0.2 mg/kg to 0.5 mg/kg. The maintenance dose of atracurium is 0.1 to 0.15 mg/kg as intermittent bolus with duration of action only 15 to 20 minutes. The infusion dose of atracurium is 4 to 12 µg/kg/min. Repeated administration of atracurium does not lead to an increase in the duration of action. The unique type of metabolism of atracurium makes it suitable for use in the critically ill patient, as it is associated with rapid recovery.

Rocuronium (ORG – 9426)

Chemically rocuronium is a vecuronium derivative. It is a steroidal muscle relaxants with intermediate duration and faster onset of action than that of vecuronium. It is developed as a non-depolarising agent that would have an onset of action closer to that of succinylcholine. The basis for this development was the observation that potency and the speed of onset of action were inversely related. It means when potency decreases, the onset of action increases. This can be explained by the fact that to compensate the decreased potency, large volume of drug is needed which increases the onset of action (Fig. 16.12).

Though, rocuronium is a derivative of vecuronium, still it is stable in solution and formulated as an aquous ready to use form. It is 7 to 8 times less potent than vecuronium, with an estimated ED_{95} value of approximately 0.3 mg/kg. Due to the same molecular weight with vecuronium and larger volume is needed for initial bolus dose due to low potency, the large number of molecules of rocuronium reach the junctional nicotinic receptors within few circulation time, causing faster onset of action. The faster onset of action of rocuronium also can be improved by the addition of opiates, ketamine, or a small dose of ephedrine which maintain a better cardiac output and thus improves the rapid delivery of muscle relaxant to the neuromuscular junction. The weaker binding ability of rocuronium molecule with receptor allow repetitive binding and unbinding and thus easy diffusion of drugs away from the receptor site which limits the duration of action.

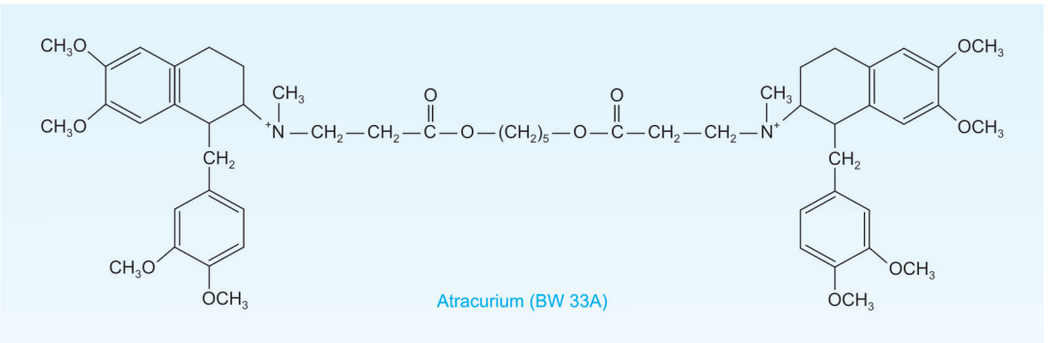

Fig. 16.10: It is a benzylisoquinolinium diaster and undergoes the Hoffmann elimination. This reaction is facilitated by the orientation of the ether oxygen of the carboxyl group toward the centre of chain

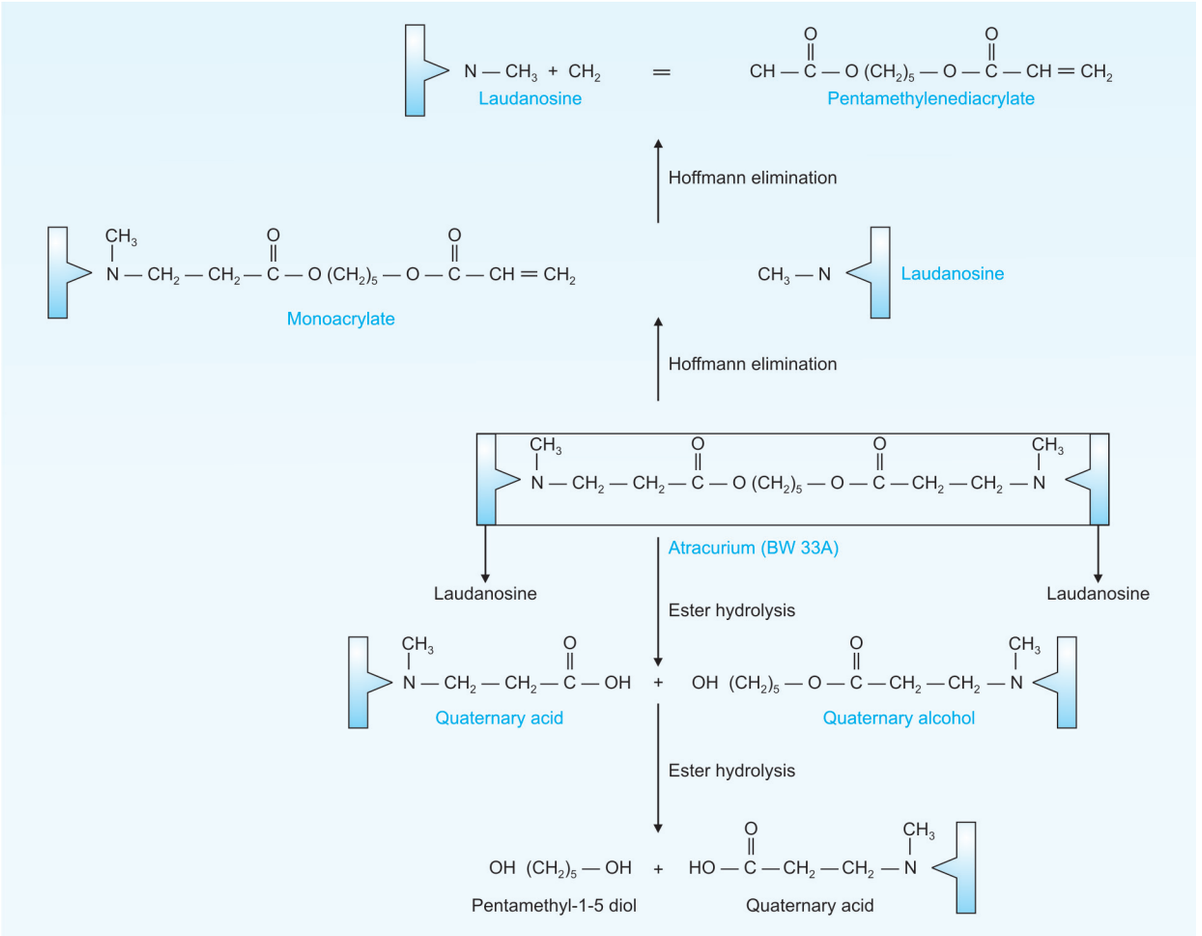

Fig. 16.11: Schematic diagram of metabolism of atracurium. The major metabolite of atracurium is laudanosine. It is excreted through urine and bile. Laudanosine may enter the CNS as it is a tertiary amine. Less than 10% of the atracurium is excreted unchanged as the parent compound

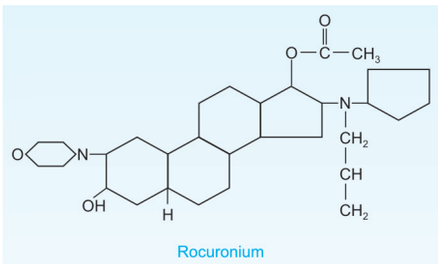

Fig. 16.12: A vecuronium derivative of faster onset and intermediate duration of action. The faster onset is conferred by lower potency. The lower potency is largely due to the D-ring substitutions with respect to vecuronium

Rocuronium is peculiar for its lower potency with faster onset of action. The onset of maximum block following an intubating dose of 0.6 mg/kg occurs in about 60 to 90 seconds, which is near similar to that of succinylcholine. More larger doses have a more rapid onset of action. However, a dose of about 1 mg/kg is required to obtain a good intubating conditions during a rapid sequence induction. The duration of action of rocuronium is similar to that of vecuronium and atracurium in comparable doses. The clinical duration of action of 0.6 mg/kg of rocuronium is 30 minutes. The repeated administration of it does not usually result in a prolonged effect. With adequate dose, rocuronium may enable tracheal intubation within 60 seconds and make it an ideal substitude for succinylcholine, during rapid sequence intubation.

It has no ganglion blocking effect and no histamine releasing property, but has mild vagal blocking effect, resulting sometimes in increase in heart rate. So, the commonly used doses of rocuronium are associated with cardiovascular stability, except only a small increase in heart rate.

Rocuronium does not undergo any metabolism. So, it is excreted unchanged through the bile and urine. Hence for elimination of rocuronium the dual renal and hepatic pathways exist. Unchanged drug has been recovered from bile and urine. Action of it is prolonged in severe

renal and hepatic dysfunction. The rocuronium is administered in an initial bolus dose of 0.6 to 1 mg/kg. The block can be maintained by repeated administration of bolus dose of about 0.1 to 0.15 mg/kg or by a continuous infusion in a dose of 10 µg/kg/minute. With the rapid onset of action, rocuronium is very useful for rapid sequence intubaion when succinylcholine is contraindicated. A useful dose in this situation is 1 mg/kg and it should be realised that this dose will have a clinical duration of action of about 1 hour. So, it is also very important to assess the airway carefully before intubation, if the use of rocuronium is contemplated in this setting.

Mivacurium

Like atracurium, mivacurium is a benzylisoquinolinium diaster and a non-depolarizing muscle relaxants. The beauty of mivacurium lies in its spontaneous hydrolysis in plasma by pseudocholinesterase like succinylcholine, but slightly at slower rate (at about 80% of the rate of metabolism of succinylcholine). This mechanism of metabolism (enzymatic hydrolysis) of mivacurium allows it to enjoy the shorter duration of action than vecuronium and atracurium, but 2 to 2.5 times than that of succinylcholine.

It has neither autonomic ganglion blocking action, nor any vagolytic action. Like atracurium, it has the potential to cause histamine release, causing facial erythema and ↓BP. Duration of action of mivacurium is 2 to 2.5 times longer than that of succinylcholine, but 1/2 to 1/3 times (Fig. 16.13) longer than that of atracurium. It can also be used by continuous infusion to maintain smooth relaxation of muscle for surgical procedure of intermediate length extending from 30 to 90 minutes. However, prolonged infusion of mivacurium may be given without any increase in recovery time. The recovery from mivacurium is not affected by the dose or by the duration of infusion. The neuromuscular block produced by mivacurium can also be antagonised by anticholinesterase (unlike succinylcholine) or by pseudocholinesterase enzyme (like succinylcholine).

90% of the injected dose of mivacurium is hydrolysed by pesudocholinesterase to mivacurium monoester and amino alcohol. The 10% of administered mivacurium is excreted unchanged through the urine. The Hydrolysed product of mivacurium is also excreted through the bile and urine. So, like succinylcholine, action of mivacurium is lengthened in patient, carrying atypical pseudocholinesterase enzyme. In heterozygotes, the duration of action of mivacurium is lengthened for 15 to 30 minutes. However, in atypical homozygotes (incidence 1 in 3000) the duration of action of it may be lengthened for 3 to 4 hours. Once the signs of recovery are begining to be noted, then antagonism by neostigmine should be initiated. If reversal is still inadequate then another dose of neostigmine is administer after ½ an hour. Alternatively, the pseudocholinesterase enzyme may be given through IV. Perhaps because of the inherent short duration of action of mivacurium, the reduction of duration of action by administering anticholinesterase is relatively small. Theoretically, anticholinersterase (neostigmine) may prolong the action of mivacurium like succinylcholine. But this has not been found to occur when the neostigmine has been administered to antogonise the neuromuscular block produced by mivacurium. However, previously administered neostigmine may prolong the effects of subsequently administered mivacurium (Fig. 16.14).

Doses

The ED_{95} dose of mivacurium is 80 µg/kg and like other non-depolarising muscle relaxant, the onset of action is dose dependent. It is the currently available shortest acting non-depolarising muscle relaxant and the duration of relaxation is only about 15 minutes, following a dose of 0.15 mg/kg ($2 \times ED_{95}$). The increase in the duration of action of mivacurium with increasing the doses is not as marked as with other non-depolarising relaxants. Intubating dose is 0.2 to 0.25 mg/kg with duration of action of only 15 to 20 minutes. The maintenance dose of mivacurium is 0.05 to 0.1 mg with duration of action of 5 to 10 minutes. Mivacurium is the most suitable agent for maintaing relaxation by infusion. Continuous infusion is the preferred method of administration of mivacurium

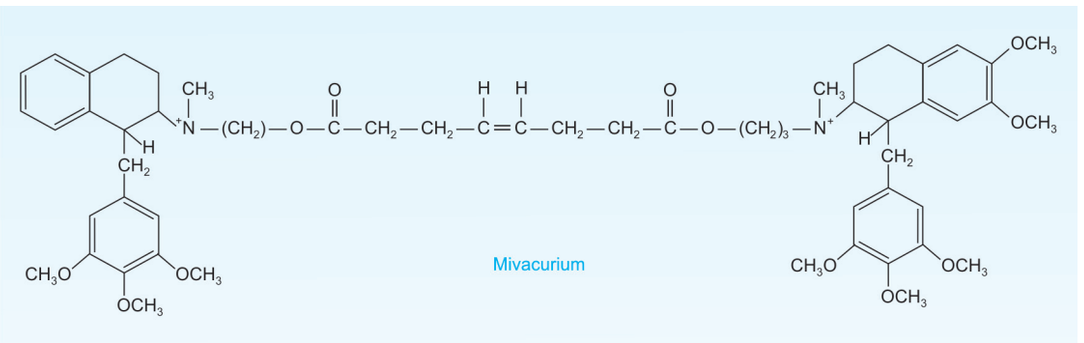

Fig. 16.13 : It is a benzylisoquinolinium disater which is hydrolysed by pseudocholinesterase at the rate of about 80% of succinylcholine. This hydrolysis is facilitated by the orientation of ether oxygen of the carboxyl group toward the quaternary nitrogen atom

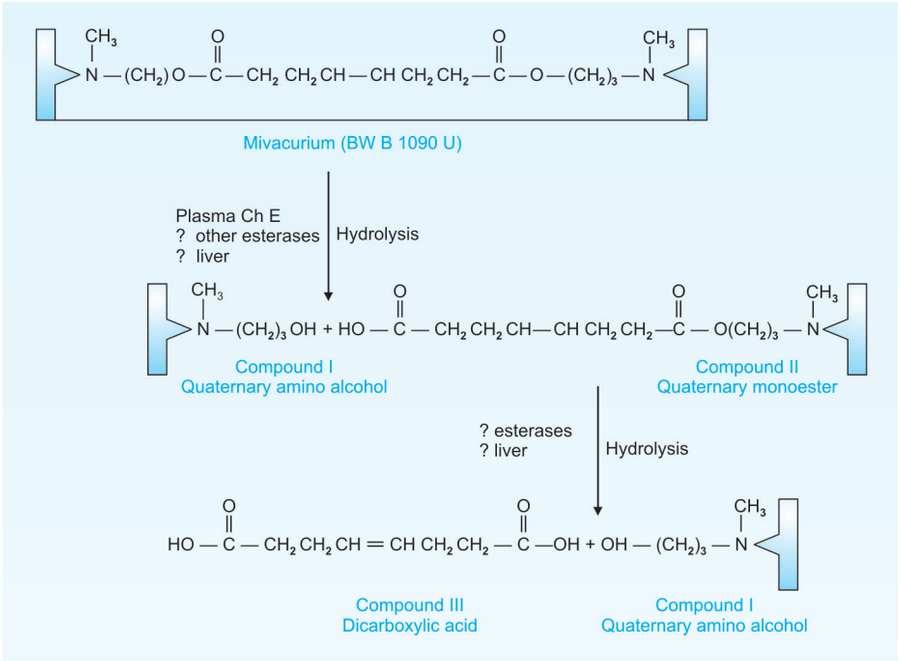

Fig. 16.14: Schematic diagram of metabolism of mivacurium. It is metabolised by plasma cholinesterase. The reaction occurs at the rate of about 70 to 80% of succinylcholine. These metabolites are inactive and carry positive charges. So their CNS enyry is minimal

for anything but brief surgical procedure. The recovery does not change significantly by repeated administration of bolus doses or infusion of varying doses and duration. It suggests minimal or no cumulative property of mivacurium. Infusion dose of mivacurium is 6 to 8 µg/kg/min.

There exist three isomers of mivacurium. Among these cis-cis isomer is hydrolysed by pseudocholinesterase very slowly, but fortunately constitutes only 5% of the commercial preparation. However, 95% of the commercial preparation is made up of cis-trans and trans-trans isomer of mivacurium which is hydrolysed very rapidly (t 1/2 β is 2 to 3 minutes). Another advantage of cis-cis isomer is that it is of less potent, about one-tenth of the neuromuscular blocking potency of other two isomers. It (cis-cis isomer) undergoes some renal excretion as well as is broken down by plasma cholinesterase. In renal failure the duration of action of mivacurium is prolonged. In hepatic failure the action of mivacurium is also prolonged due to the reduction of plasma cholinesterase activity. The same is true for elderly patient also.

Cisatracurium (51W89)

Cisatracurium constitutes about 15% of the commercial available preparation of atracurium. It is one of the 10 stereoisomers of atracurium and is very potent. It liberates only minimum amount of histamine than the parent compound. It is in clinical practice only for about last 6 years. In comparison to atracurium the ED_{95} value of cisatracurium is 0.05 mg/kg which indicates that it is 4 times more potent than atracurium (ED_{95} value of atracurium is 0.2 mg/kg). However, being more potent, the drug has slower onset of action. In the dose of 0.1 mg/kg (intubating dose 0.1 to 0.15 mg/kg) the onset of maximum neuromuscular block in cisatracurium takes about 3 to 5 minutes. Although increasing the dose (0.15 mg/kg) accelerates the onset of action, but it is still slower than that of atracurium. The duration of action of cisatracurium is 30 to 60 minutes at the initial bolus dose of 0.1 to 0.15 mg/kg and it depends on the dose. At equivalent dose, the duration of action of cisatracurium is slightly longer than that of atracurium. Cisatracurium can be used by intermittent bolus in the dose of 0.02 mg/kg with action lasting for 15 to 20 minutes or by continuous infusion in the dose of 1.5 µg/kg/minute for longer procedures (Fig. 16.15).

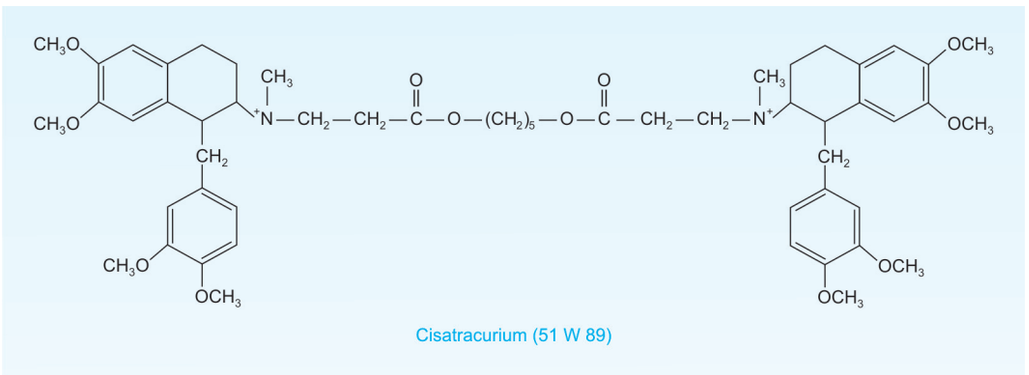

Fig. 16.15: This is the chemical structure of cisatracurium which is one of the isomers of atracurium. The R-cis and the R'-cis conformation of the structure provide greater potency and significantly reduces the side effects of release of histamine in comparison to atracurium

As cisatracurium releases the negligible amount of histamine, so it gives us a stable cardiovascular activity. Even, when administered in higher doses (eight times the ED_{95} dose), the cisatracurium does not give rise to any significant changes in arterial pressure and heart rate. It is eliminated predominantly by the Hoffmann degradation like atracurium. So, the pharmacokinetics of cisatracurium are independent of dose in healthy adult pateints. The renal clearance is responsible for 10% of total elimination of drug from the body. So, the recovery profile is not altered in patients with liver failure, but becomes slightly slower in renal failure patient. Compared with atracurium, the cisatracurium produces much less laudanosine, even when the drug is given by continuous infusion.

Rapacuronium (ORG – 9487)

Chemically rapacuronium is a steroidal non depolarising muscle relaxant. Introduction of rocuronium in clinical practice stimulates the search for muscle relaxants which have rapid onset, but short duration of action like succinylcholine. This is because rocuronium has rapid onset of action like succinylcholine, but does not have short duration of action. So, it has instigated the advent of rapacuronium which has both the rapid onset and a shorter duration of action (Fig. 16.16).

Rapacuronium is analogue of vecuronium and is of low potency with an ED_{95} value of about 0.75 mg/kg. In the dose of 1.5 mg/kg, rapacuronium produces complete block in 80 seconds, compared with 60 seconds for succinylcholine in the dose of 1 mg/kg. The rapid onset of rapacuronium is possibly due to its low potency necessiating higher doses and indicating a rapid access to the site of action. Though initially rapacuronium was thought to have short duration of action of only 8 to 9 minutes in the dose of 1.5 mg/kg, but recent studies reported this value to be about 14 to 20 minutes. The drug also showed cumulative properties − especially after repeated doses or administration by infusion. Rapacuronium caused higher rate of respiratory side effects − especially bronchospasm both in adults and children − though its exact cause has not yet been determined. Histamine release and muscarinic receptor stimulation by rapacuronium in the airways may be the probable explanation of bronchospasm. So, the drug was withdrawn from clinical use finally in March 2001, due to its higher risk of bronchospasm.

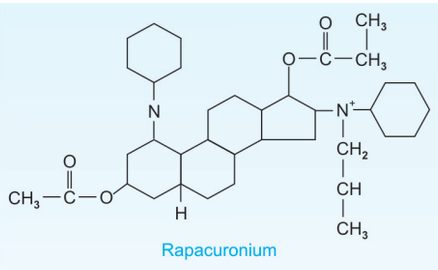

Fig. 16.16: The chemical structure of rapacuronium

ANTAGONISM OF NEUROMUSCULAR BLOCKADE

The neuromuscular blockade produced by non-depolarising muscle relaxant can be antagonized by temporary inhibition of true cholinesterase enzyme which is present in synaptic cleft and which inactivates the acetylcholine (ACh). Thus, anticholinesterase antagonize the true cholinesterase and increase the concentration of ACh and improve the neuromuscular transmission. The agents which inhibit this true cholinesterase enzyme are called the anticholinesterase or acetylcholinesterase enzyme inhibitor. The clinically commonly used cholinesterase enzyme inhibitors are edrophonium, pyridostigmine and neostigmine. They indirectly antagonise the non-depolarising block by: (i) increasing the concentration of neurotransmitter such as ACh at the motor nerve terminals, and (ii) blocking the neuronal potassium channels and thus preventing the hyperpolarisation.

Reversal of non-depolarising block by acetylcholinesterase (ACh E) inhibitor depends on five major factors.

(i) Depth of Block at the Time of Administration of ACh E-Inhibitor

The deeper the neuromuscular block will be the longer the time interval will be required between the administration of non-depolarising muscle relaxant and the administration of a standard dose of antagonist (ACh E–inhibitor) in restoring the twitch or TOF response to levels which is compatible with the clinically normal function of muscle. Usually the deeper block requires much longer time such as 15 to 30 minutes for adequate reversal. The relationship between the reversal time and the depth of block is hyperbolic. Maximum antagonistic effect of neostigmine is likely to be reached within 10 minutes after its administration.

(ii) Type of Antagonist Administered

Under standard condition and in moderate depth of block the order of rapidity of action of antagonist is: edrophonium > neostigmine > pyridostigmine. But, edrophonium is not as effective (or potent) as neostigmine in antagonising profound muscular blockade which is greater than 90% of twitch depression. As depth of block become more intense, edrophonium becomes less potent than neostigmine. The dose response curves between edrophonium and neostigmine are not parallel and become increasingly divergent as the depth of block intensifies. It indicates that edrophonium is less effective than neostigmine at very deep levels of block.

ACh E-inhibitor acts indirectly by increasing the level of ACh at synaptic cleft by inhibiting the true cholinesterase. ACh has both nicotine and muscarinic response as it acts on both the receptors. So, ACh E-inhibitors also has indirect both nicotinic and muscarinic effects. But, the nicotinic effect that is muscular contraction or

reversal of neuromuscular blockade is only desired. So, the muscarinic effect of ACh E inhibitor which is not desired should be blocked by anticholinergic agents such as atropine or glycopyrrolate. Atropine acts more rapidly than glycopyrrolate. So, atropine is better suited with rapid acting edrophonium, whereas glycopyrrolate is better suited with slower acting neostigmine.

It was initially thought that edrophonium is not suitable for antagonism of neuromuscular block, because of its too short duration of action. But, when it is used in standard large dose of 0.5 to 1 mg/kg, then a sustained action of antagonism results. Infact, elimination half-life of edrophonium in this dose is similar to that of neostigmine. So, use of edrophonium in this dose is more justified for faster onset of action, fewer muscarine side effects and standard duration of action like neostigmine.

The highly purified preparation of human pseudocholinesterase enzyme is also available. This enzyme antagonises the block produced by mivacurium and succinylcholine in patients with abnormal pseudocholinesterase activity and this antagonism may be 100%.

(iii) Dose of Antagonist

It is commonly thought that larger dose of ACh E-inhibitor can antagonise any level of depth of block more rapidly and more completely than smaller dose and this dose of ACh E-inhibitor is parallel to the depth of block. But, this is true up to a certain point i.e. maximum level of AChE-inhibitor, beyond which this is not true. For neostigmine, this maximum dose limit is 0.06 to 0.08 mg/kg (or 60 to 80 µg/kg) and for edrophonium this limit is 1 to 1.5 mg/kg. The maximum effect of both the drugs occur between 5 to 10 minutes. Further recovery that occur slowly beyond that period largely dependent on the rate of clearance of muscle relaxants from the body.

If 30 minutes after neostigmine administration adequate reversal of block does not occur, then a good rule of practice is: (a) continue the support of airway and ventilation, (b) wait for another 30 to 45 minutes which is 50% of the half live of both muscle relaxants and neostigmine, (c) administer another dose of same antagonist equal to the 50% of original dose (30 µg/kg of neostigmine). This repeat dose of ACh E-inhibitor would help to return the function of muscle power satisfactorily within subsequent 30 minutes. Neostigmine and edrophonium do not potentiate each other and should not be mixed and repeat dose should be of the original drug.

(iv) Concentration of Inhaled Anaesthetics

The inhaled anaesthetics retard the antagonism of neuromuscular block produced by ACh E-inhibitors.

(v) Rate of Clearance of Muscle Relaxants

The clearance Rate (CR) for different muscle relaxants are different. Usually for long acting drugs the CR is 1.2 to 2 ml/kg/min and reversal time interval is 20 to 40 minutes from deep depth of block which is about 95% of twitch depression.

CR of intermediate acting drugs is 3 to 6 ml/kg/min and reversal time interval is 12 to 15 minutes from 95% block. For mivacurium CR is 50 ml/kg/min and reversal time interval is 7 to 8 minutes from 95% block by neostigmine. So, higher the plasma clearance of muscle relaxant, shorter the time interval will be required for antagonism of block. If adequate reversal time interval from 95% block is not elapsed and neostigmine is administered, then after 10 minutes when the maximum antagonistic effect of neostigmine occurs, little amount of long acting drug is removed from plasma. Therefore, there is chance of recurization. So, in such circumstances restoration of adequate neuromuscular function depends entirely on the action of neostigmine, and large doses (50 to 70 µg/kg) is recommended for antagonism of long acting drug. This larger dose of ACh E-inhibitor maximally inhibit true ACh E but may cause a transient neuromuscular block by themselves.

INDIVIDUAL NEUROMUSCULAR ANTAGONIST

Neostigmine

Chemically neostigmine is an quaternary amine compound and is also an ester of an alkyl carbamic acid. It is a reversible (acid transferring) cholinesterase inhibitor. It acts by binding to the esteric site of acetylcholinesterase enzyme and thus temporary block and subsequently prevent the ACh from hydrolysis by this enzyme. Later the ACh E inhibitor is hydrolysed by the enzyme like ACh and make free the acetylcholine esterase (ACh E) enzyme but at a much slower rate than the acetylcholine. So, the ACh E enzyme remains engaged till the neostigmine is hydrolysed completely by it and cannot attack the ACh which will accumulate gradually. Thus, the accumulation of acetylcholine at the neuromuscular junction allows it to make competitive antagonism with any non-depolarising muscle relaxant that is present there. Hence, the mode of action of neostigmine is to let the accumulation of acetylcholine at the motor end-plate and the reversal of neuromuscular blockade (Fig. 16.17).

The pharmacological effects of neostigmine is indirect and is due to the accumulation of excess ACh which has both the nicotinic and muscarinic action. So, the nicotinic action of neostigmine caused by

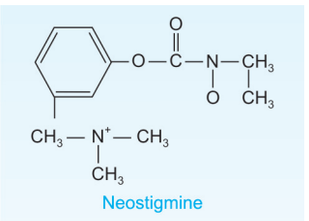

Fig. 16.17: The chemical structure of neostigmine

the nicotinic aciton of ACh is manifested as the removal of neuromuscular blockade or muscular contraction. Whereas, the muscarinic action of neostigmine caused by the muscarinic action of ACh is manifested on different organs where there is presence of muscarinic receptors such as heart, bronchial glands, intestine, blood vessels, etc. The effects of neostigmine on the cardiovascular system due to accumulation of ACh are variable and depend upon (Table 16.16) the prevailing autonomic tone. The drug may cause bradycardia, leading to a fall in cardiac output. It increases the duration of effective refractory period of cardiac muscle and decreases the conduction time in conducting tissue. In high doses, neostigmine may cause hypotension secondary to a central effect also. It increases the bronchial secretion and may cause bronchoconstriction. Miosis and failure of accomodation of the eye may be precipitated by the administration of this drug. Neostigmine increases salivation, elevates oesophageal and gastric tone, increases gastric acid output and increases gastrointestinal tract motility. Nausea and vomiting may occur. It increases ureteric peristalsis and may lead to involuntary micturition. Sweating and lacrimation are increased by neostigmine. All these effects are due to the muscarinic action of accumulated ACh caused by neostigmine.

The side effects of neostigmine are due to the excess manifestations of its pharmacological actions as described above. The cardiac arrest also has been reported after the use of large dose of neostigmine. In small doses, the drug has an indirect action on skeletal muscle leading to muscular contraction by accumulation of ACh. But in higher doses, neostigmine like other anticholinesterase may also block the neuromuscular transmission by allowing the accumulation of excess acetylcholine which acts like succinylcholine.

It is very poorly absorbed when administered orally and the bioavailability by this route is only 1 to 2%. This drug is highly ionised in solution and therefore does not cross the blood-brain barrier to any significant extent. Neostigmine is 6 to 10% protein bound in the plasma and the volume of distribution is 0.4 to 1 litre/kg. It is predominantly metabolised or broken down by plasma cholinesterases to a quaternary alcohol. Some, hepatic metabolism with subsequent biliary excretion may also occur. The 50 to 60% of an administered dose of neostigmine is excreted through urine. The rate of clearance of neostigmine is 5 to 10 ml/min/kg. and the elimination half-life is 15 to 80 minutes. The clearance of neostigmine is decreased and the elimination half-life is increased in the presence of renal impairment.

Table 16.16: Comparison between physostigmine and neostigmine

		Physostigmine	*Neostigmine*
1.	Source	Natural alkaloid, obtained from calabar bean	Synthetic
2.	Chemistry	Tertiary amine derivative	Quaternary ammonium compound
3.	Oral absorption	Good	Poor
4.	CNS effect	Present	Absent
5.	Topical action on eye	Good corneal penetration	Poor corneal penetration
6.	Direct action on cholinergic receptor	Absent	Present
7.	Prominent effect on	Autonomic target organ such as eye	Myasthenia gravis
8.	Important use	In glaucoma (miotic)	Myasthenia gravis

It is available for oral use as 15 mg tablet of neostigmine bromide and as a clear, colourless solution for injection in ampule, containing 0.5 mg/ml of neostigmine methylsulphate. A fixed dose combination, containing 0.5 mg of glycopyrrolate and 2.5 mg of neostigmine methylsulphate per 5 ml of injection, is also available for the reversal of neuromuscular blockade at the end of surgery. The adult oral dose of neostigmine is 15 to 30 mg at regular interval of 2 to 4 hours. The intravenous dose of neostigmine for the reversal of non-depolarising neuromuscular blockade is 50 to 70 µg/kg. It is administered slowly and in combination with an appropriate dose of an anticholinergic agent such as atropine or glycopyrrolate to counter act its muscarinic effect. The peak effect of the drug when administered intravenously occurs after 5 to 10 minutes of injection. A single dose of neostigmine has a duration of action for only 50 to 60 minutes.

Neostigmine prolongs the duration of the action of succinylcholine by inhibiting the plasma cholinesterase enzyme. There is also some evidence that the use of neostigmine to reverse the neuromuscular blockade is associated with an increased incidence of gastrointestinal anastomotic breakdown due to increased intestinal motility. Pyridostigmine resembles neostigmine in all these respects, but in dose-to-dose comparison it is less potent and longer acting. So, less frequent dosing of pyridostigmine is required in myasthenia gravis. The dose of pyridostigmine in myasthenia gravis is 60 to 180 mg orally and 1 to 5 mg IM or SC.

Neostigmine is used:

i. For the reversal of non-depolarising neuromuscular block,
ii. For the treatment of myasthemia gravis,
iii. For the treatment of paralytic ileus,
iv. In urinary retention.

Edrophonium

Chemically the edrophonium is a synthetic ammonium compound. Like neostigmine

it is also a prosthetic reverseble inhibitor of true acetylcholinesterase. So, it acts by competing with acetylcholine like neostigmine for the anionic site of the enzyme cholinesterase enzyme and reversibly binds to it. Thus, it left acetylcholine unbroken and accumulate to facilitate the neuromuscular transmission. A part of the effect of the drug also appears to be exerted through the prejunctional receptors and increase the liberation of ACh (Fig. 16.18).

Thus, the mode of action of edrophonium is like neostigmine, i.e. nicotinic and cholinergic. Nicotinic action improves neuromuscular transmission and prevent muscular paralysis. The cholinergic action is like ACh. So, the drug may cause bradycardia leading to a fall in cardiac output, increase in effective refractory period of cardiac muscle and decrease in conduction time. Like acetylcholine, edrophonium also increases bronchial secretion and may cause bronchoconstriction. For CNS effect, agitation and dreaming may occur by this drug and has a predictable miotic effect. Weakness of muscle due to fasciculation and paralysis may also occur due to accumulation of excessive acetylcholine when edrophonium is administered to normal subjects. The drug increases the salivation and lower oesophageal and gastric tone. It increases the gastric acid output and gastrointestinal tract motility. Nausea and vomiting may occur. Like neostigmine, edrophonium also increases the ureteric peristalsis and may lead to involuntary micturition. Lacrimation and sweating are increased by the drug.

Fig 16.18: This figure shows the chemical structure of edrophonium

The metabolic fate of edrophonium is uncertain. It is not hydrolysed by cholinesterase like acetylcholine or neostigmine. The volume of distribution of edrophonium in tissue is 0.9 to 1.3 litre/kg. The details of excretory pathways of this drug are unknown. The clearance rate of edrophonium is 6 to 12 ml /kg/minute and the elimination half-life is 110 minutes. The toxic effects of edrophonium are nothing, but only the exaggerated manifestations of its pharmacological actions which are described above. Cardiac arrest has also been reported after the use of edrophonium.

Edrophonium is usually administered intravenously. It has a more rapid onset (peak effect occurring at 0.8 to 2 minutes) and shorter duration of action (10 minutes) than neostigmine. The 'Tensilon Test' for the diagnosis of myasthenia gravis consists of the slow IV administration of 2 mg edrophonium, followed by further injection of 8 mg, if clinical deterioration does not occur. When it is used in the differentiation between myasthenic crisis and cholinergic crisis, then a dose of 2 mg of edrophonium is used first. If the weakness increases then the diagnosis is cholinergic crisis and if the weakness improves then the diagnosis is myasthenic gravis. An anticholinergic agent (e.g. atropine) must be immediately available when these tests are performed. In anaesthetic practice the dose of edrophonium for reversal of neuromuscular blockade is 0.5 to 0.7 mg/kg and is used by slow intravenous injection. This is preceded by an appropriate dose of an anticholinergic agent to counter the peripheral muscarinic side effects of this drug.

The potency of edrophonium is 12 to 16 times less than that of neostigmine. The muscarinic effects of this drug are relatively easier to counteract than those of neostigmine. Edrophonium is less predictable than neostigmine when used to reverse the profound competitive neuromuscular blockade.

Edrophonium is used:

i. For the reversal of non-depolarising neuromuscular blockade,
ii. For the diagnosis of suspected phase II block,
iii. For the diagnosis of myasthenia gravis (Tensilon Test)
iv. For the differentiation between myasthenia gravis and cholinergic crisis in myasthenic patient.

Pyridostigmine

It is an analogue of neostigmine. It was introduced for the treatment of myasthenia gravis. It has 1/4 of the potency of neostigmine. So, 10 mg of pyridostigmine in IV route is equivalent to 2.5 mg of neostigmine through same route. But the action of pyridostigmine on intestine and heart is less marked. The muscarinic action of pyridostigmine is less than equivalent dose of neostigmine. The action of pyridostigmine on neuromuscular junction is less reliable than neostigmine and takes long time near about 5 minutes to start its action. So, it is not used in anaesthesia practice (Fig. 16.19).

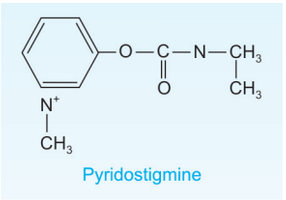

Fig. 16.19: The chemical structure of pyridostigmine

Physostigmine

It is also analogue of neostigmine and acts as cholinesterase inhibitor. But it is only used in ophthalmology as eyedrops. The difference between physostigmine and neostigmine is given below.

17 Pharmacology of Perioperative Arrhythmia

INTRODUCTION

The agents or drugs which are used to prevent the irregularities of cardiac rhythm are called the antiarrhythmic agents or drugs. Abnormal automaticity or impaired conduction of impulse or both underlie the cardiac arrhythmias. This may be paroxysmal or present continuously. It may cause sudden death, syncope, heart failure, palpitation or no symptoms. Arrhythmias are often a manifestation of underlying structural heart disease. But it may also occur in the context of an otherwise normal heart. The two most common form of abnormal cardiac rhythm is tachycardia and bradycardia. When the heart rate is more than 100/minute it is called tachycardia and when the heart rate is less than 60/minute it is called bradycardia. Tachycardia is caused by two mechanisms: Increased automaticity due to increased repeated spontaneous depolarisation or re-entry due to repeated nonspontaneous depolarisation by closed loop or re-entry circuit. But the most tachyarrhythmias are due to this re-entry mechanism. Bradycardia is also caused by two mechanisms: Reduced automaticity or abnormal slow conduction (due to block).

According to the site of origin the arrhythmias may also be supraventricular (sinus, atrial, junctional or nodal) or ventricular. Arrhythmias arising from supraventricular site usually produce narrow QRS complexes. This is because the ventricles are depolarized by impulses which pass normally through the AV node, bundle of His and Purkinje fibres. In contrast, ventricular arrhythmias produce broad bizarre QRS complexes. This is because the ventricles are activated by impulses which arise from any side of ventricular wall pass through an abnormal pathway such as myocardium. However, occasionally a supraventricular arrhythmias can produce broad or wide QRS complexes due to coexisting bundle branch block or the presence of accessory conducting tissue.

The incidence of perioperative arrhythmias varies and depends on: the definition (any minor caridac arrhythmia or any potentially dangerous arrhythmia), mode of surveilence, patient's characteristic and the nature of surgery. The factors that determine how a patient tolerates a cardiac arrhythmia usually include: The heart rate, duration of arrhythmia, the presence and severity of any underlying cardiac disease, etc. However, more or less the importance of a specific arrhythmia depends on the effects of it on the cardiac output and the possible interactions of the antiarrhythmic drugs which the patients are already taking with the drugs that are used in perioperative period for anaesthetic and analgesic purpose.

CLASSIFICATION

Perioperative cardiac arrhythmias are mainly divided according to their aetiology under two headings.

1. Disturbances of impulse formation.
2. Disturbances of impulse conduction.

Disturbances of Impulse Formation

i. Sinus rhythm: Sinus bradycardia, sinus tachycardia, sinus arrhythmia, sinus arrest, sick-sinus syndrome.
ii. Atrial rhythm: Paroxysmal supraventricular tachycardia (atrial tachycardia), atrial extrasystole, atrial flutter, atrial fibrillation.
iii. AV nodal rhythm: AV nodal extrasystole, AV nodal tachycardia, AV junctional escape rhythm.
iv. Ventricular rhythm: Ventricular extrasystole, ventricular escape rhythm, ventricular tachycardia, idioventricular tachycardia, ventricular flutter, ventricular fibrillation, torsades-de-pointes, ventricular asystole.

Disturbances of Impulse Conduction

SA block, AV block, WPW syndrome. The bundle branch block (right or left) does not cause any cardiac arrhythmia. So, it is not included in this classification.

MECHANISM OF ARRHYTHMIA (Fact file- I)

At rest in a cell there is potential difference of −70 to −90 mV across the cell membrane. This is known as the resting membrane potential (RMP). It is due to the Na^+-K^+-ATPase pump which brings out 3 Na^+ from the cell and pushes $2K^+$ inside the cell. So, there is high concentration of Na^+ outside of the cell and high concentration of K^+ inside of the cell. In this stage, the fast Na^+ channels are remained closed. But the K^+

FACT FILE- I

Genesis of resting membrane potential

The different distribution of ions across the cell membrane and the different nature of the ion channels on the cell membrane provides the explanation of the resting membrane potential. At resting condition the increased concentration gradient of K^+ inside the cell facilities its exit out of the cell via K^+ channels passively, without any help of a pump. But its electrical gradient is in the opposite direction (inward). Ultimately an equilibrium is reached when the tendency of K^+ to move out of the cell is balanced by its tendency to move into the cell. At that equilibrium, there is slight excess of cations on the outside and anions on the inside which is responsible for resting membrane potential (RMP) varing between –70 to –90 mv. This condition is maintained by Na^+-K^+ATPase pump which pumps three Na^+ out of the cell for every two K^+ pumps in. This pump is of electrogenic as it works against the electromotif force. It should be emphasised that the number of ions responsible for RMP is a minute faction of the total number present and also the total concentration of negative and positive ions are equal every where except along the cell membrane.

channels are remained opened. Therefore, the cell membrane in resting condition is relatively impermeable to Na^+ but permeable to K^+. Thus K^+ can also move passively into the cell by electromotive force other than Na^+-K^+-ATPase pump. When the cell becomes active by an impulse from outside or due to automaticity (explained later) the RMP rises to the threshold level, then the permiability of the cell membrane to Na^+ suddenly increases. This is due to the opening of fast response Na^+ channels and inactivation of Na^+/K^+ ATP are pump. Thus, Na^+ rapidly moves along the concentration gradient from outside into the cell, producing a rapid and complete depolarisation (phase 0). After this rapid and complete depolarisation, there is a short period of repolarisation or phase I. Deactivation of inward Na^+ current and activation of outward K^+ current are responsible for this short period of repolarisation or phase 1. Then, this phase 1 is followed by plateau phase (phase 2) during which complex ionic movement chiefly involving Ca^{2+} takes place. Ca^{2+} channels open during the phase 0. They remain open for 30 to 300 millisecond and account for this plateau phase. In this phase Ca^{2+} enters into the cell and balance the outward K^+ current maintaining the plateau.

After that a more rapid phase of repolarisation (phase 3) occurs. During this phase the slow inward Ca^{2+} current is inactivated and more K^+ channels open causing exit of more K^+ from the cell and restore the transmembrane potential to its resting state. But the nature of ionic (Fig. 17.1) distribution across the cell membrane is opposite to the resting state, i.e. K^+ outside of the cell and Na^+ inside the cell. At the end of this process or phase 3, the Na^+/K^+ ATPase pump is again reactivated and restores the resting ionic balance which have become already opposite during the whole action potential i.e. Na^+ is inside and K^+ is outside of the cell. This is called as phase 4. During this phase the Na^+/K^+ ATPase pump re-establishes the normal baseline concentration gradient of the relevant cations, with two K^+ ions moving into the cell for every three Na^+ ions moving out.

This sequence of events (RMP-depolarisation-repolarisation-RMP) is the pattern for nearly all the myocardial cells. But certain cells, particularly the specialized conducting tissues of the SA and AV node and the His-Purkinje system have the property of automaticity. In them, the RMP in phase 4 constantly drifts upwards until it reaches

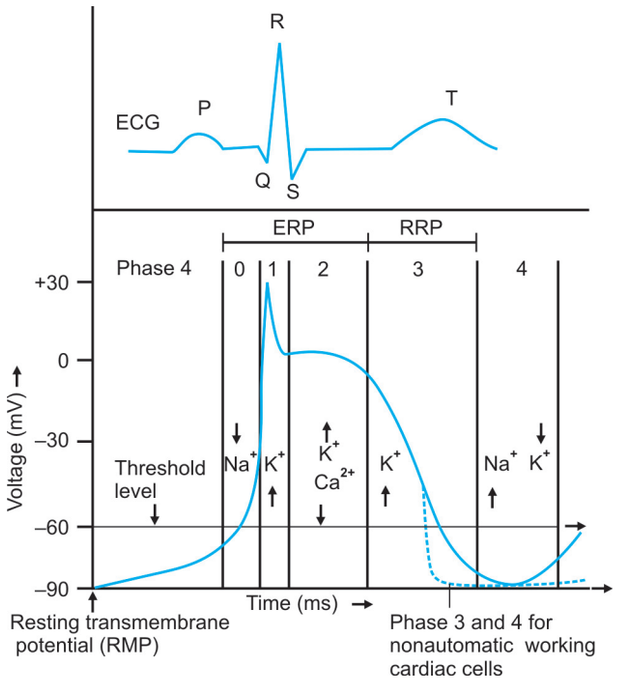

Fig. 17.1: Sequence of action potential of an automatic SA nodal cell (unbroken line) and a nonautomatic ventricular muscle cell (broken line) and its relation with ECG. Phase 4 undergoes spontaneous depolarisation from the RMP (–90 mV) until the threshold potential is reached which is the characteristic of an automatic SA nodal cell or any pace maker cell. Then, depolarisation (phase 0) occurs. Depolarisation of ventricle corresponds to QRS complex of ECG. Depolarisation of atrium corresponds to P wave. Phase 1, 2 and 3 represent repolarisation. Among them phase 3 of ventricular cell corresponds to the T wave on the ECG. The repolarisation of atrium is masked by QRS complex (depolarisation of ventricle) in ECG. The effective refractory period (ERP) is the time during which extra cardiac impulses can not be conducted, whatever may be the intensity of the impulses or stimulus. During the relative refractory period (RRP), a stronger than normal stimulus can initiate an action potential. The action potential of non-automatic working cardiac cells differ from an automatic cardiac cell such as SA node in that phase 4 of nonautomatic cardiac cell does not undergo spontaneous slow depolarisation during diastolic period which correspond with phase 4 of action potential. In the figure downward arrow indicates that the ion enters the cell and upward arrow indicates that, ion exits the cell

a threshold level (usually about −40 to −60 mV). So, the phase 4 of these cells is called the slow diastolic depolarisation phase. When RMP in slow diastolic depolarisation phase drifts to the threshold level, then the Na^+/K^+ ATP are pump is automatically inhibited and the fast response Na^+ channels reopen. This is responsible for the further massive influx of Na^+ ions into the cell and increases the transmembrane potential from −70 to −90 mV (RMP) to +20 mV (depolarisation or phase 0). Thus, again an active electrical and mechanical events of action potential are triggered off. It is thus however important to realize that this threshold level can be raised or lowered by drugs or injury and that automaticity in working cells also may be inhibited or induced by these influences (Table 17.1).

Thus, for cardiac arrhythmias five principle mechanisms have been identified. These are: enhanced automaticity, after depolarisation, re-entry, fractionation of impulse, and conduction block. Among these the first four factors are clubbed under the heading of disturbances of impulse formation and the last factor is put under the heading of disturbances of impulse conduction.

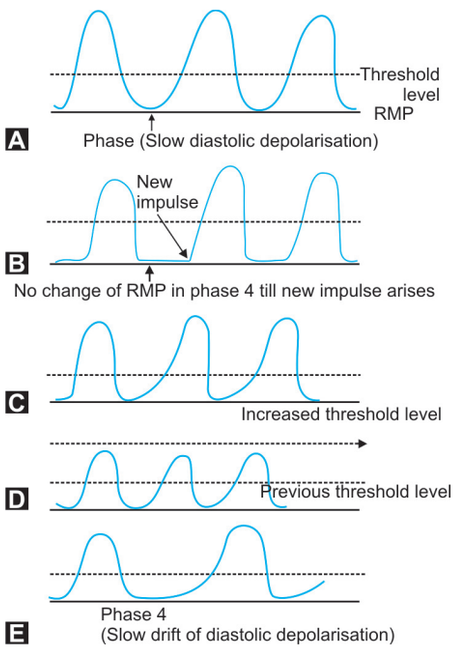
Table 17.1: Factors causing arrhythmias during perioperative period

Hypoxaemia
Hypercarbia
Electrolyte disturbances
Hypokalaemia
Hypomagnesaemia
Acid - base disturbances
Imbalance of autonomic nervous system
Increased stretching of myocardial fibre
Systemic hypertension
Valvular diseases
Congenital heart diseases
Cardiomyopathy
Myocardial ischaemia
Drugs
Catecholamines
Volatile anaesthetics
Coexisting cardiac diseases
Valvular diseases
Hypertrophy
Ventricular pre-excitation (WPW syndrome)
Prolonged QT interval syndrome
Hypo or hyperthermia
Types of surgery
Tracheal intubation

Enhanced Automaticity

The heart has many potential pace making cells and situated in SA node, AV node, bundle of His, Purkinje fibres, and Atria (atrial cells). The the SA node has the fastest inherent spontaneous discharge rate, which usually ranges around 80 beats per minute. The inherent automatic discharge rate of the potential AV nodal and the bundle of His pace making cells is about 60 and 50 beats per minute, respectively. The inherent automatic discharge rate of the Purkinje cells are about 40 beats per minute. Pacing or automaticity of cells is due to (Figs 17.2A to E) the phase 4 slow diastolic depolarisation. Decreasing the time to reach the threshold potential or increasing the slope of phase 4 (slow diastolic depolarisation phase) or elevating the resting membrane potential (i.e. making less negative) leads to enhanced automaticity and is, manifested as an accelerated heart rate. Hypoxia, hypercarbia, hypokalaemia, hyperthermia, mechanical stretching of cardiac muscle, catecholamines, sympathomimetic drugs, etc; increase the slope of phase 4 or decrease the time to reach the threshold potential. Thus, they induce or accelerate the pacemaking or automaticity, producing tachyarrhythmias. Whereas, acetylcholine, hyperkalaemia, hypothermia, etc, cause decrease in the slope of phase 4 or increase the time to reach the threshold potential. Thus, they reduce automaticity and produce bradyarrhythmia.

Hyperpolarisation, i.e. making the resting membrane potential (RMP) more negative also produces bradyarrhythmias. The automaticity also results from the sites that ordinarily lack the spontaneous pace making activity, e.g. ventricular cells. This is due to the ventricular myocardial cell damage by ischaemia causing depolarisation and automaticity. A current thus flows between these depolarized injured fibres and the normally polarised fibres (current of injury) and initiate an automaticity. Thus also arrhythmia results.



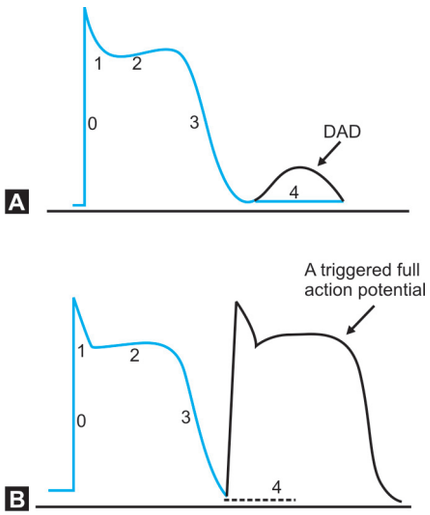
Figs 17.2A to E: The action potentials from different cardiac muscle cells with the property of automaticity (A) and without automaticity (B).
(A) SA node cell. In these cells the resting membrane potential (RMP) is continuously and spontaneously drifting in phase IV towards the threshold level. This explain the electrical basis of automaticity of the SA nodal cells or any pace maker cells.
(B) Normal working myocardial cell. In these cells RMP does not spontaneously drift to the threshold level. For the next depolarisation they wait for impulse coming from outside.
(C) Working myocardial cells damaged by injury. Like SA node, here also the RMP drifts spontaneously due to injury to the threshold level which represents a tendency to automaticity.
(D) Class Ia drugs reduce the peak of rise of the action potential. It also raise the threshold level by inactivation of Na^+ pump. This results in reduced automaticity.
(E) Class Ib drugs produce the same effect by slowing the rate at which the drift of phase 4 takes place, so that it takes longer time to reach the threshold level

After Depolarisation

Under some pathophysiological conditions, a normal cardiac action potential may be followed or interrupted by an sudden abnormal another premature depolarisation. If this abnormal premature depolarisation reaches the threshold level, then it may give rise to a secondary upstroke which then can propagate and create abnormal rhythm. Two major forms of secondary upstroke or after depolarisation are recognised. These are:

(A) Delayed after depolarisation

After an full action potential and attaining the resting membrane potential (RMP) a secondary premature deflection or depolarisation may occur at phase 4 which can reach the threshold level and initiate a single premature action potential. As this premature action potential is needed to trigger the arrhythmias and so this type of arrhythmias are called the 'trigger arrhythmias'. The examples of such trigger arrhythmias are some tachycardias, coupled beats, etc. (Figs 17.3A and B).



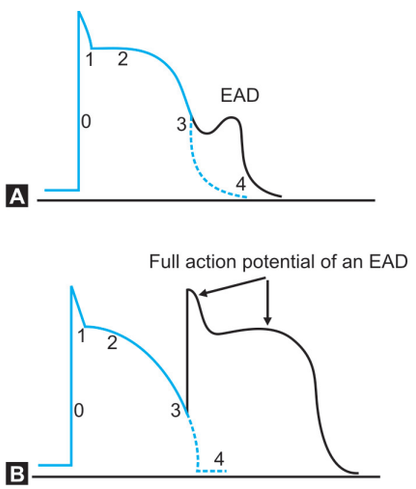
Figs 17.3A and B: A. Delayed after depolarisation (DAD), arising after full repolarisation. A DAD that reaches threshold results in a triggered upstroke and causes a full action potential B

(B) Early after depolarisation (EAD)

Sometimes phase 3 or repolarisation part of action potential is interrupted by an early premature depolarisation and thus the membrane potential oscillates. If the amplitude of oscillation of this membrane potential is sufficient enough, then a series of impulses are propagated and neighbouring (Fig. 17.4A and B) tissues are activated, causing arrhythmia. They are frequently associated with abnormally prolonged action potential such as bradycardia, low extracellular K^+ and certain drugs that prolongs the duration of action potential. When EAD is present, then subsequent sympathetic stimulation (α and β) can increase the likelihood of triggered beats. Again if the cardiac repolarisation is markedly prolonged, then ventricular tachycardia with long QT interval, known as 'torsades-de-pointes' syndrome may occur (Fig. 17.5).

Re-entry

Primarily due to some abnormality in conduction pathway, an impulse which is normally generated may recirculate in the heart muscle and can cause repetitive activation of it without the need for any new impulse to be generated. These are called the re-entry arrhythmias. It has also two mechanism: circus movement and micro re-entry.



Figs 17.4A and B: It shows early after depolarisation (EAD), interrupting the phase 3 part of repolarisation of action potential. Under some conditions EAD can not reach the threshold level and becomes unable to give a full action potential A. But sometimes EAD reaches the threshold level and initiates a full action potential causing arrhythmia B

Circus movement mechanism

When an impulse propagates by more than one pathway between two points of the heart, then part of the impulse may recirculate again and again in the heart muscle, causing repetitive activation of it without the need for any new impulse to be generated. These are called the circus variety of re-entrant arrhythmias. One of the example of this re-entry arrhythmia is WPW syndrome. In WPW syndrome there is an accessory conducting path between the atrium and the ventricle. With each sinus node depolarisation, the impulses can excite the ventricle via the normal structure (AV node) or the

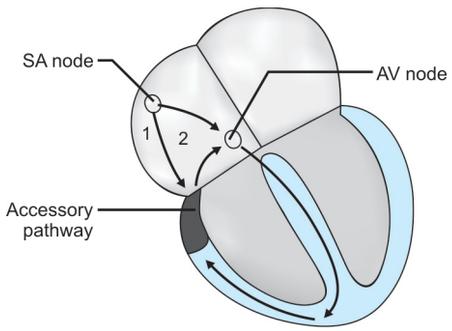


Fig. 17.5: In this patient, an accessory pathway connecting between atrium and ventricle is present and is shown by the black area. This picture explains a retrograde re-entry circuit mechanism of arrhythmia through accessory pathway. A normal or a premature atrial beat (1) cannot pass through the accessory pathway as it is refractory by the previous sinus beat. Thus the atrial beat propagates slowly through the AV node as usual. Then it reaches the accessory pathway through the Purkinje fibres and ventricular wall. Upon reaching the accessory pathway through the ventricular wall which is by now no longer refractory, the impulse re-enters the atrium (2). It then again re-enter the ventricle via the AV node and thus become a self-sustained circuit. AV nodal blocking drugs readily terminate this tachycardia or arrhythmia. Recurrences also can be prevented by drugs that prevent the atrial premature beats or by drugs that alter the electrophysiological characteristics of tissues in the circuit (i.e. they prolong the AV nodal refractoriness) or by nonpharmacological techniques that cut the accessory pathway

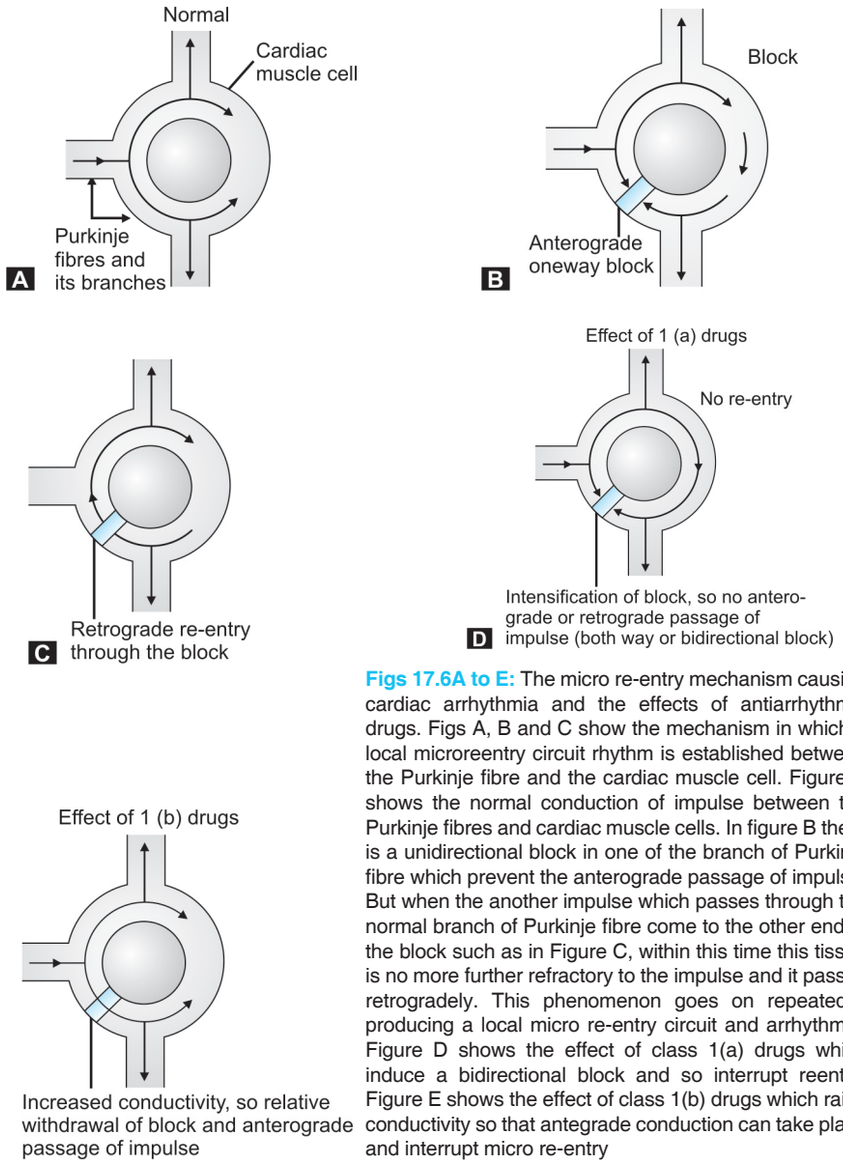
accessory pathway. But, the electrophysiological properties of AV node and the accessory pathways are different. Accessory pathways consist of fast response tissue, whereas AV node is composed of slow response tissue. Thus, with every atrial beat, conduction may fall both in the accessory pathway and the AV node. Then the impulse passing through the accessory pathway depolarise a part of the ventricle first (as it is fast conducting tissue) and produce delta waves. Then it meets the ventricular depolarisation caused by the impulse passing through the AV node and produce total QRS complex. During this period the accessory pathway is no longer refractory. Thus, the impulse which comes through the AV node re-enters the atrium via the accessory pathways and then it can again re-enter the ventricle via the AV node. It then re-enters again the atrium via the accessory pathways and such goes on again and again. Re-entry arrhythmia of this type is therefore, determined by: (i) The presence or absence of an anatomically defined accessory circuit, (ii) Heterogeneity in refractoriness among the regions of these circuits and (iii) the slow conduction in one part of the circuit than the other.

Similarly, an 'anatomically defined' re-entry circuit commonly occurs in the region of the (i) AV node causing AV nodal re-entry tachycardia and (ii) in the atrium causing atrial flutter. This is discussed in more details in chapter 6. The term paroxysmal supraventricular tachycardia (PSVT) includes the both AV re-entry and AV nodal re-entry tachycardia as both of them share the many same clinical features. In some of these cases, it is now possible to identify this re-entry circuit and to ablate the critical portions of this re-entrant pathways. It thus cures the patient nonpharmalogically and obviates the need for long-term drug therapy. This ablation procedure is carried out through a catheter advanced in the interior of the heart and requires minimal convalescence.

Micro re-entry mechanism

It is formed at the junction of Purkinje fibres with the ventricular myocardial fibres. The terminal Purkinje fibres divide into two branches or radicals which communicate directly with the myocardial cells. Usually the conduction of impulse down the each radical of these Purkinje fibres takes place at the same speed. But, if something happens and slow or unidirectionally block of conduction in one of the radical occurs, then the impulse reaches the myocardium by the second remaining radical. Then the impulse may reach from the myocardial cell to the blocked radical. In this circumstance, the retrograde conduction through blocked segment as the block is unidirectional is occured and the impulse crosses the block. Then the impulse passes again through the undamaged or unblocked radical (which is now nonrefractory) back to reach the myocardial cell, and again to the blocked radical. Thus, a self creating micro re-entry circuit is set-up, causing arrhythmia. The examples of this micro re-entry mechanism are ventricular ectopic, VT, VF, etc. (Figs 17.6A to E).



Figs 17.6A to E: The micro re-entry mechanism causing cardiac arrhythmia and the effects of antiarrhythmic drugs. Figs A, B and C show the mechanism in which a local microreentry circuit rhythm is established between the Purkinje fibre and the cardiac muscle cell. Figure A shows the normal conduction of impulse between the Purkinje fibres and cardiac muscle cells. In figure B there is a unidirectional block in one of the branch of Purkinje fibre which prevent the anterograde passage of impulse. But when the another impulse which passes through the normal branch of Purkinje fibre come to the other end of the block such as in Figure C, within this time this tissue is no more further refractory to the impulse and it passes retrogradely. This phenomenon goes on repeatedly, producing a local micro re-entry circuit and arrhythmia. Figure D shows the effect of class 1(a) drugs which induce a bidirectional block and so interrupt reentry. Figure E shows the effect of class 1(b) drugs which raise conductivity so that antegrade conduction can take place and interrupt micro re-entry

There is another re-entry mechanism which is called the functionally defined re-entry mechanism. This can happen in the absence of any anatomically distinct accessory pathway or certain block like micro re-entry mechanism. The example of this mechanism is VT in MI. Here the ischemic area is divided into two parts such as rapid longitudinal and the slow transverse segment which are electrophysiologically different. These two parts also have the different refractory period. Thus, the formation of these two different refractory areas results in alternate cyclical changes of refractoriness which allow the impulse to circulate repeatedly, among these two types of tissues with different refractory period causing arrhythmias.

Fractionation of Impulse

When the effective refractory period (ERP) of atrial or ventricular muscular fibre is brief and inhamogeneous, then a generated impulse is conducted irregularly over the atrium or ventricle. It means the impulse moves rapidly through the fibres with short ERP (which have recovered completely) or slowly through the fibres with long ERP (which have recovered partially) or does not move at all through the still refractory fibres. Thus an asynchronous activation of atrial or ventricular fibres occur, causing arrhythmia.

Conduction Block

Different types of block in the SA node and AV node, but not the bundle of His and Purkinje fibres, can also cause arrhythmia.

DRUGS USED IN THE TREATMENT OF CARDIAC ARRHYTHMIAS (Fig. 17.7)

Drugs used in the treatment of cardiac arrhythmias are mainly grouped under two headings. These are: (i) Drugs used to treat disturbances in impulse formation and (ii) Drugs used to treat disturbances in impulse conduction.

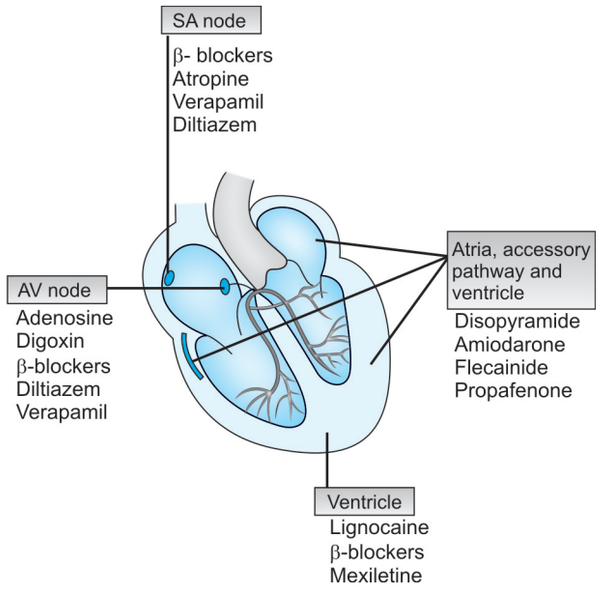


Fig. 17.7: Classification of anti-arrhythmic drugs by their site of action

A. Drugs Used to Treat Disturbances in Impulse Formation

Antiarrhythmic drugs used to treat disturbances in impulse formation act by different ways. These are by blocking : (i) different ionic channels (Na^+, K^+, Ca^{2+}), (ii) different receptors and (iii) different pumps. There are many classifications of antiarrhythmic drugs, but no one is satisfactory. Till now only the useful classification of antiarrhythmic drugs is William's classification. However, this classification also has a number of limitations in practice. This is because (i) many drugs have more than one mechanism of action, (ii) there is considerable variations in mechanism of actions of drugs in the same class and (iii) the distinct similarities between the drugs of supposedly different classes.

So, an alternative new classification of antiarrhythmic drugs such as 'Sicilian gambit' was introduced in 1990. Unlike William's classification which is purely based on the electrophysiological characteristic of the mechanism of action of drugs, this new approach is actually a gambit as in chess, rather than a finalized structure. It is based on the consideration of three factors which influences the antiarrhythmic (Table 17.2) effects of various drugs. These three factors are: (i) The molecular targets on which the drug acts, (ii) the mechanism of action, responsible for antiarrhythmic property of this agent and (iii) The clinical considerations.

However, this classification is a more complex and less easy to memorise than William's classification. But, it has the advantage of allowing better visualisation of some complex effects of newer drugs, which is unhindered by the constrants, imposed by the purely electrophysiological basis of earlier classification.

Arrhythmogenic Potentiality of Antiarrhythmic drugs

Most antiarrhythmic agents which are used clinically may themselves precipitate serious arrhythmias. Two multicentric trials have shown that the post MI patients, randomised to receive encainide, flecainide, moricizine and other antiarrhythmatic agents on a long-term basis, had higher incidence of sudden death, though initially

the same drugs had suppressed ventricular extra systole in these patients. It is possibly due to the marked intraventricular conduction slowing action of these drugs, resulting in VT and VF. It is, therefore not prudent to try and supress all the extrasystoles or arrhythmias with the drugs perioperatively (Table 17.3).

Class I : Membrane Stabilising Drugs

Drugs in this class are known as the membrane stabilisers. So, they act by blocking the fast Na^+ channels, across the cell membrane at 0 phase of action potential like local anaesthetic agents. Thus, they interfere with the onset of depolarisation and decrease the responsiveness to excitation. They also reduce the rate of phase IV slow diastolic depolarisation in automatic or pacemaker cells. There are pharmacologically diverse group of drugs in this class (Class I) which have been subclassified into IA, IB and IC. However, the primary antiarrhythmic effect of all these drugs is related to their effect on decreasing the maximum rate of voltage change during phase 0 of action potential. A number of other mechanisms may also be involved in this group of drugs, such as abolishing the re-entry currents.

Table 17.3: The 'Sicilian gambit' table

Drug	*William class*	*Channels*			*Receptors*				*Pump*
		Na^+	*K^+*	*Ca^{2+}*	α	β	*M_2*	*A_1*	*Na^+/K^+ ATPase*
Quinidine	1A	A	•		•		•		
Procainamide	1A	A	•						
Disopyramide	1A	A	•				•		
Lignocaine	1B	•							
Mexiletine	1B	•							
Tocainide	1B	•							
Propafenone	1C	A				•			
Flecainide	1C	A	•						
Propranolol	II	•				•			
Bretylium	III		•		PAG	PAG			
Amiodarone	III	I	•	•	•	•			
Verapamil	IV	•		•	•				
Diltiazem	IV								
Adenosine								AG	
Digoxin							AG		•
Atropine							•		

This is a new classification of anti-arrhythmic drugs. It is based on the activities of the membrane channels, receptors and pumps. This classification also offers a different perspective of the William's classification which only considers the electrophysiological effects

• High
• Medium
• Low

I - Inactivated state blockers
A - Activated state blocker
AG - Agonist, PAG - Partial agonist

Subclass IA

They are open state Na^+ channel blockers with moderate delay in channel recovery. Hence, they supress the A-V conduction and prolong the P-R, QRS, and QT interval and APD (action potential duration). The following drugs fall in this group.

Table 17.2: William's Classification

Class I	*Membrane stabilising drugs (fast Na^+ channel blockers)*
IA	Quinidine, procainamide and disopyramide. They block Na^+ channel and prolong action potential.
IB	Lignocaine and mexiletine. They block Na^+ channel and shorten the duration of action potential.
IC	Flecainide, encainide and propafenone. They block Na^+ channel with no effect on action potential.
Class II	β–adrenoreceptor antagonist, i.e. propranolol, metoprolol, esmolol, etc.
Class III	Drugs which increase the duration of action potential and the refractory period (antifibrillatory drugs), e.g. amiodarone, bretylium.
Class IV	Calcium channel blockers, e.q. verapamil, diltiazem, etc.
Others	Cardiac glycosides, Adenosine, Dofetilide, Ibutilide, Propafenone, etc.
For AV blocks	Anticholinergic - Atropine Sympathomimetics - Isoprenaline, etc.

NB: Some drugs have properties of more than one class. For example, amiodarone has actions of all four classes.

Quinidine

Chemically, it is a dextroisomer of quinine and an alkaloid which is available from cinchona bark. A dutch merchant had first noticed the beneficial effect of cinchona bark on irregular pulse, taken during malaria. Then, he demonstrated this to British cardiologist, Wenckebach in 1912 and subsequently quinidine was synthesized.

It reduces the rate of depolarisation or phase 0 of action potential and its overshoot, i.e. it decreases the membrane responsiveness. Thus, it depresses the cardiac excitability by (i) raising the threshold potential level, (ii) prolonging the duration of action potential and (iii) prolonging the effective refractory period (ERP) of His-Purkinje cells. Thus, it slows the intra-atrial, AV and intraventricular conduction of impulses. It extinguishes the extra systole and is

important in the prophylaxis of re-entrant arrhythmias. Quinidine has little effect on 'after depolarisation'. SA nodal automaticity is little affected by quinidine at therapeutic concentration. As ERP is prolonged, so tissue remains refractory even after the full repolarisation. The QT interval in the ECG is prolonged by quinidine. Therefore, the monitoring by ECG may provide a useful guide to the dosage of it. Prolongation of the QT interval with quinidine therapy may also has been associated with severe tachyarrhythmias.

The quinidine has anticholinergic effects. The cardiac anticholinergic effects include an increase in sinus rate. It has a variable effect on AV nodal conduction which may be depressed or enhanced, depending on the balance between the direct depression and the anticholinergic enhancement (Table 17.4).

Then anticholinergic effects of quinidine is also responsible for variety of non-cardiac effects. These are gastrointestinal irritation, nausea, vomiting, tinnitus and visual disturbances which are found in mild overdosage. Whereas, severe CNS symptoms such as confusions and psychosis may occur with major over dosage.

Table 17.4: Principles of use of anti-arrhythmic drugs

The drugs used to treat different cardiac arrhythmias are potentially toxic. So, they should be used carefully according to the following principles.

1. Many arrhythmias are benign and do not produce any haemodynamic instability. So, they do not require specific treatment and only need observation.
2. Always precipitating or causal factors for arrhythmia should be searched and corrected first, if possible. These may include: myocardial ischaemia, drug effect, hyperthyroidism, acidosis, hypokalaemia, hypo magnesaemia, excess alcohol or caffeine consumption, etc.
3. If the drug therapy is required at all, it is best to use as few drugs as possible.
4. In difficult cases, electrophysiological study may help to identify the optimum therapy.
5. Patients on long-term anti-arrhythmic drugs should be reviewed regularly. Always attempts should be made to withdraw the therapy, if the factors which precipitate the arrhythmias are no longer operative.
6. Non-pharmacological anti-arrhythmic therapy such as pacing or radiofrequency ablation of accessory path are often preferred to long-term drug therapy.

Mechanism of Action

Quinidine blocks the myocardial fast Na^+ channel in the open state. Thus, it reduces the automaticity by decreasing the maximal rate of depolarisation or phase of action potential. Some prolongations of AP by quinidine is also due to the K^+ channel blocking action. Lengthening of ERP by quinidine is due to the effect of it on the recovery of Na^+ and K^+ channels. As quinidine has some α-adrenergic blocking properties at higher doses, so it also directly dilates the blood vessels and causes the fall of BP.

Uses

Quinidine has been used to treat the atrial and ventricular arrhythmias, but is not in common use today. It is usually administered orally, because of the adverse haemodynamic consequences on parenteral use. Absorption from GI tract of quinidine is rapid and effective. Presently, quinidine is used only for maintenance and prophylaxis purposes, after AF and AFL which has been terminated by DC shock or by other measures. Recently, it is also used to prevent the recurrences of VT.
Dose: 200 to 400 mg TDS orally.

Procainamide

It is the amide derivative of local anaesthetic agent named procaine. Procaine was also found to have antiarrhythmic activity, but is not suitable clinically due to the rapid hydrolysis and marked CNS effects of it. So, in 1951, procainamide (analogue of procaine) was developed and had circumvented some of the limitations of procaine.

Like quinidine, it also decreases the rate of rise of depolarisation during phase 0 and phase IV of action potential. However, less prolongation of QT interval than quinidine is observed by procainamide. Procainamide also has the anticholinergic effect, but is less marked than quinidine. It has no α-blocking activity, so there is no fall of BP. It is better tolerated than quinidine when given intravenously.

Uses

It is orally active and is an alternative drug to quinidine, having the same spectrum of efficacy. Some patients not responding to others antiarrhythmic agent may respond to procainamide. Procainamide is more likely to increase the ventricular rate in patient with atrial fibrillation than quinidine. Thus, it is not used in the treatment of atrial fibrillation (AF) and flutter (AFL) like quinidine. Therefore, its use is usually confined to the treatment of ventricular extrasystole. In this respect it is usually used as a second line of drug after lignocaine and may be used for the treatment of multiple ventricular extrasystole, R on T phenomenon and ventricular tachycardia.

Initially, procainamide is used as IV loading dose and later with maintenance by intravenous infusions during the acute therapy of many supraventricular (except AF and AFL) and ventricular arrhythmias. But, long-term oral treatment by procainamide is often stopped, because of the many adverse effects.

Doses

For abolition of arrhythmia procainamide in the dose of 0.5 to 1 gm orally or IM is started fast. This is followed by 0.25 to 0.5 gm orally at every 2 hours interval. It can reduce the antimicrobial effect of sulfonamides, probably by generating PABA. Hypotension and marked slowing of conduction are the major adverse effects of procainamide at high concentration, especially during IV use.

Disopyramide

Like quinidine, it is also the drug of class Ia and has prominent cardiac depressant

and anticholinergic effects (which account for many of its adverse effects). It has no α-adrenergic blocking property. Disopyramide usually has no effect on sinus rate, because of opposing both the direct depressant and antivagal actions on SA node. It is used to treat both the supraventricular (atrial flutter and fibrillation) and ventricular arrhythmias (ventricular tachycardia and flutter). It may also cause atypical VT with prolongations of QT interval. Disopyramide may also be effective in slowing conduction through the accessory pathway in patient with WPW syndrome. It has marked negative inotropic effect on heart.

The anticholinergic effects of disopyramide include precipitation of glaucoma, constipation, dry mouth and urinary retention. The later is more common in males. Sometimes the negative inotropic effects of disopyramide may precipitate heart failure. It can also cause torsades-de-pointes.

It is orally active and is better tolerated than quinidine. The primary indication of use of disopyramide is the prevention of recurrences of ventricular arrhythmias. It may be better tolerated as the maintenance agent after cardioversion of atrial flutter and fibrillation.

Subclass IB

These group of drugs block Na^+ channels in both the activated and inactivated states, but do not delay the recovery of channel. They do not depress the A-V conduction. Also they do not prolong the duration of action potential (APD), effective refractory period (ERP) and Q-T interval. Class Ib group of drugs have virtually no autonomic effects. By these group of drugs the rate of rapid depolarisation or phase 0 of action and the slope of slow depolarisation in phase 4 is decreased in Purkinje fibres (PF).

Lignocaine

It is the most commonly used local anaesthetic agent and is also the most popular antiarrhythmic agent in ICU.

Lignocaine blocks both the open and inactivated cardiac Na^+ channels, but the recovery from this block is very rapid. So, it exerts greater effects on the depolarized (ischaemic) tissues. It is not useful in atrial arrhythmias. This is possibly because the atrial action potentials are so short that the Na^+ channel remains in an inactivated state only for a brief period as compared to the diastolic (recovery) times, which are relatively long.

The most prominent cardiac action of lignocaine is the suppression of automaticity of ventricular ectopic foci, but the SA nodal automaticity is not depressed. It has, practically, no effect on APD and ERP of atrial fibres. Atrial re-entry is also not affected. So, lignocaine is ineffective in treating the supraventricular arrhythmias. However, it can suppress the re-entry mechanism responsible for ventricular arrhythmias either by abolishing the one way block or by producing two way block. It also increases the threshold for ventricular fibrillation. So, lignocaine is used in the treatment of all forms of ventricular arrhythmias. The normal ventricular muscle fibres and conducting tissues are minimally affected, while depolarised or damaged fibres are significantly affected. This is due to the higher preferential distribution of lignocaine within the ventricular myocardium which has been shown to be damaged than the normal healthy ventricular myocardium and the concentration of lignocaine within the ischaemic arrhythmic areas of myocardium is the relevant factor for determining its efficacy. Lignocaine acts preferentially on the ischaemic myocardium and is more effective in the presence of high extracellular K^+ concentration. Thus, hypokalaemia must be corrected before the use of any class Ib drugs, other than phenytoin.

Lignocaine has minimal effect on normal ECG. It has no significant effect on PR interval or QRS duration. It causes little depression of cardiac contractility and no reduction of BP. There are no significant actions of lignocaine on autonomic nervous system. So, all the cardiac effects of lignocaine are due to the direct actions of it on the myocardial cells.

Lignocaine is well absorbed orally. But, because of his high first-pass metabolism in liver, adequate and constant blood levels of lignocaine are not attained by this route. So, it is not used orally. Actions of lignocane by IV bolus dose lasts only for 10 to 20 minutes. This is because of rapid redistribution of it in the tissues. On the other hand, therapeutic plasma concentration of lignocaine lies within the range of 1.5 to 5 µg/ml and plasma concentration above 9 µg/ml are likely to produce toxic effects. So, the normally accepted therapeutic scheme to maintain the desired therapeutic plasma level of lignocaine requires a loading IV dose of 1 to 1.5 mg/kg which is followed by an infusion of 150 µg/kg/min for 20 minutes and finally is maintained by infusion at the rate of 3 µg/Kg/min.

When rapidly large doses of lignocaine is administered intravenously, then seizures may occur. But during maintenance therapy, when the plasma concentration of drug rises slowly above the therapeutic level, then tremor, dysarthria, altered level of consciousness is occurred. Hence, it proves that the main toxicity of lignocaine is its dose dependent neurological effects. Other neurological symptoms of lignocaine are drowsiness, nausea, twitching, tinnitus, disorientation, nystagmus, etc. Only excessive dose of lignocaine causes cardiac depression and hypotension.

As it is ineffective in atrial arrhythmias, so lignocaine is used only in ventricular arrhythmias. It is also said that because of rapidly developing and titratable action, it is a good drug in the emergency setting like ventricular arrhythmias following acute MI, cardiac surgery and other acute conditions. Given prophylactically by infusion in acute MI, it also reduces the occurrence of ventricular fibrillation. However, a recent meta-analysis has shown that

prophylactic lignocaine fails to improve survival rate and may even increase the short term mortality. Therefore, it is no longer administered routinely to all the MI patients. This increased mortality may be due to the lignocaine induced exacerbated heart block or CHF.

Mexiletine

Chemically, it is a lignocaine analogue. So, like lignocaine, mexiletine is a local anaesthetic and an active antiarrhythmic agent. But, unlike lignocaine it is active orally. This is because the structure of mexiletine and tocainide which is also analogue to lignocaine are modified to reduce the first pass hepatic metabolism and to make them effective for oral therapy.

Pharmacologically, mexiletine is also similar to lignocaine. It increases the threshold voltage, reduces the rate of 'phase 0' of action potential or depolarisation and decrease the 'phase 4' slope. Thus, it converts the one way block to two way block. But, it has little effect on the heart rate, BP and ventricular function.

Mexiletine is almost completely absorbed orally. The incidence of adverse effects of mexiletine is relatively high than lignocaine. These adverse effects are bradycardia, hypotension, A-V block, etc.

Doses

Mexiletine is used orally as the loading dose of 400 to 600 mg stat and which is then followed by 150 to 200 mg thrice daily. Parenterally, it is used in the dose of 100 to 200 mg IV over 10 minutes, which is then followed by 1 mg/min through infusion. Parenteral mexiletine is effective in postinfarction ventricular arrhythmias, as alternative to lignocaine in resistant cases. Orally, it is used to keep the ventricular extra systole and ventricular tachycardia supressed over long duration.

Tocainide

Like mexiletine tocainide is also a lignocaine analogue and is active both orally and parenterally. It may be effective against severe ventricular arrhythmias which is refractory to other class I antiarrhythmic drugs. But, tocainide is rarely used now, because of the risk of severe agranulocytosis, thrombocytopenia (due to potentially fatal bone marrow depression) and pulmonary fibrosis.

Phenytoin and Dilantin

These are mainly antiepileptic drugs and are used very infrequently in cardiac arrhythmias. So, they are not discussed in details here.

Subclass IC

Class IC antiarrhythmic drugs are highly effective and are the most potent Na^+ channel blockers. It suppresses the 'phase 0' activity of action potential and causes a marked reduction in conduction velocity. It also prolongs the P-R interval and broadens the QRS complex. They have profound effect on HIS-Purkinje system and accessory pathways for conduction. They markedly retard the anterograde and as well as the retrograde conduction through accessory pathway in WPW syndrome.

However, recently it is discovered that this subclass of antiarrhythmic drugs have the ability to be proarrhythmic. Proarrhythmia is a phenomenon which is identified as the development of new arrhythmias or exacerbation of a pre-existing arrhythmias in response to treatment with an antiarrhythmic drug. Both the flecainide and encainide of the subclass IC drugs have been specifically implicated as proarrhythmic agent and sudden deaths occur. The precise mechanism for proarrhythmogenesis by this group of drugs is not fully understood, but it may be due to the decreased conduction in abnormal areas of myocardium which favour a re-entry mechanism.

Flecainide

Flecainide blocks the Na^+ current and delayed the rectifier K^+ current (IKr). It suppresses the 0 phase activity and increases the duration of action potential. Thus, it supresses the ventricular extra systole (VES), VT, WPW syndrome and prevent the recurrence of AF and PSVT. In recent study, it was found to increase the mortality in patient recovering from M1 and so has been withdrawn from the market in many countries. But in UK, still it is licensed for the treatment of AF and ventricular arrhythmias which are unresponsive to other therapy and in whom the structural heart disease is absent.

Encainide, a drug with very similar electrophysiological actions like flecainide, is no longer used and available.

Propafenone

It is a mainly Na^+ channel blocker. But, like flecainide it also blocks the K^+ channels. It also prolongs the PR and QRS interval, but its major action is to slow the conduction in fast response tissue. Propafenone is mainly used orally to maintain the sinus rhythm in patient with supraventricular tachycardia and atrial fibrillation. In ventricular arrhythmias it is modestly effective.

The adverse effects of propafenone therapy include increased ventricular response in patient with atrial fibrillation, increased frequency and/or severity of re-entrant VT and exacerbation of heart failure. It has β-adrenergic blocking effect and causes sinus bradycardia and bronchospasm.

Propafenone undergoes extensive first pass hepatic metabolism. It produces a metabolite, named 5-hydroxy propafenone which is equipotent like its mother compound as a Na^+ channel blocker, but is much less potent as a β-adrenergic receptor antagonist.

Class II - β - Adrenoreceptor Antagonist

The primary action of drugs in this class is to suppress the adrenergic induced automaticity by their specific membrane stabilising effect like local anaesthetic agents

which is mediated through the fast Na^+ channels blocking action.

The electrophysiological effects of β-adrenoreceptor antagonists are:

i. Decrease in automaticity.
ii. Increase in the duration of action potential, especially in ventricular conducting tissues.
iii. Increase in the effective refractory period in the AV node.

The latter effect is the most important for the antiarrhythmic effect of β-adrenoreceptor antagonists. Automaticity is decreased in both the SA node and AV junctional tissues. There is potent inhibition of catecholamine induced tachycardia and arrhythmia by this class of drugs.

In the clinically used dose range, antiarrhythmic action of this class of drug is exerted primarily through their β-adrenergic blockade. Only in very high doses, antiarrhythmic action of this group of drug is exerted by their membrane stabilizing property through fast Na^+ channel blocking action. Automaticity is decreased by this class of drug when it is due to the adrenergic influence, otherwise there is little or no action.

The most important ECG changes by the effect of this group of drug is the prolongation of PR interval. Depression of cardiac contractility and hypotension is less marked.

Individual drug in this class such as propranolol, metoprolol, esmolol, etc, are discussed elsewhere.

Class III

The characteristic actions of this group of drugs in class are: prolongation of repolarisation, widening of action potential, and increase in the effective refractory period (ERP). Tissue remains refractory even after full repolarisation. So, re-entrant arrhythmias would also be terminated. Drugs in this class are bretylium and amiodarone.

Bretylium

Bretylium tosylate is a quaternary ammonium compound. After IV injection, it produces biphasic response. Initially, it displaces or releases noradrenaline from the adrenergic nerve terminals and produces transient sympathomimetic effects. As a result initially, bretylium can produce transient hypertension and increased arrhythmias. But, this effect is rarely observed. Later, it produces adrenergic blockade and hypotension. The major direct action of bretylium is prolongation of AP and ERP and this is probably due to the action of K^+ channel blockade. It is not a Na^+ channel blocker and does not depress the automaticity. In theory, bretylium should be avoided in patients who are especially prone to the increased arrhythmias with norepinephrine release. In contrast, hypotension due to inhibition of noradrenaline reuptake is a common problem during bretylium therapy. Bretylium induced hypotension should be managed with judicious fluid replacement, but not by catecholamines. Since, bretylium effectively causes the sympathetic denervation, so the administration of normal doses of catecholamine such as dopamine may cause marked hypertension.

Oral absorption of bretylium is very poor. So, it is always used through IV route. It is excreted unchanged in urine.

Bretylium is mainly used in the treatment of VT and VF which is refractory to lignocaine and/or defibrillation. The first intravenous loading dose of bretylium is 5 to 10 mg/kg which is given over 10 minutes. Then, it is repeated up to a total dose of 30 mg/kg. The onset of action of bretylium is very slow. So, resuscitative measure for VT and VF should be continued for 20 to 30 minutes after administration of bretylium. An infusion of bretylium in the dose of 2 mg/min is used for maintenance of its action.

The efficacy of bretylium in the treatment of acute ventricular arrhythmia is still controversial, because of its slow onset of action. But, it is still regarded as a second line of drug after lignocaine for the treatment of VT and VF.

Amiodarone

Chemically, amiodarone hydrochloride is a di-iodinated benzofuran derivative and is a highly lipophilic agent. It is a long acting antiarrhythmic drug and is a structural analog to thyroid hormone. So, some of the antiarrhythmic actions and toxicity of amiodarone may be due to the interaction of it with thyroid hormone receptors. As amiodarone is highly lipophilic, so it is concentrated mainly in the fat containing tissues and is eliminated very slowly. Hence, the adverse effects of it may be very slow to resolve.

Amiodarone exerts multiple actions. It has been suggested that the amiodarone's main effects are mediated by the perturbation of lipid milieu of cell membrane in which all the ion channels are situated. On the otherhand, amiodarone is a potent inhibitor of abnormal automaticity and in most tissues it prolongs the APD and ERP.

The mechanism of actions of amiodarone are:

i. Block K^+ channels - prolong APD and ERP
ii. Block Na^+ channels - lignocaine like action - conduction is slowed and automaticity is depressed.
iii. Block Ca^+ channel and β-adrenergic blocking property.
iv. Also acts by partial antagonism of alpha and beta agonists by reducing the number of receptors and by inhibiting the coupling of agonists with receptors.

The SA node is depressed by amiodarone. So, sinus rhythm is slowed by 15%. It is secondary to the reduction of slow diastolic depolarisation in SA nodal cells by amiodarone. AV nodal automaticity is also depressed and AV nodal conduction is also slowed by 25% in the face of atrial tachycardia by amiodarone. It is due to the decreased speed of depolarisation of cells and increase in the duration of action potential. Amiodarone has no effect on the conduction through bundle of His, and Purkinje fibres and the ventricular myocardium. It has little effect on the blood

pressure and left ventricular contractility. The SVR is decreased and coronary blood flow is increased by it.

The SA node is affected slightly by amiodarone. The effect of oral dose of amiodarone on cardiac contractility and BP is minimal. But IV injection of it frequently causes myocardial depression and hypotension. There are clear differences in electrophysiological study when the drug is given IV and in chronic oral therapy. Following IV administration, the ERP is prolonged particularly in conducting and ventricular muscle tissue, but there is no prolongation of QTc interval. By contrast, during chronic oral therapy the refractory period is prolonged, chiefly in AV nodal tissue with the prolongation of QTc interval.

Amiodarone is now widely used to treat the supraventricular arrhythmias, pre-excitation syndrome such as the WPW syndrome and ventricular arrhythmias including VT, VF, etc. Its long duration of action makes it suitable for long term prophylactic use, but close monitoring is required.

Amiodarone is incompletely and slowly absorbed from the GI tract. So, by daily oral ingestion the action develops slowly over several days and weeks. But, on IV injection the action develops rapidly. Amiodarone has very poor and variable bioavailability (20 to 80%). It undergoes extensive enterohepatic circulation before entry into the central compartment, from where it undergoes extensive tissue distribution. This is due to the exceptionally high tissue/plasma partition coefficient of amiodarone. Its distribution half-life from the central to peripheral compartment may be as short as 4 hours. But, its terminal half-life is both long and variable (9 to 77 days). This is due to the result of slow mobilization of this highly lipophilic drug out of the adipose tissue. The main metabolites of amiodarone is mono-N-desethylamiodarone which also exerts antiarrhythmic effects and has a long terminal half-life.

Amiodarone is mainly used orally in the dose of 400 to 600 mg/day for few weeks and this is followed by 100 to 200 mg OD for maintenance therapy. In IV route 100 to 300 mg of amiodarone is given slowly over 30 to 60 minutes. For clinical action a therapeutic plasma amiodarone concentration in the range of 0.5 to 2 μg/ml has been suggested. However, the efficacy appears to depend as much as on the duration of therapy and on the plasma concentration of it. But the elevated plasma concentration are not useful in predicting toxicity. As because amiodarone accumulates in tissue, so initially a high oral loading dose is usually administered for several weeks and then maintenance dose is started. Maintenance dose is adjusted on the basis of adverse effects and the response of arrhythmias for which it is used. If the presenting arrhythmia is life-threatening, then the higher dose of amiodarone which is > 300 mg/day are also used, unless clear toxicity occurs. On the other hand, maintenance dose of amiodarone which is < 200 mg/day are used, if recurrence of arrhythmia is tolerated.

Amiodarone treatment may result in supratherapeutic level of iodine in plasma, which may result in either hyper or hypothyroidism. This is because amiodarone is a potent inhibitor of T_4 and thus it inhibits the peripheral change of T_4 to T_3, causing a dose and duration dependent increase in serum reverse T_3. This may account for many of the actions of amiodarone which are similar to those seen after thyroid ablation.

Amiodarone increases the concentration of serum transaminases, indicating hepatic damage secondary to phospholipidosis. A similar mechanism is also believed to account for the alveolitis (pulmonary fibrosis) which occur in about 5 to 7% of patients receiving amiodarone. This alveolitis (pulmonary fibrosis) produced by amiodarone may be insidious in onset and may present with cough, dyspnoea and diffuse pulmonary infiltration. It may occur acutely, especially after surgery in patients receiving high dose of IV amiodarone and may present as a postoperative adult respiratory distress syndrome.

Almost all patients receiving amiodarone develop corneal microdeposits and one third develop signs of CNS toxicity. Peripheral neuropathy, photosensitivity and GI upsets are also well-recognised complications of amiodarone. Hypotension, cardiovascular collapse and AV block have been reported after IV injection of it. Other dysarrhythmias may arise, especially in the presence of hypokalaemia due to the use of amiodarone.

Serious and prolonged hypotension has been described in patient who are pretreated with amiodarone alone or in combination with ACE inhibitor during anaesthesia. It is due to the decrease in systemic vascular resistance (due to vasodilation and myocardial depression) caused by chronic amiodarone therapy and is enhanced by the effects of ACE inhibitor. This exaggerated hypotensive effect produced by the combination of action of amiodarone and ACE inhibitor in mainly unmasked during the blood loss in surgery. Hypotension described in these cases is resistant to α-adrenoreceptor agonists such as metaraminol or phenylephrine and require high infusion rates of noradrenaline to maintain adequate arterial pressure. Hypotension associated with intravenous form of amiodarone is also partially due to the action of solvent which is used in its preparation.

Bradycardia and complete heart block which is resistant to atropine, adrenaline and noradrenaline also have been reported in patients who are receiving amiodarone and undergoing GA. So, it has been suggested that such patients may require temporary pacing in the perioperative period. The drug is contraindicated in porphyria.

Class IV: Calcium Channel Blockers

Calcium antagonists inhibit the inward flow of Ca^{2+} ions into the cell which

usually occurs during the mid and late phase (i.e late phase of 0, phase 1 and predominantly phase 2) of action potential.

The classification of Ca^{2+} channel antagonists recognises three subclasses. These are:

i. Papaverine derivatives (verapamil).
ii. Dihydropyridines derivatives (nifedipine, nicardipine, isradipine, felodipine, nimodipine).
iii. Benzothiazepines derivatives (diltiazem).

All the drugs in each subclass of calcium channel blocker have some specific activity on cardiac conducting tissue, cardiac muscle cells, and vascular smooth muscles. But, the dihydropyridine derivatives (nifedipine) and benzo thiazepine derivative (diltiazem) have some special activity profiles which render them ineffective as antiarrhythmic agents. So, only the verapamil is used clinically as antiarrhythmic agent. The comparisons of electrophysiological actions of these three subclass of main calcium channel blockers are shown in Table 17.5.

Verapamil

Of the many Ca^{2+} channel blockers, verapamil has the most prominant antiarrhythmic action. It predominantly acts on the SA and AV node as these tissues are mainly calcium dependent for their actions during the both phase 0 and phase 4 of action potential. It causes the competitive blockade of slow calcium ion channels of cell membrane leading to decreased influx of Ca^{+} into the cell. So, the rate of discharge in the SA node is reduced and the recovery is prolonged by verapamil. The AV nodal conduction is also strongly inhibited and the ERP is prolonged by it. Because of the powerful AV blocking effect, some drugs such as β-adrenoreceptor antagonist and halothane should be used very cautiously in patient receiving verapamil during anaesthesia (Table 17.5).

Verapamil is absolutely contraindicated in patient with digoxin toxicity. It also causes decrease in influx of Ca^{2+} into the vascular smooth muscle and myocardial cells. This results in inhibition of contraction and relaxation of cardiac and vascular smooth muscle fibres, leading to coronary and systemic arterial vasodilatation. So, the drug causes a decrease in the SVR and is a potent coronary artery vasodilator. Therefore, verapamil is used in the management of mild to moderate type of hypertension and angina.

Verapamil is mainly used in the treatment of supraventricular arrhythmias such as PSVT, AF, AFL, etc. By the effects of reduction of AV conduction, it also reduces the ventricular rate in atrial flutter and atrial fibrillation like digoxin. But the rapid action of verapamil makes it preferrable than digoxin in acute management of atrial flutter and atrial fibrillation or other causes of supraventricular tachycardia to reduce the ventricular rate. It also may be combined with digoxin for the treatment of AF to achieve a synergistic effect of low doses of both the drugs, with good control of HR and minimum undesirable side effects of both the drugs. Verapamil should not be used in the treatment of WPW syndrome associated with PSVT, because of increased risk of ventricular rate. It is only effective in treating the supra ventricular tachycardia when conduction is anterograde through the AV node and retrograde through the accessory pathways. In reverse condition verapamil is ineffective. It should never be used in broad complex tachycardia, because there is chance of VF. Adenosine is the best drug to distinguish between the broad complex tachycardia and supraventricular arrhythmias. Amiodarone is more effective in treating the broad complex tachycardia than the narrow complex tachycardia.

Intravenous administration of verapamil may cause negative inotropic effect and this may be due to synergistic effect with the hypotensive property of volatile anaesthetic agents such as halothane. Thus, profound hypotension and serious cardiac conduction disorders may occurs when verapamil and halothane or other halogenated volatile anaesthetic agents and used combinedly. Verapamil has poor efficacy in the treatment of ventricular arrhythmias. In contrast to β-blockers, verapamil prophylaxis does not reduce the mortality in post MI patients.

Table 17.5: Electrophysiological effects of three commonly used calcium channel blockers

	Verapamil	*Nifedipine*	*Diltiazem*
SA node automaticity	D	Nil	D
Ventricular automaticity	D	Nil	Nil
ERP : Atrial	Nil	Nil	Nil
: AV nodal	I	D/I	I
: Ventricular	Nil	Nil	Nil
: Bypass tract	I	Nil	Nil
ECG : RR interval	I	D	D/I
: PR interval	I	Nil	I

I = Increased, D = Decreased, Nil = No effect

Uses and doses

i. PSVT - Verapamil is the drug of choice for terminating an attack of PSVT. Only 5 to 10 mg of it though IV route over 2 to 3 minutes is effective in 80% cases. Adverse effects like bradycardia, AV block, cardiac arrest, etc., should be checked during the use of verapamil. For prevention of recurrence of PSVT, it is used in the dose of 60 to 120 mg thrice daily orally.
ii. To control the ventricular rate in atrial flutter and fibrillation, (as an alternative

to digoxin or an addition to it), verapamil should be used in the dose of 60 to 120 mg TDS.

Side effects

Verapamil can cause first or second degree heart block. Intravenous administration of it may precipitate heart failure in patients with impaired left ventricular function. It also precipitate ventricular tachycardia or fibrillation in patients with the WPW syndrome. The effects of volatile anaesthetic agents and β-adrenergic antagonists on myocardial contractility and conduction system of heart are syngergistic with those of verapamil. This drug increases the serum concentration of coadministered digoxin.

If verapamil and dandrolene are administered concurrently, then they may cause hyperkalaemia leading to ventricular fibrillation. So, these drugs are not recommended for use together in man. The drug decreases the MAC value of halotane. Chronic exposure to this drug may potentiate the actions of both depolarising and non depolarising muscle relaxants. Verapamil attenuates the pressor response to laryngoscopy and intubation.

Others Antiarrhythmic Agents

Cardiac Glycosides (digoxin)

It has been discussed in the heart failure chapter.

Adenosine

Adenosine and its physiological effects was first described in 1929. But, it has only recently been used as a therapeutic and diagnostic agent. In human body it is a naturally occurring compound (nucleoside) and composed of adenine (a purine base) which is bonded to D-ribose. It is formed in the body by two major mechanism such as the depolarisation of AMP and the breakdown of S-adenosyl homocysteine (SDH). The effects of adenosine in the CVS is mediated by its high affinity to some adenosine receptors such as A1 and low affinity to other adenosine receptors such as A2.

The activity of A1 receptor inhibits the adenyl cyclase and subsequently inhibits the production of cAMP. Thus adenosine causes depression of cardiac contractility. On the otherhand, activation of A2 receptor causes vasodilation throughout the body especially pulmonary, renal and coronary vessels producing hypotension. The pharmacological actions of theophylline, caffeine and methylxanthines are also mediated by their competitive antagonistic actions on A1 and A2 receptors. Part of the vasodilating effects of adenosine may be related to prostacyclin (PGI_2) synthesis. Though the main role of adenosine is as diagnostic and therapeutic tool in the management of supraventricular arrhythmias, but it may also have important roles as coronary and pulmonary vasodilator.

Mechanism of action of adenosine as antiarrhythmic agent

i. Action of adenosine on A1 receptor activates the acetylcholine sensitive potassium conductance in sinus, AV nodal and atrial cells. Thus it causes hyperpolarization of the cell membrane, and hence make slow or complete block the spontaneous activity of these cells.
ii. Adenosine also blocks the slow inward movement of Ca^{2+} current which is responsible for the upstroke (phase 0) of the action potential in sinus, AV nodal and atrial cells. Thus, it increases the refractoriness.
iii. Adenosine also inhibits the release of noradrenaline from the presynaptic terminals. Thus, it enhances the antiadrenergic effect.
iv. Adenosine also exerts its antiarrhythmic action by blocking the re-entry pathways, either through the AV node or through an accessory pathway.

Despite the availability of different types of sophisticated ECG machine, still now diagnosis of tachyarrhythmias is sometimes become very difficult. Because broad complex tachycardia may be due to ventricular tachycardia or supraventricular tachycardia with bundle branch block. If verapamil is used for the treatment of patient with VT mistaken for PSVT with broad QRS complex due to bundle branch block, then cardiac arrest may occur. Another therapeutic problem of verapamil is 15% of narrow QRS complex tachycardia is other than PSVT where it may can create problem. In such situation, if adenosine is injected rapidly in large peripheral veins, then it helps in differentiation between supraventricular and ventricular tachycardia with 90% accuracy, because VT remains unaffected by adenosine.

So, currently the only indication for the use of adenosine is the conversion of PSVT (including that associated with WPW syndrome), to sinus rhythm. Intravenous bolus administration of adenosine for PSVT may induce the onset of atrial fibrillation and thus should be administered only in an appropriate setting with cardioversion capability. Wide complex tachycardia arising from the ventricle, as opposed to the AV node, will not be affected by adenosine. Similarly, atrial arrhythmias (e.g. atrial fibrillation, atrial flutter, multifocal atrial tachycardia) will demonstrate only a transient slowing of ventricular rate.

Adenosine has no clinically important effects on blood pressure except transient hypotension, when administered in therapeutic dose by bolus. But continuous high dose of infusion may result in a decrease of SVR and BP. Thus, it causes a dose dependent reflex tachycardia and an increase in stroke volume and cardiac output. Adenosine also cause a dose dependent increase in myocardial blood flow which is secondary to coronary vasodilation and mediated via endothelial A_2 receptors. But this is without an increase in O_2 consumption and work load. However, the unfavourable changes in distribution of regional coronary blood flow (intracoronary steal) by adenosine have led to (Table 17.6) the myocardial

Table 17.6: Choice of drugs in the treatment of cardiac arrhythmias

Arrhythmia	*Acute*		*Chronic*	
	1st choice	*2nd choice*	*1st choice*	*2nd choice*
1. Atrial extrasystole	Not necessary		Quinidine	Propranolol Disopyramide
2. PSVT	Adenosine Verapamil	Digoxin Beta blocker	VerapamilDi-goxin	Betablocker Disopyramide
3. Atrial flutter and atrial fibrillation	Cardioversion Verapamil	Esmolol	Amiodarone Digitalis	Any of the previ-ous drugs
4. Ventricular extra systole	Lignocaine	Mexiletine Disopyramide Propranolol	Amiodarone	Mexiletine Propranolol
5. VT	Cardioversion-Lignocaine	Mexiletine Amiodarone	Mexiletine, Amiodarone	Disopyramide Quinidine
6. VF	Cardioversion	Lignocaine Bretylium	Bretylium Amiodarone	Same
7. WPW syndrome	Cardioversion	Amiodarone	Amiodarone	Propranolol

ischaemia in patient with coronary artery disease, which may greatly limit its usefulness during anaesthesia.

Adenosine also slows the AV conduction and increases the P-R interval. It can interrupt the re-entrant arrhythmias that involve the AV node. Large doses of adenosine depresses the SA node and ventricular automaticity, leading to brief periods of sinus pause, but it resolve spontaneously. Though adverse reactions of adenosine are rare and of brief duration, still it is best avoided in patients with second or third degree heart block or sick sinus syndrome.

The bolus administration of adenosine is associated with an increase in both the depth and rate of respiration. This is probably mediated by A_2 receptor, situated in the carotid body. It decrease PVR, increases intrapulmonary shunt and can lead to a drop in arterial O_2 saturation, as a result of the inhibition of pulmonary hypoxic vasoconstriction reflex. It may rarely cause bronchospasm in predisposed individuals.

Hypotensive dose of adenosine stimulate A_2 receptors, resulting in renal and hepatic arterial vasodilatation, although low doses have no effect on the glomerular filtration rate and urine output.

Adenosin has a very short half-life which is less than 10 seconds. It is due to rapid uptake of it by the RBC and endothelial cells where it is converted to 5 AMP and inosine. Almost complete elimination of adenosine occurs in a single passage through coronary circulation. Dipyridamole potentiates the actions of adenosine, while theophylline and caffeine antagonize the action of it by blocking the receptors. So, higher doses of adenosine are required for tea or coffee drinker.

The advantages of adenosine over verapamil for termination of PSVT are :

i. Efficiency of adenosine is greater than verapamil - 100% efficacy for adenosine compared with 73% for verapamil.
ii. Action of adenosine lasts < 5 sec. So, adverse effects of adenosine, even if cardiac arrest occurs - are transient and is infact the therapeutic goal.
iii. Adenosine causes no haemodynamic deterioration. So, it can be given to patients with hypotension or those receiving β-blockers. But, verapamil is contraindicated in these situations.
iv. Adenosine is safe in wide QRS tachycardia, while verapamil is unsafe in such condition.
v. Adenosine is effective in patients who are not responding to verapamil.

It may produce transient dyspnoea, chest pain and flushing. VF or ventricular stand still may occur in some patients, but it lasts only for few seconds. Bronchospasm may be precipitated in asthmatics. As adenosine has vary short duration of action, it is not suitable for recurrent cases. It is very expensive.

Dose: The therapeutic dose of adenosine is 6 to 12 mg through IV in bolus. Due to rapid metabolism in few seconds slow administration of adenosine results in elimination of the drug from the circulation prior to its arrival at the heart. So, adenosine is administered as a rapid intravenous bolus, followed by a saline flush. The initial adult dose of adenosine is 3 mg which is followed if necessary by 6 mg and then 12 mg bolus at 1 to 2 minute intervals, until the desired effects are observed. The paediatric dose of adenosine is 0.05 mg/kg, which is increased by 0.05 mg/kg to a maximum of 0.3 mg/kg. The drug acts within 10 seconds and has a duration of action of 10 to 20 seconds. No dose adjustment of adenosine is necessary in the presence of renal or hepatic impairment.

Dofetilide

It is a potent, specific and delayed rectifier K^+ current (IKr) blocker. So it acts only on heart without any extracardiac pharmacological action. Dofetilide is very effective maintaining sinus rhythm in AF. Use of dofetilide does not increase mortality in patient with advanced heart failure and acute MI.

Dofetilide is excreted unchanged by kidneys. So, in renal failure lower doses of dofetilide should be used cautiously. It is marketed first in 2000 and is currrently available only in few centres in the World. The incidence of adverse effects of it is still unknown.

Ibutilide

It also prolongs the duration of action potential by blocking the IKr and inward Na^+ current. For immediate conversion of atrial flutter and atrial fibrillation to sinus

rhythm, ibutilide is used as rapid infusion (1 mg in 10 min). The major drawback of ibutilide is toroades-de-pointes which required immediate cardioversion.

B. Drugs for AV Block (Disturbances for Impulse Conduction)

Atropine

Atropine sulphate (0·6 mg IV, repeated if necessary to a maximum of 3 mg) increases the sinus rate and sinoatrial and AV conduction. It is the treatment of choice for severe bradycardia and/or hypotension due to vagal overactivity. Atropine may also be of important value during the initial management of sympomatic bradyarrhythmias complicating the early stages of inferior myocardial infarction and cardiac arrest due to asystole. Repeated doses may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side effects include dry mouth, thirst, blurred vision and both atrial and ventricular extrasystole.

Sympathomimetics

Adrenaline

Discussed in the chapter of 'Autonomic Nervous System'.

Isoprenaline

Discussed in the chapter of 'Autonomic Nervous System'.

18 Hypertension: Pharmacology and Anaesthesia

INTRODUCTION

Any definition of hypertension is arbitray. Because in contrast to any specific disease it is often taken as a trait or chapacteristic and represents a quantitative rather than a qualitative deviation from the normal. It is the most common, asymptomatic, readily detectable and easily treatable disease which if untreated often leads to lethal complications. These complications depend also on other risk factors such as age, gender, weight, physical activity, smoking, family history, blood cholesterol, diabetes, etc. Therefore, effective management of hypertension requires a holistic approach which is based on all the identifiable risk factors and adoption of multifactorial intervention. Although, understanding of pathophysiology of elevated arterial pressure has increased but, still in 90 to 95 percent of cases the aetiology of elevated arterial pressure is largely unknown. So, the treatment of hypertension in most cases is nonspecific, resulting in large number of minor side effects and a high-compliance rate. Hence, in light of these observations, hypertension is now defined as the value of blood pressure at which level the benefit of treatment outweigh the cost and complications.

Classification of Hypertension (Based on Aetiology)

i. Systolic and diastolic hypertension
   a. Primary (essential),
   b. Secondary.
ii. Systolic hypertension
   a. Increased cardiac output
      Aortic regurgitation
      Patent ductus arteriosus
      Arteriovenous fistula
      Fever
      Thyrotoxicosis
   b. Rigidity of aorta
      Arteriosclerosis
iii. Diastolic hypertension

Classification of Hypertension (Based on Numerical Value)

Category	*Diastolic (mm of Hg)*	*Systolic (mm of Hg)*
Normal	< 85	< 130
High normal	85-89	130-139
Hypertension Mild	90-99	140-159
Moderate	100-109	160-179
Severe	110-119	180-209
Very severe	> 120	> 210

Essential or Primary or Idiopathic Hypertension

Arterial hypertension with no definite cause or explanation for its pathophysiology is said to be essential hypertension. Usually it constitutes 90 to 95% of the total cases of hypertension. Several abnormalities of varying systems that are mainly involved in the regulation of BP such as kidneys, peripheral resistance vessels, the sympathetic nervous system etc has been described in patients with essential hypertension. But it is still uncertain, whether these abnormalities of varying system which are mentioned above are responsible for development of hypertension (secondary) or are due to hypertension (primary) caused by an unknown aetiology. Also it may be the different expressions or pathophysiology of different organs to a single disease process or it may be the expressions of separate disease entities which is not known. However, the later is gradually getting ground. So, the distinction between the primary hypertension and secondary hypertension is gradually becoming blurred.

Individuals in whom the defect of any specific structural organ is responsible for the development of systemic hypertension are defined as having a secondary form of hypertension. In contrast, where the generalised functional abnormalities are the cause of hypertension (even if the abnormalities are very discrete), it is defined as the essential hypertension.

The probable theories of essential hypertension are:

Heredity

It is probably heterogeneous in nature and is multifactorial in origin. Monogenic defects (Liddle's syndrome) and susceptible genes (angiotensinogen gene) is also now reported.

Environment

Environments that is responsible for high BP includes excessive salt intake, obesity, occupation, smoking alcohol intake, etc. Blood pressure increases with age in more affluent societies and decreases with age in less affluent societies. This explains that enviornment has influence on the genesis of hypertension.

Sensitivity to salt

It is gradually receiving much attention, but pathophysiology of it is still

uncertain. This hypothesis explains that the sensitivity of individual to salt varies which is responsible for hypertension.

Renin

Renin-angiotensin-aldosterone system is an important contributory factor for hypertension. Renin is an enzyme which is secreted by the juxtaglomerular cell of kidney. It is linked with the secretion of aldosterone through a negative feedback loop. Variety of factors can modify the rate of secretion of renin. But the primary determinant is the circulatory volume status of the individual which is again particularly related to the changes in dietary Na^+ intake. The end product of the action of renin on its substrate (angiotensinogen) is the generation of angiotensin I and angiotensin II which is responsible for controlling BP by constricting blood vessels. The intake of Na^+ normally modulates the adrenal and renal vascular response to angiotensin II. With sodium (Fig. 18.1) restriction, the adrenal responses are enhanced and the renal vascular responses are reduced. Whereas the sodium loading has the opposite effect. Plasma renin activity is wider in hypertensive subject than in normotensive. As a consequence, some hypertensive patients have low-renin level and others have high-renin level.

Low renin essential hypertension

Approximately 20% of hypertensive patients have suppressed plasma renin activity. They show the features of hyper aldosteronism, manifested by expan-ded extracellular fluid volume, but not hypocalaemic (which is the feature of hyperaldosteronism). This so-called hyperaldosteronism (or pseudohyperaldosteronism) is responsible for low plasma renin level due to negative feedback mechanism. But due to some unknown reasons practically aldosterone level remains normal. So some atypical (unknown) mineralocorticoids is taken as responsible for low renin hypertension.

Nonmodulating essential hypertension

This type of hypertension constitutes about 25 to 30% of population. Here plasma renin level is normal to high and adrenal defect is opposite to that observed in low renin patients. In these patients, Na^+ intake does not modulate either adrenal or renal vascular responses to angiotensin II. So, this type of hypertension is named so.

High renin essential hypertension

Here plasma renin levels are higher than the normal range which suggests that plasma renin plays an important role in the pathogenesis of elevated BP. However, some investigators postulate that elevated renin and BP are secondary to the increase in activity of adrenergic system. It is proposed that angiotensin-dependent high renin hypertension is nonmodulating defect.

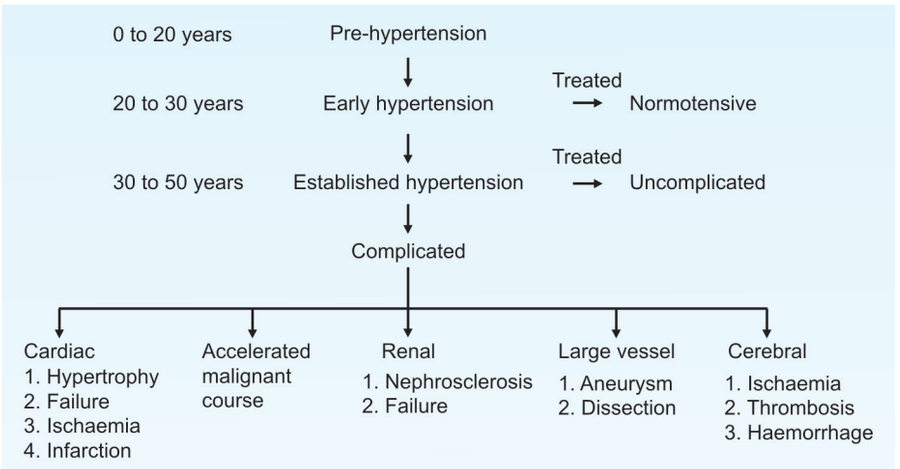

Fig. 18.1: Heredity-environment-age system

Cell membrane defect

Another postulated explanation for hypertension is generalised cell membrane defect, where there is both increase and decrease in the activity of different transport systems. Among these some abnorma-lities are primary and some are secondary. Abnormality in sodium transport reflects an undefined alteration in the cell membrane. This defect leads to the abnormal accumulation of calcium in vascular smooth muscle cells, resulting in higher vascular responsiveness to vasoconstrictor agents.

Insulin resistance

Insulin resistance and /or hyperinsulinaemia is one of the aetiological factors for hypertension. Insulin resistance is common both in NIDDM and obesity. Both obesity and NIDDM are common in hypertensive than normotensive subjects.

Hyperinsulinaemia elevates BP by the following mechanism:

i. Hyperinsulinaemia produces renal sodium retention and increases sympathetic activity which leads to increased BP.
ii. Vascular smooth muscle hypertrophy, secondary to mitogenic action of insulin is another mechanism.
iii. Insulin also modifies ion transport across the cell membrane. Thereby, it potentially increases the cytosolic calcium level in insulin sensitive vascular or renal tissue, thus leading to hypertension.

Secondary Hypertension

In minority of patients (5-10%) hypertension can be shown to be as the consequences of specific diseases or abnormalities which lead to sodium retention and/or peripheral vasoconstriction, causing elevated arterial

pressure. These are called the secondary hypertension. These specific causes have been identified and correction of this causes can cure the hypertension. The causes of secondary hypertension are:

(i) Renal

Acute and chronic glomerulonephritis, chronic pyelonephritis, polycystic renal disease, stenosis of renal artery, diabetic nephropathy, chronic renal failure, renin producing tumour, etc.

(ii) Endocrine

Acromegaly, oral contraceptive, pheochromocytoma, Cushing's disease, primary aldosteronism, congenital adrenal hyper- plasia, hyperthyroidism, etc.

(iii) Neurogenic

Increased intracranial pressure, psychogenic, polyneuritis, etc.

(iv) Miscellaneous

Coarctation of aorta, pregnancy induced hypertension, polyarteritis nodosa, increased intravascular volume, polycythemia, excess transfusion, etc.
Medications – glucocorticoids.

Effects of Hypertension

Hypertension is the most common cause of death. Patient dies prematurely due to hypertension. The adverse effects of hypertension mainly involve the CVS, kidney, retina, CNS which often can be detected by simple clinical means.

Effects on CVS

In hypertension heart has to work against excessive load due to increased SVR. So, the first compensatory change in heart is the concentric left ventricular hypertrophy to maintain the same CO. Then, gradually myocardial ischaemia develops and it damages the myocardium. Thus the function of left gradually ventricle deteriorates, cavity dilates and signs-symptoms of heart failure appear. During the compensatory phase angina may appear, and this is because of the combination of associated coronary arterial disease reducing O_2 supply and increased myocardial O_2 demand. Sound of aortic closure is accentuated and a faint murmur of aortic regurgitation is observed. Presystolic (4th heart sound) and protodiastolic (3rd sound) heart sound may be present. ECG and echocardiographic changes show left ventricular hypertrophy and ischaemia. Atrial fibrillation is common. It may be due to diastolic dysfunction, caused by LVH.

Effect on kidney

The most common renal vascular effects due to hypertension is arteriosclerotic changes in the affarent and efferent arteioles and in the glomerular tuft of capillaries. These changes cause decreased glomerular filtration rate, proteinuria, and microscopic haematuria. Renal failure contributes 10% of death caused by hypertension.

Retinal changes

Retina is the only tissue in which the arteries and arterioles can be examined directly. It also provides the opportunity to observe the progress and the effects of hypertension on vessels. When there is no arteriosclerotic change in retinal vessels, then gradually increasing severity of hypertension is associated with focal spasm and progressive general narrowing of the arterioles. After that there is appearance of haemorrhage, exudates (cotton wool) and papilloedema. These retinal lesions often produce scotoma, blurred vision and even blindness, especially when there is papilloedema or haemorrhage on the macular area. These hypertensive lesions may also develop very acutely. If therapy started immediately and results in significant reduction of BP, then the above mentioned retinal changes show rapid resolution.

If there are retinal arteriosclerotic changes which results from the endothelial and muscular proliferation, then it reflects the similar changes in other organs. These sclerotic changes do not develop as rapidly as hypertensive lesions, nor do they regress easily with therapy. As a consequence the increased wall thickness and rigidity, caused by sclerotic arterioles distort and compress the veins where the two types of vessels cross in their common fibrous sheath. Due to this arteriosclerotic changes the reflected light streak from the arterioles is changed by the increased opacity of the vessel wall.

Hypertensive retinopathy

Grade I

Arteriolar tortusity, thickening and increased reflectiveness (silver wiring).

Grade II

Grade I plus nipping or constriction at arteriovenous crossing.

Grade III

Grade II plus retinal ischaemia evidenced by flame shaped haemorrhage and cotton wool exudate.

Grade IV

Grade III plus papilloedema.

Effects on CNS

Common symptoms of patients with hypertension are headache, dizziness, vertigo, tinnitus, dimness of vision and syncope. The more serious manifestations of CNS for hypertension are due to the vascular occlusion, haemorrhage or encephalopathy. The pathogenesis of cerebral infarction (vascular occlusion) is secondary to the increased cerebral atherosclerosis. The pathogenesis of cerebral haemorrhage or stoke is the result of both elevated cerebral arterial pressure and the development of cerebral vascular microaneurysms. Stroke is the most common complication of hypertension and it may be due to cerebral haemorrhage or cerebral infarction. Hypertensive ence-phalopathy is a rare condition.

Some Terminologies Regarding Hypertension

Hypertensive emergency

It is defined as the elevation of both systolic and diastolic BP with the presence of any acute end organ disease. The organs at particular risk for hypertensive emergency are those that receive the greater proportion of cardiac output, that is the heart, brain and kidneys. So, the hypertensive emergencies include hypertensive encephalopathy, dissecting aortic aneurysm, cerebrovascular accidents, severe hypertension with progressive renal insufficiency and acute left ventricular heart failure. Hypertensive emergencies may also be caused by pheochromocytoma, pre-eclampsia, eclampsia. It may even be drug-related (MAO inhibitor and tyramine ingestion, withdrawal of α_2 agonist such as clonidine, use of sympathomimetic agents) or occur post-operatively. Hypertensive emergency is not distinguished by an arbitrarily chosen BP value.

Hypertensive urgency (or pseudoemergency)

It is described as an elevated BP (diastolic > 120 mm of Hg) with an absence of any acute end organ disease. Examples of hypertensive urgencies include perioperative hypertension, intractable nasal bleeding, hypertension associated with increased circulation of catecholamines and most commonly severe diastolic hypertension without any complications.

Hypertensive crisis

Hypertensive emergency and urgency are together encompassed in this term. Hypertensive emergencies are rare and treatment must balance the risks of lowering BP too rapidly against the persistent hypertension with continued end organ dysfunction. As for example, in case of LVF blood pressure should be reduced very rapidly, but in CVA reduction of BP should be over hours.

Malignant hypertension

In addition to marked elevation of blood pressure in association with papilloedema, retinal haemorrhages and exudates, the full blown picture of malignant hypertension may include the manifestation of hypertensive encephalopathy, such as severe headache, vomiting, visual disturbances, transient paralyses, convulsions, stupor and coma.

Accelerated malignant hypertension

Until recently, the term 'malignant' hypertension was used for the presence of papillaedema [grade IV Keith-Wagener (K-W) retinopathy], whereas the term 'accelerated' was used for the presence of haemorrhages and exudates in retina (grade III K-W retinopathy), both with markedly high BP (diastolic BP usually above 140 mm of Hg). But this funduscopic differences do not establish different clinical features or prognosis, so the term 'accelerated– malignant' hypertension is recommended and will be used from now on.

Hypertensive encephalopathy

In addition to the marked elevation of blood pressure associated with papilloedema, retinal haemorrhage and exudates etc, the full – blown picture of malignant hypertension may also include manifestation of hypertensive CNS disturbances, transient paralysis, convulsion, stupor and coma This is known as hypertensive encephalopathy. With or without structural defects of accelerated–malignant hypertension, progressively higher BP can lead to hypertensive encephalopathy.

The above mentioned manifestations have been attributed to spasm and dilatations of cerebral vessels and cerebral oedema. In some patients who have died, multiple small thrombi have also been found in cerebral vessels. CSF is clear but usually under increased pressure. MRI shows haemorrhage in and around the basal ganglia. However, the neurological deficit is usually reversible if the hypertension is promptly treated.

Mechanism of Hypertensive Encephalopathy

With changes in BP the cerebral vessels constrict or dilate to maintain a relatively constant level of cerebral blood flow (CBF). This is called the process of autoregulation and is regulated by sympathetic nervous activity. Cerebral vessels dilate progressively as pressure decreases and progressively constrict as pressure increases. When MAP reach a critical level, say around 180 mm of Hg, then the previously constricted vessels are unable to withstand such high pressure and become stretched and dilated. It occurs first in areas where the vessels are with less muscular tone, thus producing irregular sausage string pattern and later diffusely, producing generalised vasodilatation. This vasodilation allows an increase of CBF and hyperperfusion of the brain under high pressure. This causes leakage of fluid into the perivascular tissue, leading to cerebral oedema and the clinical syndrome of hypertensive encephalopathy. The figure relating the relationship between MAP and CBF demonstrates that CBF is constant between MAP of 60 and 120 mm of Hg in normotensive subject, i.e. the lower six curves. Of these lower six, upper two curves show breakthrough hyperperfusion when pressure is raised beyond the limit of autoregulation in normotensive subject. The autoregulation curve in chronic hypertensives, whose blood gradually vessels adapt to the chronically elevated BP with structural thickening mediated by sympathetic nerves, is shifted to the right (shown in the upper six curves). Even with this shift, breakthrough will occur if pressure is raised very high to levels of 170 to 180 mm of Hg.

These findings explain a number of clinical observations. At the upper portion of the autoregulatory curve of the previously normotensive people (lower six curves) who suddenly become hypertensive may develop encephalopathy at relatively low levels of hypertension. These include children with acute glomerulonephritis and

young women with eclampsia. On the other hand, chronically hypertensive patients less commonly develop encephalopathy and if so only at much higher pressure.

When BP is lowered by antihypertensive drugs too rapidly, then the chronic hypertensive patients are often unable to tolerate this reduction of BP without experiencing cerebral hypoperfusion (manifested by weakness, dizziness, etc.). These symptoms appear at levels of BP that are still above the upper limit of normal and that are well tolerated by normotensives. The reason is that the entire curve of autoregulation shifts to the right, so that the lower end is also shifted to the right with fall of CBF at levels of 100 to 120 mm of Hg of MAP (Fig. 18.2). If BP is lowered gradually then the curve shifts back toward its normal position, so that the greater reduction in pressure can eventually be tolerated. Unfortunately, chronic hypertensives may lose their ability to autoregulate and increase the risk of brain damage when BP is lowered acutely. In infracted brain tissue autoregulation is lost. Therefore, with high BP cerebral perfusion would be accentuated through the damaged tissue leading to oedema and compression of normal brain. Thus, hypertensive encephalopathy is a consequence of progressively rising arterial pressure that break through the protection of blood-brain barrier and the autoregulation of CBF.

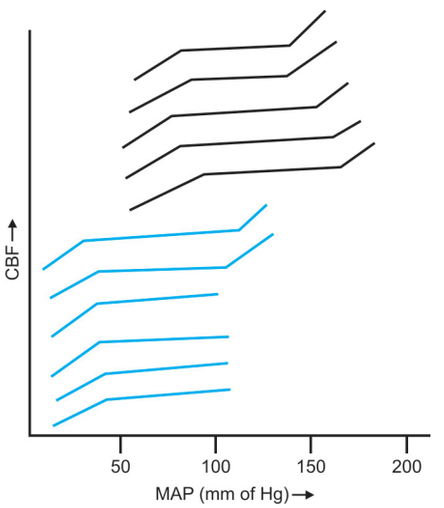

Fig. 18.2: The relation between cerebral blood flow (CBF) and mean arterial pressure (MAP) in both normotemive and chronic hypertensive patient

DIAGNOSIS OF PRIMARY AND SECONDARY HYPERTENSION

Primary hypertension is diagnosed by exclusion of secondary causes. But during the diagnosis of primary hypertension, we will have to keep in mind that the majority of abnormal signs are due to the complications of hypertension which may be mistaken as secondary causes. However, certain clues from history, clinical examination and routine laboratory tests may suggest secondary form of hypertension which dictates the need for special investigations for confirmation of it. For example:

i. Abrupt onset of severe hypertension under the age of 25 years or after the age of 50 years should lead to laboratory tests to exclude the renovascular hypertension and pheochromocytoma.
ii. History of headache, palpitation, sweating, hyperglycaemia and weight loss suggests pheochromocytoma.
iii. The presence of abdominal bruit suggests renovascular hypertension.
iv. Elevated creatinine, ↑BUN, proteinuria, haematuria, suggests renal insufficiency.
v. Therapeutic failure with initial drug therapy also suggest secondary hypertension.
vi. Characteristic facies and habitus suggests Cushing's syndrome. There are also many nonspecific findings which include: Left ventricular hypertrophy, accentuation of the aortic component of the 2nd heart sound, 4th heart sound, etc.

Pheochromocytoma

The easiest and best screening procedure for pheochromocytoma is the measurement of catecholamines or their metabolites in 24 hour urine sample, collected while patient is hypertensive. Measurement of plasma catecholamine levels is also useful.

Cushing's syndrome

A 24-hour urine test for cortisol. A urine cortisol level of less than 2750 nmol (100 µg) excludes Cushing's syndrome.

Administration of 1 mg of dexamethasone at bedtime followed by measurement of plasma cortisol at 7 to 10 am is the best screening test for Cushing's syndrome. Plasma cortisol level below 140 nmol/L (5 µg/dl) rules out Cushing's syndrome.

Investigations for All Hypertensive Patients

i. Blood glucose.
ii. Blood urea and creatinine.
iii. Blood electrolytes (hypokalaemic alkalosis is usually due to diuretic therapy, but it may indicate primary aldosteronism).
iv. Serum total and high density lipoprotein (HDL) and cholesterol.
v. Urine analysis for glucose, protein and blood.
vi. 12 lead ECG to diagnose LVH, coronary artery disease, etc.
vii. Microscopic urine analysis.
viii. White blood cell count.
ix. Serum calcium, phosphate and uric acid.

Investigations for Selected Hypertensive Patients

i. Ambulatory BP recording to assess 'white coat' or border line hypertension.
ii. Chest X-ray to detect coarctation of aorta, cardiomegaly, heart failure, etc.
iii. Echocardiography to detect and quantify the left ventricular function.
iv. Urinary catecholamine measurement to detect phaeochromocytoma.
v. Urinary cortisol measurement and dexamethasone suppression test to diagnose Cushing's syndrome.
vi. Renal ultrasonography to detect the possible renal diseases.

vii. Renal angiography to diagnose renal artery stenosis.
viii. Plasma renin activity and measurement of aldosterone to diagnose primary aldosteronism.

RENIN-ANGIOTENSIN SYSTEM (RAS)

To know the hypertension properly, renin-angiotensin system should be known in details. So, this system is discussed here. Initially, in 1970, inhibition of renin-angiotensin system was considered sensitive only for patients with high-renin hypertension. But, later it was found that ACE inhibitor was also proved to be effective in essential hypertension, with normal levels of plasma renin activity. Also recently ACE inhibitors gained widespread popularity for its use in congestive heart failure, myocardial infarction, diabetic nephropathy, renal failure, vascular disease and many other conditions associated with hypertension.

Overview

RAS control BP by short and long-term regulation. Factors that decrease the effective blood volume and reduce BP (e.g. use of vasodilators, diuretics, blood loss, low – Na^+ diet, liver cirrhosis, etc.) activate the release of renin from kidney. Renin is an enzyme that acts on angiotensinogen and catalyse this substrate to form a decapeptide, named angiotensin I from it. This decapeptide is then cleaved by angiotensin converting enzyme (ACE) to yield octapeptide named angiotensin II (A-II). This A-II acts via diverse and coordinated way to raise or maintain the arterial blood pressure. A-II causes vasoconstriction and increase peripheral vascular resistance. Thus, it contributes to the short-term regulation of arterial BP. A-II also inhibit the excretion of Na^+ and water by kidney. Thus A-II causes changes in renal function which play an important role in long-term stabilisation of BP.

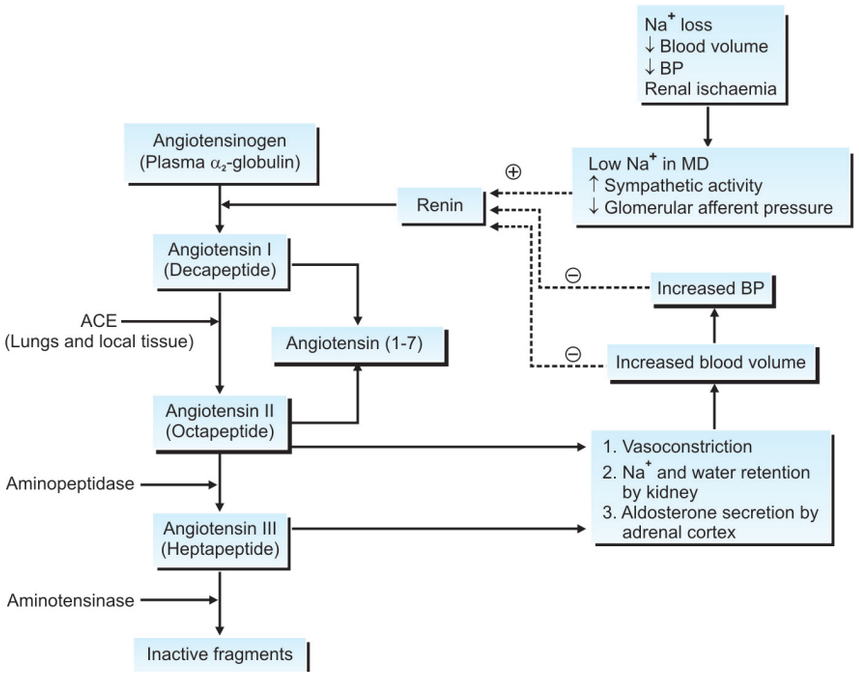

Fig. 18.3: Control of renin secretion

Renin

It is a glycosylated single chain polypeptide and is secreted by the granular juxtaglomerular (JG) cells which lie in the walls of the afferent arterioles as they enter the glomeruli. It is major determinant factor for angiotensin II (A-II) production. Its principal substrate is circulating α_2-globulin which is called angiotensinogen and convert it to angiotensin I (A-I). The first product during production of renin is preprorenin, which is processed in the ER of JG cells to prorenin. Prorenin then may be secreted directly from JG cells or packaged into immature granules where it is further processed to the active mature renin.

Control of renin secretion

The secretion of renin is controlled predominantly by three pathway. Among these the two pathways are locally acting within the kidney. The third is acting through the CNS and mediated by renal noradrenergic nerves. The locally acting two pathways within the kidney are: macula densa pathway and intrarenal baroreceptor pathway. The third pathway acting through CNS is the adrenergic receptor pathway (Fig. 18.3).

Macula densa pathway

It is composed of specialised columnar epithelial cells called the macula densa (MD). They are located in the wall of the thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus, adjacent to JG cells. A change in the reabsorption of NaCl by MD results in the transmission of chemical signals to nearby JG cells of affarent arteriole that modify the release of renin from them. Increase in NaCl influx across the MD cells inhibit the release of renin and decrease in NaCl influx increase the release of renin. This chemical signal pathways involve both the adenosine and prostaglandin. Adenosine after being released when NaCl transport increases inhibits the secretion of renin. Whereas, prostaglandin after being released when NaCl transport decreases stimulates the secretion of renin.

Intrarenal baroreceptor pathway

The increase or decrease in BP in the preglomerular vessels inhibit or stimulate the release of renin respectively. It acts through PG pathway.

β-adrenergic receptor pathway

It is mediated by the release of norepinephrine from the postganglionic sympathetic nerve terminals. Then, the activation of β_1 receptor, situated on JG cells by norepinephrine enhances renin recreation.

These three pathways regulating the release of renin are embedded in a physiological network. Increase in renin secretion enhances the formation of angiotensin II (A-II). Subsequently, this A-II stimulates angiotensin subtype I (AT_1) receptors on JG cells and inhibit the release of renin. This feedback system has been termed the short loop negative feedback mechanism. Next, A-II also increases the systemic BP via stimulation of AT_1 receptor situated on the peripheral vessels of the body. This ↑BP inhibit the release of renin by: (i) activating the baroreceptors, thereby reducing the renal sympathetic tone, (ii) increasing the pressure in the preglomerular vessels and (iii) reducing the reabsorption of NaCl in the proximal tubule (pressure natriuresis), which increases the tubular delivery of NaCl to macula densa. This inhibition of release of renin due to A-II induced increase in BP has been termed as the long loop negative feedback mechanism.

Renin release also can be influenced by a number of pharmacological agents. These are:

i. Loop diuretics stimulate the release of renin by blocking the reabsorption of NaCl at MD.
ii. NSAID inhibit the formation of PG and decrease the release of renin.
iii. ACE inhibitor and AT_1 receptor blocker interrupt both the short and long loop negative feedback mechanism and increase the release of renin.
iv. Diuretics and vasodilators increase the release of renin by decreasing BP.
v. β-adrenergic receptor antagonists decrease the secretion of renin by inhibiting the β-adrenergic receptor pathway.

Angiotensinogen

The substrate for action of renin is angiotensinogen. It is glycoprotein in nature. It is continuously synthesised and secreted by liver. Its synthesis is stimulated by inflammation, insulin, estrogen, glucocorticoids, thyroid hormone, etc. During pregnancy the plasma level of angiotensinogen increases several fold under the influence of oestrogen. Renin converts angiotensinogen to angiotensin-I (A-I).

Angiotensin Converting Enzyme (ACE)

Although spontaneous slow conversion of A-I to A-II occurs in plasma, but the very rapid conversion of it occurs due to the activity of cell membrane bound ACE which is present on the luminal aspect of the endothelial cells throughout the whole vascular system. During conversion of A-I to A-II the two end amino acids such as histidyl and leucine of A-I are removed by ACE and form the 8-amino acid polypeptide angiotensin-II (A-II). Thus, conversion A-I to A-II occurs throughout the body, but particularly it occurs in lung. Angiotensin II is then converted to angiotensin III (A-III) by aminopeptidase.

Angiotensin Peptides

There are three angiotensin peptides. These are: Angiotensin-I (A-I), angiotensin-II (A-II) and angiotensin-III (A-III). A-I is less than 1% as potent as A-II on the vascular smooth muscle, heart and adrenal cortex. A-III is formed by the action of aminopeptidase on A-II. The A-II and A-III have qualitatively similar effects, but quantitatively A-III is only 25% and 10% as potent as A-II in elevating BP and stimulating the adrenal medulla, respectively. On the otherhand, A-III is as potent as A-II in stimulating the secretion of aldosterone.

A-I and A-II is metabolised to anginotensin (1 to 7). ACE inhibitors increases, rather than decreases, the tissue and plasma levels of anginotensin (1 to 7). This because A-I levels are increased and is diverted away from A-II formation to the formation of angiotensin (1 to 7). Unlike A-II, anginotensin (1 to 7) does not cause vasoconstriction, aldosterone release, or facilitation of noradrenergic neurotransmission causing elevation of blood pressure. Anginotensin (1 to 7) inhibits proliferation of vascular smooth muscle cells. Aminopeptidases, endo-peptidases and carboxypeptidases also cause degradation and inactivation of A-I and A-II to anginotensin (1 to 7).

The traditional view of the renin-anginotensin system is that circulating renin of renal origin acts on circulating anginotensinogen of hepatic origin and produce A-I in blood. Circulating A-I is then converted by plasma ACE and pulmonary endothelial ACE to A-II. A-II is then delivered to the target organ via blood stream and produces physiological responses. But actually this traditional view is oversimplification. It can be divided into Extrinsic Local R-A system and Intrinsic Local R-A system.

The conversion of hepatic anginoten-sinogen to A-I by renin and subsequently conversion of A-I (both circulating and locally produced) to A-II occur primarily within or on the surface of the blood vessel wall, but not in circulation. This is called the extrinsic local RA system because it depends on renal and hepatic based system.

Locally many tissues including brain, pituitary, blood vessels, kidney, adrenal gland, etc., express mRNAs for renin, anginotensinogen and ACE system. This system exists independently of the renal or hepatic based system and influences the local vascular, cardiac and renal's function and structure. This is called the intrinsic local RA system.

Angiotensin receptor

The effects of angiotensins are exerted through some specific receptors, situated on the cell surface. It is identifies as two types and designated as AT_1 and AT_2. Both AT_1 and AT_2 receptor are members of the G protein coupled receptor family. Most of the biological effects of A-II are mediated by the AT_1 receptor. Whereas, the functional role of AT_2 receptors are ill defined. AT_2 receptor is widely distributed in foetal tissues, but its distribution in adult is restricted. AT_1 receptor has high affinity for losartan (AT_1 receptor blocker) than AT_2 receptor. In adult some tissues contain primarily either AT_1 or AT_2 receptor. Whereas, other tissues contain these both receptor in similar amount.

Pre-eclampsia is associated with the development of agonistic autoantibodies against AT_1 receptor and thus produce exaggerated response causing hypertension. AT_1 receptor activates a large array of intracellular signal transduction system, including the intracellular Ca^{2+} release, influx pathways, phospholipases, mitogen activated protein kinase pathways, etc. Additional Ca^{2+} also enters the cell from outside due to opening of voltage sensitive Ca^{2+} channels, located on cell membrane. This Ca^{2+} binds to calmodulin and the Ca^{2+}/calmodulin complex activates a number of intracellular enzymes that contribute to the ultimate cellular responses. This is discussed in more details in ANS chapter (Table 18.1).

Function of Renin-Angiotensin System (RAS)

This RAS plays an important role in regulating the BP for both short and long-term basis. A-II is 40 times more potent than norepinephrine in respect to increase in BP. The rapid pressor response of A-II is due to the vasoconstriction and increase in the systemic vascular resistance. A-II also increases directly the cardiac contractility, acting through voltage gated Ca^{2+} channel and indirectly increase heart rate, acting by facilitation of sympathetic tone. It also enhances the noradrenergic neurotransmission and in crease the release of adrenal catecholamines. But, the increase in BP activates the baroreceptor reflex that decrease sympathetic tone and increase vagus tone. Therefore, in summary, the main function of RAS is: Alteration of SVR, alteration of renal function and alteration of cardiac function with structure.

Mechanism by which A-II increases the systemic vascular resistance (SVR)

A-II increases the SVR via direct effects on blood vessels and via indirect effect through CNS and adrenal medulla by catecholamines.

Direct vasoconstriction

A-II contracts the precapillary arterioles and postcapillary venules (lesser extent). This is caused by the activation of AT_1 retceptor by A-II which are located on the smooth muscle cells of blood vessels. But, the intensity of contraction is different in different vascular bed. Strongest contraction occur in kidney and somewhat lesser contraction occurs in other splanchinic vascular bed. A-II induced vasoconstriction is much less in the vessels of brain. It is more weaker in those of lung and skeletal muscle. But, in these regions the blood flow actually increases, because the relatively weak vasoconstrictor response is opposed by the elevated systemic blood pressure and the ultimate blood flow depends on the intensity of contraction and rise of BP.

Indirect enhancement of peripheral noradrenergic neurotransmission

A-II facilitates the peripheral noradrenergic neurotransmission and increases BP by: (i) augmenting the release of norepinephrine from the sympathetic nerve terminals, (ii) by inhibiting the reuptake of norepinephrine into the presynaptic nerve terminals and (iii) by enhancing the vascular response to norepinephrine.

Through effects on CNS

A-II increases arterial BP by its action on the CNS. This effect is mediated by increased sympathetic outflow (Fig. 18.4) from brain due to the effect of A-II on circumventricular nuclei that are not protected by a blood-brain barrier. The CNS is affected both by blood borne angiotensin

Table 18.1: Angiotensin II

Altered renal function	*Altered SVR*	*Altered CV function and structure*
1. Increased reabsorption of Na^+ from PT.	1. Direct vasoconstriction.	1. Increased proliferation, hyperplasia and hypertrophy of myocardium.
2. Increased secretion of aldosterone → increased reabsorption of Na and excretion of K+ from DT.	2. Indirect vasoconstriction through peripheral noradrenergic neurotransmission.	2. Increased fibrosis.
3. Increased renal vasoconstriction.	3. Increased sympatheitc discharge from CNS.	3. Increased extracellular matrix.
4. Increased noradrenergic neurotransmission in kidney.	4. Release of catecholamines from adrenal medulla.	4. Increased arterial wall thickness, ↑wall tension and ↑after load
5. Increased renal sympathetic tone through CNS		
↓	↓	↓
Slow pressure response	Rapid pressure response	Hypertrophy and remodelling of heart

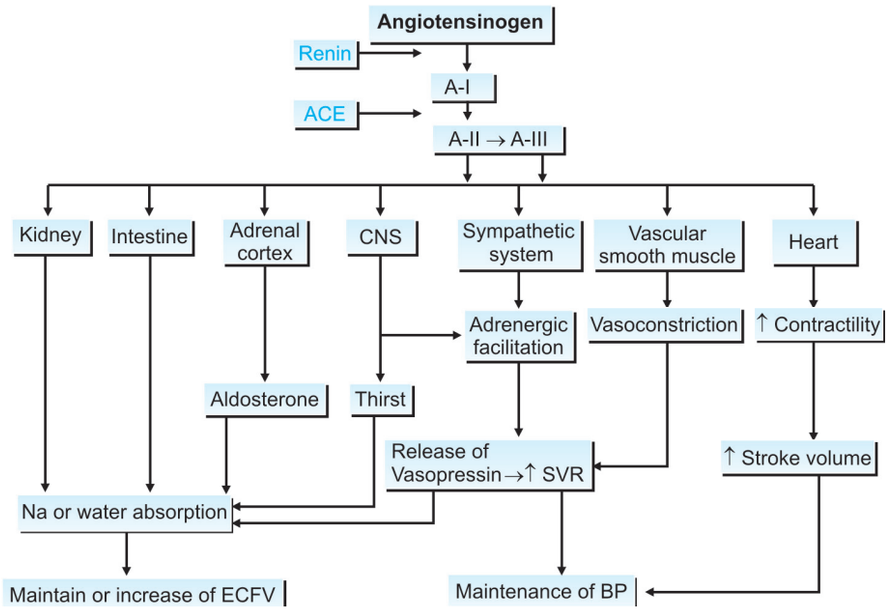

Fig. 18.4: The function of renin angiotensin system

II and by angiotensin II formed locally within the brain. The brain contains all the components of R-A system and here the A-II serves as a neurotransmitter or modulator.

Through release of catecholamines from adrenal medulla

A-II stimulates and release the catecholamines from adrenal medulla by depolarising the chromaffin cells.

Mechanism by which angiotensin II alters the renal function

A-II reduces the renal excretion of Na^+ and increase the renal excretion of K^+. It stimulates the Na^+/H^+ exchange in proximal tubule and increases the reabsorption of Na^+, Cl^-, HCO_3^-. The A-II also stimulate the secretion of aldosterone from zona glomerulosa of adrenal cortex which acts on the distal and collecting tubule to cause retention of Na^+ and excretion of K^+ and H^+. Aldosterone secretion increases under condition of hyponatraemia and hyperkalaemia and decreases in opposite condition. Such changes is due to alterations in the number of receptor for A-II at zona glomerulosa and adrenocortical hyperplasia in Na^+ depleted state.

A-II reduces the renal blood flow by directly constricting the renal vascular smooth muscle or by facilitating the renal noradrenergic neurotransmission. A-II influences the glomerulr filtration rate (GFR) in variable way by following mechanism: (i) constriction of affarent arterioles reduces GFR, (ii) contraction of mesangial cells reduces the filtration surface area and GFR, (iii) contraction of efferent arterioles causes increase in intraglomerular pressure and increases GFR.

The outcome of these opposing effects on GFR depends on the present physiological state. Normally A-II reduces the GFR slightly. But in hypotension, the effects of A-II on efferent arterioles predominate and increase the GFR. So, the blockade of renin angiotensin system cause renal failure in patient with renal artery stenosis.

Mechanism by which A-II alters the cardiovascular function and structure

Several pathological changes occur in cardiovascular structure and function by A-II and pose an increased risk of morbidity and mortality. These changes include: (i) increased wall thickness to lumen ratio in blood vessels, (ii) cardiac concentric hypertrophy, (iii) cardiac eccentric hypertrophy and fibrosis which is associated with congestive failure and infarction, (iv) thickening of the initial surface of the wall of blood vessel. All these changes are due to increased migration, proliferation, hyperplasia, and hypertrophy of smooth muscle cells, and increased extracellular matrix. The cells which are involved in these changes include vascular smooth muscle cells, cardiac myocytes and fibroblasts. All these changes in cardiovascular structure causes increase in cardiac contractility, stroke volume and BP.

Renal pressure – natriuresis curve

The intake of Na^+ and its excretion determines the arterial blood pressure. When the relation between the Na^+ intake, Na^+ excretion and the arterial blood pressure are drawn graphically, then this graph is called the renal pressure natriuresis curve. At a stable condition Na^+ intake is equal to Na^+ excretion. At some set point arterial blood pressure can be obtained from intersection of a horizontal line (representing Na^+ intake) with the renal pressure – natriuresis curve (Fig. 18.5).

When the dietary Na^+ intake is low, then renin release is stimulated and subsequent increased angiotensin II acts on the kidney to decrease the excretion of Na^+. Thus, the curve is shifted to the right to maintain the same blood pressure. Conversely, when

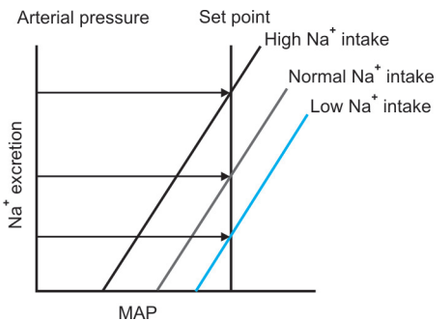

Fig. 18.5: Renal 'pressure-natriuresis' curve

the dietary Na^+ intake is high, then secretion of renin is inhibited and subsequently the withdrawal of angiotensin II causes increase in excretion of Na^+. Thus the curve is shifted to the left and blood pressure is maintained normal. The intersection of salt intake curve with the Na^+ excretion line remains near the same set point despite the large swings in dietary Na^+ intake (shown in curve as Na^+ excretion). If the curve does not shift then the arterial BP swings tremendously with different intake of Na^+. When pharmacologically the modulation of R-A system or the swings of the curve is prevented, then any changes in salt intake markedly affect the long term levels of arterial BP.

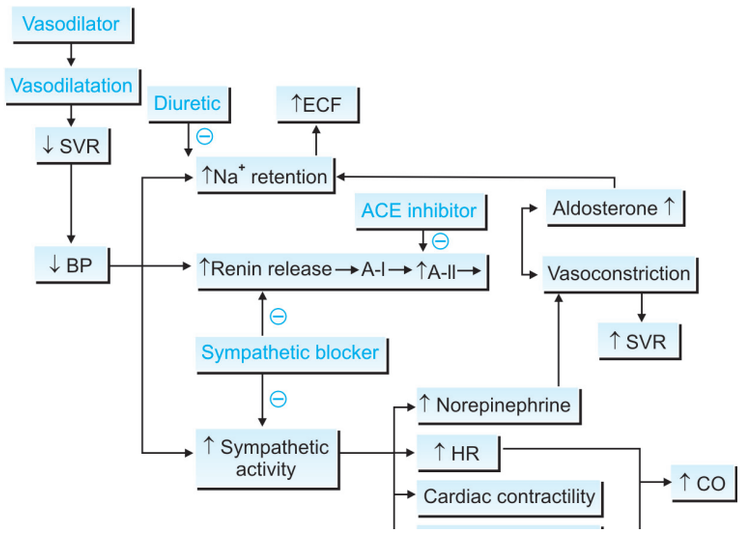

Fig. 18.6: The mechanism of secretion of renin and angiotensin

Inhibition of Renin-Angiotensin System

The inhibition of renin-angiotensin system is the main stay of the management of hypertension and its complication. It can be achieved by:

i. Decreasing the release of renin: This can be achieved by sympathetic blockers such as β-blockers and other adrenergic neuron blockers.
ii. Blocking the action of renin: This can be achieved by renin inhibitory peptides or renin specific antibodies. They interfere the rate limiting step producing A-I from angiotensinogen. But, they are not used clinically (Fig. 18.6).
iii. Blocking the action of angiotensin converting enzyme: These are called the angiotensin converting enzyme inhibitor (ACE-inhibitor) and prevent the generation of active principle A-II from A-I. These group of drugs are used extensively in clinical practice.
iv. Blocking the angiotensin receptor (AT_1): They block the action of A-II on the target cells.
v. Blocking the action of aldosterone: They block the mineralocorticoid receptors.

Angiotensin-Converting Enzyme Inhibitors (ACE-Inhibitors)

In 1960, Ferreria and his colleagues observed that the venom of pit vipers have some factors which increases the responses to bradykinin. These factors are called the bradykinin potentiating factors and reduce the BP. Following the discovery of these factors the teprotide was synthesised. It was a nonpeptide and inhibits the generation of A-II from A-I. It was found to lower BP in many patients with essential hypertension. It also exerts beneficial effect in patients with heart failure. But it had limitations of parenteral administration and brief duration of action. So, these observation lead to the search for other ACE inhibitor which could be active orally.

Then, in 1977, came captopril which was orally active dipeptide and had quickly gained wide usage. After that many ACE inhibitors was synthesised and out of that only six are currently available in India. These are captopril, lisinopril, enalapril, ramipril, benazepril, perindopril. But many others ACE inhibitors are also marketed in other countries such as quinapril, fosinopril, cilazapril, zofenopril etc. However, among all these the captopril is described as prototype, because most of its effects are common to all ACE inhibitors (Fig. 18.7).

Captopril

Chemically it is a sulphydryl containing dipeptide. It blocks the pressure action of A-I, but not that of A-II. It does not also block the AT_1 receptors. The main pharmacological action of captopril is reduction of BP by inhibiting the conversion of A-I to A-II. But the magnitude of this response in an individuals depends on the Na^+ status and the renin angiotensin activity. In individual with dietary Na^+ restriction and diuretics the response of ACE inhibitor is higher. It causes greater fall of BP in renovascular, accelerated and malignant hypertension.

Captopril decreases the SVR. It causes the arterioles to dilate. The compliance of large arteries are increased. Both the systolic and diastolic pressure fall and cardiac output increases. CVS reflexes are not impaired due to any ACE inhibitor and there is little dilatation of the capacitance vessels. So, there is no postural hypotension. The renal blood flow is not reduced, even when BP falls substantially. This is due to much dilatation of the renal vessels as A-II markedly constricts it. The coronary and cerebral blood flow are also not reduced by any ACE inhibitors or captopril.

Since, the conversion of A-I to A-II is blocked by captopril, so the plasma renin and A-I level is increased. A-I then

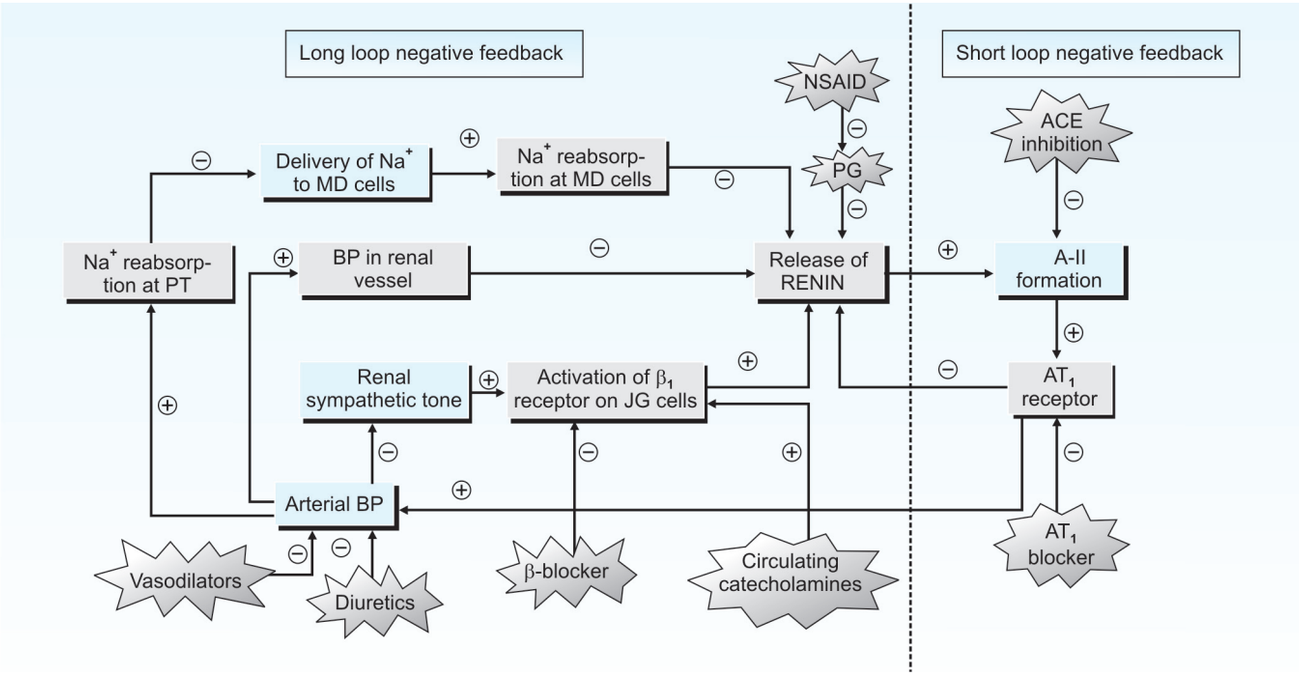

Fig. 18.7: The site of action of different antihypertensive

is redirected through another metabolic route, resulting in the increased production of peptides such as angiotensin (1 to 7). Some thought that it also contribute to the hypotensive effect of ACE inhibitors. It does not interfere the physiological secretion of mineralocorticoids (aldosterone) under the influence of ACTH, but abolish the reflex changes in plasma aldosterone mediated by A-II.

There is no strong reason to favour one ACE inhibitor over another. Because all the ACE inhibitors have (i) the same mechanism of action, (ii) the similar therapeutic indication and (iii) the same adverse effects profile and contraindications. But, they only differ in respect to the following three properties. These are the: (i) potency, (ii) whether ACE inhibition is primarily due to drug itself or to conversion of a prodrug to an active metabolites and (iii) pharmacokinetics.

Regarding the pharmacokinetics, all the ACE inhibitors differ markedly among themselves regarding their absorption, tissue distribution and elimination. This characteristic is exploited clinically to inhibit some local renin-angiotensin systems while leaving other relatively intact. Except fosinopril and spirapril which are eliminated by liver and kidney by equal proportion, other ACE inhibitors are eli-minated predominantly by the kidney. Therefore, the impaired renal function significantly reduces the plasma elimination of most ACE inhibitors. So, doses of these ACE inhibitors should be decreased in patients with renal failure. Increased plasma renin activity makes the patient hypersensitive to hypotension, induced by ACE inhibitor. So, the initial dose of it should be reduced in patients who have high plasma renin level such as salt depletion, heart failure, etc.

Captopril is well-absorbed orally (70%), but the presence of food is stomach reduces the bioavailability of it. It is mainly excreted unchanged through urine. Plasma half-life is about 2 hours. But, action usually lasts for 6 to 12 hours.

The usual doses of captopril is 25 mg twice daily which is increases gradually upto 50 mg thrice daily according to the response. Sometimes, it is wise to start with small doses such as 6.25 mg twice daily in such patients who are in diuretics and in CHF patients to avoid marked fall in BP initially (Table 18.2).

Adverse effects

The profile of adverse effect of all ACE inhibitors are same and serious untoward reactions are rare. Captopril is well-tolerated by most of the patients, especially if the daily dose is kept below 150 mg. Metabolic side effects of captopril are usually not encountered, even during

Table: 18.2: ACE inhibitor

Specially suited for:

1. Young, physically, intellectually and sexually active person
2. Left ventricular hypertrophy, LV systolic dysfunction
3. Diabetics, gout, dyslipidaemia
4. Nephropathy, high renin cases
5. Coexisting angina, peripheral vascular diseases
6. Potential MI
7. Chronic heart failure

Contraindicated

1. Pregnancy
2. Renal artery stenosis
3. Dry cough (relative)
4. Hyperkalaemia

prolonged use. All ACE inhibitors like captopril improve the insulin sensitivity in patients who are suffering from insulin resistance. They decrease the cholesterol and lipoprotein level in renal disease patients. The drug does not alter the plasma uric acid and Ca^{2+} level.

Hypotension

Sometimes, sharp fall of BP occurs after initiations of captopril or any ACE inhibitor therapy. This is particularly true for patients with persistant high renin activity such as diuretic treated and CHF.

Hyperkalaemia

Captopril or any ACE inhibitors may produce hyperkalaemia particularly in patients who is taking K^+ sparing diuretics, K^+ supplement, renal insufficiency, taking β-blocker or NSAID. But, significant retention of K^+ is rarely encountered in patients with normal renal function and who is not taking any medications.

Cough

In 10 to 20% patient captopril or any other ACE inhibitor may produce troublesome cough. It occurs within 1 to 8 weeks and is not dose related. Sometimes, the cough is so intense that it requires discontinuation of therapy. However, once the therapy is stopped, the cough disappears. This cough usually is due to accumulation of bradykinin and/or substance P and/or prostaglandin in lungs. Thromboxane antagonism reduces this captopril induced cough.

Acute renal failure

Sometimes, any ACE inhibitor or captopril may induce acute renal failure in patients with bilateral renal artery stenosis or renal stenosis in single remaining kidney or heart failure or dehydration. Normally A-II constricts the efferent arteriole and maintains adequate glomerular filtration when renal perfusion pressure is low. So, in the presence of above mentioned causes ACE inhibitors precipitate the acute renal failure.

Other less serious side effects

These are rashes, urticaria, angioedema, granulocytopaenia, proteinuria, headache, dizziness, nausea, vomiting, etc.

Foetal damage

ACE inhibitors are not teratogenic in first trimester of pregnancy. But, if it is continued during the second and third trimester of pregnancy, ACE inhibitors may produce different foetal anomalies such as IUGR, pulmonary hypoplasia, oligohydramnios, IUD, etc. These foetal anomalies are due to foetal hypotension. So, while ACE inhibitors is not contraindicated during reproductive age, but should be stopped once pregnancy is diagnosed.

FACT FILE- I

Advantages of ACE inhibitor as antihypertensive are:

1. It is safe for diabetic, asthmatic and peripheral vascular disease patient.
2. Renal blood flow is well maintained.
3. It is not associated with postural hypotension and electrolyte disturbances.
4. It prevents secondary hyperaldosteronism.
5. It prevents K^+ loss due to diuretics.
6. There is no rebound hypertension after withdrawal of ACE inhibitors.
7. It does not cause hyperuricaemia.
8. It does not produce any deleterious effect on plasma lipid profile.
9. It reverses left ventricular hypertrophy.
10. It also reverses the increased wall to lumen ratio of blood vessels that occurs in hypertensive patients.

Therapeutic Uses of ACE Inhibitors

Hypertension

In hypertension, ACE inhibitors lower the mean, systolic and diastolic blood pressure and systemic vascular resistance, except in case of primary aldosteronism. The change in the level of BP correlates well with the plasma renin-anginotensin level. There is variable vasodilator effect of ACE inhibitors at different vascular beds. But, kidney is the only exception where there is definite vasodilation and increased renal blood flow. Increased renal blood flow does not increase glomerular filtration rate. Because both afferent and efferent vessels dilates and effective filtration pressure does not increase. Blood flow in cerebral and coronary beds are usually well-maintained due to their powerful autoregulatory mechanism. Besides causing systemic arteriolar dilatation, ACE inhibitors increase the compliance of large arteries, which contributes to the reduction of systolic blood pressure and after load (Fact file- I).

Stroke volume and cardiac output increases in uncompromised heart. Baroreceptor and cardiovascular reflexes are well maintained. Still with substantial lowering of BP, the heart rate and concentrations of catecholamines in plasma increase only slightly if at all. This perhaps reflects slight alteration of baroreceptors function with increased arterial compliance and the loss of normal toxic influence of angiotensin II on the sympathetic nervous system.

Aldosterone secretion is normally reduced in hypertensive individuals, but is not seriously impaired by ACE inhibitors. Excessive retention of K^+ is encountered by ACE inhibitors only in patients who is taking supplemental K^+, renal impairment or taking other medications that reduce K^+ excretion. It has synergistic action with Ca^{2+} channel blocker, β-adrenergic receptor blocker or diuretics. Diuretics, in particular, augment the antihypertensive response of ACE inhibitors by rendering the patient's blood pressure renin-dependent.

All we have to consider that the goal of antihypertensive therapy (Table 18.3) is not just the lowering of blood pressure, but to diminish the patient's overall risk from cardiovascular complication. ACE inhibitors reduce this incidence of cardiac complication in hypertensive patients more than do other antihypertensive agents such as diuretics, β-blockers, Ca^{2+} channel blockers, etc. This is because other agents have their adverse metabolic effects and

Table 18.3: Pharmacokinetics of different ACE inhibitors

	Captopril	*Enalapril*	*Perindopril*	*Lisinopril*	*Ramipril*
Chemical structure	Sulphydryl	Carboxyl	Carboxyl	Carboxyl	Carboxyl

due to their inability to reverse the structural changes of heart and/or blood vessels that may be mediated by the circulatory catecholamines and/or renin-angiotensin system.

ACE inhibitors in left ventricular systolic dysfunction

The left ventricular systolic dysfunction ranges from asymptomatic reduction in systolic performance (cardiac output) to symptomatic severe impairment of left ventricular systolic function (Grade IV LVF). ACE inhibitors should be given to all these patients whether or not they are experiencing symptoms of overt heart failure. Inhibition of renin-angiotensin-aldosterone system by ACE inhibitors in patients with systolic dysfunction prevents or delays the progression of heart failure, decrease the incidence of sudden death and myocardial infarction.

ACE inhibitors commonly reduces the afterload and systolic tension. Both the cardiac output and cardiac index increase, as do the indices of stroke work and stroke volume in heart failure. Heart rate generally is reduced. This is due to the improvement of failure and withdrawal of sympathetic over activity. The excess volume of body fluids contracts, which reduces the excess venous return to right heart. This reduction of preload results from venodilation and increased capacity of the venous bed. The ACE inhibitors also reduce the pulmonary arterial pressure, PCWP, left atrial pressure and left ventricular filling volumes and pressure etc. Consequently, the preload and diastolic wall stress are diminished. The better haemodynamic performance caused by ACE inhibitors results in increased exercise tolerance and suppression of sympathetic nervous system. However, the role of ACE inhibitors on the diastolic dysfunction of left ventricle is still uncertain.

The ACE inhibitors reduce the overall mortality when the treatment is started during the peri-infarction period. Unless contraindicated (e.g. cardiogenic shock, severe hypotension) ACE inhibitors should be started immediately during the acute phase of myocardial infarction.

Myocardial infarction

ACE inhibitors definitely reduces the early as well as the long-term mortality from MI. However, this is true if it is administered while MI is evolving and then continued for another 6 weeks. But, during treatment it should be noted that hypotension should be avoided. ACE inhibitor is beneficial for MI, irrespective of the presence or absence of ventricular systolic dysfunction.

Diabetic nephropathy

ACE inhibitors also help to prevent or delay the progress of an end stage renal disease in insulin or noninsulin dependent diabetes. Albuminuria remains stable during therapy. Those patients who are treated with ACE-inhibitors require less dialysis, and have higher creatinine clearance. They have longer life expectancy also. So, all the patients suffering from diabetic nephropathy needs ACE inhibitors therapy, whether they are hypertensive or not.

MANAGEMENT OF HYPERTENSIVE EMERGENCY

Hypertensive emergency requires immediate reduction of BP to prevent or to minimise the end organ damage. It needs to be distinguished from severe hypertension or urgency where there is no possibility of acute end organ damage. Because aggressive therapy for hypertensive emergency and sudden reduction of blood pressure may result in potentially hazardous reduction in myocardial and cerebral perfusion with more end organ damage. So, the goal of treatment is to minimise the end organ damage due to sudden high rise of BP while preventing the complications due to sudden lowering of BP. Therefore, hypertensive emergency requires immediate lowering of BP in a controlled and predictable manner. The goal is to lower the mean arterial blood pressure (MAP) by approximately 20 to 25% of the previous value in the first hour, while maintaining adequate perfusion to the vital organs. Dropping of BP too quickly or too much can worsen the target end organ damage. With cerebral ischaemia when autoregulation is lost, then cerebral blood flow is directly proportional to the systemic blood pressure. Therefore, if BP is lowered too much, cerebral perfusion pressure in

ischaemic areas is also lowered, risking the further damage.

The recommendation for reduction of BP during management of hypertensive emergency are:

i. It should be reduced over 60 to 90 minutes to a mean BP of 120 mm of Hg
ii. 20 to 30% reduction in mean arterial pressure (MAP = diastolic BP + 2/3 pulse pressure)
iii. Reduction of diastolic pressure by one-third, but not to a level below 95 mm of Hg.

This goal should also be modified (i.e. more gradual reduction of BP) in those patients who are more susceptible to loss of cerebral blood flow (CBF), e.g. the elderly, patients with chronic hypertension and patients with atherosclerotic cerebrovascular disease.

The ideal drug for treatment of hypertensive emergency should have the following characteristics.

i. Rapid onset (controlled not precipitous) and rapid cessation of clinical effects.
ii. Predictable dose response relationship.
iii. Restoration of cerebral autoregu-lation.
iv. Lack of side effects.
v. Convenience to use.

Reasons against the use of oral agents in the management of hypertensive emergency include:

i. Unpredictable effect on MAP,
ii. Unpredictable time to peak effect,
iii. Higher failure rate than with parenteral therapy,
iv. Lack of ease in titration.

In addition, there is no less importance for the patient to be monitored vigorouslywith oral therapy, compared with the intravenous therapy. Institution of appropriate oral therapy may be required once hypertension has been controlled by parenteral agents and it is gradually withdrawn. The drugs used for control of hypertensive emergency are:

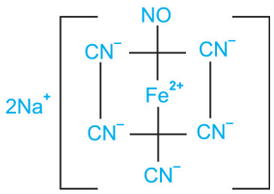

Fig. 18.8: Sodium nitroprusside

Sodium Nitroprusside

It is used primarily to treat hypertensive emergency. But the drug can be used in many situations where the, short-term reduction of cardiac preload and/or afterload is required. So, nitroprusside is used to:

i. Lower BP during acute aortic dis-section,
ii. Increase CO in congestive heart failure,
iii. Decrease myocardial O_2 demand after acute myocardial infarction,
iv. Induce controlled hypotension during anaesthesia (Fig. 18.8).

β-adrenergic receptor blocker should also be used along with nitroprusside. This is because:

i. It counteract the tachycardia due to hypotension induced by nitroprusside,
ii. Reduction of BP by nitroprusside alone can increase the rate of rise of pressure in the aorta as a result of increased myocardial contractility, thereby enhancing the propagation of dissection.

Mechanism of action

Na-nitroprusside is metabolised by the cells of the wall of the blood vessels to its active metabolite which is known as nitric oxide (NO). Then, this NO activates the guanylyl cyclase to form cyclic GMP which in turn cause vasodilatation. Thus, the mechanism of action of nitroprusside is same as nitroglycerin. But the metabolic activation of nitroprusside is catalysed by a different nitric oxide (NO) generating system which is not used for nitroglycerin. Hence, this probably

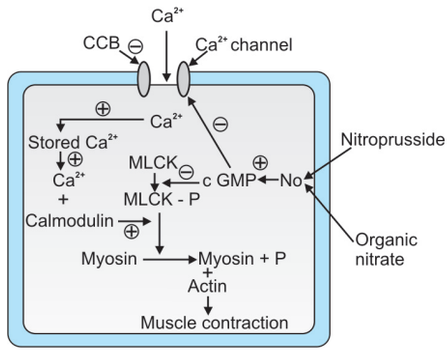

Fig. 18.9: Mechanism of action of calcium channel blocker (CCB), organic nitrates and nitroprusside. MLCK = Myosin light chain kinase

accounts for the difference in the potency of these drugs at different vascular sites. But, the fact is that tolerance develops to nitroglycerin, whereas not to nitroprusside (Fig. 18.9).

Pharmacological effects

Nitroprusside dilates both the arterioles and venules. Thus, the total haemodynamic response and CO produced by Na-nitroprusside depends on the combination of the reduction of venous pooling (↓preload) and reduction of arterial impedance (↓ afterload). In patient with normal left ventricular function, the effect of reduction of venous pooling which decreases the cardiac output is more than the effect of the reduction of afterload which increase CO. Thus, ultimately CO tends to fall. In contrast, for patient with severe impaired left ventricular systolic and diastolic function, the reduction of arterial impedence or after load is the predominant effect which leads to the rise in CO. Reduction of preload is also beneficial in this group of patient.

Nitroprusside is a nonselective vasodilator. So, the regional distribution of blood flow is little affected by this drug. Renal blood flow and glomerular filtration is maintained by nitroprusside. Plasma renin activity is increased due to hypotension and subsequent sympathetic stimulation. Unlike hydralazine, diazoxide, minoxidil

and other arteriolar vasodilators, the sodium nitroprusside usually causes only a modest increase in heart rate in respect to the reduction of BP. But, still there is an overall reduction in myocardial O_2 demand.

Absorption, metabolism and excretion

Onset of action of IV nitroprusside is 30 seconds. Peak hypotensive effect occurs within 2 minutes. When infusion is stopped, hypotensive effect disappears within 3 minutes. It is an unstable molecule and decomposes under alkaline conditions and when is exposed to light. Metabolism of nitroprusside occurs in the smooth muscle cells of blood vessel and is initiated by its reduction to cyanide and NO molecule. Cyanide is further metabolised in liver to thiocyanate and almost is eliminated through urine.

Metabolism of nitroprusside (NP)

$NP + OHbFe^{2+} \rightarrow NP^{-} + OHbFe^{3+}$

$NP^{-} \rightarrow$ 5 types CN^{-} + NO

i. $CN^{-} + HbFe^{3+} \rightarrow CNHbFe^{2+}$
ii. CN^{-} + Thiosulphate → Thiocyanate
iii. CN^{-} + Cytochrome oxidase → Cyanide toxicity

After injection, NP enter the RBC → it receives an electron from iron of oxyhaemoglobin ($OHbFe^{2+}$) → methaemoglobin ($OHbFe^{3+}$) and unstable nitroprusside radicle (NP^{-}) is formed → unstable NP^{-} spontaneously breaks into five cyanide ion (CN^{-}) and active NO group → the CN^{-} ion may involve in three reactions: (i) can bind with methaemoglobin to form cyanmethaemoglobin, (ii) can undergo in reaction with thiosulphate forming thiocyanate in liver and kidney, (iii) can bind with tissue cytochrome oxidase system, interferring normal oxygen utilisation.

Toxicity

The main side effect of nitroprusside is sudden excessive vasodilatation and severe hypotension. Hence, continuous close monitoring of BP is mandatory. So the use of sophisticated variable rate infusion pump will prevent this excessive haemodynamic response of the drug. Toxicity may also result from excessive conversion of nitroprusside to cyanide and thiocyanate. Excessive accumulation of cyanide, leading to severe lactic acidosis can occur, if sodium nitroprusside is infused at a rate of greater than 5 µg/Kg/min. But, concomitant use of sodium thiosulfate can prevent this accumulation of cyanide in a patient who receives more than usual doses of sodium nitroprusside. This is because the limiting factor in the metabolism of cyanide is the availability of substrate like thiosulfate. The risk of cyanide toxicity also increases when the nitroprusside is infused for more than 24 to 48 hours and especially if renal function is impaired. Plasma concentration of cyanide also should be monitored during prolonged infusion of nitroprusside and should not be allowed to exceed more than 0.1 mg/ml.

Nitroprusside may worsen the arterial hypoxaemia in patient who is suffering from chronic obstructive pulmonary disease. Because the drug interferes with the compensatory hypoxic pulmonary vasoconstriction reflex and therefore, promotes the mismatching of ventilation with perfusion. Rebound hypertension may also occur after abrupt cessation of short-term nitroprusside infusion. This may be due to the persistently elevated concentration of renin in plasma caused by hypotension.

Dose

Nitroprusside should be used in variable, controlled, continuous infusion according to patient's response. The usual dose of it ranges from 0·25 to 1·50 µg/Kg/min.

Organic Nitrites and Nitrates

The organic nitrates are the ester of nitric acid ($-C-O-NO_2$). On the otherhand, the organic nitrites are the ester of nitrous acid ($-C-O-NO$). The common organic nitrites and nitrates which are clinically used are: Amyl nitrite, nitroglycerine (glyceryl trinitrate), isosorbide dinitrate, isosorbide-5-mononitrate, erythrityl tetranitrate, etc. Glyceryl trinitrate is widely and officially accepted as nitroglycerin which has an explosive property. But, actually it is not nitrocompound. Because nitrocompound possess carbon-nitrogen bonds ($C-NO_2$) and is highly explosive. So, glyceryl trinitrate is erroneously called as nitroglycerin. For their actions the organic nitrates and nitrites are denitrated to release NO by nitric oxide synthetases. This NO synthetases are found in vascular endothelial and smooth muscle cells as well as in other types of cells throughout our body, including CNS. When the activity of NO synthetase and the production of NO is reduced, the individual suffer from atherosclerosis. This nitric oxide activates cyclic GMP in vascular smooth muscle cells and produce vasodilation like nitroprusside. So, the organic nitrates and nitrites are called nitrovasodilators. Normally, in vascular endothelial and smooth muscle cells endogenous NO is also formed by nitric oxide synthases, by converting L-arginine to citrulline.

Another organic nitrite such as amyl nitrite is highly volatile liquid and is administered by inhalation. This is because, usually the low molecular weight nitroglycerins are oily liquids and mode-rately volatile. Erythrityl tetranitrate, pentaerythritol tetranitrate, isosorbide dinitrate are solids and of high molecular weight without inert carrier such as lactose. Pure nitorglycerin is highly explosive.

Mechanism of action of nitrates and nitrites

The organic nitrites, nitrates, nitrosocompounds and a variety of other nitrogen-oxide containing substances, including nitroprusside, etc. lead to the formation of reactive free radical such as nitric oxide (NO). This NO activates cytosolic guanylyl cyclase → increased cGMP → inhibition of cGMP dependent protein kinase → dephosphorylation of myosin light chain → relaxation →

vasodilation. Phosphorylation of the myosin light chain regulates and is responsible for the maintenance of contractile state of the smooth muscle of vessels. Raised intracellular cGMP may also reduces the Ca^{2+} entry into the cells and contribute relaxation smooth of muscles of vends.

Pharmacological action

Low therapeutic concentrations of nitroglycerin produce predominantly venodilation and reduce preload. Thus reduction of venous pooling causes reduction of end diastolic ventricular volume (Fig. 18.10) and pressure and reduction of CO. Whereas the effects of nitroglycerin on arterioles are minimal, causing little change in systemic vascular resistance. Hence, systemic arterial pressure may fall slightly. Pulmonary vascular resistance also fall slightly. As preload falls much more than the afterload, so CO falls. The doses of nitroglycerin which do not alter systemic arterial pressure, often produce arterial dilation of face, neck and meningeal vessels, resulting in flushing and headache. Enzymes which converts nitrates to NO is abundant in venous smooth muscle compared to arterial smooth muscle cells. This is the cause of predominant venoselective properties of nitrates. On the otherhand, higher doses of organic nitrates cause both the venous and arteriolar dilation which leads to the reduction of both systolic and diastolic blood pressure and increase or decrease of CO, according to the balance between the degree of reduction of preload and afterload. The resultant compensatory tachycardia and peripheral arteriolar vasoconstriction due to reduction of CO tend to restore the systemic vascular resistance. But, this is superimposed by sustained venous pooling. Thus, coronary blood flow may increase transiently as a result of coronary vasodilation. But it subsequently decreases if CO and BP fall sufficiently, causing severe reduction of coronary perfusion pressure.

Structure of organic nitrite and nitrates	Dose and route of administration
 Amyl nitrite	By inhalation 0·3 ml for each inhalation
 Nitroglycerine	SLT—0.3 to 0.6 mg as and when needed LS—0.4 mg per spray SRC—3 to 9 mg two to three times daily TDP-1 disc (2.5 to 15 mg twice daily) (Glyceryl trinitrate)
 Erythrityl Tetranitrate	SLT—5 to 10 mg as and when needed OT—10 mg two to three times daily
 Isosorbide dinitrate	SLT—2.5 to 5 mg every 2 to 3 hours OT—5 to 10 mg every 2 to 3 hours SRC—40 to 80 every 8 hours
 Isosorbide-5-mononitrate	SLT-10 to 40 mg two to three times daily. SRC-60 mg twice daily.

Fig. 18.10: The chemical structure of different organic nitrates and nitrites

Coronary blood flow

Ischaemia is the most powerful stimulus for coronary vasodilation. Regional coronary blood flow is adjusted by the local autoregulatory mechanism. Thus, blood flow is directed from the nonischaemic nondilating vessels to the dilated ischaemic areas. Organic nitrates does not impair this autoregulation. The small vessels which are responsible for about 90% of the overall coronary vascular resistance, nitrates does not dilate these small coronary arterioles. Therefore, organic nitrates do not directly increase the myocardial O_2 supply. Vessels larger than 200 µm in diameter which are responsible for 10% of overall coronary vascular resistance are highly responsive to the organic nitrates. But vessels less than 100 µm are not or minimally responsive. Thus, organic nitrates are only able to cause dilations and prevents constriction of large epicardial vessels. In fact, nitrates do not increase the total coronary blood flow in angina patients. However, it causes only redistribution of blood flow when coronary circulation is partially occluded and area is ischaemic. Collateral flow to ischaemic regions also is increased by nitrates. On the otherhand, due to redistribution there is disproportionate reduction in blood flow to the subendocardial regions of the heart which are subjected to the greatest extravascular compression during systole. Hence, practically, an important indirect mechanism for maintaining subendocardial blood flow is the nitroglycerin induced reduction in intracavitary systolic and diastolic pressure by reducing the preload that oppose the blood flow to subendocardium. Thus, indirectly the organic nitrates decrease the myocardial oxygen requirement. Increased blood flow in ischaemic regions are balanced by decrease flow in nonischaemic areas. An overall increase in coronary blood flow does not occur. Dilation of cardiac veins may result in an improvement in the perfusion of coronary microcirculation. In patients, suffering from angina due to coronary spasm, the capability of organic nitrates to dilate the epicardial coronary arteries and particularly at the regions which are affected by spasm may be the primary mechanism by which they are benefited.

Effect on myocardial O_2 demand

Organic nitrates reduce the myocardial O_2 demand. O_2 demand is directly proportional to the ventricular wall tension, heart rate and contractility of myocardium. Ventricular wall tension is again directly proportional with preload and afterload. Because according to Laplace's law:

Tension ∝ Pressure × Radius.

Preload is determined by the end diastolic ventricular filling, volume and pressure. Increased venous capacitance with nitrates decreases venous return to the heart and decreases ventricular end diastolic volume which in turn decreases the wall tension and O_2 consumption. Reduction of preload also increases the pressure gradient for perfusion across the ventricular wall and favours the subendocardial perfusion.

Afterload is the impedance against which the left ventricle contracts and ejects its contents. Thus, it is related to the systemic vascular resistance. Decrease of systemic vascular resistance by organic nitrites and nitrates reduces the afterload and thus reduces the left ventricular wall tension during myocardial contraction. Hence, myocardial O_2 demand is also reduced. An interesting finding is that angina occurs with or without nitroglycerin at the same value of the 'triple product' (aortic pressure × heart rate × ejection time) which is porportional to myocardial O_2 consumption. It suggests that beneficial effects of nitroglycerin is the result of reduced cardiac O_2 demand, rather than an increase in the delivery of O_2 to ischaemic regions of myocardium. But, it does not exclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin where vasospasm is the cause of angina. Organic nitrates have no direct positive inotropic or chronotropic effect on heart, but may affect indirectly. The main therapeutic uses of organic nitrites and nitrates are: angina, congestive heart failure, unstable angina, myocardial infarction, variant (Prinzmetal's) angina, etc.

Absorption, fate and excretion

The lipid soluble organic nitrates are metabolised to water soluble inorganic nitrates and denitrated compounds by nitrate reductase enzyme in the liver. The denitrated metabolites are less potent vasodilators than parent compounds. Since, the liver has enormous capacity for metabolism of organic nitrates, so oral bioavailability of it is much less.

Velocity of metabolism of erythrityl tetranitrate is 3 times faster than nitroglycerin. While isosorbide dinitrate and pentaerythritol tetranitrate are metabolised at the rate of one-sixth and one-tenth of that of nitroglycerin. After sublingual administration, peak concentration of nitroglycerin in plasma reaches within 3 to 4 minutes and half-life is 1 to 3 minutes. Onset of action is more rapid if nitroglycerin is delivered by sublingual spray. Sublingual administration of isosorbide dinitrate produces maximal concentration of drug in plasma by 6 minutes and half-life is 45 minutes. Its primary initial metabolites are isosorbide-2-mononitrate and isosorbide-5-mononitrate which have longer half-life (3 to 6 hours) and these are presumed to be responsible for the therapeutic efficacy and prolonged action of the isosorbide dinitrate. Isosorbide-5-mononitrate has excellent bioavailability after oral administration. It does not undergo significant first-pass liver metabolism. So, it has longer half-life and formulated as plain tablet or sustained release capsule, both of which have longer duration of actions.

Doses and route of administration

Nitroglycerin (or glyceryl trinitrate) is the most useful drug among the other organic nitrates that can be given sublingually. It is because of its rapid onset of action, long established efficacy and low cost. The onset of action of initial 0·3 mg nitrogly-cerin, administered through sublingual route is within 1 to 2 minutes and effects do not last for more than 1 hour after its administration. So, it can be used as needed. Other nitrates that can be used sublingually are not more effective and do not appear to be longer acting than nitroglycerin. But they are more expensive.

Oral nitrates are often used to provide prophylaxis against anginal episodes. They are given initially in higher doses to provide effective plasma levels due to first pass hepatic degradation. So, to obtain a continuous plasma therapeutic level of nitroglycerin the sustained release preparation of it should be used better. The effects of this sustained released form of nitroglycerin reach the peak level at 60 to 90 minutes and last for 3 to 6 hours. The dose of isosorbide dinitrate through oral route is 5 to 10 mg for every 2 to 3 hours and through sublingual route is 2.5 to 5 mg for every 2 to 3 hours.

Application of nitroglycerin ointment also relieves angina. The Nitroglycerin disc utilizes nitroglycerin impregnated polymer for transdermal use that permits gradual absorption and a continuous steady plasma nitrate concentration over 24 hours. But, the onset of action of nitroglycerin through this route is slow with peak effects at 1 to 2 hours. IV route for nitroglycerin is only used for the management of hypertensive emergency and the dose is 2.5 to 5 µg/m with increments of 2.5 µg/min.

Ca^{2+} Channel Blockers (CCBs)

Introduction

The Ca^{2+} channel antagonists or blockers are putative it means formerly thought as but not now coronary vasodilators, and possess negative inotropic and chronotropic effects that were not seen with nitroglycerin. The negative inotropic effect of CCB results from the inhibition of excitation and contraction coupling between the action and myosin filaments due to the reduction of movement of Ca^{2+} into the cardiac myocytes. They also alter the plateau phase (phase 2) of cardiac action potential that is due to entry of Ca^{2+} into the cells.

At present, all the CCBs are divided into 5 classes. In all these classes, there are many Ca^{2+} channel antagonists. But, out of them only ten CCBs are approved at present to be used clinically. This is depicted in below:

i. Phenylalkylamine: Verapamil
ii. Benzothiazepine: Diltiazem
iii. Dihydropyridine: Nifedipine, nicardipine, isradipine, amlodipine, felodipine, nimodipine, nisoldipine
iv. Diarylaminopropylamine: Bepridil
v. Diphenylpiperazine: No drug is approved in this class.

Among these, the dihydropyridine class is the most potent Ca^{2+} channel blockers and has proliferated exceptionally.

Practically there are three types of Ca^{2+} channels. These are:

i. Voltage sensitive channel: It acts through changes of membrane potential. Voltage sensitive channel is again subdivided into three types. These are: L-type, T-type and N-type.
ii. Receptor operated channel: These channels are independent of membrane depolarisation. They act through receptors.
iii. Leak channel: Small amounts of Ca^{2+} continuously enter into the resting cell and again are forced out by Ca^{2+} ATPase pump through some tiny channels which are called the leak channel. They does not act by membrane depolarisation or through receptor (Table 18.4).

Mechanism of action

The increased contraction of striated cardiac muscle cells and nonstratiated vascular smooth muscle cells are caused by the increased concentration of cytosolic Ca^{2+}. This increased intracellular or cytosolic concentration of Ca^{2+} is caused by the increased entry of extracellular Ca^{2+} into the cell and release of more Ca^{2+} from the intracellular storage, triggered by the entry of extracellular Ca^{2+}. Hence, cytosolic Ca^{2+} concentration can be increased by influx of Ca^{2+} from outside by various stimuli. Many hormones and neurohormones as stimuli act through receptor operated Ca^{2+} channel and increase Ca^{2+} influx. While some other stimuli such as high extracellular K^+ concentration and depolarising electrical stimuli works through 'voltage sensitive' or 'potential-operated' channels and increase the Ca^{2+} influx. Again small amount of Ca^{2+} continuously leaks into the resting cell through leak channel and are continuously pumped out through 'leak-channel' by Ca^{2+} ATPase pump.

Ca^{2+} channels are made up of many subunit such as α_1, α_2, β, γ, δ. Voltage sensitive Ca^{2+} channels have been divi-ded at least three subtypes based on their conductance and sensitivity to voltage. These are L, N and T subtypes, although P/Q and R type of voltage sensitive channels have also been identified. However, among these, only the L type of Ca^{2+} channel is sensitive to dihydropyridine group of Ca^{2+} channel blockers such as nifedipine. Large divalent cations such as Cd^{2+}, Mn^{2+}, etc. also block a wide range of Ca^{2+} channels. All clinically approved Ca^{2+} channel blockers bind to $\alpha_1$subunit of L-type channel, which is the main channel forming unit.

α_1 subunit share a common topology of four homologus domains (I, II, III, IV) and each of which is composed of six putative transmembrane segments (S_1-S_6). The phenylalkylamine group of Ca^{2+} channel blockers (verapamil) bind to transmembrane segment 6 of domain IV (IVS_6). The benzothiazepine group of Ca^{2+} channel blockers (diltiazem) bind to cytoplasmic bridge between domain III (IIIS) and domain IV (IVS). Dihydropyridine group of Ca^{2+} channel blockers (nifedipine) bind to transmembrane segments of both domain III ($IIIS_6$) and domain IV (IVS_6).

Table 18.4: Voltage sensitive Ca^{2+} channels

	L-type	*T-type*	*N-type*
1. Activation threshold	High	Low	High
2. Inactivation	Slow	Fast	Medium
3. Location and function	(i) Cardiac and smooth muscle excitation and contraction	(i) SA node pacemaker activity	(i) CNS, sympathetic and myenteric plexuses—release of transmitter
	(ii) SA and AV node—rate and conduction	(ii) Thalamus and other neurons	
	(iii) Endocrine cells hormone release	(iii) Endocrine cells—release of hormone	
	(iv) Neurons—release of transmitter		

Pharmacological properties

Action on vascular tissue

Although, there is some involvement of Na^+ current for depolarisation of vascular smooth muscle, but it primarily depends on influx of Ca^{2+} current which occurs through the voltage sensitive or receptor operated channel. Due to depolarisation these Ca^{2+} channels results in the hydrolysis of membrane bound phosphatidylinositol with the formation of inositol triphosphate which acts as a second messenger to release intracellular Ca^{2+} from sarcoplasmic reticulum. Then this increased intracellular Ca^{2+} binds to protein calmodulin $\rightarrow$ activates myosin light-chain kinase $-$ phosphorylation of light-chain myosin $-$ promotes interaction between actin and myosin $-$ contraction of smooth muscle. Calcium channel blocker (CCB) inhibit these 'voltage sensitive' Ca^{2+} channels in lower concentration than that are required to interfere the receptor operated Ca^{2+}

channels. Thus all the Ca^{2+} channel blockers relax arterial smooth muscle, but have little effects on venous smooth muscle. So, CCBs do not affect the venous return and cardiac preload does not decrease significantly (Table 18.5).

Action on cardiac cell

There is some differences in excitation – contraction coupling between the cardiac muscle cells and the vascular smooth muscle cells. The difference is that among the two inward currents one is carried through fast Na^+ channel, and the other is carried through the slow Ca^{2+} channel. In SA and AV node, the depolarisation is largely dependent on the movement of Ca^{2+} through this slow Ca^{2+}channel. In the cardiac myocyte troponin inhibit the actin and myosin interaction which cause contraction. Ca^{2+} binds to this troponin and withdraw this inhibition and initiates contraction. CCB thus acts to cause negative inotropic effect by preventing the binding of Ca^{2+} with troponin by decreasing the entry of Ca^{2+} into the cell.

The Pacemaker activity of SA node and atrioventricular conduction is dependent mainly on these slow Ca^{2+} channel. Nifedipine does not affect these slow Ca^{2+} channel. Thus it has no effect on heart rate and conduction through AV node. It mainly acts on peripheral smooth muscle in a dose dependent manner. In contrast, verapamil reduces the slow inward current and the rate of recovery of slow Ca^{2+} channel. Thus, verapamil and diltiazem both reduce the rate of sinus node pacemaker activity and slow the AV conduction. This is the basis for their use in the treatment of SVT. It also causes prolongation of the AV nodal effective refractory period and the prolongation of QT_C interval. In the presence of hypokalaemia, prolongation of QT_C interval may precipitate 'torsades-de-pointes' – a potentially lethal ventricular arrhythmia.

Specially suited for:	
(i)	Asthma, COPD
(ii)	Pregnancy induced hypertension
(iii)	Physically and mentaly active
(iv)	Peripheral vascular disease (e.g. Raynaud's)
(v)	Isolated systolic hypertension
(vi)	Elderly with low renin
To be avoided	
(i)	CHF, conduction defects, sick sinus
(ii)	Receiving β-blockers
(iii)	Prostate enlargement
(iv)	LVH
(v)	Gastro-oesophageal reflux

Haemodynamic effect

CCBs decrease the coronary vascular resistance and increase the coronary blood flow. Among the CCBs nifedipine is more potent systemic vasodilator than verapamil and diltiazem. Nifedipine dilates arterial resistance vessels, but not the veins. This decrease in arterial BP stimulates sympathetic reflexes and produce tachycardia with positive inotropic effect (via sympathetic stimulation). Nifedipine relaxes the vascular smooth muscle at significantly lower concentration than those required for prominent direct effects (negative inotropic) on the heart. Arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved. So heart rate and cardiac output are increased. After oral administration of nifedipine, arterial dilatation increases peripheral blood flow, but venous tone does not change. Because of the lack of myocardial depression and the lack of negative inotropic and chronotropic effect, nifedipine are less effective as monotherapy in stable angina than verapamil, diltiazem and β-blocker.

Therapeutic uses

Hypertension

Essential hypertension is the result of increased systemic vascular resistance, caused by the contraction of vascular smooth muscle mainly arteriole which is dependent on the free intracellular concentration of Ca^{2+}. Therefore all the CCBs decrease the BP by reducing SVR by relaxing the arteriolar smooth muscle. As a consequence of reduction of BP, CCB evokes a baroreceptor mediated sympathetic discharge. So, in case of nifedipine tachycardia ensues. Whereas tachycardia is absent with verapamil and diltiazem because of their direct negative chronotropic effect on the SA node of heart. The increased compensatory adrenergic stimulation of heart serves to counter the hypotensive effect of CCB. So, hypotensive effect of CCB is excessive when used concurrently with β-blocker. As a consequence of peripheral vasodilatation (more arterial dilatation than venodilatation) CCB increase venous return which will result in increased CO, except in case of verapamil and diltiazem which exert substantial negative inotropic effect. This increased venous return is beneficial for normal heart, but not for the patient with diastolic dysfunction due to hypertensive cardiomyopathy who are at increased risk of left ventricular failure. CCB does not improve the diastolic function of ventricle. So, it is not the first choice of treatment in hypertension with left ventricular hypertrophy. All CCBs are equally effective when used alone in the treatment of mild to moderate hypertension, like β-blocker or diuretics.

There is special set of concern regarding the use of CCB in presence of IHD with hypertension. CCB does not improve the survival rate in patient following myocardial infarction. Therefore, it is not the first or second drug of choice in the treatment of hypertension in patient who have a myocardial infarction. Sublingual administration of CCB does not achieve the maximum plasma concentration any more quickly than does oral administration. It is proved that nifedipine is not absorbed by buccal mucosa when used by sublingual route. With saliva it goes to upper GI tract and through stomach it is absorbed. Hence, oral or sublingual administration of standard formulation of

nifedipine (immediate release capsule) as an approach to urgent reduction of blood pressure has been abandoned. Only short acting, and parenterally administered agents should be used in the setting of hypertensive urgencies. In the treatment of emergency of hypertension, there is no place of standard formulation of immediate release capsule of nifedipine with short half-lives through oral route. Because, it causes great oscillation in BP and concurrent surges in sympathetic reflex activity at the interval of each dosage. Thus, nifedipine is a suboptimal choice for treatment of cardiogenic pulmonary oedema. In contrast, nitroprusside causes a greater reduction in left ventricular end diastolic pressure than equipotent doses of nifedipine and nitroprusside's pharmacological effect can be regulated more effectively. So, it is a better choice than CCB for treatment of cardiogenic pulmonary oedema.

CCB is especially effective in low renin hypertension. Long acting dihydropyridine group of CCB reduce the cardiovascular mortality. CCB should not be used in patient with SA and AV nodal abnormalities and overt CF. It can be used in hypertensive patient with asthma, diabetes, and renal dysfunction. Unlike β-blocker, CCB does not alter the exercise tolerance.

Variant angina

Variant angina is due to the reduction of blood flow in myocardium, rather than an increase in O_2 demand. So, CCB protect the variant angina by attenuating the coronary spasm and dilating the coronary artery, rather than alteration in peripheral haemodynamics.

Exertional angina

CCBs also are effective in the treatment of exercise or exertional induced angina. The effectivity of these agents may result from: (i) an increase in the blood flow due to coronary arterial dilation, (ii) from a decrease in myocardial O_2 demand (secondary to a decrease in arterial BP, heart rate and myocardial contractility) or (iii) from both. Numerous double-blind and placebo-controlled studies have shown that these drugs reduce the number of anginal attack and decrease the exercise induced depression of ST segment.

The 'double product' which is calculated from 'heart rate multiplied by systolic BP' is an indirect measure of myocardial O_2 demand. Since, these agents reduce the level of the double product, so O_2 demand is also reduced at a given external work load. The beneficial effect of CCB is primarily is due to the reduction of O_2 demand rather than the increase in coronary blood flow. The concurrent therapy of nifedipine with the β-adrenergic receptor antagonist has proven more effective than when the either agent is given alone. Because the β-blocker suppresses the reflex tachycardia produced by CCBs other than verapamil and diltiazem.

Beta Blockers

These drugs inhibit the adrenergic responses which are only mediated through β-receptors and are used in the treatment of hypertension, ischaemic heart disease, congestive heart failure and certain arrhythmias. All β-blockers are competitive antagonist at the level of these receptor. The β-blocker such as propranolol was first introduced in 1963 and was a great therapeutic breakthrough. Then, it remains the prototype to which the other β-blockers are compared. After that subsequently more and more β-blockers were developed and they are classified by some properties. These are relative affinity of them for β_1 and β_2-receptors, intrinsic sympathomimetic activity, additional blockade of α-adrenergic receptor, difference in lipid solubility, capacity to induce vasodilatation and general pharmacokinetic properties. Some of these characteristic have clinical significance. These help to guide the appropriate choice of β-blockers for an individual patient.

The main effectiveness of β-blocker is found in the treatment of exertional angina. This effectiveness is primarily due to the fall in myocardial O_2 consumption or demand during both rest and exercise and due to some tendency for increased flow toward ischaemic areas. The decrease in O_2 consumption and demand by β-blocker is again primarily due to the negative inotropic, negative chronotropic and reduction of arterial BP during exercise. Not all the action of β-blockers are beneficial for all patients. Because the decrease in HR and force of contraction cause an increase in the systolic ejection period and an increase in left ventricular end diastolic volume with pressure. This tends to increase the O_2 consumption. But the net result of the effect of β-blocker is reduction of O_2 consumption during exercise. On the otherhand, some patients with limited cardiac reserve are dependent on adrenergic stimulation. In these patients the use of β-blocker can result in the profound decrease of left ventricular function. Despite this, β-blocker definitely reduce the mortality in patients with congestive heart failure.

Classification

A. Nonselective (acting both on β_1 and β_2 receptors)
   i. Without intrinsic sympathetic activity: Propranolol, sotalol, timolol, nadolol.
   ii. With intrinsic sympathetic activity: Pindolol, oxprenolol, alprenolol.
   iii. With additional α-blocking property: Labetalol, carvedilol.

(Some β-blockers activate β-receptors in the absence of catecholamines. However, this intrinsic sympathetic activity of these drugs are less than that of full agonist such as isoproterenol. These partial agonistic effect of beta-blockers are said to have the intrinsic sympathetic activity.)

B. Cardioselective (acting only on β_1-receptors): Metoprolol, esmolol, ate-nolol, acebutolol, celiprolol.

C. Selective β_2 blocker: Butoxamine. It has no clinical application.

This classification of β-blockers is not absolute. Because, some β_1 antagonist, even

though selective for this receptor have some affinity for β_2-receptor, e.g. metoprolol, acebutolol, atenolol, etc. Therefore, selectivity of β-blockers is only relative and is lost at high doses. For this reason, though by blocking β_2 receptor, still the selective β_1-blockers have lower propensity to cause bronchoconstriction, these drugs should be avoided if possible in asthmatics. Acebutolol have some intrinsic sympathomimetic activity. Some β-blockers have the property of inverse agonism and decrease basal activation of β-receptor. Celiprolol is a β_1-selective blocker that acts on heart and a β_2 selective agonist that promotes vasodilatation. Some β-blockers have membrane stabilising or antiarrhythmic action, but this appears to be significant only at higher doses.

Pharmacological properties

Cardiovascular system

The β-blocker has relatively little effect on the normal heart at rest. But, it has profound effects when the sympathetic control on heart is dominant, e.g. exercise and stress. At rest usually the tonic stimulation of β-receptor is low, so the effect of β-blocker is correspondingly low or modest (Table 18.6).

But during exercise and stress when the sympathetic system is activated, then the effects of β-blockers are also increased. Therefore, in the presence of β-blocker exercise induced increase in HR and myocardial contractility is attenuated. However, CO is not affected due to decrease in HR. This is because of the increase in stroke volume corresponding with the reduction of heart rate. In hypertension propranolol decrease CO, ↑SVR. This increase in SVR by β-blocker is due to the blockade of peripheral vascular β_2-receptor which dilates the vessels The increased SVR in also due to compensatory increase in sympathetic activity due to lowering of BP and subsequent stimulation of vascular α-adrenergic receptor. Blockade of β_2-receptor also cause the α-receptor to take upper hand and increased SVR. However, labetalol and carvedilol which is both β-blocker and α_1-receptor antagonist maintain CO with greater fall of SVR.

β-blocker reduces the heart rate. This is due to the decrease in automaticity of SA node. The β-blockers also cause slow conduction in atria and AV node and increase in the functional refractory period of AV node. Although it has been thought that these effects are exclusively due to the blockade of β_1-receptor, but β_2 adrenergic receptors in small extent are also likely to be involved in regulating the heart rate in human beings.

The total coronary blood flow is reduced by β-blockers. This is due to the blockade of dilator coronary β-receptor, but these are largely restricted to the subepicardial region. While the subendocardial area which is the chief site of origin of ischaemia in angina is not affected. But, the overall effect of β-blockers in angina patient is improvement of O_2 supply/demand status and exercise tolerance by balancing the reduction of myocardial O_2 demand by decreasing the effect of catecholamine induced heart rate, cardiac contractility and systolic BP and increasing the O_2 demand by increasing the end diastolic pressure and systolic ejection period.

(ii)	Asthma, diabetic
(iii)	Peripheral vascular disease, abnormal lipid profile
(iv)	LVF
(v)	Who need high physical and mental acitivity

As hypertensive agents

The β-blockers do not generally reduce the BP in normotensive patient, but lower it in patient with hypertension. On oral administration there is little acute change in BP. But, on prolonged oral administration BP gradually falls. Initially the total SVR is increased due to the blockade of β-mediate vasodilatation and CO is reduced with net little change in BP. But with continued treatment the resistance vessels gradually adapt to chronically reduced CO, so that SVR decreases and both the systolic and diastolic BP falls. But, all these are hypothesis and the actual cause of reduction of blood pressure by β-blockers is not known.

The probable hypothesis for antihypertensive effects of β-blockers are:

i. Decreased renin release from kidney (β_1 mediated) − Propranolol causes a more marked fall in BP in hypertensive individual who have high or normal plasma renin levels. Such patients respond at relatively lower doses of β-blocker than those with low plasma renin. However, pindolol does not decrease plasma renin actively, but is still an effective antihypertensive.
ii. Inhibition of presynaptic β-adrenergic receptor which cause the release of norepinephrine from sympathetic neurons.
iii. By acting centrally and reducing the sympathetic outflow from brain. However, the β-blockers which cannot penetrate the blood-brain barrier or poorly are also effective antihypertensive.
iv. β-blockers cannot decrease the contractility of vascular smooth muscle. But the long-term use of it can cause reduction of SVR (mechanism is not known), even in the face of persistent reduction of CO and appears to account for much of the antihypertensive effect of these drugs.

Some β-blockers have additional properties that may contribute to their ability to lower BP by peripheral vasodilatation. For example:

a. Labetalol and carvedilol directly block α_1-receptor and ↓SVR.
b. Celiprolol appears to have partial β_2-receptor agonist and cause vasodilatation.
c. Nonadrenergic receptor mediated vasodilatation by some β-blockers also contribute to decrease in SVR.

Respiratory system

In normal individual sympathetic β_2-receptor mediated bronchodilator tone is minimal. So, β-blocker has little effect on normal individual. However, in patient with asthma or COPD, such blockade can lead to life threatening bronchoconstriction. Propranolol which is both β_1 and β_2-receptor blockers is notorious for that. While the β_1 selective antagonist are less likely to increase airway resistance, but should be used very cautiously. Celiprolol with β_1-receptor selectivity and β_2-receptor partial agonism are of potential promise, but still now are of little clinical experience.

Metabolic effects

All the β-blockers modify the metabolism of lipids and carbohydrate. Although, insulin secretion is enhanced by β-adrenergic agonist, but β-blocker only rarely impairs insulin release. So, there is no effect on normal blood sugar. As catecholamines through β-receptor promote glycogenolysis and mobilise glucose from liver in response to hypoglycaemia, so nonselective β-blocker may adversely affect the recovery from hypoglycaemia and should be used cautiously in diabetic patient, receiving insulin. On the otherhand, all the β-blockers mask the tachycardia that is typically seen with hypoglycaemia.

Beta blockers block the adrenergically induced lipolysis and reduce the consequent increase in plasma free fatty acid levels. Plasma triglyceride level and LDL/HDL ratio is increased during β-blocker therapy.

Local anaesthetic effect

Propranolol acts as potent local anaesthetic agent like lignocaine. But, it is not clinically used for this purpose, because of its irritant property.

Uterus

Relaxation of uterus in response to β_2 agonist can be blocked by β-blocker. But the normal uterine activity in absence of B_2 agonist is not significantly affected by these group of drugs.

Individual drug

Labetalol

It is both α_1 and β (β_1+ β_2) receptor blocker. It has two optical isomers. So, the clinical formulation of labetalol contains four diastereomers and each of which displays different relative activities. This explains why the pharmacological activities of this drug is so complex. The resultant effect of the mixture of these isomers include selective blockade of α_1 (as compared to α_2-receptor) and blockade of $\beta_1$and β_2-receptor. There is also some partial agonistic activity on β_2-receptor and inhibition of neuronal uptake of norepinephrine. This is cocaine like effect. The potency of β-blocking mixture effect of labetalol is five fold higher than for α_1-blocker effect of it.

The antagonistic action of labetalol on both α_1 and β-adrenergic receptors result in fall of BP in hypertensive patient. The α_1-recep-tor blocked causes relaxation of arterial smooth muscle and reduction of BP by vasodilation. The β_1-receptor blockade also causes fall in blood pressure. This is caused by blocking of reflex sympathetic stimulation of heart. In addition to these the intrinsic sympathetic activity of labetalol at β_2-receptor may cause vasodilatation and reduction of BP.

It is available in both oral and intravenous form (for hypertensive emergency). The oral preparation of labetalol is completely absorbed from gut and goes through extensive first pass hepatic clearance, with bioavailability of only 20 to 40%. The elimination half-life of clinical formulation of labetalol is 8 hours.

Carvedilol

It is also a nonselective β (β_1+β_2) receptor and selective α_1-receptor antagonist and action is like labetalol. Bioavailability of carvedilol is only 20 to 30% and half-life is 10 hours.

Metoprolol

It is a selective β_1-adrenergic receptor blocker and is devoid of intrinsic sympathetic activity. After oral administration it is completely absorbed and due to first pass hepatic metabolism bioavailability is only 40%. The half-life of metoprolol is 3 to 4 hours. The use of metoprolol is contraindicated in patient with acute myocardial infarction with HR less than 46 per minute, heart block greater than first degree, systolic blood pressure less than 100 mm of Hg and moderate to severe heart failure. It is less likely to worsen the bronchial asthma, but is not entirely safe.

The usual initial dose of metoprolol is 100 mg once daily, but frequently it is used in two divided doses.

Atenolol

Like metoprolol it is also a selective β_1-antagonist, without intrinsic sympathomimetic activity. Atenolol is incompletely absorbed by oral route (50%) and half-life is 5 to 8 hours. The initial dose of it is 50 mg per day, given orally and can be increased to 100 mg per day. But, higher doses are unlikely to provide any greater antihypertensive effect. Atenolol in combination with diuretics is very effective for elderly patients with isolated systolic hypertension.

Esmolol

It is a selective β_1-receptor antagonist or blocker with little if any intrinsic sympathomimetic activity and without any membrane stabilising property. The beauty of esmolol is

that it can be administered intravenously and is of very short duration of action. The half-life of esmolol is 8 minutes. The drug contains an ester linkage and is hydrolysed rapidly by an enzyme named esterase present in erythrocytes. The onset of action of esmolol is rapid. The peak haemodynamic effects occur within 6 to 10 minutes after administration of a loading dose and the effect is substantially attenuated within 20 minutes of stopping the infusion. Strikingly, the esmolol has hypotensive effect on normal individual, but the mechanism of this action is unclear. In urgent setting, where immediate reduction of BP is needed, a partial loading dose is administered which is followed by a continuous infusion of the drug. The half-life of carboxylic acid metabolite of esmolol is much higher than that of the parent compound. So, it can accumulate in prolonged infusion but this metabolite has very low potency. Since, in urgent setting where immediate action is desired, esmolol is very helpful. The typical loading dose of esmolol is 0·5 mg/kg and for maintenance the infusion dose is 0·05 to 0·02 mg/kg/minute.

Therapeutic uses of β-blocker

β-blockers are extensively used in the treatment of hypertension, angina, acute myocardial infarction, congestive heart failure and arrhythmia. The other uses of β-blocker are: Thyrotoxicosis, pheochromocytoma, anxiety, migraine, glaucoma, essential tremor, etc.

Myocardial infarction

The use of β-blocker in the treatment of acute MI and for the prevention of recurrence has been well studied. It is confirmed that when the β-blockers are administered during the early phase of acute MI and is continued for long-term after recovery, then it may decrease the mortality by about 25%. The precise mechanism of it is still not known. But the favourable effects of β-blockers may arise from the decreased myocardial O_2 demand, redistribution of myocardial blood flow and its antiarrhythmic action. Thus, the β-blockers prevent sudden death from ventricular fibrillation during primary or subsequent attack of MI. However, there is likely much less beneficial effect, if the β-blockers are administered only for a short period. So, the β-blockers should be used for prolong period in high risk patients, except those who are not in shock, cardiac failure, have heart rate < 50/minute and with higher than first degree heart block.

Congestive heart failure

It is a very common clinical understanding that β-blockers can worsen or precipitate the congestive heart failure in a compensated patient. On the other hand, from the mechanism of action it is also clear that β-blocker might be effective in the treatment of heart failure. Again, it is clear that some but not all the β-blockers are beneficial in patient with mild to mode-rate heart failure. So, it is interesting to note how a class of a drug can move from being completely contraindicated to being almost the standard of modern care in many heart failure. The proposed mechanism of beneficial effect of β-blockers in heart failure is that the catecholamines are toxic to heart and inhibitions of its effects through β_1-receptor pathway may help to preserve the myocardial function. Again the β-receptor blocker in heart may attenuate cardiac remodelling, which might have deleterious effects on cardiac function. It also prevents the myocardial cell death, caused by continuous activation of β-receptor by sympathetic over activity in heart failure. Some β-blockers have α_1 antagonist properties and improve cardiac function by reducing the after load. So, the key point of the use of β-blocker in CCF is that it should be started with very low doses and should be increased slowly over time, depending on each patient's response.

Arrhythmias

β-blocker is also used in the treatment of arrhythmias. When arrhythmia is associated with hypertension, then α_1-receptor antagonist should be used before β-receptor antagonist. Otherwise, hypertension may be exacerbated. This is because of the loss of β_2-receptor mediated vasodilation.

There are many other therapeutic uses of β-blocker. But, there is no scope for discussion of these uses here.

Hydralazine/Dihydralazine

Hydralazine causes greater decrease of diastolic than systolic blood pressure. Because it is a directly acting arteriolar vasodilator, but without any effect on the venous capacitance vessel and coronary arteries. This hydralazine induced arteriolar dilatation is associated with powerful stimulation of sympathetic nervous system which causes tachycardia, increased myocardial contractility, increased plasma renin activity → increased aldosterone → increased Na^+ and water retention. Although most of the increased sympathetic activity is due to the baroreceptor mediated reflex, still hydralazine may stimulate the release of norepinephrine from sympa-thetic nerve terminals and augment the myocardial contractility directly. Thus, during the use of hydralazine a hyperdynamic circulatory state is present which may precipitate angina. There is no decrease in renal blood flow by hydralazine despite the fall in blood pressure (Fig. 18.11).

The sympathetic stimulation induced by hydralazine increases O_2 demand and precipitates myocardial ischaemia. Hydralazine does not dilate the coronary arteries. In the contrary, coronary arteriolar dilation produced by it may cause a

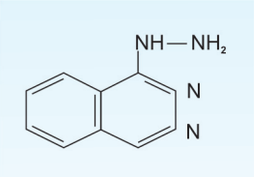

Fig. 18.11: Hydralazine

steal effect of myocardial blood flow away from the ischaemic region. So, hydralazine is contraindicated in hypertensive patient with coronary artery disease and age > 40 years. As it causes salt retention, hydralazine also may produce high output congestive heart failure. Tolerance to the hypotensive action of hydralazine develops, unless diuretics and β-blockers are given individually or together which block the compensatory mechanism.

Because of the preferential dilation of arterioles over veins, the postural hypotension is not a common problem of hydralazine. Although, hydralazine reduces the pulmonary vascular resistance, still the greater increase in CO can cause mild pulmonary hypertension. The exact mechanism of arteriolar smooth muscle relaxation by hydralazine is still not known. The probable mechanism may involve the generation of NO (Nitric Oxide) and stimulation of cGMP.

Hydralazine is also well absorbed orally, but the oral bioavailability is low. The peak hypotensive effect of hydralazine occur within 30 to 120 minutes after oral ingestion and half-life is 1 hour. The chief metabolic pathway of it is acetylation which is genetically determined. So, half of the population metabolise hydralazine rapidly (fast acetylator) and half of the population metabolise it slowly (slow acetylators). Therefore, oral bioavailability of it is higher in slow acetylators. Though the half-life of hydralazine in one hour, still its hypotensive effect lasts longer (12 hours). This is probably because of its persistent presence in the vessel wall.

Two types of toxicity of hydralazine develop. The first one is the extension of pharmacological effect of the drug itself which includes: hypotension, palpitation, angina, flushing, headache, etc. The second one is the autoimmune. So, lupus erythematosus or rheumatoid arthritis like syndrome can develop on prolonged use of hydralazine. Serum sickness, haemolytic anaemia, vasculitis, etc. also can develop and all these are immunological reaction.

Dose

The dose of hydralazine is 25 to 50 mg orally, once daily or thrice daily. For hypertensive emergency 10 to 20 mg of hydralazine is given very slowly through IV route.

Minoxidil

It is very effective in patient who is suffering from severe and some drug resistance forms of hypertension. Minoxidil itself is inactive *in vivo*. But it is metabolised in liver to minoxidil-N-O-sulfate which is the active form of it. Minoxidil sulphate like hydralazine is a very powerful arteriolar dilators but has very little effect on venous capacitance vessels.

The mechanism of action of minoxidil is like that it first activates the ATP modulated K-channel → opening of K^+ channel in arteriolar smooth muscle → K^+ efflux → hyperpolarisation → relaxation of arteriolar smooth muscle.

Like hydralazine the marked arteriolar vasodilation by minoxidil elicits strong compensatory elevated adrenergic activity, causing tachycardia and increased (Fig. 18.12) myocardial contractility with increased myocardial O_2 consumption. Thus, myocardial ischaemia can be induced by minoxidil in patients with coronary artery disease. Like hydralazine, as minoxidil dilates the arteriolar site only, so it increases the venous return to the heart and simultaneously increases CO.

Minoxidil has complex effect on kidney. Though, it dilates the renal vessels, but due to hypotension renal blood flow is actually reduced. As most of the renal dysfunction is due to hypertension, so the treatment of hypertension by minoxidil impress the renal function. The marked arteriolar vasodilation by minoxidil elicits strong compensatory increased sympathetic reflexes (as said before). Therefore, there are increased renin release → marked Na^+ and water retention → oedema and CHF. In case of minoxidil, the retention of salt and water is mainly secondary to reduced renal perfusion pressure and reflex stimulation of renal tubular α-adrenergic receptors. All these effects of minoxidil are like hydralazine and diazoxide. So, like hydralazine to offset these effects it is always practically used along with any loop diuretics and β-blockers. Used in this manner, it is effective even in severe hypertension which is resistant to combination of other drug. Thus, adverse effects of minoxidil is divided into three categories: CVS effects, salt and water retention, and hypertrichosis.

Hypertrichosis occurs in all the patients who receive minoxidil for an extended period and is particularly offensive to female patients. It is due to potassium channel activation. Growth of hair occurs in the face, back, arms and legs. Minoxidil is absorbed very well from GI tract and peak concentration in blood occur 1 hour after an oral administration. But maximum hypotensive effect of it occurs later. Because, this time is needed by liver to transform minoxidil to its active form. Its half-life is 3 to 4 hours, but action persists for 24 hours or more, as it accumulates in the walls of vessels.

Diazoxide (Fig. 18.13)

Like thiazide diuretics, chemically diazoxide is also a benzothiadiazine derivative

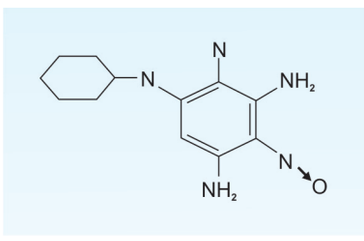

Fig. 18.12: Minoxidil

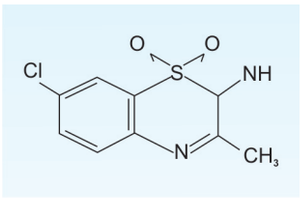

Fig. 18.13: Diazoxide

compound. But, it does not contain any diuretic effect, because it lacks the sulfonamido group. Only by IV injection it promptly decrease the tone of resistance vessels, but without any effect on capacitance vessels. So, though nitroprusside is the drug of choice, diazoxide is also used in the treatment of hypertensive emergency and had a definite place in some situation where accurate delivery of nitroprusside by infusions pump is not available and/or close monitoring of blood pressure is not possible.

Like minoxidil it also causes activation of ATP sensitive K^+ channel → increased influx of K^+ in the cell → hyperpolarisation of arterial smooth muscle cells → relaxation of arterioles. It also produces the reflex activation of sympathetic nervous system and increases the heart rate and myocardial contractility. Hence, it also increases CO. Sympathetic stimulation also cause → increase renin release → increased salt and water retention → increased level of angiotensin II. Thus, all these changes ultimately counter act the antihypertensive effect of diazoxide. Diazoxide increases the coronary blood flow. Renal and cerebral blood flow is maintained by autoregulation.

Although well absorbed orally, still diazoxide is only used intravenously in the treatment of hypertensive emergency. The initial recommended dose of diazoxide is 300 mg IV in bolus. But, this bolus dose sometimes cause severe hypotension with resultant cerebral and cardiovascular damage. So, this hypotension can be prevented by administration of diazoxide in minibolus dose of 50 to 150 mg at intervals of 5 to 15 minutes, until the desired blood pressure level is achieved. After IV bolus dose, the action starts within 30 seconds and maximum effect is achieved within 3 to 5 minutes. Diazoxide also can be given by slow intravenous infusion at a rate of 15 to 30 mg per minute.

The most common side effects of diazoxide are myocardial ischaemia, salt and water retention, and hyperglycaemia. This is because diazoxide inhibits insulin secretion from β-cells of pancreas. The myocardial ischaemia due to diazoxide results from the reflex adrenergic stimulation of heart and the increased flow to nonischaemic regions (steal phenomenon). Salt and water retention by diazoxide also cause increased plasma volume and cardiac load. But the routine use of diuretics with diazoxide in the management of hypertensive emergencies is not recommended, because these patients are frequently of volume depleted. The diazoxide solution is highly alkaline. So, pain and necrosis of tissues occur on extravasation.

It is partly metabolised and partly excreted unchanged through urine. Slow IV injection is less effective because it binds tightly to plasma proteins before bindings to vessels walls. The plasma half-life of diazoxide is 20 to 60 hours. The duration of hypotensive action of this drug is variable. It can be as short as 5 hours or as long as 20 hours.

Diuretics

Classification of diuretics as shown Table 18.7

Table 18.7: Classification of diuretics

A.	Inhibitors of Na^+ - K^+-$2Cl^-$ symporter (diuretics with high efficacy)
	(i) Furosemide, bumetanide (Sulphamoyl derivative)
	(ii) Ethacrynic acid (phenoxyacetic acid derivative)
B.	Inhibitors of Na^+-Cl^- symporter (diuretics with medium efficacy)
	(i) Thiazides: chlorothiazide, hydrochlorothiazide, benzthiazide, polythiazide, clopamide, Hydroflumethazide, etc.
	(ii) Thiazide like: Xipamide, indapamide, chlorthalidone
C.	Miscellaneous (weak efficacy)
	(i) Carbonic anhydrase inhibitor — acetazolamide
	(ii) Potassium sparing: Spironolactone (aldasterone antagomist), triamterene and amiloride (directly inhibiting renal epithelial Na^+ channel)
	(iii) Theophylline
	(iv) Mannitol—osmotic diuretics

Furosemide

It is a Na^+-K^+-$2Cl^-$ symporter (cotransporter) inhibitor and acts on the thick ascending limb (TAL) of the loop of Henle. So, it is also called the loop diuretics. Other diuretics in this group are bumetanide (like furosemide contain sulfonamide moiety), ethycrynic acid (phenoxyacetic acid derivatives) and torsemide (sulfonylurea). Diuretics acting on the Na^+-K^+-$2Cl^-$ symporter at TAL are highly effective, so they are often called as high-ceiling diuretics. This is due to: (i) as 65% of glomerular filtrate is absorbed in proximal tubule, so diuretics acting on proximal tubule have limited efficacy. The TAL reabsorbs most of the reject materials from proximal tubule and has a large reserved reabsorptive capacity. So, the diuretics which act on TAL are highly effective. (ii) Diuretics acting predominantly on post-TAL site have limited efficacy, because only a small percentage of the filtered Na^+ load reaches the post-TAL site and do not posses the reserved reabsorptive capacity.

Mechanism of action

Na^+-K^+-$2Cl^-$ cotransporter is a glycoprotein with 12 membrane spanning domains. It is only responsible for influx of Na^+, K^+ and $2Cl^-$ from the lumen into the epithelial cell of the TAL. This co-transporter captures the free energy from Na^+ electrochemical gradient which is established by the basolateral Na^+ pump and provides an 'uphill' for transport of K^+ and Cl^- into the cell. The presence of K^+ channels in the luminal membrane of the tubular cell provide a pathway for recycling of K^+ between the cell and the lumen. The presence of basolateral Cl^- channels provide a basolateral exit pathway for Cl^-. The movement of K^+ and Cl^- through their channels maintain a electrical gradient which is approximately 10 mV with the lumen positive in respect to the interstitial space. This positive potential difference

repels cations such as Na^+, Ca^{2+} and Mg^{2+} and thereby provides a important driving force for the paracellular flux of these cations into the interstitial space.

Furosemide acts as inhibitors of Na^+-K^+-$2Cl^-$ symporter. It binds to the Cl^- binding site, located on the symporter's transmembrane domain and block the symporter's function. Thus, it brings salt transport in this segment of the nephron to a standstill and causes diuresis. It prevents reabsorption of 25% of the filtered load that is absorbed in TAL. The inhibitors of Na^+-K^+-$2Cl^-$ symporter also inhibit Ca^{2+} and Mg^{2+} reabsorption in TAL by abolishing the transepithelial potential difference which is a dominant driving force for reabsorption of these cations. Thus, furosemide also causes the marked increases in the excretion of Ca^{2+} and Mg^{2+}. Furosemide has weak carbonic anhydrase inhibiting activity and increase the urinary excretion of HCO_3^-. It increases the urinary excretion of K^+ due to the increased delivery of Na^+ load to the distal tubule (increased Na^+ load in the distal tubule enhances the absorption of it and in exchange enhances the excretion of K^+ and H^+). However, K^+ loss by furosemide is less than that with thiazides diuretics. Increased HCO_3^- excretion may cause urinary pH to rise. But the predominant urinary anion is Cl^- whose excretion may increase in response to the action of furosemide. Acidosis does not develop by furosemide or causes minimum distortion of acid-base status. Mild alkalosis develops at high doses (Table 18.8).

Table 18.8: Diuretics

Specially suited for	
(i)	Renal disease with Na^+ retention
(ii)	Elderly, obese, volume overload
(iii)	Isolated systolic hypertension
(iv)	Low renin hypertension
(v)	Low cost
To be avoided	
(i)	Gout, diabetic
(ii)	Pregnancy induced hypertension
(iii)	Abnormal lipid profile

Furosemide tends to raise blood uric acid level by decreasing its renal excretion (increased reabsorption, decreased secretion). Increased uric acid reabsorption in the proximal tubule is the consequence of volume depletion caused by furosemide. However, reduced uric acid secretion is due to the competition between the diuretics and uric acid for their secretion through same secretory mechanism in PT as the furosemide is secreted at the PT, passes down the loop of Henle and acts at the TAL from luminal side. By blocking the active NaCl reabsorption in thick ascending limb, the inhibitors of Na^+-K^+-$2Cl^-$ symporter such as furosemide interfere with the critical step in the mechanism that produces a hypertonic medullary interstitium and help to concentrate the urine. Renal blood flow is transiently increased. There is redistribution of blood flow from outer to midcortical zone. Here prostaglandin may be suspected as the cause. NSAID dimi-nish the diuretic response of loop diuretics, most likely by preventing the prostaglandin mediated increase in RBF. Glomerular filtration rate generally remains unaltered due to compensatory mechanism, despite increased renal blood flow.

Furosemide also acutely increases the systemic venous capacitance and thereby, decreases the left ventricular filling volume and pressure, even before diuresis ensues. This is responsible for the quick relief of symptoms of LVF and pulmonary oedema by furosemide. These actions also may be mediated by prostaglandin. Furosemide also causes hyperglycaemia, but less marked than thiazides diuretics. It also causes hyperuricaemia which is lower than that of thiazide diuretics. The therapeutic uses of furosemide are: systemic oedema, acute LVF, pulmonary oedema, cerebral oedema, forced diuresis, hypertension, etc.

Pharmacokinetics

Furosemide is rapidly absorbed orally. Bioavailability of furesomide through this route is about 60%. As it is extensively bound to plasma proteins, so delivery of these drugs to the tubular cells by filtration is limited. On the otherhand for the action of furosemide it is effectively secreted by the organic acid transporter system in the proximal tubule and then it flows down through the tubular lumen with the tubular fluid to gain access to their binding sites on the Na^+-K^+-$2Cl^-$ symporter system of the luminal membrane of TAL. It is partly conjugated with glucuronic acid. Plasma half life is 1 to 2 hours.

Dose

Usually furosemide is used in the dose of 20 to 80 mg, once daily in the morning orally. In pulmonary oedema, 40 to 80 mg IV bolus may be given or according to the patient's response.

Toxicity, adverse effects and contraindications

The adverse effects of furosemide are rare and are mostly due to the fluid and electrolyte imbalance. So, the overzealous use of loop diuretics cause serious depletions of total body Na^+, resulting in hyponatraemia, extracellular fluid volume depletion, hypotension, circulatory collapse, etc. Increased delivery of Na^+ load to the distal tubule from TAL (due to reduction of reabsorption), particularly when combined with activation of the renin-angiotension system leads to increased urinary excretion of K^+ and H^+ causing a hypochloraemic alkalosis. Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesaemia and hypocalcaemia. Due to reduction of circulation, furosemide may precipitate thromboembolic episode and hepatic encephalopathy in patient with liver disease.

Furosemide can cause ototoxicity; tinnitus, hearing impairment, deafness, etc. It can also cause hyperuricaemia (gout) and hyperglycaemia. Other Na^+-K^+-$2Cl^-$ symport inhibitors or loop diuretics are bumetanide, ethacrynic acid, torsemide. But individual discussion of these agents

is not possible here and furosemide should be taken as their prototype.

Thiazide diuretics

The primary site of action of these diuretics is the early DT. Here, they inhi-bit Na^+-Cl^- symporter system at the luminal membrane of the tubular cells. These groups of drugs also like furosemide gain access to their site of action at the DT after secretion in the PT. After secretion through the organic secretory pathway in the PT, they pass along the loop of Henle with the tubular fluid and finally bind to the specific receptor site i.e, Na^+–Cl^- symporter system located at the luminal membrane of DT. Like the Na^+-K^+-$2Cl^-$ cotransporter system, the Na^+-Cl^- (Table 18.9) symporter system is also a glycoprotein with 12 membrane spanning domains. But, it does not bind to furose-mide or any other class of diuretics except thiazides. Due to their action, increased amount of Na^+ is presented to the distal nephron where it is exchanged with K^+. So urinary excretion of K^+ is also increased in parallel to the natriuretic effect of these groups of thiazide diuretics, like furosemide. Nevertheless, they are moderately effective, because near about 90% of the glomerular filtrate has already been absorbed before it reaches their site of action. They have a flat dose response curve. Therefore, little additional diuretics occur when the dose is increased beyond their maximum dose. They do not cause significant alteration in acid-base balance of the body. They are not effective in patient with low GFR. They decrease the excretion of urate and Ca^{2+} by the same mechanism as furosemide and elevate blood sugar due to the decreased release of insulin.

All the thiazides and related drugs are well absorbed orally and their action starts within one hour. Their duration of action is variable. The more lipid-soluble agents have larger volume of distribution, lower rates of tissue clearance and therefore, are longer acting. Most of the thiazide agents undergo little hepatic metabolism and are excreted through kidney as such. This is because they are filtered at the glomerulus as well as secreted in the PT.

Thiazide diuretics are used mainly in the treatment of oedema, hypertension, diabetes insipidus, and hypercalcicuria. Mild to moderate oedema responses better. For mobilization of oedema fluid more effective diuretics are employed initially and thiazides are considered later for maintenance therapy. They are best for cardiac oedema and less effective for hepatic or renal oedema. They are not responsive in the presence of renal failure.

Most of the adverse effects of thiazide group of drugs are due to fluid and electrolyte changes caused by them. Among these, hypokalaemia is the most significant problem. But it is rare in low doses and short period of therapy. The consequence becomes grave if the thiazide therapy is prolonged and the dietary K^+ intake is low. The hypokalaemia associated with thiazide diuretics can be prevented by: (i) high dietary K^+ intake, (ii) supplement of KCl (24 to 72 mEq/day), and (iii) concurrent use of K^+ sparing diuretics. The last two measures are not routinely indicated, but only when the hypokalaemia is documented or in special risk situations such as cardiac patients, cirrhosis, etc. Other adverse effects of thiazide diuretics are hyponatraemia, hyperuricaemia, hyperglycaemia, hypercalcaemia, etc.

Table 18.9: Thiazide group of diuretics

Drugs	*Drug (Daily, in mg)*	*Duration of action (hour)*	*Relative efficacy*
Hydrochlorothiazide	50-100	10-12	2
Polythiazide	1-3	24-48	2.5
Benzthiazide	25-100	12-18	1.5
Hydroflumethiazide	5-100	12	1.5
Bendroflumethiazide	5-10	12	2
Chlorthalidone	50-100	48	2
Xipamide	20-60	24	1.5
Indapamide	2.5-5	24-36	1
Clopamide	10-60	12-18	2

Spironolactone

It is a K^+ sparing diuretic and is chemically related to aldosterone. Aldosterone acts on DT and CD by combining with a receptor which promotes the reabsorption of Na^+ and excretion of K^+. Spironolactone acts on this receptor and inhibits the action of aldosterone in a competitive manner. Therefore, it antagonises the loss of K^+ induced by other diuretics. Spironolactone is a weak diuretic becasue most of the Na^+ has already been reabsorbed proximal to its site of action. The K^+ retaining action of spironolactone develops over 3 to 4 days after its administration. It also increases the excretion of Ca^{2+} by direct action on renal tubules.

The oral bioavailability of spironolactone is 80%. It is highly protein bound and completely metabolised in liver. As it is weak in action, so is used only in combination with other more strong diuretics. It is more effective in cirrhotic and nephrotic oedema, because it breaks the resistance to thiazide diuretics that develop due to secondary hyperaldosteronism. Therefore, it is particularly employed in refractory oedema. Given together with K^+ supplements, dangerous hyperkalaemia can occur (Table 18.10).

Triamterene and amiloride

The most important action of these two diuretics is to decrease the excretion of K^+ along with the small increase in excretion

Table 18.10: Urinary excretion of electrolytes by some diuretics and their efficacy

Diuretic	Na^+	K^+	Cl^-	HCO_3^-	Efficacy
Furosemide	+++	+	++	+	High
Thiazide	++	+	+	+	Intermediate
Spironolactone	+	–	+	+ –	Low
Triamterene	+	–	+	+ –	Low
Mannitol	++	+	+	+	High
Acetazolamide	+	++	+ –	+	Mild

of Na^+. Therefore, their action is similar to spironolactone, but independent of aldosterone. Their site of action is the luminal side of the cells of late DT and CD. At this site of the cells there are distinct Na^+ channels through which Na^+ enters the cell down its electrochemical gradient which is generated by the Na^+-K^+-ATPase pump situated at the basolateral side of cell membrane. This Na^+ entry into the tubular cells from lumen promotes the secretion of K^+ into the lumen. Therefore, if there is more delivery of Na^+ to the distal nephron, there will be more absorption of Na^+ and more excretion of K^+. Thus, all the diuretics acting proximally such as furosemide, thiazides, etc., decrease the reabsorption of Na^+ and increase the load of Na^+ in DT and CD and so increase the excretion of K^+. Triamterene and amiloride act on these Na^+ channels and block the absorption of Na^+ and reduce the excretion of K^+.

Both these diuretics are used in conjunction with thiazide or other high ceiling diuretics to prevent hypokalaemia. They should not be given with K^+ supplements, because dangerous hyperkalaemia may develop. Triamterene is partly absorbed orally and largely metabolised in liver. Its duration of action is 6 to 8 hours. Amiloride is 10 times more potent than triamterene. It decreases the excretion of Ca^{2+} and increases the excretion of urate. Thus, the hypercalcaemic action of thiazides is augmented, but hyperuricaemic action is partly annuled. It is partly absorbed orally, not metabolized in liver and duration of action is 8 to 10 hours.

Mannitol

It is an osmotic diuretic with the following properties:

i. low molecular weight (182),
ii. freely filtered at glomerulus,
iii. limited reabsorption by the renal tubule,
iv. pharmacologically inert and does not metabolise in the body.

Mechanism and site of action

Mannitol acts both at the proximal tubule and loop of Henle (primary site of action). It mainly acts by (i) increasing the osmolality of plasma, (ii) increasing the osmolality of tubular fluid and (iii) reducing the medullary tonicity. Thus, it limits the tubular water and electrolyte reabsorption.

Mannitol extracts water from the intracellular compartment and expands the extracellular fluid volume. It decreases blood viscocity and inhibits renin release. All these effects cause increased renal blood flow (RBF) (both in cortex and medulla). Increased renal medullary blood flow removes NaCl and urea from the renal medulla and reduce medullary tonicity. Thus, corticomedullary osmotic gradient is dissipated. So, decreased reabsorption of water from DTL causes dilution of NaCl concentration in tubular fluid entering ATL and diminishes the reabsorption of NaCl with water in ATL. Osmotic diuretics also inhibit the reabsorption of Mg^{2+} and Ca^{2+}. Osmotic diuretics increase the urinary excretion of nearly all electrolytes, including Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^- and phosphate.

Administration

Mannitol is not absorbed orally and has to given IV as 10 to 20% solution. 80% of the drug is excretd as intact form by kidney. Next 20% is excreted after metabolism or is excreted as intact drug through bile. Plasma half-life of mannitol is 0.25 to 1.7 hours and in renal failure it may rise to 6 to 36 hours.

Adverse effects, indications and contraindications

As mannitol is distributed in the extracellular compartment, so water is extracted from the intracellular compartment and the extracellular fluid volume is expanded. In a patient with incipient heart failure and pulmonary congestion, this may cause frank pulmonary oedema.

Mannitol should never be used in the treatment of chronic oedema or as natri-uretic. Because loss of water in excess of electrolytes can cause hypernatremia and dehydration. If acute renal failure (anuria) has already set in, kidney becomes incapable of forming urine, even after an osmotic load by mannitol. So, mannitol is contraindicated in patients who are unresponsive to test doses of the drugs. In such circumstances large plasma volume expansion by mannitol may precipitate pulmonary oedema. Sometimes, 45% NaCl is as good as or better than either mannitol or furosemide for forced diuresis in protection against the acute tubular necrosis (ATN) which may lead to acute renal failure. It is not recommended to use mannitol repeatedly in case of non-responders (no urine formation). Nowadays, loop diuretic frusemide is more frequently used to convert oliguric to nonoliguric ATN than mannitol.

By increasing osmotic pressure of the plasma, mannitol extracts water from the eye (aqueous humour) and CSF (brain). So, it is frequently used in the acute attack of glucoma and increased ICP, during both preoperatively or postoperatively to control the intraocular pressure and the acute rise in intracranial pressure. It should not be used in intracranial haemorrhage.

Acetazolamide

It is a sulfonamide derivative compound and is the prototype of a group of agents which have limited diuretic effect, but greatly help to draw a fundamental picture of renal physiology. When sulfonamides are used as chemotherapeutic agents, they cause metabolic acidosis by inhibiting an enzyme named CAase (carbonic anhydrase). This leads to the enormous study and development of acetazolamide (sulfonamide derivative) as carbonic anhydrase inhibitor.

The main site of action of acetazolamide is proximal tubular epithelial cells, which is rich in CAase at its luminal side of cell membrane, basolateral side of cell membrane (type IV carbonic anhydrase) and in cytoplasm (type II carbonic anhydrase). At the luminal side of membrane Na^+ enter into the cell in exchange of H^+ which is excreted in lumen by Na^+-H^+ antiporter system (also called Na^+-H^+ exchanger) by free energy available from Na^+ gradient established by the basolateral Na^+-K^+-ATPase pump. H^+ in the lumen reacts with filtered HCO_3^- to from H_2CO_3 which rapidly breaks into CO_2 and H_2O by the help of CAase, present at the brush luminal side of cell membrane of proximal tubular cells. Due to lipophilicity, CO_2 is rapidly diffuses in the proximal tubular cells and in the cell CO_2 again reacts with H_2O to form H_2CO_3 by the help of cytoplasmic carbonic anhydrase.

$$CO_2 + H_2O \xleftrightarrow{\text{CAase}} H_2CO_3$$

Continuous use of Na^+-H^+ antiporter system causes low H^+ concentration in the cell which stimulates intracellular H_2CO_3 to ionise spontaneously to H^+ and HCO_3^-. Increased HCO_3^- concentration in the cell (simultaneously increased electrochemical gradient of HCO_3^-) is used by Na^+-HCO_3^- cotransporter system at the basolateral side of cell membrane to transport $NaHCO_3$ into the interstitial space. The net effect of this process is transport of $NaHCO_3$ from the tubule to the interstitial space followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl^- in the tubular lumen and consequently Cl^- diffuses in interstitial space by its concentration gradient via paracellular pathway.

Acetazolamide, thus acting as car-bonic anhydrase inhibitors at cell membrane and cytoplasmic level, reduces the availability of H^+ to exchange the luminal Na^+ by the Na^+-H^+ antiporter system and results in nearly complete abolition of $NaHCO_3$ reabsorption which ensues alkaline diuresis. Secretions of H^+ in DT and CD is also inhibited. Though, H^+ is secreted at this site by an H^+-ATPase pump (proton pump), it is generated in the cell by the CAase-mediated reaction. Thus, this is a secondary site of action of CAase inhibitor or acetazolamide. In the distal tubule the absorption of Na^+ takes place in exchange of exeretion of H^+ and K^+. In the absence of H^+, the K^+ is lost in excess to preserve Na^+ producing hypokalaemia. Among all the diuretics, acetazolamide causes the most marked kaliuresis. Urine produced under acetazolamide action is alkaline and rich in HCO_3^- which is matched by both Na^+ and K^+. The fractional excretion of Na^+ may be as much as 5% and the fractional excretion of K^+ can be as much as 70%. Inhibition of transport mechanism in PT results in increased delivery of Na^+ and Cl^- to the loop of Henle, which has large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+.

CAase inhibitors also increase the excretion of phosphate. The effects of acetazolamide on renal excretion is self limiting. This is probably because as gradually metabolic acidosis develops, the filtered load of HCO_3^- decreases to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption.

Extrarenal actions of acetazolamide

(i) Other extrarenal tissues such as eye, gastric mucosa, RBC, CNS, etc. are also rich in CAase. Ciliary process of eye is responsible for the formation of aqueous humour by the help of CAase. Acetazolamide, thus inhibiting CAase reduces the formation of aqueous humour and ↓intraocular tension.

(ii) CAase inhibitors also decrease gastric HCl secretion, but needs very high dose. So, it is not applicable therapeutically.

(iii) Due to interference with carbonic anhydrase activity in RBC, acetazolamide increases CO_2 levels in peripheral tissues and decreases CO_2 exhalation by lungs.

Oral bioavailability of acetazolamide is 100%. Plasma half-life is 6 to 9 hours and excreted unchanged in urine. Adverse effects of it are very infrequent like other sulphonamides. It may cause bone-marrow depression, skin reactions and allergic reaction in patients who are hypersensitive to sulphonamides. Adverse effects of acetazolamide are mainly due to secondary effects of urinary alkalisation and metabolic acidosis. So, there is a chance of precipitation of salt of calcium phosphate in alkaline urine and calculus formation. It also causes worsening of metabolic and respiratory acidosis. Thus, it is contraindicated in COPD patient. Precipitation of hepatic coma by interfering with urinary elimination of NH_3 (due to alkaline urine) may also occur.

Therapeutic uses of acetazolamide are: glucoma, alkalinisation of urine for urinary tract infection, acute mountain sickness (only as prophylactic), etc. The probable mechanism of action is by producing metabolic acidosis, or indirectly correcting a metabolic alkalosis, especially caused by decreased excretion of H^+ through urine.

ANAESTHESIA IN HYPERTENSIVE PATIENT

Perioperative management of patients with essential hypertension, scheduled for both elective or emergency surgery is same. During perioperative management of

patient suffering from hypertension it should be kept in mind that the raised intra-arterial pressure is due to either essential hypertension or secondary hypertension associated with the following conditions such as renal disease, coarctation of aorta, pheochromocytoma, Cushing's disease, etc. A severe intraoperative uncontrolled rise in blood pressure is particularly dangerous and may cause cerebrovascular injury or left ventricular failure with pulmonary oedema. If the intramural coronary arteries have been affected previously by the atheromatous process, the raised diastolic pressure may jeopardize the myocardial blood flow especially in the subendocardial region and produce ischaemic changes in ECG which is performed for monitoring during the whole perioperative period. Decrease of workload on the ventricle by lowering the systemic vascular resistance, may relief the failure and restore an adequate myocardial blood flow with reversal of the ECG changes.

Drugs that effectively control the systemic blood pressure in treated individual should be continued throughout the perioperative period. In general, hypertensive patients where BP is not controlled preoperatively should not be scheduled for outpatient or ambulatory (day-case) surgery under general anaesthesia, because of their tendency to haemodynamic fluctuation.

Preoperative Evaluation

The aim of pre-operative evaluation of patient suffering from hypertension is to determine the adequecy of control of systemic blood pressure. It is very general concept that hypertensive patient should be treated to normotensive before undergoing elective surgery. The point behind this concept is that the incidence of hypertensive emergencies, myocardial ischaemia and other complications increased in patients who remain hypertensive or not controlled prior to the induction of anaesthesia, although the increase in BP during intraoperative period occurs regardless of the degree of preoperative control of blood pressure. On the other hand, it is also evidenced that there is no increased incidence of perioperative complications when hypertensive patients with diastolic pressure as high as 110 mm of Hg undergoes elective operations, provided there is stringent perioperative control of BP. Therefore, from the above two statements it is clear that whatever may be the preoperative status of patient regarding the systemic BP, i.e. controlled or uncontrolled, it is the stringent immediate perioperative control of BP which is most important.

Pressure obtained in the hospital setting may not represent patients's usual levels. But, high blood pressure during admission of a hypertensive patient who was previously treated and controlled clearly can predict larger possible fluctuation of it intraoperatively. It is also very common that blood pressure increases during admission in hospital due to patient's anxiety. This is called 'white coat syndrome' and this group of patient also displays exaggerated pressure responses to direct laryngoscopy during tracheal intubation and surgical stimuli during intraoperative period.

Presence of end-organ disease due to long-standing hypertension should be evaluated pre-operatively by different investigations, e.g. ECG, renal function test, echocardiography, etc. Among them, the most important is the investigation for coronary artery disease. ECG for hypertensive patient with LVH, intraventricular conduction blocks or repolarisation abnormality should also be considered. Echocardiogram is more sensitive and informative than 12 lead ECG for diagnosis of LVH. Previous history of infarction has great significance. Essential hypertension is associated with the shifts of autoregulation curve of cerebral blood flow to the right. This shift suggests that cerebral blood flow is more dependent on perfusion pressure in hypertensive patient than in normotensive patient. Urgent revaluation and treatment of hypertension is necessary for patients with presence of fundal haemorrhage, exudates and particularly papilloedema on examination of the optic fundus.

Antihypertensive drugs used in the preoperative management usually do not alter the course and conduct of anaesthesia. But the abrupt discontinuation of antihypertensive drugs immediately in pre- or postoperative period causes rebound hypertension. This may be the another cause for continuation of antihypertensive drugs during the whole perioperative period. Despite acceptance of the concept that antihypertensive drug therapy should be continued throughout the perioperative period to reduce the morbidity and mortality, there is still risk that haemodynamic instability and hypertension or hypotension may occur during anaesthesia. During anaesthesia of a hypertensive patient exaggerated decrease in BP which are sometimes associated with increase in blood loss, excessive positive airway pressure or sudden change in body position could reflect impaired compensatory peripheral vasoconstriction due to inhibitory effect of antihypertensive drugs on the sympathetic nervous system.

Induction of Anaesthesia

There is a general agreement that all the hypertensive patients should receive an oral anxiolytic agent (e.g benzodiazepine) in addition to their normal morning doses of antihypertensive drugs as a pre-operative medication before induction of anaesthesia. There is also little evidence that any particular inducing agent or technique is better than other during induction of a hypertensive patient. Still it should be kept in mind that etomidate has the lowest cardiovascular effects, but thiopental is acceptable if administered carefully. Propofol may produce excessive hypotension in hypertensive patient. Induction of anaesthesia with rapidly acting intra-venous drug is the standard practice for hypertensive patient, but keeping in mind that exaggerated decrease

in BP may occur and this is due to excessive peripheral vasodilatation. This is because all the inducing agents cause widespread venodilation causing a large decrease in venous return and cardiac output, but a minor decrease in SVR. Ketamine is contraindicated as inducing agent in hypertensive patient.

Direct laryngoscopy and tracheal intubation is associated with exaggerated increase in BP for patient suffering from hypertension. This occurs even if these patients are treated with antihypertensive drugs and rendered normotensive preoperatively. Because hypertensive patients usually cause a greater increase in plasma catecholamine concentrations than normotensives during laryngoscopy and intubation. And it is also true that intravenous inducing agents cannot adequately and predictably suppress responses evoked by tracheal intubation.

This haemodynamic responses evoked during laryngoscopy and intubation can be attenuated adequately by:

i. increasing the concentration of inhaled volatile anaesthetic agents.
ii. by using adequate dose of IV opioids prior to initiating laryngoscopy and intubation. Intravenous opioid administration should be timed, so that peak effects of the opioids are predictably matched with the stimulus of laryngoscopy and intubation,
iii. by topical laryngotracheal administration of lignocaine, immediately prior to intubatioin,
iv. by administering lignocaine IV in the dose of 1.5 mg/kg about 1 minute before induction and intubation,
v. by using nitroprusside 1 to 2 µg/kg/IV just before laryngoscopy,
vi. by using esmolol 100 to 200 mg IV. As this haemodynamic response is primarily from sympathoadrenal axis to a noxious stimulus, it is most logical to use either opioids or β-adrenoreceptor antagonists to suppress the haemodynamics response and decrease the incidence of arrhythmias and myocardial ischaemia during and after intubation. Excessive autonomic activity may also be avoided when local anaesthetic techniques are employed as an adjunct to GA.

Regardless of the drugs which are used to blunt the circulatory effect of laryngoscopy and intubation, it is generally appreciated that excessive depressant effect of drugs producing hypotension during attempts to blunt or reduce the circulatory effect is more undesirable than the transient hypertension effect produced by direct laryngoscopy and tracheal intubation.

Maintenance of Anaesthesia

There is no evidence that any anaesthetic technique is better than others in hypertensive patient. However, also no limits for deviation of arterial pressure have been proven to be safe. But deviation not more than 20% from pre-operative MAP value is generally accepted. The goal during maintenance of anaesthesia in a hypertensive patient is to adjust the depth of anaesthesia and to minimise the wide fluctuations of blood pressure. Indeed, control of perioperative BP fluctuation with different anaesthetic techniques and agents is more important than preoperative control of hypertension.

Chronic hypertension is usually associated with hypovolaemia and IHD. Regional anaesthesia is an acceptable alternative method for hypertensive patient. But it should be kept in mind that sympathetic denervation proved by RA may unmask the unsuspected hypovolaemia (if present) and cause severe hypotension which may result in myocardial ischaemia. Untreated or poorly controlled hypertensive patient may suffer with greater decrease in BP and abrupt or dangerous bradycardia. The combination of α and β adrenoreceptor agonist or a vagolytic drug combined with α-adrenoreceptor agonist is better than α_1-adrenoreceptor agonist alone for treating hypotension after RA.

The intraoperative increase in BP is mainly due to sympathetic stimulation caused by painful surgical stimuli. The incidence of intraoperative hypertensive episodes is high in patient with history of essential hypertension. This is also evident even in patients who were previously rendered normotensive by drug therapy. Volatile anaesthetics are important agents to decrease the sympathetic activity which is responsible for intraoperative pressure response. It acts in dose-depended manner by decreasing SVR and to a lesser extent by decreasing the cardiac contraction and cardiac output. There is no evidence that one volatile anaesthetic agent is better than another in that respect. Poor blood solubility of desflurane and sevoflurane compared with isoflurane and halothane may permit more rapid changes in alveolar concentration and hence the depth of anaesthesia with good control of blood pressure. Intraoperative IV nitroprusside by infusion pump is a very good way of maintaining normotension in a hypertensive patient. There is no evidence that a specific muscle relaxant is better than another for intraoperative management of patient with hypertension. Pancuronium is not contraindicated in anaesthesia of a hypertensive patient but somebody avoid it in severe hypertension.

Hypotension often occurs during intraoperative control of high BP. This hypotension can be treated by decreasing the concentration of delivered volatile anaesthetic agents and decreasing the dose of antihypertensive drugs which are using intraoperatively. Intraoperative hypotension may be caused by a low circulating blood volume (in hypertensive patient blood volume is low). So a marked fall in arterial pressure may be produced by only a modest blood loss. The assessment of blood and other intravenous fluid requirements should be made from present circulatory status, rather than by

relying solely on the eye estimation of volume of blood loss. Measurement of pulmonary wedge pressure is of particular value in assessing intravenous fluid requirements in some patients with diseased left ventricle. Sometimes, sympathomimetic drugs can be used to restore the minimum perfusion pressure in vital organ. The response to sympathomimetic drugs should be both appropriate and predictable and can be titrated with hypotension. But care must be taken when vesopressor drugs are administered because they can interact with some antihypertensive agents.

Intraoperative monitoring of a hypertensive patient depends on the patient's condition and the complexity of surgery. The monitoring can extend from simple manual BP monitoring to intra-arterial BP monitoring to automatic NIBP, ECG, pulse oximeter, capnography, PAWP, transoesophageal echocardiogrphy, etc. Intraoperative myocardial ischaemia is usually evident from the conventional 12 lead ECG. But in some instances, only one lead can be monitored during anaesthesia and intensive therapy. In such situation the CM_5 bipolar lead would appear to be the best to show ischaemia changes in ST segment and give a good demonstration of P-wave and QRS complex. In this lead the reference electrode (right arm lead) is placed over the manubrium sterni. The exploring electrode (left arm lead) is placed on the V_5 position and the earthing electrode (right lower limb lead) may conveniently be sited on the left shoulder. The ECG may then be displayed by selecting the lead I position.

Postoperative Management

Extubation under light plane of anaesthesia or allowing the patient to cough on the tube during extubation can provoke a marked sympathomimetic response with undesirable tachycardia and hypertension. So, extubation should be done under adequate or deep plane of anaesthesia. Hypertensive patient usually responds with elevated BP during early post-operative period. It is usually due to exaggerated sympathetic activity due to post-operative pain. So, postoperative elevation of BP needs prompt assessment and treatment of postoperative pain to decrease the risk of myocardial ischaemia, cardiac arrhythmias, LVF, stroke, post-operative bleeding, etc., which may also be seen in postoperatieve period. When the intraoperative analgesia derived from the N_2O or opiates or others are wear off, the resultant increase in sympathetic acti-vity due to pain can cause a marked rise in systemic blood pressure and thereby heart failure. In addition, sometimes the intraoperative tendency toward pulmonary oedema may have been masked by IPPV, because of the raised intra-alveolar pressure. So, on return to the spontaneous ventilation, the LVF and pulmonary oedema may then become apparent and result in early post-operative collapse.

The Postoperative BP control can be done by the agents which are also used during the intraoperative period such as analgesics, GTN, nitroprusside, labetalol, hydralazine, etc. NSAIDs, though effective as postoperative analgesics, are one of the most common cause of acute renal failure. So, care should be taken in their use in hypertensive patients who are possibly at the risk of renal dysfunction. The use of vasodilator drugs to treat the patient with high systolic BP and normal diastolic pressure is not usually indicated.

If Hypertension Must be Treated and Controlled in Hypertensive Patient Before Operation

Till now it is the most debatable question, because a number of studies have failed to show that hypertension is an independent perioperative risk factor. The questions that centre around are:

i. Does adequate control of pre-operative hypertension could prevent perioperative complications?
ii. How much preoperative control of BP is needed?
iii. Should elective surgery be postponed due to preoperative elevated BP, so that treatment can be instituted for hypertension and patient can be optimised?

Now several schools of thoughts exist and several studies have been carried out. But unfortunately all the studies have failed to establish a definite answer. Prys-Robert's school believes that the preoperative management of hypertension lowers the incidence of perioperative morbidity and mortality. But others do not. Patients with astherosclerotic disease, who present with raised systolic pressure, but normal or low diastolic pressure, should not be considered as true hypertensive and should not have their surgery delayed (Prys-Robert-Brown).

Postponement of surgery due to hypertension is only necessary when there is an indication that the patient will benefit certainly from introducing antihypertensive therapy or modification of existing therapy (Prys-Robert-Brown). Only patients with severe hypertension with clear evidence of end-organ damage need postponement of surgery for further work up and treatment for optimisation unless minor surgery is planned (Prys-Robert-Brown).

The school represented by Goldman and Caldera views that the peri-operative management of patients presenting with untreated hypertension depends upon the level of the diastolic blood pressure and the surgical circumstances. For elective surgery, if the diastolic pressure does not exceed 110 mm of Hg, there is no evidence of increased cardiac and CNS complications. Patients with persistent diastolic blood pressure above this level should be referred to a physician for treatment. The occurrence of severe untreated hypertension (a diastolic pressure > 130 mm of Hg) in the perioperative period is known to be

associated with an increased morbidity and mortality.

Bedford, Feinstein, Wolfsthal and their supporters believe that fluctuation of blood pressure is the condition which is most frequently, predicts the rate of perioperative complications. So, according to their opinion by careful titration the fine control of perioperative BP is more important than only the preoperative treatment of hypertension. Despite the desire to render the patients normotensive before elective surgery, there is no evidence that the incidence of perioperative complication increases if fine control of BP is done when hypertensive patients (diastolic BP as high as110 mm of Hg) undergo elective operations (RK Stoelting and SF Dierdorf).

Conclusion

Although preoperative BP has been thought to be a significant predictor of the perioperative morbidity and mortality, no data establish definitly whether the preoperative control of hypertension reduces the perioperative risk. Preoperative treatment of patient suffering from hypertension is based on the following concepts that: (i) Patient should be educated regarding the importance of hypertension and its management which usually extends postoperatively and life-long. (ii) Incidence of perioperative haemodynamic fluctuations is less in treated than untreated group and (iii) Haemodynamic fluctuation has definitive relationship to morbidity.

The main aim of preoperative management of hypertensive patient is to search for end-organ damage secondary to hypertension, i.e. changes in CNS, coronary arteries, myocardium, aorta, kidneys, peripheral blood vessels, etc., and modulations of anaesthetic management accordingly.

19 Heart Failure and its Pharmacology

INTRODUCTION

The term myocardial failure is better than the term heart failure. On the other hand, the heart failure is though an unimpressive term, still it is most commonly used. It is a pathophysiological state in which due to some abnormality of cardiac function myocardium fails to pump out blood at a rate, corresponding to the requirement of the metabolising tissue and/or can do so (in compensated stage) only at the expense of an elevated filling pressure from an abnormally elevated diastolic volume. This failure of myocardium to pump out the required amount of blood which is needed for the body at that moment may be due to primary causes where myocardium itself is responsible, or may be due to secondary causes where the myocardium itself is not diseased (e.g. sudden increase of BP, pulmonary diseases, valvular diseases, arrhythmia, etc). In primary causes the abnormalities of heart muscle may be due to cardiomyopathies, viral myocarditis, myocardial ischaemia, infarction or abnormalities of heart valve where heart muscle have been damaged due to long standing haemodynamic burden. But, in secondary causes there is no detectable abnormality of myocardial function. In such circumstances, the normal heart is suddenly presented with an excessive mechanical load that exceeds its capacity. Secondary heart failure may also occur without any excessive load on myocardial function but there is chronic impairment of ventricular filling during diastole due to some mechanical abnormalities such as tricuspid stenosis, constrictivepericarditis, endocardial fibrosis, etc. which causes failure to pump out adequate amount of blood by heart according to the requirement of metabolising tissue. However, in maximum patients the combination of impaired myocardial function (or primary heart failure) and mechanical abnormality (or secondary heart failure) both coexist, because like vicious cycle they affect each other. For example, in one form such as with volume overload when the myocardium of ventricle without any pathology is called on to deliver an elevated cardiac output for prolonged periods (secondary failure), then it gradually develops myocardial pathology leading to primary failure. Similarly, systolic and diastolic failure (discussed later) affect each other and run in a vicious cycle.

In the mildest form of heart failure, cardiac output is adequate at rest, but becomes inadequate and is manifested only when the metabolic demand is increased such as during exercise or some other form of stress. In practice, heart failure or myocardial failure may be diagnosed, when-ever a patient with significant heart disease develops the signs and symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion.

In summary, the causes of heart failure can be grouped under two headings:

i. Underlying or primary causes– Here, the pathology is within the heart muscle itself, e.g. CHD, long standing valvular lesion, ischaemia, infarction, myocarditis, arrhythmias, etc.
ii. Precipitating or secondary causes– Here, the pathology is not within the heart muscle itself, but away from it such as systemic hypertension, fluid overload, anaemia, thyrotoxicosis, etc.

In the presence of different underlying causes of heart failure, initially the heart usually remains in compensated stage with little additional reserve. So, later additional load imposed by precipitating or secondary causes results in further deterioration of cardiac reserve and manifested as frank or overt failure. In the absence of underlying primary causes, if the secondary factors become acute then the heart may also undergoes failure. Therefore, identification of such precipitating causes is of very clinical importance, because their prompt alleviation may be lifesaving. In the absence of underlying primary heart disease, the precipitating or secondary factors by themselves usually do not lead to heart failure, except in acute stage. The examples of some precipitating factors are anaemia, infection, pregnancy, thyrotoxicosis, emotion, physical exertion, fluid excess, pulmonary embolism, hypertension, etc. Precipitating causes of heart failure should also be recognised and treated more effectively than the underlying causes. Because the prognosis of heart failure where a precipitating cause can be identified, treated and eliminated, is more favourable than it is in patient in whom the underlying disease process is advanced enough to the point of producing heart failure (Table 19.1).

TYPES OF HEART FAILURE

The different types of heart failures are classified under the different headings. But

Table 19.1: Causes of heart failure

Primary	Secondary
Diseases primarily affecting the myocardium (PUMP)	Diseases of other cardiac and circulatory components except myocardium leading to secondarily myocardial failure
Causes	**Causes**
1. Ischaemic heart disease: Most common and very serious disease of the heart. It leads to myocardial damage, fibrosis or infarction.	1. Defects in control mechanism of heart, e.g. a. Valvular heart diseases b. Cardiac arrhythmias
2. Inflammation and toxic degeneration of myocardium—myocarditis	
3. Infiltration of myocardium fatty infiltration, amyloidosis, etc.	2. Defects in circulatory components, e.g. a. Systemic hypertension
4. Cardiomyopathies: a. Primary b. Secondary due to beri-beri, alcoholism, thyroid abnormality, etc.	b. Chronic lung diseases causing pulmonary hypertension. Both a and b cause increased cardiac work load.

Failure of compensatory mechanism
↓
Heart failure manifested

this different classification of heart failure under different headings is only useful in its early pathophysiological course. Because late in the course of failure the difference between them often becomes blurred. The classification are :

Acute versus Chronic Failure

This two broad classification of heart failure depends on the suddeness of the onset or the rate of development of it. With this, the causative factors for their development and the effects of these two types of failure are also different. The acute heart failure develops instantaneously within hours to few days without giving any time for compensatory mechanism to develop. But, the chronic heart failure takes weeks or months to develop with the full blown compensatory pictures. The main causative factor of acute heart failure is acute coronary arterial occlusion with infarction and/or arrhythmia. The other aetiologies of acute heart failure are pulmonary embolism, acute toxic myocarditis, acute rise of BP (malignant hypertension), etc. On the other hand, chronic heart failure is the consequence of chronic hypertension, chronic valvular diseases, chronic lung diseases, chronic anaemia, myocardial fibrosis, etc. In acute conditions the system does not get enough time for the compensatory mechanism to develop. So, the patient suddenly present with acute symptoms and signs of failure without hypertrophy of myocardium, dilatation of cardiac chambers and systemic oedema, etc. which are found as compensatory mechanism. Whereas in chronic heart failure, compensatory mechanism has got time to develop with full force. So, there is always the presence of myocardial hypertrophy of atriums and/or ventricles, dilatation of cardiac chambers, chronic systemic venous congestion, oedema, etc.

Actually, the acute and chronic heart failure are the two opposite ends of a spectrum of a single disease. But, they merge with one another by the treatment procedures or the natural compensatory processes which is shown in Figure 19.1.

Systolic versus Diastolic Failure

In systolic heart failure there is impairment of myocardial contractile function during systole leading to reduction in stroke volume, inadequate ventricular emptying and gradually cardiac dilation. There is no abnormality of venous return and ventricular filling during diastolic period of cardiac cycle (preload). A decreased ejection fraction with normal preload diagnosed by end diastolic ventricular volume within normal limit is the hallmark of ventricular systolic failure. So, measuring the ventricular ejection fraction via echocardiography provides the quantification of severity of ventricular systolic function. An ejection fraction of less than 0.45 is often viewed as the evidence of ventricular systolic dysfunction. The example of systolic heart failure are IHD, cardiomyopathy, myocarditis, etc. In IHD, there is gradual loss of the number of myocyte, leading to localised defects in ventricular wall motion and impaired systolic contraction. Myopathies, especially the idiopathic dilated cardiomyopathy results in global ventricular

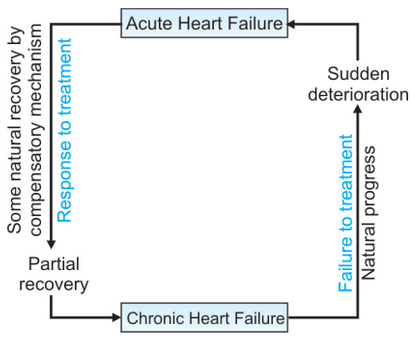

Fig. 19.1: Acute versus chronic failure

systolic dysfunction. Systemic hypertension, cardiac valvular disease, etc. also may produce systolic failure due to the chronic presence of increased afterload and gradual damage of cardiac muscle fibres.

But, they gradually produce the diastolic failure due to their subsequent effect, causing ventricular hypertrophy and leading to filling defect. However, actually in diastolic heart failure there is impaired relaxation and defect in filling of ventricle, leading to elevation of end diastolic ventricular pressure at any given diastolic volume or preload of the ventricle. The Failure of relaxation of ventricle in diastolic failure can also be caused by stiffened and/or thickened ventricle which impaired the filling of it. With diastolic heart failure, the ventricle has decreased compliance and can not adequately be filled up during diastolic period. Examples of diastolic heart failure are restrictive cardiomyopathy, infiltrative condition of heart such as amyloidosis, myocardial oedema, hypertrophic cardiomyopathy, constrictive pericarditis, ventricular hypertrophy due to essential hypertension or aortic stenosis, etc. The symptomatic congestive heart failure with normal ventricular systolic function is most likely due to diastolic dysfunction. In many patients cardiac hypertrophy and dilatation, i.e. diastolic and systolic failure can also coexist. Here, the ventricle both fills and empties abnormally.

Though, the systolic heart failure may result primarily from the abnormality of heart muscle such as in cardiomyopathy, but it may also result secondarily from the chronic excessive cardiac work load such as in hypertension or valvular heart disease. In ischaemic heart disease the systolic heart failure results from the loss in quantity of normally contracting myocardial cells.

The congestive heart failure is a condition which is coupled with multiple etiologies. These etiologies may be described as:

i. Abnormality in cardiac contraction (systolic heart failure, e.g. dilated cardiomyopathies),
ii. Abnormalities in diastolic filling (diastolic heart failure, e.g. restrictive cardiomyopathy, hypertrophic cardio-myopathy, constrictive pericarditis, cardiac tamponade),
iii. Pressure overload (afterload abnormalities, e.g. severe hypertension, aortic stenosis etc). Here the systolic and diastolic dysfunction work together. In acute form of hypertension the systolic failure is the cause. But, in chronic hypertension diastolic failure due to impaired filling for hypertrophy and systolic failure due to ischaemia caused by hypertrophy coexist.
iv. Volume overload (mitral regurgitation, aortic insufficiency).

High Output versus Low Output Failure

As the name signifies, the high output heart failure means there is an elevated cardiac output and the low output heart failure means there is decrease in cardiac output. The high output heart failure is seen in patient with hyperthyroidism, anaemia, pregnancy, beriberi, atriovenous fistula, transfusion overload, etc. In high output heart failure, though the cardiac output is high, still it is insufficient to maintain the body requirement. So, the heart has to work more and more to meet the tissue requirement and ultimately it fails like a tired horse.

On the contrary, the low output heart failure due to systolic or diastolic causes is seen in patient with ischaemic heart disease, hypertension, dilated cardiomyopathy, valvular diseases, pericardial diseases, etc.

In low output failure the A-V O_2 difference is widened, but in high output failure the A-V O_2 difference is normal or low.

Left Sided versus Right Sided Heart Failure

In human body, the cardiovascular system consists of two circulations, situated in series where the right and left heart act both as a pump in the connecting link for each of the series. The right ventricle acts as pump for the pulmonary circulation and the left ventricle acts as pump for the systemic circulation. The pulmonary circulation is the low pressure system. In it, the mean systolic arterial pressure is 15 mm of Hg and the pressure gradient between pulmonary artery and vein is 8 mm of Hg. Whereas, the systemic circulation is a high pressure system. In it, the mean systolic arterial pressure is 120 mm of Hg and the pressure gradient between the systemic artery and the vein is 90 mm of Hg. The ratio between the right ventricular mass with its coronary blood supply and the left ventricular mass with its coronary blood supply is 1:4.

The right-sided heart failure is referred to the conditions when the right ventricle fails to pump out the blood in the pulmonary circulation and the blood accumulates in and behind it. The causes of the right ventricular failure are :

i. Lung diseases, causing pulmonary hypertension such as emphysema, fibrosis, COPD, etc.
ii. Some form of cardiac valvular diseases, e.g. pulmonary stenosis, mitral stenosis, etc.
iii. Some congenital heart diseases with left to right shunt.
iv. As a consequence of left ventricular failure (Table 19.2).

The left-sided heart failure is referred to the conditions when the left ventricle fails to pump out the blood in the systemic circulation and the blood accumulates in and behind it. The causes of the left ventricular failure are :

i. The weakness of muscle of left ventricle due to IHD,
ii. Excessive workload due to systemic hypertension,
iii. Some valvular diseases such as aortic stenosis, mitral incompetence, etc.
iv. Some congenital heart diseases with right to left shunt.

The consequences or the effects of right or left-sided heart failure are mainly due to the low output and backward pressure.

Table 19.2: Causes of heart failure

1. Reduced ventricular contractility:

   Myocarditis, cardiomyopathy, IHD, myocardial infarction.
   Main features: Gradual ventricular dilatation, impaired ventricular wall motion.

2. Ventricular inflow obstruction :

   Mitral stenosis, tricuspid stenosis, constrictive pericarditis, myocardial fibrosis and other disorders that causes stiff myocardium (e.g ventricular hypertrophy).
   Main features: Small vigorous ventricle → dilated hypertrophied atrium.

3. Ventricular outflow obstruction :

   Hypertension and aortic stenosis (left heart failure), pulmonary stenosis, pulmonary hypertension (right heart failure).
   Main features: Concentric ventricular hypertrophy → try to maintain normal output → secondary changes in myocardium → ventricular dilatation.

4. Ventricular volume overload :

   Mitral and aortic reguritation (LV overload), pulmonary and tricuspid regurgitation (RV load), ASD, VSD, increased metabolic demand (high output).
   Main features: Hypertrophy and dilatation of ventricle → maintain normal output → secondary changes in myocardium → impaired contractility → dilatation of ventricle.

5. Arrhythmia:

   Atrial fibrillation, severe tachycardia, complete heart block.

In right-sided heart failure the low output to lungs from right-ventricle is usually not significant unless the right ventricular failure is a sequel to the left ventricular failure. On the other hand, due to backward pressure in RV failure the overfilling of right atrium, systemic veins and the capillaries produces the systemic oedema. Cyanosis in RV failure is the result of excess reduced haemoglobin in systemic capillaries and venules, but not due to the defective oxygenation at lungs. The measurement of pulmonary artery pressure is very important for the diagnosis of this two type of heart failure. The increase in pulmonary artery pressure may be the cause of RV failure or may be the effect of LV failure. But, in most of the cases the increased pulmonary artery pressure is due to the LV failure leading to the RV failure (combined failure). In mitral stenosis, RV failure is caused by this mechanism, but without LV failure. In chronic pulmonary diseases pulmonary hypertension and RV failure is the cause of death. In pulmonary stenosis, there is isolated RV failure which later leads to LV failure. Thus, the distinction between the right and left ventricular failure is valid and certainly useful from some clinical point of view.

However, when the heart failure exists for long time, then such classification of failing heart may no longer exist. For example, patient with long standing aortic valve disease may have ankle oedema, congestive hepatomegaly late in the course of this disease, showing the features of RV failure even though the abnormal haemodynamic burden initially was placed on the left ventricle. This occurs in part because of the secondary pulmonary hypertension and resultant right-sided heart failure arising from left-sided heart failure. But, this is also because of the retention of salt and water, characteristic of all forms of heart failure. On the other hand, the muscle bundles comprising both the ventricles are continuous and both the ventricles share a common wall—the intraventricular septum. So, failure of one of the ventricle precipitates the failure of another. Also, the biochemical changes that occur in heart failure and the factors that are involved in the impairment of myocardial function such as norepinephrine depletion and alterations in the activity of myosin ATPase, occur in the myocardium of both the ventricles, regardless of the specific chamber on which the abnormal haemodynamic burden is placed initially.

Backward versus Forward Heart Failure

The concept of backward heart failure indicates that one or other ventricle fails to discharge its full contents. As a consequence, the pressure on the atrium or venous system behind the failing cardiac chamber rises and by the result of which retention of sodium and water occurs. As a consequences of the elevation of systemic venous and capillary pressure, fluid transudates into the interstitial space. In contrast, the concept of forward heart failure indicates that one or other ventricle discharge inadequate blood into the arterial system. As a consequence, there is also salt and water retention due to diminished renal perfusion, excessive proximal tubular Na^+ reabsorption and excessive distal tubular water reabsorption through the activation of renin-angiotensin-aldosterone system.

A rigid distinction between the backward and the forward heart failure is not possible. Because, both the above explained mecha-nism appear to operate in varying extents at a given time in most of the patients with both of these type of heart failure. For example, in case of massive left ventricular infarction stroke volume, cardiac output and blood pressure is suddenly reduced due to myocardial damage which is manifested as forward failure and then the patient may succumb to acute pulmonary oedema which is a manifestation of backward failure.

COMPENSATORY MECHANISM IN HEART FAILURE

Before the development of signs and symptoms of heart failure, the myocardial reserve comes forward into action to increase or maintain the circulation of blood and to fulfil the increased or normal tissue O_2 demand. This myocardial

reserve comes forward by three different mechanisms which are called the compensatory mechanisms. These are: increased in pumping rate or heart rate, dilatation of ventricular chamber executing Starling law (dilatation of atrial chamber are ignored here) and hypertrophy of the musculature of ventricle executing increased contractility. In heart during pathological strain, all these three compensatory mechanisms come into action and try to cope for the considerable derrangement. This compensatory mechanism is mediated through activation of sympathetic and renin-angiotensin-aldosterone system (Fig. 19.2).

Heart Rate

Heart rate is an important determining factor of cardiac output because Cardiac output = Heart rate × Stroke volume. When stroke volume is reduced, then with increased heart rate cardiac output is maintained. This increase in heart rate is performed by the increase in activity of sympathetic system due to reduced cardiac output through baroreceptors, situated in the different parts of the body. Again this chronic long standing increased sympathetic activity gradually further deteriorates the ventricular function (discussed later) and accelerates the failure. So, what is beneficial and compensatory now, will be harmful later.

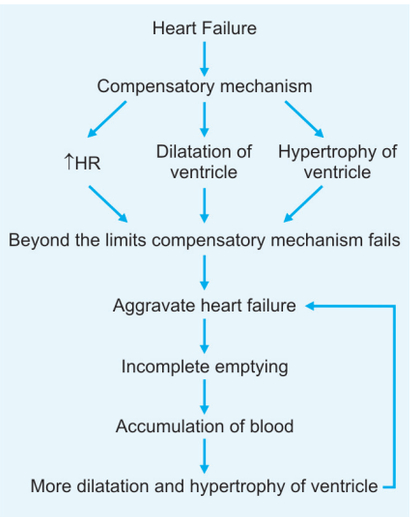

Fig. 19.2: Compensatory mechanism of heart failure

Dilatation

Under physiological condition and within a limit the volume of the ventricular chamber at the end of the diastole influences the pumping or contractile force of the ventricular musculature. The larger will be the chamber size, of ventricle due to filling by blood in diastole the longer will be the length of the ventricular muscle fibre before contraction. Again the longer will be the muscle fibre length, the greater will be the contractile force. This is called the Starling law. In this way the heart will try to maintain CO to its normal value before going to fail. Thus, the conditions where the Starling law mainly comes into action are early stages of valvular incompetence, valvular stenosis, fluid over load or other condtions where the venous return or regurgitation starts to increase. In the later stages when the end diastolic ventricular volume and the subsequent stretching of ventricular muscle fibre increases more and goes beyond the physiological limits, then the ventricular chamber starts to dilate permanently. The best example of this ventricular dilatation is valvular incompetence. In aortic incompetence the ventricular chamber dilates, because it has to accommodate the regurgitant blood from aorta as well as the normal input from the atrium. In valvular stenosis, the ventricular chamber also dilates because it has to accommodate the residual blood from present contraction and as well as from the normal input.

Hypertrophy

Ventricular hypertrophy is the another mode of compensatory mechanism of heart failure where the increase in number of muscle fibre comes into action and is able to deal with the greater workload. The only pure form of ventricular hypertrophy is best seen during the increased afterload. Left ventricular hypertrophy is most common in essential hypertension and aortic stenosis. Right ventricular hypertrophy is seen in pulmonary stenosis, pulmonary hypertension due to chronic lung diseases and also in mitral valve disease which secondarily causes pulmonary hypertension. But in clinical scenario, the both hypertrophy and dilatation come into action in different combination with their different magnitude to compensate the failure accompanying by the increased heart rate or not.

Failure of compensatory mechanism

The increased cardiac efficiency, deri-ved from all the three compensatory mechanism is limited. Beyond this limit, serious deficiency of compensatory mechanism ensures failure with definite signs and symptoms. Heart rate increases mainly in expense of duration of diastole. So, when the heart rate increases above 160 to 180/minute, then the period of diastole becomes very much shorter and ventricular filling is severely jeopardised and cardiac output does not increase. Similarly, Starling law also works within a physiological limit (plateau of the curve), beyond which further dilatation of ventricle or the stretching of muscle fibre does not increase the force of contraction. Then, the residual blood gradually accumulates in chamber which further helps in dilatation of ventricle and failure. Thus a vicious cycle sets up. Hypertrophy also fails to compensate beyond its maximum limit when the muscle mass has outgrown than its necessary blood supply, causing impairment of supply of nutrients, impairment of chemical and neural stimuli and inotropic activity. All these lead to further heart failure.

The effects of heart failure are principally seen in the peripheral organs. These are due to hypoxia and/or venous congestion. Hypoxia is well-exemplified in the acute form of left ventricular failure, where the cerebral function is seriously disrupted with transient loss of consciousness. In

chronic form of heart failure, the weakness and fatigue (which are so common symptoms) are probably the effects mainly of chronic hypoxia. But damage to organs due to chronic hypoxia is more difficult to define in chronic heart failure. This is because the effects of venous congestion and water retention in chronic heart failure are added to compensate the impaired circulation causing hypoxia. Venous congestion is responsible for oedema. Breathlessness or dyspnoea which is almost a constant feature of heart failure is essentially due to venous congestion and fluid retention within the lungs.

DETERMINANTS OF VENTRICULAR FUNCTION

Ventricular function is determined mainly by the three principle cardiac parameters. These are: Cardiac output, ejection fraction and ventricular end-diastolic volume or pressure.

Cardiac Output

The main single function of heart is to eject blood. It is measured in litre/minute and is the product of stroke volume and heart rate. Stroke volume is again determined by venous return (preload), myocardial contractility (force-velocity curve), afterload, myocardial size (hypertrophy and dilatation), wall motion abnormalities and valvular dysfunction. In addition, any alterations in sympathetic nervous system activity and humeral mediated response control the cardiac output. In the presence of mild heart failure, the resting cardiac output may be normal or adequate for the resting tissues, without any signs and symptoms of heart failure but unable to meet during stress. Whereas in severe heart failure, the resting cardiac output is even inadequate for resting tissues. When the cardiac output does not increase in heart failure corresponding with the demand of O_2 by tissues, then the usual O_2 extraction from blood by the peripheral tissues increases and lowers the O_2 content in the venous blood, producing an increased arterio – venous O_2 tension difference [$P_{a\text{-}v}$ O_2].

Venous return (Preload)

At any fixed level of contractile status of the ventricle (i.e. contractility) and afterload, the cardiac performance is profoundly influenced by the ventricular end diastolic fibre length or the end diastolic volume (EDV) which is closely related to the end-diastolic pressure (EDP). This end diastolic pressure or indirectly the end diastolic ventricular volume is called the preload. So, the terms such as EDV, EDP, venous return and preload are all interchangeable. Therefore, the cardiac performance is governed by the Frank-Starling law or principle. This Frank-Starling principle dictates the relationship between the initial fibre length of the muscle fibre of ventricle and the tension or force of contraction developed within it. It means that the stroke volume due to more forceful contraction of ventricular is increased when the tension developed in the muscle fibre before contraction is increased which is again increased when the resting length of that muscle fibre (or volume of ventricle) due to increased filling is increased. Therefore, preload is the intraventricular pressure which is closely related to the intraventricular volume at the end of the diastole and governed by the Starling law. On the otherhand, the other major determinants of ventricular preload are: Total circulating blood volume, distribution of blood volume in different organ and atrial contraction.

Total circulating blood volume

During severe haemorrhage or in hypovolaemic shock or in any other conditions where vasodilation occur, then there is absolute or relative reduction in circulating blood volume. It causes decrease in venous return → decrease in ventricular end diastolic volume (preload) → decrease in ventricular end diastolic pressure → decrease in length of ventricular muscle fibre → decrease in tension of muscle fibre before contraction → decrease in force of contraction → decrease in stroke volume → decrease in cardiac output for a given heart rate.

Distribution of blood volume

For any given blood volume the ventricular end diastolic volume or pressure which determine the cardiac output is influenced by the distribution of total blood volume between the intra- and extra thoracic compartments.

This distribution of total blood volume between the intra and extrathoracic compartment in turn is influenced by the following factors:

i. *Body position*: Upright position augments the extrathoracic blood volume and reduces the preload.
ii. *Intrathoracic pressure*: Increased intrathoracic pressure impedes the venous return and thus reduces the end diastolic ventricular volume and stroke volume, such as during valsalva manoeuvre, intense coughing, IPPV, etc.
iii. *Intrapericardial pressure*: During increased intrapericardial pressure such as in cardiac temponade, there is interference for cardiac filling and reduction of stroke volume.
iv. *Venous tone*: The smooth muscles of the walls of the veins respond to the variety of neural and humoral stimuli and control venous tone which in turn control the venous return, preload and cardiac performance, i.e. cardiac output.

Atrial contraction

Atrial contraction helps in ventricular filling and is of particular importance in patients with concentric ventricular hypertrophy. So, loss of atrial systole such as in atrial fibrillation tends to reduce the ventricular filling. Thus, the ventricular end diastolic volume and pressure (preload) and in turn the stroke volume is reduced.

Thus, now we have come to the conclusion that for all the striated muscle fibre

including the cardiac muscle fibre, the force of contraction depends on the initial length of the muscle fibre. The optimum sarcomere (cardiac cell) length associated with the most powerful contraction of the muscle fibre is 2.2 µm. At this length the actin and myosin are situated in such a fashion that they are able to provide the greatest area of their interaction and at this length the myofilaments are maximally sensitive to Ca^{2+} ion. When the sarcomere length is increased to 3.65 µm, then the thin actin filaments are entirely withdrawn from the myosin filament and no tension can be developed. Similarly, when the sarcomere are shorter than 2 µm, then the thin actin filaments will pass over one another and doubly overlapes. So, it reduces both the sensitivity of Ca^{2+} to the contractile sites and the capacity of force to develop. Therefore, the relation between the initial length of cardiac muscle fibres and the subsequent development of force is of prime importance for the functional integrity of myocardium which is stated by the Frank-Starling law.

Myocardial Contractility or Inotropic State of Ventricle (Force-Velocity Curve)

The state of mechanical contractility of all the striated muscle fibres can be expressed by relation between the velocity or the rate of shortening and the development of force during contraction within the muscle (Fig. 19.3).

The maximum velocity of contraction of muscle is written as V_{max} and in the presence of catecholamines when the inotropic state of heart is increased, the V_{max} will also increase. The contractility also depends on the intracellular Ca^{2+} concentration during systole and other neural, humoral and pharmacological factors. On the other hand, the myocardial contractility is depressed due to anoxia, acidosis, depletion of catecholamine stores and loss of functioning muscle mass as a result of ischaemia and infarction. Most anaesthetic and antiarrhythmic agents decrease myocardial contractility. Alternatively, the V_{max} will decrease when the myocardial contractility is impaired due to some factors which are responsible for heart failure. As for example, volatile anaesthetics decrease V_{max} and this effect is additive to the decreased contractility in the presence of heart failure. In clinical practice, the rate of decrease or increase of intraventricular pressure indicates the decrease or increase of V_{max} and is used as an important guide for the understanding of the inotropic state of heart.

At any given ventricular end-diastolic volume or pressure (preload) a number of factors described below determine the state of myocardial contractility or V_{max} and the level of ventricular performance, reflecting the change of ventricular function curve. All these factors act by modifying the myocardial force-velocity relation or curve and by altering the concentration of Ca^{2+} in the vicinity of the myofilaments which in turn trigger the cross-bridge between the actin and myosin.

These factors are :

i. *Adrenergic nerve activity*: Normally norepinephrine is released from the adrenergic nerve endings in the heart. Its action on the β-adrenergic receptor in the myocardium depends on the adrenergic nerve impulse traffic. This factor is most important for the myocardial contractility under physiological conditions.

ii. *Circulating catecholamines*: After adrenergic nerve stimulation of adrenal medulla, it releases catecholamines which reach the heart and augments the myocardial contractility.

iii. *Force-frequency relation*: The contractility of the normal (but not the failing) heart is augmented by the increase in frequency of adrenergic impulse.

iv. *Exogenously administered inotropic agents*: All inotrops improve the myocardial force-velocity relation and is used to stimulate the ventricular performance.

v. *Pharmacological depressants*: These incorporates calcium channel blocker, β-blockers, lignocaine, procainamide, etc.

vi. *Physiological depressants*: Hypoxia, ischaemia, acidosis electrolyte imbalance, etc. acting either singly or in combination depress the myocardial force-velocity curve or contractility and left ventricular performance at any given ventricular end-diastolic volume.

vii. *Loss of myocytes*: Ventricular performance or stroke volume is also depressed at a given end diastolic volume when there is loss of some myocardial cells as in myocardial ischaemia (transient loss), infarction

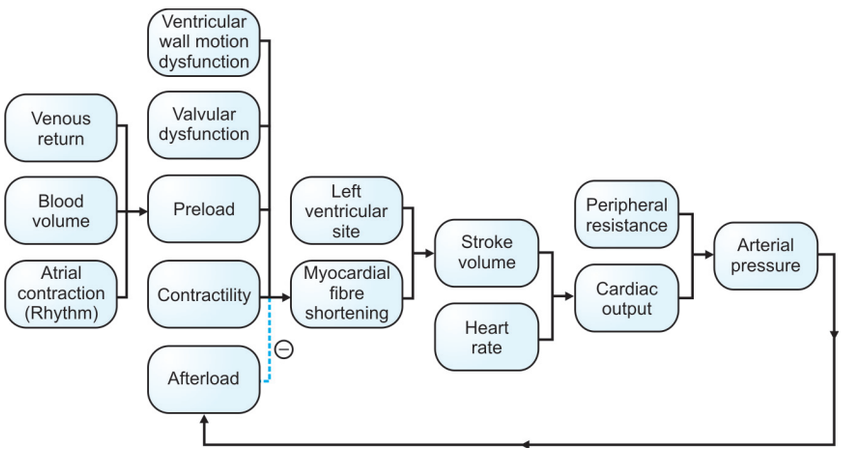

Fig. 19.3: Schematic representation of interactions among the various components that regulate the cardiac activity. Broken line represents an inhibiting effect

(permanent loss) and apoptosis (programmed cell death – can cause scattered loss of myocytes and when sufficiently widespread can impair ventricular function and cause heart failure), etc.

viii. *Intrinsic myocardial depression*: The fundamental mechanism, responsible for depression of myocardial contractility in most cases of chronic heart failure which is secondary to prolonged ventricular overload or cardiomyopathy is still unknown. It is now apparent that in this condition inotropic state of individual surviving myocytes is depressed and as a consequence the ventricular functional curve at any given ventricular preload and afterload is lowered.

Ventricular Afterload

Like venous return (preload) and inotropic state (contractility) of heart, cardiac output also depends on the afterload. But, it has negative effect on the cardiac output or stroke volume. In a contracting heart afterload is commonly equivalent to the mean aterial BP which produce impedance to ejection. At a given level of preload and myocardial inotropic state, the stroke volume or cardiac output is inversely related to the afterload i.e the load that opposes the shortening of the myocardial fibres (Fig. 19.4).

Due to any physiological cause (such as tension, anxiety, etc.) an increase in arterial pressure induced by vasoconstriction augments the afterload which opposes the myocardial fibre shortening and reduce the stroke volume and thus normalise the arterial pressure to the previous level (compensatory phenomenon). In essential hypertension, this physiological control is lost and the arterial pressure is not normalised by the previously described compensatory mechanism.

With age myocardial contractility is impaired, cardiac output falls and ventricle dilates. Then afterload or arterial pressure

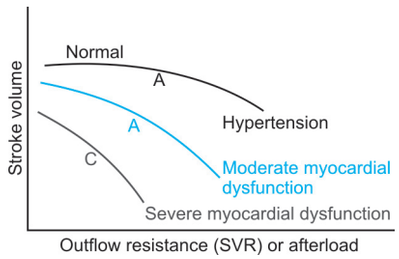

Fig. 19.4: The relationship between the stroke volume and the ventricular outflow resistance in patients with normal, hypertensive and systolic ventricular dysfunctional heart. Cardiac outflow resistance is a principle determinant of after load. An increase in SVR has little effect or stroke volume in normal heart (green curve A). In contrast, in patient with systolic ventricular dysfunction, an increase in outflow resistance or afterload is often accompanied by a sharp decline in stroke volume (curve B). With severe ventricular dysfunction the curve becomes more steeper (curve C). So, reduction of SVR, one of the component of outflow resistance, by vasodilator markedly increase the stroke volume in patient with severe myocardial dysfunction. The decrease of SVR is resulted by increase in stroke volume and subsequently prevent the fall of BP, which is caused by reduced SVR. Thus the increase in stroke volume offset the effect of reduced SVR

may rise as a result from the compensatory neural and humoral stimuli that occurs in response to a fall in cardiac output. This increased afterload may further reduce cardiac output while myocardial O_2 consumption are increased. This can set a vicious cycle.

There is some confusion regarding the afterload, systolic blood pressure and systemic vascular resistance. In the absence of any changes in size, shape, ventricular wall thickness and SVR, systolic blood pressure is usually taken as the afterload. Sometimes clinically SVR is considered as left ventricular after load which is calculated by the following formula:

$$SVR = 80 \times \frac{MAP - CVP}{CO}$$

MAP = Mean arterial pressure, CVP = Central venous pressure, CO = Cardiac output. The normal value of SVR is 1000 to 1500 dyn.s.cm^{-5}.

Right ventricular afterload is equivalent to the pulmonary vascular resistance (PVR). Like SVR, pulmonary vascular resistance also can be calculated by the following formula:

$$SVR = 80 \times \frac{PAP - PCWP}{CO}$$

PAP = Pulmonary artery pressure, PCWP = Pulmonary capillary wedge pressure. Normal value of PVR is 50 – 100 dyn.s.cm^{-5}.

Myocardial Size (Hypertrophy and dilatation)

Like the preload, contractility and afterload; the hypertrophy and dilatation of ventriclar wall also determine the amount of stroke volume. Initially, they represent the compensatory mechanism and help to maintain the cardiac output. But later they become the causes of further deterioration with reduction of output and heart failure. Hypertrophy helps to overcome the pressure overload. But it has limitations, because hypertrophied muscle functions at lower inotropic state than the normal cardiac muscle. Dilatations also leads to compensatory increase in output by Starling mechanism. But later both hypertrophy and dilatation is associated with increased O_2 requirement and decreased cardiac efficiency. Ventricular hypertrophy develops in response to chronic pressure overload such as aortic stenosis, systemic hypertension, mitral stenosis, pulmonary hypertension etc. Whereas the ventricular dilatation develops in response to volume overload such as aortic incompetence, mitral incompetence, etc.

Wall motion abnormalities

For adequate stroke volume, it requires all the ventricular muscle fibres to contract symmetrically at a time. But due to some abnormalities of muscle fibre such as ischaemia, hypertrophy, fibrosis, etc. all the portions of the ventricular walls do not contract symetrically and fully. So, ventricular emptying or output becomes impaired. The principal types of ventricular wall motion abnormalities found during echocardiography are:

akinesia (fully failure to contract), hypokinesia (decreased contraction), dyskinesia (paradoxical contraction). The severity of impairment of stroke volume depends on the size, number and the type of abnormality of the contracting areas of ventricular wall.

Valvular dysfunction

The types of valvular dysfunctions are stenosis, incompetence (regurgitation) or both and can involve any of the four valves. The stenosis of atrioventricular values such as the mitral and tricuspid valve causes reduction of stroke volume by reducing the preload, but not by altering the afterload. On the other hand, stenosis of aortic and pulmonary valve reduce the stroke volume by increasing the after laod which subsequently causes the compensatory ventricular hypertrophy, but not by altering the preload. Whereas the regurgitation of any valve decrease the stroke volume and increase the preload which subsequently causes compensatory ventricular dilatation.

Ejection Fraction

The ejection fraction is the ratio between the stroke volume and the end diastolic volume. It signifies the amount of blood filling the ventricle at the end of diastole, the amount of blood is stroked out and the amount of blood resides in the ventricle at the end of systole. Normally, the ventricle ejects 55 to 80% of its end diastolic volume during systole, resulting in ejection fraction of 0.55 to 0.8 (Fig. 19.5).

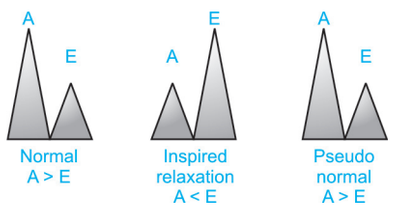

Fig. 19.5: Patterns of left ventricular filling, as recorded by diastolic doppler mitral flow velocities. A is the early diastolic filling and E is the late diastolic filling due to atrial contraction

During rest, even in the presence of heart failure, the value of cardiac output or stroke volume may be within normal limits due to compensatory mechanism, though it is depressed. Hence, the amount of stroke volume or cardiac output always cannot properly give the idea of cardiac performance. So, a more sensitive index of heart failure or cardiac activity is the ejection fraction than the cardiac output or stroke volume. In systolic heart failure, the ejection fraction is depressed, even when the stroke volume remain normal. It means with the increase of end diastolic volume (EDV) due to compensation, stroke volume may be normal, but the full amount of blood coming into the ventricle can not be ejected out and always some blood will remain in the ventricle after ejection. Alternatively, abnormally elevated EDV (normal value 70 ± 20 ml/m^2) in the presence of normal stroke volume signifies impaired left ventricular systolic function.

There are limitations in the isolated measurement of the stroke volume, cardiac output and ejection fraction for the assessment of the systolic performance of heart. The limitations are that these parameters are influenced strongly by some factors such as the ventricular filling conditions (preload) and afterload. Thus a decreased ejection fraction and low cardiac output may be observed in patients with normal ventricular function (contractility), but with reduced preload such as in hypovolaemia or with increased afterload as occurs during acutely elevated arterial pressure. So, the measurement of end systolic ventricular pressure and volume may be a useful index of ventricular performance than ejection fraction, since it is independent of both the preload and afterload. If the ventricular contractility declines, the end systolic ventricular presure and volume rises.

The diastolic performance is best assessed by continuously measuring the flow velocity across the mitral valve using the Doppler echocardiography. Normally, the flow velocity across the mitral valve is more rapid in early diastole (A) than during atrial systole (E). With impaired relaxation of the ventricle the rate of early diastolic filling declines while the rate of presystolic filling due to atrial contraction rises. With severe impairment of filling, the pattern is again pseudonormalised and early ventricular filling becomes more rapid.

End Diastolic Ventricular Pressure (EDP)

The end diastolic pressure of a ventricle runs parallel with the end diastolic volume (EDV) of it. It is also called the preload. It increases in the presence of heart failure. In the absence of failure, EDP can also increase in the presence of poorly compliant or stiff ventricle. In such circumstances, increase in EDP does not run in parallel to EDV of the ventricle which remains normal or decrease. The normal value of EDP of left ventricle and right ventricle are respectively 12 mm of Hg and 5 mm of Hg. In the absence of mitral valve disease the pulmonary artery pressure and the left atrial pressure is equivalent to left ventricular EDP. In ECG, manifestation of left atrial enlargement correlates well with the increased left atrial pressure and subsequently the increased left ventricular EDP (Fig. 19.6).

The analysis of heart as a pump has classically centered on the relation between the end-diastolic volume of ventricle (which is related to the length of the muscle fibres) and its stroke volume (Frank-Starling relation). The end diastolic pressure of the ventricle is sometimes used as synoname for end-diastolic volume. In the normal heart when the stroke volume remains within the limits, it correlates directly well with the end diastolic fibre length or volume of the ventricle (preload) and inversely with the arterial pressure (afterload). But, failed heart delivers a smaller than normal stroke volume from a normal or elevated end-diastolic volume.

So, the relation between the ventricular end-diastolic pressure and stroke work

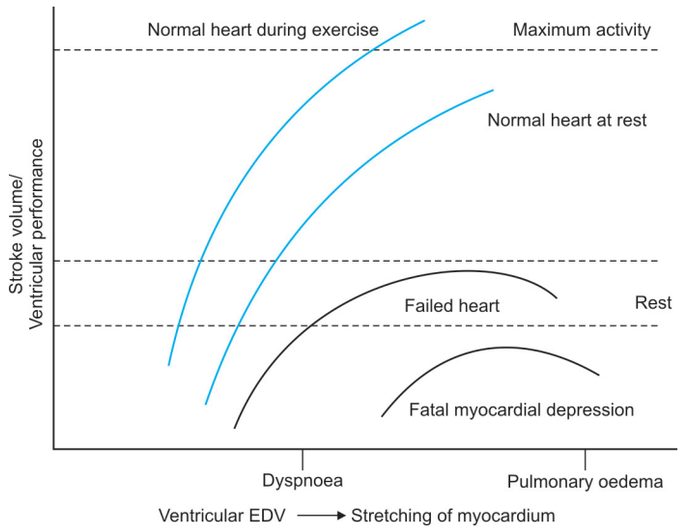

Fig. 19.6: Normal and abnormal ventricular function curve. It shows the inter-relations between the ventricular end diastolic volume (EDV) by stretching of myocardium and the contractile state of the heart. Ventricular EDV and resultant filling pressure are plotted on the abscissa and ventricular performance on the ordinate. Green lines indicate the performance or function of normal heart during rest and exercise. While red lines indicate the depressed performance of failing heart

(the ventricular function curve) needs a good and useful definition of contractility (i.e, the force of contraction) of the ventricle. An increase in ventricular contractility shifts the ventricular function curve upward and towards the left. It means, with increased contractility there is greater stroke volume at any level of ventricular end-diastolic pressure (or volume). While depression of contractility shifts the ventricular function curve to downwards and to the right. An example of shifting of the ventricular function curve to the left is exercise. During the adrenergic stimulation of myocardium, accompanying exercise, there is relatively little change in ventricular end-diastolic volume, while cardiac output, aortic flow velocity, stroke volume and the rate of ventricular pressure development are all augmented reflecting an increase in myocardial contractility.

Adrenergic stimulation of myocardium through adrenergic neurotransmitter such as norepinephrine has long been recognized. Norepinephrine activates the myocardial β-receptors and thereby increases the concentration of c-AMP. The latter in turn causes a more rapid forceful contraction by phosphorylating the Ca^{2+} channel in the myocardial sarcolemma and thereby enhancing the influx of Ca^{2+} into the myocyte which in turn, acts on the contractile apparatus.

ASSESSMENT OF VENTRICULAR FUNCTION

The assessment of ventricular function is divided into three parts: assessment of the systolic function, assessment of the diastolic function and assessment of the both ventricular systolic and diastolic function by ventricular function curve.

Assessment of Ventricular Systolic Function

The ventricular systolic function means the ventricular contractility and it is best assessed by the changes of intraventricular pressure over time during systole. It is designated as dP/dt. Measurement of this value is difficult and requires a high fidelity ventricular catheter. The usefulness of dP/dt is also limited. It may be influenced by preload and afterload.

Ventricular systolic function or contractility can also be assessed by the ejection fraction (EF), which is discussed before. In practice, this EF is the most commonly used parameter for assessment of contractility of ventricle by the formula:

$$EF = \frac{EDV - ESV}{EDV}$$

EDV = End diastolic volume, ESV = End systolic volume. The importance of this parameter is that it can be measured non-invasively by echocardiography. The limitation of importance of EF is that after a certain limit of increase in afterload, stroke volume decreases, but this reduction of EF does not indicate the reduction of contractility of ventricle, though output decreases.

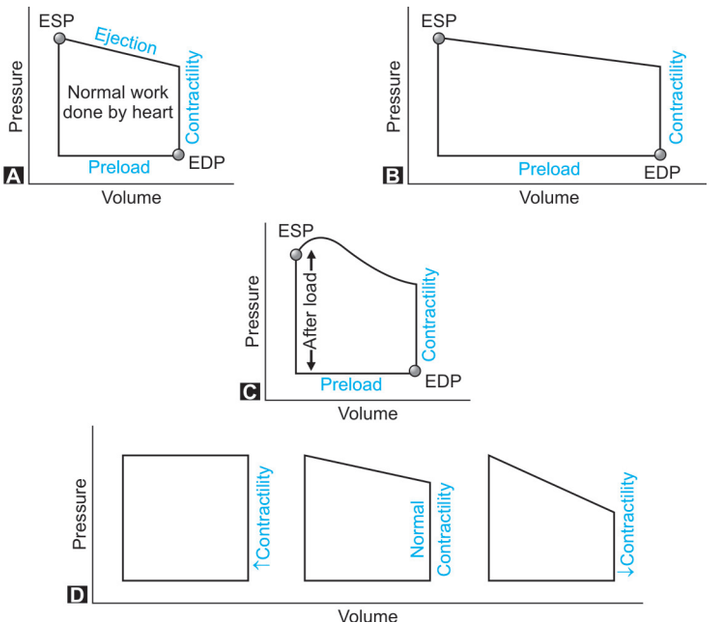
Assessment of Ventricular Diastolic Function

The ventricular diastolic function is also assessed by measuring the flow velocity of blood across the mitral or tricuspid value during ventricular diastole by Doppler echocardiography. The velocity of flow of blood across the mitral or tricuspid valve is measured or assessed by : Isovolumetric relaxation time (IVRT), the ratio of PEDF / PASF (PEDF = Peak early diastolic flow, PASF = Peak atrial systolic flow, discussed before) and the deceleration time of peak early diastolic flow (DTE) (Figs 19.7A to D).

The normal value of IVRT is 70 to 90 ms. It is greater than >100 ms means impaired relaxation and diastolic dysfunction of ventricle. The normal value of PEDF/ PASF ratio is 0.8 to 1.2. When this value is less than < 0.8, it also means impaired relaxation and diastolic dysfunction. The normal value of DTE is 150 to 300 ms, but the value above >300 ms means impaired relaxation.

Assessment of Ventricular Systolic and Diastolic Function by Ventricular Function Curve

The graph of Starling law which plots the stroke volume against the preload (described before) is useful for understanding



Figs 19.7A to D: Volume-pressure curve of single ventricular contraction
ESP = End system pressure, EDP = End diastolic pressure
A. Normal heart.
B. Increased preload with constant contractility (intraventricular pressure) and afterload.
C. Increased afterload with constant preload and contractility.
D. Increased and decreased contractility with constant preload and afterload.

the pathological states of heart and the effects of drug therapy on it. But the ventricular pressure volume curve is more useful than the previous curve. Because it dissociates the state of contractility from preload and afterload Fig. 19.7A shows the pressure volume curve of a normal ventricle. Fig. 19.7B shows the pressure volume curve with increasing preload where contractility and afterload (or intraventricular tension) is like normal. Fig. 19.7C shows the pressure volume curve with increasing afterload (or intraventricular tension) where preload and contractility is like normal heart. Fig. 19.7D shows the pressure volume curve with increased or decreased contractility where preload and afterload (or intraventricular tension during contraction) is constant.

PROBABLE THEORIES OF HEART FAILURE

There is no single unified theory which can explain the biochemical basis heart failure. Low-output cardiac failure (commonest form) due to coronary ischaemia, coronary atherosclerosis, hypertension, cardiomyopathy, valvular lesions, etc. is characterised by reduced external work done by heart in exchange of elevated O_2 consumption, i.e. the ratio of external work performed by heart and energy consumed by heart is depressed. The probable theories of heart failure are:

i. Myocardial energy which is stored in the form of creatine phosphate are depleted. Also, the activity of enzyme such as creatine kinase which is required for the shuttling of high energy phosphate between the creatine and adenosine diphosphate is reduced. So, it suggests that the reduction of myocardial energy reserves is one of the possible mechanism of heart failure.
ii. Another possible theory of heart failure is the reduction of myosin ATPase activity which could be caused by an alteration in the expression of troponin-T and/or of myosin light kinase2 activity. It could also be responsible for lowering the rate of interaction between the myosin and actin myofilaments.
iii. The third theory explains that in many forms of heart failure the delivery of Ca^{2+} to the contractile site is reduced, thereby impairing the cardiac performance. The abnormalities actually involved the sarcolemma, T-tubules or sarcoplasmic reticulum which is yet to be identified.

NEUROHORMONAL AND BIOCHEMICAL ADJUSTMENT OF HEART FAILURE

The reduction of stroke volume and the reduction of cardiac output in heart failure induce a series of neurohormonal adjustment, which may be considered to be the both adaptive (helpful) and maladaptive (not helpful). This neurohormonal adjustment involves the renin, angiotensin and aldosterone system and the adrenergic nervous system. In the face of reduction of CO though this changes are beneficial to maintain the CO and arterial perfusion pressure at the tissue level, but on the other hand, they increase the haemodynamic burden and O_2 consumption of the failing heart.

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system is activated when CO declines due to heart failure. It causes the elevation of plasma level of renin, angiotensin I and II. Elevation of angiotensin II contributes to the excessive vasoconstriction and elevation of aldosterone which again lead to the retention of salt and water. All these compensatory changes are aimed to maintain the cardiac output and blood pressure. So, one of the principles of treatment of heart failure is the blocking of this system by ACE inhibitor or angiotensin II receptor blocker or by aldosterone antagonist.

Adrenergic Nervous System

The circulating norepinephrine level is markedly elevated in heart failure patient which reflects the increased activity of adrenergic nervous system. This increased adrenergic activity in one way is adaptive by supporting the ventricular contracti-lity in heart failure. In another way, it is maladaptive as the increased adrenergic activity increases the afterload by raising the vascular resistance and causing the further myocardial damage. This latter can be prevented by the cautious use of gradually increasing the doses of β-blocker (Fig. 19.8).

CONCLUSION

The density of the adrenergic receptor and therefore, the activity of norepinephrine on these cardiac adrenergic receptor (but not the circulating catecholamine or norepinephrine level) is reduced in heart failure. These changes leads to the reduction in the activity of adenyl α cyclase and lower the intracellular concentration of cAMP. The latter in turn reduces the activation of protein kinase and subsequently the phosphorylation of Ca^{2+} channel which then reduces the trans sarcolemmal Ca^{2+} entry and as well as the phosphorylation of phospholamban, a protein in the sarcoplasmic reticulum. Thereby it depresses the reuptake of Ca^{2+} by the latter. The changes in G-protein (or guanine receptor or GR), which make couple the β-receptor with the catalytic adenyl cyclase (which is responsible for the production of cAMP), may also occur in heart failure with increased inhibitory activity.

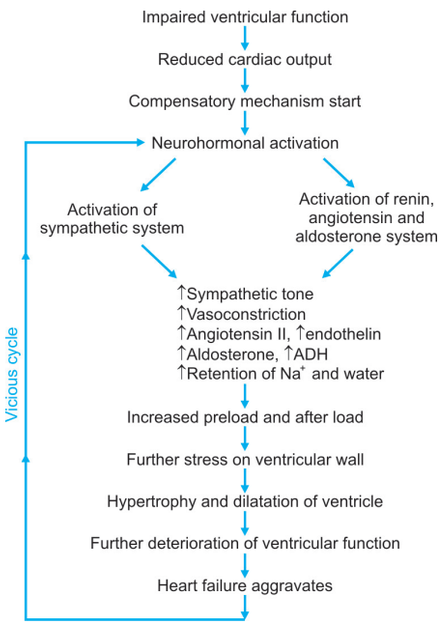


Fig. 19.8: The neurohormonal adjustment or compensatory mechanism of heart failure

Finally, we can tell that the basic problem of heart failure is the depression of myocardial contractility (or the force-velocity relationship) and the length tension curve (or the Starling law) reflecting the reduction of the contractile state of the myocardium. Usually, at rest the CO and ventricular performance is maintained within normal limits by an elevated ventricular end-diastolic volume and subsequently increased end-diastolic fibre length through the operation of Frank-Starling mechanism. This elevation of left ventricular preload is associated with elevation of pulmonary capillary pressure, contributing to dyspnoea experienced by patients with heart failure. During exercise the improvement of contractility of myocardium due to augmented adrenergic activity is attenuated by norepinephrine depletion and down regulation of the myocardial β-receptor which occur in severe heart failure. The factors that tend to augment ventricular filling during exercise in normal individual push the failing myocardium along its flattened part of the length tension curve. Although the left ventricle may perform somewhat better during exercise, but this occurs only as a consequence of an inordinate elevation of the ventricular end-diastolic volume and pressure, and therefore of the pulmonary capillary pressure. The latter intensifies dyspnoea and, therefore, plays an important role in limiting the intensity of exercise that the patient can perform. The left ventricular failure becomes fatal when the myocardial length tension curve is depressed to such a point at which the cardiac performance fails to satisfy the requirement of peripheral tissues, even at rest and/or the left ventricular end diastolic and pulmonary capillary pressure are elevated to levels that result in pulmonary oedema.

PHARMACOLOGICAL TREATMENT OF HEART FAILURE

The next part of this chapter will discuss the drug therapy of heart failure due to systolic and /or diastolic ventricular dysfunction. The systolic ventricular dysfunction due to idiopathic dilated or ischaemic cardiomyopathies is characterised by large dilated ventricular chamber. Contrary, the systolic failure due to infarction has the normal ventricular chamber. On the other-hand the diastolic ventricular dysfunction due to long standing hypertension, stenotic valvular disease or a primary hypertrophic cardiomyopathy generally leads to thickened hypertrophied poorly compliant ventricular walls with small ventricular volumes. In practice, many patients have both the abnormal haemodynamics, comprising of different degree of systolic and diastolic dysfunction. The treatment should, therefore, be according to the underlying pathophysiological process of the individual patient. So, the pharmacological treatment of heart failure can be described under two headings. The first heading describe the use of oral drugs in ambulatory patients. The second will describe the intravenously administered agents for the treatment of acute hospita-lised patients. We will only deal here the second heading. For the first heading dealing with only oral drug in an ambulatory patient suffering from chronic heart failure, you will have to consult any text book of medicine.

Primarily the treatment of any heart failure had three aims:

i. Removal of precipitating cause, e.g. treatment of hypertension, sepsis, etc.

ii. Correction of the underlying causes, e.g. mitral valvotomy, replacement of valve, etc.
iii. Control of the congestive acute heart failure state.

We will discuss here only the third component of the treatment of acute heart failure. This third component of the treatment again can be divided into three categories: (a) Reduction of cardiac work load, including both the preload and the afterload, (b) Control of excessive retention of salt and water and (c) Enhancement of cardiac contractility.

Diuretics

A variety of diuretic agents are available in practice and in patients with mild heart failure, almost all are effective. But, in patient with acutely decompensated heart with failure of sufficient severity, it is generally desirable to initiate an effective diuresis by using the intravenous doses of a loop diuretic. All the diuretics act by reducing the extracellular fluid volume or decreasing the ventricular diastolic filling pressure (preload). But usually they do not cause a clinically important reduction in CO except particularly in patient with very advanced heart failure. While, over treatment must be avoided, since the resultant hypovolaemia may severely reduce the preload and then CO and may impair the renal function. The examples of usual clinically used loop diuretics are fursemide, bumetanide, ethacrynic acid, piretanide and toresnide. They are extremely powerful and reversibly inhibit the absorption of Na^+, K^+, Cl^- through the renal epithelial cells of the thick ascending limbs of loop of Henle by inhibiting the specific protein, named the Na^+-K^+-$2Cl^-$ symporter. They depend for their adequate efficacy of action on adequate renal plasma flow and their proximal tubular secretion. Then, they are delivered to their site of action, i.e. the thick ascending limb of the loop of Henle through the lumen of renal tubule. These loop diuretics also induce renal cortical vasodilation and increase the rates of urine formation that may be as high as one-fourth of the glomerular filtration rate. These drugs also reduce the toxicity of medullary interstitial tissue by preventing the reabsorption of solute in excess of water through the thick ascending limb of the loop of Henle. The excessive use of loop of diuretics may also cause the development of hyponatraemia in heart failure patient. The increased delivery and absorption of Na^+ and fluid at the distal segment of nephron, i.e. distal and collecting tubule due to less absorption at the thick ascending limb of loop of Henle also markedly enhances the excretion of K^+, particularly in the presence of elevated aldosterone levels which is typically found in the case of heart failure.

While other diuretics loose their effectiveness when the blood volume is restored to the normal from higher levels, but the loop diuretics still remain effective despite the (Fig. 19.9) elimination of excessive amount of extracellular fluid volume. The major side effects of these loop diuretics

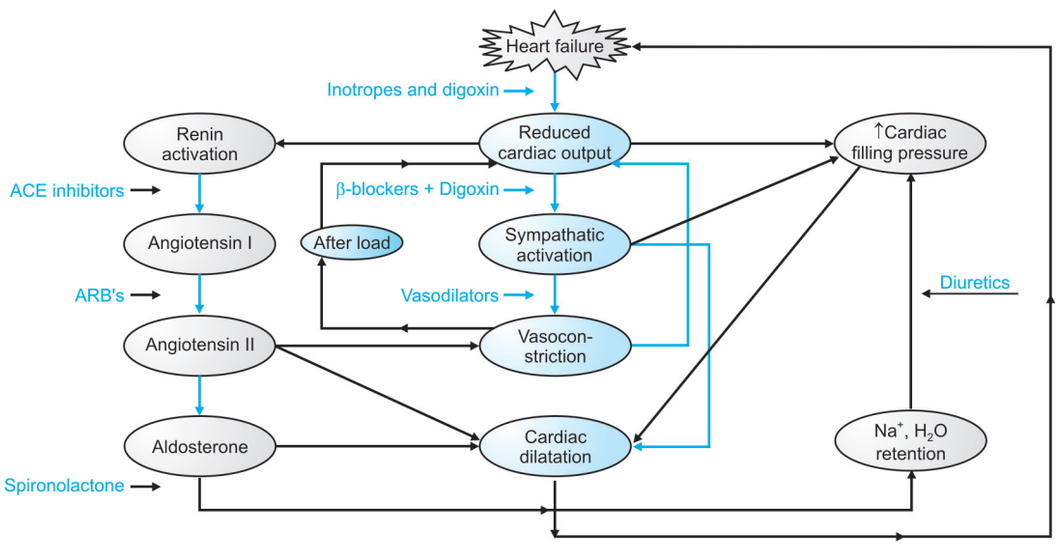

Fig. 19.9: The pathophysiological mechanism of heart failure and the different sites of action of different drugs used for its treatment. Initially heart failure is accompanied by compensatory (adaptive) neurohormonal response. It includes activation of sympathetic and renin-angiotensin-aldosterone systems. These responses initially help to maintain CV function by increasing systemic vascular tone and ventricular preload. But, with time decompensation (maladaptive) occur and the adaptive mechanism further helps to progress to the myocardial failure. Increased ventricular afterload (due to sympathetic vasoconstriction) and gradual cardiac dilatation (due to reduced cardiac output causing gradual elevated ventricular diastolic volume or filling pressure) cause a depression in systolic function. In addition, direct effect of epinephrine, norepinephrine and angiotension on the ventricular myocardium cause further dilatation and loss of contractile function. ACE = Angiotensin converting enzyme, ARB = Angiotensin receptor blocker

are due to their marked diuretic potency, which on rare occasions may result in contraction of plasma volume, circulatory collapse, reduction of renal blood flow, reduction of glomerular filtration rate and development of prerenal azotemia. The metabolic alkalosis and hypokalaemia produced by diuretics is due to large increase in the urinary excretion of Cl^-, H^+ and K^+ ions. Hyperuricemia and hyperglycemia are also sometimes observed in loop diuretics. These extremely effective loop diuretics are useful in all forms of heart failure, particularly in refractory condition and pulmonary oedema. They also produce diuresis in patient in whom thiazide diuretics and aldosterone antagonist, alone or in combination are ineffective (Table 19.3).

The loop diuretics may be administered as repetitive bolus doses which are titrated against the desired response or by constant infusion. The advantage of the latter approach is that the same total daily dose of diuretics, when given as a continuous infusion can result in a more sustained and continuous natriuresis due to the continuous maintenance of high drug levels within the lumen of renal tubules. A typical continuous furosemide infusion is initiated with 40 mg bolus IV injection, followed by a constant infusion of 10 mg/hour, with upward titration as necessary. When there is a poor response to diuretics due to reduced renal perfusion, then a short term administration of sympathomimetic drugs or phosphodiesterase inhibitors which act by increasing the CO may be necessary to achieve the response. Another useful approach for diuresis is the IV administration of dopamine at the so-called low renal doses (< 2 μg/kg/min) that can cause selective renal dopaminergic receptor stimulation and renal vasodi-latation. Therefore, it acts thereby causing a selective increase in renal blood flow without causing any systemic arterial and ven-ous constriction via α-adrenergic receptor stimulation which may occur at higher infusion rates of dopamine.

Table 19.3: Causes of resistance of diuretics in heart failure

1. Excess dietary Na^+ intake
2. Noncompliance
3. Decreased renal perfusion and glomerular filtration rate
   - (i) Hypotension or excessive intravascular fluid depletion.
   - (ii) Decline in cardiac output due to severe heart failure.
   - (iii) Aggressive diuretics and / or vasodilator therapy.
4. Primary renal pathology
5. NSAID agents

Thiazides and metolazone (thiazide related heterocyclics) diuretics are the agents of choice for the treatment of chronic ambulatory heart failure patient with severity of mild-to-moderate degree and when there is no contraindication of their use, e.g. hyperglycemia, hyperuricemia, hypokalaemia etc, or when complications are treated. When used alone, other diuretics such as spironolactone, amiloride and triamterene, etc. act as weak agent but they potentiate any thiazide and loop diuretics if they are already used. For heart failure with severe secondary hyperaldosteronism, spironolactone is very effective. In a very severe degree of heart failure which is refractory to common diuretics the combination of thiazides diuretics, loop diuretics and potassium sparing diuretics are also very effective.

Vasodilators

In a heart failure patient the left ventricular afterload is increased as a consequence of the several neural and humoral influences that tries to increase the BP by constricting the peripheral vascular bed for low CO as compensatory mechanism. These are due to the increased activity of adrenergic nervous system, increased circulation of catecholamines and increased activity of renin-angiotensin aldosterone system. In addition to the vasoconstriction the ventricular end-diastolic volume and end-systolic volume also rises in systolic heart failure. Vasoconstriction is a compensatory mechanism that tries to maintain adequate flow of blood to the vital organs. But this has no serious effect on cardiac function with normal heart, as for example hypovolaemia due to blood loss with increased sympathetic activities. But, on the other hand, in low cardiac output state due to impaired cardiac function, this vasoconstriction which increases the afterload may further reduce the CO and set a vicious cycle.

We know that afterload is a major determinant factor of cardiac output. With normal cardiac function moderate elevation of afterload does not reduce the cardiac output or stroke volume. But when the myocardial systolic function is impaired, then such increase in afterload can not maintain the stroke volume, instead it decreases. With the reduction of cardiac output there is increase in pulmonary capillary pressure leading to pulmonary congestion, oedema, dysponea, and all other signs and symptoms of heart failure. In heart failure, ventricle usually works at the peak flat portion of Frank-Starling curve. So, any additional increase in the afterload (aortic impedence) will reduce the stroke volume. Alternatively, the modest reduction of afterload in normal individual has no effect on stroke volume, but in patient with heart failure it tends to restore the stroke volume towards normal.

So, vasodilation and reduction of impedence to the left ventricular ejection i.e afterload is an important adjustment in the management of heart failure. This vasodilation is very helpful for patient with systolic heart failure. This approach is also helpful for diastolic failure by reducing the left ventricular end-diastolic pressure, left ventricular end diastolic volume and O_2 consumption, while raising the stroke volume and cardiac output, and causing only the modest reduction in systemic blood pressure. Vasodilator should not be used in patient with severe hypotension, because it may impair the tissue perfusion

and oxygenation which does not (Table 19.4) occur after a critical lower value of blood pressure in a hypertensive subject. When the chronic and acute heart failure patient is treated with vasodilators, then the cardiac output rises, pulmonary wedge pressure falls and a new steady haemodynamic state is achieved in which cardiac output increases and afterload decreases with no or only mild reduction of arterial pressure. Moreover, the reduction of elevated left ventricular end systolic pressure improves the subendocardial perfusion which further improves the myocardial contractility.

There are many available vasodilators which are used clinically. But they differ in their haemodynamic effects, site of action, duration of action and the mode of admininstration. Hydralazine, minoxidil and the alpha-adrenergic blocking agents (prazocin) act mainly on arterial system and increase the stroke volume. On the other hand, nitroglycerine and isosorbide dinitrate act mainly on the venous site of circulation and reduce preload. ACE inhibitors and nitroprusside are balanced vasodilators. They act both on the arterial and venous bed. Nitroprusside reduces the ventricular filling pressure by directly increasing the venous compliance and resulting in redistribution of blood volume from the central to the peripheral veins. It is also the most effective afterload reducing agent. It causes a fall in peripheral vascular resistance, as well as cause an increase in aortic wall compliance. These effects of nitroprusside decrease the left ventricular afterload, resulting in an increase in CO. Nitroprusside also dilates the pulmonary arterioles and reduces the right ventricular afterload. These combinations of reduction of preload and afterload by nitroprusside improves the myocardial function by reducing the wall tension, provided the blood pressure does not fall to the point where the diastolic coronary blood flow is compromised or there is no marked reflex increase in sympathetic nervous system tone causing tachycardia. Nitroprusside is particularly effective in patient with congestive heart failure due to mitral regurgitation or left to right shunt through the VSD. The increase in renal blood flow that accompanies an increase in CO, following initiation of administration of nitroprusside in patient with severe heart failure, may improve the glomerular filtration rate and increase the effectiveness of diuretics.

Nitroglycerine, like nitroprusside is also a potent vasodilator. But in contrast to nitroprusside, nitroglycerine is relatively selective for veins, particularly at low infusion rates. Thus, intravenous nitroglycerine is most often used in the treatment of acute heart failure when particularly decrease in ventricular filling pressure is desired. At higher infusion rates nitroglycerine also causes a decrease in the systemic and pulmonary arterial resistance, thereby decreasing the ventricular afterload.

Sympathomimetic Amines

The enhancement of cardiac contractility is the cornerstone of treatment of heart failure. Epinephrine, norepinephrine, isoprenaline, dopamine and dobutamine are the five sympathomimetic amines which are generally used to improve the myocardial contractility in various form of heart failure. Among them the dopamine and dobutamine are the most commonly used agents and effective in the management of heart failure, particularly in those patients who have undergone cardiac surgery, in some MI, shock, pulmonary oedema, etc. Their administration should also be accompanied by careful and continuous monitoring of ECG, arterial pressure, and if possible by PAWP (Fig. 19.10).

Table 19.4: Vasodilator drugs used to treat heart failure

Drug class	*Examples*	*Mechanism of action*	*Afterload reduction*	*Preload reduction*
ACE inhibitor	Captopril, enalapril, lisinopril	Inhibition of formation of angiotensin II	+ +	+ +
Angiotensin receptor blocker	Losartan, Candesartan	Blockade of anginotensin II receptor	+ +	+ +
Organic nitrates	Nitroglycerin, Isosorbide-di-nitrate	Nitric oxide (NO) mediated vasodilatation (nitric oxide)	+	+ + +
NO-donors	Nitroprusside	No-mediated vasodilatation	+ + +	+ + +
Direct acting on arterial smooth muscle	Hydralazine, Minoxidil	Unknown	+ + +	+
Phophodiesterase inhibitors	Milrinone, Amrinone	Inhibition of cAMP degradation	+ +	+ +
Ca^{2+} channel blocking drugs	Amlodipine, Nifedipine	Blocking of L-type Ca^{2+} channel	+ + +	+
Nonselective α-adrenergic receptors antagonist	Phentolamine	α-blocking vasodilatation	+ + +	+ + +
Selective α_1-adrenergic receptor blocker	Prazosin, Doxazosin	Selective α_1-blocking vasodilatation	+ +	+ + +
Vasodilating β/α_1 adrenergic receptor antagonist	Carvedilol, Labetalol	Selective β_1 and α_1 adrenergic receptor blockade	+ +	+ +

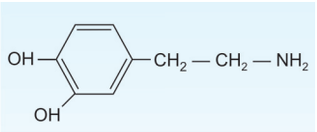

Fig. 19.10: Dopamine

Dopamine (3, 4, Dihydroxyphenyl Ethyl Amine)

It is an endogenous catecholamine and like dobutamine is a strongly positive inotropic agent which are most often used for the short-term support of circulation in advanced heart failure. Epinephrine, norepinephrine and isoprenaline are though strongly positive inotropic agent and useful in specific circumstances, but have little role in the treatment of most of the cases of severe heart failure.

Dopamine is a vary important natural central neurotransmitter and is an intermediate metabolic precursor for the synthesis of norepinephrine, epinephrine and other centrally mediated neurotransmitter. It possesses important intrinsic pharmacological properties. It is ineffective when administered orally, because dopamine is a substrate for both the MAO and COMT enzyme, present in the intestinal wall (Fig. 19.11).

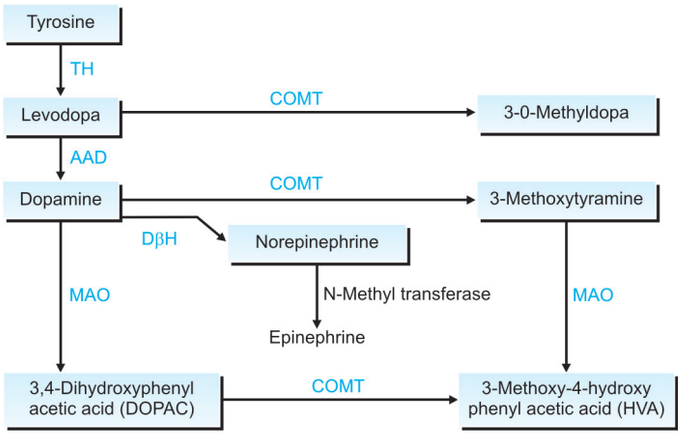

Fig. 19.11: Synthesis and metabolism of dopamine and levodopa. Levodopa is first synthesized from tyrosine which is transported into the cell by an active process present on the cell membrane. The conversion of tyrosine to levodopa is a rate limiting step and is catalysed by tyrosine hydroxylase (TH). Levodopa is then rapidly converted to dopamine by an enzyme, called aromatic amino acid decarboxylase (AAD). After that dopamine is taken up into the vesicles of dopaminergic nerve termjnals by transporter protein which can be blocked by reserpine. After its release in the synaptic cleft, the action of dopamine may be terminated by: (i) Reuptake which can be blocked by cocaine or (ii) Degradation by MAO or COMT enzyme. Metabolism of dopamine by MAO or COMT produces two metabolic products: DOPAC and HVA (Homovanillic acid). But in human beings, HVA is the primary product of metabolism of dopamine

Dopamine receptor

The action of dopamine is mediated by a family of dopamine receptors. Among them 5 subtypes of dopamine receptors are identified. These are designated as D_1, D_2, D_3, D_4, D_5. Of these the D_1 and D_5 receptor proteins have a long intracellular carboxy terminal tail and are the members of pharmacologically defined D_1 class. This D_1 class receptor stimulate the synthesis of intracellular second messenger, called cAMP and causes the hydrolysis of phosphatidyl inositol. The D_2, D_3 and D_4 receptor proteins share a common large third intracellular loop and are of the D_2 class. The D_2 class receptor inhibit the synthesis of cAMP as well as suppress the Ca^{2+} currents and activate the receptor operated K^+ currents.

All the dopamine receptors share the common structural features including the presence of seven α-helical segments capable of spanning throughout the cell membrane (Fig. 19.12). This structure identifies the dopamine receptors as the members of a large superfamily which includes other important receptors such as β-adrenergic receptors, olfactory receptors, etc. All the members of this superfamily act through the guanine nucleotide binding protein or G-protein and are discussed in more details in the autonomic nervous system chapter.

Cardiovascular effects of dopamine

Due to several distinct types of dopamine receptors and due to different affinity of dopamine to these receptors, the cardiovascular effects of dopamine vary with different doses. At low concentration (less than 2 µg/kg/min), the dopamine acts through its vascular D_1-dopaminergic receptors, especially in the renal, mesenteric and coronary beds. By activating adenyl cyclase and raising intracellular concentration of cAMP, D_1-receptor stimulation leads to vasodilation. So, infusion of dopamine in low doses increases the renal blood flow, GFR and Na^+ excretion. Thus, dopamine is often used in this small doses in the management of compromised renal function due to low CO in severe heart failure. At somewhat higher concentration (2 to 5 µg/kg/min), dopamine acts on β_1-adrenergic receptors and produce positive inotropic effect on the myocardium. In this dose dopamine also releases norepinephrine from the nerve terminals, and accounts for its effects on the heart. But, tachycardia induced by dopamine in this dose is less prominent than isoprenaline. At this level dopamine increa-ses systolic blood pressure, but has no effect on diastolic blood pressure and total peripheral resistance remains unchanged or reduce (probably because of the ability of dopamine to reduce regional arterial resistance in some vascular beds). At more higher concentration (5 to 15 µg/kg/min or higher), dopamine activates the vascular

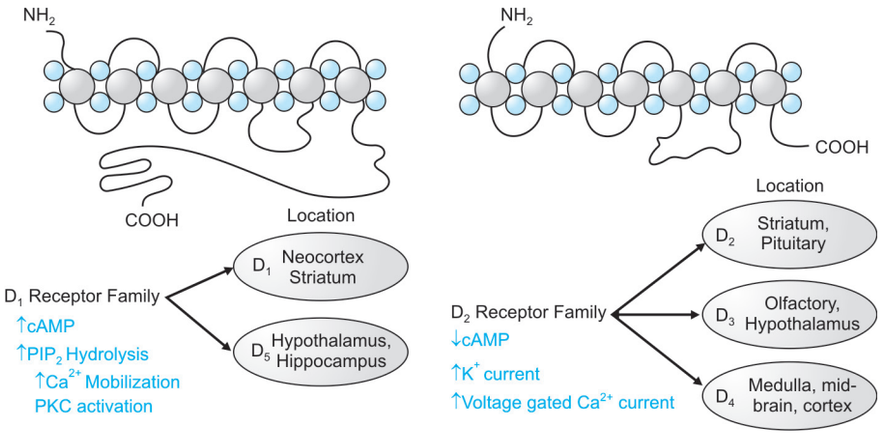

Fig. 19.12: Distribution and characteristic of different dopamine receptors

α_1-adrenergic receptor leading to peripheral arterial and venous constriction which sometimes may be desirable for the support of critically reduced arterial pressure. But this may further supress the ventricular systolic function, due to the increase in afterload.

As dopamine does not cross the blood-brain barrier readily, so it has no central effects, though there are specific dopamine receptors at the different area of CNS.

Precautions, adverse reactions and contraindications of dopamine

The adverse effects of dopamine is mainly attributable to excessive sympathomimetic activity of it. Tachycardia, anginal pain, arrhythmias, severe hypertension, headache, nausea and vomiting may be encountered during an infusion of dopamine. Hypovolaemia should be corrected by plasma, whole blood or appropriate fluids in shock patients before starting the dopamine infusions. Dopamine should be avoided in patients taking MAO inhibitors or tricyclic antidepressant compounds (Fig. 19.13).

Therapeutic uses and doses of dopamine

The indications where the dopamine is mainly used are: congestive heart failure with oliguria, low peripheral vascular resistance, cardiogenic shock, septic shock and during different cardiac surgeries.

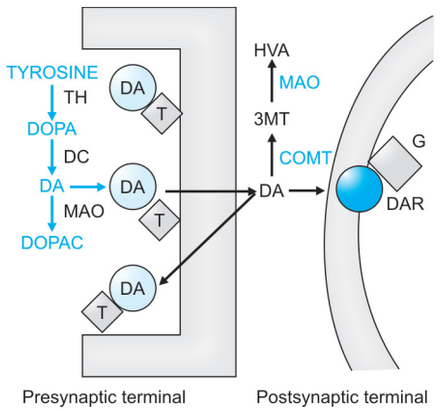

Fig. 19.13: The dopaminergic nerve terminal, where dopamine is synthesised from the precursor tyrosine by the sequential actions of the enzyme TH (tyrosine hydroxylase) producing DOPA (dihydroxy phenylalanine) and DC (decarboxylase) producing DA (dopamine). Dopamine is then transported into the storage vesicles situated in the presynaptic terminal by a transporter protein (T). Then, depolarization, entry of Ca^{2+} and release of dopamine by Ca^{2+} allows it to act on the postsynaptic dopamine receptor (DAR). Several distinct types of dopamine receptors present in the brain are discovered which explains the different action of it at different doses. The action of dopamine (DA) at the nerve terminal is terminated by sequential actions of the enzymes COMT and MAO or by reuptake of DA in the nerve terminal. DOPAC = Dihydroxyphenyl acetic acid

Initially, the dopamine infusion is usually started at a rate of less than 2µg/kg/min (low dose) and then gradually it is increased to 2 to 5 µg/kg/min (intermediate dose). The infusion rate of dopamine may be increased to 20 to 50 µg/kg/min or more as the clinical situation dictates. During the infusion of dopamine patients should be continuously monitored for the myocardial function, perfusion of vital organs, production of urine, arterial and venous pressure, ECG, etc. The reduction in urine output, tachycardia, development of arrhythmias indicate immediate termination of dopamine infusion. As the duration of action of dopamine is brief, so the rate of administration of it through infusion should be adjusted continuously to control the intensity of effect.

Usually an alteration of cardiac responsiveness to the catecholamines have been found in different stages of heart failure. So, the doses of infusion of sympathomimetic amines should be titrated according to the response of the patient. Increased sympathetic nervous system activity is observed in patient during the early part of congestive heart failure. At that stage, infusion of any β or dopa adrenergic agonist have been found to be toxic to the heart. Then, gradually the over expressions of β or dopa adrenergic receptor had lead to the dilated cardiomyopathy. After that a number of changes in β-adrenergic receptor signaling occur in myocardium in patient with long-standing heart failure. Decreased numbers and functioning of β_1-adrenergic receptor consistently have been found in chronic heart failure, leading to attenuation of β-adrenergic receptor mediated stimulation or positive inotropic response in the failing heart.

Dobutamine (Fig. 19.14)

The structure of dobutamine and dopamine is more or less same except a bulky aromatic substituent which is attached to the amino group in dobutamine. It is not a natural neurotransmitter, nor releases norepinephrine from the sympathetic nerve endings, and nor exerts their actions via dopaminergic receptors. The pharmacological effects of dobutamine are due to its direct effect on the α and β-adrenergic receptors. The

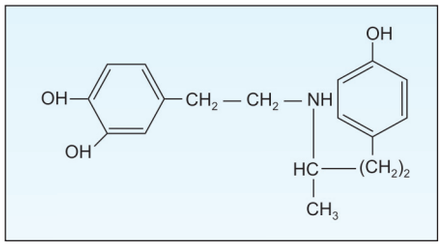

Fig. 19.14: Dobutamine

clinically used dobutamine is a racemic mixture of two enantiomers. The (−) isomer of dobutamine is a potent α_1-receptor agonist, causing marked pressure responses, whereas (+) isomer of dobutamine is a potent α_1-receptor antagonist, blocking the effect of (−) isomer (partial agonist). Thus, the mechanism of action of dobutamine is very complex. The positive inotropic action of dobutamine on myocardium is also due to its agonistic β_1-adrenergic effect. Here, the (+) isomer is about 10 times more potent than the (−) isomer of it.

In the peripheral vasculature, the α_1-adrenergic vasoconstrictive effect of (−) isomer of dobutamine is balanced by the partial antagonism of the α_1-receptor effect of (+) isomer and the vasodilatory effect is mainly due to the β_2-receptor stimulation by dobutamine. Thus, the net pharmacological effect of dobutamine is to increase the stroke volume and CO by positive inotropic action on myocardium (β_1-effect) and to decrease the systemic vascular resistance and venous filling pressure by both α, β effect. Dobutamine has no action on renal dopaminergic receptor, so it does not dilate the renal vessels. But the increase in renal blood flow and GFR by dobutamine is due to the increase in CO. Dobutamine causes no or little increase in heart rate. It has relatively more prominent inotropic effect than chronotropic effects on the heart. So, at doses that increase CO, there is little increase in heart rate than dopamine.

Dobutamine is used by infusion and is started with the dose of 2 to 3 µg/kg/min. Then, it is titrated upwards according to the patient's symptoms, and haemodynamic goals, which depends on the cardiac contractility, CO and peripheral vascular resistance. Depending on the vascular resistance and CO, the BP may increase, decrease or remains the same. In response to improved cardiovascular function by dobutamine, heart rate often declines due to withdrawal of reflex sympathetic tone. The measurement of PCWP and CO using pulmonary arterial catheter often allows the more effective use of dobutamine alone or in conjunction with other vasodilator and diuretics. However, continuous infusion of dobutamine over several days reduces its efficacy and it is due to the development of tolerance. When the tolerance develops to dobutamine after prolonged use, then it is necessary to switch over to an intravenous class III cyclic AMP phosphodiesterase inhibitory agent, e.g. amrinone or milrinone.

Like other sympathomimetic drugs, the side effects of dobutamine are also severe tachycardia, hypertension, arrhythmia, ventricular ectopic, etc. Patients with history of hypertension may be at greater risk of developing an exaggerated pressure response to dobutamine. As dobutamine facilitates AV conduction (enhancement of atrioventricular and intraventricular conduction by isoprenaline and dobutamine is same), so patients with atrial fibrillation are at increased risk of marked ventricular response rates. Dobutamine like other inotropic agents may also increase the size of myocardial infarct by increasing the myocardial O_2 demand. This risk must be balanced against the patient's overall clinical status. Infusion of dobutamine in a patient with receiving β-blocker fails to increase CO as the total peripheral vascular resistance is increased by it (Fig. 19.15).

The main therapeutic indication of the use of dobutamine is the short-term treatment of cardiac decompensation with severe hypotension that occur after cardiac surgery or in patient with congestive heart failure or in patient suffering from acute MI, because it increases the CO and stroke volume without increasing the heart rate. Half-life of dobutamine is 2 min. Onset of action of dopamine is rapid and so no loading dose is required. Steady state concentration of dobutamine is generally achieved within 10 min of starting of an infusion.

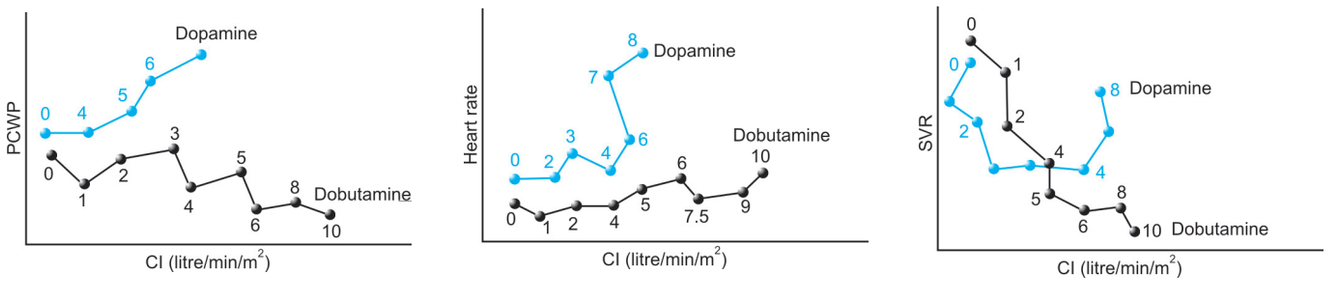

Fig. 19.15: The effects of dopamine and dobutamine on pulmonary capillary wedge pressure (PCWP), heart rate, and systemic vascular resistance (SVR) were shown in a patient with severe heart failure. Dobutamine increases both the cardiac output and cardiac index due to an increase in stroke volume. This effect of dobutamine is associated with decrease in both PCWP and SVR. It reflects both the direct vasodilation effect of dobutamine due to stimulation of β_2-adrenergic receptors and withdrawl of reflex sympathetic tone due to improved cardiovascular function. At infusion rates of dopamine exceeding 2 to 4 µg/kg per minute, it exerts a potent vasoconstrictor effect. It is evidenced by the increase in SVR and PCWP. It also decreases the left ventricular function caused by the increase in after load. The numbers shown on the figures are infusion rates in µg/Kg/minute

Phosphodiesterase (PDE) Inhibitors

Adrenaline in the form of physiological signals binds with adrenergic receptor on the cell surface and induce conformational changes of the receptor. This conformational changes of receptor permit interaction of it with stimulatory G-protein (G_S) at its binding site. This G_S-protein is now activated. The activated G_S protein now activates the enzyme, adenyl cyclase (AC), located on the cytoplasmic site of the cell membrane (cytoplasmic signalling protein). Activated adenyl cyclase now hydrolyses (not dephosphorylation) ATP to cAMP and its intracellular concentration increases. This cAMP inturn, then, phosphorylates and activate the protein kinase (PK_A) which again phosphorylates many other functional proteins including troponin and phospholamban so that they interact with Ca^{2+}, resulting in increased force of contraction. Intracellular Ca^{2+} is also made available for contraction by entry from outside by direct activation of the Ca^{2+} channel, situated on the myocardial cell membrane, by both G_S protein and phosphorylated active PK_A and as well as from intracellular stores in SR.

Now, the physiological signals outside the cell in the form of adrenaline, noradrenaline, acetylcholine, etc. are integrated within the cell as second messenger such as cAMP, cGMP, Ca^{2+}, inositol phosphates, nitric oxide, etc. and do all the cellular function. Normally, the cAMP is eliminated by hydrolysis which is catalysed by the cyclic nucleotide phosphodiesterase. Thus the phosphodiesterase inhibitors mimic the effects of adenyl cyclase activation by β agonist and act through increasing the level of cAMP by inhibiting the hydrolysis of it. Hence, the increased level of intracellular cAMP by PDE inhibitors increases myocardial contractility and causes vasodilation of both artery and vein. The first group of phosphodiesterase inhibitors, e.g. theophylline, aminophylline, etc, have been identified many years ago. But their use at haemodynamically effective dose for heart failure is plagued by side effects. In 1980 introduction of amrinone and subsequently later other phosphodiesterase inhibitor e.g. milrinone have become the cornerstone of the treatment of heart failure, alleviating the previous problems.

Amrinone and milrinone

Chemically, both these drugs are bipyridine derivatives and selective phosphodiesterase III (PDE III) isoenzyme inhibitors. Pharmacologically, they are distinct from digitalis and catecholamines and form a new class of inotropic drugs. By inhibiting the isoenzymes PDE III, which is specific for intracellular degradation of cAMP in heart, blood vessels, bronchial smooth muscle cells etc, both the amrinone and milrinone increases the intracellular level of cAMP and increases the transmembrane influx of Ca^{2+}. Thus, increased intracellular Ca^{2+} level causes direct stimulation of myocardial contractility. At the same time, they cause the balanced arterial and venous dilation with consequent fall in systemic and pulmonary vascular resistance and filling pressure of heart. Due to the stimulation of myocardial contraction and decrease of afterload the CO increases. As a result of these dual mechanisms of action (vasodilatation and increased cardiac contraction), the increase in CO with milrinone and amrinone is greater than the pure vasodilator agent such as nitroprusside when compared for a given decrease in systemic arterial pressure. Again the arterial and venous dilatation effects of these two PDE inhibitors are greater than arterial and venous dilatation caused by dobutamine when compared for a given increase in CO. However, amrinone and milrinone do not inhibit the Na^+K^+ATPase pump-like digitalis. Their actions are also independent of tissue catecholamines levels and adrenergic receptors (such as β receptor) concentration (direct action) (Fig. 19.16).

Both the amrinone or milrinone are commonly used as single agent or in combination with other oral and/or intra venous drugs for short-term treatment of patient with severe systolic right or left ventricular failure. Both the drugs are used intravenously, initially by a loading dose which is then followed by a continuous infusion. For amrinone, the initial IV bolus dose is 0.75 mg/kg and is given over 2 to 3 minutes. Then it is followed by 2 to 20 µg/kg/min through continuous infusion. As milrinone is 10 times more potent than amrinone, so the initial loading dose of it is 50 µg/kg IV which is followed by 0.25 to 1 µg/kg/min by continuous infusion. The IV action of both these drugs starts within 5 minutes. The half-lives of amrinone and milrinone in healthy subjects are 2 to 3 hours and 30 to 60 minutes respectively. This half-live becomes doubled in patient with severe heart failure.

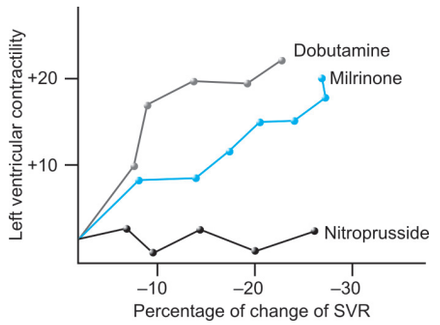

Fig. 19.16: Comparative effects of nitroprusside, milrinone and dobutamine on the gradual reduction of SVR. Among these compounds, dobutamine and milrinone (but not nitroprusside) also increases the ventricular contractility with reducing the SVR

Thrombocytopenia is the most common and prominent dose related side effect of amrinone. But it is mostly transient and asymptomatic. However thrombocytopenia is rare with milrinone (Fig. 19.17).

Milrinone is now the agent of choice among the currently available PDE inhibitors for short-term parenteral inotropic support in severe heart failure. This is because of greater selectivity of milrinone for inhibition of isoenzyme PDE III, shorter half-life and fewer side effects of it. Hence, in chronic heart failure (CHF)

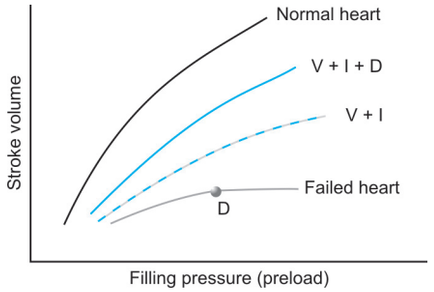

Fig. 19.17: The haemodynamic responses of the failed heart to different pharmacological interventions. V = Vasodilators, I = Inotrops. D = Diuretics. Black line represents the normal heart and red line represents the failed heart due to systolic dysfunction, with the effects of diuretics (D) alone. The other two curves show the effect of V + I and V + I + D on the failed heart. The combination of drugs produce the synergistic effect on haemodynamic responses more towards the normal heart. The diuretics alone improve the symptoms of congestive heart failure by reducing the only filling pressure of heart, but not improving the cardiac output with same ventricular function curve. Use of inotropic agents such as dobuta-mine, glycosides, etc. move the patients to higher ventricular function curve (black line)

these inotropes have no role for long-term use, but even increase the mortality.

Cardiac Glycosides

Chemically, glycosides are compound which contain both a carbohydrate (sugar) and a noncarbohydrate (nonsugar) part. It is particularly found as natural product in plants. It can be converted by hydrolytic cleavage into a sugar (glycone) and nonsugar (aglycone) component. They are also named specifically according to the type of sugar component present in it such as glycoside (glucose), pentoside (pentose) or fructoside (fructose) etc. The glycosidic compounds which have cardiac inotropic effects are called the cardiac glycosides (Fig. 19.18).

All the cardiac glycosides have a common molecular structure, i.e. a steroid (cyclopentanophenanthrene) nucleus and an unsaturated lactose nucleus (or ring) attached to the steroid nucleus at C 17 position. This steroid nucleus and the lactose ring together form the aglycone part. One or more sugar residue is attached to the

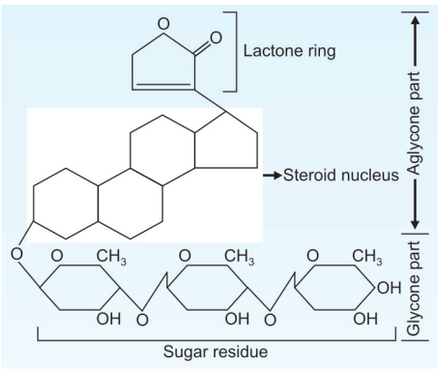

Fig. 19.18: Structure of digoxin

steroid nucleus and constitutes the glucone part of the glycoside molecule. The pharmacological properties of cardiac glycosides reside on the aglycone part. But, sugar or glycone part modifies the water solubility and the cell membrane permeability of it. There are many cardiac glycosides, available in practice. But among them only the digoxin and digitoxin are orally active, and between them only digoxin is in the widespread clinical use today. Digitoxin differs from digoxin only by the absence of hydroxyl group at C_{12} position, resulting in a less hydrophilic compound with altered pharmacokinetic property (but same pharmacodynamics) compared to digoxin.

The beneficial effects of cardiac glycosides in heart (Fig. 19.19) failure is derived from: (i) the positive inotropic effect of it on failing myocardium, (ii) the efficacy in controlling the ventricular rate in response to atrial fibrillation and (iii) the modulating sympathetic nervous system activity of it which may be an additional mechanism and contribute significantly to their efficacy in heart failure.

Mechanism of action of glycosides (digitalis)

Cardiac glycosides selectively bind to the specific site of extracytoplasmic part of the α-subunit of Na^+K^+ATPase pump situated on the cell membrane and inhibits it. As a result, there is reduction in the rate of active Na^+ extrusion and rise in intracellular Na^+ concentration.

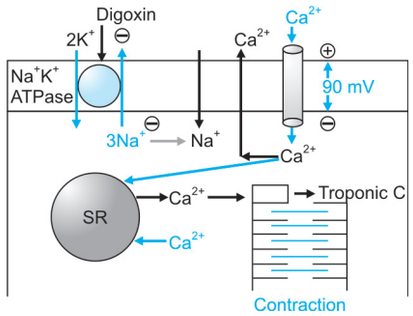

Fig. 19.19: Mechanism of positive inotropic action of digitalis (cardiac glycosides). Digitalis increases the force of cardiac contraction by not acting through catecholamine's receptor, but by its direct action on the Na^+-K^+-ATPase pump. It binds selectively with the Na^+-K^+-ATP system on the cell membrane and inhibits it. Then, inhibition of this system causes gradual accumulation and increase in concentration of Na^+ intracellularly. By the side of the Na^+-K^+-ATPase system, there is Na^+-Ca^{2+} exchange protein which extrudes Ca^{2+} in exchange of influx of Na^+. Incresed intracellular con-centration of Na^+ inhibits the further influx of Na^+ and extrusion of Ca^{2+} through this Na^+Ca^{2+} exchanger and indirectly increases the intracellular concentration of Ca^{2+} which gradually store in the SR. During depolarisation, Ca^{2+} further enters the cell through the voltage sensitive Ca^{2+} channel (A). This triggers the more release of stored Ca^{2+} from SR and thus helps in more forceful contraction. The more of intracellular Ca^{2+} concentration, the more in the force of muscular contraction. After contraction is over, Ca^{2+} is further taken back by SR. The portion of Ca^{2+} which enter the cell from outside during depolarisation is also extruded by 3 Na^+-1Ca^{2+} exchanger. This excess Ca^{2+} remains in cytosol and is taken up by SR. Thus, SR is progressively loaded with more and more Ca^{2+} and subsequently Ca^{2+} store is augmented

The relationship between the intracellular Na^+ and Ca^{2+} concentration is such that a small percentage of increase in intracellular Na^+ concentration results in large percentage of increase in intracellular Ca^{2+} concentration. Thus, the resulting increase in intracellular Ca^{2+} interacts with troponin-C and activates the cross-bridge interaction between the actin and myosin filaments that results in forceful contraction and sarcomere shortening. Moreover, the raised intracellular Ca^{2+} concentration induces a greater re-entry of Ca^{2+} through the voltage sensitive Ca^{2+} channel of 2 and 5, during plateau phase. Hence, this increased intracellular level of Ca^{2+}

is taken up by SR and its storage capacity is increased which is to be made available for the contractile elements during the subsequent depolarisation of myocytes. Thus, the contractility of myocardium is augmented and this is the mechanism of action of digitalis.

Binding of glycosides to Na^+K^+ATPase pump is slow. So the Ca^{2+} loading in SR occurs gradually and the inotropic effects of digitalis takes hours to develop even after IV administration. As the digitalis inhibit the Na^+K^+ATPase pump activity, so there is gradual depletion of intracellular K^+ (as K^+ does not enter) and this is responsible for the mechanism of all toxicities of digitalis. So, the toxicity of digitalis is partially reversed by K^+ supplementation. Excessive Ca^{2+} loading in SR results in spontaneous cycles of Ca^{2+} release and reuptake by it, producing oscillation after contraction or depolarisation. So, both the therapeutic and toxic effects of digitalis are due to this myocardial Ca^{2+} loading. These are inseparable and also explain the low therapeutic index or window of digitalis.

Electrophysiological effects of glycosides (digitalis)

The electrophysiological effects of digitalis on different types of cardiac tissues such as atrial muscle, ventricular muscle, pacemaker cells and conducting fibres are different due to their different action potential, different sensitivities and different responses to glycosides (Fig. 19.20). The Purkinje fibres and the other specialised automatic and conducting tissues in atria and ventricle are more sensitive to cardiac glycosides. The resting membrane potential (RMP) of all these tissues is progressively reversed, i.e. shifted away more from the isoelectrical level. So, the rate and amplitude of O phase depolarisation is reduced, primarily as the result of less negative value of RMP. The duration of action potential is also reduced (primarily at phase 2). Amplitude of action potential is also diminished.

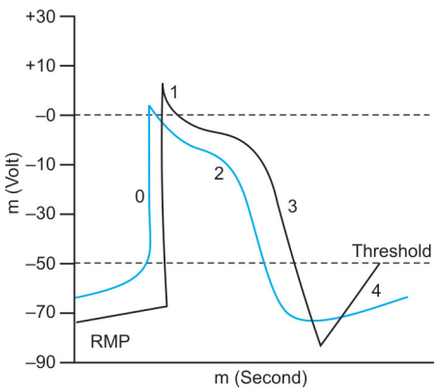

Fig. 19.20: Effects of digitalis on the action potential (AP) of Purkinje fibres (PF). Red line - digitalis untreated fibre, green line - digitalis treated fibre. RMP - resting membrane potential. The effects of digitalis differ qualitatively and quantitatively according to the types of cardiac muscle fibres. PFs, SA node and other conducting tissues are more sensiive to cardiac glycosides. For the action of glycosides, direct action and indirect autonomic influences are both important. RMP gradually shifts to the isoelectric level (i.e. decreased). So, excitability or automaticity increases due to reduction of gap between the RMP and threshold level. But this occurs in higher doses. At therapeutic concentration, automaticity is reduced (SA and AV node) by indirect vagal action which hyperpolarises these cells. In therapeutic concentrations, the slope of phase 4 also reduces that is becomes more flat which explains the reduction of automaticity in SA and AV node. In toxic doses RMP also decreases, i.e. becomes less negative. This is due to depolarisation running below the critical potential value which inactivates the fast Na+ channel. In therapeutic concentration the height of 0 phase of AP is also reduced by digitalis. This is due to more negative value of RMP at which excitation occurs. This reduction of height of AP is responsible for slow conduction and is most marked in AV node and bundle of His. In high doses the slope of phase 4 is increased in PFs which is responsible for enhanced automaticity and ectopic focus

The action of digitalis on cardiac muscle is mediated by its direct action on cells and also by the indirect action through vagus and sympathetic nervous system. At therapeutic concentration, digoxin reduces the automaticity, increases the diastolic resting membrane potential, prolongs the effective refractory period and decreases the conduction velocity or time, predominantly of the atrial and AV nodal tissues. All these are due to the increased vagal tone and decreased sympathetic nervous system activity. At higher or toxic serum concentration, the digoxin causes sinus bradycardia and /or prolongation of AV conduction, resulting heart block or arrest. On the other hand, paradoxically at more higher concentration of digoxin, sympathetic activity increases. This increases the automaticity of cardiac muscle cells that contributes to the generation of atrial and ventricular arrhythmias. Both the increased intracellular Ca^{2+} concentration and increased sympathetic activity by glycoside result in an increase in the spontaneous rate of diastolic depolarisation (phase 4) leading to ventricular ectopic, tachycardia and fibrillation. Nonuniform simultaneous increase in automaticity and depression in conduction through bundle of HIS and Purkinje system by glycoside causes arrhythmias which may lead to ventricular tachycardia and fibrillation.

Pharmacological action of cardiac glycosides

All the cardiac glycosides have similar pharmacodynamic actions. But they differ only in quantitative and pharmacokinetic properties. Digoxin is the prototype of all the cardiac glycosides and is so described here. By convention the term 'digitalis' is applied as a collective name to the whole group of cardiac glycosides (Fig. 19.21).

Digoxin has positive inotropic action and causes does dependent increase in the force of contraction of failing heart which is exquisitely sensitive to it. Systole is shortened and diastole is prolonged. When a normal cardiac muscle fibre is subjected to increased impedence to outflow, then

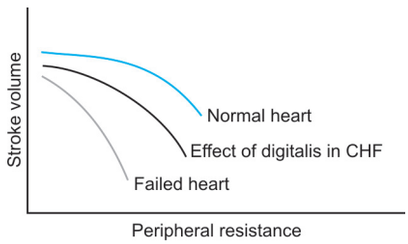

Fig. 19.21: Relationship between the peripheral resistance and the stroke volume in normal and failing heart. The figure also shows the effect of digitalis on the failed heart

by Starling principle incresed tension is generated in it so that the stroke volume is maintained considerably up to a certain higher values of impedence. While the failing heart where limitation is crossed, will not be able to do so and the stroke volume progressively decreases. But under the influence of digoxin the failing heart regains some of its capacity to contract more forcefully, when it is subjected to increased resistance for ejection. Therefore, there is more complete emptying of failing and dilated ventricles and cardiac output is increased (Fig. 19.22).

The Digoxin also increases the force of contraction in normal heart. But this is not translated into increased output, because the normal heart empties almost completely (even otherwise) and therefore further reduction of end-diastolic volume is counter productive.

The Digoxin causes decrease in HR and it is due to the improved circulation. This is more marked in failing heart where heart rate is increased as a mechanism of compensation. The improved circulation reduces the compensated sympathetic activity and thus decreases the heart rate. The direct vagal mimetic action of digoxin is also cause for bradycardia. The digoxin has direct action on SA and AV node which is also responsible for reduction in heart rate. The vagal action of digoxin manifests early and can be blocked by atropine. Whereas, the extravagal action of digoxin becomes prominent later and cannot be reversed by atropine.

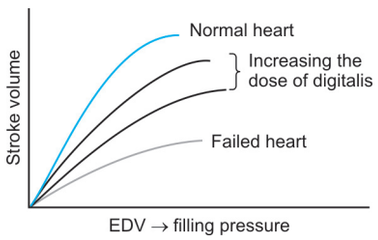

Fig. 19.22: Relationship between the filling pressure and stroke volume in normal and failed heart. It also depicts the effect of increased dose of digitalis which shifts the curve towards normal

ECG

At therapeutic level, the effect of digoxin on the ST segment is characteristic. It is one of the main effects of all the changes of digitalis on ECG. The characteristic ST segment depression seen with digoxin is described as a reverse tick and is most obvious in leads with tall R wave.

Therefore the effects of digoxin on ECG at therapeutic levels are:

i. ST-segment depression due to interference with repolarization.
ii. Reduction of T-wave size or inversion of T-wave.
iii. Shortening of QT interval – reflecting shortening of systole.
iv. Increased P-R interval due to slowing of AV conduction.

At toxic level of digoxin, the changes in the picture of ECG seen are : (i) T-wave inversion, (ii) Arrhythmias almost of any type, but especially of sinus bradycardia, paroxysmal atrial tachycardia with block, AV block, ventricular ectopic, ventricular bigeminy, ventricular tachycardia, etc.

The abnormal QRS complex of WPW syndrome under the influence of digoxin is widened, because conduction through the normal AV bundle is slowed but not through the aberrant pathways.

Pharmacokinetics

The most oral preparation of digoxin available in market have 70 to 80% oral bioavailability. Presence of food in stomach delays its absorption. Bioavailability of oral preparation of digoxin differ considerably for different manufacturers. So, it is advisable to stick to one brand. Liquid filled digoxin capsules have greater bioavailability than tablets and require dose adjustment, if a patient switches over from tablet to liquid filled capsule. Parenteral digoxin is also available for intravenous use when only oral route is impractical. Intramuscular digoxin administration causes pain and necrosis as all the glycosides are irritant to local tissues. It gets bound to muscle tissues after the IM injection and so the absorption from injection site is erratic as well as poor. Hence, the IM route for digoxin is not recommended.

All the cardiac glycosides have cumulative properties. Elimination half-life ($t_{½}$) of digoxin is 36 to 48 hours in patient with normal renal function. So, digoxin is given once a day and the steady state level with full therapeutic effect is attained after ($4 \times t_{½}$) 7 days of initiation of maintenance therapy.

Another glycosides, named digitoxin is primarily metabolised in liver which is partly to digoxin and partly undergoes some enterohepatic circulation. It is primarily excreted unchanged by the kidney, mainly by glomerular filtration. Rate of excretion of digoxin through kidney is altered in renal disease, but is parallel to the creatinine clearance. So, half-life of digoxin is prolonged in elderly and renal failure patient. Thus, the dose of digoxin has to be reduced, but is not greatly altered in renal failure.

Doses

The dose and route of digoxin administration depends on the speed of action, desired by the clinician. In many patients, the therapeutic response can occur at doses well below the maximum tolerated dose, but in some patients the reverse is observed. Generally, higher doses of digoxin is needed for severe heart failure patient. According to the therapeutic need any digitalis can be used by three methods. These are : slow oral digitalisation, rapid oral digitalisation and emergency IV digitalisation.

Slow Digitalisation (oral)

In mild-to-moderate heart failure digoxin is started orally in the dose 0.125 to 0.250 mg/day, depending on the lean body mass, as digoxin concentrates mainly in heart, skeletal muscle, liver and kidney; but not in the fat. Full theraputic response develop 5 to 7 days after initiation of therapy. If adequate response is not seen after one week, the dose is increased to 0.375 mg/

day and then to 0.5 mg/day after another 1 week.

The relief of signs and symptoms of heart failure and reduction of HR is the best guide to judge the response of action of digitalis.

Rapid digitalisation (oral)

It is done when the result is expected within few hours. It is started in the dose of 0.5 to 1 mg start, followed by 0.25 mg every 6 hours interval, with careful monitoring of toxicity, till the response occurs. It generally takes 6 to 24 hours and the total dose needed is about 0.75 to 1.5 gm. But this is seldom practised now.

Emergency IV digitalisation

This is also rarely practised now. It is only taken as a desperate measure in acute heart failure or in atrial fibrillation producing acute symptom. In such situation, digoxin is used in the dose of 0.25 mg IV stat, followed by 0.1 mg IV slowly at the interval of every hour with close ECG, BP and CVP monitoring, till response occurs. Usually, IV digitalis takes 2 to 6 hours for its full action and the total dose needed is 0.5 to 1 mg.

Current Status of Clinical Use of Digitalis

Before introduction of high ceiling IV loop diuretics, different specific arterial, venous and mixed vasodilators such as nitroprumide, nitroglycerine, ACE inhibitors, phosphodiesterase inhibitors, etc, digitalis were thought as an indispensable agent for the treatment of heart failure. But, its importance has been gradually waned away in cardiac failure. All acute, mild and moderate heart failure are treated now by diuretics and ACE inhibitors and vasodilators. Emergency IV use of digoxin is practically in extinct now. But as there is no oral inotropes for prolonged use in chronic heart failure, digitalis is still a prominent drug in chronic heart failure patients, those are not controlled by diuretics and ACE inhibitors.

Only one question exists during the prolonged use of digitalis in CHF is after decompensation how long it should be used. The answer is with the availability of diuretics, vasodilators and ACE inhibitors, there has been a trend to discontinue digitalis once compensation has been restored, specially in mild-to-moderate cases. Thus if stable clinical state has been maintained for 2 to 3 months, withdrawl of digitalis may be attempted and early reinstitution of digitalis is recommended if cardiac status declines again. There is no coincidence that digitalis prolongs the survival of CHF patients. The two major limitations for the use of cardiac glycosides are the low margin of safety and inability to reverse or retard the process which causes the heart to fail. Based on all these discussions, the international recommendation is that digoxin should be reserved for patients with CHF who have AF or for patients with sinus rhythm who remain symptomatic despite adequate treatment with diuretics, ACE inhibitors and β-adrenergic receptors antagonists.

Adverse Effects or Toxicity of Digitalis and its Management

The adverse effects or toxicity of digitalis is very high and the margin of safety is low. The adverse effects of digitalis are divided into:

Extracardiac effect

These are anorexia, nausea, vomiting, fatigue, malaise, mental confusions, restlessness, disorientation, psychosis, visual disturbances, etc.

Cardiac effect

Almost all types of arrhythmias can be produced by digitalis. These are pulsus bigeminus, ventricular extrasystole, ventricular fibrillation, ventricular tachycardia, AV junctional ectopic, partial to complete AV block, severe bradycardia, atrial extra-systole, atrial filtration and flutter, etc.

However, management of all this complications often require only dose adjustment and appropriate monitoring. Sinus arrest, second or third degree AV block are usually treated by atropine IV injection. In extreme cases temporary ventricular pacing may be needed. Even when serum K^+ level is in the normal range, still potassium supplementation should be considered for completely digitalised patients with AV junctional and ventricular ectopic beats, unless higher degree AV block is present. Extracellular K^+ promotes the dephosphorylation of $Na^+ K^+$ATPase enzyme and decrease the affinity of this enzyme for binding with cardiac glycosides. This provides one explanation for why increased extracellular K^+ reverses some of the toxic effects of digitalis. As extracellular K^+ depletion precipitate digitalis toxicity, this toxicity again causes high plasma K^+ level.

Lignocaine is used for the treatment of ventricular automaticity of digitalis toxicity which threaten haemodynamic compromise. But it does not accentuate the AV block. Electrical cardioversion carries increased risk of inducing severe rhythm disturbances in patient with overt digitalis toxicity and it should be used with particular caution.

Recently for the treatment of digitalis toxicity, antidigoxin immunotherapy is very promising and is now a great breakthrough. Purified Fab fragment from ovine antidigoxin antisera is an effective antidode for digoxin toxicity. The Fab fragment has been marketed in Europe as 'digibend' (40 mg/vial). It is nonimmunogenic. Given by IV infusion it markedly improved the survival of digitalis intoxicated patients. The total neutralizing dose of Fab is calculated from either the estimated total dose of drug ingested or the total body digoxin burden. This antidigoxin antisera can be administered intravenously with saline solution over 30 to 60 minutes. The digoxin – Fab complex is rapidly excreted by kidney. However, it is very expensive.

20 Management of Airway

HISTORY

The tracheal intubation in animals was first described by Vesalins of Padua, in 1543 and by R. Hooke of UK, in 1667. But after that there was prolonged silence and nobody had tried for intubation. Then, after a long interval, the end of the eighteenth century had again seen a flurry of researches and publications on tracheal intubation. It was triggered by the humanitarian factor for the resuscitation of drowned persons by mouth to mouth breathing. Because during that period mouth to mouth resuscitation of drowned person was condemned due to unhygienic ground. So, there was continuous search for alternative way to resuscitate a drowned person other than this unhygienic mouth to mouth artificial ventilation. Then, again after a century, in 1776, John Hunter described tracheal intubation by a metal tracheal tube. After that, in 1788, C. Kite had also described an oral and nasal intubation for resuscitation of a apparently drowned person. This is followed by James Curry who also described several different metal endotracheal tube in 1792. But, in 1827, Leroy had first showed that pneumothorax may result from high intrapulmonary pressures during artificial ventilation by tracheal tube. Then, John Snow used a tracheal catheter to resuscitate a newborn baby.

All these works described above was directed with an aim, either for resuscitation of a drowned person, or for the relief of an upper airway obstruction. Then, from 1848, passage of a metal tube or a catheter into the trachea was also routinely practised to resuscitate only the anaesthetic casualities, but not to administer sole anaesthesia. Gradually, there was a significant technical advancement to contemplate for deliberately administering anaesthetic vapours through this tracheal tube for sole anaesthetic purpose. So, John snow in 1852 had made a historical leap by intubating animals via a tracheostomy wound and providing anaesthesia through this tube. After that, in 1871, Friederich Trendslenburg of Rostock used this method in human while he was a surgical assistant to surgeon named Dr Langenbeck in Berlin. He used this method for operation in mouth. After performing a tracheostomy, he introduced a tube into the trachea and inflate the cuff for administering anaesthesia.

At that time, it had been assumed that if a tube was passed through the larynx it would not be tolerated, except tracheostomy. So, they were used to do tracheostomy for intubation. But in 1878, William MacEwen of Glasgow had first decided and try to avoid tracheostomy for intubation, if otherwise inevitable. So, after practising on the cadever, he passed a flexible metal tube through the mouth into the trachea, using his fingers as a guide in a conscious patient. Through this tube he gave choloroform and air mixture for the removal of carcinoma from the base of the tongue. A sponge was packed by him around the tube at laryngeal inlet to protect the lungs from contamination. He had also previously used rubber and gum elastic catheters into the trachea for the relief of obstruction in laryngeal diphtheria. Next in 1901, Franz Kuhn of Kassel had extended and developed this technique by using a flexible metal tube and introducing it through larynx with the help of curved wire guide after palpating the epiglottis with the fingers of his left hand. His preference was for inhalation anaesthesia and the patient was breathing to and fro through the tube. Then in 1907, Berthelemy and Dufour of Nancy, in France, blew the mixture of chloroform vapour and air into the lungs from a Vermon Harcourt inhaler through a rubber catheter which was guided into the trachea by hand, as laryngoscope was not invented at that time. It was the first kind of endotracheal insufflation technique of anaesthesia and was subsequently widely used in the forth coming World War I in 1914.

Largely after that due to their experience as anaesthetist during World War I, Mr Gillies, Mr Rowbotham and Mr Magill first used ether inhalation through one narrow gum elastic tube passed via larynx with the help of laryngoscope. During that period laryngoscope had already been invented which is described later. After that the first blind nasal intubation was performed by Rowbotham. Then, Magill also published his results of blind nasal intubation by using a wide bore rubber catheter during the years following 1928. This technique revolutionised the use of endotracheal tubes in anaesthesia, because not only it provides anaesthesia, but also

gained early control of the airway and protect it. Inflatable cuffs had been used for many years but were again reintroduced by Guedel and Waters in 1928. A pilot ballon had been described first in 1893 by Eisenmenger. It was also described in 1906 by Green and was reintroduced by Langton in 1939.

While the methods of intubation by Magill and Rowbotham had earned the support and approval of the surgeons with whom they worked, but many other surgeons discouraged the use of intubation through larynx. This was partly because of the possibility of tissue damage and partly due to conservatism. Thus, it took many years before the intubation was accepted by the all anaesthetists. Those who learnt how to perform blind nasal intubation soon realised its great advantages, especially due to the fact that it would enable a patient to be taken to the necessary level of anaesthesia very quickly by the use of relaxant and IPPV than by the use of only volatile anaesthetics which at that time was the rule. In addition, they also realised that intubation provides a clear airway, prevents laryngeal spasm and enables the lungs to be proteced against aspiration of foreign materials.

During the previous period, intubation was performed only by deepening anaesthesia by volatile anaesthetics such as ether or chloroform which was only available at that time. After that, when the muscle relaxants became available, then it was possible to perform oral intubation easily and rapidly by direct laryngoscopy. Because intubation by only inhalational anaesthetic agent was difficult and need a long time to reach the necessary deep plane of anaesthesia for it. The use of muscle relaxants to facilitate intubation in UK was pioneered by Bourne. This turning point in anaesthesia was long over due. So, the credit was given to Bourne for convincing the postwar generation of anaesthetists of the value of relaxants for rapid and easy intubation.

The traditional tubes for either nasal or oral intubation were Magill endotracheal tubes, made of mineralised rubber. The red colour of the tube is due to the presence of preservative. The oral tubes had thicker walls than the nasal ones. The angled oxford tube was thicker in the pharyngeal part and thinner in the tracheal part. Then Polyvinyl chloride (PVC) tubes had started to replace the red rubber tube, progressively from 1950. The toxicity of the PVC tube was tested by implantation test in rabbit muscle (IT = Implantation Test) or by cell culture. The Z79 was the committee in USA that originally approved anaesthetic equipment to maintain a standard and was formed first in 1956. RAE preformed tubes were first developed in 1980.

During the evolution of direct laryngoscope, indirect laryngoscopy was also evolving. The indirect laryngoscopy with mirror was first introduced by M Garcia who was a teacher of singing in london. Then, it was widely used for diagonostic purposes. But, direct laryngoscopy was pioneered in 1895 by Alfred kirstein. After that Jackson himself designed a laryngoscope which was later modified by Magill in 1926 and by Miller and Macintosh in 1932. The light was originally powered from the electric mains. But later the light was supplied by a 3 volt battery which was incorporated into the handle of laryngoscope or by a fibreoptic cable. The Macintosh blade was shorter, curved and Z shaped on cross section. Its tip entered the valecula, lifted the base of the tongue and with it the epiglottis, so that the cords could be visualised. It does not generate so much laryngospasm as it does not pass over and stimulate the posterior surface of the epiglottis. Then, it was an immediate success and has continued to be so, as it can be used in lighter planes of anaesthesia. Macintosh also developed a laryngeal forcep which bear his name and is used for directing the nasal tubes under direct vision into the larynx.

Without using muscle relaxant, cocaine was first used to supress the laryngeal reflexes during general anaesthesia by Rosenberg in 1895 and by Magill in 1928 to aid intubation. Then many sprays also have been described such as applying local anaesthetic to the larynx to supress the reflexes for intubation. But lignocaine is now generally preferred because of its lower toxicity.

To remove the different disadvantages of endotracheal intubation, initially a small mask had been tried in the pharynx, but it was rejected. Then, the invention of laryngeal mask airway (LMA) had completed the cycle of history of airway management in anaesthesia. It was first developed by an anaesthetist, named Mr A Brain and was later manufactured by an equipment company, named Colgate Medical. After that improved materials and different designs of the laryngeal mask airway, coupled with the timely arrival of propofol which deeply supresses the pharyngeal and laryngeal reflexes allowed a successful outcome of it.

INTRODUCTION

An airway is defined as the passage through which air passes into and out of the lungs during respiration. Any artificial device with a lumen inside of it and which serves as a conduit, connecting between the atmosphere and lungs is also considered as an airway. These include oropharyngeal airway, nasopharyngeal airway, LMA, other supraglottic airways, endotracheal tube (ETT), ventilator's breathing circuit etc. It is estimated that about 600 patients die each year in a developed country from complications, related to the airway management. This picture in the under developed countries is further grimmer. On the contrary, about 98% of difficult airway in relation to mask ventilation or ET intubation can be predicted by proper preoperative evaluation or assessment of patient (Table 20.1).

Table 20.1: Preoperative evaluation of patient

1.	Facial anomalies
	Maxillary hypoplasia
	Apert syndrome, Crouzon disease.
	Mandibular hypoplasia
	Pierre-Robin syndrome,
	Treacher-Collins syndrome,
	Goldenhar syndrome.
	Mandibular hyperplasia
	Acromegaly, Cherubism.
2.	Affection of temporomandibular joint
	Ankylosis, rheumatism, trauma, infection, previous surgery, etc.
3.	Problems with teeth
	Loose teeth, false teeth, protruding incisior, edentulous.
4.	Problems with tongue
	Macroglossia due to Down syndrome, hypothyroidism, haemangioma, lymphangioma, tumour, scarring, etc.
5.	Problems with mouth
	Microstomia due to burns, trauma, scarring, etc.
6.	Problems with palate
	Cleft palate, narrow arched palate, palatal swelling, haematoma etc.
7.	Problems with pharynx
	Hypertrophic tonsils, large adenoids, pharyngeal tumours, abscess, retropharyngeal or para pharyngeal abscess, etc.
	Supraglottic-epiglotitis, tumour, injury etc.
8.	Problems with larynx
	a. Glottic—Laryngomalacia, granuloma, foreign body, papillomas.
	b. Infraglottic—Congenital stenosis, traumatic stenosis, oedema due to inflammation.
9.	Problems with nose
	Choanal atresia, hypertrophic turbinates, deviated nasal septum, polyp, foreign bodies, etc.
10.	Problems with trachea
	Tracheal stenosis, tracheal webbing mass of neck deviating trachea, mediastinal mass deviating trachea, trachea esophageal fistula, tracheomalacia, foreign bodies, etc.
11.	Problems of neck and spine
	a. Neck - large goiters, skin contractures.
	b. Spine - Klippel-Feil syndrome, surgical fusion, fracture of cervical vertebrae, traumatic subluxation, etc.

The difficult airway is defined by American Society of Anaesthetist (ASA) as the clinical situation in which a conventionally trained anaesthesiologist experiences difficulty during mask ventilation or difficulty during tracheal intubation or both. *Difficult mask ventilation* is defined by ASA as the clinical situation in which it is not possible by an unassisted trained anaesthesiologist to maintain O_2 saturation more than 90%, using 100% oxygen and mask for ventilation, provided preventilation O_2 saturation level was within the normal range. *Difficult laryngoscopy* is defined by ASA as clinical situation in which it is not possible to visualise any portion of the vocal cords with conventional laryngoscope. ASA also defines *difficult endotracheal intubation* as a situation when insertion of ET tube in the larynx requires more than 3 consecutive attempts or more than ten minutes with conventional laryngoscope and experience. The later definition of ten minutes provides a margin of safety for preoxygenated patients who are undergoing elective intubation in the operating room. Because such patients in stable circumstances can usually tolerate 10 minute of attempts without any bad consequences. *'Zero class airway view'* is defined as unability to see any portion of the epiglottis after opening the mouth and tongue protrusion. Approximately 1.8% patient of the total population belongs to this class of airway view. *Failed intubation* is defined as the condition when the placement of ET tube fails after multiple attempts of intubation.

The airway is divided into an upper and lower airway. The upper airway is comprised of oral cavity, nose, pharynx (nasopharynx, oropharynx and laryngopharynx) and larynx. The nose is again comprised of external nose and nasal cavity. The lower airway includes the trachea, bronchi, bronchiole, and its subsequent divisions and subdivisinos which terminate in the alveoli. The upper airway serves to warm, humidify and filter the air or gases before it enters the lower airway. Bypassing these structures by endotracheal intubation or tracheostomy makes an anaesthetist essential to provide warm, humidified and filtered air to the patient. Among the two airways, upper airway is more vulnerable to obstruction during anaesthesia. This is because in anaesthetised patient there is loss of muscle tone which allows the tongue to fall back on the pharynx, the pharyngeal wall to collapse and occlude the upper airway at the level of laryngo pharynx and then subsequently allows the epiglottis to occlude the airway at the level of larynx.

There are many different accquired and congenital conditions which affect the upper and lower airways and cause the difficult management of it. These are listed in the Table 20.1.

ANATOMY OF THE UPPER AIRWAY

Nose

Nose consists of external nose and nasal cavity.

External nose

It is a pyramid like projection on the face. It presents a free tip or apex and a root at its junction with the forehead. The rounded boarder between the tip and the root of the nose along with adjoining area is known as the dorsum of the nose. The inferior surface of the external nose presents a pair of pyriform apertures which is called the nostrils or nares. Each nostril is bounded medially by the mobile part of nasal septum and laterally by the ala of nose (Fig. 20.1).

The frame work of the external nose is formed by some bones and cartilages. Among them the upper part is supported by bones and the lower part is supported by cartilages. The upper part is supported by the following bones such as nasal bone, frontal process of the maxillary bone and nasal part of the frontal bone.

The lower part is contributed by the following cartilages:

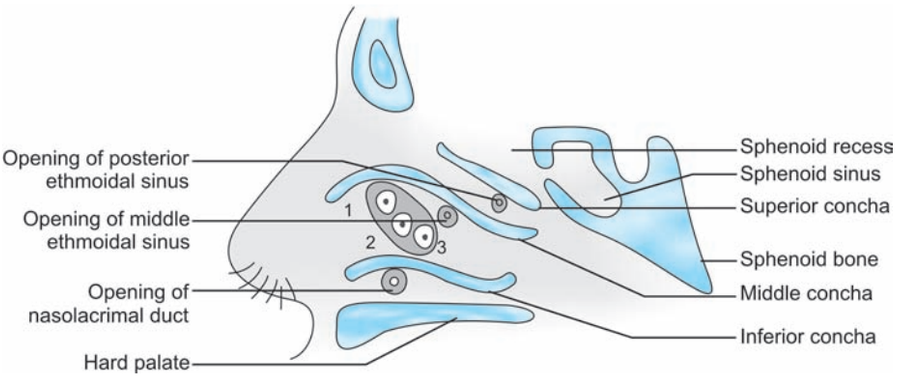

Fig. 20.1: The structures which open on the lateral wall of the nose. The cut margin of conchas are seen. 1. Opening of frontal sinus, 2. Opening of anterior ethmoidal sinus, 3. Opening of maxillary sinus

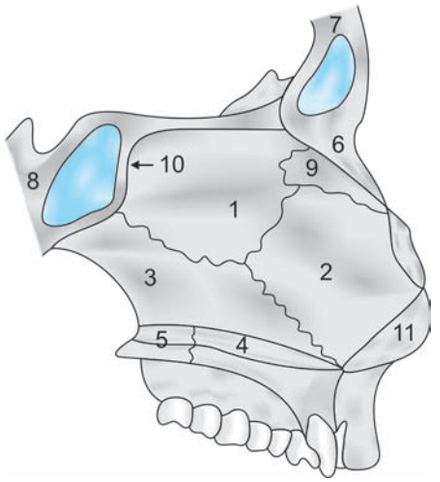

Fig. 20.2: The formation of nasal septum
1. Perpendicular plate of ethmoid
2. Septal cartilage
3. Vomer
4. Nasal crest of maxilla
5. Nasal crest of palatine bone
6. Nasal spine of frontal bone
7. Frontal bone
8. Sphenoid
9. Nasal crest of nasal bone
10. Rostrum of sphenoid
11. Septal process of inferior nasal cartilage.

i. anterior border of the septal cartilages,
ii. superior nasal cartilages, which is continuous with the septal cartilages,
iii. inferior nasal cartilage (or alar cartilage) which presents a septal process to form the mobile part of nasal septum,
iv. a few minor alar cartilages,
v. fibrofatty tissue in the lower part of the ala.

The skin overlying the bones at the root of the nose is thin and mobile. But it is thick and adherent to the underlying cartilages and fibrofatty tissue. The skin of nose is provided with multiple sebaceous glands.

The sensory nerves of external nose are derived from (i) the external nasal and the infratrochlear branches of opthalmic nerve and (ii) the infraorbital branch of maxillary nerve.

Nasal Cavity

The nasal cavity is triangular in shape and has an irregular surface. It is divided into right and left halves by the nasal septum. Each half of the nasal cavity extends anteriorly from the mucocutaneous junction of anterior nares to the nasopharynx posteriorly (posterior nares and choanac). Each nasal cavity has a roof, a floor, a lateral wall and a medial wall. The roof of the nasal cavity slopes downwards both in front and behind from the middle horizontal part. The middle horizontal part of the roof of the nasal cavity is formed by the cribriform plate of ethmoid bone. The anterior slope of the roof is formed by the nasal part of the frontal bone, nasal bone and the nasal cartilages. The posterior slope of the roof is formed by the inferior surface of the body of sphenoid bone. The floor of nasal cavity is formed by the palatine process of maxilla and the horizontal plate of palatine bone. The area of the nasal cavity close to the nostrils or anterior nares is known as the vestibule. It is lined by skin and provided with coarse hairs, sebaceous glands and sweat glands. Except vestibule, rest of the nasal cavity is lined by the mucous membrane (Fig. 20.2).

The lateral wall of the nasal cavity is irregular due to the presence of three shelf-like or scroll-like bony projections. These projections increase the surface area of the nose and ensure effective conditioning (warming and humidification) of the inspired air. Lateral wall separates the nasal cavity (i) from the orbital cavity above while the ethmoidal air sinuses interven between them, (ii) from the maxillary sinus below and (iii) from the lacrimal groove with lacrimal sac and the nasolacrimal canal with nasolacrimal duct in front (Fig. 20.3).

The lateral wall of the nasal cavity is formed by some bones. These are: nasal,

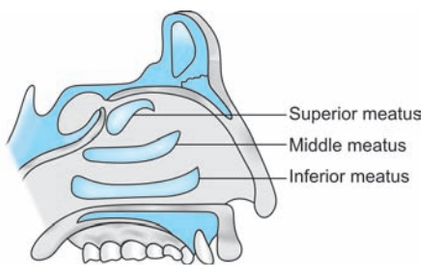

Fig. 20.3: The lateral wall of the nose

frontal process of maxilla, lacrimal, labyrinth of ethmoid with superior and middle conchae, inferior nasal concha, perpendicular plate of palatine and medial pterygoid plate of sphenoids. There is a shallow depression which is situated just in front of the middle meatus and above the vestibule of the nose. This is called atrium (Fig. 20.4).

The bony lateral wall of the nasal cavity is convoluted by three turbinates. The superior and middle turbinates are formed by the medial aspect of the lateral mass (or labyrinth) of the ethmoid bone. The inferior turbinate is formed by

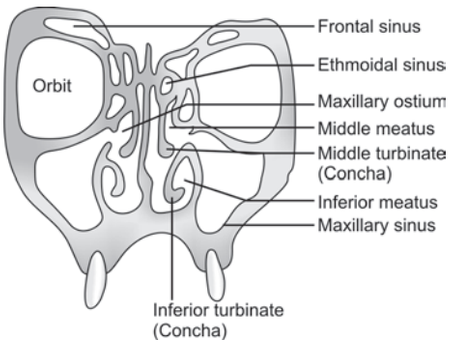

Fig. 20.4: The coronal section through nose and sinuses at the plane of maxillary ostium

separate bone called inferior nasal concha which is attached to the maxilla. In cross section, as the bones of turbinates look like whorl (turbinate) or scroll (concha), so they are named like that. Each turbinate hangs over a meatus or channel and the meatuses are named according to the name of the turbinate. The highest space in the nasal cavity above the superior turbinate is called the spheno-ethmoidal recess and sphenoidal sinus opens in this recess.

The olfactory cleft of nasal cavity is the area which lies between the superior turbinate, cribriform plate of ethmoid and the corresponding area of the septum. It is lined by specialised olfactory epithelium.

Several ducts drain on the lateral wall of the nose at the meatuses under the respective turbinate. The nasolacrimal duct open into the inferior meatus. The frontal, maxillary and anterior ethmoidal sinuses drain into the middle meatus. The posterior ethmoidal sinuses drain into the superior meatus. Sphenoethmoidal recess receives the sphenoidal sinus.

The nasal septum is situated in the midline and seperates the two nasal cavities. Posteriorly, it is bony in structure and anteriorly it is cartilagenous. Bony part of the nasal septum is formed almost entirely by vomer and the perpendicular plate of ethmoid bone. However, its margins are contributed by the nasal spine of frontal, the rostrum of sphenoid and the nasal crests of nasal, palatine and maxillary bone. The cartilagenous part of nasal septum is formed by the septal cartilage and septal process of inferior nasal cartilage. The attachement of the cartilagenous part of nasal septum are inferiorly to the maxillary crest, posteriorly to the vomer, posterosuperiorly to the perpendicular plate of the ethmoid. The nasal septum is rarely strictly in midline. It is usually deflected to one or the other side and the deflection is produced by the overgrowth of one or more of the constituent parts of it.

Mucous membrane

The mucus membrane of the nose is initially adherent to the periostium or the perichondrium with the exception at the olfactory area. At the olfactory area it is loosely attached. The nasal mucous membrane is subdivided into three parts: vestibular part, olfactory part and respiratory part.

Vestibular part

This part of the mucous membrane lies just inside the aperture of the nostril. It is lined by skin with coarse hairs, sweat glands and sebaceous glands. The hairs (vibrissae) which are curved forward here are moistened by the secretion of the sebaceous gland and arrest the foreign particles, carried by the inspired air.

Olfactory part

This part of the mucuous membrane contains the olfactory cells and its hairs. From the olfactory cells 15 to 20 olfactory nerves start which pass through the cribriform plate of the ethmoid bone and end in the olfactory bulb of cerebrum.

Respiratory part

The rest part of the mucous membrane of nose except the vestibular and olfactory area constitute the respiratory part. It is lined by thick, vascular, ciliated, columnar epithelium. The ciliated columnar epithelium is interspersed by goblet cells. It is thickest and most vascular over the lower aspect of the septum and the turbinates. Actually, over the inferior concha the mucous membrane contain masses of the erectile tissues with numerous arterio-venous shunts. It permits vascular engorgement to regulate the temperature and humidity of the inspired air. The secretion from the sub-epithelial thin walled vessels, serous glands and mucous glands contribute to the formation of mucous in the nose.

The mucous secreted in the nose has two phases – the gel phase and the sol phase. The sol phase is less viscous and is closely applied to the columnar cells of mucous membrane. The gel phase lies over the solphase and is more viscous. It moves backwards by the hooks of the beating cilia which are situated at the end of the ciliated columnar cells. The cilia beat the mucous of the nose back to the nasopahrynx. The mucus and nasal vibrissae (hair) helps to trap the contaminants or foreign particles from the inspired air. The vascularity of the nasal mucosa helps in warming and moistening of the inspired air.

Arterial supply of nose

The arterial supply of nose consists of the arterial supply of medial wall (or nasal septum) and the arterial supply of lateral wall.

A. Arterial supply of medial wall or nasal septum

The nasal septum is supplied by the following arteries.

i. Mobile part of the septum is supplied by the septal branches of superior labial artery which is the branch of facial artery (Fig. 20.5).
ii. Antero superior part of nasal septum is supplied by the anterior ethmoid artery, branch of ophthalmic artery.
iii. Postero inferior part of nasal septum is supplied by the sphenopalatine and greater palatine artery, branches of ophthalmic artery.

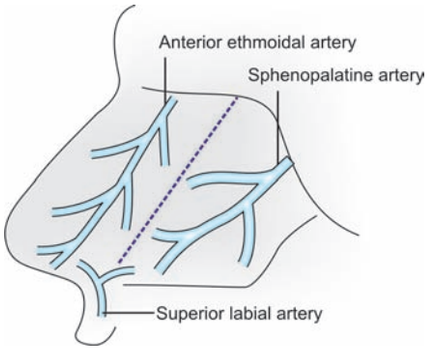

Fig. 20.5: The arterial supply of the nasal septum

An area on the antero inferior part of the septum is highly vascular and known as the Little's area of epistaxis. Because this is the common site for profuse arterial haemorrhage from nose. Here, the septal branch of facial artery, long spheno palatine and terminal branches of greater palatine arteries anastomose.

B. Arterial supply of lateral wall

Similar to the nasal septum, the lateral wall of nose is supplied by the branches of ophthalmic, maxillary and facial arteries. The branches are arranged into four quadrants.

i. Antero superior quadrant: It is supplied by the anterior ethmoid artery, branch of ophthalmic artery.
ii. Postero superior quadrants: It is supplied by the post ethmoidal artery branch of ophthalmic artery and sphenopalatine artery branch of maxillary artery.
iii. Anteroinferior quadrant: It is supplied by the alar branch of facial and terminal branches of greater palatine arteries.
iv. Postero inferior quadrant: It is supplied by greater palatine artery (Fig. 20.6).

Nerve supply of nose

Nasal septum

1. General sensory nerves – comes from the ophthalmic and maxillary divisions of trigeminal N and supply the whole septum.

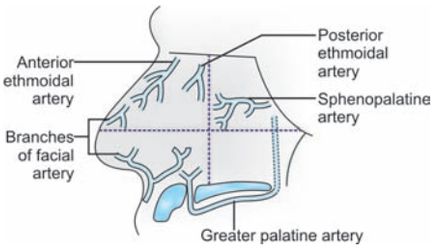

Fig. 20.6: The arterial supply of the lateral wall of the nose

   i. Anterosuperior part of septum – supplied by the intrernal nasal branch of anterior ethmoidal N – branch of opthalmic N – branch of trigeminal N.
   ii. Postero-inferior part of septum – supplied by the spheno-palatine branch of pterygopalatine ganglion – branch of maxillary N – branch of trigeminal N.
   Mobile part: supplied by the external nasal nerve, branch of the ophthalmic division of trigeminal nerve.
2. Special sensory olfactory nerves – supply the upper olfactory area (Fig. 20.7).

Lateral wall of nose

1. General sensory nerves: Like nasal septum the nerve of the lateral wall comes from the trigeminal nerve and distribute to the whole portion of it.
   a. Anterosuperior quadrant–supplied by the anterior ethmoidal nerve – branch of opthalmic nerve–branch of trigeminal nerve.
   b. Anteroinferior quadrant–supplied by the anterior–superior alveolar nerve – branch of maxillary nerve–branch of trigeminal nerve.
   c. Posterosuperior quadrant–supplied by the posterior–superior lateral nasal nerve–comes from pterygo–palatine ganglion–branch of maxillary nerve–branch of trigeminal nerve.
   d. Posteroinferior quadrant–supplied by the anterior palatine nerve–comes from pterygopalatine ganglion–branch of maxillary nerve–branch of trigeminal nerve.
2. Special sensory olfactory nerves – supply to the upper part just below the cribriform plate of ethmoidal bone up to the superior concha (Fig. 20.8).

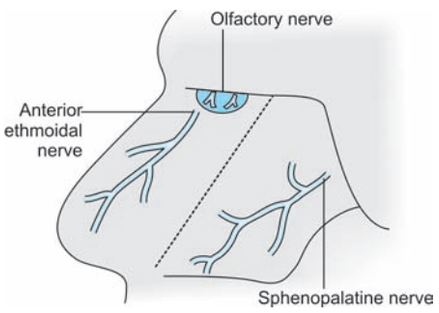

Fig. 20.7: The nerve supply of nasal septum

Functions of the nose

The nose does the following important functions.

(i) Respiration

An adult patient usually takes inspiration through the nose, provided there are no obstructions. Then, the inspired air passes through a wide curve which begins at the nostril and continues through the upper part of the nose to end at the posterior choanae. The inspired air is laminar in flow by character. However, the expired air does not follow this laminar flow like the inspired air. But, it is broken up by the turbinates into turbulent and eddies flow and then passes out through the nostrils. It has been

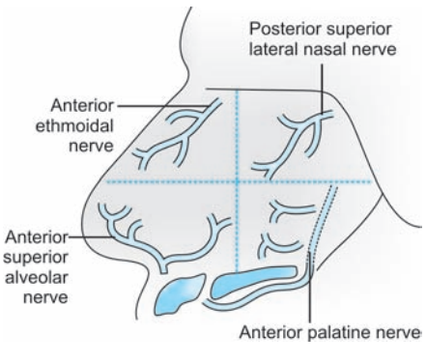

Fig. 20.8: The nerve supply of the lateral wall of nose

postulated that this is because the outlet is smaller than the inlet as the posterior choana is much larger than the nostril. Inevitably, always there is also certain degree of recirculation of air.

In a normal adult subject, the resistance for air to flow through the nose is one and half times greater than the mouth and accounts for nearly 2/3 of the total airway resistance. This explains why a patient takes mouth breathing when high air flow rates are necessary. So, it is always advisable to taste the patency of nasal passage before the nasal intubation is performed. Deflection of nasal septum sometimes become severe and diminishes the lumen of the respiratory airway. Thus, it prevents the passage of all, but the smallest of endotracheal tube.

(ii) Defence

The presence of stiff hairs in the anterior part of nasal fossa (vestibule), the thick and highly vascular (spongy) mucous membrane, the ciliated colmnar epithelium, the extensive lymphatic supply and the bacteriocidal property of the secreted mucous provide a powerful defensive action of nose against the invasion of any organism directly from air. Intermittent flushing action of the watery secretion of nose by sneesing also lies in the reserve of defence action of it.

(iii) Warming and humidification

The most important work that the nose has to perform is the warming and humidification of the inspired air, which is about 10,000 litres in 24 hours in a normal healthy adult. This is only possible due to the high vascularity of nasal mucous membrane. For example, if the temperature of the inspired air is 17°C which is equivalent to the normal room temperature is raised to 37°C which is equivalent to the normal body temperature during its passage through the nose and upper airway. The inspired air temperature also may vary from 25°C to 0°C according to the temperature of the enviornment. But, its passage through the nose produces more or less 1°C difference than that of the body temperature, when it reaches the laryngeal inlet or alveoli (Fig. 20.9).

When the air passes through the air passages, then with rising of temperature also the qauantity of water, needed to saturate the air by water vapour increases. As for example, at room temperature of 17°C the air normally contains 2 volume percent of water to become fully saturated. But, at body temperature of 37°C the air should contain 6 volume percent of water vapour to become fully saturated. The nose and the respiratory tract, therefore, have to perform this heavy task of warming and humidification of the inspired air by adding large quantities of heat and water vapour in the inspired air to make it warm and saturated with water vapour. Warming and humidification of inspired air is achieved by the dilatation of vessels of large vascular mucosal beds of the turbinates of nose. They normally change their volume after every 4 hours of interval (nasal cycle) and each side alternates.

The humidification of inspired air in the air passage is done by the supply of moisture (or water vapour) which comes as transudation of fluid from the mucosal epithelium of nose, pharynx and larynx, and to a lesser extent from the secretion of mucous glands and goblet cells, present in the nasal and pharyngeal mucous membrane. The daily volume of nasal secretions is about 1 litre. Of which about 3/4 is used to humidify the inspired air. Nose also collects the moisture from the expired air to prevent the excessive loss of water from the body.

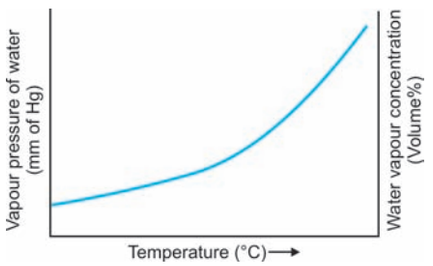

Fig. 20.9: The relationship between the tension of water vapour and the temperature

During intubation and tracheostomy, relatively dry and cool anaesthetic gases or air reach the trachea directly. Because nose and pharynx is bypassed and so proper warming and humidification of inspired air is not done. This compell the mucosa of the trachea and bronchus to perform the heavy duties of nasal and pharyngeal mucous membrane. Therefore, the mucosa of lower airways becomes dry and ciliary activity ceases in such circumstances. Later the tracheal and bronchial mucosa adapts itself to this changed condition. So, endotracheal anaesthesia is frequently followed by tracheitis and bronchitis.

In the most anaesthetic machine, compressed-dry-cooled gases are used. But, these gases are warmed itself to the room temperature before entering into the body during their passage through the long flexible breathing tube. On the other hand, by the 'to and fro' breathing system which occurs in the canister and which is situated near the patient's mouth, the temperature of the inspired gases can be raised upto 37°C (body temperature). So, this system provides (canister which is not used now) very efficient method for warming and humidification of the inspired air. But it has other disadvantages which is discussed in appropriate chapter. But during the passage of expired air through CO_2 absorber in circle system the expired air gains some heat and water vapour produced during absorption of CO_2. In non-rebreathing valve system such as if Ruben and Frumin valve is attached with the circuit, the inspired air is always at room temperature (17°C) and contains only 2 volume percent of water vapour at full saturation which is the normal content of air. But as there is no rebreathing, so the expired air at 37°C containing 6 volume percent of water vapour at full saturation passes out through the valve. In the absence of rebreathing heat with

water vapour is also lost from the body to the atmosphere. Thus it does not help to warm and humidify the inspired air.

In the circle absorption system, the inspired gas mixture contains fresh dry gases coming from cylinder and pipelines and also some expired gases containing water vapour at room temperature. The expired gas leave the patient at body temperature containing water vapour. But by the time they have traversed the breathing tube of the apparatus, they become cool to the room temperature and so have lost the major part of their water content in the apparatus. Dry, cool, fresh gas is again added to the system for inspiration and is mixed with the expired gas coming from the absorber. So, the circle absorption system does much help in warming and humidifying the inspired gases.

(iv) Resonance

Nose as surrounded by multiple air cavities, so gives some resonance to the voice and helps in talk. It also protects the transmission of sound of one's own speech to his own ears. It also equalises the pressure during respiration between internal and external pressure.

(v) Filter

Nose also helps in filtering and clearing the suspended particles from the inspired air. It also transports the mucus posteriorly to lubricate the pharynx.

(vi) Olfaction

Nose also acts as an integral part of the olfactory system.

Some methods of humidification of Inspired air

The inspired air can be humidified by various ways. These are:

(i) Direct instillation of water

Inspired air can be humidified by direct fine drop by drop instillation of normal saline into an endotracheal or tracheostomy tube.

(ii) Water bath

Here, inspired air is passed over the surface of water, kept in a thermostatically controlled and heated water bath. This type of humidifier should be placed on the inspired limb and the gases will flow from the water bath to the patient by the shortest possible route. The tube in shortest route should be insulated to prevent the heat loss with consequent water condensation during the passage of heated and humidified inspired air through the tube. Another method to deliver the inspired gas at body temperature with full saturation by water vapour but without condensation in the breathing circuit is to raise the temperature of the water bath few degrees above the body temperature for compensation to loss which occurs during passage through inspiratory limb. The exact temperature setting of the water bath depends on the surface area of the water, flow rate of gases and the amount of cooling and condensation which take place in the inspiratory limb after the water bath. This type of humidifier should always be kept below the level of the patient to prevent the water being blown accidentally into the patient (Table 20.2).

(iii) Moisture exchanger

It is also called the 'artificial nose'. It is mainly consists of replaceble condenser that can be taken out and cleaned. It is very light and a moderately efficient method of humidification of inspired air. As this system works at room temperature which is much below the body temperature, so part of the water vapour of expiratory gases is condensed on its inner surface and this condensed water again humidifies the dry inspired gases. It can not, of course, achieve full saturation owing to the lower temperature. There are two demerits of this system. One is the colonisation of bacteria and another is the increasing of airway resistance due to the condensation of moisture. These disadvantages can be overcome by using disposable and sterilised unit.

Table 20.2: The percentage of humidity of inspired gases in different anaesthetic system

Anaesthetic system	*% of humidity*
Nose	100
Close circuit	40 - 60
'To and fro' system	60 - 100
Non-rebreathing valve	0
T-piece	0

(iv) Mechanical nebuliser

This is operated by pneumatic power and breaks up the drops of water into small particles. In this system the water passes up through a capillary tube to its summit where it is crushed by the jet of air into microparticles. In this type of nebuliser 80% of the water particles are in the range of 2 to 4 microns and the remainder are smaller. So most of these particles are deposited around the bronchial level and for many patients this is sufficient. Contrary, the water particles which are less than 2 micron reach the small bronchi and alveoli. Those water particles which are above 4 microns do not float. They coalesce and fall back in the reservoir. This type of nebuliser for humidification of inspired air can be used pre and post-operatively with the face mask to improve the lung function.

(v) Ultrasonic nebuliser

This is the most efficient instrument for humidification of inspired air. Here the drops of water is passed through a capillary tube, and completely nebulized to aerosal by a vibrating transducer head which is activated by a high frequency ultrasonic energy. Here, 70% of the water particles get the size of 0.8 to 1 micron. So usually, most of the particles of less than 1 micron are deposited in the lower airways and alveoli of the lungs. At the maximum rate of 12 drops of water/ min falling on the transducer head and with a ventilator delivering of 10 litres of gas/min, 72 ml of water as vapour can be provided with each litre of gas . This corresponds to the relative humidity of 160% at 37°C.

Among all the methods of humidification of inspired air, ultrasonic nebuliser produces the most satisfactory humidification. It can also be used for the administration of water soluble aerosal drugs. The two demerits of this instrument are: (i) over hydration, due to extreme effeciency and (ii) difficulty to sterilise by conventional method.

Ciliary Activity of Airway

Throughout the upper and lower respiratory tract the continuous ciliary activity of mucous membrane plays a very important function. This is the prevention of accumulation of mucous secretion which is needed for the efficient functions of nose, pharynx and larynx. By ciliary action in the nose, the mucous secretion are swept posteriorly towards the pharynx and in the bronchial tree the mucous secretions are carried upwards towards the larynx (Fig. 20.10).

The Cilia are fine hair like structures. They are 7 µm in long and 0.3 µm in width. The tips of cilia are always bend towards the direction of the flow of mucous. In the shaft of the cilia which are occupied by cytoplasm there are microtubules containing dyenin arms. The longitudinal fibrils or microtubles in the shaft of the cilia are arranged in a fashion like that a pair of microtubles is situated in the centre and it is surrounded by nine pairs of microtubles at the periphery. The activity of the cilia depends mainly on the mucous blanket, covering it. The covering mucous blanket consists of two layers. The outer gel layer is thick and viscous. It is designed to entrap the floating particles from inspired gas such as dust, soot, microorganisms etc. The inner sol layer is thin serous like fluid. It is designed to lubricate the action of the ciliary movement. The tips of cilia come just in contact with the outer gel layer with each beat. Acting in union, the cilia set the outer gel layer in motion. Thus gathering momentum, the mucous flows towards the pharynx from nose and towards the larynx from the bronchus and trachea. They beat forward in an effective stroke pulling the gel phase by the action of hooks at the end of the cilia and then beat backward in a recovery stroke. Their action is reminiscent of a corn field being blown by the wind. This movement is called metachrony, as opposed to the synchrony where all the cilia beat together. At 37°C, the cilia of the nasal mucosa beat about 10 to 16 times per second. The average estimated speed of movement of mucous blanket over the mucous membrane is 0.25 to 1 cm/min. Thus, the entire mucous content of the nose take 20 to 30 minute to be emptied into the pharynx (Fig. 20.11).

In some conditions, ciliary action may be defective, for example, Kartagener's syndrome. This is a genetic disorder in which there is defect in the ultrastructure of the cilia. This is due to the failure of synthesis of protein which form the dyenin arm of cilia. The congenital absence of this dyenin arms which normally contain ATP and power the cilia makes the cilia immobile. So, these patients have a constantly running nose, secretory otitis media, chronic sinusities, bronchiectasis and often situs inversus. The tail of sperms have the similar structure like cilia. So that in this syndrome there is also male infertility due to reduced sperm motility.

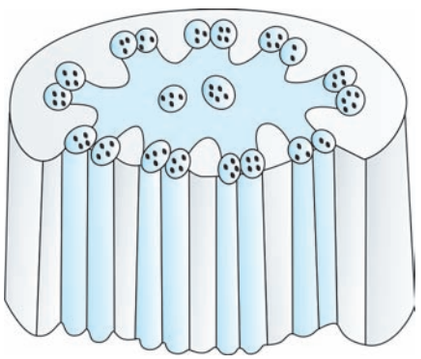

Fig. 20.10: The transverse and longitudinal section of a nasal cilium at the middle of the shaft of it

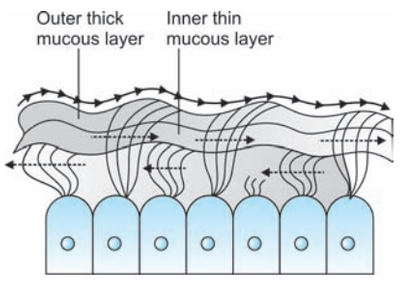

Fig. 20.11: The ciliary movement

Factors influencing ciliary activity

The factors which influence the ciliary activity are: temperature, mucous, changes in pH and drugs.

Temperature

There is a definite range of temperature when the cilia acts optimally. This is 28°C to 35°C. Ciliary activity ceases when the temperature of the mucosa falls from 7°C to 10°C. It is also depressed when the temperature of cilia rises above 35°C, while the average nasal temperature is about 32°C. Actually the direct effect of temperature on ciliary action is minimal and the effect is largely caused indirectly by alterations in the amount of mucus secreted.

Mucous

Cilia cannot work without the optimum temperature and the blanket of mucus. Drying out of the mucus blanket over them can stop ciliary activity, though the temperature is maintained at optimum level. So, excessive dry and cool air, volatile anaesthetics, atropine, etc; decrease mucus secretion and subsequently stop the ciliary activity.

Changes in pH

Cilia acts better in alkaline media. They become paralysed in acid solutions at pH 6.4 or less. A rise of pH to 8 or more also causes depression of the ciliary activity.

Drugs

All volatile anaesthetics, opiates, atropine, etc, also depress ciliary activity. But, N_2O has no effect on it.

Pharynx

The pharynx or the pharyngeal airway is a fibromuscular structure. It extends proximally from the base of the skull at the posterior aspect of the nose to distally upto the level of the 6th cervical vertebra or cricoid cartilage where it becomes continuous with the oesophagus and the larynx. Anteriorly the pharynx communicates with the nasal cavities, the oral cavity and the larynx from above downwards. Thus, pharynx is divided anatomically into nasopharynx, oropharynx and laryngopharynx (hypopharynx). Soft palate separates the nasopharynx from the oropharynx and the plane drawn at the upper border of epiglottis separates the oropharynx from laryngopharynx. Except the nasopharynx which is covered by ciliated columnas epithelium, the oropharynx and laryngopharynx is covered by the stratified squamous epithelium. The middle fibrous layer of pharynx consists of the pharyngobasilar fascia. The outer muscular layer of pharynx is comprised chiefly of the three constrictor muscles such as superior, middle and inferior constrictor muscle of pharynx and overlap one on another from below upwards.

Nasopharynx (Fig. 20.12)

It extends above from the base of the skull to below upto the level of hard palate and soft palate. Anteriorly nasopharynx communicates with the nasal cavities through the posterior nares and posteriorly it is bounded by the body of C_1 and C_2 vertebrae. Nasopharyngeal isthmus is the aperture situated between the nasopharynx and oropharynx and is surrounded by the free margin of the soft palate anteriorly and the posterior wall of the pharynx posteriorly. This opening is closed during the 2nd stage of deglutition by the soft palate. At the junction of the roof and the posterior wall of the nasopharynx and at the base of the skull, there lies a small mass of lymphoid tissue, embedding in the mucous membranes called the pharyngeal tonsil or adenoids. By the side of

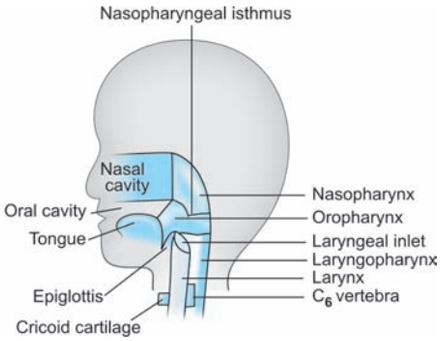

Fig. 20.12: The sagittal section of head showing the different parts of pharynx

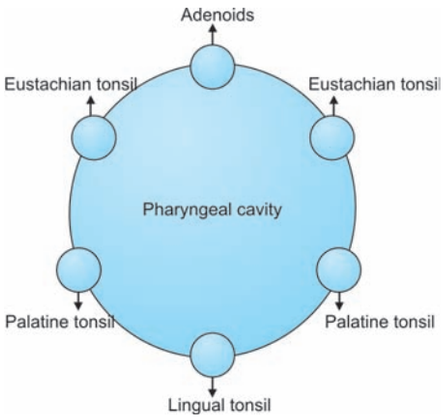

Fig. 20.13A: The ring of Waldeyer

adenoid, there is an opening of Eustachian tube, which connect the middle ear cavities with the nasopharynx. It is also lined by ciliated columnar epithelium and is continuous with the nasopharynx. There is also a collection of lymphoid tissue around the Eustachian tube opening and is called the Eustachian tonsil. Lying close to the base of the adenoids there is a small recess, called the pharyngeal bursa which often impedes the passage of a nasal endotcheal tube. If force is applied, the tube may then penetrate the bursa and can create a false passage. This may lead to the collection of blood and postoperative sepsis. As the pharynx is riched with the lymphatic supply, so the enlargement of these lymph glands and the swelling of the overlying mucosa may lead to the partial obstruction of the airway. All the lymph glands of nasopharynx are arranged in a circular fashion, called the Waldeyer ring. It consists of adenoids (A), Eustachian tonsil (E), palentine tonsil (P) lying between the pillars of the fauces, and the small lingual tonsil (L) at the base of the tongue. The motor nerve supplying to the constrictors muscle of pharynx comes from vagus. The sensory nerve supply of pharynx comes from the trigeminal nerve (Fig. 20.13A).

Oropharynx

This part of the pharynx extends from the level of hard palate and soft palate above to the level of the hyoid bone below. It is bounded above and infront by the soft and hard palate; below and infront by the dorsal surface of base of the tongue up to the upper border of epiglottis. It is bounded posteriorly by the bodies of C_2 and C_3 vertebrae. The free edge of the soft palate forms the palatine arch. From the centre of the palatine arch uvula hangs downwards. From the side of the arch, on either side, two folds of mucous membrane run downwards. These two folds of mucous membrane are raised up by the bands of muscle fibres, named the palatoglossus and palatopharyngeus muscle. They form the pillar of the fauces and between which lies the palatine tonsil. The glossopharyngeal and trigeminal nerve supplies the sensory of the oropharynx.

Hypopharynx

It is a part of the pharynx lying below the oropharynx. It extends from the plane drawn at the upper border of the epiglottis above to the lower border of the cricoid cartilage or C_6 vertebrae below, where it is continuous with the larynx in front and the oesophagus at behind. The inlet of larynx, posterior surface of cricoid and arytenoid cartilage lie in front and 4th, 5th and 6th cervical vertebrae lie behind the hypopharynx. Laterally, the hypopharynx present the pyriform fossa on each side of the inlet of larynx. Pyriform fossa is bounded medially by the eryepiglottic

fold and laterally by the thyroid cartilage and the thyrohyoid membrane. Beneath the mucosa of the pyriform fossa lies the internal laryngeal nerve which is a branch of superior laryngeal nerve (Fig. 20.13B).

The motor supply of hypopharynx comes from the cranial accessory nerve through the pharyngeal branches of glossopharyngeal nerve. Vasomotor of pharynx is supplied by the superior cervical sympathetic ganglion. The vagus nerve supply the sensory to the airway below the level of epiglottis. The superior laryngeal nerve, a branch of vagus, divides into an external (motor) nerve and an internal (sensory) laryngeal nerve that supply sensory to the hypopharynx and larynx between the epiglottis and vocal cord. Another branch of vagus, the recurrent laryngeal nerve, supply the larynx below the vocal cord and trachea.

Larynx

Larynx acts as an organ of voice, air passage and inlet valve for the lower respiratory tract.

It extends from the base of the tongue above to the trachea below. It lies opposite to the body of C_3 to C_6 vertebrae. In children it lies more anteriorly and at more higher level than adult. Larynx is consist of cartilages, ligaments, muscles and membranes. The cartilages are total 9 in number. Among them 3 are paired (arytenoid, corniculate and cuneiform) and 3 are unpaired (epiglottis, thyroid and cricoid). The epiglottis is a leaf-shaped cartilage with broad and free upper margin. The lower end of it is pointed and attached to the angle between the two laminae of the thyroid caritlage. Anteriorly the epiglottis is connected to the base of tongue by 3 mucosal folds – a median glossoepiglottic fold and a pair of lateral glossoepiglottic folds. The depression between the median and lateral glossoepiglottic fold is called the vallecula and this is the site where the tip of the blade of Macintosh laryngoscope rests. The epiglottis projects into the hypopharynx and overhangs on the laryngeal inlet. Sealing of the laryngeal inlet by epiglottis during swallowing and deglutition is not absolutely necessary. The lateral margins of the epiglottis is attached to the quadrate membrane which extends from the arytenoid cartilage (situated posteriorly) to the margins of the epiglottis (situated anteriorly). The lower free border of this quadrate membrane forms the vestibular fold and the upper free border forms the aryepiglottic fold. Arytenoid is a small pyramidal shaped cartilage and situated at the upper border of the lamina of cricoid caritlage. The Apex of arytenoid cartilage again articulates with corniculate and cuneiform cartilage.Vocal cord is attached to the vocal process of this arytenoid cartilage. Corniculate and cuneiform cartilage lie in the posterior part of aryepiglottic fold (Fig. 20.14).

The thyroid cartilage is a V-shaped cartilage and is made up of two quadrilateral laminae. They are fused > 90° angle in male and > 120° angle in female anteriorly. The line of junction of these two laminae forms in male the Adam's apple. The Posterior border of the thyroid cartilage is free and projects both upwards and downwards as superior and inferior cornu. The Inferior cornu articulates with the cricoid cartilage. On the outer surface of the laminae of thyroid cartilage there is an oblique line which gives attachment to sternothyroid, thyrohyoid and inferior constrictor muscle of the pharynx. The Upper border of the thyroid cartilage gives attachment to the thyrohyoid membrane

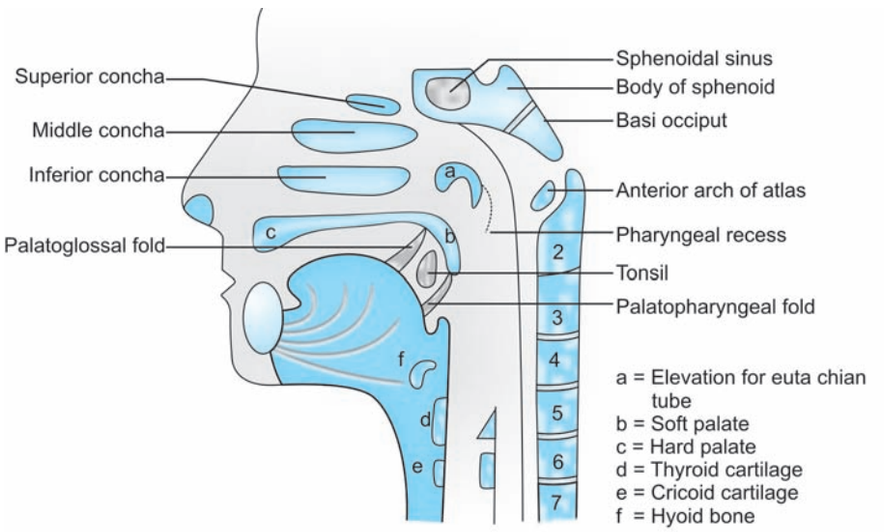

Fig. 20.13B: The sagittal section through the pharynx, nose, mouth and larynx

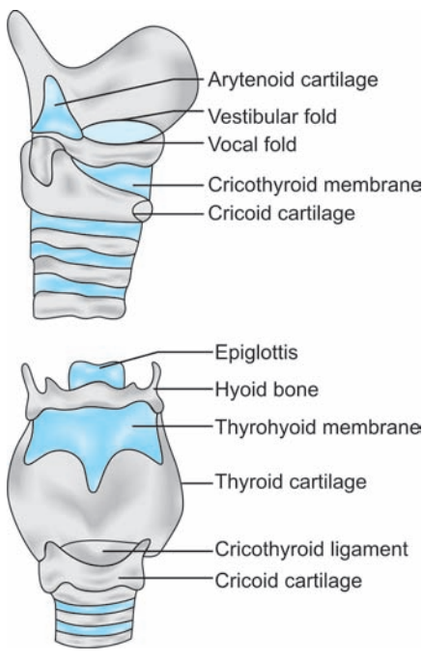

Fig. 20.14: Cartilages and ligaments of larynx

which is pierced by the internal laryngeal nerve and superior laryngeal vessels (Fig. 20.15).

The cricoid cartilage is looked like a signet shaped ring and encircles the larynx. The narrow anterior part of this ring shaped cricoid cartilage is called the arch and the broad posterior part is called the lamina. Superiorly the lamina is attached with arytenoid cartilage and at the side with the inferior cornu of the thyroid cartilage. A membrane named the conus elasticus or cricovocal membrane extends upwards and medially from the upper border of the arch of cricoid cartilage to the thyroid cartilage in front and the vocal process of the arytenoid cartilage behind. The anterior part of this membrane is thick and is known as the cricothyroid ligament. The upper free border of this conus elasticus membrane forms the vocal cord (Fig. 20.16).

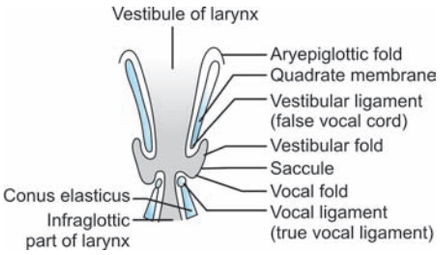

Fig. 20.16: Coronal section showing the parts of the cavity of larynx

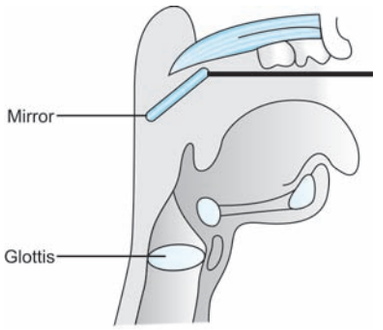

Fig. 20.17: Indirect laryngoscopy by mirror

Cavity of larynx

The cavity of the larynx extends above from the inlet of the larynx to the lower border of the cricoid cartilage below where it is continuous with the trachea. The inlet of larynx opens above in the laryngopharynx or hypopharynx and bounded anteriorly by the epiglottis; posteriorly by the interarytenoid fold of mucous membrane and on each side by the aryepiglottic fold which is the upper border of the quadrate membrane (Fig. 20.17).

Within the cavity of the larynx, on each side there are two folds of mucous membrane. The upper folds are called the vestibular folds and the space between these two vestibular folds is called the rima vestibuli. The lower folds are called the vocal cords and the space between these two vocal cords is called the rima glottis.

The vestibular fold and the vocal fold divide the cavity of the larynx into three parts. The part of the larynx above the vestibular fold is called the vestibule of larynx. The space between the vestibular folds and the vocal folds is called the sinus of the larynx and the part below the vocal folds is called the infraglottic part of the larynx. The anterior part of the sinus of larynx is prolonged upwards as a diverticulum between the vestibular fold and the lamina of thyroid cartilage. This extension of the sinus is called the saccule of larynx and contains mucous glands which helps in lubrication of the vocal folds (Fig. 20.18).

In the vestibular folds, under the mucous membrane, a narrow bands of fibrous tissue passes from the anterolateral surface of the arytenoid cartilage to the angle of the thryoid cartilage at the point of attachment of the epiglottis. This is called the vestibular ligament. On the otherhand, in the true vocal folds under the mucous membrane a tough fibrous vocal ligament extends from the vocal process of arytenoid cartilage to the angle of thyroid cartilage. Since, as there is no true submucous layer with the usual network of blood vessels within it, so the true vocal cords or folds have the characteristic pale appearance.

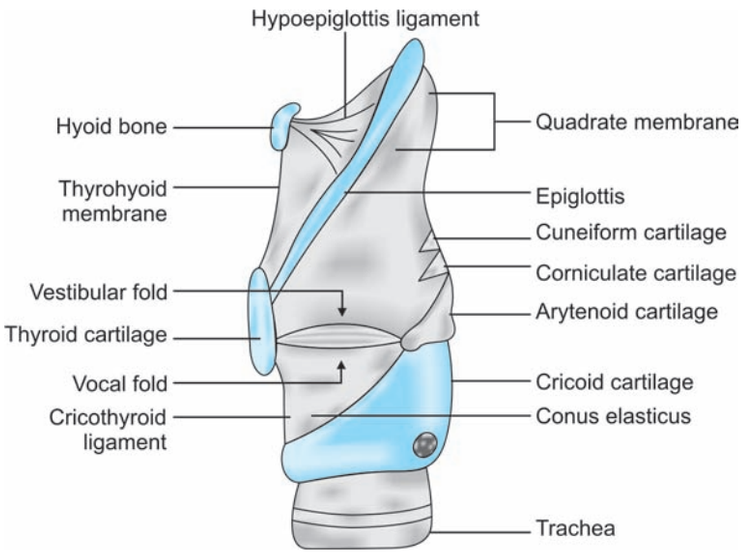

Fig. 20.15: Ligaments and membranes (mainly quadrate membrane and conus elasticus) of larynx

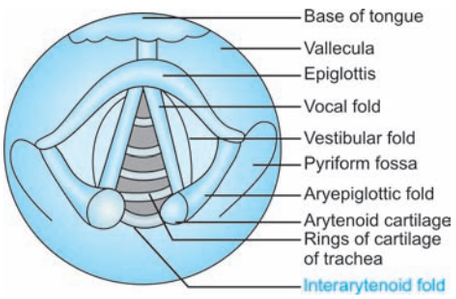

Fig. 20.18: The laryngeal image on mirror during indirect and direct laryngoscopy

In an adult the narrowest part of the laryngeal cavity is the area which is situated between the vocal cords. But in children, under ten years of age, the narrowest part of the larynx is just below the vocal cords at the level of the cricoid cartilage. The clinical significance of this anatomical difference in larynx between an adult and child is found, when small children are intubated. The significance is that in children an endotracheal tube which can be passed between the vocal cords may yet be too large to pass beyond the cricoid cartilage.

Mucous membrane of larynx

The total anterior surface of the epiglottis, upper ½ of the posterior surface of epiglottis, the upper parts of aryepiglottis folds and the vocal folds are all lined by the stratified squamous epithelium. Otherwise, the rest of the laryngeal mucous membrane is covered with the columnar ciliated epithelium. All parts of the mucous membrane of laryngeal cavity are loosely attached to the cartilages, except over the vocal ligaments and posterior surface of the epiglottis where it is thin and firmly adherent to the underlying structure. So, this prevents further spread of laryngeal oedema and accumulation of tissue fluids downwards in the larynx causing suffocation. Mucous glands are absent over the vocal cords. But they are plenty over the anterior surface of the epiglottis, around the cuneiform cartilages and in the vestibular folds. In other parts of the larynx this mucous glands are scanty.

Nerve supply of larynx

Both the superior and the recurrent laryngeal nerves which are branches of vagus supply the sensory and the motor of the larynx. The superior laryngeal nerve descends on the lateral wall of the pharynx, passes posteriorly to the internal carotid artery and at the level of the greater cornu of hyoid bone it divides into an internal and external laryngeal branch (Fig. 20.19).

The internal laryngeal branch is entirely sensory, apart from a few motor filaments

X_{SL} = Vagus superior laryngeal nerve
X_{RL} = Vagus recurrent laryngeal nerve

to the arytenoid muscles and descends on the thyrohyoid membrane. It pierces this membrane above the superior laryngeal artery and then again divides into two branches. The upper branch supplies the mucous membrane of the lower part of the pharynx, epiglottis, vallecula and the vestibule of larynx. The lower branch passes medial to the pyriform fossa beneath the mucous membrane and supplies the aryepiglottic fold and mucous membrane of the posterior part of the rima glottis. The external laryngeal branch, carrying only the motor fibres, innervates the cricothyroid muscle (Table 20.3).

The recurrent laryngeal nerve travels upwards deep to the lower border of the inferior constrictor muscle of the pharynx, accompanying with the laryngeal branch of the inferior thyroid artery. Apart from the sensory fibres which supply the mucous membrane of the larynx below the level of the vocal cords, this nerve innervates all the muscles of the larynx except the cricothyroid and a small part of the arytenoid muscles.

Summary

The upper airway derives its sensory supply from cranial nerves. This can be summarised as follows. Anteriorly the nose gets its sensory supply from the anterior and posterior ethmoidal branch of the opthalmic division of the trigeminal nerve (Vth cranial nerve). Posteriorly the nose is supplied by the sphenopalatine branch of the maxillary division of trigeminal nerve. The soft and hard palate get its sensory supply from the palatine nerve which is branch of the trigeminal nerve. The lingual nerve, a branch of mandibular division of the trigeminal nerve supply the sensory of anterior 2/3 of tongue. The glossopharyngeal nerve or the 9th cranial nerve, supply the sensory of posterior 1/3 of the tongue. Facial and glossopharyngeal nerve provide the sensation of taste of anterior 2/3 and posterior 1/3 of the tongue respectively. The glossopharyngeal nerve also provides the sensory supply to the roof of pharynx, the tonsils and the under surface of the soft palate. The vagus nerve or the 10th cranial nerve, supplies the sensory of the airway below the epiglottis through its superior

Table 20.3: Laryngeal innervation

Nerve	*Sensory*	*Motor*
Superior laryngeal (anterior or internal branch)	Base of tongue, epiglottis and supraglottic mucosa	None
Superior laryngeal (posterior or external branch)	Only anterior subglottic mucosa	Cricothyroid (tensor of vocal cord)
Recurrent laryngeal	Whole subglottic mucosa	Posterior cricoarytenoid (abductor), lateral cricoarytenoid (abductor), interarytenoid (abductor), thyroarytenoid (abductor)

laryngeal (divides into internal and external branch) and recurrent laryngeal branch which is described above (Fig. 20.20).

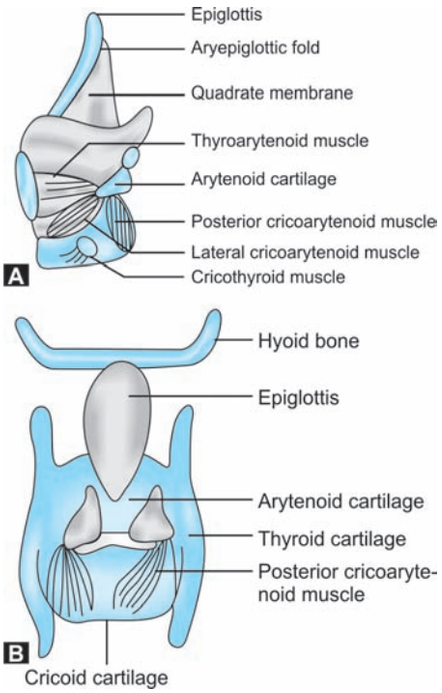
Actions of the intrinsic muscles of the larynx

i. Muscles for closing and opening of the laryngeal inlet.
   a. Closing – aryepiglottic
   b. Opening – thyroepiglottic
ii. Muscles for closing and opening of the rima glottis.
   a. Closing – lateral cricoarytenoids, transverse arytenoid, cricothyroid, thyroarytenoids.
   b. Opening – Posterior cricoarytenoids.
iii. Muscles which tense and relax the vocal cords.
   a. Tense – cricothyroid.
   b. Relax – thyroarytenoids and vocalis.

Movements of the vocal cords

Movements of the vocal cords affect the shape and size of the rima glottis as follows:

i. During quiet breathing (in resting condition), the inter membranous part of the rima glottis is triangular and the inter cartilagenous part is quadrangular in shape.
ii. During forced inspiration the both parts of the rima glottis (intermembranous and intercartilagenous) are triangular, so that the entire rima is lozenge-shaped and the vocal cords are fully abducted.
iii. During phonation (speech), the rima glottis is reduced to a chink by adduction of the vocal cords.
iv. During whispering, the intermembranous part of the rima glottis is closed, but the intercartilagenous part is widely open (Fig. 20.21).



Figs 20.20A and B: The intrinsic muscles of larynx

Applied Anatomy

i. Damage or block of the internal laryngeal nerve which is a branch of superior laryngeal nerve produces anaesthesia of mucous membrane of the supraglottic part of larynx. So, any foreign body can readily enter into the laryngeal inlet as reflexes do not work. But the function of vocal cord is not jeoparadised.
ii. Damage to the external laryngeal nerve which is an another branch of superior laryngeal nerve causes some weakness of phonation. It is due to the loss of tightening effect of the cord by paralysis of the cricothyroid muscle which is supplied by it. On the contrary bilateral damage of the superior laryngeal nerve result in hoarseness and easy tiring of voice. But airway control by vocal cord is not jeoparadised through reflexes of laryngeal inlet is impaired like the injury of internal laryngeal nerve.
iii. When both the recurrent laryngeal nerves are interrupted or blocked, then the vocal cords lie in position of complete adduction due to the unopposed action of cricothyroid muscle. So, patient suffers from stridor and respiratory distress. But airway problem is less frequent in chronic bilateral recurrent nerve interruption. This is because of various compensatory mechanisms which always develop. When only one recurrent laryngeal nerve is paralysed, the vocal cord of opposite side compensates for that. Then there is no difficulty in respiration but only deterioration of voice quality occurs. Bilateral interruption of vagus nerve affects both the superior and recurrent larngeal nerve. Thus it produces flaccid, midpositioned vocal cord as seen after administration of muscle relaxants.
iv. Larynx can be seen directly by a laryngoscope (direct laryngoscopy) or by a laryngeal mirror (indirect laryngoscopy). By these procedures one can see the base of the tongue, valleculae, epiglottis, aryepiglottic folds, pyriform fossae, vestibular folds and the vocal cords.
v. Since glottis of larynx is the narrowest part of the respiratory passage in adult, so if foreign body enters the respiratory passage, it usually lodged at glottis. Once it crosses glottis, it would easily pass through the trachea to lodge in some peripheral narrow bronchus or bronchiole.
vi. Laryngeal oedema may occur due to variety of causes which may be traumatic, allergic or infective, etc. This produces inspiratory stridor, dyspnoea and symptoms of hypoxia.
vii. Laryngismus stridulus is a condition which is characterized by attacks of laryngeal spasms in children, usually during night. In between the attacks, the child is normal.

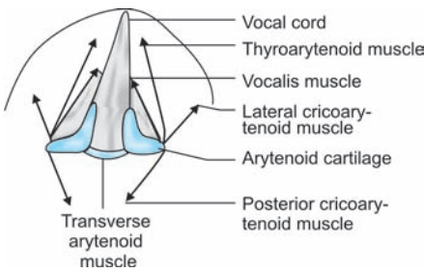


Fig. 20.21: The different directions of movement of muscles of vocal cord

Physiology of Airway Protection

The pharynx, epiglottis and the larynx protect the lower airway from aspiration of foreign bodies. An important mechanism for expelling or preventing the entry of foreign bodies into the lower respiratory passage below the vocal cord is cough. Although epiglottis covers the laryngeal inlet, but it is not always absolutely essential for the airway protection. Closure of the vocal cords by reflex mechanism is the most vital mechanism for lower airway protection, which also produces the protective laryngeal closure during deglutition. The physiological exaggeration of this reflex closure of vocal cord is called the laryngospasm. Therefore, laryngospasm consists of prolonged intense glottic closure in response to the stimulation by inhaled agents, foreign bodies or stimulation from visceras. Laryngospasm is associated with sound ranging from high peached squeaky to total absence, depending on the degree of spasm. Complete laryngospasm is usually silent and should be diagnosed and treated immediately.

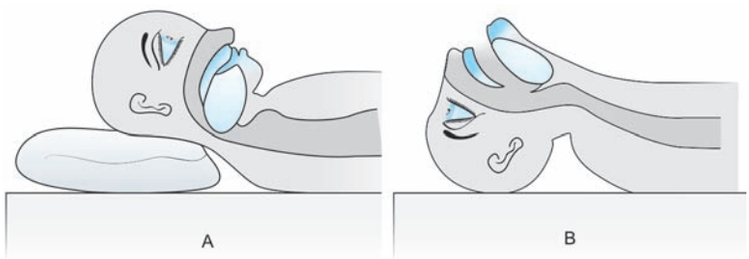
The ideal treatment for complete laryngospasm is the use of muscle relaxant and mask ventilation or intubation. But before muscle relaxants, forward displacement of the mandible, and IPPV by mask and bag with 100% O_2 should be tried. In most of the cases it is effective, because strong pressure applied manually with the help of a bag which is full of O_2 can force the gas effectively through the adducted cords. Thus, tracheal intubation can be avoided. In such situation the traditional view regarding limiting the pressure to avoid barotrauma of lungs are not important and stomach should be watched closely for if air is entering the oesophagus forcefully or not. Another way of management of laryngospasm is IV administration of propofol or thiopentone, making the patient deeply sedated, provided airway is clear of any foreign body. A patient who is scheduled for elective surgery, but experiences repeated intermittent laryngospasm and arrhythmia is a poor candidate for continued attempt of intubation.

Upper Airway Obstruction

One of the foremost duties of an anaesthetist is to maintain an unobstructed airway in an unconcious patient. This obstruction of airway may be total or partial. Partial obstruction is associated with diminished tidal volume (but not completely absent), retractive movement of the rib cages and neck muscles, tugging movement of diaphragm and snoring sound. If the obstruction is near the laryngeal inlet, then there will be inspiratory stridor. The total obstruction of airway is characterised by complete lack of movement of air in and out of the lungs or zero tidal volume which is recognised by no movement of breathing bag and paradoxical movement of the chest and abdomen. The air entry and exit from the lungs should be perceived by the feeling with hand placed over the nose and mouth, looking the non-paradoxical movement of chest and abdomen, and seeing the movement of the bag. An inexperienced person, usually wrongly interprete this retractive movement of chest, abdomen (see-saw paradoxical movement) and neck as a breathing affort. So, recognition of airway obstruction depends on the close observation of the movement pattern of the chest and abdomen and high index of suspicion (Fig. 20.22).

Upper airway obstruction is commonly due to the soft tissue obstruction byfalling back of the tongue on the posterior pharyngeal wall. It may also be due to the tumour, foreign bodies or laryngospasm, etc. But here we will only discuss the obstruction of upper airway by the base of the falling tongue (obstruction of airway by laryngospasm is discussed before). Because it is the commonest cause of upper airway obstruction during anaesthesia and is due to the relaxation of the tongue and jaw muscles. This occurs as soon as the consciousness is lost and the muscles supporting the tongue relax. So, the tongue falls back on the posterior wall of the oropharynx or hypopharynx or on the inlet of the larynx. If the tongue is brought forward by manipulation, then the laryngeal opening once again is cleared and opened. This can be achieved by the following methods.

i. Simple extension of the neck will clear the airway in 75% of cases. It causes the forward movement of mandible and the stretching of anterior tissues of the neck which, in turn, produces the forward traction of the tongue. Thus simple extension of neck release the airway obstruction.
ii. Extension of the neck also causes the mouth to fall open due to down ward pull of the neck tissues. In such condition, simple closing of the mouth in extended position of neck will often improve the airway by straightening the anterior tissues of the neck still further. Thus the resultant changes in head position have been shown to modify the upper airway resistance significantly.
iii. If there is still obstruction, airway can be restored by preventing the mandible from falling back with the tongue. This



Figs 20.22A and B: A. The fall of tongue on the posterior pharyngeal wall and the collapse of pharyngeal wall due to the relaxation of muscles of the airway (mainly genioglossus). B. Extension of neck and elevation of the angle of mandible removes the falling base of the tongue from posterior pharyngeal wall and maintains a clear airway

can be done by drawing the mandible forward and upward by placing the fingers behind the angles of the jaw and exerting an upward pressure towards roof.

iv. If the above mentioned procedures also fail, then the removal of obstruction of the airway can be accomplished with some mechanical contrivnaces, termed the oropharyngeal or nasopharyngeal airway, though other types of airways are discussed later. The idea behind both the oropharyngeal or nasopharyngeal airway is to lift the base of the tongue from the posterior wall of the pharynx and thus to remove the obstruction. The nasopharyngeal airway is better tolerated in light plane of anaesthesia than the oropharyngeal airway. But, the mere placement of any of the above mentioned airway does not gurantee unobstructed air flow. This is because these airways do not get any support from the relaxed mandible due to the relaxation of jaw muscles and is displaced. So, it is often necessary with the oropharyngeal or nasopharyngeal airway to support the mandible further by forward traction or by pressing upward at the angles of it. In the anaesthetised patient, pharyngeal and laryngeal reflexes are obtunded. If these reflexes are still active, then insertion of any airway to prevent the obstruction may precipitate further gagging, emesis or laryngeal spasm, causing more obstruction (Fig. 20.23).

Oral airways are generally made up of plastic and its size ranges from 0, 1, 2 (50 to 60 to 70 mm) for children to 3, 4, 5 (80 to 90 to 100 mm) for adults. It is inserted first with the upside down direction while passing through the oral cavity and then is rotated 180 degrees into the position of function. During insertion of oral airway teeth can be injured and the airway itself can pushes the base of the tongue into the pharynx. Thus it can actually increase the airway obstruction instead of removing it. Hence, an anaesthetist must be careful during insertion of airway.

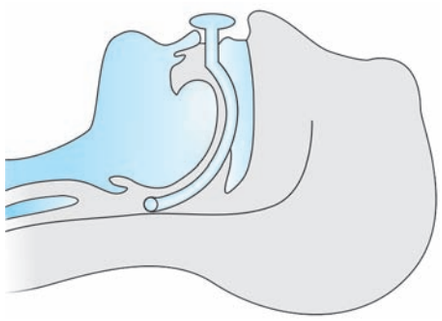


Fig. 20.23: Oropharyngeal airway elevating the tongue

To remove obstruction of upper airway by falling tongue soft nasal airways are useful for patients who are not deeply anaesthetised. However, contraindications to the use of nasal airways include coagulopathy, basilar skull fracture, large adenoids, nasal infections, nasal deformities, etc. Introduction of nasopharyngeal airway can be facilitated by phenylephrine nasal drops (causing vasoconstriction of nasal mucosa) or by lubricating the airway with lignocaine or K-Y gel. During introduction, tip of the nasal airways should be perpendicular to the face and is advanced slowly along the floor of the nasal passage. At any circumstances the tip of the airway should not be directed upward towards the cribriform plate. The length of the nasopharyngeal airways is roughly estimated by the distance from the tip of the nose to the meatus of the ear. When such manoeuvres and the use of artificial airways provide inadequate relief of upper airway obstruction by soft tissues, then the insertion of an endotracheal tube or other methods to by pass the upper airway obstruction should be comtem-plated.

EVALUATION OF THE AIRWAY

Introduction

One of the most important thing that an anaesthetist has to learn is the efficient management of airway. On the otherhand, proper evaluation of an airway is an essential part of the efficient management of airway. So, before every induction for anaesthesia, the airway of a patient should be evaluated or assessed properly by an anaesthetist. Thus, the discussion regarding the assessment and evaluation of airway has been widely accepted in anaesthesia for long time. Although, multiple predictive methods and scoring system for evaluation of airway has been suggested, but nothing can give 100% correct prediction. So, we will take only true scientific predictive protocol that all anaesthesiologists can depend upon it. This is because still now sometimes the unanticipated difficult airway in apparently normal patients sends us the signals for our inability to solve this problem.

The questions in these predictors tell us about the different terms which are frequently used such as difficult airway, difficult ventilation or difficult intubation. Because the answers to these questions are different. These three different technical skills are: unable to expose the glottis by conventional laryngoscope (difficult airway), unable to ventilate the patient maintaining $SPO_2 > 90\%$ (difficult ventilation) and unable to insert a ET tube into the larynx (difficult intubation). The former is generally termed difficult if one gets a poor view of the target organ i.e glottis (Cormack Lchane grade 3 or 4). The second is termed difficult if one without any assistance can not maintain $SPO_2 > 90\%$ by ventilating with 100% O_2. The third is termed difficult if after an arbitrary number of attempts (usually 3), the ET tube cannot be placed into the trachea (difficult intubation). All these three should be evaluated together or separately based on the history, clinical examination and radiological diagnostic tests. For easy and quick intubation good view of larynx is mandatory. So difficult laryngoscopy and bad view of larynx (difficult airway) is associated with difficult intubation. Hence, the assessment

of difficult airway and difficult intubation should be discussed together. The assessment for difficult ventilation is discussed under separate heading.

Airway can be classified on the basis of predictions and ultimate difficulties or outcome into three categories.

i. A predicted normal airway.
ii. A predicted abnormal airway.
iii. An unpredicted difficult airway.

Among them, the patients of group three are the most dangerous. Even, among the patients of group three, those which have failed intubation and mask ventilation is also not adequate, actually presents the life threatening condition.

Evaluation of airway can be performed under three headings.

Table 20.4: Common congenital syndrome causing difficult airway and intubation

(i)	Pierre-Robin syndrome:
	Micrognathia, macroglossia, cleft palate.
(ii)	Treacher-Collin's syndrome:
	Auricular and ocular defects, mandibular hypoplasia.
(iii)	Down's syndrome:
	Poorly developed nasal bridge, large tongue, small mouth.
(iv)	Klippel-Feil syndrome:
	Fusion of vertebra, restricted neck movement.
(v)	Goldenhar syndrome:
	Mandibular hypoplasia, cervical spine abnormality, occipitalization of atlas, auricular and ocular defects.
(vi)	Goitre:
	Compression and deviation of trachea.

There are many other diseases such as rheumatoid arthritis which may progress gradually and may cause airway problem during present anaesthesia which might have no airway complication during previous anaesthesia.

History

One of the most important point during history taking for evaluation of the airway is if there is any difficulty during previous general anaesthesia, more specifically during mask ventilation or ET intubation. This history should be properly documented and passed on to the next anaesthesia caregiver.

History of other previous and present diseases such as infection, trauma, neoplasia and inflammation which may affect the airway and subsequently the mode of anaesthesia should be taken properly. Some other present conditions that could predispose to difficult airway are: oedema of the face and neck, burn, active bleeding in the oral cavity, tracheal and oesophageal stenosis or aspiration of gastric content etc. There are many other congenital syndromes which are associated with airway problem and intubation difficulty during anaesthesia should also be kept in mind.

These common congential syndrome causing difficult airway and intubation are given in table (Table 20.4).

Physical Examination

After history taking, every patient should be properly examined physically to predict any difficulty of airway management during anaesthesia. Many additional clinical tests to predict difficult laryngoscopy and difficult intubation have also been described, but none of these tests is totally reliable. Their use may complement each other and also the routine physical examination of the airway. The routine physical examination of air way should start from the simple inspection of head and neck of patient to identify any obvious problem such as massive obesity, cervical collars, external injury, burns, contracture, restricted jaw movement, reciding mandible, bucked teeth, etc. to whole body inspection to some comprehensive scoring system. For example, congenital presence of some ear and hand abnormalities suggest associated presence of some congenital cardiovascular disorders and abnormal airway. Adequate nasal airway should also be evaluated before any nasal intubations (Table 20.5).

Regarding teeth; loose teeth, protuberant upper incisors, false teeth and other dental works such as crown, bridges, braces, etc. should be noted. Edentulous patients presents seldom difficulty to intubate unless other associated problems are severe. Protuberant upper incisors may make laryngoscopy difficult and can cause damage to the teeth. Severe loose teeth should be removed or fixed by ligature before laryngoscopy to avoid aspiration of it. Artificial dentures should be removed (Table 20.6).

Table 20.5: Wilson has identified five risk factors on the basis of which 0, 1, 2 points are awarded and a scoring system has been developed. A score of 5 to 10 would predict severe laryngoscopy and intubations difficulty

	Risk factors	*Scoring*
Weight	< 90 Kg	0
	90 - 110	1
	> 110	2
Head and neck	> 90°	0
	± 90°	1
	< 90°	2
Jaw movement (Inter incisor gap = IG)	IG > 5 cm	0
	IG = 5 "	1
	IG < 5 "	2
Receding mandible	Normal	0
	Moderate	1
	Severe	2
Bucked teeth	Normal	0
	Moderate	1
	Severe	2

Table 20.6: Conditions associated with difficult airway and intubations

Tumours	
	Large goitre, cystic hygroma, lipoma, haemangioma, haematoma, adenoma, papillomatosis, any tumours of pharynx or larynx etc.
Arthritis	
	Rheumatoid arthritis
	TM joints ankylosis, restricted spine.
	Ankylosing spondylitis
	Cervical spine ankylosis, restricted cervical spine mobility.
Infections	
	Abscess (peritonsilar, retropharyngeal submandibular etc), Ludwig's angina, epiglottitis, trismus, laryngeal oedema, laryngitis etc.
Trauma	
	Maxillary fracture, mandibular fracture, basilar skull fracture, cervical spine fracture, inhalation, burn, laryngeal fracture, oedema of airway, etc.
Foreign body: Anywhere in pharynx and larynx	
Obesity	
	Short neck, sleep apnoea, extra tissue in oropharynx.
Acromegaly	
	Macroglossia, prognathism.
Other anatomical variations	
	Micrognathia, high arched palate, prominent upper incisor, scleroderma, sarcoidosis.
Congenital syndrome	
	Discussed before

Next, opening of the mouth should be assessed and it depends on the function of the temporomandibular joint. Any previous and present disease of the temporomandibular joint make the mouth opening difficult and visualization of any pharyngeal and laryngeal structure is impossible. Normally, an adult should be able to open their mouth, so that there is 50 mm distance between the upper and lower incisor teeth (Figs 20.24 and 20.25).

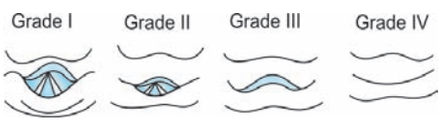

Fig. 20.24: Grading of the laryngeal view (Cormack-Lehane)

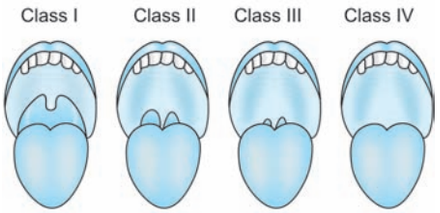

Fig. 20.25: Mallampati classification or test of oral opening

After assessment of mouth opening, oral cavity should be examined for large tongue, high arched palate, long narrow mouth, etc., which may cause difficult laryngoscopy and intubation. In 1983, Mallampati has evaluated a scoring system by observing the structure of the oral cavity through opened mouth by which difficulty of laryngoscopy and subsequent difficult intubation can be assessed or predicted. This is based on the visualisation of soft palate, uvula and faucial pillar. This test is performed with the patient sitting upright, head in neutral position, mouth opened as wide as possible and tongue protruded as far out as possible. Originally, there was three grades in Mallampati scoring system. The scoring system of Mallampati predicts approximately 50% difficult intubation. Then in 1987 Sampson and Young in their modification of Mallampati scoring system further added grade IV (Table 20.7).

Another way of assessing the difficulty in laryngoscopy or visualization of glottis and subsequent difficult intubation is to measure the distance from the symphysis of mandible to the hyoid bone. This distance should be at least 2 large finger breaths in adults. The space between the mandible and the hyoid bone is important, because during laryngoscopy the tongue is displaced into this place for visualization of glottis. If this space is narrow, glottis cannot be seen properly.

Then, the neck should be examined for its mobility, particularly for extension. A thick short muscular neck may result in difficult mask ventilation and as well as laryngoscopy and intubation. The normal amount of neck extension is 35 degrees. The measurement can be made by simple visual estimation or more accurately with goniometer. Any reduction in extension of neck is expressed in grades (Table 20.8).

Cervical spondylosis, ankylosis, rheumatoid arthritis of cervical vertebral joint etc; may restrict the flexion and extension of the inter cervical vertebrae or atlanto-occipital joint and cause difficulty in visualization of glottis by laryngoscope. Thus difficult intubation may precipitate. Extension of the neck also can be quantified by measuring the distance from the symphysis of mandible to the thyroid notch (thyromental distance) with the head fully extended. If the distance is more than 65 mm (3 large finger breaths), then visualization of the larynx and intubation will not be difficult. If this thyromental distance varies between 60 and 65 mm (or 6 and 6.5 cm) then visualization of larynx would be slightly difficult. The thyromental distance below 60 mm definitely suggests that laryngoscopy would be more difficult. The explanation of this observation is that if the thyromental distance is short then the laryngeal axis will make a more acute angle with the pharyngeal axis and it will be difficult to achieve alignment between the laryngeal and pharyngeal axis. This scoring system is developed by Patil, Sterling and Zanden. These three specific tests such as Mallampati, thyromental distance and extension at the atlanto-occipital joint together have

Table 20.7: Mallampati grading

Grade I	Anterior and posterior faucial pillar, soft palate and uvula is visible.
Grade II	Only soft palate and uvula is visible.
Grade III	Only soft palate is visible.
Grade IV	Soft palate is not visible.

Table 20.8: Mallampati grading for neck extension

Grade I : > 35 degree
Grade II : 22 to 34 degree
Grade III : 12 to 22 degree
Garde IV : < 12 degree

almost 100% reliability in predicting airway difficulty. Another way of assessment of neck mobility is the measurement of sternomental distance. If the sternomental distance is less than 12.5 cm, then intubation will be difficult. Lesser the distance greater will be the difficulty. This distance should be measured with head in full extension and mouth closed (Fig. 20.26).

It should be noted that the combination of several minor physical anomalies may result in a difficult laryngoscopy and difficult intubation even when no single factor or test is severely abnormal. Difficult intubation may occur occasionally for reasons that are currently unexplained and none of the available indices predicts it. Even though the airway may look normal on external assessment, one may come across difficulty during laryngoscopy and intubation due to the variations in internal anatomy of upper airway. Cormack and Lehan have defined four grades of laryngoscopic view and predict subsequent difficult intubation which is given below.

Grade I : Visualization of entire laryngeal aperture including full length of vocal cord and arytenoid cartilage.

Grade II : Visualization of epiglottis, aryte-noid cartilage and posterior part of vocal cord only.

Grade III : Visualization of epiglottis only.

Grrad IV : Epiglottis not visible.

Comparison of Mallampati and Cormack-Lehan grading.

Grade I Grade I

Grade IV, Grade III and IV

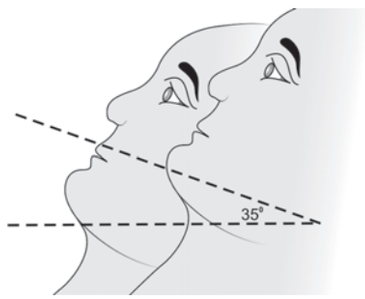

Fig. 20.26: Assessment of neck mobility by measuring sternomental distance

Grade II and III Relatively uniform distribution in all grades

The application of external pressure can reduce the incidence of grade III view from 9% to between 5 and 1%.

Investigations

The other ways of assessing the airway are laboratory investigations such as X-ray, CT scan and MRI of head and neck. Lateral X-ray of the head and neck along with distance marking between the bony land marks have been used to predict the difficult laryngoscopy and difficult intubations. In radiology plate the measurement of atlanto- occipital distance and interspinous gap between C_1 and C_2 vertebrae may also have a predictive value. Other radiological examinations for airway assessment include: decreased posterior depth of the mandible (PDM) and increased anterior depth of mandible (ADM). A ratio of more than 3.6 between the mandibular length and posterior mandibular depth has also been shown to indicate the difficult intubation by White and Kander (Fig. 20.27).

Some Rules and Laws

What is lemon law?

LEMON law stands on:

L = Look externally,
E = Evaluate the 3-3-2-1 rules,
M = Mallampati scale,
O = Obstruction,
N = Neck mobility.

Look externally

It is the external indicators of either difficult laryngoscopy or difficult ventilation or difficult intubation. It includes: presence of huge beard or large moustache, abnormal facial shape, extreme nourishmentmal or over, a person without teeth, facial trauma, obesity, large front teeth, high arched palate, receding mandible, short bull neck, severe contracture, etc.

Evaluate 3-3-2-1 rule

i. 3 finger mouth opening. The normal interincisor distance is 4.6 cm or more. While < 3.8 cm of interincisor distance predicts difficult airway and < 3 cm indicates TM joint dysfunction. If the distance is < 2.5 cm, it indicates the difficult laryngoscopic view and < 2 cm indicates laryngoscopy and intubation is impossible.

ii. 3 fingers is the normal distance between the tip of the jaw and the begining of the neck (hypomental distance), while it is fully extended. Alignment of the laryngeal and pharyngeal axis is difficult if this distance is less than 3 fingers breath (or < 6 cm) in adult. If the length varies between 6 and 6.5 cm then alignment is less difficult and while the distance is > 6.5 cm it is normal.

iii. 2 fingers breath is the normal distance between the thyroid notch and the floor of the mandible. When this distance is < 2 fingers breath, then difficult airway and intubation is predicted. (Fig. 20.28)

iv. 1 finger is the normal subluxation of lower jaw anteriorly.

Mallampati scale

Grade I: 80 to 100% easy intubation.

Grade II: Intubation is possible with proper positioning and optimal laryngeal maneuver technique.

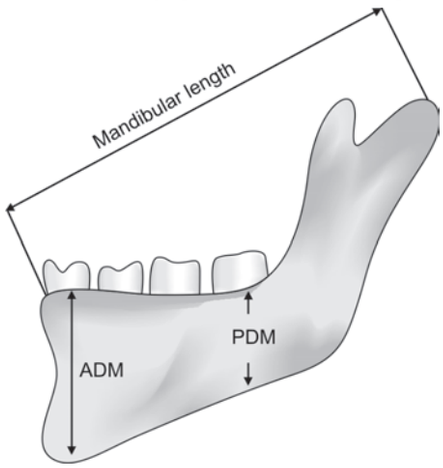

Fig. 20.27: ADM = Anterior distance of mandible
PDM = Posterior distance of mandible

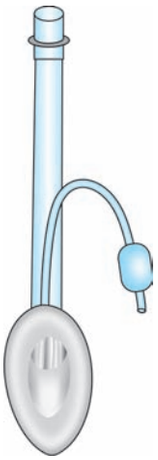

Fig. 20.28: Laryngeal mask (classic)

Grade III: Intubation is still possible with special laryngeal blade or with the use of gun elastic bougie.
Grade IV: Intubation is almost impossible.
This test should be repeated twice to avoid the false positive and false negative results.

Obstruction

For obvious difficulty during laryngoscopy and intubation anaesthetist must consider the obstruction of airway with foreign body, tumour, abscess, epiglottitis or expanding haematoma, etc.

Neck mobility

(Movement of atlanto-occipital joint and flexion-extension of the neck)
Normally the atlanto-occipital (A-O) joint movement ranges arround 35°. Limited A-O joint movement is present in cervical spondylosis, rheumatoid arthritis, halo-jacket fixation, etc. The grading of A-O joint movement is done as follows.

Grade I : > 35 degrees
Grade II : 22-34 degrees
Grade III : 12-21 degrees
Grade IV : < 12 degrees

Airway assessment based on LEMON law or method is able to stratify, successfully, the risk of difficult laryngoscopy and subsequent intubation or ventilation by mask.

What is LMMAP rule of airway assessment?

It stands for :
L = Look for external deformity of face and neck,
M = Mallampati,
M = Measurement 3-3-2-1 or 1-2-3-3 fingers,
3– fingers mouth opening
3– fingers hypomental distance
2– fingers distance between the thyroid notch and the floor of the mandible
1 – finger subluxation of lower jaw
A = Atlanto-occipital (A-O) extension
P = Pathological airway obstruction

What are the 4Ds?

The following 4Ds also suggest the difficult airways:

- Dentition filtered = Prominent upper incisors, receding chin, etc.
- Distortion filtered = Oedema, blood, vomits, tumour, infection, etc.
- Disproportion filtered = short chin to laryngeal distance, bull neck, large tongue, small mouth, etc.
- Dismobility= TM joint and cervical spine

What are the Magboul 4 Ms?

There is another easier way to memorize the prediction of difficult laryngoscopy and intubation. This is described as Magboul 4 Ms with STOP sign. The 4 Ms are:
a. Mallampati
b. Measurement
c. Movement of neck
d. Malformation
The STOP signs are
S = Skull (hydro and microcephalus)
T = Teeth (buck, protrud, loose)
O = Obstruction
P = Pathology
(cranio-facial abnormality and syndrome: Treacher-Collins, Pierre-Robin, Goldenhar's Waardenburg syndrome, etc).

Cass and James risk stratification

In 1965, they summarised 6 common anatomical causes of difficult intubation and stratification of risk. These are:

i. Short muscular neck.
ii. Receding jaw with an obtuse mandibular angle.
iii. Protruding upper incisor teeth.
iv. Long and high arched palate.
v. Poor mobility of mandible.
vi. Decreased distance between alveolar and mental ridge which is required for wide opening of mandible for introduction of laryngoscope.

Rapid assessment of airway by "1-2-3 rule"

Rule 1: Ability to insunate at least one finger in front of the tragus when the patient opens his mouth. This establishes the integrity of movement of TM joint.
Rule 2: Determing the adequacy of the opening of mouth by measuring the interincisor gap. This should be at least 2 finger breadths.
Rule 3: Measurement of thyromental distance. It should be at least 3 finger breadths.

Type variable score

i. Receding chin or temporomandibular distance less than 7 cm. 3 points
ii. Mallampati Grade IV. 2 points
iii. Restricted head extension. 2 points
iv. Protruding teeth. 2 points
v. Mouth opening < 4 cm. 2 points
vi. Vertical neck length < 7.5 cm.1 point
vii. Neck circumference > 33 cm. 1 point

The study reveals that a score of 6 or more correctly identify 22 out of 23 difficult intubation.

AIRWAY MANAGEMENT BY MASK VENTILATION

In emergency situation where the patient is apnoeic after giving muscle relevant and patient is unintubated or we fail to intubate then ventilation by mask and bag is life saving. Usually anaesthetic face mask is employed for ventilation by administering air or O_2 and/or anaesthetic gases.

The rim of the face mask is contoured or conformed to a variety of facial features to create a airtight seal with the patient's face. The 22 mm orifice of these face mask is attached to the breathing circuit of the anaesthetic machine through a right angle connector. These face masks are made of different materials which vary from rubber or plastic to silicon. It is also available in different shapes and sizes for newborn to large adult face. The transparent masks are more advantageous because they are less frightening and facilitate observation of the patient for cyanosis and vomiting.

Mask can be held with one hand or both the hands (if necessary, to fit the mask tightly over the face). If both the hands of anaesthetist are used to fit the mask on the patient's face, then an assistant is needed to ventilate the bag or anaesthetic ventilator can be used to supply the positive pressure breaths. By the thumb and the first finger of anaesthetist's left hand the mask should be held tightly on the patient's face, while the other three fingers of the hand will displace the mandible upward by giving upward thrust on the angle of it. Care should be taken that fingers should be kept on the ramus of the mandible, but not on the soft tissues of the neck and the floor of the mouth. Because pressure on the soft tissues of neck by fingers produces discomfort and push the base of the tongue towards the posterior pharyngeal wall, causing more airway obstruction. Mandibular upward displacement along with the upper cervical extension and lifting of the chin upward by fingers tend to pull the tongue and soft tissues away from the posterior pharyngeal wall. Thus, it relieves the upper airway obstruction that occurs in the paralysed and anaesthetised or unconcious patient.

But this mask ventilation is difficult for obese patient, thick neck, short neck, big face, endentulous patients, etc. In endentulous patients, the mask ventilation can be helped by leaving the dentures in place or by using packs or employing the mask strap to pull up the sagging cheeks. Mask ventilation in paediatric patients are more easier than adult patients, provided there is no laryngospasm. Though mask ventilation is very helpful in emergency condition and more easier than ET intubation, but the most serious problems with mask ventilation include failure, distension of stomach by air, pulmonary aspiration and pressure damage to the eyes.

How Do we Predict Difficult Mask and Bag Ventilation ?

Langeron et al suggested five recognised criteria as independent predictors of difficult bag and mask ventilation and that can be summarised as the word OBESE. It is a simple visual way to remember what to look for when evaluating and assessing the airway for difficult mask and bag ventilation.

O = Obese (Body mass index > 40 Kg/m^2)
B = Bearded
E = Elderly (older than 55 years)
S = Snorers
E = Edentulous

The presence of any two of these criterias is best indicated as difficult mask and bag ventilation with a sensitivity of 0.72 and specificity of 0.73.

Obesity is asociated with decreased posterior airway space behind the base of the tongue. This is due to the accumulation of fat in the pharyngeal soft tissue. Thus, it causes more impairment of airway patency during sleep due to fall of tongue on posterior pharyngeal wall and is a risk factor for obstructive sleep apnoea syndrome. Upper airway obstruction can occur early after induction of anaesthesia with the posterior displacement of soft palate, base of the tongue and epiglottis in morbidity obese patients (BMI > 40 Kg/m^2). Age is also closely related to the increased pharyngeal and laryngeal resistance to airflow and is more common in men than women. Lack of teeth and the presence of beard are also associated with difficult mask ventilation. It is due to the decrease in airtight seal of facemask and increased air leak around the mask with more difficult positive pressure ventilation.

AIRWAY MANAGEMENT BY LARYNGEAL MASK AIRWAY (LMA)

Laryngeal mask airway is a new device whose status regarding the management of airway is lying somewhere between the face mask with oropharyngeal airway and the endotracheal tube (ET). This is because it provides more definite airway than the former, but not the more reliable air way protection and maintenance than the later. It sometimes acts as an essential airway device to provide emergency airway and ventilation when conventional mask ventilation and attempts to intubation fails. Therefore, although LMA was originally developed for airway management in routine cases with spontaneous ventilation, but it is now listed in the ASA difficult airway algorithm at 5 different places as a ventilatory device or as a conduit for endotracheal intubation. It is a new device designed to maintain a seal around the laryngeal inlet for spontaneous ventilation and also permits positive pressure controlled ventilation at modest level of pressure (up to 15 cm H_2O). But because of the limited ability of LMA to seal off the laryngeal inlet tightly, the elective use of this device is contraindicated in any of the condition where there is an increased risk of aspiration and where ventilation under high pressure is needed. In patients without these predisposing factors, the risk for pharyngeal regurgitation appears to be low and the use of LMA is safe (Fig. 20.29).

Now, LMA is available in seven different sizes for neonates to large adults. LMA classic is a reusable device. It is made of medical grade silicone and is free from latex. It is to be discarded after 40 autoclaving. There are three main components of a LMA classic: an airway tube, a laryngeal mask with inflating cuff and a cuff inflating pilot catheter with balloon. The

Fig. 20.29: Proseal LMA (PLMA)

airway tube is of large bore with 15 mm standard male adaptor which can be connected with breathing circuit. Its other end is fitted to the mask which has an inflatable cuff. The cuff can be inflated or deflated via a valve located on the pilot catheter. Two aperture bars guard the distal end of the large bore airway tube. The mask of the LMA is specially designed to conform to the contours of the hypopharynx. Now, several new variants of the LMA except classic are available. These are : LMA Flexible, LMA Unique (disposable LMA, Sizes 3, 4, 5), intubating LMA or LMA Fastrach and most recently LMA Proseal. All variants of LMA, except unique variety, are made of silicone or latex free rubber. Unique variety of LMA is made of medical grade PVC. Just enough air to seal the laryngeal inlet can raise the intracuff pressure around 60 cm of H_2O. During cuff inflation, after the introduction of LMA the tube should not be hold by hand as this prevents the mask from setting into its own correct location from itself in hypopharynx. A small outward movements of the tube is often noted during inflation of the cuff as the device seats and adjusts itself in the hypopharynx.

The Proseal Laryngeal Mask Airway (PLMA) is the latest addition to the various modification of the original LMA. Like LMA, the PLMA is also made of latex free silicone and is reusable. The mask and the inflation assembly of this variety of LMA is identical to the classic variety of it. Here, the original larger ventral cuff is fixed to a second cuff which is attached to the dorsal surface of the first cuff. The dorsal cuff, when inflated, improves the seal by pushing the ventral cuff more firmly on the periglottic tissues. So a properly placed PLMA can withstand a leak pressure of approximately 35 cm of H_2O, as against 25 cm of H_2O offered by the LMA classic. The PLMA airway tube is flexible, wire reinforced and double lumened. One lumen is used as airway tube for ventilation and another lumen is used as gastric drainage tube for aspiration of gastric contents during regurgitation. The rationale to place the two tubes side by side, except at the level of the mask is to give greater stability to the device, while once placed in the oral cavity. The PLMA bowl is deeper through which traverses the drainage tube and open most distally. This drainage tube in the bowl helps to eliminate the aperture bars. However, the main purpose of the drainage tube is : to facilitate the gastric tube insertion, to divert the regurgitated fluid away from the respiratory tract and to prevent gastric insufflation. The PLMA comes with a reuseable introducer which is an easily clip-on / clip-off device. A built in bite block has also been added at the proximal end of the two tubes which prevents the patient from biting and collapsing the airway tube. It also helps to bond the two tubes firmly. Introduction of LMA needs adequate depth of anaesthesia, but not so deep as required for tracheal intubation. So, it is not suitable for conscious emergency room patients (Fig. 20.29).

LMA insertion requires an anaesthetic depth which is slightly greater than that required for the insertion of an oral airway, but lighter than ET tube intubation.Under an adequate depth of anaesthesia, an appropriate size of LMA is gradually introduced into the mouth and then into the cavity of laryngopharynx with the aperture facing towards the base of the tongue. It is performed by pressing the cuffed tip of LMA against the posterior pharyngeal wall and guided by the index finger of the dominant hand. The LMA is pushed in hypopharynx till a resistance is felt which indicates that the tip of it has reached the upper esophageal sphincter. Some anaesthetists prefer to introduce LMA with deflated cuff and some with fully inflated. But, it is better to introduce LMA with partially deflated cuff and when the tip felt the resistance, then the cuff is fully inflated again with the addition of appropriate volume of air and is secured with tape.

The correct position of the cuff should be checked by auscultation of lungs and capnography. The other signs of correct placement of LMA cuff include one or more of the following : (i) the slight outward movement of the tube after the inflation of LMA cuff, (ii) the presence of a smooth oval swelling on the neck around the thyroid and cricoid area, (iii) no portion of cuff should be visible in the oral cavity. Before taping the LMA in place, a bite block should be inserted. It not only stabilizes the LMA, but also prevents the occlusion of tube from bitting. Reinforced flexi LMA are more prone to biting and bite block should be placed, until LMA is removed.

One of the principal cause of obstruction during the use of LMA is the downward displacement of epiglottis by LMA or curling up of tongue on the laryngeal inlet. An ideally positioned cuff of LMA is bounded by the base of the tongue superiorly, the pyriform fossa laterally and the upper oesophageal sphincter inferiorly. If the inlet of oesophagus lies within the rim of the cuff, then gastric distension and reguritation become a distinct possibility. The anatomic variations of hypopharynx prevent adequate functioning of LMA in some patients. So, if an LMA is not functioning properly after attempts to improve the condition, most anaesthetists will try another LMA which is one size larger or smaller. However, introduction of LMA under direct vision with the help of laryngoscope or fibreoptic scope may prove beneficial in difficult cases (Fig. 20.30).

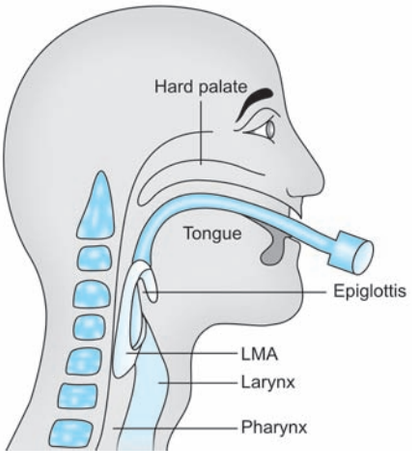

Fig. 20.30: LMA in position

The main advantages of LMA are:

i. It provides an emergency airway in patients, where either mask ventilation or tracheal intubation is difficult or has been failed.
ii. In case when intubation is not mandatory and operation can simply be done by spontaneous face mask ventilation, but airway cannot adequately be maintained by simple Guedel's oropharyngeal airway and face mask.
iii. Introduction of LMA eliminates the presence of a relatively large face mask and anaesthetist's hand on the patient's face that may interfere with surgical access, especially when the surgical site is situated over the head and neck. On the otherhand, availability of new flexible LMA provides an easy connection with the anaesthetic machine at any angle from the mouth, while resisting kinking and displacement.
iv. LMA also provides an emergency airway in awkward position, such as in the lateral and prone position of the patient and in emergency settings when laryngoscope and other equipment for intubation are not available. Instead of mouth to mouth breathing, mouth to larynx breathing through LMA in emergency condition is a better alternative.
v. LMA sometimes provides a conduit to facilitate fibre optic guided or gum-bougie guided or blind oral tracheal intubation during difficult situations of intubation. LMA, specially designed to facilitate such tracheal intubation, is now available and is called intubating LMA.

Disadvantages of LMA are: pulmonary aspiration, laryngospasm, failure to function in the presence of pharyngeal and laryngeal disease, failure to provide high inflation pressure during decreased compliance of lungs and thorax and also due to resultant leak around the cuff by high pressure ventilation. Therefore, the contraindication of use of LMA are: full stomach (e.g. pregnancy, hiatal hernia, intestinal obstruction, etc.) pharyngeal pathology (e.g. tumour, absces, etc.), pharyngeal obstruction, low pulmonary compliance (e.g. asthma, COPD, etc.) requiring peak inspiratory pressure greater than 30 cm of H_2O, etc.

AIRWAY MANAGEMENT BY COMBITUBE

Like LMA, combitube is another supraglottic airway device that provides an emergency airway when tracheal intubation is failed and mask ventilation is not effective or fails. It is a double lumen tube that combines the features of both a conventional tracheal tube and that of an esophageal obturator airway. Both the lumens of tube are connected at its proximal (outer) end with a 15 mm connector that helps it to be attached with the main anaesthetic machine. It is especially useful for patients in whom direct visualization of the vocal cords is not possible as in patients with massive airway bleeding or regurgitation, limited access to the airway and in patients in whom neck movement is contraindicated. As combitube is made of natural rubber or latex, so it may cause allergic reactions. It has two latex cuffs or balloons – one is oesophageal and another is oropharyngeal. The pharyngeal cuff or balloon is blue in colour and larger in volume (100 ml) than the oesophageal cuff or balloon (15 ml). The longer lumen is blue in colour and ends at the patient's side with multiple apertures between the two cuffs while the shorter lumen ends at the most distal end of this device (Fig. 20.31).

Combitube can function effectively whether is placed in the trachea or much more commonly in the oesophagus when it is introduced blindly. Ventilation is usually started first through the blue longer tube. This is because, placement of the distal end which proximally begin with shorter tube is usually in the oesophagus when combitube

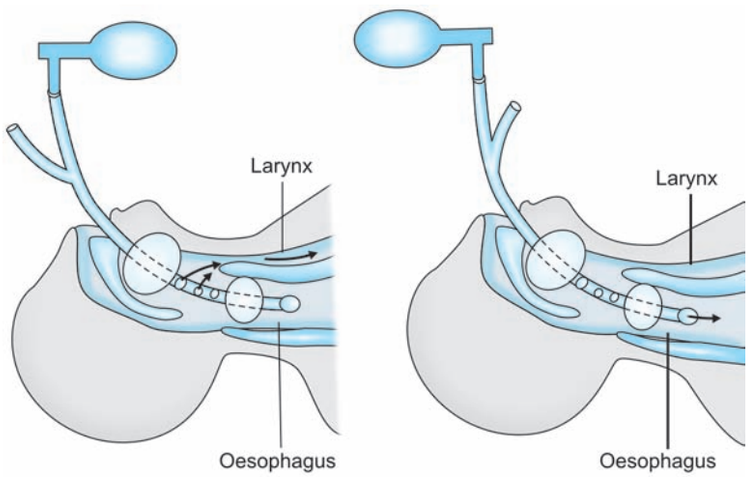

Fig. 20.31: The mechanism of action of combitube

is introduced blindly through oral cavity. Then, if auscultation of the breath sound is positive and auscultation of gastric insufflation is negative, ventilation is continued. In this situation, multiple apertures which are continuous with the longer blue lumen is situated at the laryngopharynx between the two cuffs and air passes from the laryngopharynx through the laryngeal inlet into the lungs. Under this condition, the shorter tube which ends at distal aperture and now is in the oesophagus may be used to remove the gastric fluid with a suction catheter. In such circumstances if inflation of lung is absent and the stomach is being insufflated, then ventilation should be started through the transparent shorter tube which communicate with the distal single aperture beyond the oesophageal balloon. Under this situation, the multiple apperture which are continuous with the longer blue tube and through which ventilation was done before are situated above the laryngopharynx and distal end which is connected with the transparent shorter tube is situated in the trachea. So, the air is passing from blue tube through oropharynx and oesophagus to the stomach. Then, ventilation should be continued through the transparent shorter tube which can be confirmed by auscultation of breath sound and absence of gastric insufflation.

The combitube has also been successfully used during emergency cardiopulmonary resuscitation and in such circumstances esophageal balloon provides protection from aspiration which may represent an distinct advantage of it over the LMA. But, care must be taken to avoid excessive deep placement of combitube in the oesophagus, which can further obstructs the glottic opening by the pressure of distal cuff from oesophagus. Though, it is listed in the management of difficult airway in advanced life support algorithm, still combitube is rarely used by anaesthetists now. Because they prefer LMA or other device in such difficult situations.

AIRWAY MANAGEMENT BY ENDOTRACHEAL (ET) TUBE – INTUBATION

The introduction of an ET tube into the tracheal lumen through glottic opening is called intubation. This is the best way of airway management, but not without any disadvantages or complications.

There are many indications for endotracheal intubation, but the principle head lines are:

i. maintenance of unobstructive airway,
ii. protection of airway from aspiration,
iii. application of positive pressure ventilation,
iv. adequate oxygenation and delivery of anesthetic gases.

Equipment for Intubation

The main equipment needed for intubaton are: endotracheal tube, laryngoscope and some accessories in difficult situations such as stylate, bougie, light weight, etc.

Endotracheal (ET) tube

In present practice, the commonly used ET tubes are now made of clear polyvinylchloride (PVC) with high volume low pressure cuff, though red rubber tubes with low volume and high pressure cuffs are still manufactured. The distinct advantage of a clear PVC made ET tube is that it helps to obseve the condensation of water vapour in expired air which occurs during expiration and confirm the ET-tube in the trachea. They are numbered according to their internal diameter (ID) measured in mm, as for example the internal diameter of 7 no. ET tube is 7 mm. The external diameter of ET tube varies with the thickness of the tube's wall which again varies according to the different manufacturers. Less commonly, some ET-tubes are numbered in the French scale which indicates external diameter in mm multiplied by 3. The choice of diameter of a ET tube for a particular patient always runs through a compromise between maximizing the flow of gases through a large size and minimizing trauma with a small size. Tubes are manufactured in 0.5 mm ID increments from 2.5 to 9 mm. A radioopaque line is impregnated into the wall of the tube which aid its later visualisation by X-ray in case of displacement or aid in determination of tube position after intubation. The radiopaque barium sulphate stripe also significantly lowers the temperature at which ignition of the tube occurs and thus decreases the risk of fire during laser surgery (Fig. 20.32).

An ASTM (American Society for Testing and Materials) standard for manufacturing of tracheal tube recommends the following things which include: the material from which the tube should be constructed, inside diameter, length, inflation system, cuff, radius of the curvature of the tube, markings, Murphy eye, packaging and labeling, etc. A separate standard also covers the testing of the shaft of tracheal tube for laser resistance.

The standard specifies that the radius of curvature of a conventional ET tube should be 140 ± 20 mm. The internal and external walls should be circular. A tube whose lumen is oval or elliptic in shape is more prone to kinking than one that is circular. The machine end of the ET tube receives the connector and projects from the patient mouth or nose. By cutting with scissors it should be possible to shorten this end if necessary. The patient end of the ET tube is inserted into the trachea. It usually has a slanted opening which is

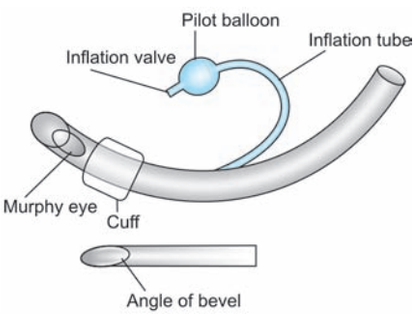

Fig. 20.32: The cuffed Murphy eyed endotracheal tube

called the bevel. The angle of this bevel is acute which is formed between the axis of the bevel and the longitudinal axis of the tracheal tube. A standard tracheal tube has a bevel angle of 38 ± 10°. The opening of the bevel looks left when viewing the tube from its concave aspect. This is because most often the ET tube is introduced in the larynx from the right side of the patient. So as the bevel faces left, it facilitates better visualization of the larynx when the tube is being inserted.

Sometimes, there is a hole on the side opposite to the bevel. This is known as the Murphy eye and an ET tube with this feature is called the Murphy-type tube. The purpose of this eye is to provide an alternate pathway for gas flow, if the bevel is occluded sometimes due to any reason. Some anaesthetists think that having such an eye is a disadvantage, because secretions may accumulate there and forceps, tube changers, fibrescope, etc, which are sometimes used for different purposes through the ET-tube may inadvertently advance through this Murphy eye instead of passing through the bevel. Some tubes have a second eye on the bevel side. This Murphy eye may also provide a measure of safety, if the tube accidently advances into the right mainstem bronchus. The endotracheal tubes lacking Murphy eye are known as Magill type tubes. Lack of Murphy eye allows the cuff to be placed closer to the tip. This may decrease the chance of inadvertent bronchial intubation.

The result of IT (implantation test) and Z-79 seal is usually stamped upon the tube. This means that the tube is compatible with human tissues, free of toxins and have no irritant properties. There are other various markings on the tube which include: (a) whether or not it is designed for nasal or oral use and (b) the distance in cm between the tip of the tube and the place where that tube is emerged either at the nose or at the mouth.

The pressure in the cuff of the tube is important. This is because high pressure in the cuff is transmitted to the tracheal mucosa and can cause ischaemic injury. So the cuff should be inflated to such a minimum volume and pressure that there is just no leak of air on positive pressure ventilation through the gap between the cuff and the tracheal mucosa. This will allow for reasonable airway protection from aspiration without excessive lateral wall pressure on the tracheal mucosa that may cause ischaemic injury and subsequent complication later. The cuff pressure that afford good protection from aspiration is 20 to 25 mm of Hg and it is just below the perfusion pressures of the tracheal mucosa which is about 25 to 35 mm of Hg. Therefore, this 20 to 25 mm of Hg cuff pressure does not cause ischaemic injury to the tracheal mucosa. The N_2O used during the maintenance of anaesthesia can also diffuse into the cuff and can increases the cuff pressure which in turn can increase the risk of ischaemic tracheal mucosal injury. But, if high volume and low pressure cuff is used for less than 24 hours, it is of no clinical significance or importance. On the otherhand, tubes with high volume and low pressure cuff produces more difficulty during insertion, because the cuff often obscures the (Fig. 20.33) view of the tip of the tube and larynx. So, the trauma to the airway by this tube is more common. The otherways to avoid this problem is to remove the air from the balloon intermittently, guided by the tension of the pilot balloon. Alternatively, cuff should be inflated by N_2O of clinical concentration or N_2O should be totally avoided from the maintenance of anaesthesia. Inflation of the cuff by 5 to 10 ml of air would be sufficient to achieve an effective seal if the selection of ET-tube is correct. If the amount of air required is more than 10 ml, then the ET tube should be changed to a size of 0.5 to 1 mm ID larger than that had already passed. High volume – low pressure cuff also increase the incidence of sore throat (due to larger mucosal contact area), aspiration, spontaneous extubation and difficult insertion due to floppy cuff. But still because of low incidence of mucosal injury, high volume-low pressure cuff are more commonly recommended now.

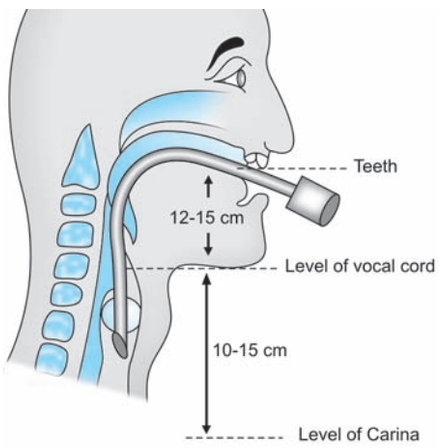

Fig. 20.33: The distances relating to the ET tube position

In younger children below the 8 years of age uncuffed tubes have generally been used. This is because the narrowest subglottic area is believed to limit the use of a cuffed tubes due to difficulty in introduction and in paediatric patients tacheal mucosa is more sensitive to ischaemic injury. In such circumstances endotracheal tube leak pressure is a clinically useful guide to confirm the proper selection of the uncuffed tube size in childrean. Leak should occur in a properly selected tubes at 15 to 20 cm of H_2O pressure and above. Below this pressure there should be no leak if the tube's size is properly selected. In this pressure there is no ischaemic injury of tracheal mucosa and aspiration.

Now, the use of a cuffed ET tube in paediatric group of patients has brought new discussion, keeping in mind the following advantages of it: require low fresh gas flow, reduce waste gas exposure to OT personal and avoide repeat laryngoscopy without any increased incidence of croup.

Generally, larynx is smaller in female than male. So, in an adult male an ET tube of 8 mm ID is appropriate, whereas for female a 7 mm ID tube is appropriate. In

adult, the glottic aperture limits the size of an ET tube, but in children the subglottic area (cricoid cartilage) is the narrowest part of larynx and limits the size of ET tube. The tube size or the internal diameter (ID) of on ET tube for children up to the age of 14 years is calculated from the formula: {(16 + age) ÷ 4}. But practically, a tube of 0.5 to 1 mm ID size, smaller or larger than the estimated must be immediately available. There are other two popular formulae for calculating the probable size or ID of ET-tube to be used for paediatric patients are:

A. For children up to 3 years or less: Age/3 + 3.5 = ID of tube in mm.
B. For children 4 years and above : Age/4 + 4.5 = ID of tube in mm.

However, a crude clinical guide to calculate the outer diameter of the ET-tube, appropriate for a paediatric patient, is that of his little finger.

A special type of ET tube is used in head-neck surgery, neurosurgery or other surgeries where there is every possibilities of kinking of it. This type of ET tube is called the armoured tube. Here, the wall of the tube is reinforced with a spiral wire to reduce the chance of kinking and collapse. This armoured ET tube is also useful when it is placed through a tracheostomy or laryngectomy stoma to provide an clear airway.

Another type of special ET-tube, called RAE (Ring-Adair-Elwin) tube, is sometimes used which is available as both oral and nasal versions. It is best used when it is necessary to keep the tube out of the respective surgical fields. The curvature of these tubes are predefined to facilitate surgery over the head and neck. There is a preformed bend in the tube that helps the outer portion of it to pass directly over the chin (oral version) or forehead (nasal versions). It may be temporarily straightened during intubation and again takes its preformed shape automatically after the introduction in trachea. Like nasal and oral versions, they are also available in cuffed and uncuffed versions. As the diameter of this type of tube increases, simultaneously the length or distance from the distal tip to the curve also increases. Usually, there is a mark at the bend. In the majority of cases when this mark is at the teeth or naris, it is assumed that the tube is correctly positioned in the trachea, provided the proper size of tube for that patient is selected. However this mark is taken only as a guide but should not be used as the sole criteria for confirming the correct positioning of the tube in trachea.

The nasal preformed RAE tube has a curvature opposite to the curvature of the oral RAE tubes. It is because when this nasal version is in place the outer portion of the tube is directed over the patient's forehead. This helps to reduce the pressure on the nares. Thus, RAE tube may be useful for oral intubation of patients who are to be placed in the prone position or is scheduled for otolaryngologic procedures. The oral preformed RAE tubes are shorter than nasal ones. The external portion of the oral RAE tube is bent at an acute angle. So, when in place it rests on the patient's chin.

These RAE tubes are easy to secure. Their use may reduce the risk of unintended extubation. The curvature of the tube allows the breathing system to remain away from the surgical field during operation, especially around the head and neck without the use of any special connectors. It also helps to protect against kinks. The long length of RAE tube may also make them useful for insertion through an LMA.

The main disadvantage of preformed RAE tubes is difficulty in passing a suction catheter through them. When necessary, suctioning can be accomplished by cutting the tube at the preformed curvature and reinserting the connector of anaesthetic machine into the cut end. They offer more resistance to airflow than conventional ET tubes of comparable size. As the length of these tubes are designed to fit the average group of patient, so a tube may be either too short or too long for a given patient. When selecting the tube size, the reference to the height and weight of a patient may be more useful than the age in years, and the user should always be alert to the possibility of bronchial intubation or accidental extubation.

Other varieties of ET tubes are : microlaryngeal tube, double lumen tube, Parker Flex Tip tube, Cole tube, spiral embedded tube, Carden bronchoscopy tube, Carden laryngoscopy tube, injectoflex tube, different laser resistant tubes, etc. Detailed discussion of these tubes is not possible here.

Laryngoscope

A laryngoscope is an instrument which helps to see and examine the larynx and also helps to facilitate the intubation of trachea. It is of two types: rigid and flexible fibreoptic. Standard rigid laryngoscope consists of two parts: detachable blade with bulb and handle containing batteries. Each standard laryngoscope blade has: (i) a spatula which compresses the tongue in the submandibular space, (ii) a flange for displacing the tongue to one side, and (iii) an open side for visualization of the larynx by elevating the epiglottis indirectly by pressing on the glossoepiglotic fold or directly by pressing on the posterior surface of epiglottis. The batteries in the handle light the bulb at the tip of the blade. Alternatively, it powers a fibreoptic bundle that terminates at the tip of the blade and acts like a bulb. This light, emitting from the end of this fibreoptic bundle, is less diffused, more intense and more direct. This rigid laryngoscope with fibreoptic bundle in the blade also can be made MRI compatible.

According to the different shapes of blade, laryngoscope may be of different types which is not possible to discuss in detail here. However, among these few are discussed below.

Macintosh Laryngoscope

It is the most popular laryngoscope for use in adult. Its blade is curved and Z-shaped

on cross section. Its tip lies beneath the pharyngeal (or anterior) surface of the epiglottis. Sizes of blade ranges from 1(smallest blade) to 4 (largest blade). Among these no 3 blade is most frequently employed for the adult use. But the no 4 blade is reserved for the unusual large or different patients. The smaller size blades are used for the paediatric patients. Tip of the Macintosh blade enters the valeculla and lifts the base of the tongue and the pharyngeal subtissues from the front of epiglottis. Thus, it elevates the epiglottis indirectly, so that cords can be visualized (Fig. 20.34).

Miller Laryngoscope

Unlike Macintosh laryngoscope its blade is straight with slight curved tip. The size of the blade ranges from 0 (smallest blade) to 4 (largest blade). Here, the tip of the blade elevates the epiglottis directly from behind and thus the cords are visualized. Another commonly used straight blade laryngoscope is Wisconsin blade which has a straight tip. Although, the straight blades may be advantageous in younger children, but the choice of blade in older children and adults is really a matter of familiarity and taste of an anaesthetist. Sometimes, in adults this straight blade Miller laryngoscope is also recommended for use in patients with a more anteriorly placed larynx. But, an anaesthetist should have a habit of using both the curved and straight blade, because when laryngoscopy becomes difficult with one type of blade, use of other type may permit adequate visualisation of glottis. For neonates and babies another type of straight blade such as oxford infant blade – is also very useful (Fig. 20.35).

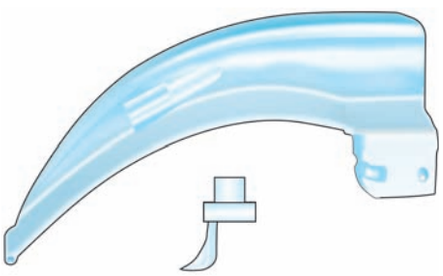

Fig. 20.34: Macintosh laryngoscope

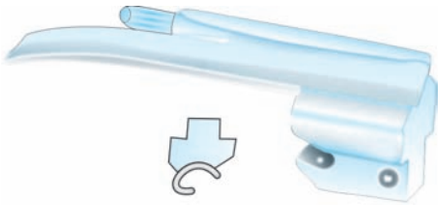

Fig. 20.35: Miller laryngoscope

McCoy Laryngoscope (Flexi – tip laryngoscope)

The peculiarity of this laryngoscope is that it has a hinged tip, assembled by lever which is positioned alongside the length of the handle on the opposite side of the blade. After insertion, once the tip of the blade is in the valeculla, pressure on the lever elevates the hinged tip with the epiglottis. This becomes specially useful for grade 3 intubation (of course in combination with cricoid pressure).

Bullard Laryngoscope

Bullard intubating laryngoscope is useful when the neck is immobile and mouth opening is very restricted. It has a long curved blades with fibreoptic illuminating system, suction port and intubation channels. It is made as both adult and paediatric versions (Fig. 20.36).

Wu-laryngoscope

Like Bullard laryngoscope, it has also a curved blade with elongated tip, fibreoptic light source, suction port, oxygen port and intubating channels through which tracheal tube is passed. It is designed to help to see the glottis in patient with very large tongue or whose glottis is very anteriorly placed. Anaesthetists should gain experience in using this Bullard and Wu-laryngoscope in normal patients, before using it urgently on patient with difficult airway. Many anaesthetists thought that these devices are preferred in patients where difficult airway is anticipated. But, others are not as they have no experience (Fig. 20.37).

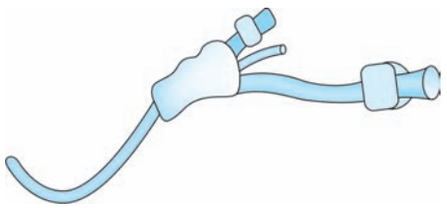

Fig. 20.36: Bullard laryngoscope

Stylet and Bougie

Stylet

It is made up of a flexible metal and is inserted into an ET tube in order to maintain a chosen shape of it. This will facilitate the intubation when visualisation of glottis is minimal or absent. It should be remembered that the tip of the stylet should not cross the tip of ET tube. Otherwise, it will injure the trachea. The other uses of stylet are: rapid sequence intubation and when the haemodynamically stressfull time for laryngoscopy should be minimised, e.g cardiac patients. During use, stylet should be lubricated to facilitate its movement

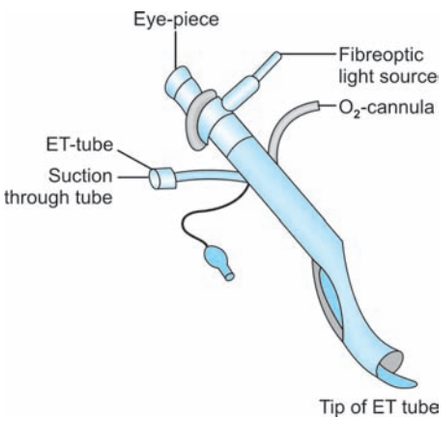

Fig. 20.37: Wu-laryngoscope

within the ET tube. The stylet should be removed as the tip of the ET tube enters the larynx to avoid undue trauma.

A special type of Stylet with a light source at the tip is called light-wand. The advantage of this light wand is that it can be guided with the ET tube into trachea by observing the movement of light under the skin of the neck from outside. Generally the room should be dark as the light can be seen adequately from the surface. The ET tube is placed over the light wand and is then introduced in the midline through the hypopharynx with the patient in standard sniffing position. The wand is then manipulated until a flare of light down the trachea is seen illuminating the neck. When the ET tube with the light wand is correctly positioned above the vocal cord in the midline, a distinct glow is seen in the anterior neck. Then, the tube is gently pushed into the trachea and the light wand is withdrawn. A special type of light wand is called 'Trachlight'.

Bougie

It is most commonly known as the gum-elastic-bougie. But, it is neither gum, nor elastic, and nor a bougie. It is actually called the Eschmann introducer and is such designed that it provides both stiffness and flexibility. The length of this introducer is 60 cm and the external diameter is 5 mm. It has a 35° bend, 2.5 cm from the patient's end which is inserted into the trachea.

Like stylet, it is also a very useful instrument to facilitate intubation when the laryngoscopic view of glottic is very poor. It is also very useful in limiting the degree of necessary neck movement during intubation with potential cervical spine injuries. It can also be used as tube exchanger. When the bougie is used, the tip of it is introduced first into the larynx through the glottic inlet blindly under reduced vision by laryngoscope. Then, keeping the laryngoscope in place, the ET tube is glided over the bougie upto the laryngeal inlet. After that 90° anticlockwise turn facilitates the glottic passage of ET tube, by presenting the bevel posteriorly. Then, bougie is withdrawn.

Technique of Intubation

In the technique of intubation the usual sequences are: pre-oxygenation, induction by administering rapid acting intravenous or volatile inducing agent, administration of rapid acting neuromuscular blocking agent, cricoid pressure, mask ventilation, laryngoscopy and followed by intubation. Both laryngoscopy and intubation are noxious stimuli and are sometimes more powerful than the surgical stimuli. So, deeper level of anaesthesia is required to blunt the stress response of laryngoscopy and intubation. This stress responses have deleterious effects on respiratory, CV and neurological systems. Thus, during laryngoscopy and intubation, these stress effects should be blunted to whatever degree if possible, especially when the patient falls into a high-risk category (e.g hypertension, CAD, ↑ICP, cerebral aneurysm, asthma, etc).

Before giving neuromuscular blocking agent, every anaesthesiologist must assesses his or her own patient, if mask ventilation will be possible or not when the patient will be fully paralysed. Therefore, if there is any doubt regarding the maintenance of patient's airway and ventilation by mask after induction and paralysis, then a conscious intubation with sedation and/or local anaesthetic agent should be considered before paralysis.

The general view regarding the pre-oxygenation is that breathing of 100% O_2 for 3 minutes or 4 vital capacity breaths with 100% O_2 before induction of anaesthesia provides added margin of safety. So, routine pre-oxygenation is optional, but strongly recommended before induction of anaesthesia and intubation for high risk group of patients. In patients with full stomach, where 'rapid sequence' intubation is chosen, there pre-oxygenation and cricoid pressure (Sellick maneuver) is mandatory and mask ventilation is not provided before intubation after administration of muscle relaxant unless unsuccessful intubation necessitiates it. Pre-oxygenation also can be omitted in patients : (i) who object to accept face mask, (ii) who are free of pulmonary diseases and (iii) who do not have any difficult airway.

Once the decision for induction of anaesthesia and intubation is taken, varieties of drugs can be used for induction and muscular paralysis and a variety of methods can be chosen to achieve the acceptable intubating conditions. For induction of anaesthesia intravenous, inhalation or oral route can also be used. But, usually intravenous route for adult and inhalation route for paediatric group of patients for induction of anaesthesia are chosen. For intravenous induction thiopental and propofol are most widely used now. But, other rapidly acting barbiturates (methohexital, thiamylal), benzodiazepines, narcotics, ketamine, etomidate, etc, also can be used. However the choice of inducing agents depends on the status of CVS, the status of CNS, effects on bronchomotor tone, presence of allergy, pharmacokinetics and pharmacodynamics of the agent etc. But among these the most important is the experience of the clinicians.

Both the depolarising and non-depolarising muscle relaxants are used for muscular paralysis, needed for intubation. But, due to some disadvantages such as masseter spasm, malignant hyperthermia, hyperkalaemia, burns, ↑IOP,↑ intracranial pressure, etc, the choice of succinylcholine for intubation has recently been questioned. However, still it is routinely used in many centres due to some of its advantages such as excellent intubating condition within a minute, rapid offset of action by ester hydrolysis if airway cannot be secured, and the patient's own ventilation will return much more quickly than any of the currently available nondepolarising muscle relaxants. So, still it is the relaxant of choice in many potentially difficult intubation cases, unless there are

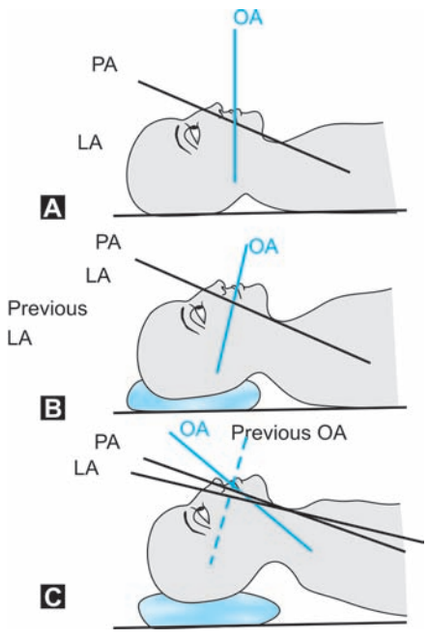
contraindications. However, recently rapid onset and excellent intubating condition produced by a nondepolarising drug such as rocuronium is achieved instead of succinylcholine. Other alternative non-depolarising drugs such as atracuronium, vecuronium, cisatracuronium etc. are not quite as rapid in onset of action as rocuronium.

Intubation may also be accomplished with only intravenous or inhalation anaesthetic agent without muscle relaxants when there is any doubt of difficult airway and failed intubation. But, this approach posses difficulties such as the potential for laryngospasm. So, a very deep level of anaesthesia should be achieved to avoid untowards laryngospasm if one wants to intubate only by intravenous or inhalational anaesthetic agents. In practice, the majority of clinicians employ lesser degree of muscle relaxation by reducing the dose of muscle relaxants (1/4th of the usual dose for quick recovery) to facilitate intubation in such circumstances.

Oral intubation

For successful oral intubation, position of the head is also very important. Unless there is contraindication for oral intubation, the head and neck is maintained in the classical 'sniffing position' to align the oral, pharyngeal and the laryngeal axes in a straight single line. Elevation of head by a small pillow with the shoulders remaining on the table first causes alignment of the pharyngeal and laryngeal axes. It causes flexion of the neck by about 25 to 35°. Then subsequent extension of the head at the atlanto-occipital joint (85°) causes alignment of oral axis with the pharyngeal and subsequently with the laryngeal axis. Thus, it serves to create the shortest possible distance and most nearly straight line from the incisior teeth to the glottic opening. But no such head elevation is required in paediatric age group (< 8 years) as their large head circumference produces the neck in flexion (Fig. 20.38).

Usually, the laryngoscope is held by the left hand of an anaesthesiologist and by the right hand mouth of the patient is opened. Then the blade of the laryngoscope is gently inserted into the patient's mouth from the right side of it and the tongue is kept left by the flange of the laryngoscope. During this procedure pressure on the teeth, gums or lips by the blade of laryngoscope should be avoided. After visualization of the epiglottis, the tip of the curved blade (Macintosh) is inserted into the vallecula and the laryngoscope is pulled forward and upward to elevate the epiglottis indirectly which expose the glottis. During that period gentle downward pressure on the cricothyroid cartilage from outside by an assistant may bring a non-visualised larynx into view. Then, the ET tube is inserted through the right side of the mouth and is pushed into the trachea between the paralysed,



Figs 20.38A to C: A. The oral axis (OA), pharyngeal axis (PA) and laryngeal axis (LA) in usual position. B. Elevation of head about 10 cm by a pillow with the shoulders remaining on the table aligns the LA with the PA. C. Extension of head at the atlanto occipital joint aligns the OA with the PA. So, these three axis more or less come on a single straight line

opened and abducted vocal cords under the direct vision. Instead of curved blade, if the straight blade is used then the tip of the blade is usually advanced behind the epiglottis, so that the epiglottis is included within the structures which are lifted up by the laryngoscope blade. Choice of the blade of laryngoscope depends on the clinicians preference and peculiar anatomy of the individual patient. When one blade does not become successful, then other types of blade become. So, skill should be developed in the use of different types of blades by an anaesthetist.

The cuff of the ET tube should lie in the upper part of trachea above the carina, but beyond the larynx or vocal cord. The cuff should be inflated with the least amount of air which is just necessary to create a tight seal in the trachea during positive pressure venitlation and minimize the injury of tracheal mucosa caused by the pressure transmitted to it from the cuff. Feeling of the pilot balloon is not a reliable sign of determining the adequacy of cuff pressure. After intubation, the chest and epigastrium are immediately ausculted. Capnographic tracing is also monitored to ensure the intratracheal location of the ET-tube. Because the persistent detection of CO_2 by capnograph is the best way of confirmation of tracheal placement of a ET-tube. But, it cannot exclude the bronchial intubation. The bronchial intubation is best diagnosed early by an increase in peak inspiratory pressure. The proper placement of an ET tube in the trachea also can be confirmed by palpating the cuff on the suprasternal notch, while compressing the pilot balloon with the other hand. The cuff of an ET-tube also should not be kept above the cricoid cartilage. Because prolonged intralaryngeal location of the cuff between the vocal cord may result in postoperative hoarseness of voice and increase the incidence of accidental intraoperative extubation. The true position of an ET tube can also be documented by X-ray. But, this is rarely needed except in ICU. If there is still any

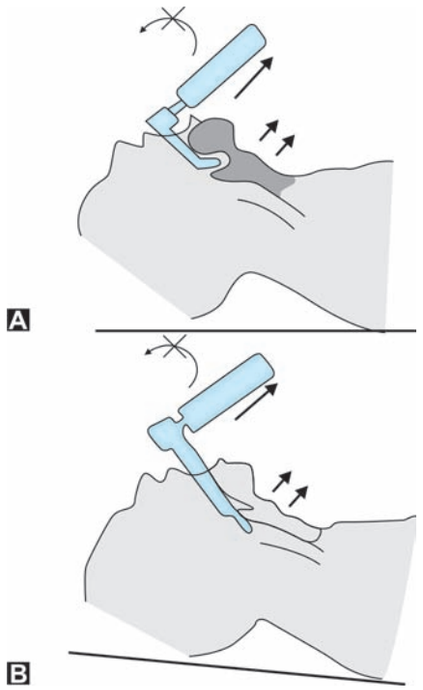
doubt, whether the tube is in the oesophagus or trachea, then it is prudent to remove the tube and ventilate the patient with a face mask (Fig. 20.39).

Under normal conditions the common causes of non-visualisation of vocal cords are mainly due to the wrong head position, or wrong blade position that is too far advanced, or not enough advanced, or reluctance to apply the adequate upward force.

The ET tube is usually inserted into the trachea by keeping the lip 23 cm away from the tip of the tube in adult male for correct position of cuff in trachea. In that position the tip of an ET tube lies 4 cm above the carina. In adult female this distance from the lip to the tip of the tube is 21 cm. Too far advancement of tube in trachea causes endobronchial intubation (usually right), whereas inadequate advancement of tube causes protrusion of the cuff through the vocal cords of larynx leading to risk of accidental extubation. In children, the distance (in centimeter) between the lips and the tip of the tube can be estimated from the formula: 12 + age/2 (Table 20.9).

There is also another simple formula to calculate the probable distance of ET tube from the mouth opening or from the external nares to the carina, which is as follows:

A. Mouth opening to carina = 0.16 × Height of child (cm) + 2.5 cm.
B. External nares to carina = 0.16 × Height of child (cm) + 4.5 cm.



Figs 20.39A and B: The proper position of the curved and straight blade of the laryngoscope during exposure of glottic opening. In figure A, the tip of the curbed laryngoscope blade (Macintosh) is placed in the space between the base of the tongue and the pharyngeal surface of the epiglottis (vallecula). In figure B, the tip of the straight laryngoscope blade (Miller or Jackson Wisconsin) is placed on the laryngeal (posterior) surface of the epiglottis. Irrespective of the type of blade, forward and upward force shown by the arrow should be applied along the handle of the laryngoscope to elevate the epiglottis and to expose the vocal cord

Table 20.9: Magboul et al scoring system

Score	*1*	*2*	*3*	*4*
Mallampati	*Grade 1*	*Grade 2*	*Grade 3*	*Grade 4*
Measurement	3 fingers mouth open	3 fingers hypomental	2 fingers thyromental	1 fingers subluxation
Movement of neck	Left	Right	Flexion	Extension
Malformation	Skull hydrocephalus	Buck teeth, Loose teeth Macro and micro jaw	Obstruction, obesity, neck swelling	Syndrome and pathology

If the patient scores 8 or higher, he is likely to be a subject of difficult intubation. Mogbul et al reported 100% correct prediction from this score, but obviously more multicentre study and data will be needed to support this opinion.

When a patient is at particular risk for aspiration due to full stomach, intestinal obstruction, gastric paresis, etc; then rapid sequence intubation is employed. Like the general principles of intubation during rapid sequence, if there is sufficient doubt about the ability to intubate such patient, then a concious intubation with judicious use of topical (Table 20.10) anaesthesia with or without sedation, should also strongly be contempleted. For rapid sequence intubation, pre-oxygenation is mandatory. Normally 4 vital capacity breaths with 100% O_2 is suffiient for nearly complete denitrogenation of healthy lung. But diseased or aged lungs require longer period of preoxygenation (3 minutes) to ensure adequate washout of N_2 from body. During very urgent surgery, where every second is counted, then four vital capacity breaths with 100% O_2 are adequate. After pre-oxygenation, intravenous rapid acting inducing agent and rapid acting muscle relaxant (usually succinylcholine) are administered. When the patient becomes unconscious, proper cricoid pressure is

Table 20.10: ET tube size and length calculated based on patient's age

Age	*ID (mm)*	*French unit*	*Distance from teeth to tip of tube in trachea (cm)*
Premature	2.5	10	10
Newborn	3	12	11
1-6 months	3.5	14	11
6-12 years	4	16	12
1-2 years	4.5	18	13
2-4 years	5	20	14
4-6 years	5.5	22	16
6-8 years	6	24	17
8-10 years	6.5	26	18
10-12 years	7	30	20
12-14 years	7 (Female)	30	22
	7.5 (male)	32	
> 14 years	7.5 (female)	32	24
	8 (male)	34	

applied to prevent aspiration whether muscle relaxant is administered or not. Proper cricoid pressure (or sellick manouvre) is applied by giving gentle downward pressure with thumb and first finger on the cricoid cartilage. This downward pressure on the cricoid cartilage occlude the esophageal lumen behind the cartilage. Because only the cricoid cartilage form a complete ring or have a posterior cartilagenous bar that can press and occlude the oesophagus and thus prevents regurgitation. But this pressure cannot prevent the regurgitation resulting from forceful vomiting. Only the force of vomiting is blunted by the muscle relaxant. Laryngoscopy and intubation in this setting are then performed without any preceding manual mask bag ventilation, if possible. If intubation is not possible in first attempt then only, mask ventilation should be started and continued while cricoid pressure is maintained. It is important to say that the cricoid pressure should be correctly applied such that it actually does not impede the visualisation of the glottis or passage of tube through it by any means. Cricoid pressure also decreases the flow of gas in the stomach and inturn limits the regurgitation.

Nasal intubation

In the operating room, oral intubation is the usual method. But, in some conditions when the surgery is performed in the oral cavity or on the mandible, or in any where on the face when both the surgeon and anaesthetist struggle for the space, then the nasal intubation is the choice. Nasal intubation is usually performed under direct vision. But, it also can be accomplished in difficult airway condition blindly or with the help of fibre optic scope under sedation and topical anaesthesia. Blind or fibre-optic nasal intubation is also chosen, where direct laryngoscopy is impossible.

However, there are certain contraindications for nasal intubation. These are: Coagulopathy, severe intranasal pathology, basilar skull fracture, the presence of CSF leak from the base of the skull, etc.

In any case when both the oral and nasal intubation has one or more contraindication, then anaesthetist must take any one decision, after discussing the relative risks and benefits of tracheostomy, oral intubation and nasal intubation with the surgeon to arrive at an acceptable compromise. Nasal intubation is sometimes chosen, because it may be quicker and more comfortable than oral intubation in the topicalised and less sedated patient (Table 20.11).

Technique of nasal intubation

Nasal intubation may be blind or under direct vision. It will be helpful if phenylephrine as a vasoconstrictor is applied on the nasal mucosa before nasal intubation. After the induction of anaesthesia and administration of muscle relaxant and mask ventilation, ET tube is introduced into the nose in a plane, perpendicular to the face up to a certain length when the tip of the tube reaches the oropharynx. Then, direct laryngoscopy is performed (in case of under direct vision nasal intubation) in the usual fashion. After that the tip of the ET tube which is seen in the oropharynx is directed into the glottis by holding and manipulating the machine end of the tube from outside of the nose.

Table 20.11: Risks factors for aspiration of gastric contents

Full stomach
< 8 hours fasting in solid food
< 6 hours fasting in milk
< 4 hours fasting in breastfeeding
< 2 hours in clear fluid
Pregnancy, obesity
Trauma
Intraabdominal pathology Intestinal obstruction
Gastric paresis (peritonitis, infection, diabetes, drugs, uremia)
Oesophageal diseases
Symptomatic reflex
Motility disorders
Uncertainty about intake of food and drink

If this is not possible then a Magill forcep may be used through oropharynx to direct the tip of the ET tube into the glottis, often with the help of an assistant who will push the nasal end of the tube. If the glottis can not be visualised by direct laryngoscopy, then the Magill forcep can still be used to guide the tip of ET tube blindly into the area of the glottis.

Blind nasal intubation is usually done in an anaesthetised spontaneously ventilated patient where spontaneous respiration facilitate the intubation blindly. This is described below. While the patient is taking spontaneous respiration, under deep sedation or anaesthesia (to prevent laryngospasm) or proper topical anaesthesia the tube is gradually inserted through the nasal cavity and then through the nasopharynx, oropharynx and laryngopharynx until the maximum breath sounds are heard from the outer end of the tube. It implies that the tip of the tube is just above the glottis. The tube is then inserted blindly into the glottis during next inspiration which tend to be deepest immediately following a cough. During forward movement of ET tube through laryngopharynx. If breath sound through the tube disappears, then it should be thought that the tube has passed into the oesophagus or pyriform fossa and must be withdrawn slightly above the level of the glottis. It is then reintroduced blindly into the larynx again and such several attempts can be tried. If still the tube does not enter the glottis, the patient's head should be extended, flexed or turned to guide the tip of the ET tube into the glottis. Usually, the tip of the tube enters into the oesophagus and extension of head is useful. If still, intubation is not possible, then help of direct laryngoscopy or bronchoscopy should be taken. As in blind procedure the entry of ET tube into the glottis is not seen directly, so it is helpful to have capnographic or bronchoscopic confirmation for endotracheal placement of the tube. Because at times, all the indirect signs of intubation may be misleading.

Blind nasal intubation in anaesthetised, apnoeic and paralysed patient may also be attempted. But as in this case there are no spontaneous breath sounds to help the placement of tube in the larynx, so this is only guided by the external observation of the tip location in the larynx.

INTUBATION FAILURE

Despite the most meticulous preoperative assessment of the airway, sometimes few patients present sudden and great difficulty during intubation. No matter how skilled, every practitioner have to encounter such patients in his practising life. So, induction of anaesthesia and use of muscle relaxant should be approached with this possibility in mind, as if a clear plan of action can be persuaded without unnecessarily panicking, if intubation failed.

These patients may be of elective or emergency cases. Failed intubation in emergency case is potentially life threatening. Because, there is a greater possibility of hypoxia both from regurgitation with aspiration (as these patients are not properly prepared by restricting the intake of food) and failed intubation. The cardinal rule under such condition is oxygenation first and everything else, i.e. regurgitation, aspiration, etc. are secondary. In such cases the majority of opinion is that, it would be wiser to allow the patient to come back to spontaneous respiration or even better to regain consciousness. Then, as the surgery is emergency and unavoidable, so one can review, rethink, plan and proceed again. The objective for these difficult patients should be not to use muscle relaxant producing apnoea until intubation has been successfully accomplished at the beginning of any anaesthesia or intubation has failed and patient is backed to spontaneous respiration. For such patients, conscious or 'awake' intubation by topical / infiltration local anaesthesia or intubation under spontaneous respiration under deep sedation or GA is ideal.

Indications for awake intubations are: (i) previous history of difficult or failed intubation, (ii) findings on physical examination that can indicate difficult or failed intubation and (iii) severe risk of aspiration. Actually, the term 'awake intubation' is applied to intubation on nonanaesthetised conscious emergency patient outside the operating room. But, this term is misnomer in OT where it is used after appropriate sedation, topical anaesthesia and/or nerve blocks to avoid laryngeal reflexes. If awake intubation has to be performed due to severe risk of aspiration, then narcotics and other IV sedatives should be used sparingly (Fig. 20.40).

Promoting local anaesthesia for awake intubation, the nerves that need to be blocked are trigeminal (nasal cavity and oral cavity) glossopharyngeal (nasopharynx, oropharynx, and laryngopharynx), vagus (supraglottic and infraglottic region). Woods and Lander describe a technique of glospharyngeal nerve block that only anaesthetizes the sensory supply

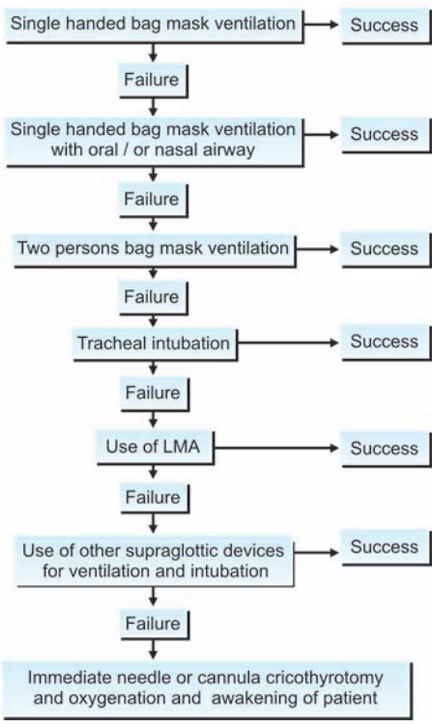


Fig. 20.40: Strategy in case of predicted or unpredicted difficult bag-mask ventilation

over the area of the back of the tongue which is innervated by this cranial nerve (glossopharyngeal IX). For this technique, by a 24 G needle, 2 ml anaesthetic drug is injected at the junction where the base of the tongue opposes with the palatoglossal fold. This causes local anaesthesia of the base of the tongue and does not appear to affect the airway integrity when performed bilaterally. This block is acceptable with full stomach also. This type of local anaesthesia allows a more comfortable laryngoscopy with lower doses of sedation. It has also been seen that if larger volume of local anaesthetic is given at that site then superior laryngeal nerve (SLN) which is the branch of vagus will also be blocked with glossopharyngeal nerve, because both the nerves lies in the same tissue plane. SLN innervates the epiglottis, aryepiglottic fold and the laryngeal structure up to the false vocal cords. This nerve can also be blocked isolatedly by giving injection of 2 to 3 ml local anaesthetic agent percutaneously between the greater cornu of the hyoid bone and the thyroid cartilage. But this block is contraindicated in full stomach patient as it impairs the protective mechanism of airway and cannot prevent the regurgitation and aspiration of stomach contents, if vomiting occurs. So, in full stomach where regurgitation and aspiration have possibility, then surface anaesthesia and analgesia of larynx (both supraglottic and infraglottic area) is the rule. For surface anaesthesia, 'spray-as-you-go forward' technique or certain variations of it, with or without cricothyroid puncture can be employed. The specific nerve blocks associated with surface anaesthesia is restricted only to the superior laryngeal nerve which can either be blocked percutaneously near the greater cornu of the hyoid bone where internal branch traverses the pyriform fossa before entering the larynx. A cricothyroid puncture for surface anaesthesia below the vocal cord is usually performed with the patient in semirecumbent position and local anaesthetic solution is

injected or sprayed in the trachea usually at the end of expiration.

The difficulty of glottic exposure in laryngoscopy can be graded ranging from 1 to 4 : in grade 1, no difficulty of viewing the glottis; in grade 2, only posterior extremity of glottis is visible; in grade 3, only epiglottis is seen; in grade 4, no recognisable structure. When intubation fails by initial attempt, mask ventilation (if muscle relaxant is used) should be resumed and situation is reassessed. As long as oxygenation is maintained by mask ventilation, the problem is not an emergency one except if the patient is not in full stomach. During mask ventilation, cricoid pressure should be maintained if the stomach is full. However, in case of topical anaesthesia and / or nerve block if awake intubation is failed, then patient's spontaneous respiration is maintained only by giving 100% O_2. After that slight sedation can be added and fibre-optic intubation can be tried.

During reassessment of upper airway after a failed intubation in first attempt, the following things that should be brought in mind and correction should be done are: Head position, laryngoscopy technique, change of the shape (curved to straight) and size of blade, etc. If repeated laryngoscopy by an experienced practitioner is unsuccessful, then the first aim should be efficient mask ventilation (obviously in paralysed patient) to prevent hypoxia and attempts to bring back the patient to the spontaneous ventilation. If mask ventilation is efficient then before bringing back to spontaneous ventilation the anaesthesiologist can also again try intubation by the help of stylet, bougie, flexi tip laryngoscope, lightwand (trachlight), etc. LMA aided intubation, indirect rigid fibre-optic laryngoscope assisted intubation, pharyngeal airway Xpress aided intubation, etc. also can be tried. If all the previous methods are failed then patient should be brought back to the spontaneous ventilation. After resumption of spontaneous ventilation, there are three options: One, the patient may be allowed to awaken and the procedure is postponed if the case is not emergency; second, the patient is awakened and intubation is further attempted with topical anaesthesia if the case is emergency; three, after resumption of spontaneous respiration, not awakening the patient, try again to intubate the patient by previously described methods such as using styllate, bougie, fibre-optic bronchoscope, blind oral or nasal intubation, etc. then the muscle relaxant can be used if the operation is emergency. Actual life threatening emergency condition arises when after the use of muscle relaxants the tracheal intubation is failed and mask ventilation is also ineffective. The management of this extremely emergency condition is discussed later.

All anaesthetist should develop skill for conscious oral intubation with direct laryngoscopy. Blind nasal intubation that avoids the discomfort of laryngoscopy is also equally important to learn.

Intubation Failed – Mask Ventilation is Effective or Patient is Breathing Spontaneously (No Hypoxia – Oxygenation is Maintained) Operation is Urgently Needed

This group of patients can be managed by the following way:

i. If the manual mask ventilation is effective enough and the anaesthetist think that he will be able to carry on the operation by only mask ventilation with muscle relaxation (if that operation needs relaxation), then he can procede.
ii. Operation also can be carried out in anaesthetised spontaneously ventilated patient through mask if muscle relaxant is not needed to complete that surgical procedure. So after muscle relaxation and failed intubation, when spontaneous respiration is re-established, the anaesthesia can be continued with volatile inhalational agents by mask without muscle relaxant.
iii. After re-establishment of spontaneous respiration in anaesthetised patient, if the patients fall in the group where operation is urgent and the full muscle relaxation is required for completion of the surgical procedure and mask ventilation is though effective, but cannot be carried out for prolonged period or the surgical site does not allow the mask ventilation, then the patients should be managed by intubation first after re-establishment of spontaneous respiration and later followed by full muscle relaxation. Intubation in this group of patients is tried first with the help of different intubation accessories. In such situation there is another option that is use of LMA. By LMA we can maintain anaesthesia by spontaneous ventilation with the inhalational agents or we can ventilate if muscle relaxant is needed. Mask ventilation or ventilation with LMA (spontaneous or IPPV) is usually satisfactory for short minor procedures, such as cystoscopy, EUA, inguinal hernia repair, etc. but not for long complicated procedures or where high pressure for IPPV is needed.

Accessories for Intubation

(a) Using stylet

Difficult orotracheal or nasotracheal intubation can be performed by employing direct laryngoscopy and using stylet which is passed though the ET tube. ET tube is directed anteriorly with the stylet.

(b) Difficult oral intubation using bougie

Difficult oral intubation may also be attempted by gliding ET tube over a long flexible 'bougie', inserted blindly into the glottis under direct laryngoscopy. Sometimes, the subsequent passage of an ET tube by gliding over the bougie is difficult. In such situation, laryngoscope should be kept in position and the tracheal tube is rotated 90° anticlockwise, in order to prevent the 'fork' created by the bevelled end

Table 20.12: Recognition of correct placement of ET-tube

- Direct visualisation of tube passing through the larynx.
- Auscultation of chest.
- Asucultation of epigastrium.
- Observation of chest movement.
- Observation of abdominal movement.
- Tension of CO_2 in expired air, confirmed by capnography.T
- Observation of condensation of water vapour in expired air in PVC ET-tube.
- Movement of reservoir bag in up paralysed spontaneously breathed patient.

of the tube and the bougie, from impacting on the posterior rim between the aryteroid cartilages. A white (Table 20.12) plastic bougie with a soft metal core is said to be easier most to place in the glottis than the older gum elastic bougie. Advancement of the distal end of the bougie over the tracheal rings produces a clicking sensation and confirms its placement in trachea. If the bougie is hollow, then jet ventilation can also be done through this channel or capanography can be attached with it which will show the characteristic pattern of PCO_2 in expired air associated with the breathing.

(c) Using light wands

Light wand was originally introduced for blind intubation, but it can be used with direct laryngoscope also (semi-blind technique). If the light at the distal end of the tracheal tube is seen to transilluminate brightly through the cricothyroid membrane, then it is confirmed that the endotracheal tube is in the larynx. If no transillumination is seen, then the tube is considered to be in the oesophagus. The advantages of light wand or trach light are: easy technique, relatively inexpensive, useful adjunct in difficult airway, does not require much neck manipulation, useful in cervical spine injury, useful in patient with limited mouth opening, less traumatic than blind nasal intubation, presence of secretion is of no problem etc. The disadvantages of light wand are: should not be used with laryngeal or tracheal polyps, tumours, inflammation, retropharyngeal abscess, foreign body, etc. In morbidly obese patients, the ability to see the glow of light may be diminished. On the contrary, in thin and frail patients some transilluminations may also occur, even when the tube tip with the light source is in the oesophagus and will confuse the anaesthetist.

(d) Blind nasal intubation

For blind nasal intubation the patient should normally have the head and neck, placed in the classical 'sniffing the morning air' position. The anaesthetist will have to first decide which of the nasal passage is to be used. Then as a first step a well lubricated nasal tracheal tube is gradually passed along the floor of the nose into the nasopharynx, oropharynx, and hypopharynx (as the patient is breathing spontaneously). After that it is ultimately introduced blindly into the trachea. But unfortunately this is very uncommon, and commonly these tubes end up in either of the pyriform fossae or in the oesophagus. In such circumstances several blind attempts with or without the help of any accessories are tried. Occasionally, they can also cause various degrees of haemorrhage. Chances of successful blind nasal intubation can be increased by the following methods :

i. Listening to the proximal end of the nasal tube and feeling the air being breathed out of the tube.
ii. Using capanography to guide the distal end of the tube into the larynx.
iii. Using the light wand which can be manipulated, so that the long shaft of the wand follows the contours of the upper nasal passage and enter the larynx.
iv. A fiber-optic laryngoscope or bronchoscope can be passed through the nasal tube to guide it into the larynx.

(e) Using LMA

LMA has also been used on many occasions for difficult intubation. It has enabled effective oxygenation by spontaneous ventilation or manual positive pressure ventilation. LMA has also enabled the passage of bougie and/or fibre-optic scope into the trachea which is again followed by the passage of an ET tube in trachea with the help of these bougies or fibre-optic scope. There is also a special type of intubating LMA (ILMA) which is called 'Fastrach LMA'. It consists of an anatomically curved, short, wide bore tube and a laryngeal cuff with a guiding stainless steel handle. It has a single moveable epiglottis elevation bar in the place of fixed aperture bars. It is available in 3 sizes and can accomodate 7, 7.5 and 8 mm ET tube within its wide bore tube for intubation (Fig. 20.41).

(f) Combitube

The most recent method of accomplishing emergency intubation–or more correctly ventilation–is the use of combitube. This is the modern version of the older oesophageal obturator airway. The principle of combitube is that this tube is inserted blindly and artificial ventilation is started through any one of the distal two ports. Depending on the results of auscultation,

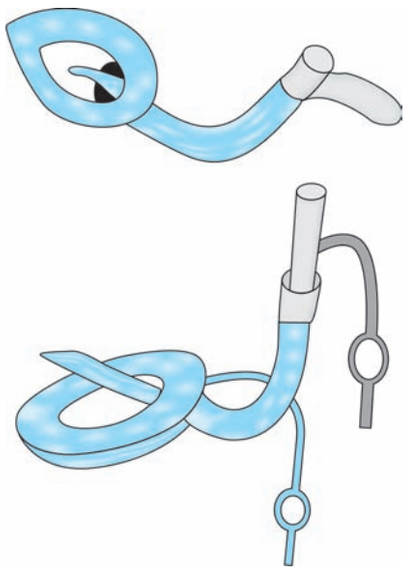

Fig. 20.41: Intubating LMA (ILMA)

any one of the two tubes is selected to ventilate the lungs.

(g) Fibre-optic instruments

Recently fibre-optic laryngoscope or bronchoscope have become an extremely important piece of instrument in the management of difficult airway. Due to their extreme flexibility, they easily can be passed either through the nose or through the mouth into the trachea and assist in intubation. The observer can also see the tip of the ET tube in trachea with the help of fibre-optic scope and confirm intubation.

When used for nasal intubation, the fibre-optic laryngoscope or bronchoscope with an ET tube can be passed through the nose into the larynx followed by the tracheal tube. Alternatively, the nasotracheal tube or airway can be passed into the pharynx and the fibre-optic scope is passed through it into the larynx, followed by the tracheal tube. The latter technique is used to prevent the tip of the fibrescope from toileting with blood, secretions or water vapour condensation to get a clear view. By contrast, the usual practice of fibre-optic scope through the oral route is to pass it first using the conventional laryngoscope, followed by an endotracheal tube. Once the intubation has been accomplished by either of these two routes or methods, the fibre-optic scope can also confirm the ET tube in the trachea by observing the tip of the tube against the tracheal ring or wall.

One of the disadvantages of fibre-optic techniques for intubation is that the instrument is delicate and expensive and can be quite easily damaged. Even in experienced hands, an intubation using these instruments can take duration which is three times longer than that of the conventional method and may be associated with marked cardiovascular resposes to intubation. It is reported that blood pressure and heart rate remain higher for a considerably longer period compared with following a normal intubation.

When Intubation is Failed and Also Ventilation By Mask is Ineffective or Not Possible

The patient who is a truly impossible candidate for mask ventilation after failed intubation presents really a life threatening emergency condition. Always the best treatment of such condition is prevention, like the other branches of medicine. So, an anaesthetist must always carefully evaluate the airway to determine the safest plan for intubation and the plan if both intubation and mask ventilation failed, before instituting muscular paralysis and general anaesthesia. In the patient who has been thoroughly de-nitrogenated by pre-oxygenation, there should be adequate time to institute one of the following procedures before serious O_2 de-saturation and consequent haemodynamic deterioration happen if such condition appears. In reality, when such circumstances will arrive, then everybody has to thought that he is often dealing with a severely anoxic patient who has suffered or is near to the brim of cardiac arrest. So, it is critical to start one of the following procedures before irreversible cardiac arrest or brain damage has ensured. The interventions during failed to intubate and failed to ventilate by mask conditions are the followings:

i. Establishment of emergency non-surgical airway and ventilation:
   After mask LMA or combitube will probably become the next non-surgical airway intervention for emergency ventilation.
ii. Establishment of emergency surgical airway and ventilation.

Emergency surgical airways can be established by many ways. These are: needle cricothyroidotomy, cannula cricothyroidotomy, surgical cricothyroidotomy, percutaneous tracheostomy (PCT), conventional surgical tracheostomy (ST), etc. Among these, the needle and cannula cricothyroidotomy is done during emergency condition when an anaesthetist 'cannot intubate and cannot ventilate by mask' the patient. Through these needle or cannula of cricothyroidotomy jet ventilation is performed for oxygenation of patient. So, this procedure may be called as the transtracheal jet ventilation (TTJV). Actually, the term 'jet ventilation' means introduction of gas (oxygen) into the tracheobronchial tree under high pressure and speed and has been used in different forms. For example, this technique may also be used during anaesthesia for bronchoscopy or laser surgery on the larynx. During anaesthesia for bronchoscopy as laser surgery on the larynx, jet ventilation via a needle, placed within the lumen of an otolaryngological laryngoscope permit oxygenation of patient without a tracheal tube intubation.

Trans-tracheal jet ventilation (TTJV) through needle cricothyroidotomy

In such TTJV a 12 to 18G needle (12 or 14G for adults and 16 or 18G for paediatric patients) is inserted through the cricothyroid membrane and is attached to a high pressure O_2 source via a low compliance circuit. For high pressure O_2 source, anaesthetic machine can also be used. For that an adaptor of ET tube of 5 mm ID which is attached to the low compliance O_2 supply tubing is inserted to the fresh gas outlet of the anaesthetic machine. At the other end of the low compliance O_2 tube (i.e. between O_2 tube and 16 G or 14 G cannula) a three way stop-cock is attached and then this stop-cock is connected to the translaryngeal 16 G or 14 G cannula. The three way stop-cock helps by preventing excessive pressure to build-up by releasing the aperture to the air in between jet inspiration. Before starting artificial jet ventilation, it is wise to fix the tube. Otherwise, high pressure through a narrow tube will tend to force the tube out of its position. It is essentially a blind technique and incorrect placement or excessive pressure can produce pneumothorax, pneumomediastinum, pneumotrachea, pneumolarynx, or pneumomediastinum. In this era

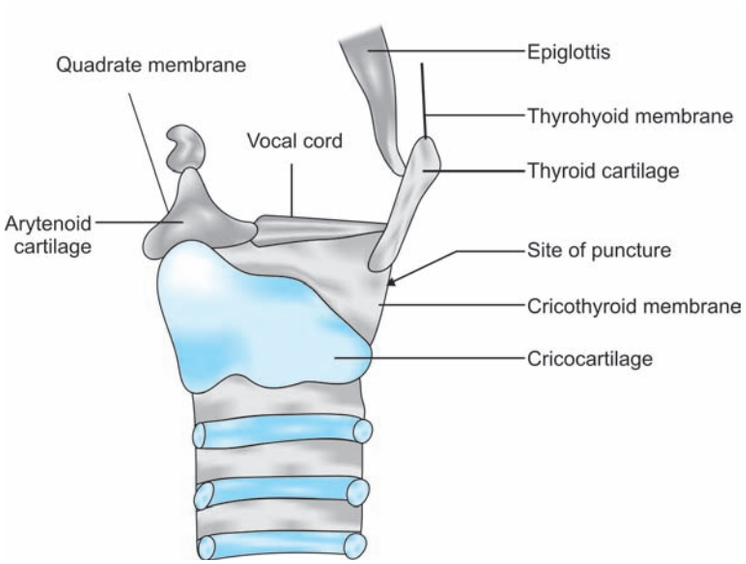

Fig. 20.42: The anatomy of cricothyroid membrane

of technological advances, flexible fibreoptic endoscope, Bullard laryngoscope, noninvasive light wand and different intubation guides are also recommended (Fig. 20.42).

This needle TTJV provides adequate ventilation as well as oxygenation and serves as an alternative emergency procedure for those who are planning to assemble a standard TTJV system through cannula cricothyroidotomy by modified Seldinger technique. TTJV, either by needle or cannula, only provides emergency oxygenation. So, always the successful TTJV should be followed up by provision of making a definite airway and ventilation by tracheotomy (precutaneous or classical) or endotracheal intubation or waking up the patient and resumption of the normal airway. In the technique of cannula cricothyroidotomy, after a needle is introduced into the tracheal lumen, a wire is passed downwards. Then the needle is withdrawn and a dilator is passed over the wire which is followed by an cannula. The advantages of this technique are that it is quick and relatively easy to perform. It is important to comment that neither TTJV or cricothyroidotomy can relieve obstruction which occur below the first few tracheal cartilages.

Surgical Cricothyroidotomy

In the 'cannot ventilate, cannot intubate by mask' condition, a classical tracheostomy cannot be performed quickly enough to save the life. In such situation emergency surgical cricothyroidotomy can also be employed to insert a small endotracheal or tracheostomy tube. Truly speaking, this surgical cricothyroidotomy is also time consuming (more than 5 minute) and may not be able to save the apneic patient's life.

For surgical cricothyroidotomy a stab incision by a short scalpel blade is made through the skin and cricothyroid membrane and the trachea is opened. Then, the incision is enlarged by using hook to pull the cricoid cartilage caudally. This helps to insert an ET tube of 5 to 6 mm ID (Table 20.13).

FIBREOPTIC SCOPE

There are some elective situations where direct laryngoscopy with a rigid laryngoscope is undesirable or impossible or if possible still the laryngeal inlet is completely out of view with this type of rigid laryngoscope. Examples of few such situations are: patients with unstable cervical spines, very poor range of motion of the temporomandibular (TM) joint, severe burn contracture of neck, certain congenital or acquired upper airway anomalies, etc. In such situations direct visualisation of larynx by fibreoptic scope and intubation with the help of it is the only answer. But, in contrast to conventional laryngoscope, its use needs intense practice. Intubation by fibre-optic scope requires longer time. So, it has no role in emergency situation where airway has to be established rapidly in the face of severe hypoxia. When the fibreopticscope aided intubation is anticipated for the elective management of a more difficult airway, then the fibre scope should be employed first, before visualisation of larynx is obscured by oedema, secretions and / or haemorrhage due to previous repeated attempt and failed intubation.

The fibre-optic scope is consist of a collection of thin glass fibres whose diameter vary between 5 to 25 µm. These collection of thin glass fibres are divided into two groups each containing 10,000 to 15,000 fibres. Among these two groups

Table 20.13: Difficult airway algorithm

1. Assessment
   - Assessment for difficult mask ventilation.
   - Assessment for difficult intubation.
   - Assessment for difficulty for patient cooperation and consent.
   - Assessment for difficulty for tracheostomy.
   - Assessment of opportunities for delivery of supplemental oxygen throughout the process of difficult airway management.
2. Consider the relative merits and demerits of the basic choices of management
   - Preservation of spontaneous ventilation vs Ablation of spontaneous ventilation.
   - Awake intubation vs Intubation after induction of GA.
   - As an intial approach for intubation taking the help non-invasive technique vs Invasive technique.
3. Difficult airway-recognised or unre-cognised.
4. Develop some other primary and alternative strategies.

one group transmits image from the target object to our eyes and another transmits light from a powerful source. In addition to all these fibreoptic scope consists of: (i) wires which control the angulation of the tip of fibres and (ii) ports for suction, injection of local anaesthetics and delivery of oxygen.

The keys to successful elective intubation by fibreoptic scope include control of secretions, adequate topical anaesthesia, proper sedation, proper defogging of lens and aligning of the scope in midline. As during any manipulation of airway, pulse oximeter is also mandatory during this procedure to detect hypoxia. During the use of fibre-optic scope aided intubation, the use of anticholinergic is strongly recommended, because excessive secretions in the upper airway may obscure the view. The tip of the scope should be defogged intermittently and frequently with warm soapy water and the entire length should be lubricated by K-Y jelly to facilitate the passage of scope through the ET tube. A patent suction port is important and a 10 ml syringe filled with 1% lignocaine solution can be attached for further topical spray through the scope. If O_2 insufflation is desired, then an appropriate source adaptable to the bronchoscope port should be available. This is useful in keeping the secretions off the tip of the fibre-optic scope and diminishing fogging as well as providing a source of 100% O_2. Preventing hypoxia during the fibreoptic scope aided intubation.

The elective intubation by fibre-opticscope may be oral or nasal and can be employed on conscious or anaesthetized patient. But among the oral or nasal route, the nasal route and among the sedated unparalysed and paralysed patient, the intubation in unparalysed patient by fibre-optic scope is technically more easier. On the otherhand, through oral route on a sedated paralysed patient fibre-optic intubation is the most difficult of the four possible technique such as oral or nasal fibre-optic intubation in sedated unparalysed or paralysed patient.

During oral intubation by fibre-opticscope on a sedated unparalysed patient, an endoscopic oral airway or a bite block should be used to protect the scope from biting by teeth. Among the oral airway PatilSyracuse airway or Williams airway or ovassapian airway has some advantages. It prevents the dorsal displacement of the tongue and keeps the instrument in midline and guides the scope past the epiglottis into the larynx (Table 20.14).

As a first step, the base of the tongue, the oropharynx and the laryngopharynx is anaesthetised topically by 10% lignocaine spray or by nebulisation of 4% lignocaine. This is done in a completely conscious patient or with minimum sedation. Then an intubating airway is inserted through mouth after topicalisation. After that the ET-tube is inserted into the mouth about 8 to 10 cm through this airway and fibre-optic scope is passed through the ET-tube. The base of the toungue, epiglottis and finally glottis is visualised in proper sequence. If tip of the scope is obstructed by the posterior pharyngeal wall (which is diagnosed by pink blurr vision), it should be turned down to visualise the glottis. If the epiglottis obstructs the vision, then the scope should be manipulated, so that the vocal cords can be seen. After visualisation of the vocal cord, the ET tube is introduced into the glottis.

Table 20.14: Possible contents in an emergency difficult airway unit

1.	Rigid laryngoscope blades of different sizes and designs.
2.	Endotracheal tube of different sizes and shapes.
3.	Different ET tube guides, such as stylets of different sizes with or without hollow inside for jet ventilation, gum elastic bougies, light wands, forceps to manipulate the patient's end of the tube in the larynx.
4.	Various supraglotic airway devices : LMA of different sizes and types Combitube
5.	Fibre-optic intubation device.
6.	Set of a transtracheal jet ventilation.
7.	Set for emergency cricothyrotomy and ventilation.
8.	Set for retrograde intubation.
9.	Capnometer for detection of CO_2 in expired air.

Fibre-optic intubation in anaesthetised patient may also be done under spontaneous or controlled ventilation in a nonparalysed and paralysed patient respectively. It is obvious that the fibre-optic intubation under spontaneous ventilation in an anaesthetized patient is more technically easier and advantageous than the controlled ventilation. But, in spontaneous ventilation, diminished anaesthetic level causing cough, vomiting, laryngospasm, bronchospasm, etc. is the definite disadvantage. On the other hand, fibre-optic intubation under controlled ventilation, apnoea is the major headache. Patient should be ventilated with 100% O_2 by mask in between the intubation attempts by fibre-optic scope or patient should be ventilated with special endoscopic mask with a sealing port (through which endoscope is introduced) that allows for the continuous use of mask and ventilation during the attempts of intubation by fibre-optic scope. During endoscopy, additional O_2 from the separate source can be administered through the injection port of the fibre-optic scope.

Nasal intubation by fibre-optic scope has the advantage that the instrument can easily be positioned directly through nasal route into the hypopharynx to visualise the glottis. If the patient is not anaesthetized, tongue causes less interference when this route is used. On the contrary, anaesthetized intubation by fibre-optic scope through nasal route is less difficult due to less soft tissue upper airway obstruction caused by anaesthesia. In anaesthetized patient a standard nasal airway or a split nasal airway can be used to keep the tongue away from the posterior pharyngeal wall. Usually, the patient is not anaesthetized for fibre-optic scope to visualise the glottis. But, only anaesthesia is employed where patient is un-cooperative

and keeping in mind that intubation by fibre-optic scope under anaesthesia is usually more difficult. This is because of the development of the upper airway obstruction by falling tongue. If there is any doubt about the ability to maintain ventilation by mask during fibre-optic laryngoscopy under anaesthesia and paralysis, then fibre-optic aided intubation should always be preceded with conscious sedation and/or topical anaesthesia instead of full anaesthesia. In topical anaesthesia, for nasal fibre-optic intubation the supraglottic, glottic and tracheal areas may be anaesthetized with 1% lignocaine, sprayed through the injection port. After awake sedation, and application of topical anaesthesia and vasoconstrictor on nasal mucosa, an nasal ET tube or split nasal airway is passed through any nares into the nasopharynx and oropharynx. Then fibre-optic scope is passed through it. Thus, in vast majority of cases glottis can be seen by this scope with minimal tip manipulation. After visualisation of glottis, it is very easy to push the tip of ET tube in the larynx with the tip of fibre optic scope inside it.

OTHER SURGICAL AIRWAY TECHNIQUE

Other surgical airway techniques except the needle cricothyroidotomy, modified cricothyroidotomy by Seldinger technique (cannula cricothyroidotomy) and surgical cricothyroidotomy are percutaneous tracheostomy (PCT) and conventional surgical tracheostomy (ST). But none is performed under emergency 'cannot ventilate and cannot intubate' (CVCI) condition. Because all these procedures are time consuming (more than 5 minutes) and may not be able to save the apnoeic patient's life. By these above mentioned cricothyroidotomy techniques (including needle, cannula and surgical cricothyroidotomy) O_2 can be provided on a short-term basis until a definite airway can be placed or the patient resumes spontaneous breathing or wakes up. So, for a definite airway PCT is most commonly performed in ICU on patients who need prolonged ventilatory support for more than 3 weeks by ET tube.

Chevalier Jackson in 1909, first defined the method of surgical tracheostomy. Before that a patient remains intubated through larynx till he becomes conscious and cannot maintain his own airway. But, prolonged intubation through larynx has many disadvantages. So, if one thinks that a prolonged intubation is needed (more than 10 days) or if it is apparent that the patient is unlikely to maintain his airway independently within 3 weeks, then tracheostomy should be done. Usually, there are two types of tracheostomy – PCT and ST. The PCT has several advantages over conventinal surgical tracheostomy. These advantages are: (i) reduced wound complications such as haemorrhage and infection, (ii) improved cosmetic results, (iii) can be easily done at the bed side in ICU, (iv) reduced duration of the procedure and (v) it can be performed by non surgeons. The disadvantages of PCT over ST is that due to narrow tract and lack of formal stoma formation in PCT, there is increased risk of delayed airway loss. Without a formal stoma and with only a narrow tract between the airway and the skin, tracheostomy tube may be displaced which can lead to death.

First PCT was reported in 1955 by Sheldon. But because of high complication rate in this technique adopted by Sheldon, Ciaglia in 1985 modified this technique and called it as percutaneous dilatational tracheostomy (PDT). PCT differs from conventional ST in that in PCT a puncture is made on the trachea in between cartilages (usually between 1st and 2nd or between 2nd and 3rd) by needle or scalpel and subsequently the puncture is dilated over a flexible guiding catheter to intorduce a small tracheostomy tube or a small endotracheal tube. Whereas in conventional ST the tracheal cartilages are dissected and cut by the scalpel. On the other hand, in cricothyroidotomy the site of puncture is cricothyroid membrane and not the tracheal cartilages. Other different techniquees of performing PCT are : Grigg's technique, White tusk / Blue Rhino technique, Pere Twist technique and Trans Laryngeal Tracheostomy Technique (TLT).

PCT is performed in the intercartilagenous area between the 1st and 2nd tracheal rings or 2nd and 3rd tracheal rings. There is increased incidence of subglottic stenosis when it is performed above the first ring. The area below the third ring is generally avoided to minimise the potential trauma of the isthmus of thyroid and to prevent the accidental injury of the inominate artery.

In conventional ST the tracheostomy tube should be placed so that it does not erode the ring and press against the cricoid cartilage. In addition, the opening should not be placed too low, so that the tip of the tube or its cuff will be too close to carina. Low placement of tracheostomy tube is also hazardous, because the innominate artery crosses anterior to the trachea low in the neck. During ST any segment of trachea should not be removed, because this might lead to greater loss of tracheal wall stability and predispose to stenosis, once healing is accomplished after removal of the tube.

SUPRAGLOTTIC AIRWAY DEVICES

These are the devices which lying above the glottic opening help in ventilation and avoid the 'tube within tube' situation that is produced by intubating the trachea by an ET tube. It provides a better unobstructed airway during spontaneous respiration than the oropharyngeal or nasopharyngeal airway. It also help in controlled ventilation if needed. LMA is such the first supraglottic airway device and has been in practice nearly 20 years, since Dr. Archie Brain in UK had first introduced it. The LMA has been used for more than 150 million times world wide, but without a single death attributed to its use. So now, LMA has a well established role in the management of patient with normal or difficult airways.

Thus, the amazing success trail of LMA has spurred the introduction over a dozen of different supraglottic airway devices other than LMA to remove the disadvantages of it. But, only some have stood the test of time, while others have dwindled into the oblivion. Some of the supraglottic airway devices which have stood the test of time include: Combitube, soft seal and laryngeal airway device, laryngeal tube suction (LTS), cobra perilaryngeal airway (cobra PLA), pharyngeal airway Xpress (PAX), streamlined linear of the pharyngeal airway (SLIPA), cuffed oropharyngeal airway (COPA), glottic aperture seal airway (GOS airway).

All the supraglottic airway devices produce minimal to nil haemodynamic instability during their placement in larynx as they avoid stimulation of the infraglottic structures. They offer minimum resistance to the patient's airway. Other advantages of supraglottic devices are: Easy insertion and smooth awakening, no inadvertent bronchial intubation, no vocal cord injury, no translocation of oral or nasal bacterial colony and no secretions into the lower respiratory tract. Among all the above mentioned supraglottic devices, LMA and combitube have been recommended as the rescue of airway in 'cannot ventilate, cannot intubate' situations. Again LMA has been recommended at five places in the ASA Task force Algorithm for the management of difficult airway, either as a ventilating devices or as a conduit for endotracheal intubation.

However, today these devices (LMA and combitube) are not only used during emergency situations, but also during elective management of the patient's airway. Ambulatory or day case surgery for patients of ASA I and II grade (ASA I patients only according to some anaesthetist) are one of the most suitable candidates for the use of these supraglottic devices. These include short procedures, not requiring controlled ventilations with muscle relaxant such as surgeries of the upper and lower limb, ear and nose surgeries, ophthalmic surgeries, short gynaecological procedures, etc. These devices are also recommended in patients with ischaemic and other heart diseases, coming for short surgical procedures under general anaesthesia, as their use is associated with lesser haemodynamic changes compared to tracheal intubation. At the end of neurosurgery, but prior to termination of anaesthesia, ET tube can be replaced with LMA as a preventive strategy against hypertension, coughing, bucking, etc. which are associated with extubation and smoother emergence. For these reasons, supraglottic devices also are used during ophthalmic surgery to prevent risk from sudden rise in IOP during intubation and extubation. The supraglottic devices are also extremely popular in patients, undergoing minor therapeutic and diagnostic surgical procedures outside the OT complex. These include: Radiotherapy, diagnostic and interventional radiology, endoscopy, ECT, cardioversion, etc. In the ever expanding horizons of the supraglottic devices, more and more number of the routine general anaesthesia, lasting for 2 to 3 hours are now also being administered using these devices. Even surgeries associated with increased intra-abdominal pressure (Laproscopic surgeries) are now being safely done using proseal LMA, LTS or combitube.

Factors which prevent the use of supraglottic airway devices include: Small oral opening and any pharyngeal pathology which prevents the proper fitting of it at the laryngeal inlet. For example, pharyngeal mass and oesophageal pathology including caustic injury contradicts the use of supraglottic airway devices like combitube and laryngeal tube suction. All the supraglottic airway devices do not offer reliable protection against regurgitation and aspiration of stomach contents, except combitube and LTS. So, they should not be used in patients with the possibility of reflux of gastric contents and aspiration of it or where retained gastric contents may be present.

These conditions include:

i. When fasting is not confirmed
ii. Morbid obesity
iii. Pregnancy where there is delayed gastric emptying
iv. Others conditions associated with delayed gastric emptying such as history of gastroesophageal reflex, hiatus hernia, etc.
v. Multiple or massive injury.
vi. Acute abdominal or thoracic injury.

But, we have to keep in mind that these above mentioned conditions are not the absolute contraindications for the use of supraglottic devices.

Supraglottic airway devices also have the limited value in patients with poor lung compliance as they cannot withstand the high inflation pressure. But, it is noted that only the proseal LMA can withstand the peak inflation pressure of 35 to 38 cm of H_2O without leak from sides.

Individual Supraglottic Device

There are many supraglottic devices, among them which are commonly used are described below.

LMA

Previously it has been already discussed.

Soft seal and laryngeal airway devices

both the soft seal and the laryngeal airway device are quite similar to the LMA of unique variety in regards to structure and single use concept. But, one major difference between the LMA of unique variety and the soft seal or laryngeal airway device is the removal of the aperture bars from both of these later devices and a softer cuff of the soft seal. So, the latter confers a better periglottic seal, which can withstand the higher inflation pressure than the LMA classic.

Laryngeal tube suction (LTS) device

LTS is basically a shorter version of combitube. It is a newly developed, multiuse, latex free, double lumen, silicon tube. Like combitube, it has both oropharyngeal and oesophageal low pressure cuffs, a ventilation outlet in between them and a second

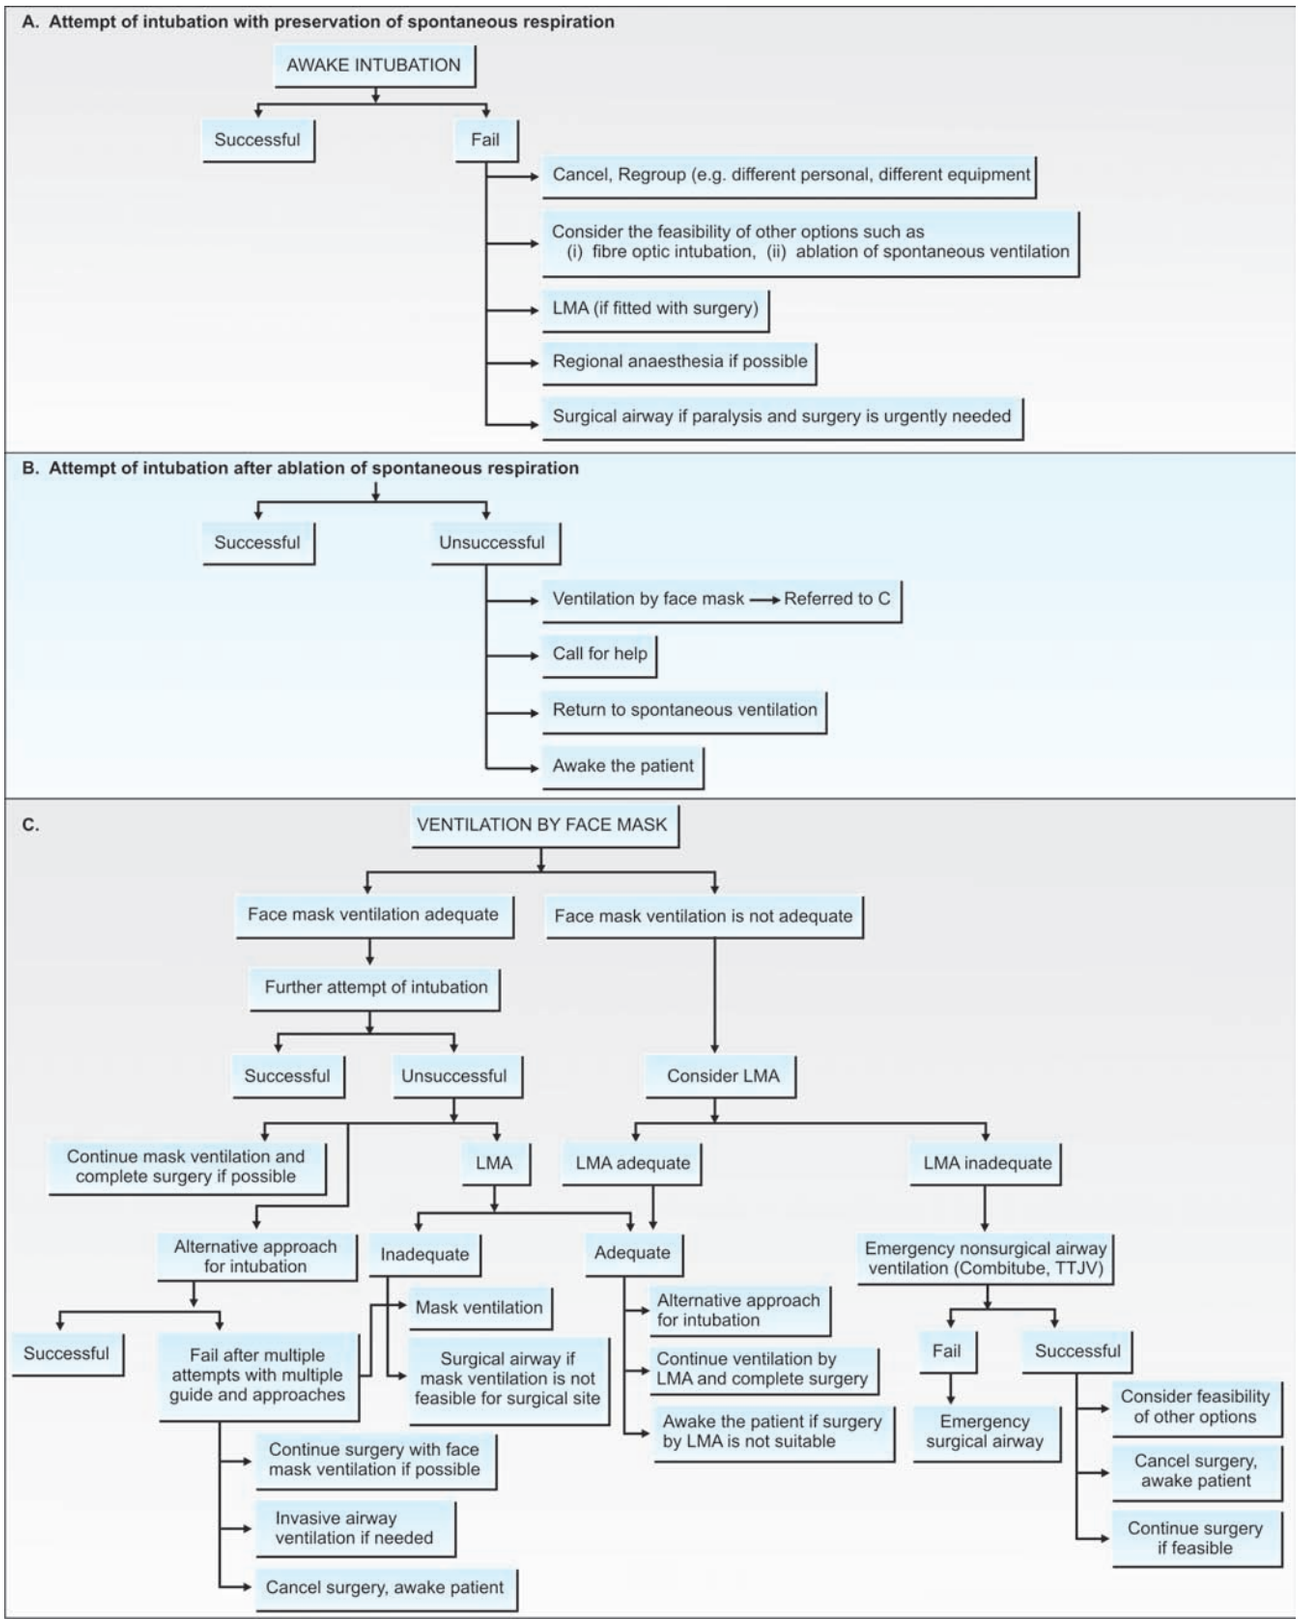

Fig. 20.43: Algorithm of airway management

tube placed posteriorly. The second tube is situated posterior to the respiratory lumen. The same inflation assembly inflates the two cuffs at a time. When correctly placed, the distal tip along with its opening and the cuff lies in the oesophagus. This effectively separates the oesophagus from the rest of the airways. Being shorter and blunder, the possibility of the oesophageal portion of the tube entering the trachea is non-existent. Laryngeal tube (LT) which is precursor to LTS has no second tube. So, it has now been replaced by LTS. Method of insertion of LTS is same as combitube. Due to the specially designed inflation line, the proximal cuff is inflated first and stabilizes the tube. Then once the proximal cuff has adjusted to the anatomy of the pharynx of the patient, the distal cuff will be inflated automatically. It is usually recommended to use a cuff pressure below 60 cm of H_2O. Like combitube there is no need to connect both the lumen alternatively for confirmation of ventilation. If ventilation is not adequate, then position of the tube can be changed by pushing it either distally or pulling it proximally according to patient size. The fine drained tube allows the insertion of a gastric tube.

Cobra Peri-laryngeal Airway (Cobra PLA)

It is a new device in the field of supraglottic airways. It consists of a tube, a cuff and a 15 mm standard adaptor for attachment with the anaesthetic machine. Distally, the tube ends at an opening with cobra head design which holds both the soft tissues and the epiglottis out of the way. Thus, it facilitates the ventilation though the slotted opening. The cuff when is inflated gently seals off the upper airway and allows improved positive pressure ventilation. Cobra PLA is usually used as an alternative to face-mask and certainly does not protect the airway from the effects of vomiting, regurgitation and aspiration.

Pharyngeal Airway Xpress (PAX)

PAX is a sterile, latex free, single use supraglottic airway device. It is used as an alternative to face-mask, LMA, Cobra PLA. The PAX supra glottic device consists of a tube, a cuff and a soft-flexible-gilled tip and is made of medical grade PVC. The tube has a standard 15 mm connector at its proximal end for attachment with anaesthetic machine. The soft, flexible, gilled tip is tapered to guide the device and help to rest the device within the cricopharyngeal recess, above the oesopharyngeal sphincter. The gilled tip is made of thermoplastic elastomer. A high volume, low pressure cuff which volume is 60 ml stabilizes the PAX within the oropharynx. Approximately, placed cuff lies just below the uvula and pushes the tongue forward for improved ventilation. An open hooded window is situated between the cuff and the gilled tip for aligned to the glottic opening. The hood is designed to lift the epiglottis forward. An anatomically curved tube can accept 7.5 mm ET tube if tracheal intubation is indicated.

Streamlined Linear Pharyngeal Airway (SLIPA)

The SLIPA is a hollow, preformed, boot-shaped airway. It is made of soft plastic and blow molded to the shape of the pressurized pharynx. As it is fitted tightly in the pharynx, no cuff is provided to seal the device in the pharynx. SLIPA is looked like a boot with 'toe bridge and heel' prominences. It is used as an inexpensive single use alternative to the LMA and to decrease the risk of aspiration if limited volume regurgitation should occur. It is available in different sizes to match the patient size (Fig. 20.43).

21 Mechanical Ventilation

INTRODUCTION AND HISTORY

For centuries, it has been felt that failure to breathe should not be allowed to proceed to death. So, expired air ventilation (mouth-to-mouth resuscitation) has been used throughout the ancient history in an effort to revive the apparently dead person especially from drowning. So, in the Second Book of Kings there is a vivid description of such a successful mouth-to-mouth breathing by the Prophet Elisha. He performed this on a child who appeared to be dead from drowning. But, the actual date of this event is not known. Then during the period of 12th and 13th century tracheostomy was usually used to perform ventilation for the treatment of drowned persons instead of by mouth-to-mouth breathing. After that between 1493 to 1541, Paracelsius and Vesalius were credited for the introduction of bellows and a pipe to ventilate the lungs through this tracheostomy wound. But only for ventilation tracheostomy was not accepted by the people during this era. Then, Elisha's mouth-to-mouth breathing was rediscovered by Tossach, in 1743. But that method of ventilation was later condemned as an unhygienic manoeuvre by the newly founded Royal Human Society. After that in 1763, the 'Society for the Recovery of Drowned Persons' was formed in Amsterdam. They declared to offer medals and prizes for new ideas and apparatuses for ventilation other than mouth-to-mouth breathing. Hence, many designs of pumps, bellows and tubes were introduced to ventilate the lungs through larynx or tracheostomy wound. In 1811, Brodie and Waterton employed the 'curare plus bellows' principle for positive pressure ventilation on the experimental animals and also suggested that artificial breathing by bellows could be used to treat severe respiratory depression in opium poisoning. Then, in 1827, Leroy demonstrated the dangers of this positive pressure ventilation such as rupture of alveoli, pneumothorax, etc. which was later confirmed by Magendie's report in 1829. So, after that positive pressure ventilation for resuscitation using bellows fell into disrepute. In 1837, Royal Human Society also criticised positive pressure ventilation by bellows and recommended the manual compression of chest (negative pressure ventilation), if artificial ventilation was necessary. So, for the next century, positive pressure ventilation by bellows went into oblivion but mouth-to-mouth resuscitation and chest compression for ventilation continued. Then again 100 years later, bellows for resuscitation or ventilation reappeared, when Kreiselman introduced his own apparatus during the second World War. Within this period of 100 year (1840–1940), most of the mechanical aids for artificial ventilation were depended on the application of subatmospheric pressure from outside the thorax (negative pressure ventilation).

During this period using the principle of subatmospheric pressure from outside the thorax for ventilation, the tank ventilator and cuirass ventilator were invented which were later claimed as a very successful apparatus for the treatment of respiratory paralysis, and respiratory failure due to poliomyelitis. First tank ventilator was patented in America in 1864. After that, different modifications to this basic design of tank ventilator were introduced over the next few years. In 1929, Drinker and his colleagues first introduced their tank ventilator for prolonged artificial respiration. This apparatus subsequently was known as the 'iron lung'. The first patient to be treated with the iron lung was a victim of paralytic bulbar poliomyelitis. The tank ventilator, introduced by Dinker and his colleagues, was also the first ventilator driven by power. In this tank ventilation the patient was placed on a mattress inside an air tight cabinet, from which only his or her head is protruded. A padded collar around the neck formed an effective air tight seal. The pressure inside the cabinet was lowered rhythmically by a system of pumps or a set of bellows during inspiration and was next allowed to return to the atmospheric level slowly during expiration. There were portholes at the sides of the tank, through which the patient could be observed and sealed ports to allow the use of manometers, blood pressure cuffs and stethoscopes. The two main disadvantages of these tank ventilators were: (i) access to the patient for nursing care and physiotherapy was restricted and (ii) the air way was not usually protected. So, vomiting and regurgitation are particularly hazardous in respect to the chance of aspiration, during this intermittent negative pressure ventilation (INPV) by tank

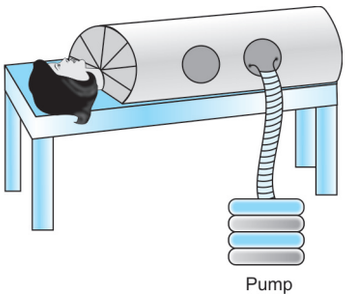

Fig. 21.1: The tank ventilator. Inside the ventilator the patient is placed in a body shaped shell. Head is outside the tank

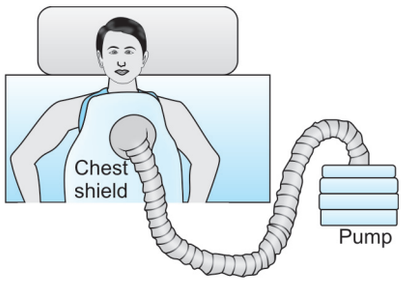

Fig. 21.2: Cuirass ventilator with chest shield (red) which is connected with pump

ventilators, even for patients who have normal laryngeal and pharyngeal reflexes. If vomiting occurs, then an emergency port should be opened immediately to equalise the pressure between the inside and the outside of the tank and thus reduce the risk of aspiration (Fig. 21.1).

Cuirass ventilator was named after the piece of a 15th century body armour, used during war. It is consisted of a breast plate and a back plate which were joined together at both side forming a rigid shell around the thorax. This rigid shell was fitted over the thorax and upper abdomen and a padded rim at the periphery around the neck and upper abdomen made contact with the skin to form an air-tight seal. A bellow was connected by a flexible tubing to the airspace situated between the skin and the shell. The expansion of bellow was able to create a subatmospheric pressure in the airspace between the chest wall and the armour plates during inspiration and allowed the chest wall to inflate and the air to rush into the lungs through airways. During expiration the pressure in the air space again became atmospheric and the chest wall deflated with the lungs and the air came out. Cuirass ventilators though work on the same principle as tank ventilator, but left patient's arms and legs free and caused less circulatory embarrassment than tank ventilators. But they were less efficient than tank ventilators and the tidal volume obtained by a given subatmospheric pressure was smaller. So, Cuirass ventilators were used as an assistants for patients who was suffering from chronic respiratory impairment with some respiratory efforts but not had complete respiratory paralysis or who were recovering from some acute episode of paralysis (Fig. 21.2).

After 1940, due to multiple disadvantages of tank and cuirass ventilators positive pressure ventilation again resurfaced by the work of Krliselman during the Second World War in 1939. During that period Krliselman's work was also supported by the development of non-depolarising neuromuscular blocking agents by Griffith in 1942. He was the first to use curare in anaesthesia. This development initiated the need for new positive pressure ventilators in anaesthesia which could be combined with newly developed endotracheal intubation techniques by Magill and Macintosh. These were more convenient for operating theatre enviornment and also solving the problem of oropharangeal and gastric secretions entering the trachea. Another cause for loosing the popularity of negative pressure ventilations by tank ventilators was that these were large and awkward devices. The poliomyelitis epidemic which occured in Copenhagen in 1952 also had enormous influence on the development of newer positive pressure ventilation techniques and ventilators. By this time, controlled positive pressure ventilation was well established in anaesthesia. During that epidemic of poliomyelitis, an eminent anaesthetist named Ibsen was called in by Prof. Lassen to help him for the ventilatory management of polio patients in the Blegdam Hospital. Then Ibsen developed the method of positive pressure hand ventilation through the tracheostomy tube and almost all the students of the medical school were appointed to help with this manual ventilation. So, medical teaching activities were temporarily suspended until polio epidemic was over. After that, Lassen and Ibsen established some basic principles for long-term positive pressure ventilation. These were careful airway control and protection, humidification of inspired air, avoidance of high inspired O_2 concentration for ventilation and meticulous physiotherapy. Once the acute phase of poliomyelitis disease was over, then weaning was accomplished by a forerunner of IMV. Then the adequacy of ventilation was assessed by oximetry and end tidal CO_2 concentration measurement. So, after the second World War in 1939, there were two stimuli for the further development of positive pressure mechanical ventilation. The first was the introduction of curare into anaesthesia. The second was the fear of health authorities that if another epidemic of poliomyelitis occured, then large number of patients might require artificial ventilations which in turn need huge manpower. So, in 1940, the first commercial automatic mechanical ventilator for anaesthesia was manufactured in Sweden for IPPV.

A dramatic fall in the mortality from polioepedemic was occured after this new technique of automatic ventilation (IPPV) had been introduced for its management and this ensured that IPPV would become the standard method of artificial ventilation than negative pressure ventilation made by tank and cuirass ventilator. Later the superiority of automatic IPPV was also confirmed by Stockholm polioepidemic in the following year and New England polioepidemic in 1955. After the intorduction

of poliomyelitis vaccine (Salk and Sabin), the incidence of poliomyelitis fell sharply. So, the ventilation skill which had been developed to fight polio epidemic were diverted to other good uses, such as anaesthesia, and for management of polyneuritis, drug over doses, trauma, asthma and complicated surgeries, etc. where prolonged artificial positive pressure ventilation was needed. After that in 1960, the indications for IPPV were broadened further and its cardiovascular effects were also investigated. The value of mechanical positive pressure ventilation in anaesthesia was also soon recognised simultaneously in Sweden, Britain and many other European countries. But during this period it was still disputed in USA, where the reliance on manual IPPV was persisted. However later, the more stringent ventilatory requirements for cardiac surgery changes this view.

After successful establishment of automatic IPPV as the ideal mode of treatment for respiratory failure, a group of patients went on to develop a lung condition, which were characterised by certain radiological changes and severe impairment of gas exchange due to prolonged ventilation. At that time such changes in lung condition was called by many names such as shock lung, ARDS, respirator lung, etc. But in 1970, the pathophysiology of such lung condition was studied intensively and PEEP was introduced. The PEEP was added to IPPV to aid better gas exchange in patients with shock lung or ARDS. But, gradual recognition of the adverse effects of PEEP on the circulation started the quest for an ideal PEEP level which would balance the respiratory advantages against the circulatory disadvantages of it. The year of 1970 also saw the development of extracorporeal circulation techniques which could ensure the adequate gas exchange for several weeks. At that period, high frequency ventilation (HFV) was also developed, but its true role in long-term mechanical ventilation was not established. In 1960, pulmonary oxygen toxicity was also blamed for the pathology of ARDS or shock lung, because toxic effects of pure oxygen on lung at standard atmospheric pressure was known for over 50 years. Hence, an inspired O_2 concentration of 50% or less was considered safe. So, after 1960, most ventilators which are in use in North America employed a venturi device to entrain air and to mix it with the principal gas flow of O_2. This evidence together with the experience which was, already gained from polio patients, established that IPPV with modest level of O_2 in the inspired gas and modest level of inspiratory and expiratory pressure may be continued indefinitely, without any adverse effects on the lungs. Then the subsequent evolution of ventilators had taken two paths. One was to fulfil the need for cheap, simple and reliable method which could be used for anaesthesia and for the majority of patients needing short-term ventilation. The other was to provide increasingly sophisticated and versatile ventilators with the facilities, necessary for treating patients with severe respiratory failure or suffering from other life threatening condition.

ARTIFICIAL INTERMITTENT POSITIVE PRESSURE VENTILATION (AIPPV)

After the Second World War, in 1939, positive pressure ventilation was established which certainly was artificial and intermittent. So this artificial intermittent positive pressure ventilation (AIPPV) can be employed and classified by three ways:

1. AIPPV requiring no apparatus – expired air ventilation (e.g. mouth-to-mouth resuscitation).
2. AIPPV using simple devices or apparatuses.
3. AIPPV using sophisticated instruments manual ventilation Boyle's machine or automatic ventilation by ventilators.

1. AIPPV by Using No Apparatus or Mouth-to-mouth Resuscitation

It was previously described that Elisha's mouth-to-mouth positive pressure ventilation which was gone out of vogue today due to development of tracheostomy and bellows, was rediscovered by Tossach in 1743. But, again as the mouth-to-mouth method of breathing was unhygienic, so Royal Human Society had condemned it and recommended some other methods of ventilation, described below. But in 1954, Elam and in 1958, Safar showed that the other methods of non mouth resuscitation, (recommended at that time by Royal Human Society), such as Holger-Nielsen method, Schafer's method, or Sylvester's method failed to provide adequate ventilation. So, since that time mouth-to-mouth breathing or expired air resuscitation had again become the method of choice when equipments are not available, except for those who have inhaled toxic gases or who are the victims of cyanide poisoning (Figs 21.3 and 21.4).

2. AIPPV by Using Simple Devices

Many simple devices had made the positive pressure ventilation through mouth more easy, more acceptable, more hygienic and more effective than mouth-to-mouth ventilation. This devices are so simple that it can be carried in pocket. AIPPV using these simple devices are of the following types. This may be expired air ventilation or fresh air ventilation, enriched with O_2.

Mouth ventilation by mask

Here, the device is nothing but a simple transparent Laerdal pocket face mask. The angle piece is replaced by a short, straight tube to which the resuscitator's lips can be applied for forceful blow. A nipple can be added on the body of the mask, so that through it O_2 can be added to the inspired gas. This device makes the IPPV procedure more hygienic and O_2 enriched expired air can be used to ventilate the patient (Fig. 21.5).

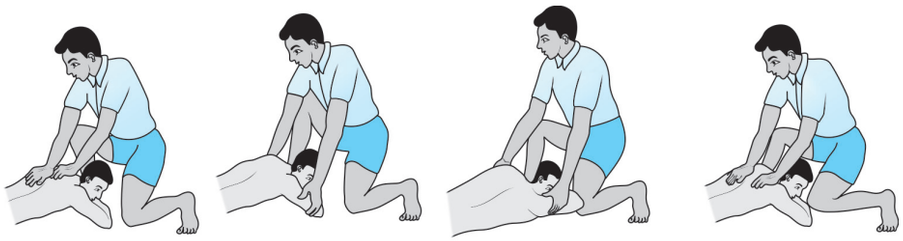

Fig. 21.3: Holger-Neilson's manual method for artificial respiration.

Fig. 21.4: Schafer's manual method for artificial respiration

Mouth ventilation by air-way devices

Here, different types of airways are used for expired air ventilation by mouth. The different types of airways are: Safar S-tube, Brook airway, oesophageal obturator airway, etc. Safar S-tube is a double Guedel airway and is used both as a pharyngeal airway and for ventilation. Brook airway is slightly sophisticated where a non return value in used which allow the expired air from patient to pass out. In oesophageal obturator airway, a large cuffed tube is designed to obstruct the oesophagus which prevents the reflux of gastric contents during ventilation (Fig. 21.6).

Bag-valve-mask ventilation

Here, resuscitator's mouth is not used for expired air ventilation. Instead a self refilling bag is used to ventilate the patient by mask. Between the bag and the mask, a non rebreathing valve is incorporated which help the expired air from patient to pass out. O_2 can be administered, if available, through a side tube, but a reservoir tube is necessary to deliver 100% O_2. Example of one such ventilation is by Ambu bag (Fig. 21.7).

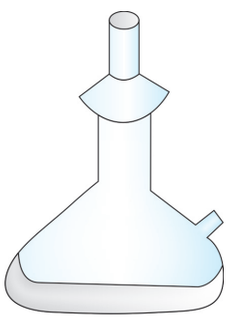

Fig. 21.5: Laerdal pocket mask

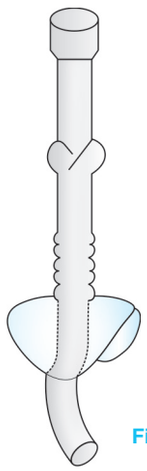

Fig. 21.6: Safar-S-tube

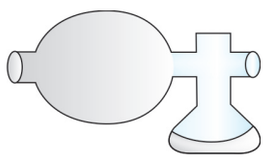

Fig. 21.7: Ambu-bag with mask

3. AIPPV Using Sophisticated Instrument

AIPPV using sophisticated instrument can be conducted manually or automatically. When it is conducted maunally, the best example is bag-mask ventilation by Boyle's apparatus. Automatic artificial intermitent positive pressure ventilation also can be performed by ventilators.

The power mechanism (electric or pneumatic) forms an important part of the driving system of an automatic ventilator. The only electrically driven ventilator uses only electrical source for its complete working. Here both the electronic and mechanical components which are incorporated in this type of only electrically driven ventilator, is such designed that this ventilator uses only the electrical source for its complete working. Except the anaesthetic ventilator which uses the anaesthetic gas mixture from Boyle's machine, the air is sucked inside the other type of ventilators (which are used in critical care unit) from the atmosphere, and this is blended then with the external source of O_2 to meet the desired FiO_2. During inspiration, the air is pushed by the ventilator through the bellow system into the patient's airways. These only electric driven ventilators find a good application typically during transport of a patient.

On the other hand, both pneumatically and electrically operated ventialtors need a source of highly compressed, pressurised air to operate the mechanical components of the ventilator, in addition to the electrical source for the complete control of it. The source of compressed air can be provided from external or internal sources. The external source of compresed air is available either from a cylinder or from an air compressor which is permanently build in the ventilator or through an air compressor available for the use of hospital. Some ventilators incorporate piston assembly or turbine technology in their system as the internal source of compressed air. This turbine compresses the room air, after

it is sucked inside the ventilator. In such ventilator systems, there is no need for an external source of compressed air for their function.

An automatic positive pressure ventilation has four stages:

i. Inspiration – inflation of lungs.
ii. Changing over from inspiration to expiration – cycle.
iii. Expiration – deflation of lungs.
iv. Changing over from expiration to inspiration – trigger.

The term 'cycling' is referred to the changing over from inspiration to expiration and the term 'triggering' is referred to the changing over from expiration to inspiration (Table 21.1).

Inspiration

In positive pressure ventilation, inspiration can be instituted by presenting a preset pressure or a preset volume of air to the patient's upper airways. So, as a result of difference between the upper airway pressure and the alveolar pressure, gas flows into the lungs of patient. This cause of flow results in delivery of fixed (in VCV) or variable volume of air (in PCV) in the patient's lung.

So, according to the preset pressure presentation or preset volume presentation the ventilators can be first classified into:

Table 21.1: Classification of ventilators

1.	According to power and control mechanism
	i. Pneumatically driven and operated
	ii. Electrically driven and operated
	iii. Both
2.	According to cycling mechanism
	i. Time cycling
	ii. Volume cycling
	iii. Flow cycling
	iv. Pressure cycling
	v. Combinational cycling
3.	According to trigger mechanism
	i. Time or ventilator triggered
	ii. Patient triggered

i. Pressure controlled (or generated) ventilator (PCV)– Here, ventilator applies a fixed pressure set by operator to the upper airway during inspiration. So due to this fixed pressure pattern, the volume of air delivered to the patient during inspiration may vary according to the condition of lungs.
ii. Volume or flow controlled (generated) ventilator (VCV) – Here, ventilator delivers a fixed volume of air set by operator to the lungs during inspiration. Like PCV, as fixed volume of air is delivered to the patient, so the pressure in the airway may vary according to the conditions of the lungs.

Pressure controlled ventilation (PCV)

In pressure controlled or generated or pressure limited ventilation (PCV), the peak inspiratory pressure or P_{max} is preset by operator and is maintained for the whole set inspiratory time. So, the flow or volume of air entering the patient's lungs will depend on the set pressure pattern, lung compliance, airway resistance, and the time allowed for inspiration. The flow of air in alveoli decreases as the alveolar pressure gradually increases with the increasing alveolar volume and ceases when the alveolar pressure equals to the applied set airway pressure. So, the delivered tidal volume will depend on all the factors which affect the flow. In PCV, the normal airway pressure is typically set in the range of 15 to 30 cm of H_2O, while pressure above 50 cm of H_2O can be associated with an increased risk of barotrauma. However, High pressure (even above 50 cm of H_2O) is sometimes set in cases of ARDS, to inflate the stiff lungs and here the PCV is preferred mode of ventilation. The PCV is also used for obstructive lung diseases, where resistance for airflow into the lungs is very high. In neonatal and paediatric patients PCV is also indicated, since the peak airway pressure is controlled and barotrauma can be avoided.

Advantages of pressure controlled ventilation are

i. As the flow rate or volume varies depending on the patient's lung compliance and airway resistance, so there is no flow or volume starvation.
ii. It protects against barotrauma. So, it is essentially used for neonatal and paediatric group of patients.
iii. Since the fixed peak airway pressure is maintained throughout the inspiration, so it ensures that not only the healthy alveoli do not over inflate but also, the non participating alveoli are recruited resulting in better gas exchange.

Disadvantages of PCV are

i. The tidal volume may decrease, if the compliance deterioates or the resistance increases. In such situations the setting of pressure should be changed, as if the delivered tidal volume can be adequate.
ii. Required tidal volume delivered to the patient cannot be assured.
iii. Minute ventilation should be closely observed to ensure adequate alveolar ventilation.

In pressure controlled ventilation, adequate alveolar ventilation and oxygenation can be achieved by the manipulation of various ventilator settings. Patient's alveolar ventilation depends on minute volume. Minute volume depends on tidal volume and respiratory rate. In PCV tidal volume cannot be controlled directly by knob. Tidal volume depends on pressure (PIP-PEEP) and time constant. Time constant depends on resistance and compliance. Time constant cannot be controlled by knob, while only preset pressure is controlled by knob, thus controlling the tidal volume indirectly. Respiratory rate depends on inspiratory time and expiratory time and I:E ratio, all of which can be controlled by knob. So, in PCV ventilation is controlled by controlling the knob of pressure (PIP – PEEP), respiratory rate, inspiratory time, expiratory time and I:E ratio, according to

the resistance and compliance of airways and lung tissues. The last four parameters are integrated and when any two of these four is changed, then other two will change automatically. Oxygenation can be improved by increasing FiO_2. In PCV, pressure is the independent variable and volume is the dependable variable. In lung pathology when compliance decreases and resistance increases, then the pressure is set such that an adequate volume of air is delivered according to that set pressure. The ultimate arterial oxygenation and $ETCO_2$ is maintained by setting the knob of pressure, inspiratory time, expiratory time, I:E ratio, FiO_2, PEEP and flow pattern.

Pressure controlled ventilation differs from pressure cycled ventilation and pressure support ventilation (PSV). In pressure cycled ventilation, the inspiration is terminated when the peak set pressure level is reached, whereas in pressure controlled ventilation, the peak pressure is held constant in the form of plateau until the inspiratory time has elapsed. Difference of pressure controlled ventilation from PSV will be discussed later in the next paragraph. The most salient feature of PCV is that the maximal airway and alveolar pressures are controlled. Whereas the tidal volume and subsequently the minute volume and alveolar ventialtion cannot be controlled which depend on compliance, resistance and ventilatory pattern. The effective tidal volume is the result of the product of compliance and P_{max}. The level of P_{max} which is the necessary inspiratory pressure level are chosen or set, depending on the tidal volume required, but the pressure exceeding 35 cm of H_2O should generally be avoided.

In both, pressure controlled and pressure support ventilation, a set or fixed pressure is controlled by the machine. But the difference between the two involves the inspiratory time which is machine controlled in the former and patient controlled in the latter.

The special advantages of PCV for its decelerating flow are:

i. Since the flow of air during PCV is decelerating, so the peak airway pressure due to airway resistance occurs early in inspiration, and the peak airway pressure due to elastic recoil resistance does occur at the end of inspiration. This produces less variability of peak airway pressure than during volume – controlled ventilation.
ii. Effective ventilation in cases of distribution disorders in lungs. The decelerating inspiratory flow characteristic of PCV reduces overinflation of well ventilated 'faster alveoli'.
iii. Improved gas exchange due to characteristic of decelerating flow.
iv. PCV like pressure – support ventilation is also especially suited for ventilation during losses due to leakage (e.g. fistulla, uncuffed tracheal tube) as an increased flow to maintain the preselected pressure can automatically compensate these losses to a certain degree.

In reality, PCV or PSV refers to how the different type or mode of breaths are modified by pressure, rather than specifying it as a particular mode or type of breath. PCV can be delivered in conjunction with CMV, ACMV, SIMV, etc. It was actually been available for many years in conjugation with IMV in neonatal ventilators. A number of variants of PCV have recently been introduced into the clinical practice which include PC-IRV, APRV, intermittent mandatory pressure release ventilation and bilevel positive airway pressure ventilation.

The initial settings for PCV include FiO_2, air way pressure level (P_{max}) and the end expiratory pressure, as well as back up mode and rate. P_{max} is adjusted to ensure adequate tidal volume. Back-up mode and rate is chosen to provide adequate minute ventilation in the event of decreased intrinsic respiratory drive and may be supplied either in pressure control or SIMV mode.

Volume controlled ventilation (VCV)

In a volume controlled or limited ventilation (VCV), a preset amount of minute volume is delivered to the patient in a fixed inspiratory time set by the respiratory rate and the tidal volume in machine. The breath (inspiration) is triggered on by the timing interval determined by the set respiratory rate. Then, it cycles off into the expiratory phase when the inspiratory time has elapsed. By controlling the respiratory rate and tidal volume knob the minute volume should be fixed or preset. That prefixed minute volume should be delivered during fixed inspiratory time. The alveolar and upper airway pressure that is developed due to this inspired volume will depend on the volume and flow pattern of gas delivered by the ventilator, lung complainace, airway resistance and the time allowed for inspiration.

Volume (or flow) controlled (or generated) ventilators are thought as strong ventilators than PCV, because the minute volume (set by the tidal volume and respiratory rate) delivery will not change with the patient's lung characteristic, i.e. compliance and resistance. Here the minute volume is independent or fixed factor and the airway or alveolar pressure is dependent factors which are affected by the changes in lung compliance and airway resistance. If lung compliance decreases and resistance increases, then airway or alveolar pressure will also increase as ventilators will try to ventilate the preset volume of gas within the preset time. So, barotrauma can happen. Thus to avoid barotrauma, minute volume (by tidal volume and respiratory rate) should be set carefully according to the compliance and the resistance of lungs and should not be used in paediatric patients (mainly neonates and infants) and pathological lung conditions. Here as the pressure is variable so it cannot be controlled directly according to wish. Indirectly it can be controlled by adjusting the preset

tidal volume level and inspiratory time (independent variable). In normal lungs with normal compliance and resistance, if volume is set wrongly, then barotrauma can also occur.

In contrast, pressure controlled ventilators are thought as weak ventilators, because the minute volume will change as the patient's lung characteristic changes. So, to maintain the adequate ventilation independent variable such as pressure should be controlled accordingly. In this ventilators airway pressure is the independent variable, volume is dependent variable (cannot be controlled directly, can be controlled through pressure) and are affected by changes in lung compliance and airway resistance.

The main indications of volume controlled ventilation are: intraoperative IPPV, restrictive lung diseases, patients weighing more than 10 kg (where lung's compliance and resistance are thought to be normal). Adequate ventilation and oxygenation can be achieved in volume controlled ventilation by manipulation of minute volume (tidal volume and respiratory rate) and FiO_2. Tidal volume can be set according to patient's body weight (10 to 12 ml/kg) and minute volume can be set by controlling tidal volume and respiratory rate knob. After setting a minute volume if airway pressure goes to the allowable maximum limit (not causing barotrauma) and still oxygenation is not adequate, then oxygenation can be improved by increasing the FiO_2. In volume controlled ventilation oxygenation cannot be improved by further increasing the minute volume in fear of barotrauma. In such situation for better oxygenation PEEP can be used with increasing FiO_2.

Advantages of VCV are:

i. Pressure time waveform of a volume controlled ventilation (VCV) should be ramped one. Because the ramped pressure time waveform helps to maintain minimum mean airway pressure.
ii. Guaranteed preset volume is delivered during each breath which ensures proper ventilation.

Disadvantages of VCV are:

i. The resulting high distending peak airway pressure can cause barotrauma.
ii. Distending or peak airway pressure will increase, if compliance of lung decreases and resistance of airway increase. So, it is mandatory to correctly set the high pressure alarm limit.
iii. Unequal ventilation of different alveoli with different resistances and time constant can occur. The flow of air takes the path of least resistance. Hence, the alveoli with lower resistance and short time constant will be overinflated. Whereas the alveoli with higher resistance and long time constant will be under inflated.
iv. Since, the flow and subsequently the volume is fixed in VCV, so an improper flow setting can cause flow hunger for the patient. This may cause discomfort and hypoxaemia to the patient. In VCV, if lung's characteristics change frequently, then you will have to keep eye continuously on pressure gauge and according to that you have to control or preset the minute volume by controlling the tidal volume knob and respiratory rate knob for avoidance of barotrauma (Fig. 21.8).

Whereas in PCV if lung's characteristics change frequently you will have to keep eye continuously on the computer screen giving tidal volume/minute volume data or breathing bag of ventilator or SPO_2 level for tidal volume and according to that you have to adjust the pressure setting knob for proper ventilation and oxygenation. In some volume control ventilator

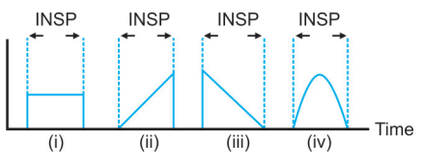

Fig. 21.8: (i) Constant flow, (ii) Accelerating flow (ramp), (iii) Decelerating flow, (iv) Sine flow

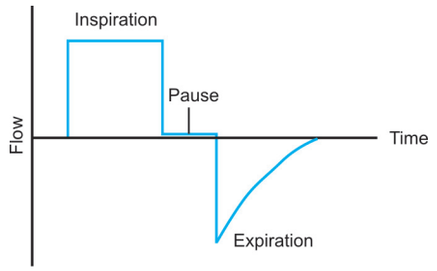

Fig. 21.9: Flow time waveform (square pattern) with end inspiratory pause

there is no pressure gauge. In such circumstances an idea of airway pressure, produced by preset volume on the background of certain compliance and resistance of lungs should work in mind (Fig. 21.9).

In a ventilator, the distinction between the pressure generated and volume or flow generated is important. A cheap and simple ventilator use a weighted concertina bag to generate a constant volume during inspiration. Even today these ventilators remain adequate for the majority of patients who require artificial ventilation during anaesthesia. The more sophisticated modern ventilators are fitted with devices which measure the instantaneous flow of gas during inspiration. This information can be incorporated into the feed back loop of ventilator to ensure the delivery of some predetermined volume and flow pattern. As a result, there is now greater emphasis on the flow pattern, produced by a ventilator during inspiration. In theory, ventilator can produce any flow pattern or waveform. But the four main waveforms are: sine wave, ramp or accelerating flow, top hat or constant flow, reverse ramp or decelerating flow. No matter, what flow pattern is chosen, but the inspiratory flow in any pattern can be modified further by adding an end inspiratory pause (EIP). Towards the end of inspiration, the flow of gas ceases, but the lungs are held inflated for a variable period which is called the 'pause time'.

Changing over from inspiration to expiration

Changing over form inspiration to expiration may be: Time cycled, volume-cycled,

pressure-cycled, flow-cycled or combination of them.

In time-cycled ventilation, expiration occurs after a predetermined duration of inspiraton. It is most popular. The time cycle may be of electronic, mechanical or pneumatic controlled. If a ventilator is time cycled, the change from inspiration to expiration will occur after a fixed time interval, no matter what airway pressure has been reached or tidal volume has been delivered. But in volume controlled and time-cycled ventilator, minute volume is preset by tidal volume and respiratory rate. So, inspiratory time (time cycled) is fixed by I:E ratio, leaving the airway pressure is only variable. Sometimes confusion arises by seeing the excursion of the inflating bellows, which create the optical illusion of being volume cycled, though infact they are time cycled and volume controlled. To ensure delivery of a preset volume in a preset time, the ventilator must have sufficient power to overcome the circumstances where there is increase in airway resistance or decrease in lung compliance.

In volume-cycled ventilators, there is some confusions as to what volume cycling really means. Ideally, a volume cycled ventilator would change over to expiration when the desired tidal volume had been delivered to the patient's lung, whatever may be the time needed. Unfortunately, lung expansion is not easy to measure and volume-cycled ventilators rely on measuring the volume of gas leaving the ventilator. So, if there are leaks in the apparatus or if the connecting tubes are distensible, then the volume leaving the ventilator may be very different form the volume which reaches the lungs. It has been suggested that the meaning of true volume cycling should apply to those ventilators which measure the gas volume leaving the ventilator and compare it with the volume which the patient exhales. This would be better regarded as a form of volume cycle during ventilation. But, unfortunately very few ventilators have these facilities.

Others forms of cycling, such as flow cycling, pressure cycling and combination cycling are also possible. But, neither of these are commonly used. In flow cycling, the end of inspiration will depend on the inspiratory flow. The moment when the inspiratory flow reaches the level of a predetermined flow, then the inspiration is terminated and the expiratory phase begins. Flow cycling is generally used for pressure support ventilation. In pressure cycling, when the airway pressure reaches a preset peak inspiratory pressure (PIP), set before hand by the operator, then the ventilator will end the inspiratory phase. Other parameters such as inspiration time, tidal volume and flow are variable. The time taken to reach the peak pressure level will depend on the airway resistance and lung compliance. In such circumstances before adequate inspiratory volume expiration will start. It is important to note that pressure cycling must be differentiated form pressure control ventilation. If an adjustable pressure safety value is set to low value, the change over from the inspiration to expiration may become pressure cycled in some ventilators that would otherwise be time cycled or volume cycled.

The present day ventilators offer the facility to use a combination of the above four cycling mechanisms. One cycling mechanisms is used as the basic mechanism and the second one is used as a secondary back-up. PSV is an example of combination cycle. In PSV, flow cycling is the primary, whereas time and pressure cycling forms the secondary back-up.

Expiration

The majority of ventilators allow passive expiration to atmosphere and the pressure created in the upper airway at the end of expiration is atmospheric. But, this atmospheric pressure at the end of expiration can be modified by applying: (i) Negative end expiratory pressure (NEEP), (ii) Espiratory retard (ER), or (iii) Positive end expiratory pressure (PEEP).

During the early development of ventilators, the use of negative pressure (subatmospheric) at the end of expiration was advocated to expediate the expiration. But this NEEP is not used now, though many ventilators still provide this facility. The main disadvantage of NEEP is that it causes early closing of the bronchiole of smaller diameter and subsequently air trapping in alveoli. So, in the second phase of evolution of ventilator, to prevent this peripheral airway collapse in chronic lung disease with obstructive airway, a variable resistance is placed in the expiratory limb of ventilator which reduce the expiratory flow rate. This is called expiratory retard. It tries to maintain a pressure above the atmospheric level in alveoli and peripheral airways and so prevents their early closure. Thus, the idea of positive pressure during expiration had developed.

Positive end expiratory pressure (PEEP) is the positive pressure above the atmospheric level (atmospheric level is regarded as baseline or '0' cm of H_2O) which is presented artificially in the expiratory phase of respiratory cycle. This above atmospheric pressure level (positive pressure) is preset by operator and is generated by the ventilator. This set positive pressure during expiration prevents the early closure of alveoli and peripheral airways. Thus, they try to maintain a patent airway with inflated alveoli and gaseous exchange. The ideal level of this PEEP does offer no resistance to expiratory flow. The PEEP can be used as a stand-alone mode or in combination with other modes. The physiological level of PEEP is 0 to 5 cm of H_2O. PEEP $\geq$ 10 cm of H_2O can be used in the treatment of ARDS. PEEP improves ventilation and thus oxygenation. But, the disadvantage is it reduces the cardiac output.

The mechanism of action and advantages of PEEP

i. It helps to prevent the collapse of smaller airways and alveoli and also try to inflate the already collapsed alveoli.

Thus, it helps in the better participation of gas exchange. It reduces the dead space to tidal volume ratio.

ii. It prevents atelectasis as positive pressure is maintained at the end of expiration and increases the expiratory time.

iii. It gradually lowers the alveolar distending pressure due to more and more alveolar recruitment.

iv. It helps to improve the functional residual capacity.

v. It reduces the left to right shunt by increasing the pulmonary arterial pressure and PVR.

vi. It improves the V/Q ratio.

The disadvantages of PEEP

i. Increased levels of PEEP can cause barotrauma.

ii. If higher PEEP level is maintained, then it causes increased intrathoracic pressure. This high intrathoracic pressure, in turn, impedes the venous return and reduces cardiac output. So, PEEP should be maintained at a level balancing between the need for better oxygenation and the reduction of cardiac output.

iii. It decreases renal perfusion (from increased renal venous pressure).

iv. Since higher level of PEEP reduces the venous return, so it causes the increased intracranial pressure.

v. It increases hepatic congestion (from increased hepatic venous pressure).

vi. It worsens the right to left intracardiac shunts (Fig. 21.10).

Sometimes, in few circumstances positive airway pressure is developed automatically at the end of expiration. This is called auto-PEEP. Auto-PEEP is also known as the intrinsic PEEP. It occurs due to air trapping in the alveoli, caused by inadequate expiratory time due to high respiratory rate or severe airway obstruction with high expiratory airway resistance. The auto-PEEP means the presence of PEEP that is automatically created at the end of expiration due to any obstruction (spasm) in conducting part of airway or due to inadequate expiration for high respiratory rate. The difference between auto-PEEP and extrinsic PEEP is that in auto-PEEP there is peripheral airway closure first (due to airway spasm) resulting air trapping in alveoli and positive end expiratory pressure in alveoli. These trapped air does not help in gas exchange. But in extrinsic PEEP, which is created by machine artificially, airway pressure is maintained above the atmospheric level at the end of expiration and thus prevents the closure of peripheral airway and alveoli (with positive pressure in alveoli) which helps in gas exchange.

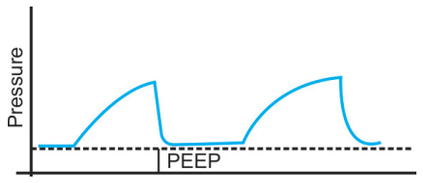

Fig. 21.10: Pressure - time curve shows PEEP in mechanical ventilation

Auto-PEEP is not reflected or detected in the ventilator manometer which will continue to show either zero (if extrinsic PEEP is not applied) or set PEEP level (if extrinsic PEEP is applied and in such case if auto-PEEP is again developed). To monitor the level of auto-PEEP, the expiratory port of ventilator should be occluded before the start of inspiration in next breath. Auto-PEEP can increase the work of breathing, since the patient has to overcome the auto-PEEP level to trigger the ventilator. It also more increases the intra thoracic pressures, leading to more reduction of venous return and cardiac output. Auto-PEEP can be eliminated or kept under control by increasing the expiratory time or by reducing the inspiratory time or by reducing the airway obstruction by bronchodilator.

In extrinsic PEEP, when used correctly, the peak airway pressure may significantly be less than the predicted sum of peak end inspiratory pressure measured prior to application of PEEP and positive airway pressure applied. If positive end expiratory airway pressure (PEEP) is applied in a situation where additional alveolar recruitment cannot or does not occur, then it can have detrimental effects on both haemodynamics and lung mechanics. A decrease in lung compliance still with the addition of PEEP indicates that additional gas exchanging units or alveoli are not being recruited and that the PEEP is unlikely to be of clinical benefit. The useful effect of PEEP is exhausted at about 15 cm of H_2O. At pressure exceeding 15 cm of H_2O, the alveolar diameter does not increase more with increasing PEEP level. The alveolar tissue cannot be stressed further by applying more and more high pressure, so that there is a danger of overdistension and alveolar rupture (barotrauma). This effect begins at the level of PEEP which is about 15 cm of H_2O. When addition of PEEP results in improvement in lung compliance and oxygenation, but a decrease in cardiac output, then it may be that the intravascular volume depletion is present. The PEEP level should be selected such that sufficient oxygenation is provided with FiO_2 not exceeding 0·6 (or 60%) and is most commonly employed when an $FiO_2 \geq 0{\cdot}5$ (50%) is needed for more than few hours to avoid hypoxia. During its application as PEEP is increased in small steps, titrated against the effect, similarly it should also be decreased slowly. Abrupt termination of PEEP therapy can result in pleural effusion, in addition to hypoxia. The extubation of patient is usually done at the PEEP level of 3 to 5 cm of H_2O, because 'physiological PEEP' is held at this level by the closure of the glottis.

Changing over from expiration to inspiration

Changing over of ventilation from expiration to inspiration needs some trigger factors which determine the start of inspiration after a period of expiration. This changing over is called trigger and is either determined by ventilator (ventilator triggered and can be preset) or by patient (patient

triggered). In a ventilator triggered breath, inspiration starts depending on the timing (time triggered), set on the ventilator by the clinician. Ventilator triggers inspiration after a preset duration of expiration or after a preset duration of the entire respiration (inspiration + expiration). This should not be confused with the time-cycled change over from inspiration to expiration (I → E = cycling, E → I = triggering). If the entire respiratory cycle is used for triggering, then any increase in the inspiratory time will lead to corresponding decrease in the expiratory time. This change may have a profound effect on inspiratory/expiratory ratio and results in auto-PEEP. In a ventilator triggered the time is preset (time triggered) and the patient is completely paralysed. There is no patient's effort to inspiration and this type of time trigger is used in CMV mode of ventilation. On the other hand, in patient triggered, the breath is initiated by the patient's effort and then immediately ventilator changes over from expiration to inspiration. Assisted ventilation provided by ventilator is not possible without patient triggering.

Patient triggered ventilation has the following advantages:

i. It reduces the duration of ventilatory support
ii. It reduces the weaning time
iii. It improves the level of blood gases
iv. It lowers the oxygen dependency.

Patient trigger mechanism are of various types, such as: Pressure triggering, flow triggering, chest wall impedence triggering and abdominal wall motion triggering. The last two patient triggering mechanisms are not commonly used. The two most common types of patient triggering mechanisms are: pressure triggering and flow triggering. Whereas in ventilator trigger, time triggering is the most commonly used mechanism.

Pressure triggering

The pressure triggering is used when the patient tries to take breath spontaneously. When the patient tries to take breath, then there is drop in the airway pressure. This drop in airway pressure is sensed by the ventilator and results in start of inspiration which is delivered by the ventilator. The trigger level on the ventilator is set as pressure unit of cm of H_2O. The ventilator continuously monitors and senses the airway pressure. For the ventilator to be triggered and deliver a breath, it is essential that the drop in airway pressure by the patient's own respiratory effort must exceed the set trigger or sensitivity level. If the pressure drop in the patient's airway which is transmitted to the ventilator's circuit is not sufficient enough, then the ventilator cannot sense it and will not be triggered to deliver a breath.

In the commercially available ventilators, the sites for pressure sensing are: (i) inside the ventilator, (ii) At the patient's airway (proximal triggering) or (iii) At the carina (distal triggering). The proximal and distal triggerings are more sensitive as compared to the drop of pressure being sensed inside the ventilator. The commonly used values for pressure triggering are in the range of −0·5 cm of H_2O to −3 cm of H_2O. It must be noted that the negative value indicates the drop in pressure below the zero or atmospheric level, when PEEP is not set. But, when PEEP is applied then this negative triggering pressure should be calculated from the set level of PEEP pressure. For example, if PEEP is set at +10 cm of H_2O and pressure trigger sensitivity is set at −3 cm of H_2O, then patient must generate a drop of pressure upto +7 cm of H_2O (10 − 3 = 7) from +10cm of H_2O to trigger the ventilation by ventilator.

The triggering sensitivity is referred to the negative pressure which is generated by the patient to stimulate the ventilator to deliver a breath. Trigger sensitivity is reduced means at more negative pressure, ventilator will be stimulated and this will increase the work of breathing of patient. On the other hand, trigger sensitivity is increased means at slight negative pressure, ventilator will be stimulated. When the trigger sensitivity is increased then as the ventilator delivers the breath at slight initiation of patient's effort to take breath, so the patient's capability of taking its own full breath will be diminished and wearing from ventilator will be delayed. If the trigger is set at maximum sensitivity level, then the ventilator will often perform at autocycle. So, the trigger should be set at such maximum sensitivity level that does not cause autocycling and usually this pressure is −0.5 to −3 cm of H_2O.

Flow triggering

In flow triggering, a continuous flow is present in the ventilator circuit during the expiratory phase. Due to continuous flow in the ventilator circuit during expiration, there is also a continuous flow at the exhalation valve. But when the patient makes a spontaneous effort for inspiration, then the flow is suddenly interrupted at the exhalation valve of the ventilator. Hence, the machine senses this interruption of flow and initiates a delivery of breath. For flow triggering to be functional, the anaesthetist needs to set a flow sensitivity setting in litres per minute. When the patient breaths spontaneously, the generated flow gradient must be higher than the flow trigger level, set by the clinician for the ventilator to sense and to initiate a breath delivery. The commonly used values of flow triggering are in the range of 0.6 to 4 litres per minute. In some ventilators, the trigger flow may need to be set, whereas in some ventilators there is a fixed preset flow to trigger the machine.

However, it is very important to note that triggering is not just a method, but rather the application of a method that affects the patient's work of breathing and ventilator synchrony. The trigger sensitivity setting must be optimized after proper assessing the patient's own ability to trigger. In the initial stages of the ventilatory support, the trigger must be set at more sensitive level. It means at less negative

value as for example −1 cm of H_2O for pressure triggering or 0.5 litre per minute for flow triggering. As the patient's condition improves, the trigger sensitivity should be decreased, because the patient will gradually try to take breath by himself.

Inspiratory/Expiratory Time Ratio (I : E)

The I : E ratio have an important effect on the removal of expired gases and on the mean intrathoracic pressure which again have an implication on oxygenation and cardiac output. Usually, an adequate time is required for the removal of expired gases without any air trapping. So, the expiratory time is greater than inspiratory time. Normally, the I:E ratio is about 1:2, i.e. the duration of expiration is twice than that of inspiration. It limits gas trapping and optimises the mean intrathoracic pressure. In obstructive lung disease, this I:E ratio is less than 1:2, i.e. the expiration becomes more prolonged than normal. In such circumstance there also occurs gas trapping due to spasm of peripheral airways and reduction of cardiac output. For volume cycled ventilators, I : E ratio can be achieved by adjusting V_T , respiratory rate and inspiratory flow rate. Whereas, in time cycled ventilators, the I : E ratio is adjusted by controlling the respiratory rate and inspiratory time.

While setting respiratory rate on ventilator for a spontaneously breathing patient the following points should be kept in mind; These are: (i) The patient's actual rate demand, (ii) The patient's anticipated ventilatory requirement, and (iii) The impact of rate setting on breathing time. The ventilators are not capable of varying inspiratory time and flow which is set by the operator. For example, with machine back up at a rate setting of 12 breaths / minute, the total cycle time (T_{Tot}) for each breath is 5 sec. If the I:E ratio is set at 1:2 or if V_T and flow have been set at 0·5 litre and 0·34 litre/sec, respectively, then T_I (inspiratory time) is fixed at 1·5 sec and expiratory time (T_E) will be 3·5 sec. If the patient actually triggers at 24 breaths/min, then T_{Tot} declines to 2.5 sec. T_I remains fixed at 1·5 sec, because it is determined by the preset machine (back up) rate, the I : E ratio or the inspiratory flow settings. The T_E must now decrease from 3·5 sec to 1 sec and the actual I:E ratio will increase from 1:2 to near about 2:1. At a rate of 40 breaths / min (T_{Tot} = 1.5 sec), T_E becomes '0' and then 'fighting with the ventilator' must result. For these reasons, the machine back up rate should always be set close to the patient's actual respiratory rate. If the actual respiratory rate initiated by patient is very high that effective ventilation cannot be achieved, then the patient needs additional sedation and possibly neuromuscular blockade.

Tidal volume (V_T)

It is generally accepted that V_T should be in the range of 10 to 15 ml/kg of body weight for most of the patients. Because small tidal volume (6 to 8 ml/kg) promotes the development of microatelectasis. While very large tidal volume can cause barotrauma and cardiovascular decompensation.

However, in some conditions such as obstructive lung disease, ARDS, etc; it is probably safer to choose a relatively low tidal volume (5 to 7 ml/kg) to avoid complications. While setting V_T, it is important to consider the role of compliance of the connecting tube of the ventilator circuit. This is approximately 3 to 4 ml/cm of H_2O during peak pressure. So, during inflation certain amount of tidal volume will not be delivered to the patient. But as the airway pressure falls and the tubes return to its original size, then this volume will be measured as exhaled volume, if a spirometer is attached on the expiratory limb of ventilator circuit.

Inspiratory flow

The inspiratory flow rate is the measurement of velocity at which the breathing gas is supplied to patient. It is an important determinant of patient's work of breathing. If the ventilator's inspiratory flow rate is chosen less than the patient's flow demand, then the patient will increase his inspiratory efforts in an attempt to improve his gas delivery. Thus, it will increase the patient's work of breathing. So, to minimize this work of breathing, the ventilator's inspiratory flow rate should be fixed above the patient's peak flow demand. On the other hand, if the inspiratory flow rate are very high during volume controlled ventilation, then it can lead to increased inspiratory peak pressure. Thus, over inflation of healthy lung leads to an impaired V/Q ratio and increased intrapulmonary shunt. So, a balance has to be reached. Constant flows of 60 to 70 litres/min are well tolerated in ventilator dependent patients and it does not manifest significant levels of auto-PEEP. Flow rates may require modification in certain circumstances such as COPD or asthma. Here higher flow rates (70-100 litres/min) are often used to shorten the inspiratory time and to lengthen the expiratory time. Thus, potentially it reduces the degree of auto-PEEP and hyperinflation.

Pressure control and pressure support ventilation can deliver the high initial flow rates. This may be advantageous for patients with high initial flow demands or those with severe lung disease and high minute ventilations.

FiO_2

FiO_2 should be selected as high as necessary to save the patient's life when emergency condition arised and as low as possible to prevent O_2 toxicity when patient's condition is stable. The increased inspired O_2 concentration to maintain P_aO_2 should always be understood as symptomatic treatment. In case of respiratory failure, it is common practice to initiate ventilatory support with an FiO_2 of 1 (i.e. 100% O_2). In such circumstance It is advised to ignore the potential for oxygen toxicity during the first few hours of ventilatory management

by 100% O_2. Then, it should be decreased gradually. One instance, where clinician must minimise FiO_2 at all costs, is a patient who has received bleomycin or amiodarone. Because, these drugs make the lungs extremely susceptible to injury (oxygen toxicity), mediated by O_2 radicals.

DIFFERENT MODES OF MECHANICAL VENTILATION

The mode of mechanical ventilation is defined as the configuration of flow, pressure and volume of gas which is delivered to the patient in a specific characteristic manner, coupled with cycling and triggering mechanisms. Thus, the ventilation mode also specifies the manner in which the ventilator breaths are controlled, cycled and triggered. The controlled factors are operator specified values, such as : airway pressure, volume and flow that cannot be exceeded during inspiration and expiration. If the specific values of any of the parameter are exceeded, then inspiratory flow is immeidately stopped and the ventilator circuit is vented to atmospheric pressure or to the specified PEEP value. Cycle refers to the factors that determine the end of inspiration and trigger defines what the ventilator senses to initate an inspiration.

The mode of ventilations are:

i. Controlled Mechanical Ventilation (CMV) − It may be of two types VCV or PCV.
ii. Assisted Mechanical Ventilation (AMV).
iii. Assist Control Mechanical Ventialtion (ACMV).
iv. Intermittent Mandatory Ventilation (IMV)
v. Synchronised Intermittent Mechanical Ventilation (SIMV).
vi. Positive End Expiratory Pressure (PEEP).
vii. Continuous Positive Airway Pressure (CPAP).
viii. Bilevel Positive Airway Pressure (Bi-PAP).
ix. Pressure Suport Ventilation.
x. Inverse Ratio Ventilation.
xi. Airway Pressure Release Ventilation (APRV)
xii. Spontaneous Ventilation.
xiii. Apnoea Back-up Ventilation.
xiv. Dual Mode Ventilation.

Controlled Mechanical Ventilation (CMV) – VCV or PCV

Here, all the breaths delivered to patient are totally controlled by the ventilator and ventilatory pattern is totally independent of patient's breathing effort. In CMV mode, the ventilator is totally nonresponsive to the patient's spontaneous respiratory efforts and requirements, still if the patient starts to take breath. So, CMV is usually used in totally paralyzed patient. If this mode is used in a partially paralysed patient or the patient starts to take breath spontaneously, then there will be a fight between ventilator and patient (i.e. breath stacking or starvation – anyone can occur). So, this mode is not useful for spontaneously (even slightly). In this controlled mode of ventilation, the breath is delivered to the patient by ventilator at a preset fixed respiratory rate and pattern (volume or pressure), determined by the ventilator controls. Here, every breath is time cycled and time triggered. For volume controlled breaths or ventilation (VCV), the set volume is delivered to the patient in the set inspiratory time, irrespective of the developed airway pressure which are determined by the lung mechanics. The fixed minute volume is totally controlled by the ventilator. Since, very high pressure (if it develops due to altered lung mechanics as pressure is dependent variable) can cause barotrauma. So, to ensure patient's safety the volume controlled ventilators should be equipped with a pressure release valve and high pressure alarm to alert the clinician. Whereas in pressure controlled breaths or ventilation (PCV) the set pressure plateau is maintained for the set inspiratory time for each breath. Like volume controlled ventilation, PCV is also time cycled and time triggered. During inspiratory phase, a given pressure is immediately imposed at the airway opening and this set pressure remains at this user specified level throughout the inspiration. Since, the inspiratory airway pressure is specified by the operator, so the tidal volume and inspiratory flow rate are dependent variables and are not user specified. PCV is the preferred mode of ventilation for neonates and infants and for patients with increased risk of barotrauma and for postoperative thoracic surgical patients in whom the shear forces across a fresh suture line should be limited. When using PCV, minute ventilation and tidal volume must be monitored by seeing the amount of gas delivered to ensure adequate ventilation (whereas in VCV airway pressure should be monitored). Inadequate or over adequate minute ventilation can be altered through changes in respiratory rate or through changes of the set pressure by pressure control knob (Fig. 21.11).

The PCV mode is used as a control mode with a normal I:E ratio or with increase I:E ratio. It could also be used in combination with PSV mode of ventilation. At present, the primary indication for PCV is ARDS patient to whom the conventional IPPV with PEEP is not effective, i.e. specifically those patients: Who are on an FiO_2 of 1, have a positive inspiratory pressure (PIP) of > 50 cm of H_2O, higher PEEP levels of > 15 cm of H_2O, higher assist control rates > 16 respiratory rate, have low PaO_2 and low lung compliance. Now a special form of CMV, i.e. the pressure regulated

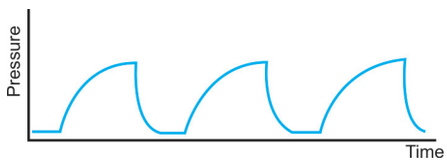

Fig. 21.11: Controlled mechanical ventilation (CMV) and time cycled

volume control mode (PRVC) of ventilation is available on many sophisticated ventilators. This mode has advantageous features of both the VCV and PCV mode of ventilation. It incorporates tidal volume as a servo parameter to ensure adequate volume delivery in PCV mode. Usually in our anaesthesia practice, we administer constant flow, pressure limited or regulated, volume controlled, time cycled ventilation that is often regulated up to 35 cm of H_2O to prevent barotrauma.

Some common indications for the use of CMV mode of ventilations are:

i. Neuromuscular paralysis – drug induced as in general anaesthesia (commonly the volume controlled ventilation), or neuromuscular pathology such as myasthenia gravis, paralytic poliomyelitis, etc.
ii. Prolonged apnoea.
iii. Severe central nervous system depression – such as high dose narcotic, brain trauma, spinal cord injury, etc.
iv. Postoperative patients with complete paralysis.
v. Patients who have fatigue of respiratory muscles and need for maximal rest of it.

Some complications or disadvantages associated with CMV mode are :

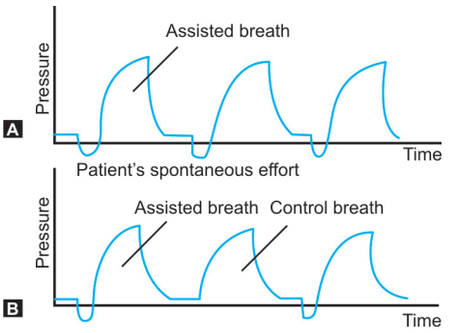
i. During incomplete paralysis as the patient's trigger efforts are not sensed and supported by the ventilator, so it can cause patient's discomfort and agitation during recovery.
ii. This CMV mode is unresponsive to the changing minute ventilation and airway pressure requirements of the patient.
iii. Total controlled mechanical ventilation for a longer period can inhibit the contraction of respiratory muscles which are then prone to atrophy. Because this mode is generally used in patients, who are fully paralyzed with muscle relaxants or in patients with poor or no spontaneous attempts to respiration. It is also used when the patient's respiratory drive is suppressed with heavy doses of narcotics and sedatives due to any reasons.

Assisted Mechanical Ventilation (AMV)

Here, every breath of patient is assisted by mechanical ventilator, but breath rate is completely controlled by the patient. Ventilator only supplements the patient initiated or triggered breath during changing over from expiration to inspiration (E → I). But initiation of expiration (I → E) is time cycled. The initiation of breath by ventilator (inspiration) occurs as a consequence of a sensing device which detects patient's initiated breath as a fall in airway pressure below the end expiratory pressure (pressure triggered). This amount of fall in patient's airway pressure required to trigger a breath by ventilator is reffered to as trigger sensitivity, which can be adjusted. So, for the proper functioning of this mode, it is essential to set optimum trigger level sensitivity, so that all the patient's efforts to inspiration are recognised by the ventilator. Thus, every recognised patient's effort is assisted by the ventilator, either by a volume controlled breath or by a pressure controlled breath. As this ventilatory mode is time cycled, so the spontaneous respiratory rate of the patient must exceeds the control back-up repiratory rate of ventilator or the ventilator's set respiratory rate should be kept below the patient's spontaneous effort rate. In this mode, ventilator does not respond to patient's apnoea, as there is no system for control or mandatory breath (Figs 21.12A and B).

Assist Control Mechanical Ventilation (ACMV)

Assist control mechanical ventilation is a combination mode where 'assist' refers to the ventilator's supplementation of patient initiated breaths and 'control' refers to the mandatory preset (back-up) ventilation when there is no patient's initiation of breath. An inspiratory cycle is initiated



Figs 21.12A and B: A. Assisted mechanical ventilation (AMV) B. Assist control mechanical ventilation (ACMV)

either by the patient's inspiratory effort or by the ventilator, if patient's effort is not detected within a specified time window by a timer signal. If the breath which is delivered by ventilator is due to the patient's spontaneous efforts, then it is called the assisted ventilation and if the breath delivery is due to the set respiratory rate in the ventilator in the presence of apnoea, then it is called the controlled ventilation. As every breath (assisted or controlled) is a mechanical breath, hence volume or pressure controlled delivery will be as per the ventilator's settings. It is important to set the proper trigger sensitivity and back up respiratory rate, matching with the patient for proper working of this mode. An insensitive trigger setting will inadvertently change the ACMV mode to CMV mode. If the spontaneous respiratory effort rate of the patient exceeds the control back-up rate, then no control breaths are delivered and the ventilator will function completely in assisted mode. However, if the patient's spontaneous effort is less than the control back up rate, then the volume or pressure control breaths will be provided at appropriate intervals. As compared to control mechanical ventilation mode (CMV), in patient with slight spontaneous efforts, this ACMV mode allows for better synchronomy between the patient and the machine. So, it can be applied to both awake, sedated or fully paralyzed unconcious patients. Since, it

has been shown that CMV mode used for more or less than 48 hours results in reduction in diaphragmatic muscle mass and a decrease in the diaphragmatic twitch tension, so it has been suggested that minimal amount of work is required to prevent the reductions in diaphragmatic strength and endurance. During ACMV mode with optimum ventilator settings, the load faced by the inspiratory muscles should not be enough to cause fatigue of the inspiratory muscles or respiratory distress, but should be sufficient enough to prevent muscle atrophy.

With assisted ventilation on optimal ventilator settings, the pressure-time product of inspiratory muscles which is the measure of work of breathing will be average 50% of that obtained during spontaneous breathing. While when SIMV mode is used as a primary mode of ventilation and SIMV rate is set such that 50% of the minute ventilations is delivered by the mechanical ventilator, then the pressure-time product per minute will be average 80% of the values obtained during spontaneous breathing. This workload may not be sustainable in many patient. Therefore, it is desirable to increase the level of ventilatory support, until the patient appears comfortable.

ACMV is the recommended mode for primary initiation of mechanical ventilation. Because, it ensures a back-up minute ventilation in the absence of an intact respiratory drive and also allows for synchronization of the ventilator cycle with the patient's inspiratory effort. However, it never allows the patient to take a full breath by himself (difference from SIMV). Problems can arise when ACMV is used in patients with tachypnoea due to nonrespiratory or nonmetabolic factors such as anxiety, pain, or airway irritation, etc. In such situation, respiratory alkalemia due to high respiratory rate (which is due to full ventilatory assistance for each patient initiated breath) and excessive washout of CO_2 may produce trigger myoclonous or seizures. Also COPD patients who are tachypnoic may develop auto-PEEP on ACMV mode of ventilation, with potential for barotrauma. Auto-PEEP also limits venous return, decreases cardiac output and increases airway pressure. ACMV mode is not effective for weaning the patients from mechanical ventilation, because it provides full ventilator assistance for each patient initiated breath.

Indications for use of ACMV mode are:

i. Patients who are earlier put on CMV mode for complete muscular paralysis or apnoea but now is gradually initiating spontaneous respiratory efforts.
ii. Patients who have own stable respiratory drive with any capability of triggering the ventilator.
iii. The ventilator should be set to achieve minimum 80% of the minute ventilation. This is a prove to be a good setting of the ACMV mode.
iv. Postoperative patients coming out of the effects of complete muscullar paralysis and anaesthesia.

Advantages of ACMV mode are:

i. Atrophy of respiratory muscles seen in CMV and AMV mode can be prevented in ACMV mode. This is due to the spontaneous efforts, being assisted and supported by the ventilator.
ii. It avoids patient agitation. This is because the patient can now get assisted ventilation for his or her spontaneous efforts from the ventilator.
iii. As the patient is allowed to control his or her respiratory rate, so the minute volume, and the P_aCO_2 of patient can be normalized.

Complications of ACMV mode are:

i. If the patient's respiratory rate increases in ACMV mode, then the auto-PEEP will develop. This will cause the mean intrathoracic pressure to increase, affecting the venous return and cardiac output.
ii. Increased respiratory rate will increase the minute volume and subsequently the mean alveolar presssure causing barotrauma.
iii. If the patient respiratory rate is high and is being assisted at higher rates, then it can result into hyperventilation causing hypocapnia and repiratory alkalosis.

Intermittent Mandatory Ventilation (IMV)

In IMV the ventilator delivers intermittent mandatory breaths in a predetermined pattern (volume or pressure controlled ventilation, time cycled with set respiratory rate) and allow the patient to breath spontaneously in between the mandatory breath. This mode is a combination of control mechanical ventilation mode (CMV) with a facility to support the patient's spontaneous efforts fully. The point where IMV differs from CMV is that in between the ventilator's breath, the breathing circuit is open and patient can breath fresh gas at his own rate and tidal volume. There is no option of synchronisation between the ventilator's breath and the patient's breath. All spontaneous breaths are fully patient's controlled or all controlled breaths are ventilator's control. So, ACMV = CMV + AMV (not a single full spontaneous breathing is allowed). But IMV = CMV + full patient's spontaneous breathing (not a single spontaneous breathing is assisted). In ACMV, all the ventilation is machine controlled, but some are triggered and some are not triggered. But, in IMV there is no trigger and all or none principle is followed (i.e. if patient breaths he will take the full breathe, otherwise machine will force him to take breathe).

'Breath stacking' is the major limitation of this IMV mode. This is because as the ventilator is allowed to deliver some mandatory breath, the rate of which is set by operator and the patient is also permitted to breath spontaneously, so at times it is seen that the patient is fighting with the ventilator. This is due to sometimes patient's

exhalation is superimposed by the ventilator's inspiration. Hence, the patient faces a high expiratory resistance which is called the 'breath stacking'. So, due to the problems of breath stacking, the IMV mode is now replaced with a mode which deliver the mandatory breath when necessary and synchronises the ventilator's breaths with patient's efforts, i.e. SIMV. IMV can be used as a full ventilatory support mode or as a weaning mode.

Advantages of IMV mode are:

i. Decreased requirement of sedation and muscle relaxation,
ii. Better ventilation to perfusion (V/Q) matching,
iii. Lower mean airway pressure,
iv. Avoidance of respiratory alkalosis,
v. Expediated weaning,
vi. Prevention of respiratory muscle atrophy or discoordination,
vii. Reduced likelihood of cardiac decompensation.

Disadvantages of IMV mode are:

i. Increased risk of CO_2 retention,
ii. Increased work of breathing and respiratory muscle fatigue,
iii. Stacking of breath.

Setting of this mode include: mandatory rate, mandatory tidal volume/minute volume, I:E ratio, trigger sensitivity, high and low pressure alarm, respiratory rate, tidal volume display.

Synchronised Intermittend Mandatory Ventilation (SIMV)

SIMV = CMV + AMV + patient's full spontaneous breathing or ACMV + patient's full spontaneous respiration. In SIMV mode the patient spontaneously breaths and intermittent ventilator's breaths are synchronised and if there is no spontaneous breath ventilator takes over the whole reponsibility producing mandatory ventilation (CMV). Synchronisation means ventilator waits for patient's spontaneous inspiration. If the inspiration is not sufficient enough (measured by triggered sensitivity), then machine assist the ventilation (AMV). In between CMV and AMV, patient takes full spontaneous respiration if he can. In SIMV, it is important to set an optimal trigger sensititivity level, so that the patient can have optimum amount of spontaneous respiration and this optimum amount of ventilation is assisted and the next optimum amount is fully controlled. So, to achieve this the ventilator must creates a timing window which divides the expiratory time into non-synchronisation interval and synchronization interval. Synchronisation interval is responsible for mandatory breath and nonsynchronisation interval is for assisted spontaneous breath. If the patient's spontaneous efforts occur in the synchronization interval, then the next schedule mandatory breath will be shifted accordingly and will be delivered as assisted ventilation to the patient in response to the patient trigger. In the absence of patient's effort during synchronization interval the mandatory breath is delivered as per the set breath rate interval. On the otherhand, any patient's effort in the nonsynchronization interval will result in a ventilator assisted breath which is completely patient controlled (Fig. 21.13).

The mandatory breaths, which are delivered to the patient will not exceed the set SIMV rate. Usually the mandatory rate in SIMV is set such that even if the patient has no spontaneous attempts, still adequate minute ventilation is delivered to the patient. Usually, a minimum rate of 8 to 10 breaths per minute with a tidal volume of 8 to 10 ml/kg is set for mandatory breaths. When the spontaneous attempts are rigorous and adequate, the patient is weaned off this mode.

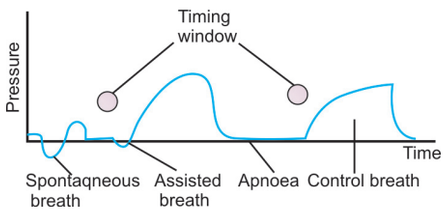


Fig. 21.13: Synchronised intermittent mandatory ventilation (SIMV), volume controlled

The major difference between SIMV and ACMV is that in former the patient is allowed fully to breathe spontaneously i.e without ventilator assistance, in between the delivered breaths by ventilator (assist or control). However, mandatory breaths are delivered in synchrony with the patient's inspiratory efforts at a frequency, determined by the operator. If the patient fails to initiate a breath, the ventilator delivers a fixed tidal volume breath and resets the internal timer for the next cycle of respiration. SIMV also differs from ACMV in that only the preset number of breaths is ventilator assisted.

SIMV allows patients with an intact respiratory drive to exercise inspiratory muscles in between the assisted breaths. This characteristic makes the SIMV a very useful mode of ventilation for both supporting and weaning of an intubated patient. SIMV may be difficult to use in patients with tachpnoea, because they may attempt to exhale during the ventilator programmed inspiratory cycle. When this occurs, then the airway pressure may exceed the inspiratory pressure limit, or the ventilator's assisted breath will be aborted or minute volume may drop below that programmed by the operator. In such setting, if tachypnoea occurs in response to the respiratory or metabolic acidosis, then a change to ACMV will increase minute ventilation and help to normalize the pH, while the underlying pathology is further evaluated.

Advantages of SIMV mode:

All the advantages and disadvantages of SIMV are like IMV mode of ventilation.
Advantages are:

i. It reduces the work of breathing,
ii. It lowers the mean airway pressure,
iii. It expediates weaning,
iv. It prevents respiratory muscle from atrophy, because the patient can breathe spontaneously,

v. It reduces ventilation – perfusion mismatch,
vi. It aviods breath stacking.

Limitations of SIMV mode

Sometimes, the mandatory respiratory rates which are set in the ventilator does not provide adequate minute ventilation, if the patient develops apnoea. In such circumstances, respiratory rates delivering lower than the adequate minute ventilation should be closely monitored. Otherwise, the ventilator is set with an appropriate apnoea back-up ventilation mode if available on the ventilator.

Mandatory Minute Ventilation (MMV)

This is also a servo contolled (i.e. feedback controlled) ventilation mode similar to SIMV. But, it differs from SIMV in that instead of predetermined respiratory rate (as in SIMV respiratory rate is preset), a predetermined fixed minimum amount of minute volume that the ventilator is bound to deliver to patient is the criteria for the mode of this mechanical breath. So, this mode of ventilation also can be called as SIMMV. Like SIMV, the MMV mode is also useful for spontaneously breathing patients. During MMV, the ventilator continuously measures the actual patient's spontaneous minute volume that he or she inhales and compares it with the clinician set minimum minute volume. If the patient's spontaneous minute ventilation goes below the set mandatory minute ventilation, then the ventilator automatically takes over the responsibility and the difference between the two volumes is then delivered as mandatory breaths by the ventilator. If the patient's spontaneous minute ventilation is higher than the set mandatory minute volume, then no ventilator breaths will be delivered.

MMV may be a useful method of ventilation for patients with fluctuations in ventilatory drive or who are being weaned from the mechanical ventilation. During weaning as the patient can contribute gradually more control over the spontaneous portion of the tidal volume, so the mandatory minute volume can be decreased automatically gradually. A good strategy of MMV mode is to set the MMV value as little as below the desired minute ventilation of the patient. If the patient experiences the apnoea episode, the ventilator automatically takes over the responsibility and delivers additional mandatory breaths. In some ventilators, MMV function is replaced by 'apnoea back up' mode which works on the criteria of low minute volume alarm limit.

The advantages of MMV is that it is useful in preventing hypoventilation and simultaneously permits complete spontaneous breathing. The disadvantages of MMV is that under distress the patient may have a breathing pattern of rapid respiratory rates and shallow tidal volume. This rapid breathing pattern of the patient may be identified by the ventilator as the predetermined minimum minute ventilation is met. Thus, this rapid shallow respiration causes inadequate alveolar ventilation and muscle fatigue.

Pressure Support Ventilation (PSV)

The pressure support ventilation combines the advantages of pressure control ventilation with spontaneous breathing. As the breathing is spontaneously maintained in PSV, so the patient himself determines the respiratory rate, inspiratory time and tidal volume. Each inspiratory effort of the patient is assisted by the ventilator at a preset level of inspiratory pressure. So, PSV is a patient triggered and pressure or flow cycled ventilation. Because as the chosen pressure is constant, so the flow decreases as more and more the lungs are filled (decelerating flow). Thus, when flow comes to zero against a certain elevated pressure, inspiration ends and expiration starts. Flow cycling forms the primary criteria for termination of breath in PSV. The other safety back up criteria are time and pressure. During PSV the inspiratory phase is terminated when inspiratory air flow falls below a certain level. In most ventilators this flow rate cannot be adjusted by the operator. If PSV is used, patient receives ventilatory help, only when the ventilator detects an inspiratory effort (patient triggered) (Fig. 21.14A and B).

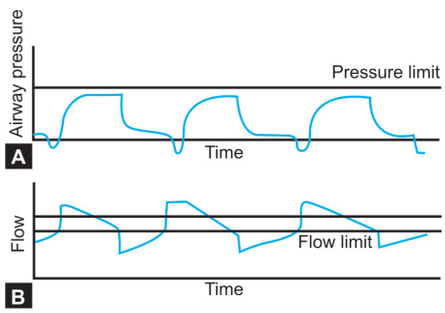
Thus patient initiates a pressure support when

i. There is fall in pressure of airway,
ii. The spontaneous inspiratory flow touches the value of certain limit (for example between 1to15 litre/min),
iii. The inhaled volume is less than 25 ml during spontaneous breathing.

PSV can be used as an independent mode or in combination with SIMV and CPAP modes. In combination with SIMV, it ensures volume cycled back up for patients whose respiratory drive is depressed, either spontaneously or as a result of various therapeutic manoeuvres.

The pressure support stops when

i The inspiratory flow goes back to zero or the patients actively exhales,
ii. The inspiratory flow goes below 25% of the maximum flow,
iii. Both the above criteria become inoperative or when the time of exhalation takes more than 4 seconds − a safety mechanism.



Figs 21.14A and B: Airway pressure and airway flow versus time during PSV. All the breaths are patient triggered and flow cycled. Inspiration is cycled off when the inspiratory flow drops below a predetermined threshold level which is internally set in the ventilation circuit

The advantages of PSV are:

i. Maximally reducing the work of breathing this mode enhances the patient's comfort on ventilator.
ii. Maximize patient's control on respiration.
iii. No haemodynamic consequences.
iv. With the change in work of breathing, pressure support can be adjusted (decreasing the level of pressure support during weaning and increasing the levels of pressure support when patient gradually deteriorates). Normally, to overcome the airway resistance (including the tubing system of ventilator, ET tube, etc.) a pressure suport of 5 to 10 cm of H_2O is required.
v. A preferred mode of weaning from mechanical ventilator. PSV is well tolerated by most of the patients who are being weaned. PSV parameters can be set in such a way that it can provide a full or a nearly full ventilatory support and can be withdrawn slowly over a period of days in a systemic fashion where gradually load is applied on the respiratory muscles.
vi. Provide an insight of the patient's repiratory status i.e. if patient is in the state of normal work of breathing (weaning) or not. For example, a patient with COPD, exhibiting good clinical status and normal gas exchange with normal pressure support (3 to 7 cm of H_2O) is a good candidate for tracheal extubation.

It is observed that addition of PSV mode to the spontaneous breathing pattern causes increase in tidal volume and decrease in respiratory rate. Increased tidal volume and decreased respiratory rate cause increased alveolar ventilation. Increased tidal volume (V_T) produces a decrease in the ratio between deadspace and tidal volume (V_D / V_T) and thus better gas exchange. Studies have demonstrated that addition of PEEP can increase the efficacy of PSV and much reduces the work of breathing in patients with COPD, presenting with intrinsic PEEP. So, combination of PSV with PEEP may be the optimum way to support the ventilation.

The limitations of PSV mode are :

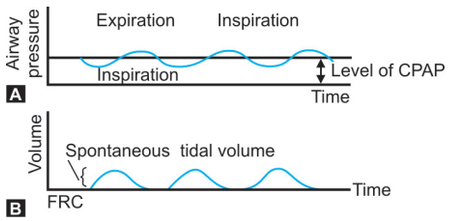
i. It is applied only to the patients who breath spontaneously.
ii. When high pressure support is needed then PSV mode is not good. Then, PCV is far better mode.
iii. As PSV is a flow-cycled ventilation, so if there is any circuit leak, then it causes continuous flow and continuous delivery of airway pressure, even during patient's spontaneous expiration. This can lead to severe haemodynamic compromise. Thus, autocycling caused by circuit leak allows inspiration to be triggered.
iv. With this mode, patient with unreliable inspiratory effort may receive inadequate ventilation.
v. High airway pressure, if there is high level of pressure support.

Continuous Positive Airway Pressure (CPAP)

Like PEEP, it is not a true mode of ventilation, because patient is already breathing spontaneously with full effort. The ventilator provides fresh gas flow to the breathing circuit during the whole cycle of respiration and produces in the circuit a constant operator specified pressure that can range from 0 to 25 cm of H_2O. Basically, CPAP is like PEEP (which is maintained only at the end of expiration), but it differs from later in that CPAP is applied continuously both during inspiration and expiration and only during spontaneous breathing. Unlike PEEP, CPAP cannot be applied during controlled ventilation, whereas PEEP can be applied both during controlled and spontaneous ventilation. CPAP can also be administered to the patient non invasively by using a mask attached to the patient's face with harness. It is also a popular weaning mode (Figs 21.15A and B).

Bi-Level (or Phasic) Positive Airway Pressure (BIPAP)

BIPAP is a unique ventilatory mode which covers the entire spectrum from complete mechanical ventilation to full spontaneous



Figs 21.15A and B: Airway presure and lung volume versus time profiles during CPAP. Breathing is spontaneous and no ventilator assist is provided. The spontaneous profile is superimposed on an elevated mean airway pressure that the user specifies

breathing. It is a variation of PCV, but differs from it that in BIPAP spontaneous breaths is possible. BIPAP ventilation indicates two levels of positive presure and thus it is named so. Among the two levels of positive pressure, one level is maintained during inspiration (inspiratory positive airway pressure – IPAP) and the other level is maintained during expiration (expiratory positive airway pressure – EPAP). IPAP is always greater than EPAP in BIPAP. But when IPAP is equal to EPAP it results in CPAP, otherwise EPAP is similar to PEEP. Patient can breathe spontaneously at both IPAP and EPAP. BIPAP is available on ventilators or as separate BIPAP machine. The various forms of BIPAP are classified according to the respective proportions of mechanical ventilation and spontaneous breathing present in it. These classification include:

i. There is no spontaneous breathing → CMV − BIPAP.
ii. There is spontaneous breathing at the upper pressure level →APRV − BIPAP.
iii. There is spontaneous breathing at the lower pressure level → IMV − BIPAP.
iv. Continuous spontaneous breathing, both equal pressure levels → CPAP.
v. There is spontaneous breathing at both the pressure level → Genuine BIPAP.

On a ventilator, BIPAP is possible by administering PCV (a type of CMV) in conjugation with PEEP or PSV in conjugation with CPAP. For the BIPAP mode, two levels of pressure and inspiratory – expiratory time have to be set. BIPAP mode also

can be used by noninvasive ventilation via a facemask.

This BIPAP mode is said to have a number of advantages over conventional modes of ventialtion. Because as EPAP is applied during expiration, so it enhances alveolar recruitment, improves functional residual capacity and oxygenation. On the otherhand, IPAP improves hypoxaemia and/or hypercapnia by imrpoving tidal volume delivery by pressure support or pressure control ventilation. Other advantages of BIPAP include: it allows spontaneous breathing, require less sedation, need higher inspiratory drive and reduce atelectasis (Fig. 21.16).

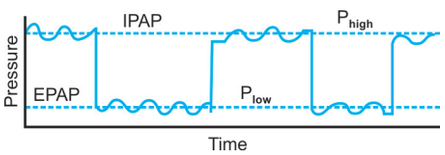


Fig. 21.16: Biphasic Positive Airway Pressure (BIPAP)

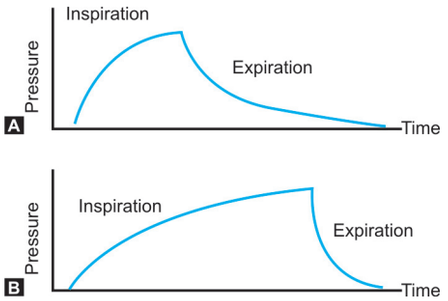
Inverse Ratio Ventilation (IRV)

During normal spontaneous respiration or in conventional mechanical ventilation, the inspiratory time is lesser than the expiratory time, i.e. I:E ratio is ≤ 1(1:1 to 1:4). But, IRV refers to a special type of mechanical ventilation in which the I:E ratio is set to greater than one (i.e I:R is ≥ 1 which varies between 1:1 to 4:1). By increasing this ratio to more than one, inspiratory time is made to prolonge and expiratory time is made to reduce. When IRV is used in conjunction with PCV or VCV, it is called as PC − IRV or VC − IRV (Figs 21.17A and B).

There are certain advantages after increasing the inspiratory time than expiratory. These advantages are:

i. Increase in inspiratory time causes increase in mean airway pressure (MAP), but without increasing the peak airway pressure, despite a constant tidal volume and PEEP level. This helps to open the collapsed alveoli. Within a certain range of increased MAP, there is a direct linear relationship between MAP and oxygenation.



Figs 21.17A and B: Inverse ratio ventilation (IRV).
A. Normal ins : exp ratio
B. Inverse ins : exp ratio

ii. In poorly compliant lungs such as ARDS, acute lung infections, etc. the alveoli are become of long 'time constant' (i.e. slow alveoli). It means they require longer inspiratory time for full inflation which is not possible by standard duration of inspiration during conventional ventilation. So, prolonged inspiratory time in such circumstances sustains the alveolar inflation and improves alveolar ventilation. This also decreases the dead space in diseased lung (V_D / V_T is reduced) and improves the oxygentation with better matching of ventilation – perfusion ratio.

The decrease in expiratory time also has certain effects. Due to the reduction of expiratory time, tidal volume cannot be expired completely, so intrinsic PEEP or auto – PEEP develops. This intrinsic PEEP also avoids the end-expiratory alveolar collapse of the slower lung compartments which give rise to an increase in FRC, increase in gas exchange area, and reduction of the intrapulmonary R to L shunt. Intrinsic or auto-PEEP has its own disadvantages, but here only the advantageous part is taken into account. It is important to say that IRV (or auto PEEP) is not a substitude for extrinsic – PEEP. The extrinsic PEEP is very important. It helps for the stability of those faster alveoli that empty completely under IRV. Also the effect of external PEEP is additive to the effect of internal PEEP and helps for a damaged lung compartment.

In PCV and VCV in conjunction with IRV (PC-IRV and VC-IRV), inspiratory time can be extended or modified by :

i. Applying an end – inspiratory pause,
ii. Decreasing the inspiratory flow rate,
iii. Changing from a constant to a decelerating flow pattern. The inspiratory flow during PCV is initially high. Then it decreases gradually as the alveolar pressure rises with lung inflation. This decelerating inspiratory flow pattern results in a better distribution of ventilation. It is also associated with increased MAP for any given tidal volume, inspiratory time and improved gas exchange.

Methods of setting IRV :

i. The IRV is likely to be most effective only during early period in the course of development of ARDS, when the recruitable lung units are still there.
ii. The decision of IRV is to be taken, only when the patient is unable to be properly oxygenated at acceptable levles of PEEP, FiO_2 and peak alveolar pressure on conventional PCV or VCV with CMV or ACMV mode of ventilation.
iii. The arrangement for extensive monitoring should be started including blood gas analysis, CVP, arterial line, etc.
iv. Deep sedation and neuromuscular paralysis should be added to prevent dys-synchronous breathing, to enhance comfort and to allow the measurement of MAP which reflect the lung distension.
v. If patient is already in VCV, then as a first step to change over to VC–IRV from VCV constant flow should be changed to decelerting flow. This will approximate the inspiratory flow pattern of PCV with its possible gas exchange advantages. In many ventilators, this will decrease the mean inspiratory flow rate, extend the inspiratory time and increase the MAP.

Airway Pressure Release Ventilation (APRV)

APRV is a new ventilatory mode and is not well understood till now. Presently only one ventilator (Drager Evita) can provide this APRV mode of ventilation. In this mode the patient is allowed to breath spontaneously during which high CPAP is applied. It is used on patients with decreased lung compliance such as ARDS, ALI (Acute Lung Injury), etc and on those patients who had decreased FRC. This is because in APRV mode air way pressure is much lower than conventional ventilatory mode if the conventional modes are applied in such pathological conditions of lungs. This mode should not be used on patients with high airway resistance (such as in bronchospasm), because success of this mode depends on rapid increase and decrease in airway pressure and rapid emptying of the lungs (Fig. 21.18).

Airway pressure release ventilation is nothing but a CPAP mode at high pressure level in which release valve is opened for a short time (1 to 2 second). When the release valve is opened for short time (automatically at a set pressure level), the high ventilatory CPAP pressure comes to a lower level (or zero) allowing lungs to exhale. Thus, the APRV breaths dance between the high and low CPAP levels. The gas delivery to the patient depends on the pressure gradient, patient's lung compliance and airway resistance.

The, APRV combines the features of CPAP and PCV mode. In this mode, the inspiratory flow valve is opened throughout the ventilatory cycle such that the patient is allowed to breathe spontaneously at any point during the high CPAP breathe. Through short pressure release, expiration and CO_2 elimination is ensured and again it return to the original CPAP levels which provides mechanical inspiration. If the patient is not breathing spontaneously, PC-IRV and APRV are indistinguishable.

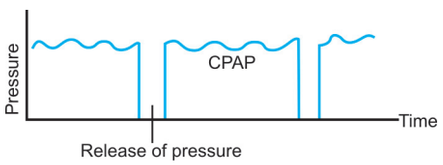


Fig. 21.18: Airway pressure release ventilation (APRV)

Apnoea Back-up Ventilation

This mode of ventilation provides mandatory breaths when the patient suddenly goes in apnoea due to any cause. So this mode of ventilation is also known as the safety mode, because it provides a mandatory ventilatory support during unpredicted apnoea. It is used in combination with all the modes and especially with SIMV and CPAP for spontaneously breathing patients. In completely controlled mode such as CMV, patient is automatically aponeic and thus this mode is not needed. So, apnoea back-up ventilation mode must be set for spontaneously breathing patients. The ventilators monitor the time period continuously during which the patient is taking the spontaneous breathing and/or there is sufficient inspiratory mandatory minute volume (MMV). When either of the criteria is violated, then the ventilator immediately starts delivering mandatory breaths to the patient. This will continue still the patient resumes spontaneous breathing and/or there is an increase in the inspiratory minute volume. In some ventilators this mode needs to be set, while in others it is automatically set.

Dual Control Mode (Dual Mode Ventilation)

It is one of the newer mode of ventilation and provides the advantages of both volume control and pressure control or pressure support ventilation. As it is a volume controlled, so ventilation guarantees the calculated volume delivery and also as it is pressure controlled ventilation, so also, it provides fine control over the distending pressure. It also provides more patient and ventilator flow synchrony for spontaneously breathing patient. Hence, combination of both the volume and pressure control can offer better ventilation solution to the patient. Even though it is called the dual control, still the ventilator actually controls either pressure or volume, but not both at the same time. In this mode, the target volume is set and the maximum pressure limit is also set. The ventilator automatically makes changes the pressure level breath by breath, but within a limit (set by the clinician) to achieve the target volume at the least possible pressure. It offers a full ventilatory support in the form of mandatory breaths, when needed and also it offers partial ventilatory support in the form of spontaneous breath. Actually the dual control mode is a volume target and pressure control (VTPC) mode (Dual Control = Volume Target + Pressure Control).

Dual control mode may be of three types:

i. Volume targeted pressure control and ACMV − Here breaths are patient or time triggered, time cycled, volume targeted and pressure control.
ii. Volume targeted pressure support − Here all the spontaneous breaths are supported by the ventilator. The breaths are patient triggered, volume targeted, pressure supported and flow or pressure or time cycled.
iii. Volume targeted pressure control and SIMV − Here the user sets a number of time or patient triggered mandatory breaths which are volume targeted and pressure control. In between the mandatory breath, there are also spontaneous breaths which are also volume targeted and pressure supported.

The advantages of dual control mode are :

i. Better ventilator and patient synchrony.
ii. Reduces the need for sedation.
iii. Keeping distending pressure under control this mode assures delivery of adequate tidal volume.

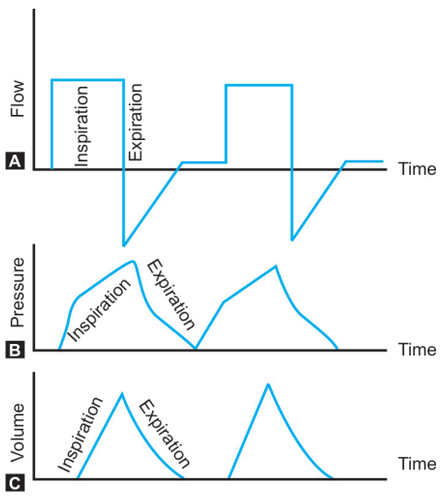
iv. Reduces work of breathing.
v. Helps quicker weaning.

WAVEFORM IN MECHANICAL VENTILATION

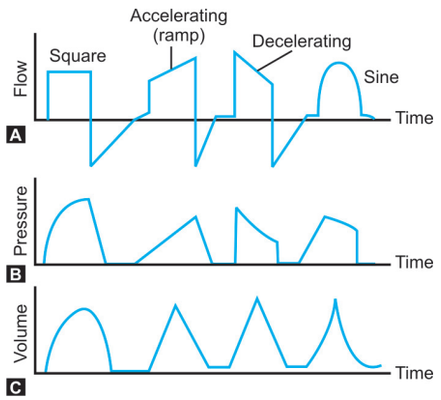
To optimise the mechanical ventilation, proper monitoring of four parameters of it is essential. These four parameters of ventilation are: Pressure, flow, volume and time. The real time graphic displays of these parameters as waveform and loop on the ventilator front panel offers the clinician to evaluate the adequacy of ventilator settings and to monitor the patient's response to ventilator therapy. So, the all newer mechanical ventilators are now equipped with a graphic package that displays many selected (by clinician) ventilator waveforms and loops, facilatating assessment of the patient's condition (Fig. 21.19A to C).

Any single variable parameter, displayed against time is known as the waveform graphic. When viewing the waveform graphics which is also called 'scalar', the time is conventionally shown on the horizontal (X) axis, whereas the the flow, volume and pressure are plotted on the vertical (Y) axis. Therefore, there are three main waveforms: Flow vs Time, Pressure vs Time and Volume vs Time and each waveform has its own characteristic which is shown in (Fig 21.19). Flow itself is again of four patterns: Square (constant), accelerating, decelerating and sine. Therefore, the pressure and volume waveforms also differ for each flow pattern which is also shown in figure (Figs 21.20A to C).

There are two graphic displays in loops: pressure–volume loop and flow-volume loop. Loops are the two dimensional graphic display of two parameters. When the pressure-volume loop is viewed, the horizontal (x) axis is used to indicate the pressure (in cm of H_2O) and volume (in ml) is displayed on the vertical (Y) axis. On the other hand, when viewing the flow-volume loop, then the horizontal (X) axis is used to indicate the volume, whereas the flow is displayed on the vertical (Y) axis. In vertical flow axis the inspiratory curve is plotted above the baseline and the expiratory curve is traced below the baseline. However, it is not unusual to see a completely reverse pattern where the inspiratory component is presented below the baseline (Figs 21.21 and 21.22).



Figs 21.19A to C: The typical flow-time, pressure-time and volume-time waveform. Among these only the flow-time waveform has negative deflection below the baseline and helps in proper interpretation of expiration. These waveforms also differ during mechanical and spontaneous ventilation, during volume controlled and pressure-controlled ventilation, and during different flow patterns



Figs 21.20A to C: Flow time, pressure-time, and volume-time waveform which corresponds with different flow patterns, during mechanical (not spontaneous) volume controlled, time cycled ventilation

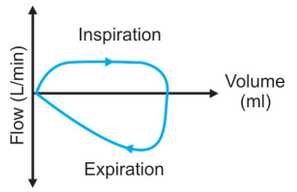


Fig. 21.21: Flow-volume loop

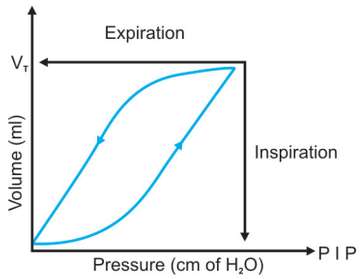

Fig. 21.22: Pressure-volume loop

Flow-Time Waveform

This waveform shows the gradual changes in flow during inspiration and expiration with time. In the graph, time is represented by the horizontal X-axis (in second) and the flow is represented by the vertical Y-axis (in litres per minute). The flow above the X-axis represents inspiratory flow and the flow below the X-axis represents the expiratory flow. Commonly, the two types of flows are used in clinical practice: constant or square flow and decelerating flow. The constant or square waveform of flow is the characteristic of volume controlled ventilation, whereas the decelerating waveform of flow is the characteristic of pressure controlled ventilation. However, most of the ventilator allow a clinician to select a specific flow pattern that is most suitable to the patient. Flow time waveform is similar for both mechanical and spontaneous breath. The flow time curve for a spontaneous breath resembles a sine waveflow pattern.

In the constant flow (a typical feature of classic volume-controlled ventilation), the flow rate during inspirations remains constant throughout the inspiratory phase. At the start of the inspiration, the flow quickly rises to the set value and then remains constant until the set tidal volume has been delivered (square area of the

curve). Then the flow rapidly falls to zero level at the begining of the pause time. At the end of the pause time, the expiratory flow begins, the course of which depends on the resistances in the ventilator system and on the parameters of lungs and airways (Fig. 21.23).

In decelerating flow (a typical feature of pressure controlled ventilation mode), the flow falls constantly after having reached an initial high value. This is because as the filling volume in the lungs increases, the pressure in the lungs also rises and flow starts to fall. Then at the end of inspiration the pressure in the lung is equal to the pressure in the breathing system, so there is no further flow.

In flow-time wave graphic, the tracing below the baseline, representing the expiratory flow is significant, because it shows the lung's characteristic and the airway resistance. Moreover, only the flow-time waveform demonstrates a significant tracing below the baseline. The other waveforms stay above the baseline except pressure-time waveform where a very small deflection occurs below the baseline when the patient initiates inspiration spontaneously.

Components of Flow-time Waveform

The square form of a flow time wave pattern will be used here throughout this discussion to identify the each component of graph during the inspiratory and expiratory phase of a mechanical volume controlled ventilation. Component 1 consists of initiation of flow at the beginning of inspiration. At this time, the exhalation valve is closed to permit a mechanical breath which deliver a preset volume to the patient's lungs. In second component, the peak inspiratory flow rate (PIFR) level is reached instantaneously by constant flow pattern. The flow remains at this constant peak level until the inspiration is terminated. The third component consists of the end of delivery of inspiratory flow and begining of expiration. This event occurs after the preset tidal volume is delivered. At this time the exhalation valve opens to allow for passive exhalation.

The expiration component of flow-time waveform, whether from mechanical or spontaneous breath, is generally a passive maneuver. After the end of inspiration expiratory flows reach their peak value instantaneously and then gradually return to the baseline. Usually, there is no gap between the end of inspiratory flow and the start of expiratory flow. In normal flow-time waveform, the transition from the inspiratory phase to the expiratory phase is smooth and there is no time interval. The components of expiratory flow are: Initiation of expiration, peak expiratory flow rate (PEFR) and duration of expiratory flow (or expiratory time T_E).

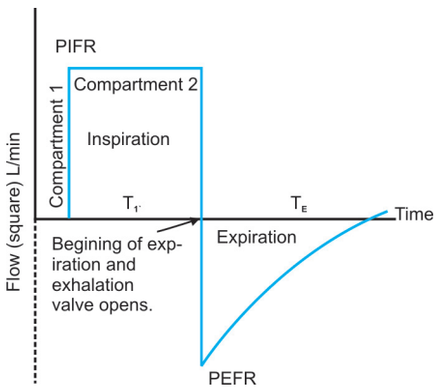

Fig. 21.23: Flow-time waveform (square pattern) in volume control ventilation. T_I = Inspiratory time, T_E = Expiratory time

Recognition of Common Abnormalities of Flow-time Waveform

The flow-time waveform helps in recognising of certain respiratory disorders. Different lung disorders show different flow time patterns. The common abnormalities are asynchrony between the ventilator and the patient, incorrect setting of inspiratory time, auto-PEEP and airway obstruction.

Asynchrony

If there is a dip in the inspiratory flow plateau, it suggests asynchrony. Asynchrony occurs when the patient's demand is more than the set ventilator's flow rate. This condition can be corrected by: increasing the inspiratory flow, adjusting ventilator's trigger sensitivity or changing the mode of ventilation according to the patient's demand (Fig. 21.24).

Incorrect inspiratory time setting

Incorrect inspiratory time setting is recognised by time interval between the end of inspiratory flow and the start of expiratory flow which is not present in the normal flow-time waveform, where the transition from inspiration to expiration is smooth. This can be corrected by: increasing the set inspiratory time and increasing the flow rate. If inspiratory time is set very short, then the inspiratory flow is suddenly stopped due to start of expiratory flow. Compare this with a smooth transition from inspiratory phase to expiratory phase in normal condition. This short inspiratory phase can be corrected by increasing the inspiratory time (Figs 21.25A and B).

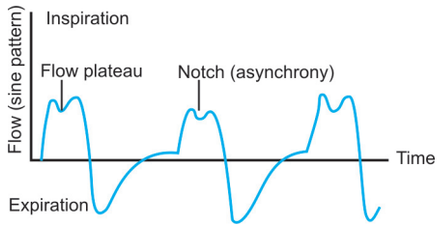

Fig. 21.24: Flow-time waveform (sine pattern) shows asynchrony between the ventilator and the patient. In normal flow-time waveform the flow plateau is smooth and no notch indicates adequate flow

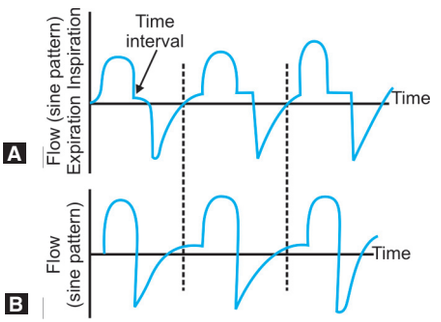


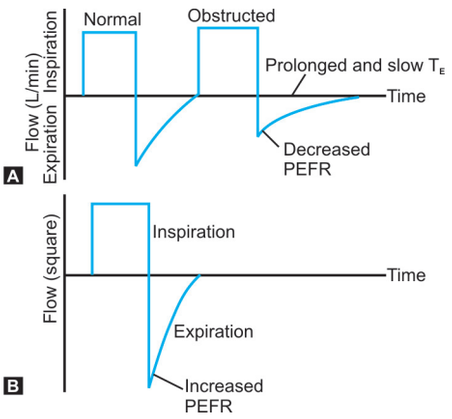
Figs 21.25A and B: A. Incorrect inspiratory time setting in flow-time waveform (sine pattern). B. Rectification has been done

Airway obstruction and active exhalation

Exhalation is normally passive. The expiratory flow pattern and PEFR depend upon the changes in patient's lung compliance, airway resistance, as well as patient's active efforts to exhale. Increased airway resistance due to bronchospasm or accumulation of secretions in the airway may result in decreased PEFR (peak expiratory flow rate) and a prolonged expiratory flow (T_E). If the patient begins to exhale actively using accessory expiratory muscles, this may result in an increase in PEFR and a shorter duration of expiratory flow. Flow waveform can also verify the clinically suspected bronchoconstriction. In such cases, the PEFR is reduced and the expiratory flow returns to the baseline very slowly. Administration of bronchodilator improves PEFR and allows for an expiratory flow to return to the baseline within normal time period (Figs 21.26A and B).

Airtrapping or auto-PEEP

Normally, the expiratory flow returns to baseline prior to the next breath. In the event, when the patient is unable to exhel completely leading to air trapping in alveoli, then the expiratory flow does not return to zero level or baseline and the subsequent inspiration begins below the baseline. It indicates insufficient expiration and the presence of auto-PEEP. The presence of auto-PEEP or airtrapping may result from: inadequate expiratory time, too high respiratory rate, long inspiratory time, and prolonged exhalation due to bronchoconstriction. Even though the auto-PEEP is best detected from the flow time waveform, but its magnitude is not directly measured from this graphic. A higher inspiratory flow rate (in volume cycled ventilators) or short T_I (in time-cycled ventilators) allows for a longer T_E and may eliminate auto-PEEP. Auto-PEEP can also be eliminated by increasing the PEEP level and bronchodilator therapy (Fig. 21.27).



Figs 21.26A and B: A. Flow-time waveform (square pattern) normal and obstructed, B. Response to bronchodilator, it has the same effect like active exhalation

Pressure-time Waveform

This waveform shows the gradual changes in airway pressure with time. In typical pressure-time waveform, the horizontal X-axis represents time in seconds and the vertical Y-axis represents the changes in pressure of airway in cm of H_2O. During mechanical ventilation, the inspiratory prssure rises in an upward direction above the baseline, while the expiratory pressure returns to baseline level. But, during spontaneous breathing, the inspiratory pressure moves in the downward direction below the baseline, while the expiratory pressure rises above the baseline at the start of expiration and then returns to baseline again. Thus, this pressure-time waveform during spontaneous ventilation is not same as that of controlled ventilation. Again in controlled ventilation pressure-time waveform differs in volume controlled and pressure controlled ventilation. In volume controlled ventilation, the pressure-time waveform again changes according to the flow of pattern, such as constant (square), declerating, accelerating and sine.

A typical pressure vs time waveform in volume controlled ventilation (with constant or square flow) is shown in figure. Here, the inspiration starts at point 1. At the begining of inspiration, the pressure between the points 1 and 2 increases instantly due to the resistances in system. The level of the pressure at point 2 is equivalent to the product of resistance and flow. After point 2, the pressure increases further gradually in straight line till the point 3 (Fig. 21.28) is reached (the peak pressure point). At point 3, the peak or maximum pressure is called the peak inspiratory pressure (PIP). The gradient of this curve is dependent on the inspiratory flow, airway resistance and the overall compliance of the lungs. Increased airway resistance (Raw) and/or decreased lung compliance result in an increased PIP. Up to point 3, the ventilator applies the set tidal volume and thereafter no further flow is delivered. So as there is no flow at this point (point 3), the pressure level quickly falls to the plateau pressure (point

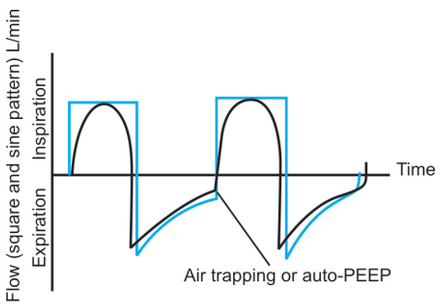


Fig. 21.27: Flow-time waveform (square pattern-red line and sine pattern - green line) showing air trapping

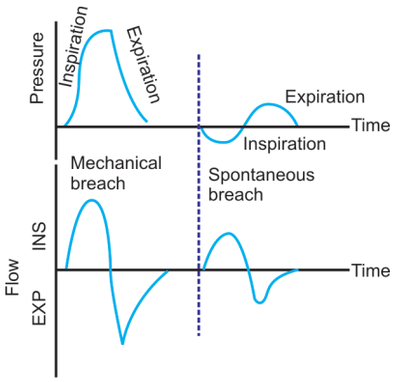

Fig. 21.28: Typical pressure - time waveform with corresponding flow - time waveform

4). This drop in pressure is equivalent to the rise in pressure, caused by the resistance at the beginning of inspiration and finally shows the compliance of lungs. After that there may be slight decrease in pressure between the points 4 and 5. The possible reasons for this drop is more and more recruitment of lungs and leaks in the system. The plateau pressure level is dependent on the compliance of lung and tidal volume. During the plateau time, no volume of air is supplied to the lung and the inspiratory flow comes to zero. At the point 4 passive expiration begins due to elastic recoil of thoracic wall and lungs. PEEP can be confirmed only by a pressure-time waveform and pressure volume loop. PEEP is present only when the baseline pressure remains above zero. The pressure-time waveform also varies with the triggering mechanism of the mechanical breath. If the breaths are initiated at the baseline at fixed intervals, the mode is definitely time tirggered and a control mode. In an assisted mode, the patient initiates the breath by generating a negative pressure. This event can be observed on the pressure-time waveform where a small negative deflection below the baseline precedes a mechanical breath. The ventilator sensor recognizes the patient's effort and delivers a mechanical breath (Fig. 21.29).

Although the dynamic mechanics of lungs can be observed from this pressure-time waveform, still the addition of an inspiratory pause provides some more information to calculate the static mechanics. For example the plateau pressure (P_{Plat}) or alveolar pressure is obtained by the activation of an inspiratory pause control knob which can produce a pause. During this manoeuvre the exhalation valve is kept in a closed position and the volume is held constant in the lungs for a moment. For clinical purposes, the plateau pressure is the same as the alveolar pressure at the end of inspiration. This measurement provides a means of measuring the static lung compliance. The transairway pressure which can be calculated by deducting the plateau pressure from the peak inspiratory pressure ($P_{TA} = PIP - P_{Plat}$) reflects the pressure required to overcome the airway resistance. In bronchospasm, the pressure required to overcome the recoiling force (lung compliance) can be determined. The static lung compliance can be obtained by dividing the volume of the lung by the plateau pressure minus (See Fig. 21.7) PEEP, if present (Fig. 21.30).

In pressure controlled ventilation, the pressure-time waveform has a different shape. Pressure increases rapidly from the lower pressure until it reaches the upper pressure level and then remain constant for the set inspiratory time. The drop in pressure during the expiratory phase follows the same curve as in volume controlled ventilation.

The pressure-time waveform is useful in :

i. Evaluating the peak inspiratory pressure (PIP),
ii. Determining the PEEP or CPAP level,
iii. Setting the ventilator trigger sensitivity levels,
iv. Indicating the changes in airway resistance and lung compliance.

Recognition of common abnormalities

From the diagnostic point of view some changes in the pressure-time curve have profound clinical significance. The common abnormalities which are found in the clinical practice in pressure time waveform during volume controlled ventilation are described below:

i. The large negative movement below the baseline of a pressure-time waveform in mechanical ventilation indicates excessive trigger work. It increases patient's work of breathing, because patient needs to do excessive work to trigger the ventilator to deliver a breath. This condition can be corrected by adjusting the trigger sensitivity setting in such a manner that the ventilator is made more sensitive to the patient's effort and thus reduces the work. But, during recovery the trigger sensitivity is reduced gradually to increase the work of breathing which helps in weaning (Fig. 21.31).
ii. In normal pressure-time waveform the peak pressure is achieved quickly and then a plateau pressure is maintained steadily. Failure to maintain a steady plateau pressure with a notch indicates a leak or an inability to deliver the required flow. This condition can be corrected by identifying and rectifying the leak in ET−tube or in ventilator circuit or by increasing the inspiratory flow (Fig. 21.32).
iii. The changes in the inspiratory airway resistance is also indicated in pressure-time curve by the increase or decrease

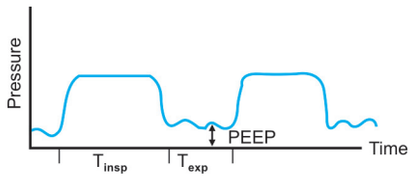

Fig. 21.30: Pressure-time waveform in pressure controlled ventilation

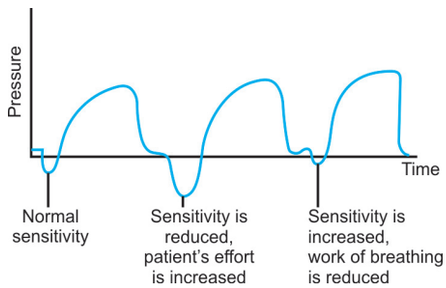

Fig. 21.31: Pressure-time waveform (when flow-time is sine pattern) shows different trigger sensitivity

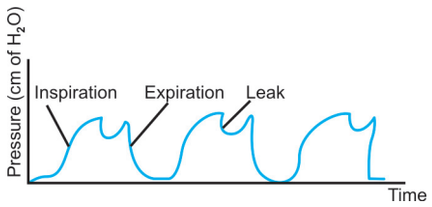

Fig. 21.32: Pressure-time waveform (with flow-time sine pattern) shows leak as peak inspiratory pressure level is not maintained

of peak pressure level, but without changes in the plateau pressure level. If the peak pressure increases with no change in the plateau pressure, then it indicates an increased airway resistance (R_{Aw}) and vice versa. The difference between the peak pressure and the plateau pressure indicates the pressure required to overcome the airway resistance (Fig. 21.33).

iv. The total pressure generated at the airway during mechanical ventilation is comprised of two components: (a) Pressure required to distend the respiratory system (lung) which is determined by the compliance and (b) The pressure required to overcome the airway resistance through natural and artificial airways. In peak pressure, gas is delivered to the alveoli and the lung is held inflated at that end inspiratory volume. Thus peak inspiratory pressure indicates the both airway resistance and compliance of lungs and thorax. Whereas the plateau pressure indicates the alveolar distending pressure only, i.e. the pressure required to distend the chest wall and lungs (compliance) (Fig. 21.34).

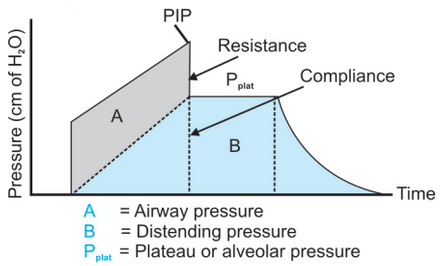

Fig. 21.33: This normal pressure - time waveform shows different components of inflation pressure

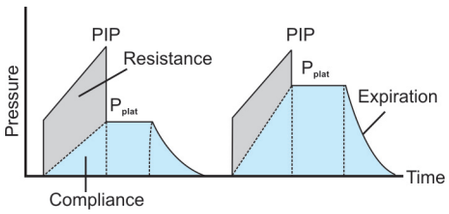

Fig. 21.34: Pressure-time waveform, increased resistance and decreased compliance

So, peak inspiratory pressure (PIP) = Resistance + Compliance and plateau Pressure = Compliance.

Thus, if the peak pressure and the plateau pressure both increase or decrease in same direction, then it reflects the changes in lung compliance. If both the pressure increase in a similar proportions simultaneously, then it indicates decrease in lung compliance and vice versa (in increased airway resistance only peak pressure increases).

v. When the pressure does not return to baseline before the next inspiration, then it indicates that expiratory time is inadequate (inspiration starts before completion of expiration) or PEEP is applied. If expiratory time is not adequate, then it can be corrected by increasing the expiratory time.

vi. During volume controlled ventilation, in the inspiration the rate of rise of pressure (slope) is related to the peak inspiratory flow settings and can be used to adjust the peak flow rates. Inadequate flow rate is indicated when the pressure rises (slope) very slowly, or sometimes is indicated when there is a depression in the inspiratory limb of the pressure contour (Fig. 21.35).

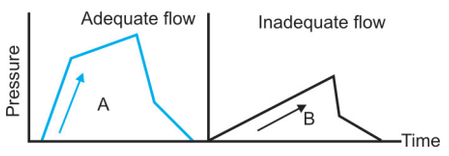

Fig. 21.35: Pressure-time waveform (volume controlled) with adequate (A) and inadequate inspiratory flow (B)

vii. High flow rate also can be determined by pressure-time waveform. It is indicated by shorter inspiratory time than normal.

Volume-time Waveform

This waveform shows the gradual changes in the volume, transferred to the lungs during the inspiratory and expiratory phase of respiration. In a mechanical ventilator the total inspiratory volume is derived from the integration of flow over time. In this waveform, the horizontal X-axis represents time in seconds and the vertical Y-axis represents volume in cubic centimetres (cc). During the phase of inspiratory flow, the volume increases continuously. Then during the pause it remains constant and next during expiration the transferred volume decreases as a result of passive (Fig. 21.36) exhalation. The volume-time waveform for mechanical and spontaneous breath are similar in pattern. Again the volume-time waveform in mechanical volume controlled and pressure controlled ventilation are more or less is same. Information obtained from this volume-time waveform includes: A visual representation of inspiratory time, tidal volume, inspiratory pause, expiratory phase and expiratory time (Figs 21.37A and B).

Interpretation

i. If the expiratory volume tracing does not return to the baseline at the end of expiration, then it indicates the leaks in endotracheal tube or at any place in the ventilator breathing circuit. By the graphic pattern the site of leak can be

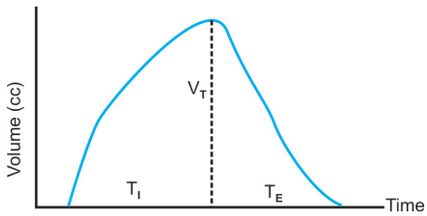

Fig. 21.36: Volume - time waveform without any inspiratory pause

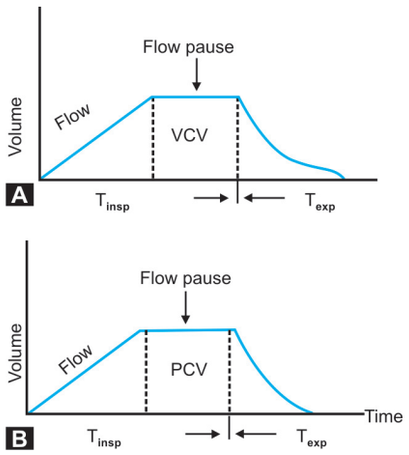

Figs 21.37A and B: The volume - time waveform where there is gradual changes in the volume during inspiration and expiration in volume controlled and pressure controlled ventilation. Here an inspiratory pause is used.

located. The amount of leak also can be easily estimated by measuring the distance from the plateau to the end of the expiratory tracing (Fig. 21.38).

ii. If the expiratory volume tracing moves very slowly towards the baseline, then it indicates the slow movement of expiratory gases due to any obstruction. Hence it can lead to an auto-PEEP, since the exhalation is not completed. It can be corrected by administering the bronchodilators or increasing the expiratory time or decreasing the inspiratory time (Fig. 21.39).

iii. If the expiratory volume tracing goes downwards, touches the baseline and then further goes below the baseline,

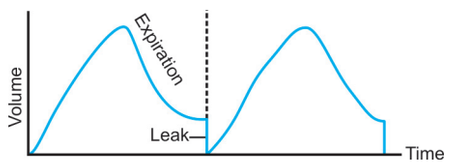

Fig. 21.38: Volume - time waveform showing leak.

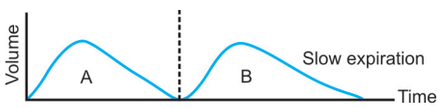

Fig. 21.39: Volume - time waveform A. Normal expiration, B Slow expiration

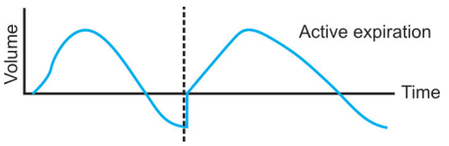

Fig. 21.40: Volume - time waveform showing active expiration due to cough, agitation or severe obstruction

then it indicates that the expired volume is more than the inspired volume and it is due to coughing, patient's agitation or auto-PEEP. It can also occur if the flow transducer is not properly calibrated (Fig. 21.40).

Pressure-Volume Loop (Fig. 21.41)

The pressure-volume loop indicates the changes in pressure and the corresponding changes in volume of lungs. Initially, inspiration begins from the FRC level which corresponds to the crossing of X and Y axis. Then, inspiration terminates when the preset volume or pressure (in VCV and PCV respectively) is achieved. After that expiration begins and the tracing returns to the FRC level at the end of exhalation. From this pressure volume loop, we can get PIP and tidal volume (V_T). Usually FRC level is situated at the junction of X and Y axis. But when PEEP is applied, then FRC level increases and shifts right wards along the X-axis from where inspiration begins (Fig. 21.42).

From the tracing of pressure-volume loop the type of breathing also can be recognised. For example, when the tracing is counter clockwise, then the delivered breath is mechanical one. On the other

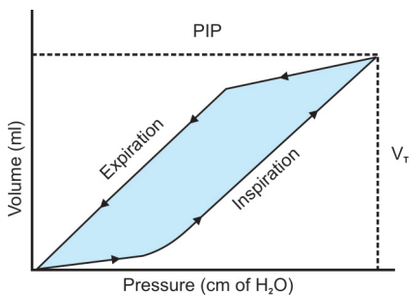

Fig. 20.41: Pressure-volume loop

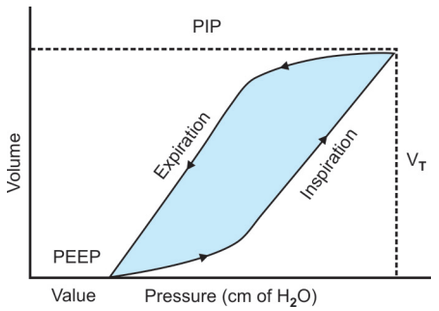

Fig. 21.42: Pressure-volume (P-V) loop with PEEP

hand, a clockwise tracing (Fig. 21.43) indicates a spontaneous breath. In an assisted mechanical breath the first part of tracing begins clockwise which indicate patient's spontaneous effort. Then, the last part of the tracing shows the counter clockwise direction which indicates mechanical breath (Fig. 21.44).

The major advantage of this loop is that it can provide a quick assessment of work of breathing. Because work of breathing is calculated from the product of pressure and volume (work of breathing = pressure × volume). Within this work of breathing,

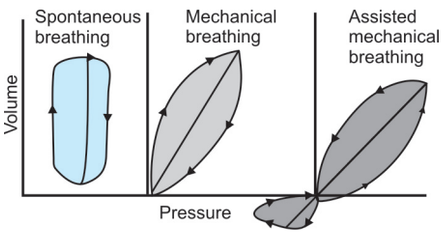

Fig. 21.43: Different types of breathing in P-V loop

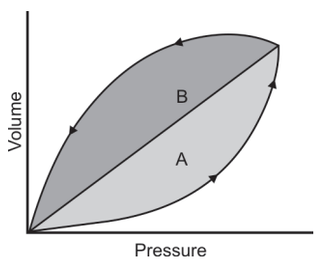

Fig. 21.44: Assessment of work of breathing by P - V loop. (A) Normal resistive work, (B) Normal elastic work

elastic and resistive part also can be classified. Both on the inspiratory and expiratory limb of pressure-volume tracing, there is a point where the slope is suddenly changed. This point is called the inflection point. It represents sudden changes in pressure responsible for opening and closing of alveoli. The lower inflection point means the opening pressure of alveoli and the upper inflection point means the closing pressure of alveoli. The higher opening pressure indicates the decreased compliance of lungs (stiffer lungs) and causes the loop moving laterally to the right along the pressure axis. During setting of PEEP, the lower inflection point is recommended to optimize the recruitment of alveoli and it will prevent the repeated opening and closing of alveoli (Figs 21.45 and 21.46).

A shift of loop to the right indicates decreased lung compliance and to the left indicates increased lung compliance. This can be judged by observing the pressure required to deliver the same tidal volume in three loops. This is applicable only in volume targeted ventilation. But in pressure targeted ventilation the tidal volume (V_T) is the changing variable, where peak inspiratory pressure (PIP) is constant.

An increased resistance of airway due to obstructive lung disease is responsible for abnormal widening of only the inspiratory part of tracing and exhibits a wide pressure volume loop. This abnormal widening of pressure – volume loop is known as the increased 'hysteresis'.

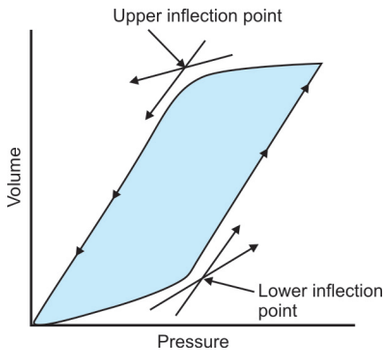

Fig. 21.45: Inflection points in P-V loop

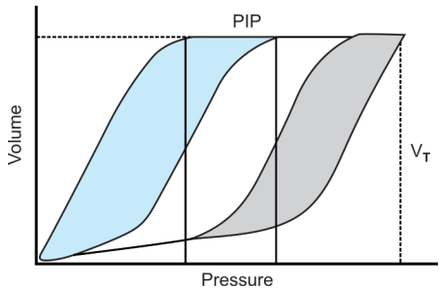

Fig. 21.46: Changes of lung compliance in P - V loop (Volume Controlled Ventilation). PIP is different but VT is same

Normally, the direction of a pressure-volume loop is counter clockwise and indicates mechanical breath. But a clockwise direction before mechanical breath indicates patient's effort for breathing. Adjusting the sensitivity of ventilator one can minimise or increase the effort of breathing and thus decrease or increase the work of breathing. In pressure-volume loop it is recognized by a significant clockwise deflection of a tracing below the baseline (Figs 21.47 and 21.48).

When the expiratory tracing of a pressure-volume loop does not return to zero level on the axis of volume, it suspects an airleak. On the other hand, an insufficient inspiratory flow is recognised by a scooped out pattern in the middle of inspiratory limb exhibiting a notch during mechanical breath (Figs 21.49 and 21.50).

Alveolar over distension is a common manifestation during ventilation of patient with ARDS by VCV mode and is detrimental to patients. This is classically seen in pressure-volume loop which is known as 'Beak effect' or 'Duckbill'. It is characterised by an increase in airway pressure without an appreciable increase in volume. In such circumstances, switch over to pressure targeted ventilation (PCV) with appropriate safe pressure level or reduction of tidal volume are indicated. (Figs 21.51 and 21.52).

Flow-Volume Loop

In this loop, there is no set convention in assigning the inspiratory and expiratory component around the volume or X-axis.

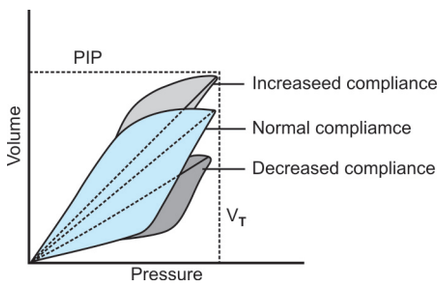

Fig. 20.47: Changes of lung compliance in P-V loop (Pressur 21.e Controlled Ventilation). PIP is same but VT is different

Fig. 21.52: Duckbill effect of P-V loop

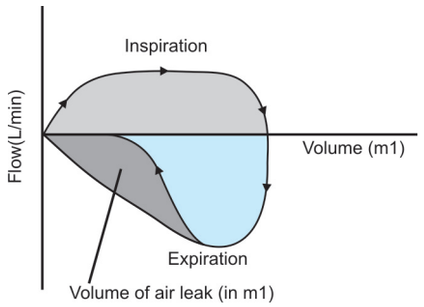

Fig. 21.54: Air leak in a F-V loop

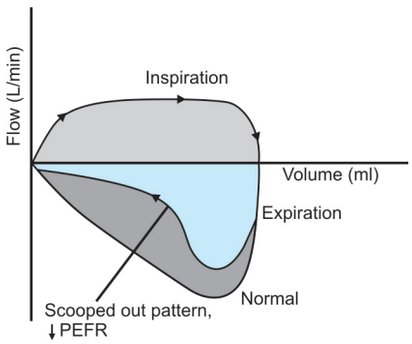

Fig. 21.56: Increased airway resistance in F-V loop

Some ventilators produce flow volume loop with inspiration on the upper half and expiration on the lower half. While in others it is reverse. A flow-volume loop provides information such as: tidal volume, beginning of inspiration and end of expiration, peak inspiratory flow rate (PIFR) and peak expiratory flow rate (PEFR) (Fig. 21.53).

Ideally, the inspired and expired volume should be equal. But with an airleak expired volume will be less than an inspired volume. This can be indientified from a flow-volume loop when the volume indicates the magnitude of airleak (Fig. 21.54).

In an air trapping or auto-PEEP condition the expiratory flow does not return to the zero level. But inspiration must begin from the zero flow level. So the expiratory tracing will jump abruptly from the trapped level to the zero level for the next inspiration (Fig. 21.55).

An increased airway resistance due to bronchospasm also can be diagnosed by a flow-volume loop. It is characterised by a scooped out pattern of the expiratory limb and decreased PEFR. Administration of bronchodilator may show an improvement in both the configuration of the expiratory tracing and PEFR. A continued scooped out configuration of the expiratory tracing and low PEFR suggest ineffectiveness of the bronchodilator therapy (Fig. 21.56).

22 Intraoperative Monitoring

INTRODUCTION

Monitoring of a patient is the key aspect of anaesthesiology. But, with the more and more development in the subject of anaesthesia, the range and complexity of the available monitors used in this discipline have also been increased rapidly. For example, the stethoscope, sphygmomanometer and electrocardiogram (ECG) are now supplemented by the pulse – oximeter, expired gas analyzer, processed electroencephalogram (EEG), evoked potential monitor, transesophageal echocardiography and a host of many others. While this has brought undoubted benefits, but their sophistication and complexity have also brought additional problems. The main problem is that they are very costly to use in every case and is not available in small hospitals and rural areas. So, till now there has been little progress towards an international consensus, regarding their use.

During the use of different monitors, high index of suspicion should always be kept in mind, regarding their accuracy. So this requires a constant comparison with clinical observation. Monitors may be tired by the end of the day. Calibration may slip and zero's may drift. So, they can not always provide a sleepless vigilance that we would like. Also, many problems in instrumental monitoring arise due to the patient machine interference at the site of contact. For this reason, repeated clinical examination and its corroboration with the instrument monitoring is still of primary importance.

But, the most primary equipment of clinical monitoring is the various special senses of the attending anaesthetist. The anaesthesiologist also develops a special sixth sense. This is a subconscious mental computation resulting from the observation, and previous experience which warns him of the impending wrong events and allows him to take a prompt action before hand to meet the need of a patient.

The basic clinical monitoring of patients during anaesthesia are:

i. Non-invasive blood pressure by sphygmomanometer,
ii. Pulse, by clinical palpation,
iii. Peripheral circulation,
iv. Degree of filling of the jugular vein,
v. Colour of the skin, mucous membrane and blood coming out of the surgical exposure,
vi. Temperature,
vii. Urine output (> 0.5 ml/kg/hour),
viii. Respiratory movement of chest and movement of anaesthetic bag,
ix. Depth of anaesthesia – by HR, BP, perspiration, lacrimation, movement of the body etc.
x. Muscle tone,
xi. Pupils.

As per definition, a 'monitor' is an instrument which is used continuously or at intervals to measure the condition or parameter of a patient that should be kept within prescribed limits and it reminds or gives us warnings when this condition or parameter goes beyond that limit. In a monitor, the mechanical energy within a physiological variable is converted into an electrical signal by a transducer. Then, it is processed and transmitted on the screen for display and to an automatic recording system for recording. In a monitor the physiological electrical signal, such as in ECG, is also amplified, processed and displayed on the screen. Accurate detailed recording of parameter is also a fundamental of monitoring.

Pen and paper are still the most reliable tools for anaesthetic records. Although automated recording is available nowadays, but the automated records are not regarded as infallible. The anaesthetist should initialise all the monitoring errors on any automated record sheet.

The manufacturers of early monitors generally paid little attention to the type of presentation. So, during that period the OT clinicians or anaesthesiologists were presented with a collection of boxes for monitoring of each parameter or physiological events of the body. In addition, an increase in the number of sensors attached to the patients for each parameter also led to a progressive increase in the number of boxes which cause predictably confusing results.

Recently, the tendency has changed with the development of a single central display unit, which allows a single monitor screen to provide a wide range of items for measurements. Also, addition and omission of information can easily be done by just changing the modules of a single multimonitor. In such central display unit faulty modules too, can be changed easily. While there are many benefits of this multimonitor approach in terms of clarity

and consistency, but the threat of information overload is still present. The current multimonitor may display up to six waveforms and digital values of different physiological parameters, with different colours and sizes which are alterable by the operator. In a stressful situation, there is limited ability for an operator to absorb all the information. So, a complex and crowded multimonitor is almost useless in acute crisis. Therefore, it is vital that the most important information is easily seen during crisis and not obscured by a mass of interesting, but nonessential life saving data.

Before taking steps for the treatment of a patient with the help of the results of a monitor, some points should always be kept in mind. These are:

i. Different companies use different methods to measure the same parameter in their instruments. So the results may not be the same in different instruments. Unfortunately, companies are usually reluctant to disclose the details of how their machine operates. They only do this to protect their market.
ii. During the measurement of some physiological variables such as the depth of anaesthesia, the electrical activity of brain is measured and is then transformed into mathematical data. This is then compared to a reference value, which is different for different companies. So, accuracy of result may vary.
iii. A monitor which functions well in an OT may give faulty results in an aircraft or ambulance, due to the noise or vibrations.
iv. Monitors may also provide additional hazards for a patient. Because, they are usually made of potentially magnetic material. When such a monitor is taken into the vicinity of a MRI machine, then its magnetism is likely to be accelerated by the huge magnetic field of MRI machine and may cause severe injuries to the patient or may even give inaccurate results. The strong magnetic field may also induce electrical current in the wires placed near the monitor, with the possibility of burning of patient due to heat. So, all the anaesthetic equipments used in radiology unit should, therefore, be made of non-magnetic material or moved outside the magnetic field with long cable to monitor the patient from outside of the radiology room. Several manufacturers now make specific MRI-compatible equipments.
v. Monitors should be checked, serviced and calibrated at regular intervals, set by the manufacturer. Because, many components used in the monitors may degrade with time and lead to suboptimal performance.
vi. Many equipments have been designed to be used for adults only. Their use in children, especially in neonates, may produce unreliable results.

NEUROMUSCULAR MONITORING

Introduction

Muscle power in an awake patient can easily be evaluated through some voluntary test. But, in an anaesthetised patient this is impossible. So, in an anaesthetised patient the muscle power is tested directly by nerve stimulation and indirectly by muscle tone, movement of anaesthetic bag, tidal volume, head lifting (for 5 sec), just after recovery by anticholinesterase, etc. The other indicators of adequate recovery of muscle strength include the ability to generate an inspiratory pressure of at least −25 cm of H_2O and a forceful hand grip. But, all these indirect methods are influenced by multiple factors other than the neuromuscular blockade by muscle relaxants. For example, twitch tension is reduced due to hypothermia of monitored muscle group by about 6°C. So, for accurate information about the status of neuromuscular function, a direct method by using a nerve stimulator is employed. This assesses the muscle power by the response of muscle to electrical nerve stimulation.

But, till now only a few anaesthesiologists use the nerve stimulator to assess the neuromuscular function or muscle power during anaesthesia. Instead, they use only clinical criteria for the evaluation of neuromuscular block, during and after anaesthesia. But, interest in monitoring the neuromuscular block by a nerve stimulator during anaesthesia has been growing over the past few years due to:

i. Increase in awareness, regarding the problems of postoperative residual neuromuscular blockade,
ii. Variations in patient sensitivity and also variations in sensitivity among some group of muscle to neuromuscular blocking agents,
iii. Use of long acting muscle relaxants,
iv. Use of continuous infusion of short acting muscle relaxants, etc.

There is no contraindication for the use of nerve stimulator for neuromuscular monitoring. But, certain sites may be excluded for the surgical procedure.

General Principles

The reaction of a single muscle fibre causing contraction to an electrical stimulus is an all-or-none phenomenon. But, the response of the whole muscle does not follow this all-or-none rule. Here, the response depends on the number of muscle fibres that are activated by the electrical stimulus or blocked by drugs and the amount or intensity of the stimulus. If a nerve is stimulated with sufficient or maximum electrical intensity, then all the muscle fibres supplied by that nerve will react. So, during neuromuscular monitoring all the stimuli should be of maximum strength or above. In practice, the electrical stimulus which is applied to a muscle is usually 20 to 25% above the maximum intensity to achieve the maximum response. This stimulus is called the supramaximal stimulus. To deliver a supramaximal stimulus, the peripheral nerve stimulator must be capable of generating at least 50 mA current with 100 ohm load.

But, one of the disadvantage of supramaximal stimulus is pain and discomfort. Though this drawback of supramaximal stimulus does not cause much problem during intraoperative period or anaesthesia, but it causes definite problem during recovery, as the patient may be awake enough to feel the pain. So, some researchers advocate electrical stimulus below the maximum level. This is called the submaximal stimulus. The disadvantage of this submaximal stimulus is its poor accuracy which is not very acceptable. So, the usual recommendation is to use a supramaximal stimulus, whenever possible.

The character of the stimulus should not only be supramaximal but will also be square wave, i.e. monophasic and rectangular. Biphasic stimulus will cause repetitive firing or burst of action potential and will increase the response to subsequent stimulation, leading to inaccurate results.

The standard optimal duration of stimulus (or pulse) should be 0.2 to 0.3 millisecond. Duration of stimulus exceeding 0.5 millisecond will cause direct stimulation of the muscle and give inaccurate results.

So, the electrical stimulus for monitoring of neuromuscular functional status should be a rectangular pulse of 0.2 to 0.3 millisecond and of supramaximal intensity (100 to 200 mV).

The Sites of Nerve Stimulation and Muscle Responsiveness

For stimulation of a nerve in neuromuscular monitoring, either silver chloride pads (used in ECG) or subcutaneous needles are used over the superficial peripheral motor nerve. Any superficially located peripheral motor nerve may be used for neuromuscular monitoring. But it must be remembered that different muscle groups supplied by a motor nerve have different sensitivities to neuromuscular blocking drugs. For neuromuscular monitoring, the evoked mechanical response (i.e. contraction) or electrical response (EMG) of the innervated muscle is observed. Direct stimulation of the muscle should be avoided. So, the electrodes should be placed over the course of the nerve, but not directly on the muscle itself. Ulnar nerve stimulation to see the response of adductor pollicis and facial nerve stimulation to see the response of orbicularis oculi are the most commonly monitored motor nerve and its supplying muscle respectively.

Among these, the ulnar nerve is the most popular nerve for neuromuscular monitoring and the elbow or the wrist are the most convenient sites. But the median, posterior tibial, common peroneal and facial nerves are also sometimes used. When the ulnar nerve at the site of the wrist is selected for neuromuscular monitoring by electrical stimulus, then the electrodes are placed over the volar side of the wrist. One electrode is placed 1 cm proximal to the point, where the proximal flexion creases of wrist crosses the tendon of flexor carpi ulnaris muscle. The second electrode is placed 2 to 3 cm proximal to the previous one. The stimulation of ulnar nerve at the wrist causes only flexion of the fingers and adduction of the thumb. When the ulnar nerve is selected at the elbow, then the second electrode is placed over the ulnar groove at the elbow.

While placing the electrodes, two things have to be kept in mind. These are : (i) avoid placing the stimulating electrode too close to the recording electrode, and (ii) avoid direct stimulation of the long flexors of the forearm. When the ulnar nerve stimulation is selected at elbow (this site is mainly chosen for paediatric patients), the active negative electrode should be placed at the wrist to ensure a maximal response. When the electrodes are placed close to each other at the wrist, then the polarity of electrodes are not important.

When the temporal branch of facial nerve is selected for neuromuscular monitoring, then the negative electrode is placed over the nerve directly and the positive electrode is placed anywhere over the forehead.

Regarding the muscle responsiveness, different groups of muscle have different sensitivity to neuromuscular blocking drugs, and the results obtained from one group of muscles cannot be extrapolated to other groups of muscles. For example the diaphragm is most resistant to neuromuscular blocking drugs than any other group of muscles of the body. In the second order, the muscles which will come in reference to resistance are the abdominal and respiratory muscles. This is followed by the laryngeal muscles and lastly the muscles of face. The most sensitive muscles to neuromuscular block are adductor policies, abdominal muscles, muscles of the limbs, the upper airway muscles and the masseter. So, keeping in mind the different sensitivities of different group of muscles, we can say that the neuromuscular functional status or intensity of block in adductor pollicis will not be the same as in the diaphragm. Thus, during anaesthesia and surgery the total elimination of response to a single twitch or TOF stimulation of the adductor pollicis does not exclude the possibility of the movement of diaphragm, causing cough, hiccup etc. On the other hand, if the most sensitive muscle such as adductor policies is chosen as the neuromuscular monitoring guide for the administration of muscle relaxants during surgery, then there will be less chance of an overdose of muscle relaxants. Again, the advantage of taking the most sensitive adductor pollicis muscle as a monitoring sample is that sufficient recovery of adductor pollicis (i.e. when TOF ratio exceeds 0.7) signify there is no residual block in the diaphragm.

Patterns of Electrical Stimulus

Five patterns of electrical stimulation for neuromuscular monitoring are used in clinical anaesthesia. These are:

i. Single-twitch stimulation,
ii Train-of-four (TOF) stimulation,
iii. Tetanic stimulation,

iv. Post-tetanic count (PTC) stimulation,
v. Double-burst stimulation.

(i) Single twitch stimulation

In a single twitch stimulation, a single supramaximal electrical stimulus of frequency 1 to 0.1 Hz (one stimulation after every 1 to 10 seconds) is generally used. After very intense or complete neuromuscular block (100%) by depolarising or non-depolarising muscle relaxants, there will be no initial response to any electrical stimulus (whatever may be the intensity) and this phase is called as the 'period of no response'. Then, when the block gradually dissipates from its 100% intensity or after incomplete paralysis by non-depolarising agents after its administration, the evoked contraction response to a single-twitch stimulation is small or even incomplete and there is successive fade in response during successive single-twitch stimuli. In contrast, during progress of block to no response phase after administration of depolarising muscle relaxing agent or during dissipation of depolarising block from its 100% intense block (i.e. from the phase of no response period), there is a well sustained response (no fade) to successive single-twitch stimulus.

(ii) Train-of-four (TOF) stimulation

In TOF stimulation, four successive single-twitch supramaximal stimuli of 0.02 millisecond (200 µs) duration are given at an interval of 0.5 second, i.e. at a frequency of 2 Hz (0.1 Hz = 1 impulse in 10 seconds, 1.0 Hz = 10 impulses in 10 seconds or one impulse every second, 2 Hz = 20 impulses in 10 seconds, i.e. one impulse every 0.5 second) and each stimulus causes the muscles to contract. In a normal condition before a muscle relaxant is administered, all the four evoked responses are ideally the same, i.e. the TOF ratio (dividing the amplitude of the fourth response by the amplitude of the first response provides the TOF ratio) is one. During intense or 100% complete neuromuscular block (both by depolarising and nondepolarising agents), there is no evoked muscular contraction response to TOF. This phase is called the 'period of no response' and indicates intense or near about 100% block. After administration of nondepolarising muscle relaxant when the intensity of block is gradually increased, then the TOF response shows the characteristic fade (i.e. the amplitude of response gradually decreases and the 4th response disappears) and is inversely proportional to the degree of block. Disappearance of the fourth response indicates > 75% block, the disappearance of third response indicates > 80% block and the disappearance of second response indicates > 90% block. When there is no response the even first stimulus, then the block is 100%. Surgical relaxation usually requires 70 to 90% neuromuscular block. Sometimes, it is difficult to estimate the train-of-four ratio. So, it is more convenient to visually observe the sequential disappearance of muscle responses or twitches, as this also correlates well with the degree of block.

After the administration of muscle relaxant in an intubating dose, intense neuromuscular blockade occurs initially. In this phase, the patient is intubated. In this intense phase of blockade (100%), there is no response to any stimulus of TOF or single-twitch stimulation or any other type of electrical stimulation. Duration of this no - response period depends on the type of muscle relaxant, the dose and the sensitivity of the patient to that drug. After this phase which lasts only for a few minutes, a single response appears first after TOF stimulation. Surgical relaxation phase begins now and surgery is started. Gradually 2nd, 3rd and 4th responses appear to TOF stimulation and a good correlation exists between the degree of neuromuscular blockade and the number of responses reappearing to TOF stimulation. When only one response appears against the four stimulus of TOF, then, the block is 90 to 95% and when all the four responses appear the block is 60 to 85%. The presence of one or two responses by TOF stimulus indicates sufficient relaxation for most surgical procedures. The reversal of neuromuscular block should not be attempted, when it is in intense or in no-response phase. Reversal should be tried when at least two or preferably three responses appear by TOF stimulation. Reversal in the intense phase will often be inadequate, regardless of the dose of reversal (Fig. 22.1).

The appearance of 4th response in TOF stimulation heralds the recovery phase. When the TOF ratio is more or less 0.4, the tidal volume is normal. But the vital capacity and inspiratory force are below the normal and the patient cannot raise his head or arm. When the TOF ratio is around 0.6, the patient can lift the head for 3 seconds, but vital capacity and inspiratory force are still below the normal. At a TOF ratio around 0.7, the patient can lift

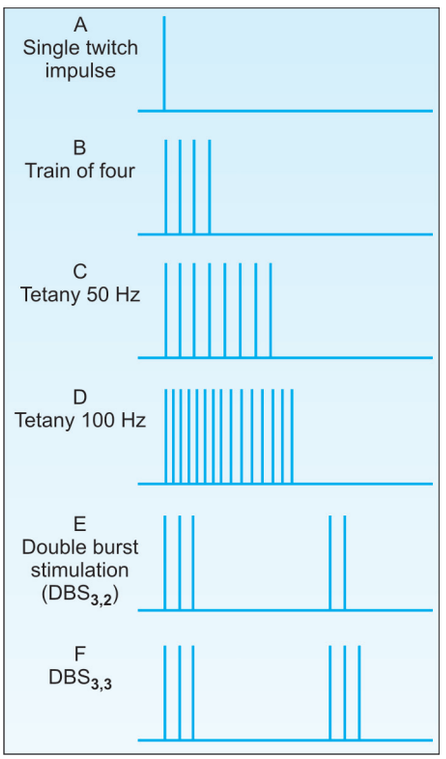

Fig. 22.1: Schematic diagram of the various patterns of electrical stimulus for monitoring of neuromuscular function

the head for 5 seconds, cough, protrude the tongue and open his eyes. Vital capacity and inspiratory force become normal at TOF ratio of 0.8. Adequate recovery from neuromuscular block in clinical anaesthesia is considered when TOF ratio varies between 0.5 to 0.7. TOF ratio of 0.8 indicates absence of residual neuromuscular block.

During a depolarising neuromuscular block (phase I) in the intense phase (100% block), there is no response to TOF stimulus like the nondepolarising muscle relaxant. Then, when the intense phase gradually dissipates, the response to TOF stimulus starts to appear, but does not show the characteristic fade, instead shows a sustained response, though of low intensity. In contrast, when some patients who have genetically determined abnormal plasma cholinesterase activity, are given the same dose of succinylcholine, then they show a non-depolarising like block, characterised by fade in the response to TOF stimulus. Such a block is called the phase II block. Also, when succinylcholine is given at repeated intervals, or by prolonged infusion, then phase II block also sometimes precipitates (Fig. 22.2).

Phase II block, due to prolonged infusion of succinylcholine in normal genotype, should be differentiated from phase II block due to abnormal genotype (with abnormal cholinesterase activity). Phase II block with normal genotype can be reversed by cholinesterase inhibitors. But the effect of cholinesterase inhibitors in phase II block with abnormal genotype is unpredictable and should not be used or used with extreme caution. This unpredictability can vary from re-potentiation of block to temporary improvement to full reversal. So, even if the neuromuscular function improves promptly, still patient's surveillance should continue for at least an hour.

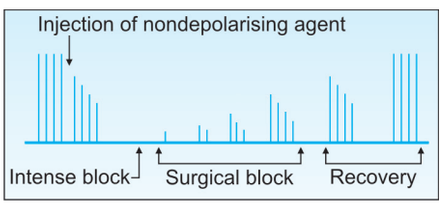

Fig. 22.2: Schematic diagram of changes in response to TOF stimulation during block, and recovery from nondepolarising muscle relaxants

The advantages of TOF stimulation in monitoring neuromuscular block is that the degree of block can be read directly from the TOF ratio, even though a preoperative value is lacking. It is less painful and does not affect the degree of block, like tetanic stimulation. It has a great advantage mainly during non-depolarising block.

(iii) Tetanic stimulation

The tetanic stimulation consists of multiple and very rapid single – twitch electrical stimulation given successively. It is commonly used at a frequency of 50 to 100 Hz for 5 seconds (1 Hz = 10 stimuli in 10 seconds. So 50 Hz = 500 stimuli in 10 seconds. So duration of every stimulus is 20 milliseconds). The effect or evoked response of tetanic stimulation on the normal muscle is a sustained contraction, without post-tetanic facilitation or fade. The effect of tetanic stimulation on a depolarising block is same as that of normal muscle, i.e sustained contraction but of low amplitude (according to the intensity of block, no response when block is 100%) and no post-tetanic facilitation or fade (when muscular response is found with <100% block). During nondepolarising and phase II block, when the block is intense, then obviously there is no response to tetanic stimulation like the single twitch and TOF stimulation (period of no response). When intensity of block progresses after the administration of the muscle relaxant, then the response to tetanic stimulation also shows the gradual fade and post-tetanic facilitation which ultimately shows no response with 100% block. Similarly, with the passage of time when the intense block gradually disappears after the no response phase, then the response to tetanic stimulation with fade and post-tetanic facilitation reappears. Thus, in nondepolarizing and phase II block the response to tetanic stimulation is not sustained but fade occurs and post-tetanic facilitation is seen (Fig. 22.3).

Probable mechanism of 'fade'

In normal circumstances when tetanic stimulation is given, then a large amount of ACh is released from the stored site. This causes depletion of the store of ACh and so its release gradually decreases. Thus, at the end of the process of tetanic stimulation an equilibrium is settled, when the release and synthesis of ACh becomes equal. At this stage of equilibrium, muscle response to tetanic stimulation is still sustained and does not show any fade. This is simply because the amount of ACh and the number of post-synaptic receptors where ACh acts is much greater than what is necessary to evoke a response. It means that there is a great margin of safety at the post-synaptic membrane. When this margin of safety is reduced by nondepolarising neuromuscular blocking agents, or phase II block, then the decrease in release of ACh during tetanic stimulation produces 'fade'.

Another explanation of fade is that it may be due to the prejunctional effect of nondepolarising agents. It reduces the amount of Ach available for release at the nerve terminals during stimulation. This is called blockade of ACh mobilisation. The absence of fade in case of nondepolarising neuromuscular block correlates well with clinical recovery. Fade is more obvious during double-burst or sustained tetanic stimulation, than following repeated single-twitch stimulation or TOF stimulus. So, the first two methods are more preferred to determine the adequacy of recovery.

The post-tetanic increase in twitch response is called the post-tetanic facilitation. This is due to the increase in synthesis and mobilization of ACh, caused by a tetanic stimulation which continues for

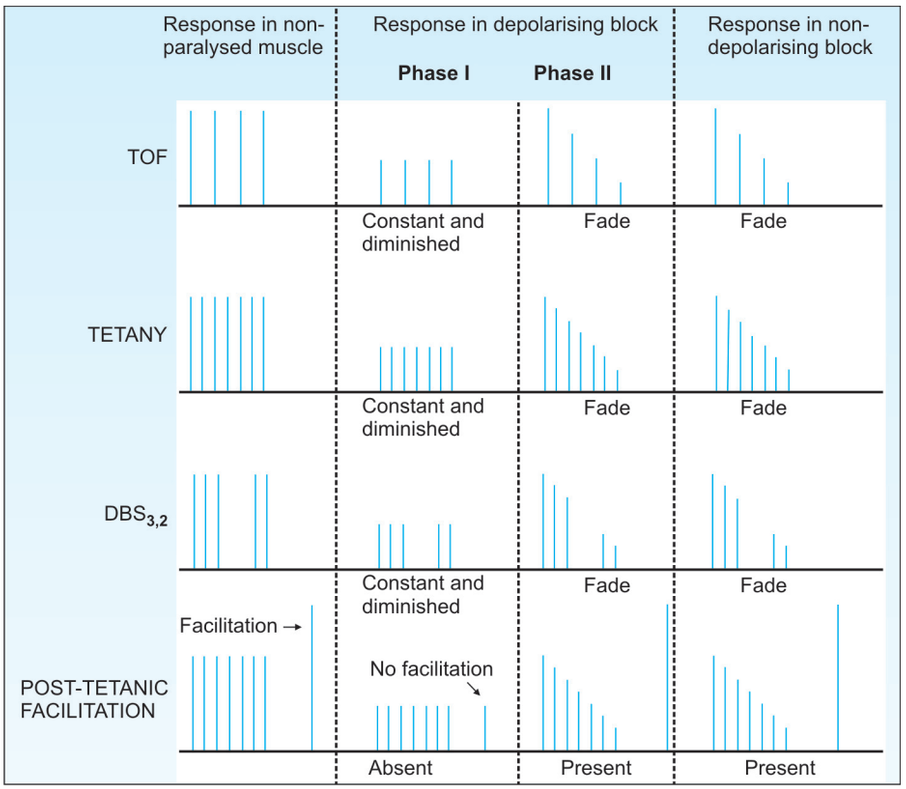

Fig. 22.3: This schematic diagram shows the different responses of muscle to different stimuli in nonparalysed state and both depolarising and nondepolarising blocks

sometime, even after discontinuation of the stimulus. The degree and duration of post-tetanic facilitation depends on the degree of neuromuscular block by nondepolarising agents. It is evident in partial depolarising block and disappears within 60 seconds of tetanic stimulation.

The disadvantages of tetanic stimulation is that it is very painful and cannot be used in an unanaesthetised patient. Tetanic stimulation has very little place in everyday clinical anaesthesia practise, because all the information can be easily obtained from TOF nerve stimulation response.

(iv) Post-tetanic count (PTC) stimulation

After administration of large intubating dose of a non-depolarising muscle relaxant during rapid sequence intubation, intense muscular block (100%) occurs in which single-twitch, TOF, tetanic stimulation or any type of stimulation does not create any response (no-response phase). So, to know the degree of block in this intense no response phase the post tetanic count stimulation method is used. However during very, very intense block, there is no response to post-tetanic stimulation also. As the intensity of block gradually dissipates and before the first response to TOF stimulation reappears, the response to single-twitch stimulation after a tetanic stimulation (so called post-tetanic stimulation) appears. Then, with the passing of time the number of responses to a single-twitch stimulus after a tetanic stimulus gradually increases and is counted. Increase in the number of count indicates the gradually waning of block, and the first single response to TOF stimulus will occur. As the block further wanes, the consecutive four responses to TOF stimulation arise. So, the post-tetanic count (PTC) stimulation is used to quantify the intensity of no response phase of neuromuscular block of the peripheral muscles, when the other types of stimuli (single twitch, TOF, tetanic) fail to respond in the 'no-response phase'. The PTC is used by applying tetanic stimulation (50 Hz for 5 secs), and then observing the post tetanic response to a single twitch stimulation, given at 1 Hz frequency and 3 seconds after the end of tetanic stimulation.

(v) Double-burst stimulation (DBS)

Without a recording instrument, muscular response to a stimulus (single-twitch, TOF or PTC) cannot be visualized or felt by any tactile means, which may help to evaluate or exclude the small degree of residual neuromuscular block. So, DBS was developed with the specific aim of allowing manual detection of small amounts of residual neuromuscular block, after recovery. With DBS, it is easier to feel 'fade' in the response.

DBS consists of two short bursts of high frequency tetanic stimulation at an interval of 780 milliseconds. It represents two variations. The $DBS_{3,3}$ pattern consists of three short (0.2 milliseconds or 200 µs duration) high frequency tetanic bursts, separated by an interval of 20 milliseconds (50 Hz), followed by another three bursts, 750 milliseconds later. $DBS_{3,2}$ consists of three 50 Hz impulses of 0.2 milliseconds duration, followed by two such impulses, 750 milliseconds later. The $DBS_{3,3}$ pattern is more in clinical use than the $DBS_{3,2}$ pattern. It is more sensitive than TOF stimulation for clinical (i.e. visual) evaluation of fade. In control study, the feel of two muscle contractions in response to DBS is equal. In a paralysed condition, the second response is weaker than the first (i.e. 'fade'), which can be felt easily. Thus, absence of fade in response to DBS usually means absence of clinically significant residual neuromuscular blockade. Measured mechanically, the TOF ratio correlates closely well with the DBS. The feeling and tactile evaluation of response to DBS, is superior to the tactile evaluation of response to TOF stimulation.

Recording of Evoked Response

By three methods we can record and measure the evoked muscular response to a stimulus.

i. Recording of evoked mechanical response of muscle (i.e. contraction) to stimulus (mechanomyography).
ii. Recording of evoked electrical response of muscle to stimulus (electromyography).
iii. Recording of evoked acceleration response of muscle to stimulus (accelero-myography).

(i) Mechanomyography (MG)

Here, the evoked contraction response developed by the muscle due to a stimulus is recorded and measured. This is most easily achieved in clinical anaesthesia by measuring the thumb movement due to electrical stimulation. When the ulnar nerve is stimulated by a nerve stimulator, the adductor policis muscle of thumb contracts and acts on a force displacement transducer which converts this mechanical force into an electrical signal. Then this signal is amplified, displayed and recorded.

(ii) Electromyography (EMG)

Here, the compound action potential of muscular contraction, produced by stimulation of a peripheral nerve is recorded. In clinical anaesthesia, the evoked electrical response from contraction of a muscle is most often obtained from the muscles of thenar and hypothenar eminences of hand innervated by the ulnar or the median nerve. Both the surface or needle electrodes can be used, but the needle electrodes have no extra advantage over the surface electrodes. In commercially available machines for evoked EMG, the results are displayed either as a percentage of control or as a TOF ratio and the results may also be given as 'twitch height' in the print-out.

Advantages of EMG over MG are:

i. Easier to set up,
ii. Response reflects only those factors which influence the neuromuscular transmission,
iii. Response can also be obtained from muscles which are not accessible to mechanical recording.

Disadvatages of EMG are:

i. EMG response is very sensitive to electrical interference, i.e. diathermy.
ii. Placement of electrodes is very critical and may cause false negative results with slightest variations.
iii. If the stimulating electrodes lie closer to the muscle than the nerve, then the muscle is stimulated directly and the recording electrode picks up the signal directly from the muscle even when neuromuscular transmission is completely blocked.

(iii) Acceleromyography (AMG)

It is a newer and simpler method of measuring and recording the neuromuscular function. It measures the acceleration of contraction of thumb muscles instead of force produced by contraction of muscle, after stimulation of a motor nerve. When the muscle mass of thumb is fixed, then the acceleration of contraction of thumb muscle is directly proportional to the force of contraction (Newton's second law) and this evoked acceleration of contraction, is measured. In clinical practice an accelerometer is fixed to thumb and the ulnar nerve is stimulated. Then the exposure of electrode of an accelerometer to the force of contraction of muscle generates an electrical voltage which is proportional to the acceleration of contraction of thumb muscles in response to nerve stimulation. This voltage signal is then analysed and displayed on a recording system.

It is a small handy instrument which fulfills most of the requirements of a neuromuscular monitoring unit and so, is used routinely during and after operation.

Stimulating Electrodes

The electrodes which transmit electrical impulses from a stimulator to a nerve are classified into surface electrodes and needle electrodes. Surface electrodes are most commonly used and are made up of rubber or disposable pregelled silver chloride like the ECG electrodes. The minimum conducting area of an electrode for monitoring of neuromuscular block should be 7 to 8 mm in diameter which is needed to transmit adequate current for the underlying nerve. Skin should be properly cleaned before using the electrodes and the old rubber electrodes should not be reused as it increases impedance.

Needle electrodes are used when the supramaximal responses cannot be obtained by surface electrodes. The needles should be placed subcutaneously and not within the nerve. If specially coated commercially made needle electrodes are not available, then the ordinary steel needles made for injection can also be used as electrodes.

MONITORING OF THE RESPIRATORY SYSTEM

Introduction

During anaesthesia, in addition to its normal function, i.e. O_2 uptake and CO_2 excretion, the respiratory system also transfers the inhalational anaesthetic agents into the circulation. So, the function of respiratory system can be monitored clinically by examination of patient and also instrumentally by measuring the different volumes and capacity of lungs during ventilation, the concentration of gases in inspiratory and expiratory gas mixture, and the tension of different gases in blood by blood gas analysis.

The measurement of total minute ventilation is simple. But, the more relevant portion of minute volume, i.e. alveolar ventilation is much more difficult to measure. The alveolar ventilation can be considered as a relatively fixed portion of minute volume. Because the physiological dead space, which is invariably increased during anaesthesia, remains a reasonably constant fraction of the tidal volume.

Over a wide range of tidal volume, the alveolar ventilation can be calculated from the equation which is written as:

$$V_A = V_E - V_D$$

V_A = Alveolar ventilation,
V_E = Respiratory minute volume (or minute ventilation),
V_D = Dead space ventilation.

The alveolar ventilation can also be calculated from PCO_2 of the exhaled gases, or alveolar PCO_2 (P_ACO_2) and arterial PCO_2 (P_aCO_2) from the following equation :

$P_ACO_2 = K (P_aCO_2 / V_A)$

So, if the PCO_2 of the exhaled gas (P_ACO_2) is known in relation to the arterial PCO_2 (P_aCO_2), then the alveolar ventilation can be calculated from the above equation.

The alveolar ventilation can also be calculated from another equation.

$P_ACO_2 = K (Vco_2/V_A)$, Vco_2 = CO_2 production

In this equation, P_ACO_2 is a function of only two variables. Since in clinical practice, the Vco_2 is relatively constant, therefore P_ACO_2 is only the determinant factor of alveolar ventilation (V_A), to which it is inversely proportional, i.e.

$P_ACO_2 \propto 1/V_A$

So, measurement of the end tidal CO_2 tension (P_tCO_2), which indicates P_ACO_2 is another way of monitoring the function of respiratory system.

Till now, the relationship between P_ACO_2 and ventilation has been discussed. Now, the relationship between P_aCO_2 and P_ACO_2 shall be discussed. If the CO_2 production remains constant, then the difference between P_ACO_2 and P_aCO_2 is dependent on the following factors, such as: (i) diffusion non equilibrium, (ii) ventilation / perfusion (V_A/Q) mismatching, and (iii) right to left shunting.

Diffusion non-equilibrium

It is the difference between the pulmonary capillary blood CO_2 tension and the P_ACO_2. This can occur under two conditions: (i) increased pulmonary blood flow to a level such that the blood lacks sufficient time in the alveoli, disabling gas tension to reach its equilibrium, and (ii) thickening of the alveolar capillary membrane, such that the rate of diffusion of gas from capillary to alveolus is slowed. In practice, there has never been any evidence of diffusion non-equilibrium for CO_2. Similarly, diffusion non-equilibrium of O_2 very rarely exists. It exists in patients with intestinal fibrosis or in patients with normal lung function, but undergo severe exercise.

V_A/Q mismatch

The CO_2 dissociation curve in blood is a monotonically increasing one. Therefore, it is possible for a lung unit with low P_ACO_2 to compensate for lung units with high P_ACO_2, producing a normal P_aCO_2 in the face of substantial V_A/Q mismatch. On the otherhand, unlike the CO_2 dissociation curve, the O_2 dissociation curve in blood has a plateau at the point at which Hb is fully saturated. Therefore, V_A/Q mismatch always results in arterial hypoxaemia, but not hypercarbia.

Right to left shunt

Discussed elsewhere.

Clinical Monitoring of Respiratory System

The continuous direct clinical observation of the colour of a patient (such as the mucous membrane, skin, lips, colour of blood, etc.), the respiratory rate of it, the movement of chest and breathing bag etc. help us to judge the adequacy of ventilation. The colour of mucus membrane of a patient can be used to assess the oxygenation. But anaemia, polycythemia, changes in the shape of O_2 dissociation curve, or poor lighting may lead to mistakes. Different anaesthetic agents, sedatives and opioid analgesics are potent depressants of respiration. Thus, hypoxic brain damage can occur in a few minutes if the respiratory system of a patient is not monitored properly and treated efficiently. So, in cases where the anaesthetised patient is breathing spontaneously, then a constant observation of patient by the anaesthetist is needed to detect any tracheal tug, paradoxical chest movement or failure of the reservoir bag to move adequately etc. Because, it indicates partial or complete airway obstruction.

Free passage of air through airways can also be confirmed clinically by hearing the sound of clear airflow through the nose or the mouth. It also can be confirmed by feeling the warmth of expired air at the back of the hand if it is placed by the anaesthetist himself. Snoring, rattles or complete silence indicates impending or complete airway obstruction. Maintaining a clear airway in an anaesthetised patient is a great skill. It requires much practice with constant vigilance to every detail and a pair of strong forearm muscles to push the mandible upwards and forwards towards floor in a nonintubated patient. Clinically, periodic auscultation of chest by a stethoscope also confirms the position of endotracheal tube and detects any accumulation of secretions, pneumothorax or bronchospasm, if present. Thus, we can ensure the monitoring of respiratory system clinically.

Monitoring of the Respiratory Function by Precordial and Oesophageal Stethoscope

Many anaesthetists still believe that during anaesthesia a patient's respiratory system should be monitored by a precordial or oesophageal stethoscope even in the presence of many electronic gadgets. But, though they (precordial stethoscope and oesophageal stethoscope) have many advantages, still they are being gradually replaced by modern pulse-oximetry and capnography for better bedside monitoring of the respiratory function. Oesophageal stethoscope is a very simple, cheap and much informative instrument for clinical monitoring of respiratory system. It has the advantage of ensuring that the anaesthetist stays in close contact with the patient. It is a small balloon-tipped probe that is inserted into the oesophagus through mouth and connected to

either a standard stethoscope head-piece or a moulded ear-piece. When the length of an oesophageal stethoscope has been adjusted so that the balloon is opposite to the heart, then it also provides a constant monitoring of heart rate and breath sounds together. It is especially very useful in children, because it may detect any air embolism by hearing the characteristic mill-wheel murmur. By a precordial or oesophageal stethoscope we can also detect the bronchospasm, moist sounds, or any other adventitious sound of the lungs early, before it is reflected through pulse-oximetry and capnography. ECG leads, pacemaker electrodes, temperature probe and/or ultrasound probe for continuous intraoperative oesophageal echocardiography can also be incorporated with the oesophageal stethoscope. The information provided by the precordial or oesophageal stethoscope are: confirmation of ventilation, quality of breath sound, confirmation of heart beat (even when there are multiple artefacts in cadiac monitors) and quality heart sound (a soft tone is associated with hypotension and low cardiac output). The main disadvantages of oesophageal stethoscope are that it can not confirm the bilateral equal breath sound after endotracheal intubation or cannot exclude the bronchial intubation. It should be avoided in patients with oesophageal varices or strictures.

Monitoring of the Respiratory System by Measuring the Respiratory Rate, Airway Pressure, Tidal Volume and Disconnection Alarm

Measurement of respiratory rate

It is usually measured clinically. It can also be obtained from the capnograph or continuous ECG monitor. When the ECG leads are used to monitor the respiratory rate, then a very high frequency electrical current is passed accross the thorax of patient from the chest electrodes and then the electrical impedance which changes cyclically with respiratory movement is measured. From this cyclical changes of electrical impedance, the respiratory rate is calculated and displayed.

Measurement of airway pressure

High airway pressure may cause damage to the alveoli, reduce the cardiac output and predispose to pneumothorax in all patients receiving positive pressure ventilation. So, the airway pressure should be measured continuously or intermittently. The airway pressure is usually measured by simple mechanical pressure gauges or electronic gadgets which are attached to the ventilators or even to the Boyel's machine. However, the narrow tracheal tube, long breathing system or high respiratory rate may not accurately reflect the correct airway pressure measured by the mechanical gauges.

Airway pressure is increased due to bronchospasm, pulmonary oedema, pneumothorax (↓lung compliance), head down position, reversal of neuromuscular block, laparoscopy (↓ thoracic compliance), plug of airway by sputum, or kinked tracheal tube (equipment problem) etc. On the otherhand, airway pressure is suddenly decreased due to disconnection of breathing system, any leak in the circuit or empty cylinder (Table 22.1).

Table 22.1: Causes of changes in airway pressure

A.	*Causes of increase in pressure*
	Bronchospasm
	Pneumothorax
	Pulmonary oedema
	ARDS
	Less surfactant
	Consolidation and collapse
	Reversal of neuromuscular paralysis
	Laparoscopy
	Head down tilt
	Kinking of breathing tube
	Plug of sputum
B.	*Causes of decrease in pressure*
	Sudden disconnection
	Low gas flow

Measurement of tidal volume

The measurement of tidal volume is an important way of monitoring the function of respiratory system. It confirms the ventilation of patient and optimises the ventilator settings. For the measurement of tidal volume by bedside method, spirometer has been used for many years. But, although this device is small and provides accurate result, still it has some disadvantages. The disadvantages are: (i) water vapour in expired air causes inaccuracies, (ii) weight of spirometer dictates its use at the machine end of breathing circuit, resulting in in accurate result (iii) its use is restricted mainly to the circle system when the volume of expired gas is measured as tidal volume, (iv) its tendency to under-read at low tidal volume and over-read at high tidal volume.

In modern tidal volume monitors there is a small connector which is attached to the ET tube. Two tubes lead from this connector to the pressor sensors which is situated in the body of main TV monitor. Measurement of small, differential pressure changes between the two tubes allows the calculation of airway pressure and inspired-expired tidal volume. The modern anaesthetic machines which have an integrated circuit and ventilator have hot-wire anemometer for measurement of tidal volume. It uses an electrically heated hot wire, placed across the flow of air. Airflow cools the wire and thus decreases its electrical resistance, from where the amount of airflow during each breath (tidal volume) can be calculated. These devices are simple and reliable. But, they are delicate enough and need great protection.

Most multi-monitors now have the facility to integrate the measurement of flow, pressure and time in order to produce the real-time measurement of compliance, flow-volume loops and pressure-volume

loops along with the tidal volumes and other parameters of lung volume. These displays are especially useful in patients whose lungs are difficult to ventilate. It is also helpful where there are rapid changes in compliance of lungs, such as during one-lung anaesthesia.

Disconnection alarm

Most breathing systems have a disconnection alarm, as they have multiple connections which are dislodged easily, causing failure of ventilation and harm to the patient. Disconnection alarm detects the cyclical changes in airway pressure and gives an alarm if there is any unexpected change (high or low) in pressure during ventilation. They are usually battery-powered and some need to have the alarm limits, set manually. But most, automatically detect the normal range, and then sets off an alarm if any significant change in respiratory rate, tidal volume or airway pressure occurs. They may also set off an alarm, if high airway pressure is sensed somewhere.

Monitoring of Respiratory System by the Measurement of Quantity of O_2 in Blood

One of the most important function of respiratory system is the delivery of O_2 from air to blood. So, the measurement of O_2 level in blood by measuring the oxygenation saturation, oxygen tension, total oxygen content, mixed venous O_2 tension, etc. are among the some methods of monitoring the respiratory function.

Measurement of oxygen saturation in blood

The O_2 saturation of blood is usually measured noninvasively by pulse oximeters which works on the principles of oximetry and plethysmography.

Oximetry

When light passes through a solute dissolved in solvent, then it is partly transmitted, partly absorbed and partly reflected back which depends on the concentration of solute. This principle of transmission, absorption and reflection of light is used in several monitoring devices to estimate the concentration of this dissolved solutes. In an oximeter, absorption of infrared light is used to estimate the concentration of oxy-Hb (as solute) which remains in plasma (solvent) by using Beer-Lambert's law.

The Beer's law dictates that the solvent (e.g plasma) is transparent to a particular frequency of light which is used for oximetry. Whereas, the solute (haemoglobin – reduced or oxy) absorbs this light and that absorption is directly proportional to the concentration of Hb.

On the other hand, the Lambert's law states that when a beam of light falls on a semitransparent, homogeneous substance, then due to absorption the intensity of transmitted light decreases exponentially, as the distance travelled through the solute increases and is proportional to the distance. So, the two laws (i.e. Beer and Lambert laws) can be combined and reproduced as:

$A = d\ c\ E$ ..... (1)

A = Absorbance of the light,

d = Distance,

c = Concentration of the solute,

E = Absorption coefficent of the solute, which is constant for a given molecular weight and specified wavelength of a light.

The absorption coefficients of the most common four types of Hb [oxyhaemoglobin (O_2 Hb), carboxyhaemoglobin (COHb), methaemoglobin (metHb) and reduced haemoglobin (HHb)] at the working range of wavelength of red and infrared light which are used for oximetry are obtained from a graph which is given next. So, for the four types of Hb, the equation will be:

$A = d\ (C_1E_1 + C_2E_2 + C_3E_3 + C_4E_4)$ ..... (2)

The normal blood contains nil or negligible amount of MetHb and COHb, and they do not take part in O_2 carrying. In a normal individual the blood contains mainly the reduced Hb and OxyHb which takes part in transport O_2. So, to measure the O_2 saturation we can shorten the equation (2) to equation (3) by measuring the absorption of light by the only two relevant haemoglobin such as oxy and reduced.

$A = d\ (C_1E_1 + C_2E_2)$ ..... (3)

So, if the MetHb and COHb were not present in the blood sample, then the concentration of O_2Hb and HHb, i.e. C_1 and C_2 could be determined by using the light of two wavelengths only instead of four wavelengths which is required to measure the concentration of 4 types of Hb.

From the figure, it is observed that at a wavelength of 800 nm of a light, the coefficent for O_2Hb and reduced Hb are the same. So, if an oximeter uses this wavelength of light and no MetHb or COHb were present, then the equation would be reduced to:

$A = d\ E_{800}\ (C_1 + C_2)$

Thus, the total sum of OxyHb and reduced Hb could be determined by using the light of a single wavelength only. Using lights of two wavelengths, the concentration of the two types of Hb can be determined separately and from there the percentage of individual Hb may be calculated easily.

So, the percentage of saturation of total Hb by the O_2 is:

$O_2Hb/\text{Total Hb}\ (O_2Hb + HHb) \times 100$

This is the value of SPO_2 in percentage, where S stands for saturation and P stands for pulsatile. Certain other abbreviations related to it are: SaO_2 = arterial O_2 saturation and SVO_2 = venous O_2 saturation. The abbreviation SPO_2 is used, because the oximeter can not differentiate an artery from a vein, but can only recognize the O_2 saturation of pulsatile tissues which is usually of the arterial system, i.e. capillary. So, practically the SPO_2 and SaO_2 are equivalent. This Beer-Lambert's law can also be applied to measure the concentration of other mixture of gases and vapour in blood.

If in any pathological condition, the concentration of MetHb and COHb increases, then the equation will be :

$SpO_2 = [O_2Hb / (O_2Hb + HHb + MetHb + COHb] \times 100\%$

Now, we are considering the equation (2). If absorbance is measured by a single light of a specific wavelength (h), and the coefficient for the four types of Hb at that wavelength is known from the graph, then the preceeding equation would contain four unknowns: C_1, C_2, C_3, C_4 (as E_1, E_2, E_3, E_4 are known from graph). So, to solve this problem of four unknowns the light of four different wavelengths are needed. Similarly, to know the two unknown such as C_1 and C_2 in equation (3) we need two lights of different wavelength, considering that CoHb and metHb is absent in blood. *In vitro,* the concentration of four or more types of Hb is measured by laboratory oximeters which use light of four or more wavelengths passing through a cuvette, filled with a solution of lysed red blood cells (Fig. 22.4).

Therefore, theoretically, an oximeter will require light of four different wavelengths to measure the fractional saturation of each type of haemoglobin, otherwise it may lead to erroneous results. But, this is not available clinically.

In clinical non-invasive oximetry the red and infrared lights of two separate wavelengths are transmitted through a tissue bed. There are many light absorbers, i.e. different types of tissues are present in the path of transmitted light. These are skin, soft tissues, muscles, bones, venous blood, etc. (nonpulsatile part), and the arterial or capillary blood (pulsatile part). But, the pulse oximetry does not take into account the effect of absorption of light by these non pulsatile tissue, because by some intelligent calculation it is deducted from pulsatile tissue, which is described later (Fig. 22.5).

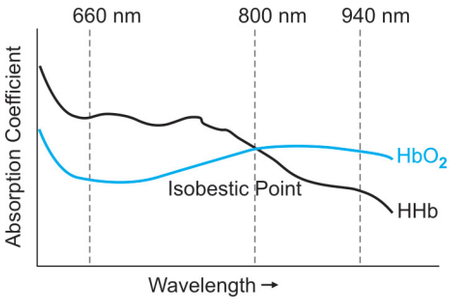

Fig. 22.5: Absorption spectra of oxy and reduced haemoglobin. For two types of Hb, two lights of different wavelengths (660 nm and 940 nm) are needed to get their absorption coefficient, respectively. By the light with a wavelength of 800 nm, we get a single coefficient, where the respective coefficients of HbO_2 and HHb are same and measures the total Hb

On one side of the probe which is used in pulse oximeter, there are two light emitting diodes (LED) which release red (660 nm) and infrared (940 nm) light respectively. On the other side of the probe there is a photo cell which detects the transmitted light after passing through the tissues and its absorption. The electrical output from the photodetector or cell consists of a steady signal (X), which results from the absorption of light by the non-pulsatile tissues, such as, bones, muscles, fat, venous blood, etc. On this steady nonpulsatile signal, a pulsatile signal (Y) is superimposed, resulting from the absorption of light by the pulsatile arterial or capillary blood, coming in the light-path. These two raw signals of which one is nonpulsatile and another pulsatile are then processed complexly by the microprocessor. The Y component is measured relative to the X component which is independent of the intensity of incident light. Then the ratio (R) of amplitude of the red and infrared pulsatile signal is determined, (using an algorithm), which is related to arterial O_2 saturation.

The pulsatile expansion of the capillary arterial bed increases the length of absorption path and thereby increases the absorption. As pulse-oximetry uses only two wavelengths of light – red light (660 nm) and infrared light (940 nm), so the pulse-oximeter first determines the Y component of absorption at each wave length, and then divides this value by the corresponding X component of absorption at each wavelength to obtain a 'pulse-added' absorption. The oximeter, then, calculates the ratio (R) of this 'pulse added' absorption which is emperically related to the percentage of arterial O_2 saturation (SaO_2).

$R = (Y_{660} / X_{660}) / (Y_{940} / X_{940})$

$= (Y_{660} / Y_{940}) \times (X_{940} / X_{660})$

Y_{660} / Y_{940} = Ratio of pulsatile components of absorption at 660 and 940 nm of wave-length.

X_{940}/X_{660} = Ratio of non-pulsatile components of absorption at 940 and 660 nm of wavelength (Fig. 22.6).

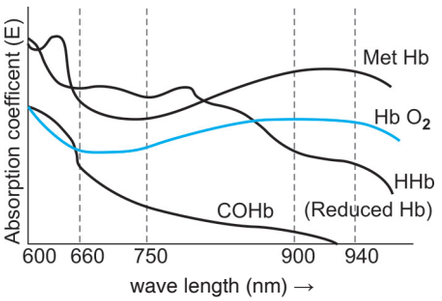

Fig. 22.4: Coefficients are plotted against the transmitted light absorption spectrum in the wavelength range, of the four species of Hb

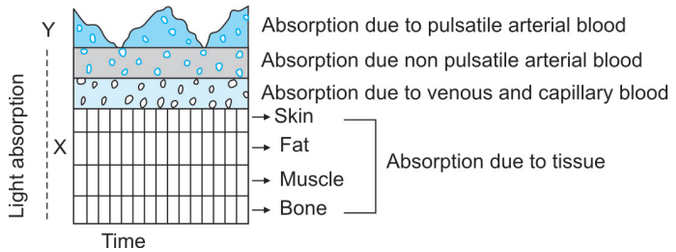

Fig. 22.6: Diagrammatic representation of the absorption of light by a living tissue. Arterial blood is the only pulsatile component of all the light absorbers in living tissues – Y components. The X component represents all the non pulsatile absorbers

The curves used in different commercial devices are prepared by different companies. These are based on the experimental studies, conducted by the companies on different group of human volunteers. Although, each curve is the property of this manufacturer, but the system being used is similar. So, the curves are very similar. For example, when the ratio of red to infrared absorbance is 1, the saturation of O_2 is 85% for all the machines.

For the best sensitivity, the difference between the ratio of absorption of red and infrared light by HbO_2 (oxy-haemoglobin) and HHb (reduced haemoglobin) at the two wavelengths should be maximised. At a wavelength of 660 nm the HbO_2 absorbs light 10 times less than reduced Hb and at a wavelength of 940 nm the absorption coefficient of HbO_2 is much greater than that of reduced haemoglobin (HHb).

Ear oximeter (which acts on the principle of simple oximetry, but not on pulse oximetry) has no ways of differentiating between the pulsatile arterial SO_2 of haemoglobin and nonpulsatile venous SO_2 of haemoglobin. So, it is applied on the ear with the idea that the earlobe contains predominantly arterial blood, and the reading shows the arterial SO_2. But, one cannot be sure that the earlobe contains only arterial blood. So, the other pulse oximetres, except the ear oximeter, are able to make this differentiation by assuming that the pulsatile portion of signal is entirely that of arterial blood. This is almost always true, except under unusual clinical conditions such as high venous pulsation in tricuspid regurgitation.

Pulse oximetre in practice

In practice, on one side of the probe of the pulse oximetre there is a light emitting diode (LED) which transmits two lights such as a red light at 660 nm of wavelength and an infrared light at 940 nm of wavelength from one side of the finger. It also has one photo diode, i.e. a sensing transducer on the opposite side of the finger. When the two LED are activated, it transmits two lights through the finger alternatively. Then, passing through the different tissues of finger the absorbed light on the opposite side is transduced into an electrical signal by the photo diode and is passed on to the computer. There, the ratio of absorption of these two lights by oxy- and reduced Hb is calculated electronically by a microprocessor, from where the SPO_2 is derived by an internally stored algorithm.

The measurement of SO_2 by light absorption technique was in existance for many years like ear oximeters, but it could not determine the pulsatile portion of the O_2 saturation. So, the development of pulse principle or plethysmography has increased substantially the reliability of such monitors and resulted in their extremely widespread use. However, the main drawback of this pulse oximetry is its insensitivity to the large changes in arterial PO_2 at the higher end of Hb-O_2 dissociation curve, i.e after reaching 100%, saturation it cannot be increased further with the increase in O_2 tension in blood.

In neonates when the repeated arterial puncture is not technically feasible to measure the arterial PO_2, then capillary PO_2 which is every close to arterial O_2 is measured by this pulse oximeter. But, capillary PO_2 is definitely lower than arterial PO_2. This difference can be reduced by taking capillary blood sample from prewarmed heel site, where there is abundance of local blood flow relative to the local tissue O_2 consumption. In contrast, in capillaries where PO_2 is significantly lower than arterial PO_2, but there the capillary SO_2 approximates arterial SO_2. This is because of the shallow slope of the lower part of the Hb-O_2 dissociation curve.

The other technical problems of pulse oximeter and their solutions are :

i. The LED in the probe do not emit light of a fixed wave length (monochromatic light), but usually emit light in a spectrum which should be narrow. But, certain companies use light in the range of wide spectrum. The central wavelength of this emission spectrum varies among the diodes of different manufacturers. But, this variation should not be more than 5 nm (e.g. 660 ± 5 nm). A shift in the centre of wavelength of light spectrium emitted by LED causes changes in the measured absorption coefficient and results in an error in the estimation of oxygen saturation. A light of narrow spectrum within acceptable range of wavelength increases the accuracy. If a light of wide range of wavelength for emission is used, then the pulse oximeter should be programmed accordingly to accept the centre wavelength of both the red and infrared light and also allow the device to correct internally and automatically the values for the different wave lengths. But, this will be a very costly affair.

ii. Another problem of pulse oximeter is that the photodiodes which are used opposite to the LED in the sensor probe, can not differentiate the light of different wavelengths, i.e. whether the light is coming from red, infrared or roomlight source. This problem is eliminated by alternating the red and infrared LED light sources on and off at a frequency of 100 times per second. After absorption through tissues, when the red light is on the photo diode detector, it produces a current in which roomlight also takes part. Then, similarly after absorption through tissues, when the infrared light is on the photo diode or detector, it also produces a current with the roomlight. Finally, when both the LED are turned off, then the photodiode detector produces the signal from roomlight only. Computer in the pulse oximeter eliminates all these common factors of light interference by calculating the ratio. This is a very clever design, but sometimes different sources of light

produces different artifacts which can be minimised by covering the sensor with an opaque shield.

iii. Another problem arises when the amplitude of signal ratio is very low. Usually, all the oximeters have devices to amplify their signals. But, with the amplification of signal, the noise is also amplified. So, to prevent this type of artefact a minimum value for signal to noise ratio is incorporated, below which level the device displays no value for SPO_2. Some oximeters display low-signal strength error message and some others display a plethysmographic wavelength for visual identification of noise.

iv. Patient's motion which is equivalent to high AC to DC signal ratio also produces artefacts. These artefacts are eliminated by increasing the signal averaging time (i.e., the device averages its measurements over a longer period of time). But, the longer averaging time also slows the response time to an acute change in SO_2. So, many pulse oximeters have a system to select one from several time-average modes. Some oximeters use sophisticated algorithms to identify and reject spurious signals.

Causes of errors in pulse oximetry

As clinically the pulse oximeter takes the help of two lights of two different wave lengths, so the presence of Hb species other than the reduced Hb and oxy-Hb may cause erroneous readings. In a research laboratory, the sophisticated pulse oximeter uses multiple lights of separate wave lengths and by this device this error can be reduced.

Carboxy-haemoglobin (COHb)

The carboxy-haemoglobin is formed during carbon monoxide (CO) poisoning. In the presence of COHb, there is falsely high pulse oximeter reading. When the concentration of COHb is 50%, then the pulse oximeter reading is about 95%. The probable explanation is that at 940 nm of wave length the COHb has no absorption and therefore does not contribute to total absorbance. At 660 nm of wave length, COHb has an absorbance close to that of O_2Hb. So, the O_2 saturation becomes falsely high.

Methaemoglobin (MetHb)

At 940 nm of wavelength the absorption of light by MetHb is highest among other species of Hb, and at 660 nm of wavelength the absorption of light by MetHb is very close to reduced Hb. Thus, the absorption ratio of 1:1 of methaemoglobin corresponds to O_2 saturation of 85%. Therefore, SPO_2 is falsely low when it is truely high (> 85%) and SPO_2 is falsely high when it is truely low (< 85%). Independent of actual arterial O_2 saturation, SPO_2 shows to be 85% in the presence of high MetHb concentration.

Structural Haemoglobinopathies

Absorption spectrum of HbF and HbA is more or less same. So, HbF has no major effects on pulse oximetry. There is also no significant effect of HbS on pulse oximetry. Only, it should be kept in mind that the sickle cell disease has a rightward shift of Hb-O_2 dissociation curve and, therefore, at any given P_aO_2 value, the SPO_2 will be lower than the expected.

Anaemia

Anaemia causes false negative pulse oximetry result. Polycythemia has no apparent effect on pulse oximetry.

Nail-polish

Blue nail-polish with an absorption spectrum near about 660 nm causes a false negative result. Nail polishes of other colours have minimum effects.

Jaundice

Bilirubin has no significant effect on pulse oximetry. But nonpulsatile oximetry may measure a falsely low value.

Skin

Very thick skin and deep pigmentation can result in reduced signals and cause slightly low false results. Otherwise, no significant effect is reported.

Movement

Movement, especially shivering, can falsely depress the SPO_2 reading.

Blood flow

Reduced amplitude of pulsation due to low tissue perfusion can cause difficulty in obtaining signals and thus gives a false low SPO_2 reading.

The causes of low tissue perfusion are low cardiac output, severe anaemia, hypothermia, increased systemic vascular resistance, etc. So, in addition to SPO_2 the pulse oximeter also provides an indication of tissue perfusion from pulse amplitude. Again, as SPO_2 is normally close to 100%, so only gross abnormalities are detected. Depending on a particular O_2-Hb dissociation curve in a patient, the 90% saturation reading in a pulse oximeter indicates the P_aO_2 of less than 65 mm of Hg. This compares with clinically detectable cyanosis, which requires 5 gm of reduced Hb and usually corresponds to an SPO_2 of less than 80%. In the absence of gross pulmonary diseases and low FiO_2, the bronchial intubation will usually go undetected by pulse oximeter.

Other causes

Other causes of artefacts of pulse oximetry are excessive ambient light, methylene blue dye, venous pulsation in a dependent limb, malpositioned sensor with leakage of light from LED to photodiode, bypassing arterial bed (optical shunting), etc.

Special uses of pulse oximeter

Other than the measurement of O_2 saturation in capillary blood the two special uses of pulse oximeter are: (i) measurement of mixed venous oxygen saturation (SVO_2), and (ii) non-invasive brain oximetry. SVO_2 continuously varies with the changes of

Hb concentration, cardiac output, arterial O_2 saturation and the whole body O_2 consumption. So, interpretation of SVO_2 is much informative but is very complex. It requires the placement of a PAC containing fibreoptic sensor in pulmonary artery that continuously measures the SVO_2 in a manner similar to a pulse oximeter.

A special type of noninvasive pulse oximetry can also measure the regional O_2 saturation (rSO_2) of haemoglobin in brain. Unlike ordinary pulse oximetry, it measures the venous, capillary and arterial blood O_2 saturation of brain tissue and represents an average reading. So, it is helpful to know the O_2 status or circulation of the brain during hypothermia, cerebral embolism, hypotension, hypoxia, etc,. where there is a dramatic decrease of rSO_2. In this type of special noninvasive pulse oximetry, a sensor is placed on the forehead which emits light of a specific wavelength and then measures the amount of reflected light after absorption by brain tissue. It works on the principal of infrared optical spectroscopy.

Measurement of O_2 Tension (PO_2) in Blood

Other than the measurement of saturation of O_2 in blood by noninvasive method, the most straightforward method of assessing the respiratory function is to measure directely the arterial O_2 tension (P_aO_2) from blood sample. This is done by the following methods.

(A) By oxygen electrode: the polarographic method

This is usually done by Clark polarographic O_2 electrode. The Clark's polarographic O_2 electrode consists of a platinum cathode and a silver anode. They are connected to a battery through a meter which measures the flow of current and this flow of current is proportional to the amount of O_2 present in solution.

As in any resistive circuit and according to the Ohm's law an increase in voltage increases the flow of current. However, this polarographhic electrochemical cell which measure the O_2 concentration or tension does not obey this Ohm's law ($E = I \times R$), but rather exhibits a plateau. That means with in certain range the increase in voltage does not increase the flow of current, but the increase in O_2 tension increases the flow of current. This is called polarogram. The platinum and silver electrodes are immersed in an electrolyte cell. A membrane, permeable to O_2 only but not to the electrolyte, covers one surface of the cell. A polarising voltage, ranging between 600 to 800 mV is applied in the circuit. O_2 diffuses through this membrane and reacts at the platinum cathode producing hydroxyl ions. For this reaction, electron is needed and it is supplied by the silver chloride anode. Thus, the reduction of O_2 which occurs at the platinum cathode corresponds with the oxidation which occurs at the silver chloride anode by the following reactions.

$$O_2 + 4\ e \rightarrow 2\ O_2^-$$
$$2\ O_2^- + 2\ H_2O \rightarrow 4\ OH^-$$
$$4\ Ag \rightarrow 4\ Ag^+ + 4\ e^-,$$
$$4\ Ag^+ + 4\ Cl^-$$

Thus multiple small cells are setup and tiny electrical circuits are generated which is dependent on the O_2 tension at the platinum cathode. The current meter measures the current produced by the consumed electrons in the reaction at the cathode and this consumption of electron is proportional to the local PO_2 (Fig. 22.7).

This polarographic method needs withdrawal of blood sample to measure PO_2. To obviate this need of drawing blood samples, intra-arterial PO_2 monitors have also been developed recently by using fibreoptic technique. This technique uses a particular property of O_2. This particular property of O_2 is to absorb energy from excited electrons of a fluorescent dye. To elevate the electrons in the dye to a higher energy state an incident light is used. These excited or highly energised electrons may then return to a lower energy level by emitting photons. Molecular O_2 by absorbing the energy inhibits this photon emission. This process of inhibition which is called fluorescent quenching is related to the concentration of O_2 and is used to measure the PO_2.

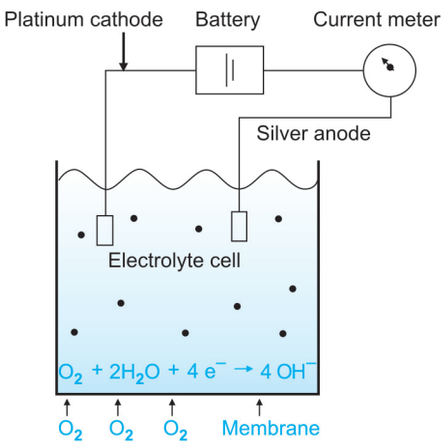

Fig. 22.7: Schematic diagram of the Clark polarographic O_2 electrometer. The circuit consists of a current meter which is connected to a platinum cathode, a silver anode, and a battery (voltage source). These electrodes are immersed in an electrolyte cell which have a membrane, permeable only to O_2 but not to the electrolytes. O_2 diffuses through the membrane and reacts with the platinum cathode. Here it receives electrons (e^-) and reacts with water and produces OH^- ion. This OH^- ion the reacts with the silver anode and gives up electrons. Thus small electrical circuit is generated. The current meter measures the current produced by these two electrodes and the concentration of O_2, which is responsible for this production of current

(B) By galvanic or fuel cell

A galvanic cell converts chemical energy (oxidation – reduction by O_2) into electrical energy and thus the generated potential is dependent on the O_2 concentration needed for the chemical reaction. At the cathode end (made by gold mesh) O_2 is reduced to hydroxyl ions by its reaction with electron and water and at the anode the lead is oxidised by removing electron. This chemical reaction produces a potential gradient and hence a flow of electrical current. This is measured and read out digitally on the screen of monitor with audible alarms. Unlike O_2

electrode in polarographic method, this fuel cell does not need any battery and is also cheap, portable and reliable. This also needs little maintenance. But, inaccurate response to calibration with O_2 and air suggests that the fuel cell is exhausted and should be replaced. The chemical reaction which takes place in fuel cell uses up the components of the cell. So, its life depends on the concentration of O_2 to which it is exposed and on the duration of exposure. Usually, a fuel cell lasts for 6 to 12 months.

(C) By transcutaneous electrodes

This is a non-invasive method of measuring PO_2 of blood. This device also consists of a small or miniaturized Clark O_2 electrode. The probe of this device is attached to the skin with an adhesive tape through a contact liquid to form an airtight seal and the area is also heated to 43°C by this probe. At this temperature the blood flow to the skin is increased and the capillary O_2 diffuses out of the skin. This allows the accurate measurement of PO_2 by the attached electrode. Actually, the measurement of PO_2 by this transcutaneous method ($PtcO_2$) reflects the capillary PO_2 which is lower than the P_aO_2. So, the skin is warmed to 43°C to increase the capillary blood flow and then $PtcO_2$ correlates well with P_aO_2. The main disadvantage of heating the probe electrically to improve the cutaneous circulation is burning of skin on prolonged use. Also, unlike the original electrode in blood-gas machine, this miniaturised probe contains only one drop of electrolyte. So, when the sensor is heated continuously to 43°C, then this elevated temperature causes the electrolyte to evaporate very quickly and reduces the life span of this device.

Peripheral vasoconstriction, thick adult skin and reduction of cardiac output causes a decrease in $PtcO_2$ level. This is because of cutaneous hypoxia due to hypoperfusion and may produce erroneous results. However, this technique is particularly useful in infants, in whom the local skin blood flow tends to be high and capillary PO_2 is as close as to the arterial PO_2 and in whom repeated drawing of arterial blood is technically difficult and may cause anaemia. Another disadvantage of transcutaneous O_2 electrodes is that the time constant of PO_2 measurement is nearly a minute. So, sudden decrease in P_aO_2 cannot be detected quickly enough to take any appropriate measure. Prolonged application may also cause skin burn. Problems also occur with surgical diathermy. Because, the heated circuit provides a return path for the cutting current which may overheat the transcutaneous electrode and cause burn.

Measurement of O_2 Content

The measurement of total O_2 content in blood is also a type of monitoring of the respiratory function. It can be measured from the value of O_2 saturation of the Hb, Hb concentration and the tension of O_2 in blood, using the formula below :

Oxygen content of blood (ml/dl) =
$[SO_2\ (\%) \times Hb(gm/dl) \times 1.34] + [0.0225 + PO_2\ (KPa)]$

The Oxygen content in blood can also be measured by Van Slyke technique, using chemical and volumetric analysis.

Measurement of Mixed Venous O_2 Saturation (SVO_2)

Mixed venous O_2 saturation is obtained from the equation

$SVO_2 = SaO_2 - [VO_2 / 13.9 \times Q \times (Hb)]$

Q = Cardiac output, [Hb] = Haemoglobin concentration,

VO_2 = Oxygen consumption.

Mixed venous O_2 saturation is decreased in circumstances where there is low SaO_2, low cardiac output, low [Hb], elevated VO_2, etc, Low SVO_2 is also found in all those conditions which produce impairment of O_2 delivery to the tissues. So, measurement of SVO_2 is very helpful in detecting any condition that may impair tissues oxygenation. The SVO_2 can be measured intermittently by taking blood sample from pulmonary artery catheter or continuously by a pulmonary artery catheter which is equipped with a fibre optic bundle and oximeter. Low level of SVO_2, usually less than 60%, may sensitively indicate an abnormality of any of the factors which are mentioned above.

Measurement of Tissue Oxygenation

Till now, the measurement of arterial oxygen level (saturation, tension or content) has been discussed which is an indicator of the status of respiratory function. But, adequate arterial oxygenation does not always indicate adequate tissue oxygenation, because there are many other factors which determine the tissue O_2 level, such as, local tissue blood flow, rate of O_2 consumption by tissues, acid base status, temperature, etc. So, for appropriate monitoring of the respiratory function of a patient, measurement of the level of O_2 in tissues or tissue-oxygenation is important.

Tissue oxygenation or O_2 level in tissues is measured by the tissue PO_2 measuring electrodes which has certain problems. These problems are :

i. Tissue destruction by electrodes,
ii. Since different tissues have different blood flow and different O_2 consumption levels. So different tissues have different PO_2 level, rather than a single standard value as in blood.
iii. Area within the same tissue, changes in oxygenation have been demonstrated under varying local conditions.

Recently, tissue oxygenation is being measured by using light whose wavelength falls within the near infrared band (wavelength 650 to 1100 nm) and which can penetrate the tissue reasonably well. Commercially, such an instrument is available which using this technique can measure the O_2 saturation of brain tissue. To measure the brain tissue O_2 level, the incident light is applied on the scalp from where it enters the brain. Then, a small proportion of light is scattered and returns back after

its absorption by brain tissues to the analyzer by a fibre optic bundle. The absorption and the intensity of this reflected light depends on the O_2 level of tissues and thus the machine measures the O_2 level of it. The measured O_2 saturation of brain includes arterial, capillary and venous blood. But, it is heavily weighted towards the values of venous blood. Whereas, pulse oximetry measures only the arterial O_2 saturation, as it only measures the pulsatile portion of the tissue. So, it indicates the amount of O_2 delivered to the tissues, but does not indicate the amount of O_2 diffused in it or the consumption and need of O_2 by it.

Recently, it has also become possible to measure the tension of oxygen at the intracellular level by mixing the light of different wavelengths. This is more likely to provide a better estimation of O_2 availability at the cellular level than the currently available clinical monitoring parameters. This technique has been used to monitor the intracellular changes of muscle and brain tissue during respiratory acidosis, hypoxia and cardio-pulmonary bypass.

Measurement of Inspired O_2 Concentration

An anaesthetic apparatus usually supplies the O_2 and anaesthetic gases to the patient. Thus, it regulates the arterial PO_2, and the uptake and elimination of inhalational anaesthetic agents by lungs. So, the knowledge of composition of the inspired gases, at least the concentration of O_2, is important for the routine monitoring of a patient.

Therefore, it is mandatory to analyse the inspired gas for O_2 concentration constantly during the all forms of anaesthesia. This will ensure that hypoxic mixtures are not used and will also confirm that the desired concentration of anaesthetic agents are being delivered. Thus, the delivery of an adequate amount of O_2 is so crucial for safe anaesthesia that multiple safety monitoring systems, including using of an oxygen analyser in the circuit are considered mandatory.

During low-flow closed circuit anaesthesia, the inspired concentration of O_2 cannot be calculated from the rotameter, if nitrous oxide is being used. So, measurement of inspired O_2 concentration becomes mandatory, as part of the intraoperative patient monitoring

The O_2 concentration in inspired gases can be measured by the following ways:

1. Paramagnetic O_2 analyser

Most of the monitors have a paramagnetic sensor. It uses the property of O_2 which is based on its weak attraction by a magnetic field. As most of the other anaesthtic gases are diamagnetic, so they are weakly repelled by a magnetic field. Two unpaired electrons, spinning at the same direction in the outer electron shell of O_2 atom make this molecules strongly paramagnetic, i.e. attracted towards a magnetic field.

In the chamber of a paramagnetic monitor there is a small sphere, filled with nitrogen. The sphere is suspended from a bar that is free to rotate by a strong magnetic field. In a normal condition, i.e. when exposed to air, the bar finds a position where the force exerted on the sphere by the magnetic field is balanced by the torsion of the suspending wire. If the O_2 concentration in the chamber increases, then the O_2 is attracted towards the magnetic field. This inward movement of O_2 displaces the sphere and causes the bar to rotate. This small twisting movement of the bar is measured and then amplified. Thus when calibrated, the O_2 concentration in the chamber may be calculated easily from the position of the bar. This instrument identifies and accurately measures the O_2 concentration in a mixture of gases over a wide range. It is reliable and a fast method. But, unfortunately, it cannot measure continuously the breath by breath changes of O_2 concentration and its sample volume is large.

2. Polarographic O_2 electrode and O_2 fuel cell

Some monitors use polarographic O_2 electrodes and some use O_2 fuel cell for the measurement of concentration of O_2 in the inspired gas. Although the response time for both of these instruments is long, but they are cheap, compact, portable and are of sufficient accuracy for clinical use, as a continuous monitor for inspired O_2 concentration. The fuel cell measures the partial pressure of O_2, instead of its concentration and its accuracy is usually around ± 2% with a response time < 10 sec. The long life (2000 hours when exposed to 100% O_2) and robustness of fuel cell lends it a valuable device for this role and it should be available with all the anaesthetic machines.

Before each use the analyser should be calibrated by exposure to air and 100% O_2.

Monitoring of Respiratory System by the Measurement of CO_2 in Blood

Measurement of CO_2 tension in blood

Like O_2 tension, measurement of CO_2 tension in the blood also reflects the status of respiratory function. So, monitoring of PCO_2 in blood is another way of monitoring the respiratory function of a patient. But except monitoring of respiratory function, measurement of PCO_2 of blood also monitors the acid-base status, cardiac function, function of the anaesthetic machine, etc. Blood PCO_2 can be measured directly or indirectly in different ways, some of which are described below.

1. Directly by CO_2 electrode

It is also called the Severinghaus CO_2 electrode and is used in the blood gas analyzer to measure the PCO_2 of blood.

This CO_2 electrode acts by measuring the changes of pH in blood. As a pH electrode, it is kept in contact with a thin layer of bicarbonate buffer solution which is separated from blood or plasma by a thin

teflon or silicone membrane. This membrane is only permeable to CO_2 but not to blood cells, plasma or charged ions. The whole unit is maintained at 37°C. The CO_2 diffuses from blood into the buffer solution through this membrane, and causes a change in H^+ concentration of solution which is reflected as the CO_2 tension on the screen of monitor. The electrode is calibrated by equilibrating the buffer solution with two known CO_2 concentrations which establish the relationship between pH and PCO_2.

2. Indirectly by transcutaneous measurement of PCO_2

Transcutaneous CO_2 electrode is nothing but a miniature modification of Severinghaus electrode which is used in the blood gas machine to measure the CO_2 tension of blood. Here, the CO_2 diffuses through a membrane into the cell, where it reacts with water and produces carbonic acid. The pH sensitive glass electrode, then, reacts to this change in concentration of hydrogen ions by producing a small electromotive force which can then be measured as the partial pressure of CO_2. After the introduction of Severinghaus CO_2 electrode in 1958, it was first used in a blood-gas analysing machine. Then, in 1970, this electrode was miniaturised and incorporated into a transcutaneous probe to measure the blood CO_2 tension through skin non-invasively (Fig. 22.8).

The advantages and disadvantages of this transcutaneous CO_2 probe is similar to that of transcutaneous Clark O_2 probe or an electrode which is used to measure the blood O_2 tension. Actually, transcutaneous CO_2 electrode measures the capillary PCO_2. So, to get the actual arterial PCO_2, the blood flow should be increased in the capillaries by warming the skin to 44°C through the probe. Again, heating of Severinghaus CO_2 electrode and applying it to the surface of skin increases the metabolic production of CO_2 in the tissue, resulting in a higher PCO_2 than the actual arterial

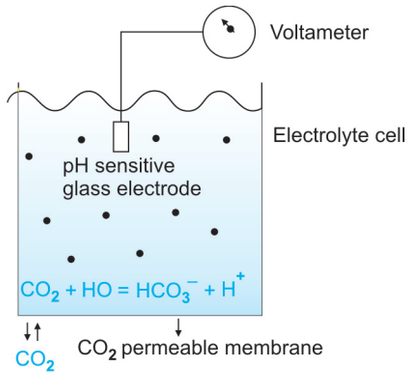

Fig. 22.8: Diagrammatic representation of a Severinghaus CO_2 electrode. This device consists of a pH sensitive glass electrode and an electrolyte cell, having a CO_2 permeable membrane covering on the surface. The gas electrode is immersed in the electrolyte cell. Through the permeable membrane, CO_2 diffuses into the cell. Then, it reacts with water producing carbonic acid and changes the pH. The pH electrode then detects the change in pH, which is directly proportional to the CO_2 concentration

PCO_2. Another disadvantage is that unlike the CO_2 electrode used in blood-gas machine in transcutaneous electrodes, the used electrolyte is only a few millimetre in amount. So, the continuous heating of probe to 44°C causes quick evaporation of water from the electrolyte, and hence results in a short life span of the transcutaneous probe. However, in the newer transcutaneous probes all these disadvantages are removed by incorporating some newer technologies and electronic calibration.

The main advantage of this transcutaneous CO_2 probe is that repeated withdrawal of blood to measure the blood PCO_2 is not required which is very helpful in children.

Measurement of end tidal CO_2 tension ($ETPCO_2$)—Capnography

The measurement of $ETPCO_2$ is another way of monitoring the respiratory function. The end tidal CO_2 tension ($ETPCO_2$) is used as an estimation of P_ACO_2 and hence P_aCO_2, because the level of P_ACO_2 and P_aCO_2 run parallel and very close to each other, except in some rare circumstances where the arterial and alveolar CO_2 tension difference is high. The normal gradient between P_ACO_2 and P_aCO_2 is 2 to 5 mm of Hg. It reflects the volume of alveolar dead space, i.e. the number of alveoli which are ventilated, but not perfused. Thus, any increase in the alveolar dead space by reduction in lung perfusion, such as, air embolism, ↓BP, ↓cardiac output, etc. decrease the expired CO_2 concentration and lessens the $ETCO_2$ tension and increases the $P_ACO_2 - P_aCO_2$ gradient. This gradient is also increased when there are other causes of impairment of lung perfusion and the end-tidal CO_2 level does not reach the arterial level. So, sometimes the $ETCO_2$ value should be checked with arterial blood samples, especially in more complex situations. These include: severe pulmonary diseases and situations where the accurate control of arterial CO_2 level is critical to save the life. So, the end tidal CO_2 ($ETCO_2$) analysis has achieved a high degree of popularity.

A variety of techniques can be used for the measurement of $ETCO_2$ concentration and its tension, such as, mass spectrometry, Raman's analysis, infrared absorption technique, etc. But, the last is used in majority of capnometers (Table 22.2).

Infrared radiation of 1 to 15 µm (1000 to 15000 nm) of wave length is absorbed by all the gases which have two or more dissimilar electrons at the outer orbit of their atoms. In the infrared absorption method, an infrared light beam is projected through the gas sample and then the intensity of this transmitted light is measured after its absorption while passing through it. However, this absorption of infrared light is different in degrees, depending on the concentration and the absorption spectrum of the gas to be analysed. CO_2 absorbs infrared light with a characteristic peak at the wavelength close to 4.3 µm (4300 nm). Several other molecules, such as, N_2O, CO, water vapour and O_2 can also absorb the light in this area of spectrum (absorption spectrum of N_2O and CO is 4.5 and 4.7 µm respectively). Thus, they may

Table 22.2: Conditions of end tidal CO_2 tension

A.	**Conditions of raised end tidal CO_2 tension**
	Hypoventilation
	Rebreathing
	Malignant hyperthermia
	Pyrexia
	Sepsis
	CO_2 inhalation
	Laparoscopy by CO_2
	After release of tourniquet
	Faulty equipment, exhausted sodalime
B.	**Conditions of low end tidal CO_2 tension**
	Hyperventilation
	Bronchial intubation
	Hypothermia
	Hypometabolism
	Hypoperfusion
	Pulmonary embolism
	Leak in breathing circuit
C.	**No tracing of graph of end tidal CO_2 tension**
	Oesophageal intubation
	Disconnection of breathing circuit
	Cardiac arrest

interfere with CO_2 measurement, especially if the composition of incident light includes wavelengths, other than those in a very narrow spectrum around the CO_2 absorption peak. But in practical use, the fixed geometry of this gas (CO_2) sampling cell, a narrow band infrared light source and a compensating electronic circuits of a computer can often automatically correct the interference by other gases. After absorption, a special photo cell detects and transduces the absorbed infrared radiation to a continuous electrical output. The modern CO_2 analyzers for clinical use are very stable, but it require calibration to its zero point routinely at a regular time interval.

To ensure the accuracy, most monitors modify the principles of infrared absorption technique by different methods to measure the CO_2 content accurately in several ways. Sometimes the beam is usually turned on and off upto 4000 times per minute to provide a zero light reference. Sometimes the infrared light from a single light source is usually split and passed through two indentical chambers : one contains the gas mixture to be analyzed and the other is empty. The absorption of CO_2 is then calculated by comparing the two beams. Lastly, each beam may be reflected through the chamber for several times by a series of mirrors to increase the amount of absorption and make it easier to measure.

Modern multimonitors for measurement of $ETPCO_2$ use infrared light of several wavelengths and are, therefore, able to automatically detect the concentration of various other gases which are present in the mixture. This method is also used to monitor different anaesthetic agents during inspiration and expiration. Estimation of the end-tidal O_2 tensions ($ETPO_2$) can also be used as a monitoring parameter for respiratory function, because $ETPO_2$ is equivalent to P_AO_2 and hence P_aO_2. But this is not always true, because of the variable alveolar and arterial oxygen tension gradient (A-a). In a normal individual, the gradient is less than 10 mm of Hg. But in a V_A/Q mismatch, this -a oxygen tension gradient will be very high, resulting in an arterial hypoxaemia which is not reflected by $ETPO_2$. But usually the V_A/Q mismatch has no effect on the relation between the $ETPCO_2$ and P_aCO_2. Futhermore, if a patient receives high inspired O_2 concentration, then the $ETPO_2$ will be falsely high and shall overestimate the P_aO_2. Even a dead patient may show high $ETPO_2$, if he is ventilated with 100% O_2.

A capnometer is usually of two types: (i) side stream capnometer, and (ii) main stream capnometer.

A. Side stream capnometer

In a side stream capnometer the main infrared analyser module is situated out of the anaesthetic circuit at a distance from the patient within the multimonitor. So, it constantly drains the gas sample of around 150 ml/min by a small pump via a fine gauge tubing. But the main analyser should be placed as close to the patient as possible. This will reduce the amount of gas drained out from the circuit. The infrared analyser module or sensor may be a separate unit or may be housed in the main multimonitor which measures the other parameters of the patient. The side stream capnometer is less reliable, but is less liable to accidental damage. The infrared measuring cell i.e. the core of the instrument should be protected from water vapour and other particulate matters, as they may cause erroneous readings due to their higher infrared absorption. Usually water vapour present in the expired air condenses at room temperature in the sampling tube and accumulates in a water trap which is then filtered out from the sampling gas before entering in the main analysing module. In critical-care settings or in very long cases, where inspired gases are warmed and humidified properly, then work load increases on the water-separating system of the capnometer as the inspired air has high water content.

The disadvantages of side stream capnometer are:

i. There is some delay in detection and measurement of PCO_2. This is further increased if the tubing, leading from the anaesthetic circuit is too long or too wide. This delay is called the 'CO_2 flight time'. It can be minimised and the sensitivity can be increased by using high gas flow rates (upto 250 ml/minute) for sampling and narrow short tubing (low dead space) assemble, compatible with the position of equipment with respect to the patient breathing circuit. On the otherhand, if the tidal volume is small such as in a paediatric patient, then this high rate of aspiration (gas sampling) may draw much fresh gas from the circuit and dilute the $ETCO_2$ reading. Low aspiration rates (less than 50 ml/minute) can also delay $ETCO_2$ measurement and underestimate it during rapid ventilation by drawing fresh gas from the circuit.

ii. Multiple connection sites in the assembly of side stream capnometer such as sampling gas pump, flow regulation, water-trap etc., may cause increased incidence of gas leakage or breakage and erroneous result.
iii. If the sampling flow exceeds the expired gas flow, then contamination from the fresh gas source may occur which may give inaccurate reading. The rate of gas sampling can be adjusted from 50 to 500 ml/minute, but the usual volume of the gas sample is maintained between 50 to 150 ml/minute.
iv. In certain circumstances such as during paediatric anaesthesia, the removal of 150 ml of gas from the circuit may affect ventilation. So, most monitors incorporate the facility to return the measured gas to the circuit through a second tube. Thus, this second tube also helps to prevent the OT pollution by anaesthetic gases coming out from capnometer.

B. Main stream capnometer

In a main stream capnometer there is no system of continuously drawing of sample gas by a pump. The sensor or the main infrared analyzing module of the mainstream capnometre is placed along the breathing circuit itself, resulting in a quick and accurate measurement of PCO_2 from expired gases. The analysis of end-tidal PCO_2 correlates well with the concentration of CO_2 in the alveoli and hence in the arterial blood. So, to get a correct result, mixing of expired gas with the fresh gas should by prevented. So, the instrument should be placed as close to the alveoli as possible. Hence, the measuring head is placed in close proximity to the ET tube (Table 22.3).

The advantages of main stream capnometer are:

i. No gas is subtracted from the breathing circuit, so does not effect the ventilation.
ii. No suction pump or other device is required for sampling which add complexities to the mechanical system.

Table 22.3: Indications of use of capnometer

1. Confirmation of tracheal intubation.
2. Confirmation of adequate ventilation.
3. Detection of hyperthermia (malignant or not).
4. Detection of rebreathing.
5. Detection of V_A/Q mismatch.
6. Detection of pulmonary embolism.
7. Detection of malfunctions of inspiratory and expiratory valve.
8. Confirmation of continued ventilation or detachment at any part of circuit.
9. Detection of cardiac activity during CPR.

iii. No uncertainty in gas sampling.
iv. Response time is faster.

The disadvantages of main stream capnometer are:

i. The measuring chamber is usually heated to about 40°C to prevent water condensation in the chamber window. So, the heated sensing head should be kept away from direct contact with the patient's skin.
ii. It is relatively heavy and must be supported to prevent ET tube kinking.
iii. Sensor's window must be kept clean of mucous and other particles to prevent false reading.
iv. Calibration is problematic.

Periodically the capnometer should be calibrated by using the gases of known concentration, guided by the respective companies. Mainstream capnometers are often equipped with calibration sample cells, sealed with a mixture of CO_2 and N_2 of known concentration. In some instruments, the room air is sampled in the mainstream cuvette for calibration and bring the CO_2 level automatically to zero.

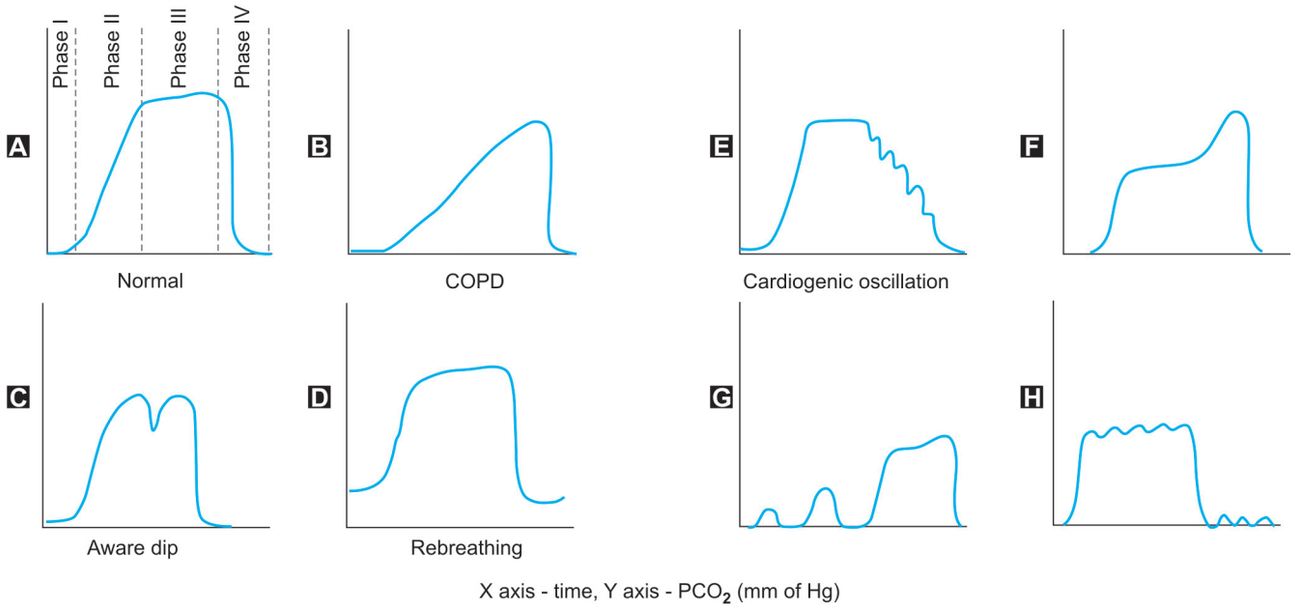
Capnographic wave form

In the capnographic wave form or tracing there are four phases Among these the phase I, II and III corraborates with expiration and phase IV corraborates with inspiration. In phase I the expired gas which comes out from the anatomical dead space such as the ET-tube and the large airways are devoid of CO_2. This is because they contain only the fresh gas and so in this phase there is no rise in PCO_2 in tracing which follows the base line. This phase I is followed by phase II. In short phase II as the expiration continues, so a rapid upstroke of PCO_2 level is recognised. This is called the 'rising front of CO_2'. This is because the anatomical dead space gases, mixed with the alveolar gases containing CO_2 now, starts to excrete and the concentration of CO_2 increases rapidly to a plateau level. Expiratory flow is highest in the beginning of expiration and then tapers off in an exponential fashion during the last third of the expiratory time. So, this phase II is followed by phase III which is called the alveolar plateau. This represents the constant slowly rising part of the graph and reaches a peak at the final phase of expiration. This represents final $ETCO_2$ tension value. The cause of this constant rising of PCO_2 in phase III is that gradually expired gases containing more and more CO_2 coming purely from the alveoli (not mixed with anatomical dead space gases) reaches the analyser. This is because CO_2 excretion from the pulmonary capillaries into the alveoli continues at a nearly constant rate during expiration and this CO_2 molecules are not diluted by the lung volume which becomes progressively smaller by the exhalation process. This gradual and relative increase in the concentration of CO_2 in the smaller lung volume is responsible for the constant slowly rising part of the graph or phase III. Slow exhalation as in the acute asthma patient induces a steeper alveolar plateau. Thus, the end of the phase III or alveolar plateau represents the final $ETCO_2$ tension. In a normal individual the $ETCO_2$ tension is 2 to 3 mm of Hg less than P_aCO_2. But, the chronic pulmonary diseases and acute V_A/Q mismatch wides this difference. At the end of phase III when expiration still continues and lung volume (FRC) goes below the closing capacity, then expired CO_2 concentration rise sharply at the end of phase III or the alveolar plateau. This is also

responsible for the peak of phase III. The phase III is followed by phase IV which is characterised by rapidly decreasing value of CO_2 tension towards the inspired value. This is caused by the inspired gas being sucked into the analysing site. The capnograph value during inspiration represents the CO_2 tension or concentration in the inspired air which depends on the type of the breathing circuit, fresh gas flow respiratory rate and the amount of rebreathing. Rebreathing of the expired gas containing CO_2 due to any reason causes an inspired level of CO_2 tension above the baseline. The probable causes of rebreathing are: improper circuit with increased dead space, low fresh gas flow, exhaustion of CO_2 absorber, high respiratory rate etc.

In a side stream capnometer the sampling flow rate has a greater impact on the capnograph value. So, it should be taken into account during interpretation. Sampling flow rate by suction pump in a capnometer can vary between 50 ml to 400 ml/min, but usually in an adult it is adjusted to 150 ml/min. When respiratory gas flow decreases below the sampling value, such as in paediatric anaesthesia or low-flow anaesthesia, then the capnometer contributes significantly to the bulk flow, in and out of the respiratory circuit (Fig. 22.9). In this situation, for sampling the monitor should aspirate gas alternatively from the trachea or the inspiratory limb, causing an oscillatory graph in phase III and IV which is known as 'cardiogenic oscillation'. It appears as a small, tooth like, regular wave at the end of expiratory phase.

Other probable explanations of cardiogenic oscillations are: (i) it is due to the contraction and relaxation of heart and the movement of intrathoracic great vessels of lungs which forces the air out of the lungs in oscillating fashion. So, this rate of oscillation matches with the heart rate.



Figs 22.9A to H: Schematic diagram for analysis of $ETCO_2$ tension waveform. Phase I represents the gas of anatomical dead space. So it does not contain CO_2 and seen as flat phase running along the base line. A raised phase I (See Fig. D) suggests rebreathing or malfunctioning of inspiratory and expiratory valve or an exhausted soda lime. Phase II represents the rapid rise of tracing after phase I. This is due to the exhaled gases coming first from anatomical dead space and then alveoli and so containing gradually more and more CO_2. This corresponds to begining of expiration. A slanted upstroke (See Fig. B) represent obstruction of airway during expiration. This obstruction may be due to asthma, COPD, kinking of airway, secretions, etc. No plateau is reached before next inspiration and the gradient between $P_{ET}CO_2$ and P_aCO_2 will increase. Phase III consists of a nearly horizontal plateau which corresponds with exhalation of gas coming entirely from alveoli. During expiration the gas leaving the alveoli comes from different parts of alveoli. Hence, this phase represents the average concentration of CO_2. The end of plateau represents the end tidal CO_2 concentration or tension when it attains fairly a constant level. In normal individual it is usually 3 to 5 mm of Hg lower than P_aCO_2. Measurement of slope of Phase III is a non-invasive method for estimating cardiac output, since mixed venous blood flow contributes to the generation of slope. Appearance of dips (See Fig. C) in this phase indicates spontaneous respiratory efforts in a paralysed patient or artefacts from the surgical manipulation in abdomen. Phase IV represents the beginning of inspiration which shows the rapid fall of CO_2 tension towards the base line. One may see (See Fig. E) some oscillation called 'cardiogenic oscillation' in this down stroke. They are believed to be due to the contraction and relaxation effect of heart and intrathoracic great vessels on the lungs, causing air to flow in and out. Fig. F indicates some leak in sampling line during IPPV. It results in a plateau of long duration and a brief upswing at the end of phase III. The plateau height is inversely proportional to the size of leak. The brief upswing is due to the next inspiration when positive pressure transiently pushes undiluted end-tidal gas through the sampling line. Fig. G shows return to spontaneous ventilation. The first breath is small. The subsequent breath increases in height with gradual resumption of normal waveform. Fig. H shows irregular plateau and/or base line. It may be due to displacement of ET-tube in the upper larynx or lower pharynx. It may also be due to pressure on the chest which causes small volume of gas to move in and out of the lungs

(ii) Negative intrathoracic pressure, low respiratory rate, reduction of vital capacity, increased heart size ratio, low tidal volume, low inspiratory and expiratory ratio, muscular relaxation, etc, may cause cardiogenic oscillations. But, in most of the cases it can be corrected by increasing the flow rate, respiratory rate, tidal volume or by applying PEEP. It is very common in the paediatric group of patients, because the size of infant's heart is relatively greater than the thorax. If the capnometer is less sophisticated or the wave of oscillations are large, then the instrument may count each wave as a breath and display an erroneously high respiratory rate.

The Inaccurate reading by a capnometer is also produced, if the sampling gas is diluted with the fresh gas from the circuit. This occurs :

i. If the fresh gas flow is too high,
ii. If the gas sampling site is far away from the patient,
iii. If there is high respiratory rate,
iv. If the tidal volume is small (particularly in neonates and infants) in comparison to the size of breathing system.

Normally, the end-tidal CO_2 tension ($ETPCO_2$) varies between 35 to 45 mm of Hg. The PCO_2 above 45 mm of Hg is called hypercapnia and below 35 mm of Hg is called hypocapnia.

Causes of hypercapnia:

i. Fever and malignant hyperpyrexia.
ii. Depression of the respiratory centre due to any cause with concomitant reduction of total ventilation and elevation of PCO_2.
iii. Reduction of ventilation, caused by partial paralysis of the respiratory muscles, neuromuscular transmission disorders, high spinal anaesthesia etc.
iv. Acute respiratory distress including acute asthma, pulmonary oedema, acute exacerbation of COPD, respiratory failure etc.
v. Inadequate ventilation in a controlled ventilated patient.
vi. Insufflation of CO_2 in the peritoneal cavity, during laparoscopy.
vii. Defects in mechanical ventilation setting.
viii. IV administration of bicarbonate.
ix. Inadequate fresh gas flow.

Causes of hypocapnia:

i. Hyperventilation
ii. Increased dead space in presence of normal P_aCO_2. In some alveoli where there in no blood flow, there is no transfer of CO_2 from blood to alveoli. Thus the gas emanating from such alveoli containing no CO_2, dilutes the exhaled gas with CO_2 coming from other region of the lungs and $ETCO_2$ tension decreases.
iii. High sampling rate in presence of an elevated fresh gas flow rate for side stream capnometre.
iv. In atelectasis, where alveoli are perfused but are ventilated, then there is a shunting of mixed venous blood and no diffusion of CO_2 from blood to alveoli.

In atelectasis there is high P_aCO_2, and normal or low $ETCO_2$ tension. This causes high arterial and alveolar end-tidal CO_2 tension difference (P_aCO_2-$ETPCO_2$), which ensures one of the indications of delivery of PEEP ventilation. This low $ETCO_2$ tension in atelectasis is due to the impairment of diffusion of CO_2 from the blood in to alveoli. Excessive PEEP again causes over distension of the alveoli which hamper perfusion and CO_2 exchange, causing high P_aCO_2 and $ETPCO_2$ difference. So, optimum PEEP should be maintained.

Sometimes, a sudden dip in the alveolar plateau phase or phase III during controlled ventilation indicates initiation of spontaneous respiration. This is due to the passing of a small bolus of fresh inspired gas in the sampling site by a sudden onset of spontaneous inspiration. This dip can be interpreted as (i) recovery from anaesthesia, (ii) activation of respiration, induced by sudden stimulation from the surgical site, (iii) inadequate inspiratory power during switching over from mechanical to spontaneous ventilation and (iv) first sign for the need of reversal of neuromuscular blockade.

Monitoring of Anaesthetic Gases

For three reasons each component of a mixture of anaesthetic gases or vapours are analysed and measured in practice, both during inspiration and expiration. These reasons are :

i. To establish the identity and concentration of individual anaesthetic agent which is required for better control and delivery of anaesthesia to patient, including the judgement of depth of anaesthesia and also the stability of haemodynamic system.
ii. To detect and reduce the atmospheric pollution.
iii. To assess the metabolic or cardio-respiratory function by measuring cardiac output, either by analysing the respired gases (O_2, CO_2 and N_2) or by using inert tracer gases, such as helium, argon, etc.

The concentration of different anaesthetic gases or agents such as nitrous oxide, halothane, isoflurance, sevoflurane, etc., used during anaesthesia (including O_2 and CO_2 also) are measured by the following various methods.

(i) Mass spectrometry

The mass spectrometer, which once upon a time was a special laboratory tool for research purposes only, has now become a common operating room instrument for measuring the concentration of anaesthetic gases. It measures the concentration of individual gases in a mixture, largely depending on the basis of their molecular weight. The basic principle on which the mass spectrometer works is based on the ratio between the quantity of charge of a molecule after its ionisation (q) to its mass (m), i.e. (q/m) (Fig. 22.10).

Gas samples are passed through an electron beam (ionizer) which strips from the individual gas molecule one or more electrons and gives them a positive charge. Then, after ionisation the ions of individual

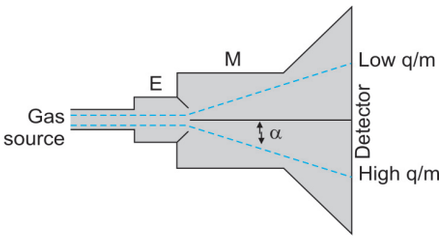


Fig. 22.10: Schematic diagram of a mass spectrometer. Gas molecules at low pressure are ionised and accelerated by an electrical field (E). The ions are then passed through a perpendicular magnetic field (M) that deflects their path through an angle α. This deflection angle is determined by the ratio of charge to mass (q/m) of the ions and is used to identify the species of the gas

gas molecules are passed through a magnetic field, oriented perpendicular to their direction of motion. The side ways magnetic force deflects each ion by an angle 'α', and falls on the photodetectors. The deflecting force (i.e. the path of the ion becomes curved) is proportional to the charge 'q', and the sideways acceleration from this force is inversely proportional to the mass 'm' of the molecule. Therefore, the angle of deflection 'α' is the function of q/m. Thus, photodetectors which are placed at specific locations measure the individual gas concentration, which is proportional to the count of molecules deflected per minute.

During measurement the gas samples are drawn from the anaesthetic circuit into an evacuated ionising chamber, where they are bombard by electron beams. Then, the positively charged ions are passed through a slit from the ionising chamber to the next chamber. In the next chamber these ions are accelerated by a plate to which negative voltage is applied. The magnetic field from the plate deflects the ions according to their charge and mass-ratio (q/m). Then, the number of ions that strike on the detector is proportional to the partial pressure of the gas sample. Thus the streams of ions of different gases are detected by varying the accelerating and focusing voltage. Hence, thus, a mass spectrum is produced by relating the detector output on the Y-axis (calibrated to the concentration of gas) and by accelerating the voltage on the X-axis (calibrated to the molecular weight).

The ability of a mass spectrometer to measure the concentration of different individual gases depends upon the charge/mass ratio. Since, most of the ions created by the ionisation are singly charged due to the missing of a single electron, so the most important variable is, therefore, the molecular weight. Hence, the two different gases of same molecular weight such as N_2O and CO_2 are not distinguishable ordinarily by a mass spectrometer, using the principles outlined above.

During ionisation, some molecules also lose two electrons, instead of one and become doubly charged. So, they behave like ions, with half of their mass. Also, during ionisation some molecules become fragmented causing a secondary peak, rather than a single peak for each gas molecule, such as during the identification and quantification of CO_2 and N_2O. Both the CO_2 and N_2O produce a parent peak at 44 Da but also produce a secondary peak at 12 Da and 30 Da, respectively.

Mass spectrometer is a bulky and expensive instrument, but has a very short response time which is approximately 100 to 200 milliseconds. So, the original implementation of its use in anaesthesia has placed it in a remote-central location. Hence samples are conveyed by a tubing from multiple operation theatres to the remote-centrally located spectrometer for analysis of gases used in anaesthesia on a time-sharing basis. This time-sharing basis increases the delay time and because of the greater length of the tubing necessary to convey the sample gases from the patient to the machine. Recently, a number of small spectometer instruments are available for use in individual operating rooms. These instruments typically can measure the O_2, CO_2, N_2O, N_2, halothane, enflurane, isoflurane, etc., simultaneously.

(ii) Raman scattering analyser

When a photon from a light source collides with a molecule of any gas, then there is some absorption of kinetic energy from the photon. After that this photon is scattered sideways having a lower energy level and longer wave length. This phenomenon is called the 'Raman scattering'. In this phenomenon, the degree of absorption of energy by a gas molecule from the falling photon and the wavelength of the scattered photon or light depends upon the molecular weight and the structure of the gas molecule. Spectral analysis of that scattered light may, therefore, be used to measure the concentrations of individual gas in the mixture. As a photon source the light which is usually used is argon laser with the wavelength of 488 nm. This type of gas analyser is fast, accurate and relatively compact for measurement of CO_2, N_2, O_2 and other anaesthetic gases.

(iii) Infrared absorption technique

This technique is used in most of the modern monitors with the same principle as for the measurement of CO_2 in a capnometer and with the same problems. The advantages of this technique are rapid and an accurate analysis with identification of each gas present in the mixture. In this method, the infrared light beam is first projected through the gas sample and then the intensity of the transmitted light after absorption is measured. Gases, whose molecules contain two dissimilar atoms or more than two electrons in their outer orbit absorb infrared radiation in the same region of spectrum.

The CO_2 absorbs light with a characteristic peak at the wavelength close to 4.3 μm (4300 nm). Several other molecules of anaesthetic gases such as N_2O, O_2, CO and water vapour also absorb light in this area of the spectrum. Thus, CO_2 measurement is disturbed especially if the composition of incident light includes wavelength, other than those of a very narrow spectrum around the CO_2 absorption peak (Fig. 22.11).

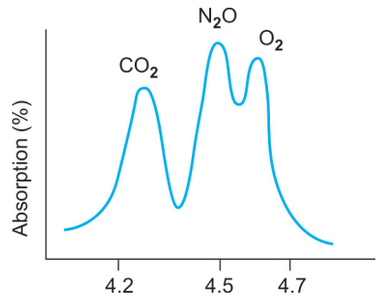

Fig. 22.11: Infrared analyser is an instrument which gives a continuous recording of the concentration or tension of CO_2. It is also used to measure the other volatile anaesthetic agents by careful selection of the infrared wavelength which depends on the potential components of the gas mixture. Use of a specific infrared wavelength of 4.2 μm for the analysis of CO_2 should avoid interference from the presence of N_2O and O_2. The infrared radiation is emitted from a hot wire and a particular wavelength is obtained by passing it through an interference filter. There may be a rotating disc which permits passing of infrared light of different specific wavelengths and simultaneous analysis of various types of gases. Basically, the amount of absorption of radiation is proportional to the concentration of CO_2 and other gases present in the analysing chamber. After passing through the sample analysing chamber and absorption, the radiation is focussed on the photo detector situated on the opposite site. Greater the absorption of infrared radiation by the gas sample, lesser the radiation monitored by the detector. Consequently, it is possible to process the detector output electronically to indicate the concentration of the gas present. Most of the newer instruments use a second beam, which passes through the reference chamber. Any changes in output which are not due to changes in CO_2 concentration in the sample cell, also appear at a reference detector and is subtracted from the output of the sample detector. Such an analyser is called a double beam instrument

As discussed above, the infrared absorption technique is used to analyse the molecules having only a diapole atom, therefore, it can not be used to identify O_2 and nitrogen.

(iv) Gas-liquid chromatography

Chromatography was originally introduced in 1906 by a Polish botanist, named Tswett, for separation of different colour pigments, present in a plant extract. It is of four different types such as : (i) paper chromatography, (ii) thin layer chromatography, (iii) column chromatography, and (iv) gas-liquid chromatography. The gas-liquid chromatography is a very helpful instrument to analyze and separate the components of gases in a mixture. Not only that, in addition, it may be used to analyse the blood samples containing different solute such as the volatile, intravenous, local anaesthetic and anticonvulsant agents etc. In combination with the mass spectrometer, it is also an important analytic tool, because the mass spectrometer identifies the molecular fragments present in any concentration which are eluded from chromatography.

Measurement of Central Respiratory Drive for Monitoring of Respiratory Function

The main causes of respiratory failure are: depressed central ventilatory drive, abnormalities of pulmonary mechanics, and impairment of respiratory gas exchange. Among these, the depressed central ventilatory drive is the commonest cause of respiratory failure. So, the measurement of ventilatory drive is very important for the assessment of function of respiratory system, particularly in anaesthesia where most of the anaesthetic agents are respiratory depressants and also in the process of weaning of patients from mechanical ventilators. Ventilatory drive is measured directly by minute ventilation (V_E) and indirectly by P_aCO_2 level. But clinically the measurement of V_E and P_aCO_2 is very difficult. So, various measures for the assessment of neural respiratory central drive have been sought.

These are:

i. Divisioning and examining the respiratory waveform into inspiratory and expiratory components.
ii. By measuring the inspiratory flow rate (tidal volume/inspiratory time). The draw back in this method is that many patients have high ventilatory drive, but is not able to translate this drive into a respiratory output, because of their impaired ventilatory mechanics.
iii. Measurement of the rate of respiration is also a method of monitoring the respiratory drive. But, the main disadvantage is that respiratory depression does not always indicate reduction of the respiratory rate. In narcotic-induced respiratory depression, tidal volume is mainly depressed with a little change in the respiratory rate.
iv. Measurement of P_{100} is another sophisticated method for assessing the respiratory drive. The P_{100} is defined as the maximum negative inspiratory airway pressure, which is obtained 100 milliseconds after a temporary occlusion of the airway in a spontaneously breathing patient. It is an useful index of the respiratory drive without being affected by any volumentary effort and changes in respiratory mechanics. The normal value of P_{100} is 1 to 2 cm of H_2O and is not appreciably noticed by a patient during its measurement. Possibly, one could also use P_{100} as a guide to the discontinuation of mechanical ventilation, after general anaestheisa.

Monitoring of Pulmonary Mechanics

Till now, we were monitoring the function of respiratory system by measuring the concentration of O_2, CO_2 and other anaesthetic agents in blood, inspiratory and expiratory air. Also, we have tried to monitor the function of respiratory system by measuring the ventilatory drive which are described just before. But, now we will discuss the monitoring of the functions of respiratory system by measuring the respiratory mechanics.

There are four principal determinants for the measurement of pulmonary mechanics. These are: flow, pressure, volume and time. From them we can monitor the respiratory mechanics by measuring the compliance and resistance and by drawing the different loops such as flow-volume loop, pressure-volume loop, etc. But, it should be kept in mind that all these parameters are interrelated.

A. Flow

The measurement of flow of gases (both inspiratory and expiratory) is useful for two reasons: (i) measurement of resistance and compliance requires measurement of both flow and pressure, and (ii) from the measurement of flow the most ventilators calculate the different lung volumes, such as: tidal volume, minute volume, etc. by multiplying it with time. Again from volume, the computers of modern ventilators can also calculate the volume-pressure curve, the flow-volume curve, compliance, resistance, etc. So, before the measurement of any parameter, measurement of flow and pressure is most important. The flow is measured by the following methods.

Rotameter

It is a variable orifice (constant pressure change) type of flow meter. Another type of variable orifice type of flow meter is a peak flowmeter. Rotameter consists of a vertical glass tube, inside of which a metal alloy-made bobbin rotates. At the bottom of the rotameter there is fine flow control valve which controls the flow of gas. When this bottom valve is opened, then the pressure of the gas forces the bobbin up in the tube and gas starts to flow. The inner wall of the rotameter tube is cone shaped. This causes the pressure to remain constant throughout the range of flow. The tube is calibrated according to the amount of gas flow, keeping the pressure of constant and so the bobbin rotates freely. Each rotameter and its calibration is specific for a specific gas. The laminar flow in a rotameter is found at low-flow rates and depends on the viscosity of that gas. But, turbulent flow predominates at a higher flow rate and it depends on the density of that gas. It is the commonest type of flow meter which is used in all the anaesthesia machines to measure the flow of gas.

Peak flow meter

This instrument can measure a peak flow rate upto 1000 litre/minute and is very useful clinically. In this instrument there is a vane, which rotates during the flow of air through it or a piston which moves against a constant force, produced by a light spring. The maximum position, adopted by the vane or piston, depends on the peak expiratory flow rate and this position is held by a ratchet. Then, the reading is obtained from a mechanical pointer which is attached to the vane or the piston. Serial measurement of peak expiratory flow rate is useful to assess the prognosis in asthmatic patients. This measurement may be performed using a hand-held Wright's peak flow meter.

Bourdon gauge flowmeter

It is already said that the two above mentioned flow meters are of variable-orifice, but pressure-change is constant. But, this Bourdon gauge flow meter and pneumotachograph (discussed next) are of variable pressure-change but fixed-orifice flow meter. This gauge is calibrated to the gas flow rate according to the pressure changes across a fixed orifice. However, these rugged flow meters are useful for measuring the flow of gas from cylinders at high pressure.

Pneumotachograph

When patients are being ventilated mechanically, then the respiratory parameters are easily measured. It is also relatively easy to make such measurements continuous by a pneumotachograph. The pneumotachograph measures the flow rate by sensing the pressure changes across a small but fixed orifice. Usually the tidal volume is measured by observing the displacement of inflating bellows, or by passing the respired (inspired + expired) gas through a respirometer. But in some machines the gas flow are also measured by pneumotachographs. In a pneumotachograph, a differential pressure transducer records any tiny pressure change across a slight obstruction to the flow of gas. Then, the pressure-transducer transduces it into a continuous electrical output, which is integrated to give the amount of flow and volume digitally. The obstruction produced in pneumotachograph may be in the form of a gauge screen (screen type – pneumotachograph), or a bundle of small tubes aligned along the airway (Fleisch pneumotachograph). The pressure change against the obstruction in pneumotachograph is related to the flow rate and from this pressure change the flow is measured in a pneumotachograph. Pneumotachographs are not accurate over a very wide range of gas flow rate and are also affected by humidity, temperature, gas composition, etc. So, it requires frequent calibration, correction and compensation. In some ventilators, the measured minute volume is compared with the selected or set volume and an alarm is sounded off, whenever there is a discrepancy. A vortex – type pneumotachograph which is also frequently used in modern mechanical ventilators works by measuring the interruptions of an ultrasonic beam, placed across a tube which disrupts the laminar flow, resulting in vortices.

Ultrasonic flowmeter

This instrument works by measuring the speed of ultrasonic waves, propagated parallel to the direction of flow.

Hot-wire anemometers

It consists of an electrically heated wire, placed across the flow of a gas stream. The flow of gas tends to cool the wire and changes the electrical conductivity, thus sending changes in electrical signal. The changing electrical signal reads the amount of gas flow.

Flow is also measured by the amount of additional electrical current, necessary to maintain the wire at a constant temperature during flow of gases, because when gases flow over a wire, it cools down. This method is highly sensitive for measurement of gas flow, but is highly dependent on gas temperature and contamination of gas with water droplets.

B. Volume

Different lung volumes are measured by the following ways.

Dragger volumeter

This is a very simple and accurate device which measurer the volume of dry gas. But, it is affected by moisture. Here, the volume of gas that flows through this volumeter is measured by measuring the rotation of two light, interlocking, dumb-bell shaped rotors which is directly proportional to the flow of gas.

Wright spirometer

This device contains a light mica vane which rotates within a small cylinder. Then, the inflowing air volume which is to be measured is directed to it by a tangential slits. Thus, during the flow of air through a wright spirometer the rotation of vane drives a gear chain with a pointer on a dial, from where the flow rate can be measured. From the flow rate the machine calculates the volume of air or gases that flow through it. Thus, the minute volume can be read directly and then the tidal volume can be calculated from this reading and the respiratory rate.

It has dead space of only 25 ml and is of low resistance which is self rectifying. Although, the response in this spirometer is nonlinear, still it is reasonably accurate in the relevant range of minute volume (4 to 15 litres/min). But, the Wright spiro meter seriously over-reads at a high minute volume (>15 lit/min) and under reads at a low minute volume (<4 lit/min). This is due to the inertia of moving parts of machine. As with many other devices, its accuracy also deteriorates when it becomes wet. It is also clinically a very useful and convenient instrument for co-operative and unanaesthetised patients. But for more accurate measurement of lung volumes in a cooperative patient, dry gas meters and other sophisticated pulmonary function analysers may be employed. However, these instruments are not in common use in the ITU.

Alternatively, a bellows-type of dry gas spirometer (e.g. the vitalograph) can be brought to the bed side to measure the peak expiratory flow rate, vital capacity and times expiratory volume (e.g. FEV_1).

Integration from flow signal

Volume is also measured indirectly from the flow rate. The flow signal from different flow meters is integrated electronically over the time to measure the volume.

Indirect method to measure volume

In an unintubated anaesthetised patient the volume of ventilation can also be measured by monitoring the changes in external dimensions of thorax and abdomen, either clinically by direct observation or by using one of the techniques mentioned below.

In an unintubated, anaesthetised patient the volume of thorax is measured from the movement of thorax and abdomen by a magnetometer. This works by measuring the anterio-posterior and lateral thoracic and abdominal dimensions and is called pneumography. Here, some nonelastic tapes are placed around the chest and abdomen. The ends of the tapes are connected to the displacement sensors and the volume is measured. Another method of measurement of volume is from the movement of the thorax and the abdomen by using coils of wire, sewn into an elasticated strap that encircles the thorax and the abdomen. The expansion of the chest and the abdomen increases the space between the coils. So, it alters the inductance, generated by a high frequency AC current and converts it into electrical signal. This method is called the 'Respiratory Inductance Plethysmography'. The self inductance of the coils which changes in proportion to the changes of the encircled areas can be calibrated to provide continuous monitoring of the volume of ventilation. As the result of this method is sensitive to the changes in posture and position of the body, so it cannot be used during surgery on thorax and abdomen.

In an intubated patient, measurement of the tidal volume, respiratory rate and from these the measurement of minute ventilation is easy. Now, these parameters are routinely measured by modern mechanical ventilators.

Measurement of the ventilatory volume in a conscious patient has been discussed before, during the discussion of flow and volume measurement (by spirometer, vitalograph, etc.)

C. Pressure

Methods of measurement of pressure has been discussed before (See the measurement of airway pressure).

Pulmonary Compliance

During the process of expiration when the lung volume reaches at the level of functional residual capacity (FRC), then the pressure at the level of mouth and alveoli is same and atmospheric, So, of position there is no tendency of gas to flow in and out of the lungs. In such position, the tendency of the lungs to collapse (due to the elastic tissue of lungs and chest wall and the surface tension of alveoli all of which constitute the elastic resistance) is exactly counter balanced by the outward pull of chest wall. After that during the process of inspiration gas may, now, be made to flow into the lungs by (i) reducing the pressure in alveoli by primary expansion of chest wall due to spontaneous breathing caused by the contraction of inspiratory muscles which constitutes the work of breathing, or (ii) by increasing the pressure at the mouth (IPPV).

So, each method of inspiration causes a development of pressure gradient between the mouth and alveoli, resulting in flow of gas into the lungs and thus causing volume changes in it. Hence, the relationship between the change in volume (Δv) of lungs and thorax, and the pressure gradient (Δp) is known as compliance (c). At the end of inspiration, gas flow stops and the pressure in all the alveoli again becomes

same as that of the mouth and atmosphere. The force acting to impede this flow of gas during inspiration into the lungs are: (i) the elastic resistance of the lung parenchyma and soft tissue of chest wall (ii) the nonelastic resistance of chest wall comprising the movements of bones at joints (iii) the nonelastic frictional resistance due to the flow of gas through air passage. So, for air to flow into the lungs, a pressure gradient has to develop to overcome all this elastic and nonelastic resistance of the lungs and the chest wall.

Thus from the point of view of inspiration and to produce tidal airflow the lungs are passive organs and rely solely on the work done actively by the diaphragm and the intercostal muscles. Under normal resting conditions all the work is done actively during inspiration, while expiration is passive. During IPPV the work is done by the breathing machine and again this is also usually done during inspiration, while the expiration is generally passive.

Hence, during inspiration expansion of both the lungs and chest wall requires a distending force which is expressed as volume change (ml) per unit change of distending pressure (cm of H_2O), and this is called as the compliance (c).

Therefore, Compliance (c) = Increase of Volume (Δv) in ml/Pressure gradient (Δp) in cm of H_2O

$C = \Delta v / \Delta p$

For air to flow into the lungs and to make a volume change, a pressure gradient (a negative or positive i.e. Negative in normal spontaneous breathing, and positive in IPPV) should be developed to overcome the elastic and nonelastic resistance and frictional resistance. So, the relationship between compliance (c) and resistance (E) is reciprocal, i.e.

$C = 1/E$ or $C = \Delta p / \Delta v$.

The total resistance include both the elastic and nonelastic resistance of the lungs and the chest wall, and also the frictional resistance. Total compliance (CT) is the sum of the compliance of the lungs (C_L) and the compliance of the chest wall (C_{CW}). The relationship between the total compliance (C_T) and the individual compliance of lungs (C_L) and chest wall (C_{CW}) is

$1/C_T = 1/C_L + 1/C_{CW}$ or

$C_T = (C_L\ C_{CW})\ (C_L + C_W)$

The individual compliance of the lungs and the chest wall in a normal healthy person is approximately same and it is about 0.2 litres/cm of H_2O (200 ml/cm of H_2O). Thus the final and total change in volume of chestwall with lungs (i.e. thorax) is 0.2 litre and this is obtained by pressure gradient of 1 cm of H_2O, exerted both by the chestwall and lungs each. So, the total pressure gradient exerted together by the chestwall and lungs is 2 cm of H_2O. Thus, the total thoracic compliance is 0.1 litres/cm of H_2O or 100 ml/cm of H_2O. However, the normal average value is 50 to 100 ml/cm of H_2O.

To detect only lung compliance (C_L), volume change (Δv) and trans pulmonary pressure gradient (which is $P_A - P_{PLU} = \Delta P$) should be measured. To detect only the compliance of the chest wall (C_{cw}), volume change Δv and transmural pressure gradient ($\Delta p = P_{PLU} - P_{ENVIORNMENT}$) should be measured. Thus, to determine the total compliance (C_T), the volume changes (Δv) and the transthoracic pressure gradient ΔP ($\Delta p = P_A - P_{ENVIORNMENT}$) should be measured. In clinical practice, individual C_L and C_W are not measured but only C_T is measured.

The compliance is approximately linear over most of the ranges. But, it is lower when the volume of lung is very small i.e almost fully deflated or when the volume of lung is very high i.e almost fully inflated.. The former is due to the added force needed to expand the collapsed areas of the lung, and also to overcome the surface tension effects. The latter is due to the elastic fibres of the lung reaching their maximum limit.

The lung exhibits hysteresis, i.e the compliance differs both during inflation and deflation. If the compliance is measured when the flow of air has ceased as during breath holding or apnoea in anaesthesia, then it is known as the static compliance. But, when the volume changes of the lung and the thorax in relation to pressure changes is measured during the process of respiration, then it is known as the dynamic compliance. For example, during inspiration the work is done to expand the lungs and the thorax from their resting position at FRC. In a healthy supine, paralysed patient, a sustained inflation pressure of 1kpa (10 cm of H_2O) will increase the lung volume to about 0.85 litres. So, static compliance is 0.85 lit/pka or 85 ml/cm of H_2O, or 0.085 L/cm of H_2O. However, during an inflation if it is necessary to consider the dynamic compliance, then it is nearly about 70% of the static compliance.

Measurement of compliance

We can measure both the static (C_{STAT}) and dynamic compliances (C_{DYN}). It is measured by the pressure-volume relationship, through curves or loops. In this curves and loops the changes in lung volume are displayed on the vertical axis against the inspiratory or expiratory pressure changes which is displayed on the horizontal axis. It is important to know that the pressure used to calculate the total compliance may be that of at the end of inspiration or plateau pressure (P_{PLAT}). This is for determination of static compliance. However, during the period of inspiratory gas flow the peak airway inspiratory pressure (P_{PK}) is necessary for determination of dynamic compliance. For calculation of compliance always the end expiratory pressure (PEEP) must be subtracted from the peak pressure or plateau pressure. The PEEP value is usually obtained from the airway pressure monitor at the end of expiration.

So, $C_{DYN} = V_T / (P_{PK} — PEEP)$

$C_{STAT} = V_T / (P_{PLAT} — PEEP)$

V_T is the tidal volume, which is fixed in volume-cycled ventilators. When there is a development of auto-PEEP, then it should

be considered in the place of PEEP in the above mentioned equation. Otherwise, the measurement of compliance shall be affected. Auto-PEEP is developed when there is insufficient expiratory time. This is because it prevents complete emptying of the lungs and elevates the end expiratory alveolar pressure. This is not detected directly by the airway pressure monitor. Auto-PEEP causes ↓cardiac output, ↓BP and even EMD (electromechanical dissociation), when the patient is on a ventilator. The auto-PEEP is most likely to be present, when there is an increase in airway resistance or compliance causing prolongation of (Fig. 22.12) the expiratory time. It also occurs when high ventilation rates are required. The measurement of auto-PEEP is accomplished by obstructing the exhalation port of the ventilator, while waiting for the onset of next ventilator breath. Alveolar pressure will then become equal to that of the ventilator circuit and auto-PEEP can be measured on the airway pressure monitor. During the measurement of auto-PEEP, it is important to prevent fresh gas flow from entering the circuit, which shall falsely elevate the auto-PEEP.

The total static compliance can also be measured in an intubated patient by occluding the tube and measuring the pressure in the system. After that the tube is unclamped and the volume of air or gas expired is collected and measured in a spirometer. From this, a pressure – volume curve can be plotted and the total static compliance can be measured. For the measurement of only static compliance of lung, the pressure gradient between the airway and the pleural space has to be measured. The direct measurement of intrapleural pressure by placing the tip of a sampling catheter within the pleural space is not possible practically. So, the oesophageal pressure, which closely parallels the intrapleural pressure is measured. Since this measurement is a static one, so it is made with the patient holding his breath, after having inspired a known volume of air from the spirometer. The procedure is then repeated a number of times with different volumes, so that a pressure volume curve can be constructed. This is usually linear and gives an average value of the static lung compliance. Compliance of the chest wall is obtained by subtraction of the lung compliance from the total thoracic compliance. During measurement of the compliance, compliance of the anaesthetic circuit, including humidifier and the gas warming system (which may be as high as 10 ml/cm of H_2O) must be accounted too, for an accurate result.

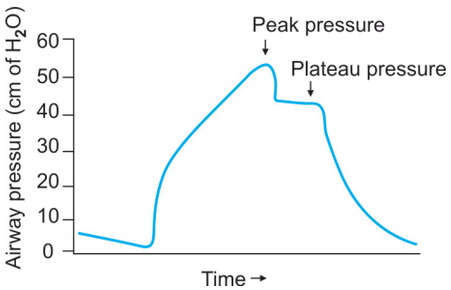

Fig. 22.12: Airway pressure waveform against time. Decrease in the static compliance causes increase in the plateau pressure. Whereas the decrease in the dynamic compliance results in an increase of peak airway pressure. Peak airway pressure is related to both the airway resistance and the thoracic compliance, whereas plateau pressure is only related to compliance

Values of the measured compliance should always be read in relation to the predicted normal value of a person of the same sex, age, height, weight, lung volume and FRC. Any change in FRC, such as, a simple change in posture can produce a change in compliance. Total static compliance is decreased during atelectasis, pulmonary oedema, pneumothorax, emphysema, mitral stenosis, external compression on the chest, ↑intra-abdominal pressure by any cause, ↑pressure on the rib cage, ↑intrathoracic pressure (pleural effusion), etc. Total dynamic compliance is decreased by an elevated airway resistance, such as, due to bronchospasm, mucous plug, kinking of airway or tubes, induction of anaesthesia, etc. It has been known for many years that the induction of anaesthesia itself causes a decrease in compliance, which is due to the increased elastic recoil property of the lungs after induction. A typical value of the static compliance of the lungs and chest wall in an anaesthetised, paralysed patient is 85 ml/cm of H_2O. Whereas in the supine, conscious patient it is 120 ml/cm of H_2O.

Decreased thoracic compliance to less than 25 ml/cm of H_2O is unlikely to result in a successful weaning off from the mechanical ventilation. During anaesthesia many factors operate at the same time, affecting the compliance and the situation changes so often that it is frequently impossible to relate any change in compliance to a specific single agent or procedure. For example, drugs may affect the muscles of the thorax and change the compliance. The secretions in the respiratory tract, alterations in the cardiac output, constriction of the bronchioles or dilatation of the pulmonary vessels, etc. – also alter the compliance.

Resistance

For air to flow in and out of the lungs, a pressure gradient has to be developed at the cost of energy. Work of breathing supplies this energy which is responsible for this propulsion of air. But, the flow of air in and out of the lungs is opposed by some factors or force which is called the resistance (R). So, the function of the work of breathing is to supply energy which will overcome this resistance by creating a pressure gradient, and thus helps the air to flow. Hence, the relationship between the pressure gradient (Δp) and the flow or the rate of change of volume (Δ) is influenced by the resistance. So, the resistance (R) is defined as the change in pressure per unit change in volume, or

$R = \Delta p/\Delta v$

This equation of resistance is equal to the equation of elasticity, but is reciprocal to compliance. The normal value of total resistance in respiratory system is 1.5 cm of H_2O/lit. But, under anaesthesia it may rises as high as 9 cm of H_2O/lit.

There are three essential components of resistance. These are:

i. Elastic resistance due to lung parenchyma itself and soft tissue of thoracic wall.
ii. Nonelastic resistance due to the movement of the structure of chest wall.
iii. Frictional resistance in airway due to the movement of air.

(i) Elastic resistance of the lungs

During inflation the changes in the lung volume occur as a result of the expansion forces applied to the lungs, which is expressed as pressure. This is the concept of compliance. Whereas the concept of elastance or elastic resistance is opposite to the compliance which prevents this change in volume.

Thus, to summarise, the compliance which is the change in volume per unit change of pressure works against the resistance, which is change in pressure per unit change in volume.

The elastic resistance of lungs is also the force which tends to return the lungs to its original size after stretching or inflation and is responsible for the air exit. It should not be thought of as the force required to expand the lungs. One of the principal factors causing the elastic recoil of the lung is the presence of elastic fibres within the pulmonary tissue. Another important factor contributing to the elastic resistance is the surface tension of the fluid, lining the alveolar walls. At larger lung volumes, connective or elastic tissue elements predominate in the elastic resistance. Whereas, at lower lung volumes the effects of the surface tension predominate in elastic resistance. The important role of surface tension of the fluid, lininig the alveolar walls, is to draw the opposing walls closer together, so that the alveoli collapse. If this fluid is only water, it would exert a considerable elastic pull of about 70 dynes/cm. But, fortunately, the presence of surfactant (detergent like agent which reduces surface tension) in the alveolar wall reduces this collapsing pull to as little as 2 to 8 dynes/cm.

The alveolar wall is always lined with a thin layer of fluid and the curved surface of the lining fluid on the alveolar wall creates a tension. This tends to make the surface area of the alveoli which is exposed to the air as little as possible, and hence the alveoli collapse. Thus this collapsing force or tension in alveoli is called the surface tension. It follows the Laplace rule i.e.

$P = 2T / R$ or $T = ½PR$

where, P is the alveolar pressure, T is the surface tension and R is the alveolar radius.

From the above equation it is clear that radius is directly proportional to the surface tension. If the radius of the alveoli decreases, i.e. when the alveolar size reduces during expiration, then the surface tension tending to collapse will increase and a vicious cycle is established. It can be explained simply by the fact that liquid molecules are crowded much closer together on the curved lining surface when the alveoli decreases in size and thus gradually increases the collapsing pulling surface tension force (elastic resistance).

But, in fact this does not happen. as alveoli are coated with a detergent like chemical, called surfactant, which reduces the surface tension or elastic recoiling property of the alveoli. As the alveoli deflate and the size decreases, the amount of surfactant per unit area of alveolar membrane increases, and so the surface tension is more and more reduced, which is proportional to the increase of surfactant due to the reduction of alveolar radius. In this way, the action of surfactant becomes more efficient, when the alveoli decrease in size. Therefore, contrary to what would be predicted on the basis of Laplace's law, the elastic recoiling resistance of the smaller alveoli is lesser than the larger alveoli, and hence smaller alveoli can be inflated more easily than the larger ones.

(ii) Non-elastic structural resistance

Nonelastic structural resistance is composed of the thoracic wall, the diaphragm and the abdominal contents and is due to the movement of these structures among them.

(iii) Airway frictional resistance (Non-elastic)

Airway resistance is important because it is dependent on the length and size of the lumen of the bronchial tree. Airway resistance also depends on the type of flow. The flow of air through the bronchial tree may be turbulent or laminar. Laminar flow occurs at low flow rates and in the smaller bronchi. Laminar flow rate (V) is related to the driving pressure (δp) by Poiseuille's law or equation, i.e.

$V = \delta p \pi r^4 / 8nL$

where, r is the radius of the tube, L is the length of the tube and n is the viscosity of gas.

Radius of the tube is critical. Halving of the tube diameter reduces the flow by a factor of 16, for the same driving pressure (δp). This has a very important implication in paediatric practice. Because, to maintain the same flow in a tube which is reduced half in diameter, the driving force should be increased by 16 times.

Laminar flow occurs when the gas passes down the tube, less than a certain critical velocity. When flow exceeds the critical velocity, it becomes turbulent. Airway resistance in turbulent flow can be lowered by density. This explains why low density gases, such as helium, diminshes the resistance to flow, in severe upper airway obstruction.

The total cross-sectional area of the airway increases as branching occurs. Therefore, velocity of airflow decreases. Laminar flow is therefore chiefly confined to the airways, below the main bronchi. The flow in the trachea is turbulent during most of the respiratory cycle. Airway resistance is estimated indirectly by monitoring the flow-time or volume-time relationship, in a passive exhalation after manual inflation of the lungs.

MONITORING OF THE DEPTH OF ANAESTHESIA

Introduction

Conceptualisation of the depth of anaesthesia is very complex. It ranges from in-depth scientific discussion of MAC (Minimum Alveolar Concentration of the anaesthetic) to the clinical assessment of light, moderate and deep anaesthesia.

Horace Wells failed to demonstrate the anaesthetic properties of N_2O in 1845, when the patient screamed out of pain during dental extraction, even though he later could not recall the sensation of pain (loss of memory, but no loss of pain sensation). One year later, WTG Morton succeeded in anaesthetising a patient named Gilbert with ether. Gilbert later reported that he had been aware of the surgery, but had experienced no pain (loss of pain sensation, but no loss of memory). Thus, it seems that Well's patient was aware of pain, but had no post-operative recall. While Morton's patient had some post operative recall, but there was no awareness of pain. After that, 158 years have passed. But, still the assessment and monitoring of the depth of anaesthesia which includes both the depth of analgesia and the depth of loss of memory remains evasive. Even now, despite the fact that awareness under anaesthesia is terrifying both to the patients and also to the anaesthesiologists, still the general notion regarding the awareness under anaesthesia remains cloudy.

History

A greek philosopher in 100 BC had first described the analgesic and amnesic properties of Mandogra. The word 'Anaesthesia' was also first used by him. Then, after a long gap in 1721 the word 'Anaesthesia' first appeared in Bailey's English Dictionary. There it was described as 'the loss of sensation, but not the loss of consciousness'. After that in 1771, in Encyclopedia Britanica the word anaesthesia was defined as 'the privation of senses'. Now, anaesthesia is defined as the triad of analgesia, hypnosis and skeletal muscle relaxation, with recent addition of the depression of autonomic nervous system.

For long time immobility in response to a noxious stimulus has been used as the measure of the depth of anaesthesia. But, it was before the appearance of muscle relaxants. So, after the routine use of muscle relaxants in practice of anaesthesia, there appears many problems regarding the assessment of depth of anaesthesia, as the movement part is removed by the paralysis of muscles. So, to circumvent these vexing problems, the anaesthetists have turned towards the more easily quantifiable EEG changes, as a measurement of the depth of anaesthesia.

In 1847, after the introduction of ether in 1846, Plomley had first defined the depth of anaesthesia by describing it in different stages, starting from the onset of anaesthesia to the surgical end-point. These stages, described by Plomely were: intoxication, excitement and the deeper levels. In the same year a Paris physiologist, named Marie Flourens concluded that ether with the deepening of anaesthesia, causes the depression of CNS gradually in order of the higher cerebral centres, the cerebellum, the spinal cord and finally the medulla oblongata, where the respiratory and cardiovascular centres are located. Then, in 1847, John Snow who became very interested on ether soon after its introduction, described five stages of etherisation as a concept of depth of anaesthesia in his publication. Among these five stages, the first three were of light anaesthesia. The fourth comprised of what we would regard as surgical anaesthesia and in the fifth, respiration became progressively impaired. In the same year two deaths were reported from ether anaesthesia. So, the early 1900's saw the introduction of premedication, different sedatives and opioids and more other rapid acting anaesthetics such as N_2O, ethylene etc., as the anaesthetic excitement phase could be traversed more rapidly by them. So, the attempt to measure the depth of anaesthesia by only the degrees of etherisation soon became blunted.

Then, in 1911 the concept of a balanced anaesthesia had come, when George Washington taught that psychic stimuli could be obliterated by light general anaesthesia, while noxious impulses due to surgery could be blocked by local analgesia. After that in 1926, John S. Lundy of Mayo clinic first introduced the term 'Balanced Anaesthesia' by combining different methods such as premedication, regional analgesia and general anaesthesia, so that pain relief was obtained by judicious mixing of agents and techniques.

Then, in 1937, Guedel's book named 'In halational Anaesthesia' was published. In this publication he described the depth of anaesthesia in four stages in a case of unpremedicated ether anaesthesia, with four planes of stage III. Then in 1954, Artusio expanded Guedel's stage I, describing it more into three planes:

- In plane I, the patient had no amnesia oranalgesia,
- In plane 2, the patient had total amnesia, but partial analgesia,
- In plane 3, the patient had complete analgesia and amnesia.

After that, for a long time the clinical signs to measure the depth of anaesthesia, defined by Guedel and Artusio, had significant practical utility during the administration of ether and chloroform.

Memory and Awareness

Before the introduction of ether, in 1846, any surgical operation was like a dream to the physician and a nightmare to the patient. So, there are many stories of torture and suffering by the victims of surgical operation, performed before the introduction of ether. But, even with the passage of time and dramatic improvement of medical science with the introduction of many potent drugs, equipments and methods, till now the vivid descriptions

of pain and recall during surgery have not been eliminated completely.

Two degrees of inadequate depth of anaesthesia has been described by Vickers. The first degree involves the retention of memory of an event that occurred while under anaesthesia. This retention of memory or awareness is termed as the 'recall' and represents a conscious or explicit memory. This conscious memory involves spontaneous recall without the aid of any clue. This positive information may help in enhanced patient recovery. The second degree of inadequate depth of anaesthesia involves patients with no memory of events, i.e. no recall, but have the responsiveness to the auditory input or verbal command, which is called the 'wakefulness'. This 'wakefulness' has been described as the response of a patient to a verbal command during and after surgery without recall. This detection of meaningful auditory input under anaesthesia has also been termed as the unconsciousness or implicit memory. This implicit memory or memory in an unconscious state may alter the behaviour or performance of a patient. This negative information could have deleterious psychological effects postoperatively.

Although, lot of literature exists regarding the intraoperative recall and wakefulness, but much of it is anecdotal. As a result, our understanding of the factors relevant to a patient's recall or wakefulness is limited.

The incidence of memory (explicit or implicit) during anaesthesia is probably underestimated. This is because very often only the conscious recall is taken as an evidence but implicit memory or memory in unconscious state cannot be taken into account. The incidence of intraoperative awareness or wakefulness has been reported to be about 0.2 to 2%, but it may be as high as 40% in high risk situations like trauma, caesarean section, etc. where narcotics and sedatives are used less judiciously. The incidence of intraoperative memory or recall is similar to both the volatile agents and the TIVA technique. The incidence of recall is high in patients who are given anaesthesia with only N_2O, O_2 and muscle relaxants than with potent inhaled anaesthetics. However, the use of potent inhaled anaesthetics does not guarantee the lack of recall. The intra operative awareness or recall can also occur with high dose of opioid anaesthesia, though it was not thought so previously.

There are many ways of rendering adequate depth of anaesthesia. But what is 'adequate' is difficult to define. We don't have definite end points to measure the adequacy, unlike analgesia. The only reliable end point for consciousness is absence of response to a voice command, but this does not distinguish light sleep from a deeper one. However, most patients end up with more hypnotic effect than necessary during intraoperative period and probably is the cause of postoperative drowsiness and delay in discharge from the hospital. At the same time, when large doses of opioids and muscle relaxants are used to suppress the somatic and autonomic responses, then hypnosis is usually inadequate. It has been shown that even maximum doses of opioids fail to suppress the conscious awareness or memory formation. In a recent study, even at Bispectral Index (BIS) values of 60 to 70 which correspond to adequate hypnosis, 2/3rd of the patients respond to voice commands, though fortunately only 1/4th of the patients recall episodes of awareness.

Unfortunately, there is no 'gold standard' to compare the different states of anaesthesia. So, some argue that the 'depth' is a wrong term. It is better to know whether the patient is adequately anaesthetised or not. So, to divide these states into various levels seems practically inappropriate.

Grades of awareness:

i. Explicit memory with recall.
ii. Expicit memory without recall.
iii. Implicit memory.
iv. Not aware.

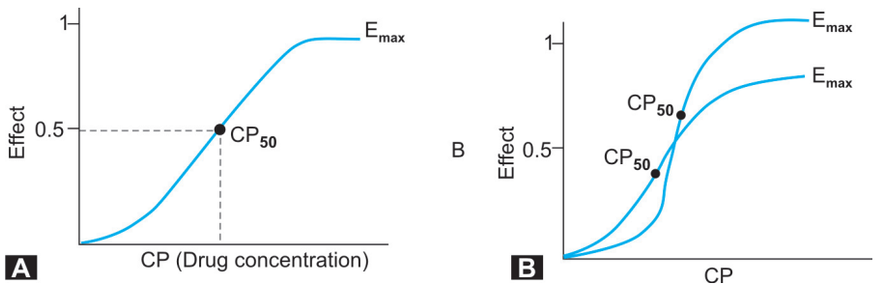
The last stage is only obtained in deep anaesthesia with no sign of awareness or recall at all.

The memory may be explicit (needs effort to recall) or implicit (effortless). An explicit memory system is more sensitive to the effects of GA. With increasing anaesthetic concentration, there is little effect on conscious awareness, but explicit memory is lost. Further increase of anaesthetic concentration abolishes awareness, but implicit memory may be present leading to post-operative psychosomatic dysfunctions.

Pharmacodynamics and Depth of Anaesthesia

Actually, the process of anaesthesia and its depth is nothing but the pharmacological responses (or pharmacodynamics) of an anaesthetic agent. The pharmacodynamics of anaesthetic agents again depend on pharmacokinetic of them. So, before discussing the clinical and electrophysiological methods of measuring the depth of anaesthesia, we must try to understand the pharmacological concepts of it, i.e. pharmacokinetics and pharmacodynamics of the anaesthetic agent which is related to the depth of anaesthesia. Actually, anaesthesia is the pharmacological response of an anaesthetic drug (pharmacodynamics) and its depth, i.e. the intensity of action depends on the administered dose, the concentration of it in blood and the elimination of that drug (pharmacokinetics) from the body. So, measurement of the depth of anaesthesia is governed by the pharmacokinetics of that agent and is nothing but the pharmacodynamic measurement of it (Fig. 22.13).

Though, a continuous measurement of the depth of anaesthesia is actually a continuous measurement of the pharmacodynamics of the anaesthetic agent being used, but we indirectly measure it by measuring the blood concentration of the drug (pharmacokinetic factor) and plotting the concentration versus effect relationship on



Figs 22.13A and B: A. The relationship between the plasma concentration of a drug (CP) and its effect is a sigmoidal curve, where: E_{max} = maximal drug effect, CP_{50} = the plasma concentration of the drug that produces 50% of maximal effect. Slope of the curve = rate of change.
B. Two anaesthetic agents have different concentration - response curves, with different maximal effects. CP_{50} values are also different

a graph. Actually, the concentration and effect (kinetic-dynamic) relationship of a drug is a sigmoid-shaped curve. The lower minimal or baseline effect and the upper maximal effect of an anaesthetic agent are the extremes of drug response. However, the mid-point between the baseline and the maximal effect is commonly referred to as the CP_{50}. This indicates the plasma concentration of a drug that results in 50 percent of its maximal effect. This parameter indicates the potency of the drug and the sensitivity of the individual to that drug. Although, CP_{50} can be measured and the concentration-versus-effect curve of a drug can be generated, but there are some limitations of this methodology. Because the concentrations-effect curves of two drugs have two different curves, and if the maximal effects differ, then the CP_{50} values cannot be used to compare the drug potency or the individual sensitivity to it. There are also some other limitations, such as the type of stimulus given to measure the response of a drug (Table 22.4).

The MAC Concept for Measurement of Depth of Anaesthesia for Volatile Anaesthetic Agent

At equilibrium the partial pressure of inhaled anaesthetic agents should be similar in all the body tissues e.g. alveolus, blood and brain. Thus, the measurement of end tidal concentration of an anaesthetic agent which is representative of the alveolar concentration is nothing but an indirect measurement of the concentration of this agent in brain which is again parallel to the depth of anaesthesia. This is because cerebral perfusion is very large and most of the volatile anaesthetic agents are highly lipid soluble. So, it is possible to achieve easily an equilibrium between the end tidal alveolar, arterial and brain concentration (or partial pressure) within 15 minutes of exposure to a constant alveolar anaesthetic concentration.

So, MAC is defined as the minimum alveolar concentration of inhaled anaesthetic agent, which is required to prevent 50 percent of the subjects from responding to a painful stimulus with gross powerful movement. In this definition, there are two things which are not properly explained: (i) the nature of the stimulus and (ii) the extent of the response. Therefore, for determination of MAC in human beings initially surgical skin incision is taken as the standard noxious stimulus, because skin incision represents a reproducible form of supramaximal surgical stimulation. Again, respone to stimulation must entail a positive, gross, purposeful muscular movement, usually of the head or extremities, and this is taken as the standard response.

Regarding the type of stimulus and the type of response to the stimulus, there is some controversy in MAC concept for measuring the depth of anaesthesia. For responses, twisting and jerking of head is also considered as positive, but twitching or grimacing is not. Coughing, swallowing, chewing response are not considered as positive movement for responses. Similarly, there are also other stimuli which are stronger than the initial skin incision. These are intraoperative profound surgical manipulation, peritoneal traction, endotracheal intubation, etc.

Thus, MAC concept has been expanded by using different noxious stimuli and observing their different clinical response. These are MAC-awake, MAC-intubation, MAC-skin incision, MAC-BAR etc.

MAC-awake

'MAC-awake' is the minimum alveolar concentration of an inhaled anaesthetic agent that would allow opening of the eyes on verbal command. This type of stimulus and response is used during emergence from anaesthesia. Thus, stimulation is less intense than surgical skin incision, and response occurs at lower concentrations of anaesthetics than movement to skin incision.

MAC-intubation

'MAC-intubation' is the minimum alveolar concentration of an inhaled anaesthetic

Table 22.4: Pharmacokinetic and pharmacodynamic components of the dose-response relationship

Dose of a drug → Concentration in blood → Response in tissue	
↑	↑
PHARMACOKINETICS	PHARMACODYNAMICS
Initial volume of distribution	Concentration or response relationship
Distributional clearance	Threshold effect
Steady state level	Maximal effect
Metabolic clearance	Slope factor
Terminal elimination	Equilibrium delay or hysteresis

agent that would inhibit the movement and coughing during endotracheal intubation. Here, the stimulation is more intense and the response is inhibited by minimum alveolar concentration of the anaesthetic agent which is necessary for that strong stimulus.

MAC-BAR

'MAC-BAR' is the minimum alveolar concentration of an anaesthetic agent which is necessary to prevent the adrenergic response to skin incision and is measured by the concentration of catecholamines in the venous blood.

All the MAC values are nothing but the representation of concentration or dose effect relationship curves (i.e. pharmacokinetic-pharmacodynamic relationship) of that inhaled agent. But the difference of it depends on the type of the noxious stimuli, used to elicit the different types of responses. However, for measuring the depth of anaesthesia, the MAC concepts have other limitations also (which cannot be discussed fully here).

Methods of Measuring and/or Monitoring the Depth of Anaesthesia

The depth of anaesthesia is measured and/or monitored by the followind methods:

A. Clinical or conventional methods of monitoring , and
B. Brain electrical activity monitoring.

A. Clinical or conventional methods of monitoring

This is performed by (i) some clinical techniques or signs, (ii) isolated forearm technique, (iii) lower oesophageal contractility technique, (iv) heart rate variability technique, etc.

Clinical signs

Among the clinical signs that are used to assess the depth of anaesthesia are: checking for any movement, any response to commands, eyelash reflex, pupillary response, perspiration, tearing, etc. Conventional monitoring also includes ASA standard monitoring. For measurement of the depth of anaesthesia by clinical signs the most commonly used scoring system is the Evan's score (or PRST system). This scoring system assesses the autonomic activity, related to the changes in systolic pressure (P), heart rate (R), sweating (S) and tear (T). It is a very simple system and does not require any sophisticated instrument. But, the parameters are not specific for the type of anaesthesia or the anaesthetic agent and the results can vary widely among the individuals. The score ranges from 0 to 8. But, the mid point seldom exceeds which reflects the inadequacy of the scoring system. This can be explained by the fact that tachycardia secondary to anticholinergic drugs such as atropine makes the heart rate uninterpretable. This is also applicable to β-blockers, opiates, etc. which obtund the sympathetic system activity producing bradycardia and stops response to pain.

Isolated forearm technique

This technique of detecting awareness was used previously in clinical practice and in some experiments during research. Here, a tourniquet is applied on the upper arm and inflated above the systolic blood pressure, before administration of the muscle relaxant. Movement of the hand either to command or spontaneously or after skin incision indicates awareness. But the absence of movement does not indicate the absence of wakefulness. Because, some argue that a response to command intraoperatively is a late sign of attempting to prevent awareness. However, not all responding patients have a recall. One limitation of this technique is the available fixed time due to the tourniquet-induced ischaemia, before patients are unable to move their hands.

Lower oesophageal contractility (LOC)

After full skeletal muscle relaxation by a neuromuscular blocking agent, the smooth muscles of the lower half of the oesophagus still retain their potential contractile activity. This activity is related to the CNS depression and so is used to measure the depth of anaesthesia. Two types of smooth muscle activity in the lower oesophagus are detected: one is the spontaneous lower oesophageal contractions (SLOC) and another is the provoked lower oesophageal contraction (PLOC). SLOC is under the control of higher centres and can be induced spontaneously by emotion and stress in an awake individual. It arises spontaneously and is not affected by muscle relaxants. It can be detected only by a pressure transducer. On the otherhand, PLOC is induced by a provoked stimulation by inflating the balloon in the lower oesophagus and the interpretation is similar to SLOC.

Both SLOC and PLOC are reduced in latency and amplitude during general anaesthesia. But, the published data about its use in the monitoring of depth of anaesthesia is limited. One way of improving the available information is by combining the measurement of SLOC frequency with PLOC amplitude which leads to the derivation of the oesophageal contractility index (OCI). The OCI is easy to interpret and can be used in the presence of muscle relaxants. However, the general opinion is against this method and it is now considered unreliable in measuring the depth of anaesthesia.

Heart rate variability (HRV)

It is postulated that the anaesthetic agents first acts directly or indirectly on the brain stem. Then, it inhibits the cerebal cortex through the ascending efferent projections from the midbrain. Therefore, the measurement of one of the important brain stem mediated autonomic activity, such as, heart rate, which is not affected by any factor other than the anaesthetic agent is a good method to monitor the depth of anaesthesia. The special analysis of the heart rate variability reveals three components: (i) circadian low frequency fluctuation,

(ii) baroreceptor attributed medium frequency fluctuation, (iii) respiration induced high frequency fluctuation. The last component is also called the respiratory sinus arrhythmia (RSA), which is manifested by an increased heart rate during inspiration and a decreased heart rate during expiration. This is mediated by a parasympathetic reflex, connecting the stretch receptors in the lungs to the vagal motor neurons, innervating the heart. RSA is easily recognised by the ECG monitor, which is time locked to R-wave peak. Using an on-line analysis of RSA, it is found that RSA is reduced during anaesthsia and is increased during recovery, while it is also related to the depth of anaesthesia.

Though RSA is useful for monitoring the depth of anaesthesia, but needs a healthy myocardial conducting system and an intact autonomic nervous system. Any factor which affects these two systems, such as, β-blocker, conduction block, autonomic neuropathy, etc., may interfere with the result.

B. Electrophysiological approaches to monitor the depth of anaesthesia

The realisation that anaesthetic drugs affect the EEG dates back to the discovery of electrical activity in brain. The electrical activity of brain in animals was first noted by Richard Caton of Liverpool, in 1875. But, he was unable to record it. Then, in 1920, development of electronic amplifiers allowed the recording of low voltage electrical activity of brain. Berger, in 1929, recorded the changes in electrical potential by placing electrodes on the scalp of human beings. In 1930, Berger also measured the influence of chloroform on EEG. Then in 1931, he described the alpha rhythm. In 1934, Adrian and Matthews developed the clinical use of electroencephalogram (EEG). Then, Gibbs postulated that EEG might be used to measure the depth of anaesthesia and also reported in 1937 that anaesthetic agents change EEG activity from a high frequency-low voltage to a low frequency – high voltage character. In 1952, Faulconer demonstrated the relationship between the concentration of ether in blood and the pattern of EEG with the increased depth of anaesthesia.

EEG represents the cortical electrical activity, derived from the summated excitatory and inhibitory post-synaptic potentials of the large and symmetrically arranged pyramidal cells in the cortical layer III and IV of which are again controlled by subcortical thalamic nuclei. Originally, it was thought that EEG waves were the summated action potential of the cortical cells, discharging in a volume conductor. But, this concept has changed and now it is thought to be due to the current flowing in the fluctuating dipoles which are formed by the dendrites of cortical cells or cell bodies. Cortical dendrites are the forests of dense units placed in the superficial layers of cerebral cortex. Dendrites are the sites of local non-propagated hypopolarisising and hyperpolarising potential changes, induced by the excitatory and inhibitory axo-dendritic synapses. Dendrites are not the processes for conduction and do not propagate action potential. Action potentials are propagated through the axonic terminals. When the excitatory axo-dendritic synapses are activated, then current flows in and out of the cell body and the axo-dendritic endings, causing a wave like potential fluctuation in the volume conductor. Thus, EEG is the potential fluctuation in volume conductor, but not the actual action potential and is conducted through the axon only. Thus the dipole, formed in between the dendrites and the cell bodies, fluctuates constantly due to the excitatory and inhibitory axo-dendritic synapses.

The electrical activity of the cerebral cortex is mainly of two types: spontaneous and evoked. The spontaneous EEG which is used to measure the depth of anaesthesia is again classified into raw and processed.

Raw EEG

The record of spontaneous electrical activity of the brain is known as the electroencephalogram (EEG). Whereas the process of recording of changes in electrical potential in various areas of the brain by means of electrodes placed on the scalp is known as electroencephalography, and the instrument used in recording is known as electroencephalograph. An EEG record may be bipolar or unipolar and consists of different types of rhythmic waves. Bipolar EEG is the record of fluctuations of potential between the two cortical electrodes. Whereas the unipolar EEG is the record of potential difference between a cortical electrode and an indifferent electrode placed on any part of the body. EEG is a more complex signal with very low amplitude of 50 to 200 μv and with frequency that is classified conventionally into four categories: delta waves (0 to 4 Hz), theta waves (4 to 8 Hz), alpha waves (8 to 13 Hz) and beta waves (>13 Hz).

The EEG is more or less a non-invasive indicator of the cerebral function. When the patient is unresponsive or unconscious, then EEG helps to assess the cerebral physiology. But, recording of the electrical activity of brain with acceptable low level of artefacts and interferences is very difficult. This is because EEG signals are very small and easily masked by extraneous activities, such as, muscular contractions. So, it requires careful, secure and correct placement of electrodes for correct recording and interpretation. Then, they have to be amplified and filtered for frequencies which are outside of the optimal range. Again, multiple channels are required and the interpretation can be tedious and time consuming.

All the anaesthetic agents can cause changes in the cortical neural activity, reflected by the EEG. However, frequency changes are never accurate diagnostic tools and they have to be interpreted with a particular relevant context. For example:

i. Induction of anaesthesia – increases the β-activity with decrease in the α-rhythm.
ii. Deepening of anaesthesia – 'θ' or 'δ' activity predominates.
iii. Further deepening of anaesthesia – results in a burst suppression (Fig. 22.14).

Processed EEG

Actually, the unprocessed raw EEG is not a practical tool for monitoring the depth of anaesthesia. Hence, many techniques are developed to process and analyse this raw EEG. So, gradually sophisticated and automated analysis of various processed EEG components have generated several potentials for measuring the depth of anaesthesia. But, still there are two generic problems with these processed EEGs.

These are: (i) Dissimilar anaesthetic agents generate different EEG patterns, and (ii) Various pathophysiological events other than anaesthesia also affect the EEG such as hypotension, hypoxia, hypercarbia, etc. Such events may also modify both the patient's level of consciousness and the expected EEG pattern, which can be generated by any given anaesthetic agent and thus confuse the interpretation.

The recording of raw EEG involves accumulation of large amount of information on the EEG paper. But, newer computer analysis techniques can distill and summarise the raw EEG into a condensed (data reduction), descriptive format which is called the 'processed EEG'. In a processed EEG after distillation or filtration and amplification the analog signal is converted to a digital signal. Then, various signal processing algorithms are applied to the frequency, amplitude and latency of the signal to derive a phase-relationship data which generates a single number. This single number system is often referred to as 'index' which is typically scaled between 0 and 100. This index represents the progression of clinical states of consciousness such as awake, sedated, light anaesthesia, deep anaesthesia, etc. Artefact recognition algorithm which is used to avoid contamination and spurious index is an important component of the software in most monitors. Although EMG activity from the scalp muscles (as electrodes are placed on it) is considered as an artefact from the view point of pure EEG analysis, but it may be a very important source of clinically relevant information. Because, sudden appearance of the frontal EMG activity suggests somatic responses to noxious stimuli, resulting from inadequate analgesia and may give a warning of impending arousal. For these reasons, some monitors separately provide information on the level of EMG activity.

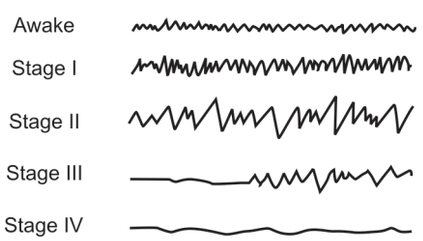


Fig. 22.14: Increasing plasma concentration of thiopentone, produces a characteristic progress of changes on EEG
Stage I: Frequency and amplitude of waveforms increase
Stage II: Decrease in frequency and an increase in amplitude is observed
Stage III: Thiopentone produces burst suppression pattern
Stage IV: It shows an isoelectric EEG

For the processed EEG two methods of data reduction such as: (i) Fast Fourier Analysis and (ii) Aperiodic Analysis are used. The Fast Fourier Analysis method measures the power of EEG and is used to derive the spectral edge. So, this power spectral analysis by fast fourier the depth of anaesthesia is performed on the blocks of EEG and the result is displayed either as a spectral array or as a power in a series of frequency bands. The characteristic of anaesthesia is a shift to a lower value of the dominant frequency power. The median power frequency (Median Power Frequency – MPF) with 50% of power above or below its value; or the spectral edge frequency (Spectral Edge Frequency – SEF) with 95% of power below its value, both have been used routinely to measure the anaesthetic depth. For example, MPF of less than 4.8 Hz predicts loss of consciousness and is the basis of its use in closed-loop delivery of drugs in TIVA. Most of the newer anaesthetic monitors used to measure the depth of anaesthesia include a module for monitoring EEG and its processed forms like SEF, MPF etc. Then periodic analysis is performed by serially examining each wave, recording its wavelength and its peak to peak amplitude. Another method of data reduction, such as bispectral analysis has been used to predict the movement in response to surgical stimulation, i.e. depth of anaesthesia.

Therefore, the combined power and spectral analysis modules provides the following measurements: two channels of raw real-time EEG wave, continuous spectral analysis of each channel of EEG, total power, percentage of total power in each frequency band, spectral edge frequency, mean dominant frequency, peak power frequency and a continuous impedance for each electrode.

Other Processed EEG's

Other than Median Power Frequency (MPF) and Spectral Edge Frequency (SEF), which have been already discussed, the other processed EEGs are: Bispectral EEG, Narcotrend, Patient State Analyser, Evoked Potential Monitor etc.

(i) Bispectral EEG (BIS) monitors

The characteristics of this Bispectral (BIS) EEG monitoring system include:
i. It is a more advanced EEG signal processing approach than the traditional Fast Fourier methodology.
ii. It has a greater correlation among the huge collection of clinical data (patient's movement, haemodynamics, drug concentrations), EEG data and advanced multivariate statistical data to create a BIS parameter.
iii. BIS analysis specially measures or is more sensitive to the hypnotic

component of the anaesthetic agent. But it does not measure or is less sensitive to the analgesic components of an anaesthetic agent.

iv. BIS in EEG monitoring definitely improves the quality of anaesthetic regime.

Before BIS in EEG monitoring the signals were processed only by time domain, i.e. only by the frequencies. Frequency analysis involves the amplitude (power), frequency (rate) and phase angle. Actually in the traditional power (Fourier) spectral analysis, only the frequency and amplitude (power) estimation were used and information on the phase angle was ignored. This is because power spectral analysis assumes that the frequency component is independent and does not interact. However, this is not always true. So this disadvantage is overcome by Bispectral (BIS) analysis which is nothing but a higher order statistical approach. This approach involves taking EEG, removing artefacts and then performing spectral calculations by both Fourier and Bispectral methods. This method analyses both the linear and non-linear components of EEG and quantitates them. After that a set of EEG features are combined, like power frequency, beta-activation and burst suppression to give a statistical valid prediction of sedation and hypnosis. Thus, to compute the BIS several variables which are derived from the time domain (burst supression analysis) and frequency domain of EEG (power spectrum, bispectrum, interfrequency-phase relationship) are combined into a single index of hypnotic level. Additional clinical data (such as movement or no movement to skin incision, along with equilibrated anaesthetic concentration data) and statistical data are also used to identify the components of EEG that appear to correlate best with the clinical and pharmacological end point.

Thus, BIS is a complex parameter composed of a combination of time domain, frequency domain and also higher spectral subparameters which are derived from the various clinical data. The BIS module and the software which are present in the depth of anaesthetsia monitoring machine uses EEG signal upto 47 Hz, and computes it to a dimensionless number in a numerical scale of 0 to 100, where 0 is the isoelectric or cortical electrical silence and 100 is the awake. Response to voice command is unlikely when BIS is below 70. BIS less than 60 indicates deep sedation. No subject is responsive to any stimulus when BIS is less than 57.

BIS has been validated for many commonly used anaesthetic drugs. It shows a good correlation with the end tidal sevoflurane concentration as well as measured blood propofol concentration. Studies have shown that the use of BIS can decrease the consumption of anaesthetic agents. So it also helps in speed of awakening and in a faster discharge. The utility of BIS is maximal when the anaesthetic regimen is a combination of low doses of opiate analgesis with high doses of hypnotic drugs which is titrated to the bispectral response. For the BIS to reflect maximally, higher doses of hypnotic drugs with lower doses of opiates should be used. The higher doses of opiates result in a significant synergistic interaction with the hypnotic drugs. Also, the reduced amount of hypnotic drugs result in less profound hypnotic EEG effects on CNS and therefore a less sensitive BIS response. It appears that the synergistic interaction of opiates and hypnotics to reach the clinical end point does not correlate well with the EEG effects of hypnotics. The pharmacodynamic relationship of BIS to hypnotic drug concentration is unchanged (i.e. lowering of BIS with increasing hypnotic drugs) if opiate concentration increases.

The clinical use of BIS monitoring involves separating the hypnotic and analgesic components of an anaesthetic regimen. During routine anaesthesia with small to moderate doses of analgesic drugs, an adequate dose of hypnotic agents are used and it keeps the BIS level at the range of 50 to 60. During intense surgical manipulation if BIS increases and patient exhibits movement or haemodynamic responses, then it should be corrected by increasing the dose of hypnotic agent and and thus lowering the BIS value to 50 to 60 range. On the contrary, if BIS remains lower, but the movement and haemodynamic responses continue, then incremental doses of opiates should be added to increase the analgesic component of anaesthetic regimen, until the movement and haemodynamic responses are controlled.

BIS demonstrates the dose-response relationship of hypnotic effects of intravenous and inhalation anaesthetic agents, such as propofol, midazolam, halothane, etc. and correlates well with the clinical assessment of the level of anaesthesia. It is the first processed EEG technique to be used for correlation between the behavioural assessment and the level of consciousness. Ketamine and sometimes N_2O, however, cause EEG activation, complicating the BIS interpretation. Baseline BIS value is not decreased by N_2O at an inspired concentration upto 50%. However, during surgery, the antinociceptive effect of N_2O may be responsible for the observed decrease in value of BIS. As the paediatric EEG only approaches the adult pattern by about 5 years of age, so it cannot automatically be extrapolated to young children. But still, healthy adult EEG data are used to authenticate the BIS algorithm of children, because early investigation suggests that BIS may be valid in children, older than 1 year of age. Comparison of BIS values at various clinical end points between the adults and children suggests that BIS performs similarly in adults and children in respect to dose-response relationship of anaesthetic agents. Its use is also rapidly expanding, especially during care of a critically ill patient admitted in the ICU.

BIS has also been used in cardiopulmonary bypass, vegetative states, CPR,

hypoglycemic coma, etc. But here an increase or decrease in BIS may not always reflect adequate awareness or lack of it. Recently, it has been seen that when BIS is used along with ECT, then values fall to 26 to 28. This is due to the post-tictal EEG depression after ECT. Hence, in such circumstances correlation of BIS with the awakening is affected. It may be unreliable in conditions like dementia. Also, electro magnetic operating systems used in surgeries might affect the BIS monitoring.

Like an EEG signal, BIS is also subject to interference and artefacts, particulaly from EMG activity which can artificially elevate the BIS value. So, some monitors also show a display of signal quality index and an indicator of EMG interference. As there is no 'gold standard' monitor against which BIS can be compared, so studies have used predictive probability that is likely to occur in various clinically relevant end-points such as the loss of consciousness, recovery, recall, etc, at different BIS values. The probability of post-operative recall is very low when BIS is kept < 60 intra-operatively (Table 22.5).

(ii) Narcotrend monitor

This EEG derived monitor used for assessment of depth of anaesthesia performs automatic computer analysis of raw EEG during anaesthesia. In this system two electrodes are placed on the forehead of patient and a third electrode serves as a reference. It uses a 6 letter classification with 14 subclassifications. The letters are A to F, where A represents an awake patient and F denotes burst suppression. In between these the the B and C represent the sedated and light anaesthesia of patient, respectively. With this system the stages D and E are aimed (D = general anaesthesia, E = general anaesthesia with deep hypnosis) at steady-state anaesthesia. During practice, B and C should be avoided and F is considered unnecessarily deep.

Table 22.5: Comparison between BIS and Narcotrend

1. BIS ≈ 100 to 85 = A and B levels of Narcotrend system (A = Awake, B = Sedated)
2. BIS ≈ 85 to 65 = C levels of Narcotrend system (C = Light anaesthesia)
3. BIS ≈ 65 to 40 = D and E levels of Narcotrend system
4. BIS ≈ < 40 = F (burst suppression)

(iii) Patient state analyser

The patient state analyser is also an EEG derived colour-coded patient safety index (PSI) which is recorded on a scale between 0 to 100. Green colour indicates the hypnotic state and comes in the 25 to 50 PSI range. Yellow indicates deep hypnosis and involves an index below 25. Blue indicates burst suppression. Whereas white indicates artifacts which the analyser machine identifies and discards. The main advantage claimed with this system is that there is little interference with cautery, electromagnetic operating system or noise pollution (Table 22.6).

(iv) Cerebral state monitor

It is a handheld device that analyzes a single channel EEG and presents a cerebral state index (CSI) which is also scaled between 0 to 100. In addition, it also provides EEG suppression percentage and measurement of EMG activity. The monitor is also on-line and evaluates the amount of instantaneous burst suppression (BS) during each 30 seconds period. The CSI is a unitless scale from 0 to 100, where 0 indicates a flat EEG and 100 indicates EEG activity corresponding to awake state. The range of adequate anaesthesia is defined to be between 40 and 60.

Evoked potential

The evoked response or activity in the cerebral cortex is elicited directly by stimulating the cortical surface (Direct Cortical Evoked Response) or indirectly by stimulating the peripheral sense organs like: the retina − by photostimulation (Visual Evoked Potential – VEP), the ear − by auditory click (Auditory Evoked Potential – AEP) or the peripheral sensory nerve endings (Somato Sensory Evoked Potential – SSEP). The type of stimulation may be sensory, electrical, magnetic or even cognitive in nature. The two major types of evoked potentials are sensory (SEP) and motor (MEP), which assess the functional integrity of sensory and motor pathways respectively and is greatly influenced by the effect of narcotics, drugs, and physiological conditions, like sleep, etc. The most commonly used evoked potential for assessing the depth of anaesthesia is SEP. Here, the stimulus is applied at the peripheral nerves and the resulting response is recorded centrally at the cerebral or cortical level. The evoked waves consists of some positive, followed by a few small negative and then by many larger and more prolonged positive deflection. The first positive-negative wave sequence is called as the primary evoked response, while the second one is called as the diffuse secondary response. This evoked response can be separated by means of a special computer from the underlying spontaneous EEG.

Table 22.6: Colour-coding of PSI

Green (25 - 50)	:	Hypnotic state
Yellow (< 25)	:	Deep hypnosis
Blue	:	Burst suppression
White (artifacts)	:	Discarded

The computer techniques which process the EEG signals, first extract the evoked potential from the underlying spontaneous cortical electrical activity after the respective stimulus. Thus, evoked response represents a time versus voltage relationship that can be quantified by measuring the post-stimulus latency and inter-peak amplitude in the waveform.

The evoked responses are used primarily (i) to monitor the functional integrity of neural structures, (ii) to identify the anatomical integrity of neural structures and (iii) to diagnose the neurophysiological conditions. As evoked response is sensitive to anaesthetic drugs, so they have been used to measure the effect of

anaesthetic drugs on brain and also the depth of anaesthesia.

There are several advantages and disadvantages of using evoked potentials for monitoring the effects of anaesthetic drugs and the depth of anaesthesia.

Advantages:

i. Body's response to some form of stimulation forms the pivot for assessing the depth of anaesthesia.
ii. Measuring the evoked potential is a noninvasive and continuous method of measuring the body's response to appropriate stimuli.

Disadvantages :

i. Though all the anaesthetic agents cause changes in evoked response, but there is no standard to measure the drug effect that enables one to identify or characterise this drug effect or the depth of anaesthesia.
ii. There is no known parameter to measure the evoked response.
iii. There are also technical, clinical and practical complexities of recording the evoked responses, like stimulus characteristics (intensity, duration etc.), electrode placement, recording equipment, recording technique etc.

Auditory evoked response or potential (AEP)

Among all the evoked response, AEP is the most important. So, it is only discussed here. Sense of hearing is the last to be lost and first to be recovered during induction of anaesthesia and return of consciousness respectively. This is the basis of using the auditory evoked response for measuring the consciouness and depth of anaesthesia. The applied auditory impulses hit the cochlea of the ear, then it travels via the eighth nerve and reach the brain stem. The auditory stimuli are given as clicks from ear phones. Normally, 1024 clicks at the rate of 6 per second are given, depending on the background noise. Any disturbance in hearing could affect the ability of AEP to reflect the depth of anaesthesia.

The auditory evoked response is again divided into (i) the brain – stem response, (ii) the early cortical response and (iii) the late cortical response.

Brain-stem responses

This is also termed as Brainstem Auditory Evoked Potential (BAEP). These occur within the first 10 milliseconds and consists mainly of six waves, labelled as I to VI. The BAEP is presented as a smooth curve, therefore, typically only the wave V can be detected. They are preserved with all the volatile anaesthetic agents and change very little with anaesthesia. So, they are not so useful to us.

Early cortical responses

This is also termed as Middle Latency Auditory Evoked Potential (MLAEP). These occur within 10 to 80 milliseconds and are designed as PoNo, PaNa, PbNb, etc. These responses, especially Nb shows graded changes with the effect of anaesthetic agents and are so useful to grade the depth of anaesthesia. Nb with a frequency of 47 secs is 100% sensitive and specific for explicit memory during isoflurane anaesthesia. All the volatile anaesthetic agents suppress the early cortical response component of AEP to a similar extent at equipotent MAC. All the volatile anaesthetics increase the latency and decrease the amplitude in a reversible dose-concentration related manner. N_2O decreases it in a progressive dose related manner, due to an increase in the auditory threshold. Intravenous anaesthetic agents also change the evoked potential similar to the inhaled anaesthetics, except benzodiazepines. Ketamine does not affect the early cortical response. Opioids produce only the partial suppression, even in high doses. High doses of opioids do not suppress the consciousness or sensory function. Thus, benzodiazepines, ketamine, opioids and MAC 0.5 volatile agents preserve the early cortical response and so cannot be used to prevent the intra-operative awareness.

Reversible headphones or earphones deliver the active auditory stimulus. Cost effective disposable surface electrodes are used to measure the AEP and the subsequent result enables to measure the patient's level of consciousness. From the mathematical analysis of the AEP waveform, the device generates an AEP index that provides a correlation of depth of anaesthesia with the anaesthetic drug concentration. The AEP index is scaled from 0 to 100. In contrast to other EEG indices, the AEP corresponds with low probability of consciousness at less than 25, rather than the higher numeric threshold associated with the other monitors. More recently AEP index is scaled from 0 to 60. When using this 0 to 60 range, fewer oscillations are observed, while the patient is awake. When asleep, the graphical resolution of the lower index value is higher. It is recommended to use the AEP index in 0 to 60 range. AEP index is very specific and sensitive. When compared to SEF, MPF and BIS, then AEP index is most sensitive in distinguishing transition from consciousness to unconsciousness.

Late cortical responses

This is also termed as Long Latency Auditory Evoked Potential (LLAEP). These occur after 80 milliseconds and are designated as P_1N_1, P_2N_2 etc. These evoked responses are very less sensitive to anaesthetic drugs and volatile agents. Hence, they are of no practical use. The disappearance of P_1N_1 indicates transition from consciousness to unconciousness. Other single derivative derived from the late cortical response like second differential, first differential, coherent frequency, ARX index, etc. are all being evaluated, but are not so promising.

Other Monitors

The other equipments which are used to monitor the depth of anaesthesia are :

i. Positron Emission Tomography (PET)

ii. Super Conductive Quantum Interference Device (SQUID)
iii. Ocular Microtremor Monitoring (OMT)

(i) PET

PET scanning is an invasive method and cannot be used in routine cases.

(ii) SQUID

It is non-invasive, measuring the functional activity of the brain, but is very expensive.

(iii) Oculomicrotremor (OMT) monitoring

Oculomicrotremor is a high frequency physiological tremor of the eye, present in all the subjects and is related to the toxic activity in the brainstem oculomotor neurons. It has been shown that OMT correlates well with the level of consciousness. OMT is suppressed by thiopentone, propofol and sevoflurane. It is measured by a piezo-electric strain gauge technique where probe is placed on the conjunctiva or closed eye. Earlier, the probe was placed on the anaesthetised sclera. But nowadays it can be placed on the closed eyelid. End tidal sevoflurane concentration of 1 to 2% does not decrease OMT, nor decrease BIS, though it shows a falling trend. When compared to BIS, OMT may exclude an aware patient more accurately than BIS, though the graded measure of emergence is better seen with BIS. OMT remains depressed until just before the first response to verbal command appear. Hence, it is more useful as an awareness monitor, than the depth of hypnosis monitor.

MONITORING OF THE CARDIOVASCULAR SYSTEM

Introduction

The cardiovascular system is responsible for the transport of different substrates, products of their metabolism, and adequate oxygen to tissues and CO_2 to lungs, in order to support their continued normal function. Thus, the adequate organ function reflects the adequacy of performance of the cardiovascular system. So, clinically sometimes we measure the urine output, skin colour, body temperature, mental status, sensory or motor functions (cerebral indices), etc. for monitoring of the adequacy of function of cardiovascular system. But, it is not always true or possible due to the presence of some intrinsic end organ dysfunction. Because this kind of clinical monitoring requires the absence of intrinsic end organ dysfunction. So, direct monitoring of different facets of CVS by instruments is more practical and reliable than the only clinical monitoring of the function of end organs. But, both the complexity and diversity of monitoring (both noninvasive and invasive) of CVS by instruments depends on many variables, such as the nature of surgical procedure, fragility of the patient's cardiovascular system, considerations of the risks and costs of various monitoring techniques, etc. So, the ultimate and final decision regarding the extent of the monitoring of CVS by instruments depends on the judgement of anaesthetist, who choose a particular technique for monitoring will provide sufficient information with minimum risks and cost to optimise the management of a particular patient.

History

It was the 28th January of 1848, when the first death due to anaesthesia was reported and it was an excision of an ingrowing toenail during administration of choloroform. This was just 2 years after the first public demonstration of anaesthesia by ether and the patient was only 15 years old, named Hannah Greener. However, before that another two deaths were also reported unofficially in March 1847. The first was a young woman at Yrantham, named Lincs and the second was a 52 years old man at Essex.

So, nearly a century and a half later this incident still reminds us that even a rudimentary awareness and a minimum monitoring of patient's cardiovascular system can avert many of the mishaps. Also, the development of newer and far less toxic anaesthetic drugs than choloroform emphasises that the necessity of adequate and careful monitoring of CVS is still not less important today or in future, than it was thought previously at the time of invention of anaesthesia. At that time, the assessment of patient's cardiac performance was entirely subjective, i.e. without any equipment. Then, the remainder of 19th century saw little or no advancement in the development of objective monitoring with equipments during anaesthesia.

In 1860, Joseph Clover had first initiated the monitoring of a patient by keeping his fingers on patient's pulse, while administering choloroform. Then the end of that century, a feather was added to the vulcanite face-piece to monitor the respiration by observing its movement. Then in 1894, Earnest. A. Codman, a surgeon of Harvard, developed a system of intraoperative monitoring and a record-keeping system at the Massachusset's General Hospital. After that, in 1903, a routine and a new form of cardiac monitoring protocol was first placed in anaesthesia practice in USA. This had included the measurement of systolic blood pressure by Riva-Rocci's sphygmomanometer, measurement of heart rate, measurement of respiratory rate, etc. The mercury manometer was first used to measure the blood pressure by Poiseuille in 1828. Then, in 1834 Herrison developed a crude instrument which was placed directly over an artery to measure the blood pressure. Vierordt was the first to estimate the amount of counter pressure which is just necessary to obliterate the arterial pulse. After that Jules Marey and Von Basch had become the pioneer in clinical sphygmomanometry (sphygmo means pulse, manometer means measurement of pressure of liquid and gas in a container). Riva Rocci first introduced the blood pressure cuff in 1896, although

the breadth of cuff he used was only 5 cm. Then Von Recklinghausen drew attention to the importance of the width of cuff to get better results.

Then in 1905, Korotkoff, a Russian physician, described the sphygmomanometric sounds using stethoscope from large peripheral artery during deflation of the cuff. This was called the Korotkoff sounds and still remains the standard technique for blood pressure measurement manually in all the spheres of medical care. After that in 1911, Mckesson added the measurement of respiratory rate and the measurement of inspired O_2 concentration to the monitoring armamentarium of anaesthesia. The oximetry was first performed as early as in 1913. Then, there was a steady development in the sphere of monitoring during anaesthesia with the Einthoven's discovery of ECG. This was the early 1960 and was done by using a cathode ray oscilloscope which eventually led to its gradual introduction into the anaesthetic practice.

The oscillotonometer principle which was first developed in 1931 by Von Recklinghausen by using a cuff to sense the changes in arterial pulsations has now become the corner stone of methodology for most of the today's automated noninvasive blood pressure measuring devices. Originally, Von Recklinghausen used the oscillations of a needle to indicate the systolic and diastolic pressure. Later in 1970, automatic oscillotonometers were developed by various equipment companies. Here the changes in pressure of the cuff is detected by the transducer of the monitor which is analysed and presented digitally as systolic, diastolic and computed mean arterial pressure.

Though the intra-arterial BP was first measured invasively by Stephen Hales, in 1733, by direct cannulation of an artery of an animal, but it was not in practice till 1949 when Peterson and Dripps developed a safe, percutaneous arterial cannulation method. However, in the next decade the developement of transducer technology and arterial catheters made the invasive BP monitoring a standard and widely accepted method in all the areas of critical care.

Venous pressure was also first measured by Stephen Hales in 1733 on a mare. But, then after a long interval it was first measured on man by Fray in 1902 and was first used clinically in 1910. Then in 1929, Forssman's pioneering work on human cardiac catheterisation which was first done on himself, stimulated the progress of this chapter. This landmark achievement and also the development of many better materials for manufacturing of catheter allowed the subsequent completion of many important cardiac investigations which have formed the basis of understanding of our current use of central venous pressure monitoring. The first plastic (polythene) intravenous catheter was used in 1945, and the plastic central venous catheter was developed rapidly after this.

Lagerlof and Werko had first reported the value of pulmonary capillary wedge pressure (PCWP) as a reflection of the left vetricular filling pressure. Finally in 1970, the development of flexible, ballon tipped and flow directed Swan-Ganz catheter by Swan had made the pulmonary artery catheterisation possible routinely. After that, Seldinger developed a guide wire directed deep vascular cannulation technique which added a great safety and ease to this type of cardiac monitoring. Now, the modern pulmonary artery catheters provide a variety of additional diagnostic and therapeutic tools such as determination of cardiac output by thermodilutional technique, determination of mixed venous oxygen saturation by oximetry, atrial or ventricular pacing and many others. Thus, gradually it became the hallmark of a 'full' invasive cardiac monitoring system in anaesthesia and critical care unit.

Blood – gas analysis was first started by Pflunger as early as in 1872. Then, Leland Clark developed polarographic oxygen electrode in 1956, which forms the basis of modern oxygen electrode. At the same time, the polio epidemic in Copenhagen had stimulated the search for different methods of measuring the arterial PCO_2. At first, Astrup had measured the pH of blood with different CO_2 concentration to determine its PCO_2. But later, the development of CO_2 electrode greatly facilitated this measurement and a full acid-base picture could be derived from the Siggard – Anderson nomogram. However, today these calculations are performed by a microprocessor. Capnography was first used clinically in 1960, although the infrared analyser was first employed as early as in 1865.

However, the most unique addition in the armamentarium of intraoperative cardiac monitoring system took place in 1954 with the first use of ultrasound in cardiology by Edler and Hertz. But their one dimensional motion (M-mode) analysis has rapidly given way to the two dimensional (2-D) echocardiography. It displays different cardiac anatomy in various planes, even in real time. The development and use of transoesophageal transducer was first established in 1980 by Hisanaga. Then, gradually TEE has gained significant popularity in anaesthesiology and has built a stable platform for continuous, noninvasive, high quality intraoperative monitoring of the cardiac functions. Moreover the addition of doppler technology and colour-flow imaging have further established TEE as an important tool in modern anaesthesia practice.

Clinical Monitoring

The priciple aim of function of cardiovascular system (CVS) is to ensure adequate supply of O_2 to tissues. The supply of adequate amount of O_2 to tissues (or O_2 content) is the product of cardiac output (CO), haemoglobin concentration and haemoglobin by saturation of O_2. Clinically, the haemoglobin concentration and saturation

may be estimated by looking at the mucous membrane and the skin. The CO may be estimated clinically by the pulse volume, urine output and warmth of extremities. Therefore, observation of a good pulse, pink skin and warm extremities, especially when combined with urine output of > 0.5 ml/kg/hr implies that there is unlikely to be any cardiovascular problem, provided there is no peripheral vascular disease.

In children, the observation of capillary circulation by capillary refill time provides a valuable indication of a stable cardiac status, as peripheral vascular diseases are rare in children. The capillary refill time is the time taken by capillaries to be refilled, after the digit has been exanguinated by firm pressure. When a finger has been kept under pressure for 3 seconds, then a capillary refill time of less than 1.5 seconds is considered normal. But a time greater than 5 seconds is indicative of impaired circulation or shock. While the patients presented with complex cardiovascular problems may require more sophisticated monitors, but still the value of direct observation of patient and the examiner's fingers on the patient's pulse, can never be underestimated. But in practice, sometimes dimmed theatre light and surgical drapes may cause difficulties for direct observation of patient and clinical monitoring. So, in such situation electronic monitors become essential. But still direct observation of patient should always be maintained as far as possible and should be taken as supplementary to the instrumental monitoring. Therefore, for many healthy patients who are undergoing minor procedures, the above mentioned physical signs and clinical monitoring may provide a considerable important portion of the total cardiovascular monitoring. But, when the operation becomes more complex or the patient presents with more advanced unstable CVS, then the extent of supplementary electronic monitoring grows accordingly. However, still the careful clinical assessment of patient helps the clinician to confirm or refute the information, derived from the important monitoring systems.

Monitoring by Stethoscope

In 1818, Lacnnce had first introduced the stethoscope in general medical practice. After that 100 years have passed, when in 1908, Harvey Cushing first proposed that stethoscope could be used for continuous routine monitoring of CVS during surgery.

Two types of stethoscopes are used for continuous cardiovascular monitoring during surgery. These are the precordial stethoscope and the oesophageal stethoscope. They provide simple breath sounds and heart sounds continuously throughout the operation. In a precordial stethoscope the metal bell is strapped on the precordium. Then both the heart sounds and breath sounds are heard through a long tube and a custom moulded monoaural plastic ear piece. Electronically amplified stethoscopes also have been designed in an attempt to improve the quantity and clarity of the heart rounds and breath sounds. Stethoscope with wireless system using radio transmitted signals have also been developed. Wireless stethoscopes also allow continuous monitoring of CVS, while the anaesthetist pays attention to the other monitors instead of sitting by the side of patient. An oesophageal stethoscope is minimally invasive, but provides clear breath sounds and distinct heart sounds when the tip is positioned at 28 to 30 cm from the incisors. By this core body temperature can also be measured via a thermistor which is incorporated in the tip of the oesophageal stethoscope. Specially configured oesophageal stethoscopes also permit recording of transoesophageal ECG which sometimes may be come useful in diagnosing atrial arrhythmias, right ventricular ischaemia or posterior left ventricular ischaemia. Transoesophageal atrial pacing also can be accomplished by these transoesophageal stethoscopes, which is equipped with bipolar pacing electrodes on its outer surface.

But the routine use of the pulse oximeter, capnometer and other electronic monitors, driven by their ubiquitous usefulness and imposed law, has diminished recently the wide spread application of precordial and oesophageal stethoscopes in clinical practice, despite their immense utility in basic patient monitoring. Currently, the precordial and oesophageal stethoscopes are used intraoperatively in institutions where there are no electronic monitors. Then, their role in diagnosing important respiratory problems, such as bronchospasm, crepts etc., probably exceed their value as continuous monitors for the circulatory system.

Failure of these stethoscopes to detect untoward events is more frequent than the electronic monitors and it is due to the difficulty to concentrate continuously or to listen to both the heart and breath sounds simultaneously.

Heart Rate Monitoring

It is the most simplest and non-invasive (or rather least invasive) form of monitoring CVS. It acts as an important guide in determining the influence of anaesthetic agents on CVS, reaction of CVS to surgical stimuli and any underlying cardiovascular pathology. The monitoring of the heart rate (pulse rate) by keeping 'fingers on pulse' is ubiquitous and is fundamental of all the monitoring. But practically, it is not always possible due to other engagements of an anaesthesiologist. However, fortunately most of the monitors (invasive or noninvasive) used during anaesthesia practice provide a continuous audio and numerical display of the heart rate.

In ECG monitors the heart rate is displayed by measuring the QRS interval by recognising the peak of R wave on a beat-to-beat basis. The electrocardiographic measurement of heart rate begins with an accurate detection of R-wave and measurement of R-R interval, which is displayed and updated by every 5 to 15 seconds. The automatic noninvasive blood pressure

devices also usually display the heart rate by counting the cuff oscillation. The invasive blood pressure monitoring system derives the heart rate from the arterial and as well as from the pulmonary artery waveform. Pulse oximeter computes and displays the heart rate from capillary pulsation.

All the heart rate monitors, like other monitors, are also subjected to errors from artefacts, pathological states or other therapies (Table 22.7).

Pulse Rate Monitoring

The electrical depolarisation and the systolic contraction of heart per minute is called the heart rate. It generates a palpable peripheral arterial pulsation and its rate per minute is called the pulse rate. Pulse deficit is the difference between this heart rate and the pulse rate. So, the monitoring of pulse rate is more important than the heart rate and is very helpful to make an idea of the peripheral organ perfusion. This is because all the cardiac systoles (which produce the heart rate) do not produce sufficient cardiac output which is responsible to produce a palpable pulse and peripheral circulation. The typical example of pulse deficit is AF in which the short R-R intervals compromise cardiac filling during diastole and results in a reduced stroke volume with an imperceptible peripheral arterial pulse. Thus, all the cardiac systoles do not end in palpable peripheral pulses and there is a deficit between the heart rate and the pulse rate in AF. The other extreme example of difference between the heart rate and the pulse rate is EMD (electro mechanical dissociation). This is actually a condition where the electrical activity and contraction of heart is present, but there is no or minimal stroke volume. Therefore, there is presence of heart rate, but absence of pulse rate. This is usually seen in patients with cardiac tamponade, extreme hypovolaemia, extreme peripheral vasodilatation, anaphylactic shock, etc.

Table 22.7: Some common errors in heart rate monitors

1. ECG monitors often count pacemaker artefacts (especially atrial) - resulting, the faulty heart rate.
2. When the T-waves are exceptionally tall, ECG monitor counts these T-waves in addition to QRS complexes, causing an apparent doubling of the actual heart rate. Intra-aortic balloon pump counter pulsation also can cause the same doubling error in blood pressure (from arterial form) - derived heart rate.
3. Presence of pulsus paradoxus apparently reduces the actual heart rate to half.
4. Electrocautery invariably interferes the counting of heart rate by ECG monitor.

On the monitor's screen we get the heart rate from ECG tracing and the pulse rate from different pulse sources. For example, pulse oximeter uses the capillary pulsation where an optical transducer measures the capillary volume changes (plethysmograph) and provides the pulse rate for most patients, except in patients with severe arterial occlusive diseases or marked peripheral vasoconstriction. Pulse rate is also obtained by electromechanical transducers in NIBP devices which determine the pulse rate by counting the oscillations in the pressure cuff. When during direct and invasive arterial pressure measurement a catheter is in place in side the arterial lumen, then the arterial pressure waveform also provides a reliable pulse rate. The peizo-electric devices of Doppler probes are also used for pulse rate monitoring. The output of these monitors is displayed upon an oscilloscope. Qualitative index of the pulse volume and flow may be obtained from this oscilloscope.

Pulse rate counting using intra-arterial pressure tracings may sometimes be misleading, when the non-systolic arterial pulsations are detected by the monitor and are counted separately. For example, when a patient is treated with an intra-aortic balloon pump, then the pressure pulse resulting from the balloon inflation during diastole may be detected, producing a fictitiously high pulse rate. When the morphology of pulse becomes double-peaked, (which is called bisferiens pulse), such as those arising in patients with aortic valve regurgitation, then it may also produce a similarly increased (doubled) pulse rate. In contrast, patients with pulsus alternans may have an inappropriately low pulse rate (half), due to the diminished magnitude of every alternate arterial pulsation. In such cases, counting of pulse rate from the pulmonary artery pressure wave-form can provide a reliable pulse rate.

Monitoring of the CVS by ECG

Electrocardiography during monitoring of CVS warns us about the changes in heart rate, its rhythm and the development of any ischemia which may precede to the bad haemodynamic changes. The disturbances in potasssium and calcium levels of blood may also be recognisable from ECG during monitoring of CVS. However, a major limitation of ECG in cardiovascular monitoring in cardiovascular monitoring is that there is no indication of cardiac output, which may fall to be zero inspite of a normal ECG tracing. The quality and ease with which the electrical signals of heart may be obtained is due to the improvement in electronics and electrode design. Thus, the 'mat' electrode has greatly reduced the time required to establish a good interface. With many systems, however, the signal is interfered following the use of electrosurgical diathermy. But, recently many commercially available ECG monitors are capable of rejecting the diathermy interference (Fig. 22.15).

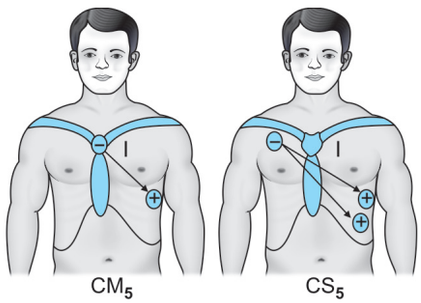

Fig. 22.15: Monitoring of the CVS by ECG

The standard lead II is the commonly used lead configuration for monitoring, which allows the excellent detection of any intraoperative arrhythmias. But, it does not always show the ischaemic changes, which may only be visible in lead V_5. So, the unusual bipolar lead named CM_5 (central manubrium to the fifth intercostal space in the left anterior axillary line) allows an excellent detection of both the ischaemia and arrhythmias. Therefore, it is always recommended for continuous intraoperative ECG monitoring.

Another lead, named CS_5 (central subclavicular) is also very important for intraoperative ECG monitoring. Here, the right arm (RA) electrode is placed under the right clavicle, the left arm (LA) electrode is placed in the V_5 position and the left leg (LL) electrode is placed in its usual position. In this CS_5 lead arrangement, the lead I is selected for the detection of anterior myocardial wall ischaemia and the lead II is selected for the detection of inferior wall ischaemia or arrhythmia. If a unipolar precordial V_5 lead is not available, then this CS_5 bipolar lead is the best and easiest alternative for monitoring of myocardial ischaemia and arrhythmia (Table 22.8).

Arterial Blood Pressure Monitoring

Measurement of blood pressure is one of the most fundamental parameters for monitoring of cardiovascular function. It represents the force of contraction of heart that drives the blood to flow from centre to periphery (systolic pressure) and also represents the load against which heart has to work (diastolic pressure). The peak pressure generated within the vessels during systolic contraction of ventricle is called the systolic blood pressure and the continuous pressure within the blood vessels during diastolic relaxation of ventricle is called the diastolic blood pressure. The pulse pressure is the difference between these two pressures. The average arterial pressure over a period of full cardiac cycle is termed as the mean arterial pressure. It is a time-weighted average pressure, which prevails throughout the whole cardiac cycle. So the mean blood pressure is approximately equal to the diastolic pressure plus one-third of the pulse pressure, i.e,

Mean BP =DP + 1/3(SP – DP)

The monitoring of the function of cardiovascular system is aimed at to assess the amount of cardiac output, which is required to maintain the oxygen-flux. So, the most important parameter for monitoring of CVS is the cardiac output or flow. But, it is very difficult to measure the cardiac output clinically and it has been discussed in the last part of this chapter. So, to monitor the perfusion of organs which is the most important function of CVS, we measure HR and BP. But, fortunately the more easily monitored parameter such as HR and BP bear some constant relationship with CO, by the following equations :

Pulse rate = CO ÷ Stroke Volume

Blood pressure = Cardiac Output × SVR

Arterial blood pressure is generally affected by the site where it is measured. This is because the pulse wave moves peripherally along the wall of the arterial tree. So, this pulse wave may distort the pressure waveform which moves along the column of the blood, leading to an exaggeration of the systolic and pulse pressure. The level of the measuring site of BP relative to the level of heart also affects the value. This is because of gravity. In patients with severe peripheral vascular disease there may be a significant difference in the value of measured blood pressure between the right and left arm and between the arms and legs. However in such circumstances the higher value should be taken for these patients.

The easily measured parameters of cardiovascular function such as BP and pulse rate are less reliable than the CO and SVR, which are more reliable but difficult to measure. For example, if the SVR is high, then the BP will also be high but the cardiac output will be low which cannot be understood by the level of the blood pressure only. Thus, the arterial pressure should be viewed as an indicator, but not always as a measurement of organ perfusion. All types of anaesthesia, no matter how 'trivial', is an indication for the measurement of BP. But its frequency and technique of measurement depend on the gravity of surgery, the condition of patient and the experience of anaesthetist. Generally, the measurement of BP which in based on noninvasive oscillometric principle and is measured after every 3 to 5 minutes interval is adequate in most cases.

Blood pressure is measured mainly by two techniques: indirect (non-invasive) and direct (invasive). The noninvasive method of measurement of BP is based on the technique of palpation, Doppler,

Table 22.8: Some effects of electrolyte and other disturbances on the ECG

Hyperkalaemia	Appearance of tall and tented T wave, appearance of wide bizarre QRS merging with the T wave. Disappearance of P wave, ventricular extrasystole, fibrillation or asystole.
Hypokalaemia	Flattening or inversion of T-wave, increase of PR interval, depression of ST segment, appearance of U-wave, apparent longation of QT interval, atrial, ventricular extra systole, ventricular tachycardia.
Hypercalcaemia	Reduction of QT_C interval, blending of T with QRS.
Hypocalcaemia	Prolongation of QT_C interval.
Hypomagnesaemia	Prolongation of QT_C interval.
Venous air embolism	Right heart strain pattern, atrial and ventricular extra systole.

The QT interval varies with the heart rate. So, when it is corrected to a heart rate of 60 beats per minute, then it is signified as 'QT_C' ($QT_{Corrected}$)

auscultation, oscillometry and plethysmography (Fig. 22.16).

1. Indirect or non-invasive methods

The most indirect methods for measurement of BP are based on the principle of Riva-Rocci sphygmomanometer. The use of this method consists of inflation of a pneumatic cuff, occlusion of blood flow of a large artery and then sensing the sequence of physical changes that occur in and around the just opened artery as the pressure is released and blood flow begins. Originally, Riva-Rocci described the measurement of systolic blood pressure by the disappearance of the radial pulse when the cuff was inflated (cuff-inflation technique). But nowadays a variation of this Riva-Rocci method is employed where both systolic and/or diastolic pressures are measured during the deflation of cuff and when pulse reappears (cuff-deflation or return-to-flow technique). The reappearance of pulse which helps in detection of systolic and diastolic blood pressure is detected by palpation, doppler, auscultation or oscillometry method. This indirect methods of BP measurement may be intermittent or continuous.

(i) Non-invasive intermittent techniques

BP can be measured intermittently and non-invasively either manually or by an automatic machine.

Manual method

This is the most simplest way of measurement of BP and is based on auscultation of the Korotkoff sounds. Using a Riva-Rocci sphygmomanometer cuff, Korotkoff an another scientist, applied a stethoscope on the artery, directly below the cuff to auscultate the sound which is generated as the cuff was slowly deflated and the blood starts to flow through the just opened arteries. This sound is created by a complex series of audible frequencies, produced by the (i) turbulent flow of blood, (ii) vibration of unstable arterial wall and (iii) shock wave formation as the external occluding pressure on a major artery is reduced. When the pressure cuff is deflated gradually after its inflation, then the pressure level where the completely occluded artery just opened and blood starts to flow through a narrow opening of arterial lumen first producing sound (Phase I) by the above mentioned mechanism is considered as the systolic pressure. Then, gradually the character of the sound changes (phase II and III). Finally, the sound becomes muffled (phase IV) and becomes absent (phase V). The pressure where the sound becomes muffled or absent (phase IV and V) is taken as the diastolic pressure. In certain pathological conditions such as inaortic incompetence the phase V may not occur and phase IV is continuous.

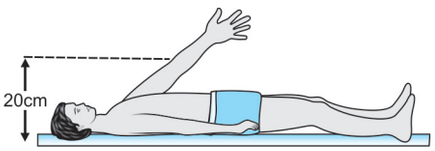

Fig. 22.16: Difference of arterial BP (mm of Hg) at different sites of measurement. This difference is equal to the height of an interposed column of water (cm of H_2O). This is obtained by multiplying the numerical value of the water column by this conversion factor (1 cm of H_2O = 0.74 mm of Hg)

The accuracy of BP, measured by this manual method, depends on the width of cuff and the rate of the release of pressure. The width of cuff should be at least 20 to 30% of the circumference of the limb and the pneumatic bladder should cover at least half of the circumference of arm. A cuff of 14 cm wide and 30 cm long is considered satisfactory for accurate measurement of BP in adult. An excessively narrow cuff produces a falsely high value and an excessively wide cuff shows a falsely low value. Similarly, the optimal rate of the release of pressure for accurate result is 3 mm of Hg/sec. The rapid release of pressure causes falsely low value. If we calculate the rate of deflation of cuff with the HR, then the deflation of pressure of 2 mm of Hg per beat will further increase the accuracy. As the generation of Korotkoff sounds depends on the blood flow, so the pathological or iatrogenic causes which decrease the blood flow, such as cardiogenic shock or use of vasopressor agents, etc, can result in a falsely low blood pressure reading. Aneuroid manometer needs frequent calibration for correct results. During shivering, the pneumatic cuff may need a high occluding pressure due to low compliance of the underlying tissues. So, it may result in pseudohypertension.

Sometimes, only the systolic pressure is estimated by inflating the cuff around the upper arm to a high pressure above the systolic level and then detecting the return of radial pulse when the cuff is deflated (palpation method). When the cuff pressure in gradually decreased, then the pressure level at which the pulse is first palpated is taken as the systolic pressure. Despite its crudeness, this method is very helpful in situations where other monitoring devices are not available and where a patient has suddenly deteriorated, necessitating only systolic pressure measurement as life-saving.

Automatic method

The standard ausculatory method which is used manually to measure the blood pressure often fails, when the arterial blood pressure is less than 60 mm of Hg. This is because the Korotkoff sounds are of too low-pitch to be audible at that pressure. In that situation, BP can be measured intermittently by automatic noninvasive methods based on the oscillotonometric principle or ultrasound technology (doppler principle and arteriosonade). This automatic non-invasive blood pressure (ANIBP) measurement devices provide consistent and reliable data. Again, many of these machines can compute an accurate mean arterial pressure (MAP) from the systolic and diastolic pressure which is a very valuable haemodynamic parameter (Table 22.9).

Table 22.9: Disadvantages of oscillometry

1. Inaccurate, if systolic BP is < 60 mm of Hg.
2. Inaccurate, if arrhythmia is present.
3. Inaccurate in the presence of a wrong-sized cuff.
4. Inaccurate during movement of limbs.
5. Discomfort in an awake patient.
6. Does not provide continuous or beat-to-beat result.
7. If the interval between the two measurements is too short, there is chance of skin and nerve damage.
8. Back flow of blood into the IV cannula, if it is in the same arm.
9. Delay in drug reaching the circulation.
10. Malfunctioning of the pulse oximeter, if it is used on the same limb.

In the oscillotonometric principle the variations or oscillation of pressure within the cuff which is transmitted from the arterial pulsation during deflation are sensed by the electronic monitor and are used to determine the values of arterial blood pressure. Originally, in Von Recklinghausen's BP measuring device (sphygmomanometer) this principle of oscillotonometer was used which sense the arterial wall motion and displays this as an oscillation of a pointer on a scale. The systolic blood pressure is that at which small oscillations of needle suddenly increase in amplitude when the cuff pressure is reduced and blood starts to flow. Unfortunately, at that time interpretation of the diastolic point was controversial and subjective. Later the second cuff which was originally used in Von Recklinghausen's device is replaced by stethoscope with hearing the sound first by Korotkoff (Korotkoff's sound). But now this technique has become even more accurate than the conventional sphygmomanometry, and has been improved by electronic devices. Arterial pulsations make small oscillations in the completely sealed air of the cuff. These oscillations are absent or very small if the cuff is inflated above the systolic pressure and the artery is completely occluded with no flow of blood through it. Mercury or aneuroid manometer provides an unreliable and gross measurement of these small oscillations. But, when the intracuff pressure is decreased to the systolic blood pressure after its initial inflation to a higher pressure, then the oscillations are markedly increased. Maximum oscillation occurs at MAP after which it again decreases. The electronic devices measure the pressure at which the amplitude of oscillation changes. Then from these changes, a microprocessor calculates the systolic, mean and diastolic blood pressure, using an algorithm. Thus, oscillometric principle needs identical consecutive pulse waves for its measurement. So, it is unreliable during arrhythmias.

The ultrasound technology for measurement of (Fig. 22.17) ANIBP uses the doppler principle to determine the blood flow distal to the cuff or the arterial wall motion. In arteriosonade principle the motion of the arterial wall is sensed by ultrasound when blood starts to flow through large arteries during deflation of cuff after its initial occlusion by inflation of cuff above the systolic blood pressure. The main drawback of this ultrasound technology is that it requires an extreme attention to the placement and securing of ultrasound transducer directly over the artery. Because, dislodgement of the transducer from just over the arterial site leads to sudden loss of information and disturbs the attention of anaesthetist who has to quickly decide whether the cause of failure is with the machine or with the patient. The ultrasound technique is not suitable for measurement of diastolic BP but has the added advantage of using the probe as a pulse monitor.

What is Doppler effect ?

It is the shifting of frequency of the reflected ultrasound wave, when the reflecting source moves relative to the point from where the ultrasound is originating. It can be explained in this way that the pitch of a moving vehicle increases or decreases as it approaches or departs. Similarly, the frequency of the reflected ultrasound wave will increase or decrease from a moving object, causing a shift in frequency. A Doppler probe transmits an ultrasonic signal, which is reflected from the underlying moving tissue which may be the blood flow. Then, the shift of reflected frequency is detected by the detector incorporated within the same probe. Thus, the difference between the transmitted and received frequency causes the characteristic changes of sound, which indicates the nature of blood flow.

(ii) Non-invasive continuous technique

In this technique, the BP is measured continuously and non-invasively from the finger by using a microprocessor and

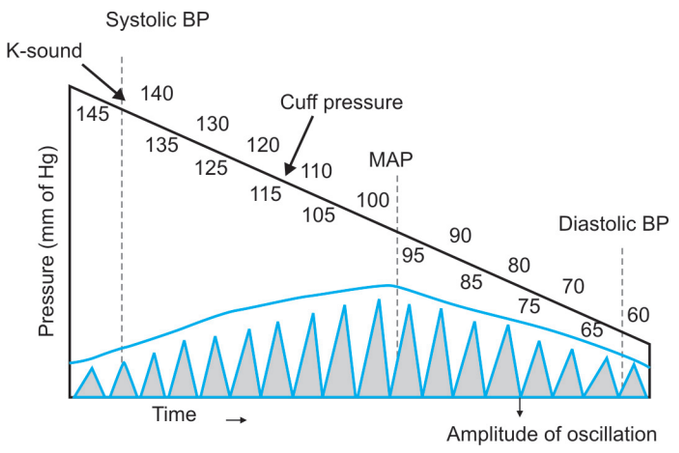

Fig. 22.17: The principle of oscillometric method for determination of arterial BP

servo-technology (arterial-volume-clamp method). This is better known as the servo-plethysmomanometer. In this device there is a cuff within which there is an infrared photoelectric probe that produces a photoplethysmograph and continuously measures the size (diameter) of digital arteries by transillumination. The cuff pressure and the photoplethysmograph interact through a sophisticated servocontrolled mechanism and tracks the arterial pressure throughout the cardiac cycle which is displayed on the monitor screen as a numerical value and a continuous waveform.

Recently, the BP is also measured noninvasively and continuously by devices which use the changes in arterial (Fig. 22.18) wall elasticity by arterial tonometry. Arterial tonometry actually is a version of 'applanation tonometry'. Here, a superficial artery (usually radial) is compressed and partially flattened against the underlying bone. Then this flattened arterial surface serves as a transducer for intravascular pressures, acting perpendicularly against the vessel wall. An array of piezoelectric crystals, positioned on the skin overlying this flattened portion of artery senses this perpendicular arterial pressure changes and translates them into a continuous arterial pressure waveform. Previously, it was thought that this arterial tonometry is better than other forms of continuous noninvasive pressure monitoring. But, unfortunately the more recent clinical studies have identified limitations of this device in paediatric patients and in patients receiving vasodilating drugs.

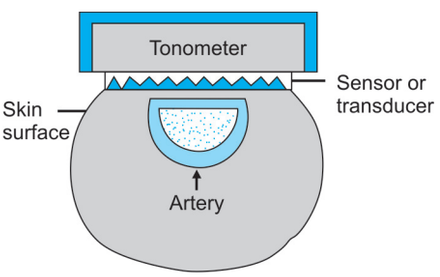

Fig. 22.18: Schematic diagram of a tonometer for continuous beat-to-beat measurement of the arterial BP non invasively

So, now in terms of absolute accuracy of blood pressure measurement, the intermittent oscillometry appears to be superior than the radial artery tonometry.

The role of these newer, continuous and noninvasive BP monitors is still unclear. This is because there is still some doubt about the accuracy of their result (compared with the invasive method). Again, though it is still controversial whether these devices can actually supplement the continuous invasive monitoring or not, but there certainly will be a population of patients in whom these techniques shall find a niche and become an important part in their monitoring armamentarium.

2. Direct or invasive method

This requires an intraarterial cannula of 20 to 22 G in diameter (a Teflon catheter causes less thrombosis than a catheter made of polypropylene) to be inserted into an artery for direct measurement of blood pressure. The radial artery is usually first chosen in an adult for direct invasive intra arterial BP monitoring and the femoral artery is used more often in children. The radial artery is commonly chosen, because of its superficial location and collateral flow. The collateral circulation is very important to prevent distal ischaemia and necrosis due to arterial injury by unsuccessful attempt. Only 5% of total individuals have incomplete palmar arches and inadequate collateral flow to radial artery. Ulnar artery cannulation is more difficult, because of its deeper position and more tortuous in nature. If a patient's radial artery is punctured but cannulation is unsuccessful, then the ipsilateral ulnar artery should never be tried for fear of compromised blood flow to the portion of hand distal to it. The anaesthetists are also very fond of brachial artery cannulation, for invasive measurement of blood pressure because: (i) it is easily identified in the antecubital fossa and (ii) its proximity to the aorta provides less waveform distortion (the more peripheral is the position of artery, the more is the waveform distortion). But, as it is nearer to the elbow, so it is more predisposed to kinking during flexion of the forehand. On the otherhand, the femoral artery provides an excellent access to intraarterial cannulation for continuous invasive BP monitoring. But it is more prone to pseudoaneurysms, sepsis, thrombosis and atheroma. As the dorsalis pedis and posterial tibial artery are far away from the aorta, so they have the most distorted waveforms and are not chosen for invasive intraarterial BP monitoring. The another chosen site for intraarterial BP monitoring is the axillary artery. But the axillary artery is surrounded by the nerves of brachial plexus. So, any unsuccessful cannulation can produce haematoma and nerve damage.

After insertion into the artery, the cannula is attached to a transducer (fluid filled electromechanical strain gauge) by a narrow-bore, low-compliance pressure tubing. Then the entire system is attached to a flushing system through a stopcock for flushing the catheter and to prevent thrombus formation. Many systems incorporate an automatic flushing device with a continuous slow (1 to 3 ml/hour) infusion of heparinised saline (1 unit/ml), or a spring controlled valve that allows a peroidic high pressure flushing for clearing the arterial line after a blood sample is taken. The practice of using heparinised saline may unnecessarily expose the patient to heparin and hence increase the risk of immune-mediated thrombocytopenia. The stopcock in the system provides a site for blood sampling and allows the transducer to be exposed to atmospheric pressure which establishes a zero reference value. But, the newer systems include a needleless sampling port and an in-line aspiration system. These permit blood sampling without the use of sharp needles and allow the aspirated waste blood to be returned to the patient within a closed system.

The pressure transducer is set at the level of patient's left ventricle and is opened to

air to obtain a reference pressure which is taken as zero. When the pressure is zeroed, then the transducer converts the pressure changes directly into the changes of electrical resistance which are measured by the monitor. Thus, the transducer is calibrated and on this zero level the arterial pressure is superimposed and measured. A real-time arterial pressure waveform is usually displayed in addition to digital values of the pulse rate and the systolic, diastolic and mean arterial pressure on the screen of monitor. In a few patients, there is marked discrepancy between the arterial pressure measured invasively and non-invasively.

Though the invasive pressure is more likely to be accurate, but it is more complex, expensive, and not without any fear of major complication. So, a patient's arterial pressure is mostly measured non-invasively in less critical patients.

Prior to initiating pressure monitoring, the pressure transducer should be zeroed, calibrated and positioned to an appropriate level of the patient. Because the accuracy of invasive BP monitoring depends on correct calibration and zeroing procedure of transducer. The stopcock at the level of desired point of measurement is opened, which is usually at the mid-axillary line. This activates the zero trigger in the monitor. Then, if the patient's height is altered by lowering or raising the OT table, then the transducer should also be moved accordingly, or should be zeroed to the new level of midaxillary line. The zero reference point of the transducer should be checked regularly to eliminate the drift. In a sitting position of the patient, the arterial pressure in the brain differs significantly from that of the left venticle. In such a position, the arterial pressure of brain is determined by setting the transducer to zero at the level of the ear.

The damping effect during invasive BP monitoring is caused by some part of the measuring system. It may be caused by (i) the bubbles of air in the tubing, (ii) too long or too elastic tubes, (iii) a kinked cannula or arterial spasm. The damping produces a graph, which reduces the amplitude of measurement of systolic and diastolic pressure, tending towards the mean pressure.

The direct or invasive arterial pressure measurement has become a standard monitoring procedure for any high risk patient during anaesthesia or in patients with severe circulatory instability caused by an underlying medical condition, or when the planned operative procedure causes large and sudden cardiovascular changes. The other indications for intraarterial cannulation for invasive BP measurement include: induced hypotension, end-organ diseases necessitating precise beat-to-beat pressure measurement, and the need for repeated blood-gas analysis. It is also commonly used for the patients in intensive care unit and in high dependency areas. Extensive experience with this technique over the years has demonstrated its value and safety, so that current indications for its use have become numerous. Also, the threshold for applying it has been lowered to encompass its use in nearly all seriously ill patients, or complicated surgical procedures. (Few indications for arterial cannulation are listed later).

Limiting the blood flow in vessels and thus causing ischaemia distally is the chief complications of intra-arterial cannulation and measurement of BP invasively. This usually does not happen due to the presence of a collateral blood supply. So, before a radial intra-arterial cannulation, it is advisable to check the efficiency of collateral circulation (for radial and ulnar artery it is done) by Allen's test or Weber's test. Allen's test is simple, but not so reliable. In this test, the patient first makes a tight fist and exanguinates his hand. Then the operator occludes the radial and the ulnar arteries by his finger. After that the operator releases only the ulnar artery and the collateral flow through the radial artery and the palmar arterial arch is confirmed by flushing of thumb within 7 seconds. Delayed return of colour of the thumb in between 7 to 15 seconds indicates an equivocal test. If the delay is greater than 15 seconds then insufficient collateral circulation is confirmed. Alternatively, collateral circulation distal to the radial artery occlusion can be diagnosed by a Doppler probe, plethysmography or pulse oximetry.

The advantages of direct arterial pressure measurement are:

i. Accuracy.
ii. Beat to beat observation or continuous real time monitoring of changes in blood pressure.
iii. Very essential when there is a very rapid swing of blood pressure.
iv. Also accurate even at very low pressure level, where cuff based measurement techniques may prove impossible.
v. Helpful in some morbidly obese patients or those with burned extremities.
vi. Arterial cannulation also helps to obtain blood samples frequently. New devices allow continuous monitoring of the arterial blood-gas values using fibre-optic sensors placed directly into the artery through the vascular catheter.
vii. Intentional pharmacological or mechanical cardiovascular manipulation, such as intra-aortic balloon counter pulsation, deliberate induced hypotension and administration of vasoactive drug infusions are possible.

Various physiological and pathological states can produce a generalised arterial pressure gradients, i.e. different levels of pressure at different sites of body. Thus, the difference in BP at different heights of measurement can be equalised by the addition or subtraction of height of an interposed column of water (cm of H_2O) multiplied by a conversion factor (1 cm of H_2O = 0.74 mm of Hg). Larger differences are seen between the peripheral and the central arterial pressures in patients with shock. For example, the femoral artery systolic pressure may exceed the radial artery systolic pressure by more

than 40 mm of Hg in septic shock, patients receiving norepinephrine infusions, etc. This difference has significant therapeutic implications during the management of critically-ill patients. Other vasoactive drugs, neuroaxial block, different patient's position and changes in the patient's temperature also produce gradients that alter the relation between the central and the peripheral arterial pressure measurements. Hypothermia and thermoregulatory vasoconstriction also causes the radial arterial systolic pressure to exceed the femoral artery systolic pressure. (Table 22.10).

The complications of direct arterial cannulation are:

i. Bleeding,
ii. Thrombosis and arterial damage,
iii. Ischaemia of tissues distal to artery,
iv. Embolisation,
v. Sepsis,
vi. Needs high skill to insert,
vii. Expensive.

The intraarterial blood pressure monitoring is a gold standard as it provides a continuous beat-to-beat accurate pressure measurement. So, the quality of waveform which depends on the dynamic characteristics of intra-arterial catheter-tubing and the transducer system is very important. Because a false reading leads to inappropriate therapeutic intervention and diaster (Table 22.11).

Table 22.10: Indications of arterial catheterisation for continuous beat to beat measurement of BP

1. Anticipated CVS instability such as severe cardiovascular disease, major trauma, massive transfusion, major surgery etc.
2. Direct manipulation of CVS such as during cardiac surgery, major vascular surgery, induced hypotension, etc.
3. Surgery with severe cardiovascular diseases such as valvular diseases, history of MI, severe angina, etc.
4. Massive obesity where indirect measurement of BP is not possible or inaccurate.
5. When frequent blood sampling is required such as for blood gas analysis, severe acid-base disturbance, severe electrolyte imbalance, severe sepsis, coagulopathies, etc.

An arterial pressure waveform is an expression of summation of simple sine and cosine of waves (Fourier analysis). So, for accurate results the catheter-tube-transducer system must respond adequately to the high test frequency of arterial waveform, or the frequency of measuring system must exceed that of the arterial wave form (average 16 to 24 Hz). The frequency of modern measuring system is > 200 Hz and so if gives very accurate results. The damping coefficient of transducer and other parts of measuring system should be optimum which ranges between 0.6 to 0.7. Because underdamping is a serious problem and may lead to overshooting with a falsely high BP. The dynamism of the catheter-tube–transducer system can be improved and damping can be reduced by: eliminating the unnecessary stop cocks, minimising the tube length, using the low compliance tubes and removing any air bubble from the system.

What is a pressure transducer?

The transducer is a device where the mechanical energy of pressure wave is converted into an electrical signal. It contains a diaphragm which is distorted by an arterial or venous pressure wave. Most of the transducers are of the resistance-type and work on the strain-gauge principle. Here, the diaphragm is made of multiple silicone crystals which are arranged as a Wheatstone bridge circuit. The stretching or pressure on the silicone crystals causes change in resistance and change in voltage output, which is proportional to the pressure applied to the diaphragm.

Table 22.11: Pressure at different sites of cardiovascular system

Site		Range (mm of Hg)	
svc		0 - 5	4
ra	Systolic	4 - 8	6
	Diastolic	0 - 5	4
RV	Systolic	15 - 30	20
	Daistolic	0 - 10	5
PA	Systolic	15 - 30	25
	Diastolic	5 - 15	10
PCWP	Mean	5 - 15	10
LA	Systolic	10 - 15	10
	Diastolic	5 - 0	5
LV	Systolic	80 - 120	110
	Diastolic	5 - 10	8

SVC = Superior venacava, RA = Right atrium, RV = Right ventricle, PA = Pulmonary artery, LA = Left atrium, LV = Left ventricle

Central Venous Pressure (CVP) Monitoring

The overall cardiac performance depends on the filling of heart during diastole, i.e. the end diastolic filling volume and pressure of right atrium for right ventricular function and the end diastolic filling volume and pressure of left atrium for left ventricular function. So, the monitoring of CVP at the junction of SVC and right atrium reflects the filling and function of the right side of the heart directly and also the filling and performance of the left side of the heart, indirectly. Whereas, the measurement of PCWP from the pulmonary capillary which is connected to the left atrium without any valve reflects more or less indirectly the pressure of the left atrium and the function of the left side of the heart. This is because the Sterling's law relates the stroke volume or cardiac function with the end diastolic filling volume and pressure. Again, the relationship of these parameters, i.e. filling pressure and stroke volume depend on the state of the intrinsic myocardial performance, i.e. contractility of heart and the status of pulmonary vasculature (Table 22.12).

Although the CVP or right heart filling pressure is the indicative of circulatory volume or right heart function, but it is often possible with appropriate assumption to use CVP for monitoring and management of the left heart function. For example, the low left ventricular output or low systemic BP due to blood or fluid loss

Table 22.12: Complications during central venous cannulation

1.	Injury to vital structures such as carotid artery, trachea, oesophagus, other large blood vessels.
2.	Injury to lung and pneumothorax.
3.	Bleeding, Haematoma (Haemothorax, hemomedia-stinum).
4.	Unable to stop bleeding by pressure.
5.	Arrhythmias, heart block.
6.	Sepsis, bactaerimia, endocarditis.
7.	Thrombosis, embolism.
8.	Cardiac puncture.

or due to any condition causing reduction of preload can be diagnosed by measuring the CVP. However, the measurement of pulmonary capillary wedge pressure has drawn attention to the inadequacy of CVP as a measurement of left heart function, because there are major differences between the two pressure systems. Such discrepancies are particularly common during pump failure due to endotoxaemia, myocardial infarction, etc. Here, CVP is highly elevated, but cardiac output is very low due to the intrinsic failure of myocardial contractility or performance. Rapid infusion of small amount of fluid may also be a useful clinical test for the determination of cause of failure, i.e. whether due to reduction of preload or intrinsic pump failure. The measurement of CVP by catheterisation of SVC not only helps to measure directly the pressure of the right side of the heart or indirectly the pressure of the left side of the heart, but also has some other functions such as:

i. Rapid infusions of fluid to correct severe hypovolaemia and shock.
ii. To administer some vasoactive drugs that might irritate and injure smaller peripheral veins.
iii. For hyperalimentation.
iv. For aspiration of air from air emboli during craniotomy in sitting position.
v. For comprehensive cardiac monitoring during major vascular surgery, and during all cardiac surgery for placement of pulmonary artery catheter (PAC).
vi. For insertion of transcutaneous pacing leads.

In a normal individual the average value of CVP varies between 0 to 5 cm of H_2O. It depends on the intravascular volume status, the intrinsic tone of the musculature of the vessels and the functional integrity of the right side of the heart. It reflects the filling pressure or volume and subsequently the stroke volume of the right ventricle. As the tip of the CVP catheter is located at the junction of SVC and RA, so it is exposed to the changes in intrathoracic pressure. Hence, inspiration will increase or decrease the CVP, depending on whether the ventilation is controlled or spontaneous. But, whatever may be the pressure, it should be measured at the end of expiration.

It is reduced in hypovolaemia due to any cause but is increased during heart failure, pulmonary embolism, IPPV, cardiac tamponade and fluid overload etc. Ideally for measurement of CVP, the tip of the catheter should be placed just above the right atrium or at the junction of right atrium and SVC. Advancing the catheter too far may cause arrhythmias and even damage to the myocardium. If monitoring of the pulmonary arterial pressure and the left atrial pressure is planned, only then the pulmonary artery catheter (PAC) should be advanced beyond the right atrium and the right ventricle into the pulmonary artery. Because of the large swings in the pleural pressure which may accompany the mechanical ventilation, it is preferable that all the measurements of central venous pressure should be made with the ventilator disconnected.

There are usually three techniques which are a adapted by anaesthetists for central verous cannulation to monitor CVP.

These are:

i. A catheter over a needle technique. This is similar to simple peripheral venous catheterisation.
ii. A catheter through a needle technique, which requires a large-bore needle stick
iii. A catheter over guidewire techinque, which is commonly known as Seldinger's method.

The central venous cannulation for measurement of CVP is also usually done by any of the three routes.

(i) Long catheter through the brachial or femoral vein

The more peripheral veins such as the brachial veins in the antecubital fossa or femoral vein in the femoral triangle are also chosen for central venous cannulation using a long catheter. Sometimes, the cephalic or basilic vein on the outer upper arm may also be used. But, here success is less likely due to the long tortuous route of these veins. Otherwise, this method is relatively easy and has a very low incidence of acute and serious complications. But, unfortunately, the tip of the cannula commonly fails to reach the central vein, if these peripheral superficial veins are used. Infection and thrombophlebitis are common, if the catheters left in-situ for more than 48 hours in any route.

(ii) Subclavian vein

As the subclavian is a large vein and quite close to SVC, so a short central venous catheter can be inserted easily through the skin into this vein. For subdavian cannulation either supra or infraclavicular approach in adopted. But, the infraclavicular approach to this vein for central venous cannulation is most commonly accepted. During cannulation, the angle of the needle should be low and tangential to the ribs, in order to avoid the perforation of the pleura. The subclavian artery is posterior to the vein in this line of approach. So, its puncture may result in significant haemomediastinum and haemothorax. In this approach the overlying clavicle affords easy fixation of catheter to the skin and this is comfortable for the patients too. But, unfortunately as the needle, wire and the catheter are not inserted under direct vision, so accidental perforation of the adjacent subclavian

artery or pleura is common. Importantly, if arterial bleeding occurs, it may not be evident and cannot be controlled by external pressure because of the position of the clavicle. Damage may also be caused to the brachial plexus, which runs along the main vessels. Because of the higher incidence of these major complications, subclavian cannulation is generally used only where specific advantages are evident.

(iii) Internal jugular veins (IJV)

This route is the safest and most reliable for central venous cannulation because:

i. The vein is close to the skin
ii. The consistent predictable anatomic location of IJV within a palpable land mark
iii. The short, straight (right IJV) and valveless course of IJV to the SVC and right atrium
iv. Bleeding if occurs can be controlled by direct external pressure
v. Success rate is more than 90% in both adults and children.

However, due to the proximity of internal jugular vein to the carotid artery, cervical spine, major nerves and pleura, the life threatening complications are still relatively common during central venous cannulation through this route.

Whatever is the route, the central venous catheter should be inserted only when a clear indication for measurement of central venous pressure is present. For central venous cannulation always the safest route should be chosen and catheter should be removed at the earliest opportunity. Careful technique and adequate observation of the patient is mandatory, including a mandatory chest X-ray after insertion of catheter. During the central venous cannulation the ECG should be continuously monitored in order to observe any dysarrhythmias which can occur if the tip of catheter crosses the SVC and right atrial junction, or when the catheter is more advanced into the right ventricle and PA to monitor the other filling pressures. If the direct pulmonary arterial pressure monitoring is planned, then it should be established prior to the central venous cannulation.

The complications of central venous catheterization are (i) Immediate → arrhythmias, bleeding, pneumothorax, damage to the thoracic duct, oesophagus and other vital structures, carotid artery injury, cardiac puncture, catheter embolisation, etc. (ii) Delayed → sepsis, thrombosis, kinking, displacement of catheter, etc.

The central venous pressure measurement can be made either by a simple water filled manometer, connected to a running fluid line via a stopcock or by an electronic transducer and digital display. The measurement of CVP by water manometer is simplest, least expensive and sufficient in many cases for general assessment of intravascular volume status. When CVP is measured by water manometer, then the right atrium of patient's heart and the zero point of the manometer scale should be kept at the same level. As the normal value of CVP varies between 0 to 5 cm of H_2O due to low pressure system, so a small change in the relative height of reference, e.g. when an operating table is moved up and down may lead to an appreciable error. In practice, a single measurement of CVP is unreliable as the value is altered in an unpredictable manner by several factors, such as positive pressor ventilation, patient's position, etc. The response of CVP to a fluid challenge is more valuable. In hypovolaemic patients the initial change in CVP is small with a rapid infusion of fluid. But, with continued infusion the CVP increases more quickly as normovolaemia is achieved. Contrary, in patients who are overloaded with fluid or have a heart failure, even a small amount of intravenous fluid causes a marked increase in CVP at initial phase. Sudden increase in CVP may also be caused by events such as pulmonary embolism, myocardial infarction, pneumothorax, etc.

The CVP monitoring during anaesthesia and surgery are very useful in determining the overall fluid volume status of patient, the effect of fluid or blood loss and in guiding the replacement therapy. The responses of CVP to fluid replacement therapy can also provide information regarding the venous compliance and the functional efficiency of the right side of the heart.

When a pressure transducer is used for monitoring of CVP, then the device displays the pressure unit in millimetre of Hg, but not in centimetres of H_2O as in a water manometer (1.36 cm of H_2O = 1 mm of Hg). It is also important to understand that during monitoring of this low pressure system the transducer should be placed and zeroed at correct level, i.e. the right atrial level. The zero reference at the level of right atrium or the manubriosternal joint and the manometer scale or the transducer must bear a constant relationship. The waveform of CVP which is displayed on the screen of the electronic device is actually a wealth of information. The venous pressor waves reflect the normal sequences of the mechanical events of cardiac cycle. The first large positive deflection 'A' wave is caused by atrial contraction, which is quickly followed by a small positive 'C' wave due to the bulging of tricuspid valve in the atrium with the onset of ventricular systole. Then, this 'C'wave is followed by 'X' descent due to the atrial relaxation which is again followed by a late positive deflection 'V' wave due to the gradual accumulation of blood in the venacava and the right atrium. Finally, the 'Y' descent is caused by the opening of tricuspid valve and rapid right ventricular filling. In atrial fibrillation the 'A' wave is absent, as there is no effective atrial contraction. However, sometimes large 'A' waves (canon waves) also occur in some arrhythmias, such as heart block, nodal rhythm, etc. when atrium contracts against a closed tricuspid valve. The tricuspid regurgitation, ventricular overfilling or heart failure etc. cause distortion and an increased size of the 'V' wave (Fig. 22.19).

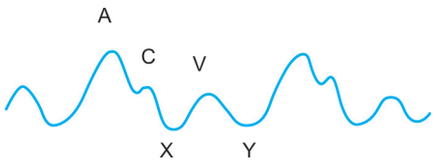

Fig. 22.19: Central venous pressure wave

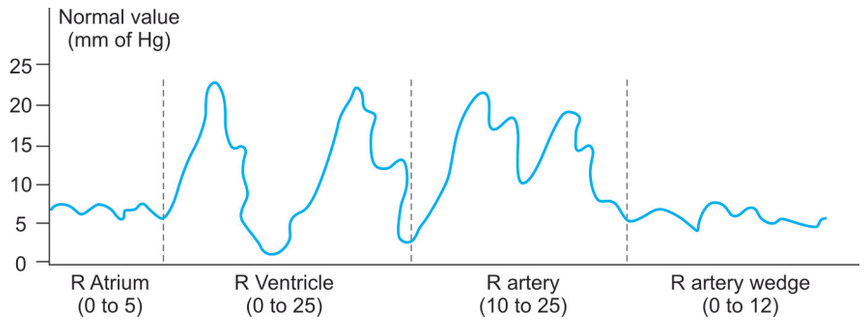

Fig. 22.20: This is a diagrammatic representation of the pressure wave form which is seen on the monitor, while the tip of the pulmonary artery catheter is advanced through the right atrium and right ventricle and ultimately to lie in the pulmonary artery. The right atrial pressure wave is characterised by low systolic and low diastolic value. The right ventricular pressure wave is characterised by high systolic and low diastolic value. The main pulmonary artery pressure wave is characterised by high systolic and high diastolic value. Pulmonary artery wedge wave is characterised by low systolic but high diastolic value. When the balloon is inflated with the tip of the catheter wedged in a branch of a pulmonary artery, immediately the pulmonary artery wedge pressure wave form is seen on the monitor. The pressure values, shown here, represent in a normal spontaneously breathing patient.

Pulmonary Arterial Pressure Monitoring

Starling first demonstrated that the left ventricular flow or cardiac output is directly proportional to the LVED fibre length, which is again proportional to the LVEDV. LVEDV is again directly proportional to LVEDP which we try to measure indirectly by pulmonary artery pressure (PAP). Thus, one of the main determinants of CO and hence O_2 delivery to the tissues is the left ventricular end diastolic volume (LVEDV), which assumes the amount of blood ready to be pumped out during left ventricular systole. But it cannot be measured directly. So, if left ventricular compliance is normal, then the left ventricular end diastolic pressure (LVEDP) can be used as an indicator of LVEDV. Thus, the measurement of LVEDP is very vital for determination or assessment of left ventricular performance and CO.

Again, unless an abnormal pressor gradient exists across the mitral valve, then the left atrial pressure (LAP) and pulmonary venous pressure (PVP) reflect LVEDP. On the otherhand, the measurement of pressure in the small pulmonary artery reflects the PVP which ultimately reflect (Fig. 22.20) the LAP, LVEDP and CO. So, the measurement of pressure in a small pulmonary artery by wedging the tip of a pulmonary artery catheter which is known as PCWP gives us a vital clue of CO. The entry and wedging (by inflation of a balloon) of the tip of a pulmonary artery catheter into small pulmonary artery (capillary) ceases the phasic and pulsatile blood flow distal to the wedging portion of this small pulmonary artery. Thus, it leaves a static column of blood between the catheter tip and the pulmonary veins and left atrium. Now, the pressure detected at the small pulmonary artery where the tip of the catheter is wedged is called the pulmonary capillary wedge pressure (PCWP) and approximates subsequently with the PVP, diastolic LAP, LVEDP and LVEDV. Thus PCWP which is also termed as PAOP (pulmonary artery occlusion pressure) provides an indirect nearly accurate estimation of the preload or diastolic filling of the left side of the heart under most circumstances. But, when diastolic LAP exceeds 15 mm of Hg due to mitral stenosis or other causes, then PCWP may be a poor detector of LAP and subsequently LVEDV or LVEDP. Sometimes, in the absence of PCWP pressure the pulmonary artery pressure is also taken indirectly as the left ventricular filling pressure. This inference is based on :

CVP $\propto$ PA $\propto$ PCWP $\propto$ PV $\propto$ LAP $\propto$ LVEDP $\propto$ LVEDV (Fig. 22.21).

But in ill patients, particularly in those with right ventricular failure, pulmonary oedema, mitral valve diseases, and those receiving positive pressure ventilation,

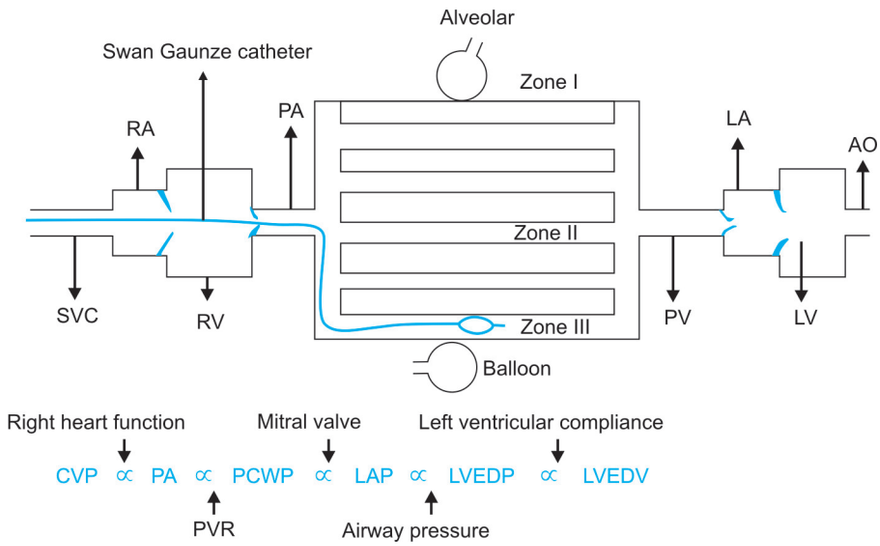

Fig. 22.21: Relationship between various determinants of cardiac output

etc; the relation between the pulmonary artery pressure (or pressure of the right side of the heart) and LAP or PVP (pressure of the left side of the heart) is uncertain. Unfortunately, as it is not possible to cannulate the left atrium easily, so we try to estimate or measure indirectly the LVEDP (proportional to LVEDV – which is again the main determinant of CO) by measuring the pressure of the right side of the heart by measuring the PCWP, PAP, RVP, CVP, etc.

On the basis of relationship between the PA pressure, PV pressure and alveolar pressure (P_{ALV}), the lung is divided into three zones (I, II and III). For the measurement of PAP and PCWP the tip of the pulmonary artery catheter (PAC) should be in zone III, where PVP exceeds alveolar pressure and the capillary conduit is completely opened being capable of directly transmitting the pressure of blood from left side of heart to the right side. In the supine position, as a large portion of lung remains in zone III, so it is assumed that the tip of PAC always remains in zone III. When the patient is ventilated with high positive pressure or PEEP, then most of the zone III will be converted to zone II or I. In this situation, the relationship between PCWP and LAP is lost. The maximum limit of PEEP is 10 cm of H_2O, below which the relationship is maintained.

In an average the pulmonary artery diastolic pressure (PADP) which is about 10 mm of Hg is often used as a good indicator of PCWP which is about 9 mm of Hg . But in some situations, where the pulmonary artery diastolic pressure increases such as in pulmonary hypertension (or ↑ PVR) due to hypoxia, hypercarbia, chronic obstructive lung diseases or vasoactive drugs, etc., then PADP does not correlate well with PCWP or pressure of the left side of heart. Therefore, to summarise, it can be stated that in conditions where the left heart function correlates well with the right heart function and there is no condition suggesting grossly abnormal PVR, then CVP can be trusted as sole indicator of the overall left sided cardiac filling pressure and cardiac output.

The pulmonary artery catheter (PAC) usually have three lumens and a thermistor near at the tip. The most distal lumen opens at the tip and is connected proximally to a pressure transducer which displays the pressure waveform on the monitor screen. Proximal to the tip, there is another lumen which is used to inflate the balloon. There is another proximal lumen, which is used for the measurement of CO. In addition to the measurement of CO, the PAC is also used for sampling of mixed venous blood. However modern PAC have five lumens with provisions for CVP monitoring port, extra-venous infusion ports, a fibre-optic bundle for blood O_2 saturation measurement, and a lumen for the passage of wire for ECG recording and atrial or ventricular pacing.

Insertion of PAC first requires the insertion of a central venous cannula at any site. Then, PAC can be placed successfully through any of the central venous cannulation sites. But, the right IJV is preferred by most of the clinicians. External jugular vein may also be used. But the success rate is less than IJV. If neck veins are not available, then left subclavian vein is next preferred to the right subclavian vein. Because, the left subclavian vein courses to SVC in a smooth gradual turn than its right counterpart. Prior to insertion of every PAC, it should be checked by inflating and deflating the balloon and irrigating all the three or five intracatheter lumens with heparinised saline. The distal lumen is connected to an electronic pressure transducer which is zeroed at the mid-axillary line. After the introduction of the PAC through the valved port of the introducer used for central venous cannulation, the distal port of PAC is connected to the pressure transducer. When the catheter is first placed into the SVC and a central venous waveform is seen on the monitor, then the balloon is inflated. If the central venous waveform varies with respiration, then it confirms the intrathoracic position of the tip of the catheter, but either in the superior venacava or RA. At approximately 15 cm distance from the insertion point the distal tip should enter the RA. The balloon is inflated with air, the volume of which is according to the manufacturer's recommendation (usually 1.5 ml). It protects the myocardium and endocardium from injury by the tip of the catheter. It also allows the flow of blood or the right ventricular output to direct the catheter forward from chamber to chamber and from chamber to main artery. On the otherhand, the balloon is always deflated during withdrawal or for any manipulation.

After its introduction the pulmonary artery catheter is first advanced towards the RA and then towards the tricuspid valve from SVC. From this point onwards ECG monitoring for detection of any dysrhythmias is very important. This is because premature ventricular contractions (PVC) are often seen during PAC insertion and its passage through the different chambers of heart which may require intervention. As the PAC advances, then the ballooned tip of the catheter tends to move towards the pulmonary artery from the right ventricle by the direction of the flow of blood. Although some manipulation may be required, but it usually advances easily through the right atrium and the right ventricle into the pulmonary artery. However the corresponding changes in the measured pressure can be observed over the screen as the catheter advances. The location of the tip of the PAC is also determined by identifying the characteristics of the pressure waves of that cardiac chambers and vessels which are encountered during its passage. The advancement of catheter tip from chamber to chamber is facilitated by the different phases of cardiac cycle and also by the flow of blood as PAC is

a flow-directed catheter. For example, the catheter tip with balloon passes from the SVC into the right atrium and then to the right ventricle during diastole. But, the catheter passes from the right ventricle to the pulmonary artery during systole.

The location of catheter tip in the right ventricle is characterised by a sudden increase in systolic pressure and a wide pulse pressure. Then from the right ventricle to the pulmonary artery (PA), the catheter passes on during the systole, and the location of the tip of the PAC at PA is characterised by a sudden increase in diastolic pressure and a narrow pulse pressure. The entry of the tip of the catheter into the PA normally occurs by 35 to 45 cm distance from the entry site. The catheter further advances through the pulmonary artery, until it eventually fills the lumen of a small pulmonary artery to become wedged and to lose much of its pulsatile character as seen in the small PA. In this position, the tip of the catheter is isolated from the proximal part of this small PA by the balloon. The transducer then measures the pressure of the pulmonary capillaries which are in continuity with the pulmonary veins and hence the left atrium in front. This is then taken as the measurement of the left atrial pressure at diastole. If the balloon is deflated at this wedged position, then the pulmonary artery wave form is restored again and at the end of each measurement of left atrial pressure the balloon must be deflated to avoid pulmonary infarction. During passage of catheter through the right atrium, right ventricle and pulmonary artery, there is chance of knotting. So, to prevent knotting the balloon should be deflated and the catheter is withdrawn, till the pressure changes do not occur at the expected distance. In very difficult cases, such as, in low cardiac output, pulmonary hypertension, congenital heart diseases, etc, the catheter advancement by flotation of the balloon can be enhanced: (i) by the deep breaths of patient, (ii) by positioning of patient in a right lateral or head-up position, (iii) by increasing the cardiac output, (iv) by administering a small dose of inotropic agent, etc.

If the wedging of catheter occurs before the maximum inflation of balloon, then it signals its overwedged position. In such condition the catheter should be withdrawn slightly, because there is a chance of pulmonary artery rupture which may carry 50 to 70% mortality rate. So, the PAP should continuously be monitored to detect any overwedged position which is an indication of catheter migration. The correct position of catheter is also confirmed by the lateral chest X-ray. Usually, most catheter migrate caudally (basal portion of lungs) and to the right side (right lung). But, sometimes it wedges anterior to the venacava, where the true pulmonary capillary pressure is less than the alveolar pressure. This results in a spuriously elevated pressure measurement during IPPV.

The relative contraindication of pulmonary artery catheterization are: complete LBBB which may lead to complete heart block, W-P-W syndrome and Ebstein malformation which may lead to severe arrhythmias. The risk of complications increase with the duration of catheterisation. So, it should not be kept for more than 72 hours.

Though, the PAC can provide invaluable information for the care of critically ill patients, but still there are several pitfalls in the procedure of measurement and interpretation of these data. So, it sometimes make the PAC a counter-productive and even hazardous tool. For example, the balloon of the catheter is inflated blindly only by the observing the PA pressure tracing, which guides the balloon's position. But, unfortunately the PA pressure waveform can be distorted by artefacts and can misguide the actual position of the catheter balloon, whether it is properly wedged or not. This confusion may result in an erroneous and dangerous over-inflation of balloon, causing severe complications. So, the routine use of PAC should not be performed, till the benefits over balance the risks. Thus, the decision of monitoring with a PAC depends on the clinical judgement of the anaesthetist who must weigh all the pros and cons of this process in the background of the status of the particular patient, the proposed surgical procedure and the particular process setting.

The complications of pulmonary artery catheterisation are: tachydysrhythmias (such as PVC, VT, VF etc.), heart block (RBBB, LBBB or complete AV block in patients with prior LBBB), endocarditis, pulmonary embolism, pulmonary infarction, pulmonary artery rupture, sepsis (positive catheter tip culture), tricuspid and/or pulmonary regurgitation, etc. (Table 22.13).

Monitoring of the Left Atrial Pressure (LAP) Directly

Directly the LAP is measured only during open cardiac surgeries. This parameter affords a more definite data of the left ventricular filling pressure. Thus, it provides a definite direct assessment of the left ventricular filling volume and performance of the left side of the heart. The LAP monitoring also directly helps in the diagnosis of malfunctions of the mitral value prosthesis. Direct LAP monitoring is usually

Table 22.13: Complications of pulmonary artery catheterisation with reported incidence (%)

Bleeding	5 -10 %
Mural thrombus	25 - 60 %
Thrombophlebitis	6 - 10 %
Arterial puncture	1 - 3 %
Pneumothorax	0.3 - 4 %
Air embolism	0.5 - 1 %
Minor arrhythmia	4 - 68 %
Severe arrhythmia (VT, VF)	0.5 - 60 %
RBBB	0.1 - 4 %
LBBB	0.1 - 8 %
Pulmonary artery rupture	0 - 1 %
Pulmonary infarction	0.1 - 5 %
Positive culture at catheter tip	1 - 34 %
Endocarditis	2 - 9 %
Catheter knotting	1 - 2 %

performed by putting a thin catheter into the left atrium through a purse-string suture in the right superior pulmonary vein. The catheter is then brought out of a wound through the infraxiphoid portion of the chest wall and is connected to a pressure transducer.

Monitoring of Cardiac Performance

The principal function of CVS is to supply the oxygenated blood to the tissues. So, the principal aim of monitoring of cardiovascular system should be the monitoring of the efficiency of performance of the heart as a pump. Efficiency of the performance of the heart as a pump is only assessed by measuring the following parameters such as cardiac output, mixed venous O_2 saturation (SVO_2) and SVR.

(i) Cardiac Output Measurement

The measurement of CO is a straight forward method for the assessment of efficiency of cardiac function, because CO is the revealing indicator of the entire functional efficiency of CVS. The importance of knowing the CO can also be explained from the fact that a patient with normal BP and PCWP may have poor vital organ perfusion if there is high SVR, causing low CO and SVR can not be measured easily. So, the knowing of cardiac output is very vital, and is measured by the following methods: invasive and noninvasive.

1. Invasive methods

A. Fick's principle

It was shown by Fick that the amount of O_2 consumed per minute (VO_2) by an individual is equal to the difference between the arterial and venous O_2 content ($CaO_2 - C_VO_2$) multiplied by the cardiac output (CO).

Therefore, $VO_2 = (CaO_2 - C_VO_2) \times CO$

$$CO = (VO_2) / (CaO_2 - C_VO_2)$$

The O_2 consumption can be calculated from the difference between the O_2 content in the inspired air and the expired air. Again, from the arterial line we can measure the arterial O_2 content and from PAC the venous O_2 content. Alternatively, Instead of O_2 cardiac output can also be measured by the Fick's principle using CO_2. The steps are as follows:

i. CO_2 output per minute is determined with Douglas bag,
ii. Alveolar air is collected and its CO_2 tension is determined which is identical to that of the arterial blood,
iii. Alveolar air is again collected after holding of the breath for 5 seconds, which is identical to that of the venous blood.

Therefore, CO = CO_2 output in minute / $(P_aCO_2 - P_VCO_2)$

Cardiac output can also be measured invasively by the indicator-dilution technique and the thermodilution technique. But, the variations of Fick's principle are the basis of these indicators dilution and thermodilution method for the measurement of CO.

B. Indicator dilution method

This method is not used in clinical practice, so is not discussed here.

C. Thermodilution method

This is a gold standard invasive method for the measument of CO. In this method a bolus of cold water is injected through the proximal lumen of PAC in the right atrium. Then when the cold water passes from the right atrium through the right ventricle to the pulmonary artery, then a thermistor at the tip of the PAC measures the difference in temperature of blood in the pulmonary artery, before and after the injection of cold water. Now, we know that the degree of changes in temperature is inversely proportional to the output of the right ventricle which is equal to the cardiac output of the left ventricle, and it is determined from this change in temperature. The temperature change is high, if the flow or cardiac output is high and the temperature change is low when the flow or cardiac output is low. Thus, a plotting of changes of temperature against time produces a thermodilution curve. Computer in the device computes the CO from this temperature difference data.

Though, it is the gold standard method, but it has some drawbacks. These are :

i. The Injection of bolus cold water may be too slow or too fast.
ii. There are possibilities of poor mixing of cold water within the blood.
iii. there are chances Ectopic heart beats, causing variation of CO.
iv. Variability of CO with each breath.
v. Time consuming.
vi. All the drawbacks of pulmonary artery catheterisation.

Practically, several measurements are taken. But the most extreme results are discarded and the average of three closely paced results are taken.

Recently, through PAC small filament or coil is used at the tip which is electronically heated periodically and provides small pulses of heat into the blood, proximal to the pulmonary valve instead of bolus cold water. It also contains a thermistor that measures the change in temperature blood of pulmonary artery. Then, the computer in monitor device determines the CO by cross-correlating the heat production and the change in temperature. Thus these monitors provide a continuous measurement of CO and also gives us the record of changes of CO with time graphically.

Though, this method has multiple benefits, still PAC is an invasive technique and has all the complications similar to pulmonary artery catheterisation (listed above) which leads to a search for a more safer and easier method.

2. Non-invasive methods

A. Doppler – ultrasound technology

Measurement of CO by Fick's Principle is invasive and an expensive one. The popular and gold standard thermodilution technique for measurement of CO also use the Fick principle and needs PA catheterisation

with all its risks. So, these limitations led to the exploration and development of newer non-invasive method for determination of CO by ultrasound. The doppler ultrasound technology measures the blood velocity by using the principal that frequency of a wave changes if it is reflected off from a moving object. Thus, doppler ultrasound technology measures the velocity of blood in the ascending or descending aorta (according to the route and position of the probe) over a period of ejection time (T_{EJ}), and determine an average velocity value (V_{AVG}) for each heart beat. It also measures the cross-section of aorta (ascending or descending) – $Area_{AO}$. Then, the device calculates the CO by multiplying V_{AVG}, $Area_{AO}$, T_{EJ} and HR.

Thus, $CO = V_{AVG} \times Area_{AO} \times T_{EJ} \times HR$

The ultrasound probes are placed on the suprasternal notch or in the oesophagus, or in the trachea with ET-tube. The probe emits an ultrasonic sound wave that is then reflected off the red cells in aorta. The machine, then, measures the velocity of blood, the cross sectional area of the aorta and various patterns of flow to calculate the CO. The Estimation of stroke volume and cardiac contractility are also possible by this method. If the descending aorta is used, then the proportion of CO directed to the upper arms, head and neck must be assumed and the calculated flow through the descending aorta should be adjusted accordingly to determine the CO. When the probe is placed on the suprasternal notch, it measures the velocity of blood at the aortic valve. It can also emit continuous waves (CW) and pulse waves (PW) for continuous and intermittent measurement of the CO. Through transoesophageal route the probe is attached to the tip of the standard oesophageal stethoscope and determines the velocity of the blood flow in the descending or thoracic aorta. The transtracheal device uses a special type of ET tube with a PW doppler ultrasound transducer incorporated in its tip and measures the velocity of blood flow in ascending aorta.

The great advantage of this ultrasound device is that it is noninvasive, easy to use and provides an almost instantaneous measurement of CO with a very low incidence of complications. But the disadvantage is that, unfortunately, the probe usually has a very narrow angle of detection, and the calculated velocity is much dependent on the angle between the direction of sound waves and direction of the red cells in which they travel. (Since the cosine of this angle Q is a part of the doppler formula for velocity measurement). So, a constant alignment between the probe and the blood flow through aorta is necessary. Small movements of probe, therefore, changes the calculated CO markedly.

The recent clinical trials have shown that these doppler ultrasound monitors are unable to determine an absolute value of CO reliably. So this technique has been dismissed as inaccurate and impractical for routine use. They are used more now to provide a trend with time. They are, therefore, very useful in guiding perioperative fluid management, but have a limited scope in the intensive care unit.

B. Transthoracic impedance plethysmography technology

This technique was first reported by Kubicek and his colleagues. They used the principle that, as the amount of blood in the thoracic wall varies with each heart beat, it causes a corresponding change in the electrical conductance or impedance of the thorax. From these changes of impedance of the thorax, an impedance plethysmograph is developed, from which CO is determined (using an algorithm and the computer). Due to its high noninvasiveness and more or less accurate results, it has an increased acceptibility in the intraoperative and critical care cases. In practice, the main disadvantage of this method is interference from other electrical equipments and changes in electrode conductance, which may produce unreliable results.

(ii) Measurement of mixed venous O_2 saturation (SVO_2)

SVO_2 is possibly a more comprehensive measurement of the cardiac performance, than the CO itself. This is because it also reflects whether the CO is adequate enough to meet tissue metabolic needs or not. SVO_2 is a function of:

i. level of arterial O_2 saturation, SaO_2,
ii. the rate of O_2 consumption, VO_2 and
iii. the concentration of Haemoglobin Hb.

So, $SVO_2 = (SaO_2 - VO_2) / (CO \times 1.34\ Hb)$

An advantage of this method is its ability to provide a continuous assessment of the cardiac performance. The disadvantage is that SVO_2 depends on multiple variable parameters (as the above equation says). So, when any of these variables change significantly, one cannot assume that a change in venous O_2 saturation results solely from a change in CO or cardiac performance.

(iii) Measurement of SVR

Cardiac performance also can be assessed indirectly by the measurement of systemic vascular resistance (SVR). It is measured from the formula:

$SVR = (MAP - CVP) / CO \times 80$

MAP = Mean Arterial Pressure (mm of Hg)
CVP = Central Venous Pressure (mm of Hg)
CO = Cardiac Output (L/min)
[×80] = Factor to convert Wood units (mm Hg/L/min) to (dynes/s/cm^5)

The normal value of SVR is 15 Wood units (range 10 to 20 Wood units) or 1200 dynes/s/cm^5 (range 800 to 1600 dynes/s/cm^5).

23 Peripheral Nerve Block

INTRODUCTION AND HISTORY

Two American surgeons, named Halsted and Hall, had first injected cocaine at the peripheral sites near ulnar, musculocutaneous, supratrochlear and infratrochlear nerve and produced nerve block for minor surgical procedures in 1880. Then, James Leonard Corning used Esmarch bandage in 1885 with peripheral nerve block and had tried to prolong the duration of action of local anaesthetic agent by arresting the circulation and reducing the absorption of it from the tissues. This idea was further advanced by Barun using epinephrine mixed with LA agent as chemical tourniquet in 1903.

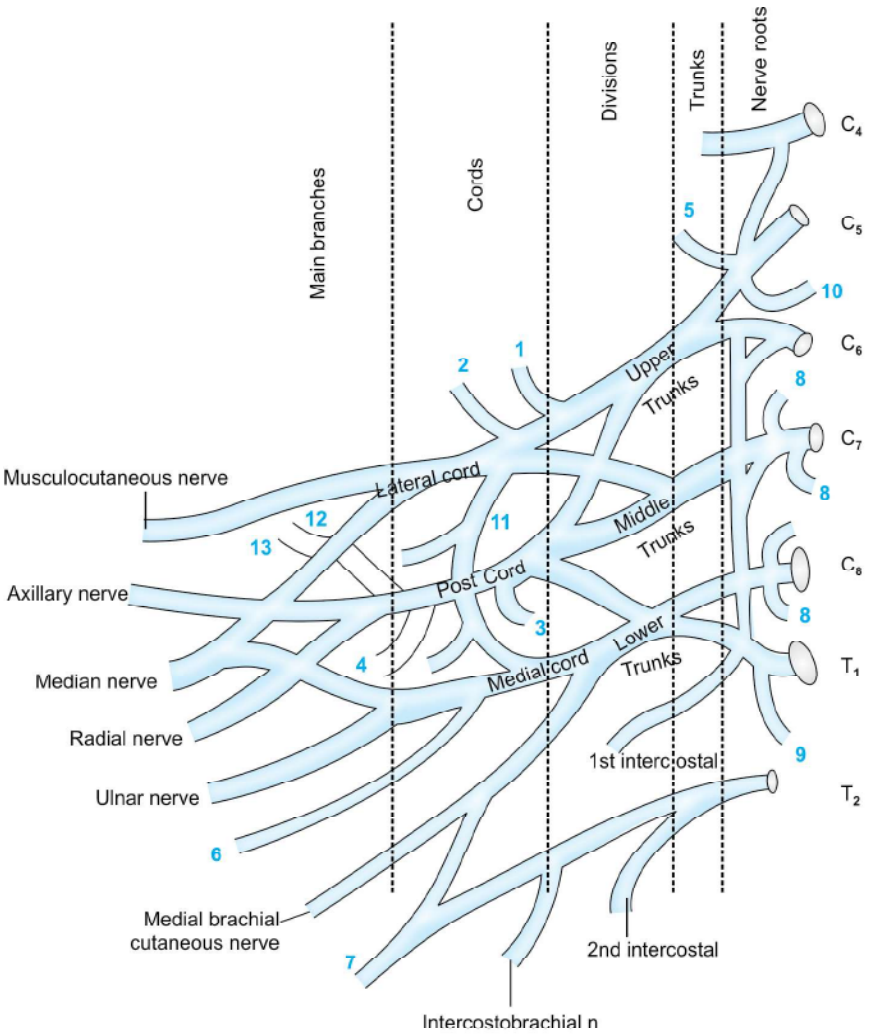
At the beginning of civilization, though the surgeons were the pioneer, regarding the early discoveries of regional anaesthesia but the developing speciality of anaesthesiology had gradually dominated over it. So, after that the role of regional anaesthesia or peripheral nerve block has expanded from the operating room to the arena of postoperative recovery and pain management clinic by holding the hand of anaesthetist. Previously, the peripheral nerve block was applied only on the adult and selected group of patients. But later it was proved that with the appropriate selection of patients and with the help of sedation the regional techniques of peripheral nerve block can also be used for all the age group of patients. There are different techniques of RA for extrimities. But, the duration of surgery influences both the type of regional technique selected and the choice of local anaesthetic agent used. The plans for postoperative pain relief also influence the approach to the peripheral nerve block or technique of RA.

Any anaesthesiologist does not under estimate the role of sedation during surgery under RA or peripheral nerve block. For example, many perfect brachial plexus block has been undone due to the inadequate management of sedation. Regional blockade on the extremities or peripheral nerve block has wide application by not only providing the surgical anaesthesia and analgesia, but as well as treating the chronic pain syndromes involving the extremities. RA on extremity (upper or lower) or others regional anaesthesia on trunk, including sympathetic ganglion blockade, have also several other advantages during the postoperative period, compared with general anaesthesia. These include: decreased requirement of sedation, decreased nausea and vomiting, minimum stay in hospital, early discharge and a smooth transition from parenteral to oral analgesic or other drugs as the block or anaesthetic effects dissipate gradually. During peripheral nerve block continuous infusion of local anaesthetic agents near a peripheral plexus of nerve via a percutaneous catheter has also become an increasingly common form of regional anaesthesia, if surgery is prolonged or post operative analgesia is needed.

UPPER EXTREMITY BLOCK OR BRACHIAL PLEXUS BLOCK

Applied Anatomy

The brachial plexus provides the complete motor and nearly the total sensory innervation to the upper limb. It is formed by the anterior primary rami (or ventral rami) of C_5, C_6, C_7, C_8 and T_1 spinal nerve with variable contribution from the anterior primary rami of C_4 and or T_2 spinal nerve. These anterior primary rami (or ventral rami) are called the roots (Fig. 23.1) of brachial plexus. The after exit from their respective intervertebral foramen, these spinal nerves first cross the transverse process of corresponding cervical vertebra at the same level and lie between the anterior and middle scalene muscle. The anterior scalene muscle arises from the ant.tubercle of transverse process of seven cervical vertebrae (C_1 to C_7) and take insertion on the scalene tubercle of first rib in front of the subclavian artery. The middle scalene muscle also arises from the posterior tubercle of the transverse process of seven cervical vertebra (C_1 to C_7) and takes insertion on the 1st rib behind the subclavian artery. The prevertebral fascia which arises from the ant and posterior tubercle of the transverse processes of seven cervical vertebrae, after first investing both the scalene, fuse laterally and enclose the brachial plexus in a fascial sheath. This is called the brachial plexus sheath. Thus, the brachial plexus sheath is continuous from its origin at the level of seven transverse processes of cervical vertebrae in the neck to its distal insertion at the level of the origin of coracobrachialis muscle. Hydrostatically this brachial plexus sheath is intact throughout its course. So, filling of this sheath with LA agent at various levels is the basis of brachial plexus block



1. Nerve to subclavian muscle
2. Suprascapular nerve
3. Subscapular nerve
4. Thoracodorsal nerve (or nerve to latissimus dorsi)
5. To phrenic nerve
6. Medial antebrachial cutaneous nerve
7. Medial brachial cutaneous nerve
8. To longus cervicis and scalene muscles
9. Long thoracic nerve (or nerve to serratus anterior)
10. Dorsal scapular nerve
11. Anterior thoracic nerve
12,13. Upper and lower subscapular nerve

Fig. 23.1: The brachial plexus

for conducting different type of regional anaesthesia (RA) of upper extrimity. As the roots of the brachial plexus emerge through the groove between the anterior and posterior tubercles of the transverse process of the seven cervical vertebrae, therefore it also emerges through the groove between the scalene anterior and scalene medius muscle, because they take origin from the anterior and posterior tubercle respectively. So, they lie in a fibrofatty tissue space which is situated between the two sheaths of fibrous tissue (brachial plexus sheath) investing these two muscles. Laterally, this sheath also extends into the axilla as a coveing membrane around the brachial plexus as it emerges into the axilla.

Between the scalene muscles (anterior and middle) the nerve roots of the brachial plexus, i.e anterior primary rami of C_{5-8} and T_1 spinal nerve unite and first form the three trunks of brachial plexus. There they lie cephaloposterior to the subclavian artery as it courses along the upper surface of the first rib. The superior trunk is formed by the union of the anterior primary rami of C_5, C_6 and sometimes C_4 nerve root. The middle trunk is formed by the anterior primary rami of the C_7 nerve root alone. The inferior trunk is formed by the anterior primary rami of the C_8 and T_1 nerve root and sometimes from T_2 nerve root. After their formation these three trunks of brachial plexus converge towards the apex of axilla to meet the anatomical needs of neck, which requires hypermobility in all directions. This convergence of nerve trunks is maximally tightest just medial to the first rib, which is about 4 cm lateral to the tranverse processes of C_6 vertebra. At this point, the brachial plexus assumes its most compact arrangements and block of it at this level cause rapid and complete surgical anaesthesia and analgesia of the upper limb. The trunks of brachial plexus in the neck lie in the posterior triangle and is also invested by the sheath of prevertebral fascia. In the posterior triangle the trunks of brachial plexus are superficially placed and covered only by skin, platysma and deep fascia. In such position they are also crossed by a number of structures such as the inferior belly of omohyoid, external jugular vein, tranverse cervical artery and supraclavicular nerves. Within the posterior triangle of neck, in a thin subject, the trunks of brachial plexus can also easily be palpated by the fingers. The upper and middle trunks of brachial plexus lie above the subclavian artery as the artery crosses the 1st rib. But the lower tunk lies behind the artery and it may make a groove on the rib immediately posterior to the subclavian artery (Fig. 23.2).

At the lateral border of 1st rib each trunk of brachial plexus divides into anterior and

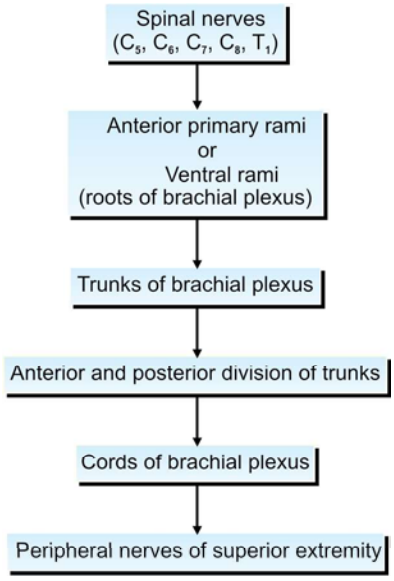


Fig. 23.2: Formation of brachial plexus

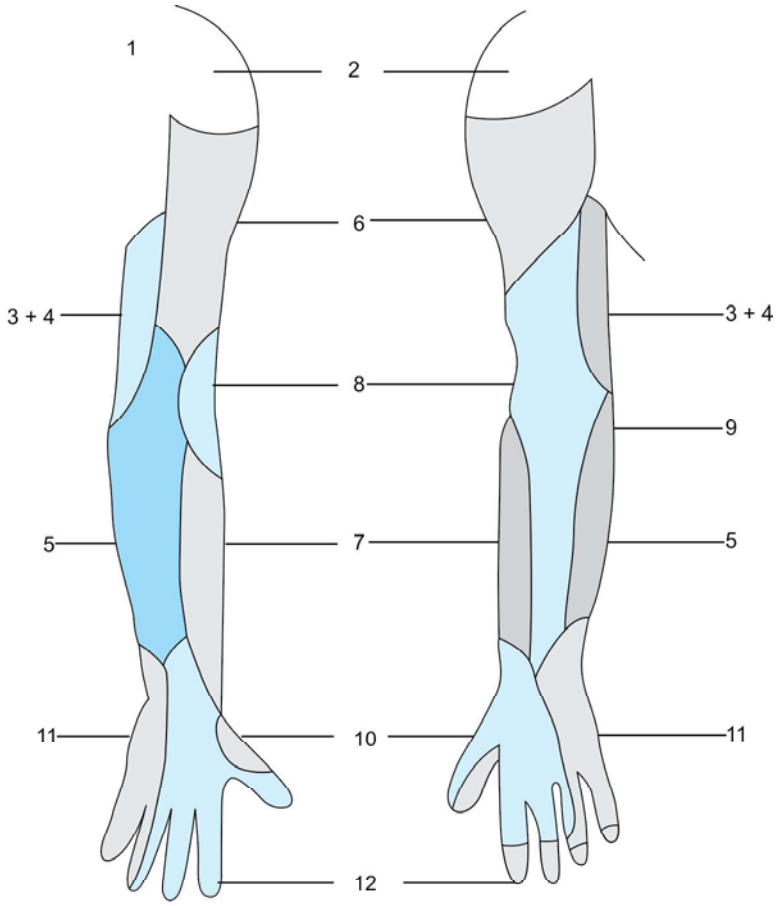
posterior divisions that passes posterior to the middle 1/3 of the clavicle. Then, the different combinations of joining of the anterior and posterior division of the three trunks form the cords of brachial plexus just when they enter into the axilla. Within the axilla these cords are named as lateral, posterior and medial according to their relationship with the 2nd part of the axillary artery which is situated within the same brachial sheath. The superior (or anterior) divisions of the superior and middle trunk joins to form the lateral cord. The inferior (or posterior) divisions from all these trunks join to form the posterior cord. The anterior division of inferior trunk continues as medial cord. Within the axilla at the lateral border of pectoralis minor muscle these cords again divide into peripheral nerves supplying the upper extremity.

Among the peripheral nerves of upper extremity, the musculocutaneous nerve which arises from the lateral cord of brachial plexus is the most proximal branch. So, the proximity of this nerve explains why it is the most commonly spared nerve during the axillary approach of brachial plexus block. The next highest or proximal branch of the brachial plexus, after musculocutaneous nerve, is the axillary nerve and it arises from the posterior cord. Its position also explains why surgical procedures, requiring wide spread total upper extrimity motor block are conducted most often by the technique or approach which is more proximal than the axillary approach of the brachial plexus block. After the axillary nerve, the median nerve arises from the lateral and medial cord. The radial nerve arises from the posterior cord and the ulnar nerve arises from the medial cord respectively.

Beside the terminal branches or peripheral nerves which arise from the cords, several branches also arise from the roots of brachial plexus providing motor intervation to the rhomboid muscle (C_5), subclavian muscle (C_5, C_6), serratus anterior muscle (C_5, C_6, C_7), etc. Suprascapular nerve arises from the C_5, C_6 nerve root and supply the muscles of the doral aspect of scapula and sensory to the shoulder joint. So, to block these nerves higher approaches for brachial plexus block such as the interscalene approach is necessary (Fig. 23.3).

For brachial plexus block four sites or approaches for injection of local anaesthetic agents are chosen such as: interscalene, supraclavicular, infraclavicular and



1. Supraclavicular nerve
2. Upper lateral cutaneous nerve of arm
3. Medial cutaneous nerve of arm
4. Intercostobrachial nerve
5. Medial cutaneous nerve of forearm
6. Lower lateral cutaneous nerve of arm
7. Lateral cutaneous nerve of forearm
8. Posterior cutaneous nerve of arm
9. Posterior cutaneous nerve of forearm
10. Radial nerve
11. Ulnar nerve
12. Median nerve

Fig. 23.3: The cutaneous distribution of peripheral nerves over upper extremity

axillary. The indications, results, technique and complications of brachial plexus block are specific for each site or approach. The site should be selected according to the surgical requirement, potential complication and anaesthesiologist's ability or skill. The proximal branches of brachial plaxus arising from the roots at cervical region are usually blocked only by the interscalene approach of brachial plexus block. The axillary approach of brachial plexus block takes places at the site of origin of the terminal branches of the plexus. At this level the terminal branches have a constant relationship to the axillary artery. For example the median nerve is lateral to the artery, the ulnar nerve is medial to the artery and the radial nerve is posterior to the artery. This constant relationship of these nerves helps in easy identification and complete block of these nerves through axillary route.

The composition of the brachial plexus can be summarized as follows:

1. Five roots

These roots are made by anterior primary rami of C_5 to T_1 spinal nerves and situated between anterior and medial scalene muscles. These roots receive grey rami communication carrying only post ganglionic sympathetic fibres from the cervical sympathetic chain. For example : C_5 and C_6 roots receive post-ganglionic sympathetic fibre from the middle cervical sympathetic ganglion. C_7 and C_8 roots receive post ganglionic sympathetic fibre from the inferior cervical sympathetic ganglion. T_1 root receives pos tganglionic sympathetic fibre from T_1 sympathetic ganglion.

The roots of brachial plexus give branches to:

i. longus cervicis muscle (C_{5-8})
ii. scalenes muscle (C_{5-8})
iii. serratus anterior (C_{5-7}) (long thoracic nerve)
iv. subclavian muscle (C_5, C_6)
v. rhomboidus muscle (C_5) (dorsal scapular nerve)
vi. phrenic nerve (C_5)

2. Three trunks (in the posterior triangle of neck)

There are three trunks (a) Upper (C_{5-6}), (b) middle (C_7 alone), and (c) lower (C_{8-1}). These trunks give branches : nerve to subclavian muscle and suprascapular nerve.

3. Six divisions (behind the clavicle)

Each trunk divides into an anterior and posterior divisions. These divisions do not give any nerve branch.

4. Three cords (within the axilla)

a. Lateral cord – It is formed by the union of anterior divisions of upper and middle trunks. It gives the following branches: lateral pectoral nerve, musculocutaneous nerve and lateral head of medium nerve.
b. Medial cord – It is the continuation of anterior division of lower trunk. It gives the following branches: medial pectoral nerve, medial cutaneous nerve of arm, medial cutaneous nerve of forearm, medial head of medium nerve, ulnar nerve.
c. Posterior cord – It is formed by the union of post divisions of all the three trunks. It gives the following branches: upper subscapular nerve, nerve to lattissimus dorsi (thoracodorsal nerve), lower subscapular nerve, axillary nerve and radial nerve.

The branches arising from the roots and trunks of the brachial plexus is situated in the neck above the clavicle and so these are called the supraclavicular branches. But, the major distribution of the brachial plexus is derived from its cords and are situated below the clavicle. Therefore, they are called the infraclavicular branches.

Interscalene Approach of Brachial Plexus Block

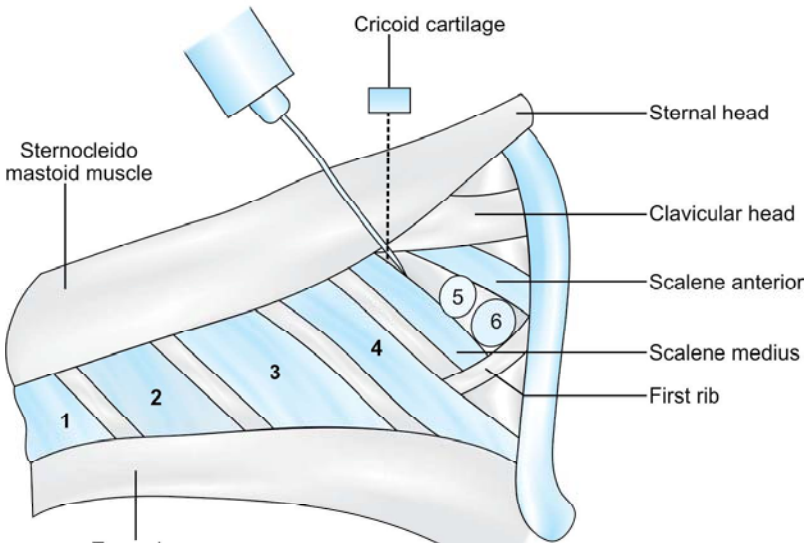
Among all the approaches of brachial plexus block, it is the most proximal and cephalad approach. So, all the complications related to this approach of brachial plexus block are due to its proximality to the vital structures in neck. It is performed at the level of the roots and trunks of brachial plexus and most often at the level of superior trunk over the transverse process of C_6 vertebra

Indication

The principal indication for interscalene approach of brachial plexus block is the surgeries over the proximal part of upper extremity, e.g shoulder and upper arm. This is because surgery over shoulder requires partial cervical plexus block with the full brachial plexus block and this is only achieved by interscalene approach. On the other hand, for forearm and hand surgery this approach can also be used (Fig. 23.4).

But the block of inferior trunk of brachial plexus which supply mainly the forearm and hand (C_8, T_1) is often incomplete and frequently require supplementation by isolated ulnar N bock for adequate surgical anaesthesia along their distribution. The nerves responsible for thoracic innervation from brachial plexus enters the thorax through axilla, but they remain outside the brachial plexus sheath. So, if the surgical incision for surgeries on upper extrimity involves the medial side of the upper part of thorax and axilla as in the transdeltoid approach for surgeries on upper extrimity, then these areas might remain unblocked by the interscalene approach of brachial plexus block. Similarly, if the skin surface which are innervated by the nerves arising from C_2 to C_4 segment of spinal cord is involved in surgery it may not be blocked by this approach of brachial plexus block and may requires supplementation by paravertebral injection. An inferior axillary surgical approach for the operation on shoulder joint may also require too large, skin area, so this approach of brachial plexus block is of no help.

The brachial plexus block may still be used with light GA for extended pain relief of upper extrimity. Scarring developed from the previous surgery could be



1 = Semispinalis capitis, 2 = Splenius capitis, 3 = Levator scapulae, 4 = Scalene posterior, 5 = Brachial plexus, 6 = Subclavian artery

Fig. 23.4: The site of interscalene approach of brachial plexus block

another obstacle to the use of pure regional anaesthesia (brachial plexus block) for the repeated shoulder surgery. This is due to the isolation of some nerve structure from the action of LA agent by the developed fibrosis. So, the use of nerve stimulator and elicitation of paresthesias is recommended with this technique, in order to place the needle accurately near the nerve. In the posterior triangle the brachial plexus sheath is very thin and so the feeling of piercing the sheath by needle is very difficult during interscalene approach of brachial plexus block.

Technique

The anatomical background for the correct interscalene approach for the brachial plexus block is the exact identification of location of brachial plexus in the groove which is formed by the overlapping of anterior and middle scalene muscles at the level of cricoid cartilage. This overlap occurs over the transverse process of C_6 vertebra. The entire brachial plexus is accessible at this point from outside, because the complete sheath of brachial plexus is formed here. Any injection within the sheath at this level of nerve trunk will have access to the entire brachial plexus including the roots and cords. By the use of nerve locator and motor evoked response or paresthesia felt in the arm, the origin of specific nerve is also identified which helps in specific nerve block. But, injection of drug outside the sheath will not result in block. So, the knowledge of the branches of nerves of brachial plexus which lie outside the brachial plexus sheath will prevent these potential failure of block. Examples of such instances are the suprascapular N, axillary N, long throcic N, etc, which leave the sheath at this level. So, the paresthesia to the anterior chest (pectoral area) or the area of the scapula or the acromion region which is due to the stimulation of these nerves, lying outside the plexus sheath should not be mistaken as a confirmatory sign of brachial plexus entry of needle at this level.

For the interscalene approach of brachial plexus block, patient should lie in supine position with head turned away from the side of the block. The posterior border of sternocle domastoid muscle is palpated first by asking the patient to lift the head. Then, the interscalene groove (where middle and ant. Scalene muscle cross each other) can be palpated by rolling the finger laterally from the post border of the sternocledomastoid muscle over the belly of the anterior scalene muscle. Then a line is drawn laterally from the cricoid cartilage to intersect the interscalene groove which indicates the level of transverse process of C_6 vertebra. After proper sterile preparation, a 4 cm short beveled needle is inserted perpendicularly to the skin, with 45° caudal and slightly posterior angulation. Needle is then advanced in that direction until the paresthesia is felt. This usually occurs at very superficial level. A click may be detected, if blunt needle is used when it goes through the prevertebral fascia. If bone is encountered within 2 cm of skin, it is likely to be the transverse process of C_6 vertebra. Nerve stimulator may be helpful to identify the individual nerve of brachial plexus or the plexus itself. The perceived feeling anywhere in the arm is a reliable indicator of the superior trunk of brachial plexus. Appreciation of paresthesia over the region of scapula, acromion or pectoral area indicates the suprascapular, axillary or long thoracic N, respectively which are not located within the sheath of brachial plexus and there is chance of failure. After getting paresthesia over the arm (which indicates that the tip of the needle within the sheath) the needle should be fixed at that position and it can be helped by using a flexible extension tubing. After negative aspiration, 10 to 40 ml of LA drug is injected incrementally, depending on the desired extent of block. There is a definite relationship between the volume of LA agent and the extent, depth and duration of regional anaesthesia. For example, 40 ml of LA solution is associated with complete cervical and brachial plexus block for prolonged period.

Complications

Ipsilateral phrenic nerve block with diaphragmatic paralysis occurs in all most all the patients during interscalene approach of brachial plexus block. It causes 25% reduction in pulmonary function. This is due to the anterior spread of LA solution

over the anterior scalene muscle blocking the phrenic nerve. This may cause dyspnoea in respiratory compromised patient. Therefore, sedation required for these patient to tolerate these symptoms also have negative impact. On the other hand, the ipsilateral involvemant of vagus, recurrent laryngeal nerve and stellate ganglion with the concomitant block of brachial plexus through interscalene approach has little or no significance, but related symptoms may require assurance or sedation. For postoperative pain relief after the total shoulder replacement surgery under GA the interscalene approach of brachial plexus block can be adopted, but only after confirming that there is no nerve damage during surgery. Otherwise, later this block should be blamed for nerve injury what was done during surgery under general anaesthesia. If the needle is long enough and the direction is caudal, then any of the epidural or subarachnoid block can be precipitated during the interscalene approach of brachial plexus block. This is due to the close proximity of dural sleeve over the spinal nerves and the site of interscalene approach for brachial plexus block. As several important vascular structures are also in close proximity to the site of injection, so during interscalene approach of brachial plexus block repeated aspiration and incremental dose of LA agent should be given which guard against the inadvertent intravascular injection of drug. In this approach of brachial plexus block the nerve damage or neuritis can also occur like any other peripheral N block.

Supraclavicular Approach for Brachial Plexus Block

The advantage of this approach for brachial plexus block over the interscalene approach is that a small volume of LA drug can be delivered directly near the three trunks where they are compactly arranged, resulting in rapid onset and reliable dense brachial plexus block. But the rate of complication may restrict this approach. During the application of this technique the incidence of complication (risk) should be balanced with the benefit (rapid and dense block) achieved by it. Distal to the transverse processes of cervical vertebrae the prevertebral fascia invests the nerve of brachial plexus, forming the brachial plexus sheath. When the nerves of brachial plexus passes over the first rib, then this sheath of it becomes complete and formed a neurovascular bundle which lies posterior and inferior to the clavicle at about its midpoint. For this approach of brachial plexus block striking the 1st rib with needle is the land mark. Then, walking of needle in the correct plane on the surface of the rib will lead to the identification of brachial plexus. Another landmark for this approach of brachial plexus block is the apex of palpable subclavian artery which can be traced cephalad to identify the interscalene muscular interval. Lateral to the subclavian pulse at the level of the clavicle the supraclavicular part of brachial plexus can be found. During interscalene block if the crossing of anterior and middle interscalene muscle is traced distally toward the clavicle then the brachial plexus also can be approached at the supraclavicular level (Fig. 23.5).

Indication

Three anatomical points are important for the performance of supraclavicular approach of brachial plexus block. These are:

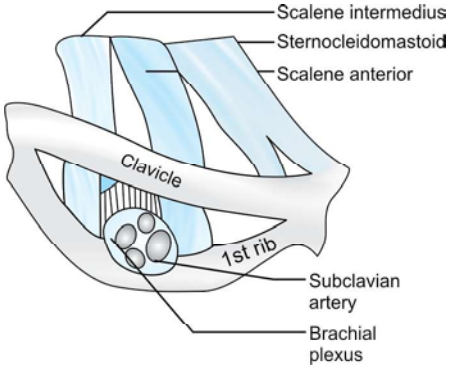


Fig. 23.5: The brachial plexus with subclavian artery on 1st rib

i. The three trunks of brachial plexus are clustered vertically over the first rib and liecephaloposterior to the subclavian artery which often can be palpated in a thin patient.
ii. The neurovascular bundle lies posterior to the clavicle at about its midpoint.
iii. The first rib acts as a barrier for the needle piercing the pleural dome.

This approach is applicable for any surgical procedures of upper extremity, where the brachial plexus block can be used theoretically. But due to the sparing of most proximal part of brachial plexus by this approach and thus not blocking the nerves which arise from the roots and supply over the shoulder somebody would recommend the interscalene approach when the surgical procedure is performed on the shoulder. However, practically supraclavicular approach for brachial plexus block with adequate amount of LA drug usually provide adequate anaesthesia for any surgical procedure on shoulder with reasonably high success rate. This is because large amount of LA drugs, placed at this site can easily spread cephalad and block the roots of brachial plexus.

Technique

The patient is first placed in supine position with head turned to the opposite site. Then at the midpoint of clavicle, the pulse of subclavian artery is felt, and the point just lateral to the pulse is the site of injection. If pulse is not palpable, then midpoint of clavicle is also the landmark for the site of injection of LA agent for this approach of brachial plexus block. Proper aseptic measure is taken. Then, for this block a 22 to 25 G and 1″ long blunt beveled needle is selected. It is advanced through the skin wheal in a caudal, but slightly medial and posterior direction toward the subclavian pulse, until the paresthesia is encountered. If no paresthesia is elicited, then the needle is advanced more until the 1st rib is encountered by the tip of the needle. If artery is encountered, needle

is withdrawn till blood is no longer aspirated. After encounterment with the 1st rib, the needle is walked on the rib, first lateral and then medial direction, until the paresthesia is elicited. When paresthesia is encountered then 20 to 30 ml of LA drug is injected. The caudal direction of needle must be avoided which increases the (Fig. 23.6) incidence of the entry of the tip of the needle into the pleural cavity and the lung parenchyma at their apex and development of pneumothorax. Advancing the needle deeper than the reasonable length to encounter the 1st rib must be avoided for fear of also pneumothorax. If any air is aspirated, then chest X-ray is mandatory. Air aspiration does not preclude complicating the block, because fine needle usually prevents significant air leak from the lung producing pneumothorax. So, it is unwise to discharge an outpatient without overnight observation after brachial plexus block through supraclavicular approach, particularly if there is an increased chance of pneumothorax.

The modified plumb-bol's technique for this approach of brachial plexus block needs the same patient position.The needle entry site is at the point where the lateral border of sternocleidomastoid muscle inserts on the clavicle. After aseptic preparation, 22G and 4 cm a long short bevel needle is inserted through the skin, while mimicking a plumb bob suspended over needle entry site. Often paresthesia is encountered prior to contacting the 1st rib or subclavian artery. If no paresthesia is elicited, needle is directed cephalad. If still no paresthesia is elicited then the needle tip is directed caudal until the 1st rib is contacted.

Complication

The incidence of pneumothorax after supraclavicular approach of brachial plexus block is 0.5 to 0.6 % and is most common in this approach. The incidence of pneumothorax, even in experienced hands, is more if routine diagnosis is sought by X-ray than clinical findings. Subclinical pneumothorax is more common than symptomatic pneumothorax. The onset of symptoms is sometimes delayed and may take 24 hour. Therefore, routine X-ray just after the block is not justified. Injury of subclavian artery and subclavian vein are also possible in this approach, like injury to the thoracic duct (on left side). Injury to the nerves of brachial plexus may also happen from direct traumatic needle insertion within the nerve or intra-aneural injection of LA agent. Other complications of this approach of brachial plexus block include: phrenic nerve block (40 to 60%), Horner's syndrome, neuropathy and cervical sympathetic block which only requires reassurance.

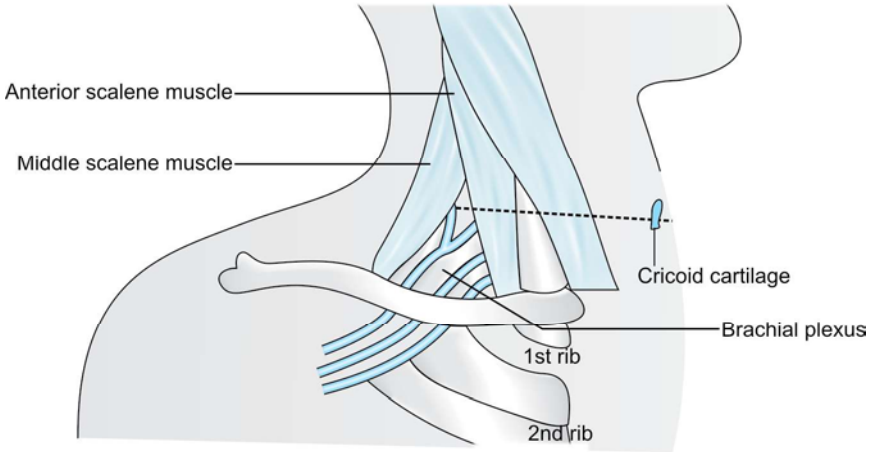

Fig. 23.6: The site of interscalene block, supraclavicular block and infraclavicular block

Infraclavicular Approach for Brachial Plexus Block

This approach of brachial plexus block is only described for historical reasons. Infraclavicular approach offers same advantages as supraclavicular approach. But high complication rate due to (i) the long distance crossed by the needle, (ii) very closeness of the needle to the parenchyma of lungs and great vessel and (iii) the scarcity of experienced anaesthetist to teach this technique has made its application limited (Fig. 23.7). So, the excessive high rate of complication for potential pneuomothorax, trend to limited hospitalization time, quick discharge of patient and increasing the number of outpatient extremity procedures under the regional anaesthesia have made this approach now obsolete. As the divisions of brachial plexus pass over the 1st rib and move towards the posterior surface of the clavicle, their tight and vertical disposition is still maintained.Then the plexus (cords) passes under the clavicle and move towards to the axilla, passing just inferior to the coracoid process. At this point, the brachial plexus is still directly over the first rib in the horizontal plane and this rib theoretically prevents any needle approaching the plexus at this site from entering the thorax. The infraclavicular part of brachial plexus is also tightly arranged within its sheath and any access of plexus at this level will result in rapid exposure of the entire plexus to LA agent. The disadvantage of approach for brachial plexus at this site is that it lies two to three inches deep to the surface, making it more difficult to approach.

Indication

Like supraclavicular, in this approach there is also high failure rate in blocking the branches, arising from the proximal part of brachial plexus which is only possible by inerscalene method. So, the

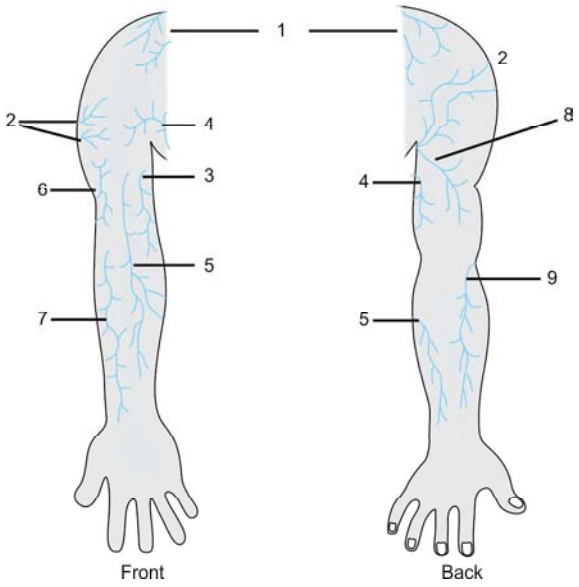

Fig. 23.7:

1. Lateral supraclavicular nerve ($C_{3,4}$)
   It arises from cervical plexus - divides into three - medial, intermediate, and lateral - pierces the deep fascia of neck and descends over clavicle - supplies skin over deltoid, pectoralis major as far down as the level of a horizontal line drawn from 2nd costal cartilage.
2. Upper lateral cutaneous nerve of the arm ($C_{5,6}$)
   It is a branch of axillary nerve - supplies skin over the lower half of deltoid muscle.
3. Medial cutaneous nerve of the arm ($T_{1,2}$)
   It arises from the medial cord of brachial plexus - supplies skin on the medial side of the arm.
4. Intercostobrachial nerve (T_2)
   It arises from 2nd intercostal nerve - crosses axilla - pierces deep fascia of upper arm - supplies the floor of axilla and medial side of upper arm.
5. Medial cutaneous nerve of forearm (C_8, T_1)
   It arises from the medial cord of brachial plexus - pierces deep fascia at middle of the arm - supplies skin over the front of upper arm between basilic and cephalin vein - also supplies the medial half of forearm.
6. Lower lateral cutaneous nerve of the arm ($C_{5,6}$)
   It is a branch of radial nerve - arises from radial nerve before it leaves the radial groove of humerous - pierces the deep fascia 2 to 3 cm below deltoid tuberosity - supplies skin of the front, lateral and posterior side of upper arm.
7. Lateral cutaneous nerve of the forearm ($C_{5,6}$)
   It is the continuation of musculocutaneous nerve - pierces deep fascia lateral to biceps muscle, 2 cm above elbow - supplies the skin of both the front and back of lateral side of forearm - also supplies the skin over the ball of thumb.
8. Posterior cutaneous nerve of the arm (C_5)
   It arises from the radial nerve in axilla - pierces the deep fascia a little below the posterior fold of axilla - supplies a wide area of skin on the back of arm from the level of deltoid tuberosity to the elbow.
9. Posterior cutaneous nerve of the forearm (C_{6-8})
   It arises from the radial nerve - pierces the deep fascia 2 to 3 cm above the elbow - passes downwards behind the lateral epicondyle - descends on the back of forearm upto the wrist - supplies skin of the back of forearm from elbow to wrist

block of brachial plexus through this route is not the choice for shoulder surgery which need the block of brachial plexus more proximally. Because the most proximal approach only such as interscalene approach can block the nerves or branches of brachial plexus arising from root which supply the shoulder. But, in contrast to interscalene approach the high success rate is anticipated of ulnar nerve block in this approach. This approach is also relatively contraindicated for out patient, because of its potential risk for subclinical pneumothorax like supraclavicular approach which may be manifested after the patient has left the hospital. Like supraclavicular brachial plexus block, the distinct advantage of this approach is that rapid high density block can be achieved without requiring movement of hand prior to the onset of anaesthesia. This is unlike the axillary approach where hand is moved before the block which causes pain due to injury for which surgery is advised or due to presence of any contracture which prevents abduction and circumduction of axilla.

Technique

The patient is positioned supine and the head is turned towards the opposite direction. After proper aseptic measure, a skin wheal is raised on the inferior border at the midpoint of clavicle. Then a 22G and 3" long needle is advanced at 45° angle towards the humeral head through this skin wheal. The insertion point of needle should be just lateral to the subclavian pulse if it can be identified. Always the needle should be advanced away from the chest wall to reduce the chances of entry of the needle into the apex of lung producing pneumothorax. The right position of needle can be identified by ilicitation of paresthesia. If bone (coracoid) is encountered by the needle, then it should be withdrawn and advanced again with slightly different direction. During aspiration test by a fluid filled syringe if air is aspirated, then chest X-ray is must. If a long insulated needle is available, then the nerve stimulator can also be used to elicit motor-evoked response for better identification of brachial plexus (Fig. 23.8).

Complication

The most common complication of this approach of brachial plexus block is pneumothorax and hemothorax which may not be detected at the time of block, but can be serious later on. Thoracic duct injury, on the left side, would be an insidious occurance. The injury of other great vessels and nerves of chest are also common.

Axillary Approach for Brachial Plexus Block

It is the most common approach of brachial plexus block for surgery on upper extremity.

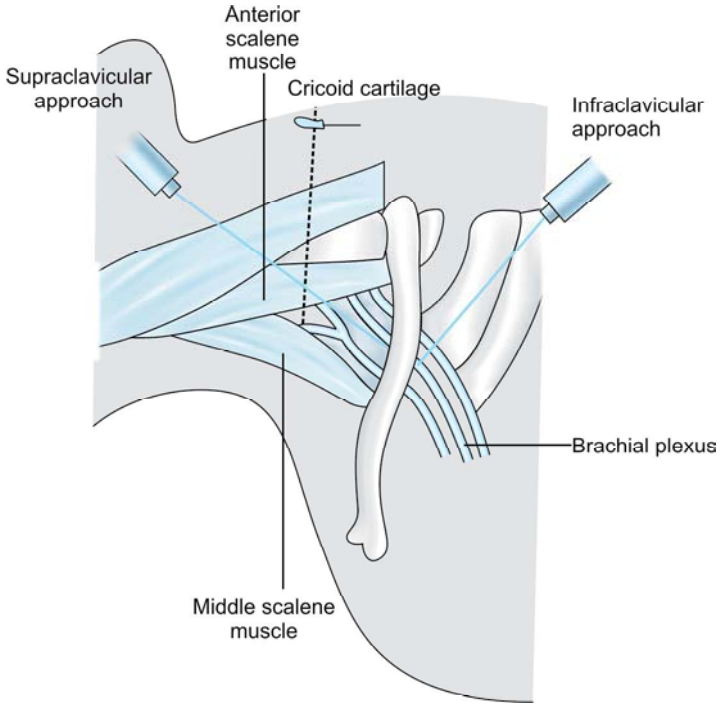

Fig. 23.8: Using nerve stimulator to elicit motor-evoked response for identifying brachial plexus

This is because of easy performance, reliability for hand and forearm anaesthesia, widespread familiarity of this approach, and low complication rate. This block is ideally suited for out patients and can also easily be adopted for pediatric group. The axillary approach for brachial plexus block is unsuitable for upper arm and shoulder surgery. Because musculocutaneous and other nerves arising from the proximal part of brachial plexus is often spared by this approach and should be supplemented separately at axilla or elbow. Patient who can not abduct his hand due to injury or other causes should not be selected for this approach of brachial plexus block.

Applied Anatomy

In axilla, the axillary artery lying within the sheath of brachial plexus along with the nerves, forms an important landmark. The brachial plexus is represented in axilla as cords and peripheral nerves. Cords are named as medial, lateral and posterior, according to their relationship with the axillary artery. The lateral cord is branched out terminally into the musculocutaneous nerve and contributes to the formation of median nerve. The posterior cord creates axillary and radial nerves. The medial cord gives rise to ulnar nerve and contributes to the formation of median nerve with the contribution from lateral cord. These terminal branches of brachial plexus also maintain the same relationship with the axillary artery like their primary contributors. Thus, the radial nerve remains posterior to the artery, ulner nerve remains medial to the artery and median nerve remains lateral to the artery. When the brachial plexus block is performed most proximally (interscalene approach) then the distal nerve such as usually the ulnar nerve is spared frequently and when the brachial plexus block is performed distally (axillary approach) then the proximal branches such as the musculocutaneous nerve is spared frequently. The medial part of the upper arms get sensory innervation from the branches of T_1 and T_2 spinal nerves which lies outside the brachial plexus and comes from thoracic wall. These nerves are called the medial brachial cutaneous and intercostobrachialis nerve and are found in the subcutaneous tissues of axilla. These nerves cannot be blocked by the axillary approach of brachial plexus block. These can be blocked by a separate subcutaneous field block at the medial site of upper arm. For this a vertical line, created by the skin wheal is infiltrated upward to the deltoid prominence and downward to the edge of the triceps. Then about 5 ml of local anaesthetic agent is deposited at this straight line in the subcutaneous tissue. A 25 G spinal needle can be a convenient tool for this injection (Fig. 23.9).

The neurovascular bundle in axilla around the brachial plexus is a multicompartmental structure. It make no complete, but partial barrier for diffusion of drug among the compartments. So, due to this multicompartmental structure, some recommend multiple injection site for axillary block to produce better results. But, some practitioners are reluctant to reenter the sheath of brachial plexus for second time after a bolus LA agent has already been injected. Because they fear that if nerve is pierced during the entry of sheath by needle in 2nd time will, leave the patient unaware (due to 1st time block) of pain and will cause potential severe nerve damage. So, controversy surrounds between the single versus multiple injection technique and still it remains unresolved. The elicitation of parasthesia for successful axillary block is also controversial, because of reportedly higher risk of nerve damage. Although actual data are limited, but motor evoked response by nerve locator is very helpful for success of axillary block.

Technique

There are four different techniques for axillary approach of brachial plexus block, depending on the different method of placement of needle tip within the sheath of brachial plexus. These are: transarterial technique, 'sheath-pop' technique, elecitation of paresthesia technique, and nerve stimulator technique.

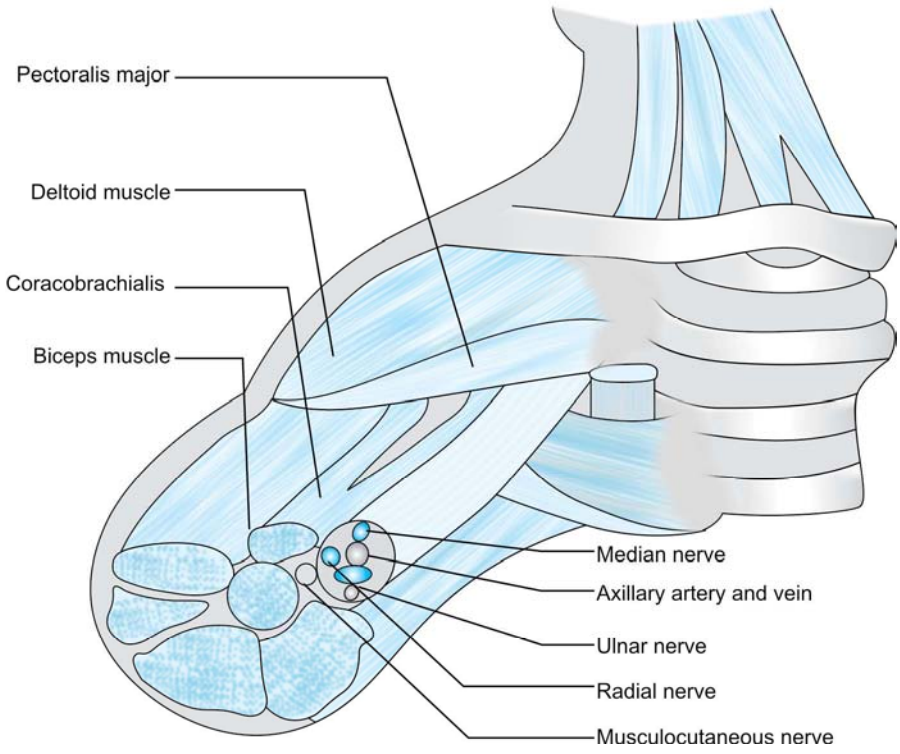

Fig. 23.9: The brachial plexus in axilla

The patient should be first placed in supine position. Then the arm is positioned at right angle to the body and elbow is flexed to 90°. The dorsum of the hand should rest on the bed or pillow. This is called the neutral position of the arm. Any further dorsal or ventral displacement of arm from this neutral position will distort the palpation of axillary artery. The more dorsal displacement of arm may accentuates the prominence of the underlying head of humerus and flattens the contents of the overlying sheath of brachial plexus which may make the palpation of axillary artery difficult.

The axillary artery is first palpated in axilla and then it is fixed against the head of the humerus. After that a skin wheal is raised directly over the artery by LA agent. Whenever possible, the most proximal area of pulse appreciation is selected. This is because the sheath begins to loss distally from this point. The best proximal site of injection of LA agent for brachial plexus block in axilla is the site of skin fold, formed by the crossing of the pectoralis complex arsing from the thorax with the arm.

After injection of LA agent arm should be returned to the patient's side. This will allow the head of the humerous to move further from the sheath and ensure the maximum proximal spread of the LA agent. This is because filling of the sheath as far proximally as possible with the anaesthetic agent from the site of injection results in better regional block. After a time span of 2 to 3 minutes, arm can be repositioned and any supplemental blocks (for medial brachial cutaneous nerve, inter costobrachiales nerve and musculocutaneous nerve) if indicated can be performed.

Methods of Identifying the Brachial Plexus Sheath

As previously described, there are four different techniques or methods for identifying the brachial plexus sheath. But all these techniques that have in common in them is the positioning of arm which allow the best palpation of axillary artery and maximize the anatomical information from the palpation of this surface anatomy.

A. Transarterial technique

In this technique a skin wheal is raised first by the LA agent at the most proximal site, where the pulsation of axillary artery is appreciated best. The anaesthetist's nondominant hand is positioned at this site in such a way that it can identify the pulse best, but will not occlude the arterial flow. For easy operation of this technique, the needle is usually connected first to an extention tubing and then to the syringe. It will help for the maximum needle control and fixation of it, if needed. In this transarterial technique the needle will pierce the artery and blood is to be aspirated during the passage of its tip through the arterial lumen. The needle will advance gently through the palpable pulse, perpendicular to the plane of artery, while a constant gentle aspiration by syringe is applied by the assistant. When aspiration of blood ceases, then it implies a sign that the tip of the needle is just beyond the arterial wall at its posterior surface. Now, 40 ml solution of LA agent is injected posterior to the artery. Alternatively half of the LA solution is injected posterior and half anterior to the artery. But, a great care must be taken to avoid intravascular injection of LA agent by using test dose or using epinephrine as marker in it. Some investigators report nearly 100% success of axillary brachial plexus block with this transarterial technique. But, some practioner avoid this transarterial technique in the belief that it is unnecessarily traumatic (Fig. 23.10).

B. 'Sheath pop' technique

This axillary approach for brachial plexus block is developed by identifying the brachial plexus sheath, without piercing the axillary artery or eliciting paresthesia, i.e not injuring the vessels and nerves. This

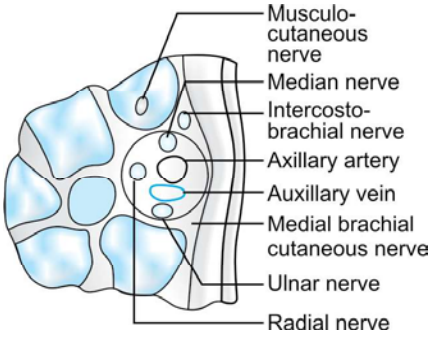

Fig. 23.10: Auxillary block

technique is facilitated due to the development of new blunt short beveled regional needles. This small, blunt, short beveled regional needle maximizes the tactile information during its insertion through the brachial plexus sheath. Due to the superficial nature of the artery, the short length of the needle is selected. After the appropriate positioning and creation of a sterile field, the needle is directed towards a position next to the underlying pulse. Usually the sheath is approached lateral to the pulse. The blunt-bevel needle is advanced through the skin until the axillary sheath is entered by the side of the axillary artery, as evidenced by a 'fasical click' (sheath-pop). Then, the needle is advanced 1 mm further into the sheath from distal to proximal where upto 40 ml drug is injected after negative aspiration. By this technique the success rate is very high, but it is most difficult to teach. Benefits of this technique is elimination of persistent paresthesia or compressive hematoma of axillary artery which is occurred due to directly prick of the nerve and artery.

C. Elicitation of paresthesia

It is one of the most oldest method for identification of nerve or its plexus for conduction block. Elicitation of paresthesia also can be applied easily for brachial plexus block, like other nerves and the result can be improved by anatomical approach, based on the dermatomes involved in the proposed surgical procedure. So, the knowledge of the proper location of nerves of brachial plexus in axilla is essential. The success of block for a given terminal nerve of plexus is further improved by injection only at that site from where the paresthesia is elecited. The axillary artery is the correct constant landmark creating a fixed relationship with these nerves. Again correct identification of paresthesia requires extensive knowledge of the terminal sensory components of these nerves. For example, the elecited paresthesia in the hand must easily be identified by its origin. If it is located in the dorsal aspect of thumb, then the radial nerve is implicated. If the paresthesia is located in the midpalm, especially on the palmar surface, then the median nerve is implicated.

Selection of the needle used to elicit paresthesia is controversial. Some thought that large blunt needle push the nerve away causing less chance of piercing it. Whereas fine needle may more likely enter the substance of nerve and can cause more injury to the nerve. But, some thought that fine needle will cause less nerve injury if nerve substance is inadvertently entered at all than the blunt needle.

During the initial injection, paresthesia perhaps is slightly increased due to the pressure, caused by the LA agent on nerve. This pressure initially induces the activation of nerve fibres (i.e. action potential of nerve fibres) and increases the conduction through it, before the Na^+ channels are blocked. Thus it increases the paresthesia initially. The advantage of this technique is that it relatively increases the success rate of block in selected dermatomes. But, the potential complication rate may increase due to the intentional elicitation of paresthesia by piercing the nerve. Whether this techniques of elicitation of paresthesia would influence the rate of persistant paresthesia postoperatively is unknown.

D. Nerve stimulator technique

With the minimum required frequency and voltage, it is possible to stimulate and elicit the motor activity of a nerve with little or no painful sensation. Thus, it helps to verify the placement of the tip of a needle very close to the nerve. Again, the use of variable voltage nerve stimulator, combined with insulated needle also increases the success rate. Because this combination gurantees that current can be delivered only to the tissues near to the desired nerve, adjacent to the injecting port of the needle. But, it is difficult to prick the blunt insulated needle through the dermis. So, after raising a skin wheal the passage of insulated needle through the dermis is facilitated by the passage of similar gauge sharp needle before and thereby avoiding the bending of regional insulated needle or folding of the insulating layer over the needle. Nerve stimulator unit is turned on after the skin is penetrated by the needle and during search for the nerve. The current is kept at 1 mAmp or less and at 2 Hz frequency to avoid the recruitment of nociceptive fibres, when the nerves are searched for. If pain occurs stimultaneously with the motor evoked response, patient may move his limbs involuntarily and may displace the needle. Gentle muscle movement elicited from an appropriate nerve muscle unit confirm the correct needle placement. Then decrease of voltage to 0.5 mAmp or less and still elecitation of muscle movement indicate very closeness of needle tip to the nerve and high probability of successful block. The further confirmation of the correct placement of needle is also possible if the equipment allows the injection of LA agent during the delivery of current. If injection is given during the stimulation of nerve, initially there is an increase in the magnitude of motor evoked response analogous to pressure paresthesia. This increase of motor evoked response should be followed quickly by decrease and gradual abolition of the movements of muscles as injection proceeds.

If the nerve stimulator technique is employed without the use of an insulated

needle, then the current density flowing along the entire shaft of the needle must be considered and a large area will be stimulated. There is also another technique to increase the probability that the injecting port of needle will be close to the part of the nerve, eliciting motor evoked response. For that, the needle is advanced gradually till the response occurs, then withdrawn until it just disappears and again moves forward in the same track until the response barely occurs again.

The complications of nerve stimulator technique are same as others. Insulated or noninsulated needle may encounter the artery, vein or nerve and may be the potential for injury.

Continuous Brachial Plexus Block with Catheter

Since 1940s, the continuous brachial plexus block has been described. It is usually obtained by placing and securing a catheter in the vicinity of the nerves of brachial plexus.This can be performed by technique using both the catheter 'over' and 'through' the needle methods. Catheter 'through' and 'over' the needle method means it can be passed through the needle after it pierces the skin or needle can be threaded through the catheter before piercing the skin. Longer catheter is helpful for better fixation and provide superior blockade, if the tip of the catheter lies more proximal to the plexus. However, stimulating electrode with catheter is not available still now for continuous brachial plexus block.

The advantages of this technique are:

i. Potential prolongation of surgical anaesthesia if needed,
ii. Decreased risk of toxicity of LA agent as small incremental doses are used,
iii. Postoperative pain relief,
iv. Sympathectomy.

Disadvantages are:

i. Increased incidence of inadequate surgical anaesthesia, as repeated small does are given
ii. Infection,
iii. Difficulty in securing catheter causing kinking, migration, etc.

Indications for continuous brachial plexus block with catheter are:

i. Upper extremity or digit replantation,
ii. Total elbow arthroplasty,
iii. Reflex sympathetic dystrophies for which prolonged pain relief by sympathectomy are advantageous.

SUPPLEMENTAL BRACHIAL PLEXUS BLOCKS—MEDIAL BRACHIAL CUTANEOUS AND INTERCOSTOBRACHIALIS NERVE BLOCK (FIG. 23.11)

Brachial plexus block alone cannot anaesthetize some area over the medial upper part of the arm which is supplied by the T_1 and T_2 segments of spinal cord through the medial brachial cutaneous and intercostobrachialis nerve. They remain outside the brachial plexus sheath. So, sometimes to make the brachial plexus block complete supplemental peripheral block of these nerves are sometimes necessary. The medial brachial cutaneous nerve and the inter-costobrachialis nerve are found in the subcutaneous tissue over the medial part of the upper arm. So, they can only be blocked by subcutaneous tissue field block over the medial part of the upper arm. For this field block a skin wheal is created along a transverse line which extends anteriorly upto the deltoid prominence and posteriorly upto the edge of triceps. Then, about 5 to 10 ml of LA agent is deposited at this straight line in subcutaneous tissue to block the medial brachial cutaneous and the intercostobrachialis nerve.

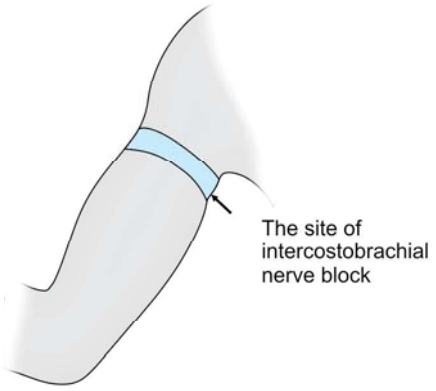

Fig. 23.11: Medial brachial cutaneous and intercostobrachial nerve block

DISTAL UPPER EXTREMITY CONDUCTION BLOCK OF INDIVIDUAL NERVE

This can be performed as sole anaesthetic technique with limited dermonates or as supplemental for partial brachial plexus block. Each of the peripheral nerve (musculocutaneous N, Radial N, Median N and Ulnar N) is identified and can be blocked at the level of elbow or wrist according to the need. Intravenous upper extremity regional anaesthesia is also a type of peripheral upper extremity block (Fig. 23.12).

Musculocutaneous Nerve

The individual conduction block of this nerve is frequently used to supplement the primary brachial plexus block, because there is high incidence of sparing this nerve when axillary route is approached. It is specially useful in surgical procedure where complete motor block of the upper arm is required by brachial plexus block through axillary route. It is also equally effective in blocking this nerve on the radial and dorsal surface of the foreman and hand where the terminal sensory supply of this nerve is located (Fig. 23.13).

Anatomy

This nerve is the continuation of the lateral cord of brachial plexus. It lies external to the brachial plexus sheath

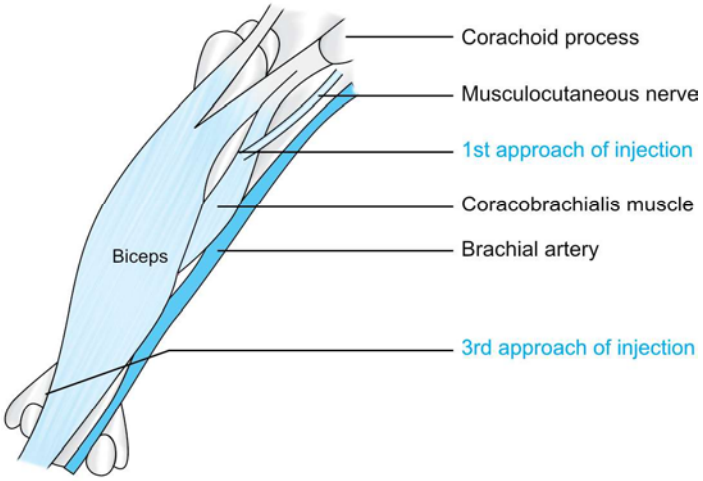

Fig. 23.12: Musculocutaneous nerve block (right side)

and passes through the substance of coracobrachialis muscle, lying posterior to the artery. It leaves the axilla by piercing the coracobrachialis muscle. This is the 1st site for block of this nerve, when it lies within the coracobrachialis muscle. Then, the nerve follows the axillary artery towards the arm where it gives of numerous motor branches supplying the coracobrachialis, both heads of biceps and the medial part of brachialis muscle. The nerve then exit the coracobrachilis muscle and runs downward and laterally between the biceps and brachialis muscles to reach the lateral side of arm (2nd approach of block). It then extends upto the elbow. At the elbow it pierces the deep fascia on the lateral side of the tendon of the biceps and continued as the lateral cutaneous nerve of forearm (3rd approach of block) and supplies the skin on the radial side of the anterior surface of forearm. Block of this nerve at the first approach causes complete motor loss of biceps and coracobrachialis muscle, weakness (partial motor loss) of brachialis muscle and sensory loss over the lateral half of the forearm (Fig. 23.14).

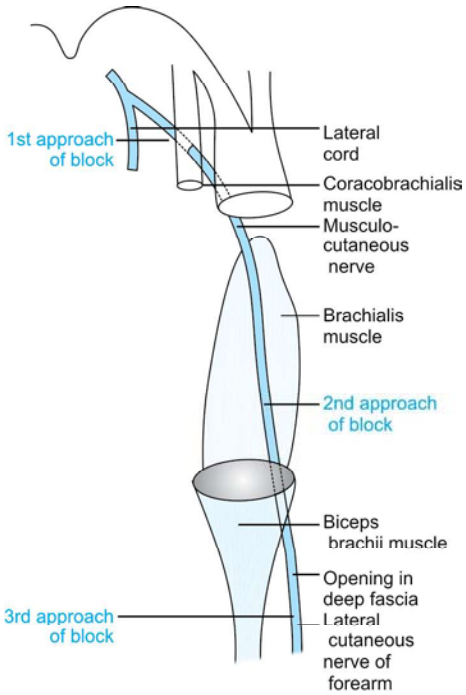

Fig. 23.13: The course of left musculocutaneous nerve

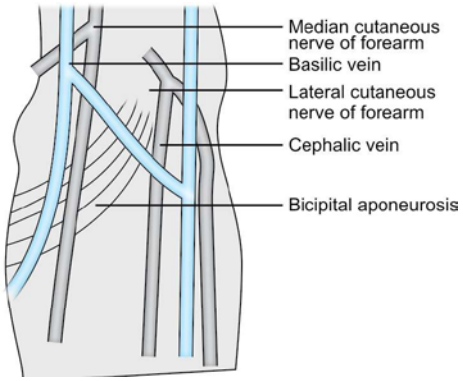

Fig. 23.14: Structure over the roof of cubital fossa

For the 1st approach of block, the substance of coracobrachialis muscle is palpated and pulled upward first. Then, a 22 G blunt, short beveled needle is inserted into the substance of the muscle and 5 ml of local anaesthetic agent is injected locally. For the 2nd approach of block, biceps is found between the skin and the nerve. So, the biceps muscle is pulled upwards by fingers and the nerve is left behind over the brachialis muscle and humerous (Fig. 23.15).

Then, the needle is inserted perpendicular to the surface of the skin down to the humerous. After contact with the bone by the needle, 5ml of drug is injected. For the 3rd approach of block the lateral cutaneous nerve of forearm which is the continuation of musculocutaneous nerve can be blocked at 1cm proximal to the intercondylar line, immediately lateral to the biceps tendon. Infiltration of 5 ml of LA solution subcutaneously at this site provides an excellent block of this nerve (Table 23.1).

Table 23.1: Musculocutaneous nerve

A. Branches:

1. *Muscular*
   - To the coracobrachialis
   - To the both heads of biceps brachii
   - To the medial part of brachialis (lateral part of brachialis is supplied by radial nerve)
2. *Atricular*
   - To the elbow joint
   - *Sensory*

Lateral cutaneous nerve of forearm

B. Effect of block:

1. *Motor loss*

Biceps and coracobrachialis are paralysed. The brachialis is weakened because a part of it is also supplied by the radial nerve. So, due to paralysis of these muscles flexion of the elbow joint becomes weak. But still it is possible by the unaffected part of the brachialis and superficial flexors of elbow joint in supine position of hand.

2. *Sensory loss*

It is present only over the lateral half of forearm. But clinically this area of sensory loss is less due to the overlapping of the adjacent cutaneous nerve which are not affected.

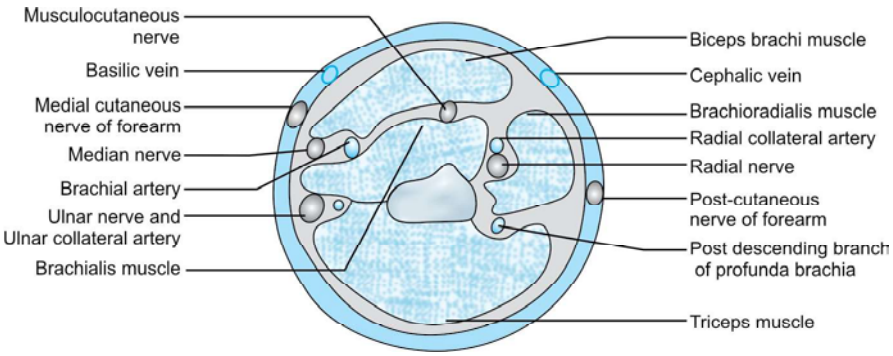

Fig. 23.15: Transverse section passing through the lower one third of the arm

Radial Nerve

The radial nerve can be blocked proximally at the level of arm and also distally at the level of elbow and (Fig. 23.16) wrist. It depends on the purpose of the supplementation of brachial plexus block or individual block of this nerve. Above the elbow, the nerve is a mixed one and contains both the motor and sensory component. But at the wrist, the block of radial nerve is purely sensory.

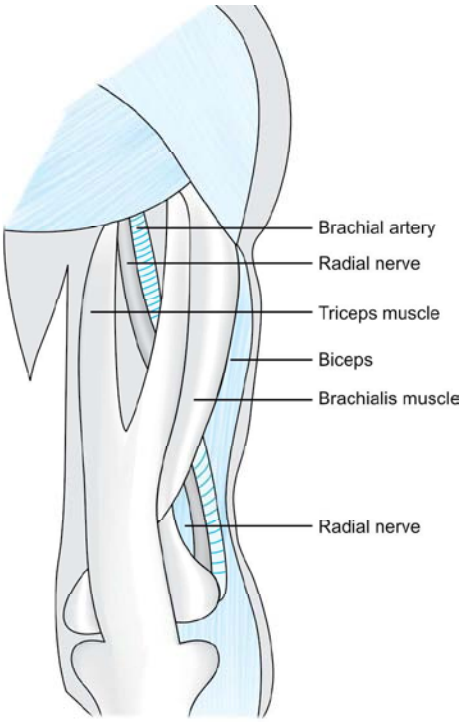

Fig. 23.16: Radial nerve block under triceps muscle and at the proximal site of elbow (posterior surface of nerve)

Anatomy (Fig. 23.17)

Radial nerve is the continuation of the posterior cord of brachial plexus. After exit from the axilla the nerve enter the spiral groove on the post surface of the humerus in between the long and medial head of triceps (1st approach of block of this nerve). At the spiral groove, it gives off branches as the lower lateral cutaneous nerve of arm and postcutaneous nerve of forearm. Then, after running through the spiral groove with arteria profunda brachialis the radial nerve pierces the later intermuscular septum and enters the anterior compartment of arm, 4 to 6 cm above the elbow. In the anterior compartment of arm, the radial nerve reaches in front of the lateral epicondyl where it passes between the epicondyl and the head of the radius (2nd approach of block at the elbow). Here, the nerve divides into deep motor branch (posterior interosseous nerve) and superficial sensory branch. The superficial sensory branch descends with the radial artery along the lateral side of the forearm (Fig. 23.18).

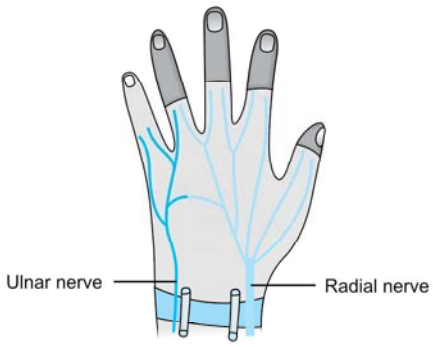

Fig. 23.17: Showing ulnar and radial nerve

Then, 7 cm above the wrist joint or the styloid process of radius the nerve winds round the lateral border of the forearm deep to the tendon of brachioradialis muscle and passes to the back on the dosal surface of the forearm. Then, going to the base of the forearm, it pierces the deep fascia and passes superficial to the extensor reticulum, medial to the cephalic vein (3rd approaches of block at wrist). Finally, it reaches on the back of the hand where it divides into five digital branches, supplying fingers. The motor posterior interosseous nerve descends on the back of the forearm by passing between the superficial and deep fibres of supinator muscle. Then the nerve passes on the abductor policies longus and extensor policis brevis. After that it passes deep to the extensor policis longus and extensor retinaculum to end as pseudoganglia.

The most proximal approach (1st approach) of radial nerve block is selected when the complete motor paralysis of elbow is essential, because at this level the radial nerve supplies all the muscles which are responsible for the movement of elbow joint. For the 1st approach of radial nerve block the lateral edge of the triceps muscle and the musculospiral groove of the humerus are palpated first. Then a blunt needle is introduced between the two heads of the triceps muscle towards the humerous and 5 to 8 ml of LA drug is injected after contact of needle with

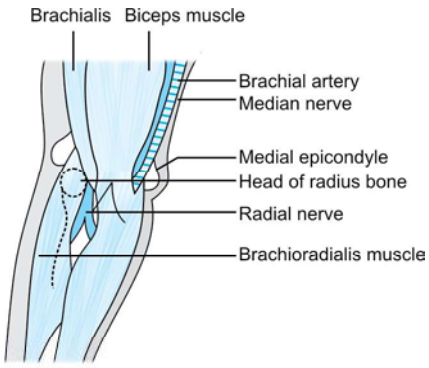

Fig. 23.18: Radial nerve block at antecubital fossa

the bone on the spiral groove is felt. Like other field blocks, the needle is withdrawn and again advanced forward with different directions for one or more injections close to the humerous at different locations (Fig. 23.19).

For the 2nd approach, the radial nerve can be blocked at the elbow as it passes over the anterior aspect of the lateral epicondyle. A 22 G, 4 cm needle is inserted at the intercondylar line, 2 cm lateral to the biceps tendon and is advanced till the bone in encountered. Then the area between the lateral epicondyl of humerous and the head of radius is infiltrated by local anaesthetic agent as a field block. To avoid nerve injury, elicitation of paresthesia should be avoided. If paresthesia is elicited, the needle should be relocated prior to any injection.

The terminal part of the radial nerve is purely sensory and is subcutaneous in the distal forearm. At the distal part of the forearm it first runs overs the radius, then sweeps from the ventral to the dorsal surface of the wrist and supply the area shown in figure. At the wrist level the nerve can be blocked at the site where it is subcutaneous and palpable. For the 3rd approach of radial nerve block (at wrist) the extensor pollicis longus tendon is identified first when the patient extends his thumb. Then needle is inserted subcutaneously over the tendon at the base of the 1st metacarpal bone. The injection should be subcutaneous and superficial to the tendon. 2 ml of LA agent is injected proximally along the tendon and 1 ml is injected as the needle passes at right angle across the 'anatomic snuff box' (Table 23.2).

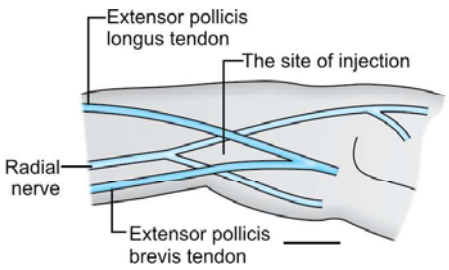

Fig. 23.19: Radial nerve block at the left wrist.

Table 23.2: Fact file of naval nerve

A. Branches

1. *Motor*
   - To the long and medial head of triceps
   - To the lateral part of brachialis
   - To the brachioradialis
   - To the extensor carpi radialis longus and brevis
   - To the supinator
   - All the extensor group of muscle of forearm
2. *Sensory*
   - Posterior cutaneous nerve of arm
   - Lower lateral cutaneous nerve of arm (upper lateral cutaneous nerve of arm is the branch of axillary nerve)
   - Posterior cutaneous nerve of forearm
   - Dorsal digital branches supplying lateral and medial side of thumb, lateral side of index finger upto middle phalanx, adjacent sides of index and middle finger up to middle phalanx and adjacent sides of middle and ring finger upto middle phalanx

B. Effect of block

At the wrist

Only sensory loss of digits supplied by this nerve

At the elbow

- Sensory loss as the wrist
- Motor loss—all the extensor of wrist causing wrist drop. When an attempt is made to extend the fingers, the proximal phalanx remains flexed. But the middle and distal phalangs will be extended by the unaffected interossei and lumbricals.

At the spiral groove

- Sensory loss as wrist
- Motor loss as elbow plus muscles of back of arm.

Ulnar Nerve

Among all the peripheral nerve blocks of the upper extremity, the ulnar enrve block at the level of elbow is most easily performed. But, it is most likely to cause nerve injury from the incorrect technique. It can also easily be accomplished in Guyton's canal at the wrist, in much the same way as the median nerve block in the carpal tunnel. The block of ulnar nerve is usually performed for anaesthesia of the hypothenar region, the fifth finger and the ulnar half of the fourth finger, which is shown in the Figure 23.20.

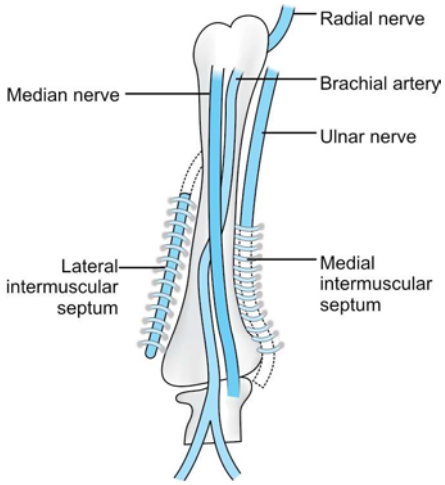

Fig. 23.20: The course of different nerves in right arm (anterior aspect)

Anatomy

After exit from axilla, the ulnar nerve first runs along the medial side of the brachial artery which is a continuation of axillary artery. Then, at the middle of the arm the nerve pierces the medial intermuscular septum from anterior to posterior and runs down on the back of the medial epicondyl of the humerous (site of block at elbow) where it is covered by the arcuate ligament. Ulnar nerve, then, enters the (Fig. 23.21) front side of forearm by running between the 2 heads of the flexor carpi ulnaris and descends downwards on the flexor digitorum profunds muscle. Here, it is overlapped by flexor carpi ulnaries muscle in the upper part, and by the skin and deep fascia in the lower part. The nerve then enters the hand along with the ulnar

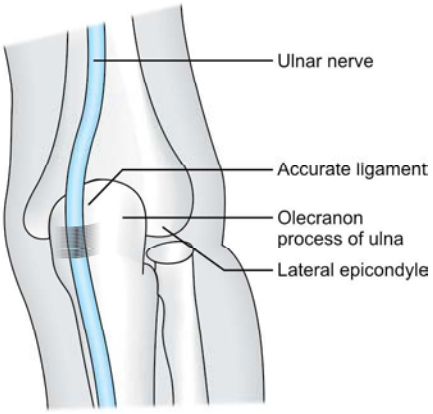

Fig. 23.21: Ulnar nerve block at elbow

artery running in front of the flexor retinaculum, but lateral to the pisiform bone (site of block at wrist). Here, the ulnar nerve is located in the interval between the ulnar artery and the flexor carpi ulnaris tendon (Fig. 23.22).

On entering the hand, it divides into terminal muscular and sensory branches. The muscular terminal branches supply the palmaris brevis, all hypothenar muscles, adductor pollicis, all dorsal interossei, and 3rd and 4th lumbricles. The sensory branches supply the palmar medial side of the little finger and the adjacent palmar sides of the ring and little finger. At the middle of the forearm, the ulnar nerve gives a cutaneous branch which pierces the deep fascia and descends in front of the flexor retinaculum and supply the skin of the medial side of the palm. Another dorsal cutaneous branch arises from the ulnar nerve, 5 cm above the wrist which supplies the medial side of dorsum of hand, medial dorsal side of little finger and adjacent dorsal sides of little and ring finger. The block of ulnar nerve at this side provides only the sensory loss along the ulnar side of the hand, little finger and the ulnar half of ring finger. The ulnar nerve can most easily be blocked at its subcutaneous position which is situated posterior to the medial epicondyl of elbow (block at elbow). But, block at this site is associated with high incidence of neuritis. So, use of very fine needle, avoidance of intraneural injection and small amount of drug reduces this

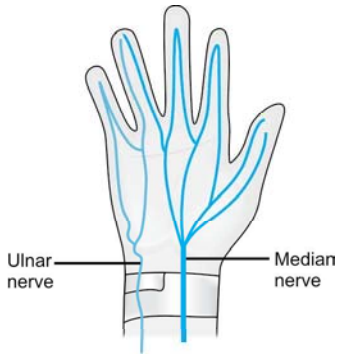

Fig. 23.22: Location ulnar and median nerve

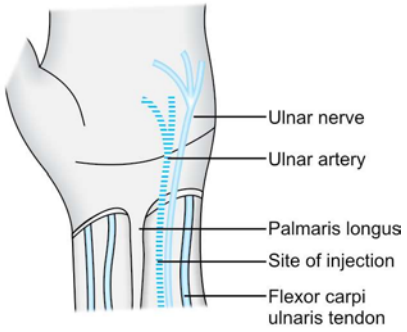

Fig. 23.23: Ulnar nerve block at wrist

incidence. At elbow the LA agent should be injected in a fanwise fashion without elicitation of paresthesia (Fig. 23.23).

At the wrist, the nerve is located in between the ulnar artery and flexus carpi ulnaris tendon, which can easily be defined by forced flexion of wrist. Then, needle is inserted perpendicular to the skin upto the depth of artery and 3 to 5 ml of drug is injected in a fanwise fashion (Table 23.3).

Table 23.3: Fact file of ulnar nerve

A. Branches:

1. *Muscular*
   To the flexor carpi ulnaris, medial part of flexor digitorum profundus, hypothenar muscles, all dorsal interossei, 3rd and 4th lumbricals, adductor policis.
2. *Sensory*
   Palmar and dorsal surface of hand, little finger, medial side of ring finger.

B. Effect of block:

At the wrist

Motor loss: All the intrinsic muscles of hand except those supplied by median nerve, i.e. all interossei, 3rd and 4th lumbricals, hypothenar muscle. Thus it produces claw hand, loss of power of abduction of 2nd to 5th digits, loss of power of adduction of thumb.

Sensory loss: Loss of sensation of little finger and medial side of ring finger.

At the elbow

Motor loss: Same as block at wrist plus paralysis of the medial part of flexor digitorum profunds going to the little and ring finger. So, the distal phalanges of these fingers are not acutely flexed as in claw hand.

Sensory loss: Same as loss at wrist plus medial side of dorsal and palmar aspect of forehand.

Median Nerve

The median nerve can easily be blocked in the antecubital space at the level of elbow or in the carpal tunnel at the level of wrist. The anatomical land marks for the median nerve are constant and are readily accessible for conduction block. The median nerve block is performed for anaesthesia over the median dermatomes of the hand which is shown in Figure 23.24.

Anatomy

The median nerve is formed by the union of medial head coming from the medial cord and lateral head coming from the lateral cord of brachial plexus. In the axilla, this nerve first runs along the lateral side of the axillary artery. Then it exits the axilla and descends on the brachialis muscle still lying at the lateral side of the artery. At the insertion of coracobrachialis muscle, the nerve crosses in front of the artery and then further descends down on the brachialis muscle to reach the cubital fossa where it is covered only by bicipital aponeurosis (Fig. 23.25).

After that, the median nerve enters the forearm between the two heads of pronator teres. Then, it runs downwards in forearm on the flexor digitorum profundus muscle, but deep to the flexor digitorum superficialis muscle. About 5cm above the flexor retinaculum, it becomes more superficial lying only deep to the deep fascia. Now, the nerve enters the palm deep to the flexor retinaculum and through

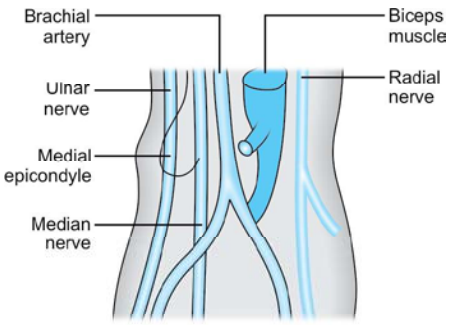

Fig. 23.24: Acute cubital fossa and its contents (left arm)

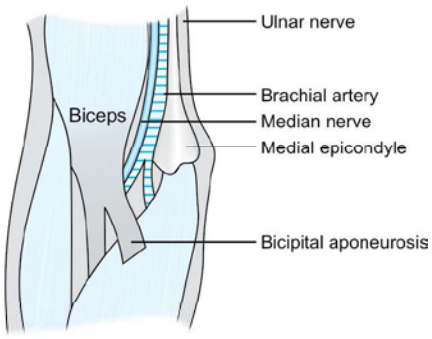

Fig. 23.25: Median nerve block at elbow

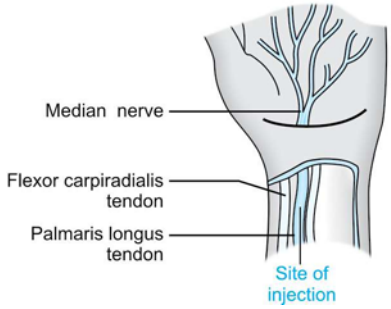

Fig. 23.26: Median nerve block at wrist

the carpal tunnel, i.e. the space between the flexor retinaculum and carpal bones. On entering the palm the nerve supplies the muscles of thenar eminence, 1st and 2nd lumbricals and sensory to the palmar aspect of thumbs, index finger, middle finger and lateral side of ring finger. In the lower part of the forearm a cutaneous branch arises from the median nerve. It pierces the deep fascia and enters the palm superficial to the flexor retina culum to supply the skin of lateral aspect of palm. Block of the median nerve provides only the sensory loss over the palmar aspects of the thumb, index finger, middle finger, radial half of ring finger and nail beds of the same digits. The median nerve can be blocked at elbow in the antecubital fossa or at the wrist. At the cubital fossa where the nerve is only covered by bicipital aponeurosis, the relation of the nerve with the vessels from lateral to medial is biceps tendon, brachial artery and median nerve. This is the major landmark for the median nerve block in the antecubital fossa at the intercondylar line elbow. For the median nerve block in antecubital fossa the brachial artery is palpated first and then 3 to 5 ml of drug is injected medial to the artery (Fig. 23.26).

At the wrist the median nerve is located in between the palmaris longus and flexor carpi radialis tendon and can be blocked by injecting 2 to 3 ml ofv LA agent in between these two tendons, proximal to the wrist crease. For this block the patient is asked to flex the wrist against resistance which help these tendons to be prominent. As the nerve passes deep to the retinaculum, through the carpel tunnel, needle should be passed through the retinaculum with the feeling of loss of resistance and then the drug is injected. A superficial palmar branch of the median nerve, supplying the skin of thenar eminence does not pass below the retinaculum. This branch should also be blocked separately by injecting 0.5 to 1 ml of LA solutions, subcutaneously above the retinaculum (Table 23.4).

Table 23.4: Fact file of median nerve

A. Branches

1. *Muscular*
   To the pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum superficialis, flexor policis longus, lateral part of flexor digitorum profundus, pronator quadratus.
2. *Sensory*
   Skin over the thenar eminence, later half of palm and palmar aspect of fingers including the nailbed of thumb, index, middle; and lateral half of ring finger.

B. Effect of block

1. *At the wrist*
   Motor loss : Thenar muscles and 1st and 2nd lumbricals are paralysed. Thus it causes wasting of thenar prominance and inability to oppose the thumb.
   Sensory loss : Loss of sensation of digits supplied by this nerve. Carpal tunnel syndrome affect this nerve producing wasting of thenar muscles and pain in digits supplied by this nerve.
2. *At the elbow*
   Motor loss: All the muscles of palm supplied by this nerve, all the flexors of wrist, pronator teres and quadratus. Thus it causes loss of flexion of wrist, loss of pronation.
   Sensory loss: Same as loss at wrist.

INTRAVENOUS REGIONAL ANAESTHESIA OF EXTREMITY

This technique was first described by a German surgeon, named August Bier, in 1908. So, it is also called as the Bier's block. During that period, after its introduction, it was very much popular in clinical practice. But, it had gradually lost its popularity due to the evaluation of other less risky procedures of conduction block such as brachial plexus block and other individual nerve block which the help of nerve stimulator.

General Consideration

The Bier's block is an excellent technique of regional anaesthesia for short surgical procedures (<90 minutes) over the extremities, mainly the superior extremity. When the peripheral venous system of extremity is filled with LA agents, then backward diffusion of the LA agents into the tissues provides dense motor and sensory block. The duration of this type of anaesthesia is mainly limited by the length of time that the pneumatic tourniquet can be inflated without any ischaemic injury of limbs which is usually about 60 to 90 minutes. In Bier's block patient's safety depends on the integrity of the pneumatic tourniquet, which must be inflated to a pressure which is high enough to prevent the reaching of LA agent in the systemic circulation and this pressure is maintained until a safe time interval between the inflation and deflation is reached, regardless of the duration of surgery during which period the drug is completely diffused into the tissue. It is because though a very low concentration of local anaesthetic agent is used, still a bolus high volume is injected into the venous circulatory system directly after the tourniquet is inflated. This technique or type of regional anaesthesia can be applied to any surgical procedure distal to the elbow or knee, provided its expected duration is one hour or less and it allows a site for placing a small intravenous

catheter in the distal dorsum of the hand or foot. Due to any surgical reasons when an anaesthetist becomes reluctant to deflate the tourniquet even after exceeding an hour from the time of inflation, then pain elicited by the tourniquet which is usually a normal phenomenon after a specific time interval, can result in failure of this type of RA, even though the sensory anaesthesia at the surgical site is still in effect. On the other hand, very short surgical procedures (under 10 to 15 minutes) should be taken into account and the pneumatic tourniquet should not be deflated within 45 minutes after injection of LA agent, even though the surgery has been completed long before. In orthopedic procedures where vigorous manipulations are required, then attention must also be given to the potentiality of disrupting the integrity of tourniquet and distribution of drug in the systemic circulation after its absorption from the affected limb causing CVS and CNS toxicity. Bupivacaine is not recommended for this Bier's procedure due to the high incidence of its systemic toxicity and death. Other rare complication of Bier's block are compartmental syndrome and loss of limb.

Advantages of Bier's Block

i. Easy administration.
ii. Rapid onset.
iii Rapid recovery.
iv. Complete muscular relaxation.
v. No special skill.
vi. Controllable extent of anaesthesia.

Disadvantages of Bier's Block

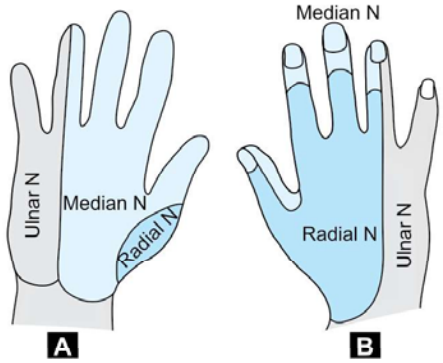
i. Tourniquet discomfort.
ii. Rapidity of recovery leading to post operative pain.
iii. Difficulty in providing blood less field.
iv. Difficulty in exanguination for painful hand.
v. Sudden, accidental or early deflation of tourniquet may lead to toxic reaction.

Technique

As a first step in this technique, an intravenous cannula is placed as distally as possible, for giving LA agent on the upper or lower extremity which is to be blocked. Another intravenous cannula is also placed on the opposite limb for giving drugs in emergency. Double tourniquet is applied on the operated side proximal to the surgical field. After exsanguination of limb by elastic esmarch bandage, the proximal pneumatic cuff is inflated first to approximately 50 to 100 mm Hg higher than the systolic pressure of this patient. Then, calculated total dose of local anaesthetic agent (4 to 6 mg/kg of 0.5% lignocaine without epinephrine and preservative) is injected IV slowly through the canula. Then onset of the effect of regional anaesthesia starts within 5 minutes. If the patient complains of tourniquet pain, then the distal tourniquet which overlies the anaesthezed skin is inflated, and the previous proximal tourniquet which is situated on the non anaesthetized skin is released or deflated. The use of single wide cuff pneumatic tourniquet during intravenous regional anaesthesia allows the lower inflation pressure which causes less incidence of neurological complications in contrast to high inflation pressure with narrow double pneumatic cuffs. Somebody inflates and deflates the proximal and distal cuffs alternately to increase the patient's tolerance. At the end of the completion of surgical procedure, care must also be taken in deflating the tourniquet, so that patient is not suddenly exposed to the bolus dose of local anaesthetic agent which is absorbed from the affected limb causing CVS and CNS toxicity. The tourniquet can safely be released minimum after 25 minutes from its application. It may also be deflated for one or two seconds and reinflated again. Thus, this maneuvers are repeated several times with certain pause between each step to reduce the systematic LA toxicity. If minor CNS or CVS sign appear at any time between the consecutive deflations, then the interval between the deflation of cuff is increased.

DIGITAL BLOCK

The digital branches of the radial, ulnar and median nerve first run in the intermetacarpal interval or space. Then they divide and enter the base of each digit from the four corners, close to the palmar and dorsal surfaces of each digit. The duplication of dorsal and palmar digital nerves demands that the injection technique for digital block must takes into account this duplication of nerves. In addition, these nerves are small and only sensory and would be very intolerant to the intraneural injection of LA agent or hydrostatic pressure produced from outside on the nerve due to increased volume of the drug. A 25 G (or more fine) blunt bevel needle is selected for digital block with a length of 1 inch or less. The injection usually starts with the entrance of needle on the dorsal surface, proximal to the web space. Then the needle is directed to the palmar side, close to the perioteum of the metacarpal head. Elicitation of paresthesia is avoided and if it occurs, the needle is redirected. Then 2 to 3 ml of LA agent is injected as the needle is withdrawn. A good digital block is assured by gentle massage of the web space after injecting the drug and withdraw of the needle (Figs 23.27A and B). Local anaesthetic agent with vasoconstrictors should not be used for the digital block due to the fear of ischaemia and necrosis of fingers. The maximum volume of drug which is usually 2 to 3 ml on each side should not exceed. The excessive volume of drug can cause vascular insufficiency and gangrene as a result of digital artery occlusion by the mechanical pressure effect. Digital nerve block is commonly used and is very effective method for wide varieties of minor outpatient surgical procedures on the digits.



Figs 23.27A and B: Sensory innervation of radial, ulnar and median nerve of the hand. A. Palmar surface, B. Dorsal surface

WRIST BLOCK

Wrist block is a very superficial and easy to perform technique for regional anaesthesia. It is devoid of any systemic complications. So, it should be in the armamentarium of every anaesthesiologist. Actually wrist block is nothing but the ulnar, medial and radial nerve block at the same sitting at the level of wrist. The wrist block is commonly performed for any hand surgery where tourniquet is not required or as a supplementation for incomplete brachial plexus block.

At the wrist, the median nerve is located between the tendons of palmaris longus (medially) and flexor carpi radialis (laterally).The palmaris longus tendon is often made most prominent among all the tendons at the wrist and the median nerve passes immediately lateral to it. At the wrist this nerve can be blocked by inserting a needle at that position (by the lateral side of palmaris tendon) until it pierces the deep fascia or retinaculum when the fascial 'click' is appreciated. If the 'click' is not felt, then the needle is further inserted until it contacts the bone. After contact with bone, the needle is slightly withdrawn for 2 to 3 mm and the local anaesthetic agent is injected.

At the wrist the ulnar nerve is situated between the ulnar artery (pulsation may be felt) and the tendon of flexor carpi ulnaris at the level of the ulnar styloid process. At this level, the ulnar nerve is blocked by inserting a needle under the tendon of flexor carpi ulnaris muscle, close to its styloid attachment. The needle is then advanced further for 5 to 10 mm and 3 to 5 ml of local anaesthetic agent is injected at that site.

At the wrist the radial nerve (superficial branch) runs along the medial aspect of the brachioradialis muscle and lateral to the radial artery. It quits the artery about 7 cm above the styloid process of the radius. At that level, the nerve winds round the lateral border of the forearm between the tendon of brachioradialis and the radius, and then passes to the back of the forearm. Going to the back of the forearm, it pierces the deep fascia and descends superficial to the extensor retinaculum, medial to the cephalic vein. Above the styloid process, it gives off the digital branches for the skin of the dorsal aspect of thumb, index finger, middle finger and lateral half of the ring finger. Several of its branches pass superficially over the anatomical 'snuff box'. The radial nerve block requires a more extensive infiltration because of its less predictable anatomical location and divides into multiple smaller cutaneous branches. A subcutaneous infiltration of 5 ml of local anaesthetic agent, just above the radial styloid process is done aiming medially. The infiltraton is then extended further laterally using another 5 ml of local anaesthetic agent.

LOWER EXTREMITY BLOCKS

Like upper extremity, the lower extremity blocks are less popular. This is because:

i. There is widespread acceptance and safety of spinal and epidural anaesthesia for lower extrimity.
ii. Like brachial plexus, nerves supplying the lower limbs are not anatomically clustered at one place where they can easily be blocked
iii. With anatomical consideration these blocks are technically more difficult and require more training
iv. Persistent block of any major nerve of lower extremity makes the patient unambulatory and causes an unacceptible side effect for outpatients (Fig. 23.28).

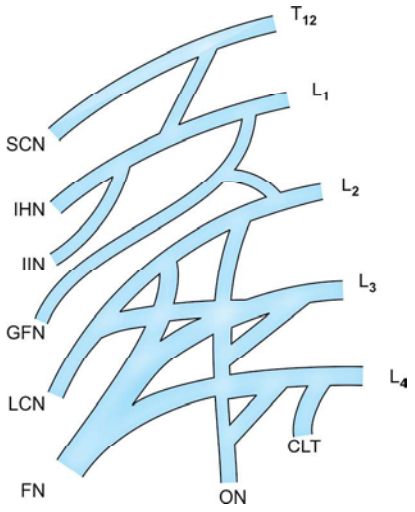
But, still there are some advantages of lower extremity block. These are:

i. Postoperative pain relief,
ii. Lack of complete sympathectomy (as is occurred in central neuroaxial block) which make it ideal for very ill patients.

Nerves supplying the lower extremity are sciatic, femoral, lateral femoral cutaneous and obturator nerve. These nerves can be blocked as proximal as at the lumbosacral plexus or as distal as at the toes, depending on the surgical procedure and the postoperative plan for analgesia.

Anatomy

The nerves supplying the lower extremity is derived either from lumber plexus and/or sacral plexus. The lumbar plexus is formed by the anterior or ventral rami of upper four lumbar spinal nerves (L_1, L_2, L_3, L_4). The 1st lumbar spinal nerve receives a contribution from T_{12} spinal



SCN = Subcostal nerve, IHN = Iliohypogastric nerve, IIN = Ilioinguinal nerve, GFN = Genitofemoral nerve, LCN = Lateral cutaneous nerve of thigh, FN = Femoral nerve, ON = Obturator nerve, CLT = Contribution to lumbosacral trunk

Fig. 23.28: Formation of lumbar plexus

(subcostal) nerve. And the anterior rami of the 4th lumbar spinal nerve gives a contribution to the L_5 spinal nerve forming the lumbo sacral trunk which take part in the formation of sacral plexus. The lumbar plexus lies in the space situated between the psoas major (infront) and quadratus lumborum (behind) muscle. This space is called the psoas compartment. So, the lumbar plexus block at this level is also called the 'psoas compartment block'.

The branches of lumbar plexus emerges from the lateral border of the psoas muscle. These branches are:

i. Iliohypogastric N. (L_1),
ii. Ilioinguinal N. (L_1),
iii. Genitofemoral N. (L_1, L_2),
iv. Lateral femoral cutaneous nerve of thigh (L_2 L_3 dorsal division),
v. Femoral N. ($L_{2,3,4}$ dorsal division),
vi. Obturator N. ($L_{2,3,4}$ ventral division).

The sciatic nerve is not the only branch of lumbar plexus, but it arises from both the lumbar and sacral plexus. It is formed by the combination of two major nerve trunks: tibal nerve (ventral branches of L_4 L_5 S_1 S_2 S_3) and common peroneal nerve (dorsal branches of L_4 L_5 S_1 S_2 S_3). The posterior cutaneous nerve of thigh (dorsal division of S_1 S_2 and ventral division of S_2 S_3) is a branch of sacral plexus.

LUMBAR PLEXUS BLOCK

The lumbar plexus block is usually indicated for knee surgery, any surgery on thigh (only antero lateral aspect), saphenous vein stripping, for chronic pain management of lower extremity, etc. It eliminates the need for individual nerve block such as the femoral nerve, lateral femoral cutaneous nerve of thigh and obturator nerves. When combined with sciatic nerve block, this lumbar plexus block can be used for any surgery on lower extremity.

The lumbar plexus can be blocked by two technique: (i) psoas compartmental technique or block and (ii) '3-in-1' technique or perivascular block.

Psoas Compartment Technique

In this technique needle is placed into the space between the psoas major and the quadratus lumborum muscle and a large volume of LA drug is injected into this space to block the iliohypogastric, ilioingninal, genitofemoral, femoral, obturator and lateral femoral cutaneons nerve of thigh causing surgical anaesthesia of groin, hip and anterolateral portion of thigh. This technique must be combined with the sciatic nerve block for regional anaesthesia of the entire lower extremity (Fig. 23.29).

Technique

The patient is first placed in the lateral position with the hips are flexed and operated side is up. Then the intercrestal line is identified which corresponds to the 4th lumbar spine or L_3 – L_4 intervertebral space. From 4th lumbar spine, a point which is situated 3 cm caudal and 5 cm lateral is marked. This is the site for injection for psoas compartmental block. Then after proper antiseptic skin preparation a 22 G and 15 cm long needle is advanced perpendicular to the skin from the site of injection till it contacts with the 5th lumbar transverse process. After that the needle is slightly withdrawn and redirected in cephalad direction till it slips off the tranverse process of 5th lumbar vertebra. Now, it is sure that the needle is within the substance of the psoas muscle. At this position, high resistance should be felt if a glass syringe filled with air or saline is connected with the needle and piston is pushed. Now, the needle which is already attached with the 20 ml air or saline filled syringe is slowly advanced till the loss of resistance is detected as like epidural technique. Nerve stimulator offers further confirmation of this point by motor evoked response from the femoral or obturator nerve. The needle is manipulated until the twitches of quadriceps muscle are seen or felt at 0.5 mA or less voltage. Thus, following successful identification of the lumbar plexus in psoas compartment, 30 to 40 ml of local anaesthetic agent of choice is injected with intermittent aspiration to rule out any intravascular injections (Fig. 23.30).

The complication of psoas compartment block are: Increased risk of possible epidural block, subarachnoid block (the dural sleeve over the nerve root containing subarachnoid space is no more than 2 to 4 cm from the site of injection), intravascular injection; peripheral nerve damage, sympathetic block secondary to extravasation of local anaesthetic agent, etc. Though unilateral sympathetic block has little significance, still one of the advantage of psoas compartment block over the spinal or epidermal anaesthesia is that the incidence of hypotension is less if this occurs. The proximity of the pelvis and pelvic viscera to the psoas compartment makes the infection a potential issue of this type of block especially, if the needle makes undetected contact with the lumen of these

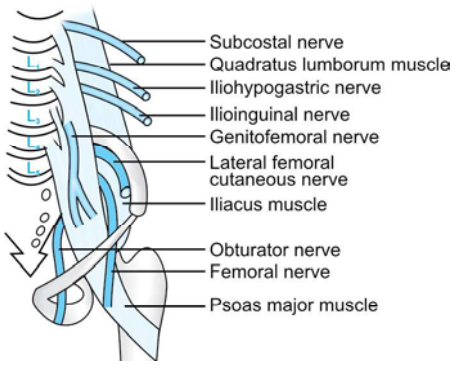


Fig. 23.29: Nerves arising from lumbar plexus

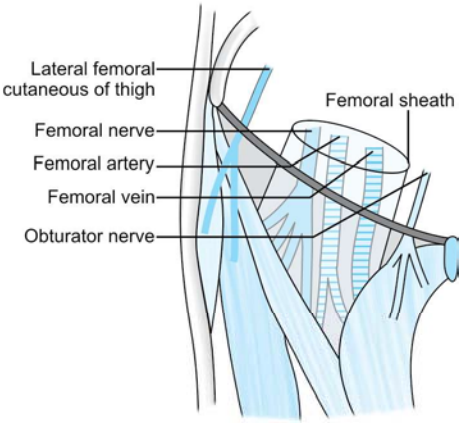

Fig. 23.30: The site of femoral nerve block

visceras. This psoas compartment block requires adequate sedation and analgesia as these are very deep invasive procedure and the needle traverses the multiple muscular planes. The success rate of this block is dependent on the volume of LA agent. A volume of less than 30 ml in an adult patient of 70 kg weight are less reliable in achieving anaesthesia of the entire lumbar plexus. When surgery requires the use of tourniquet or anaesthesia is required on the posterior aspect of the leg, then the sciatic nerve block must should accompany the psoas compartment block. This can easily be achieved in the same patient with the same position as psoas compartment block.

Perivascular Approach (3-in-1 Femoral Block)

Technique

This technique is the modification of the classic approach of single femoral nerve block in the femoral triangle. The idea of this modified technique is that a sheath surrounding the nerve roots while arising from lumbar plexus extends downwards as the femoral sheath in the femoral triangle. So, it acts as an enclosed conduit around the femoral nerve, artery and vein for the spread of local anaesthetic agent proximally, if it is injected within the femoral sheath below the inguinal ligament at the femoral triangle, maintaining a distal pressure. Thus, it results in proximal spread of LA solution into the psoas compartment-from femoral triangle. The femoral sheath is confluent all the way proximally upto the origin of the nerves from the lumbar plexus in the prevertebral area of the lumbosacral region. At the same proximal location, the lateral femoral cutaneous nerve and the obturator nerves are also formed and are situated within this sheath. So if local anaesthetic drugs tracks proximally, it will also bathe these three nerves at their origin; resulting in '3-in-1' blocks (femoral nerve, lateral femoral cutaneous nerve and obturator nerves).

The modification of the technique which converts the only femoral nerve block into the '3-in-1' block mainly involves the pressure, applied distal to the injection site in the femoral triangle and the increased volume of local anaesthetic agent (20 versus 40 ml). This method also requires selecting the site of injection as close to the inguinal ligament as possible. The sheath covering the femoral nerve, artery and vein becomes incomplete distally at a variable distance just below the inguinal ligament. So, beyond this point any attempt to fill the sheath and try to induce proximal spread of LA agent will be unsuccessful. Placement of pressure distal to the injection site in the femoral triangle must be as complete as possible, but without disrupting the needle placement within the femoral sheath. Confirmation of needle placement within the sheath is not different from that of the classical approach of individual femoral nerve block.

A continuous '3-in-1' femoral block can also be accomplished with insertion of a catheter within the femoral sheath of femoral triangle. If the femoral sheath is catheterized correctly and the catheter is advanced for upto 5 to 8 cm proximally, then the injected LA solution will be very close to the lumbosacral plexus and the complete block of all the nerves of the plexus becomes a high probability.

The inguinal ligament is marked as a line, connecting the pubic tubercle and the anterior superior iliac spine. Then, the femoral artery is marked by its pulsation-just below the injurinal ligament. After that a short beveled, 22 G and 5 cm long needle is advanced lateral to the artery in cephalad direction after piercing the skin, subcutaneous tissue and femoral sheath. Then 20 to 40 ml of drug is injected incrementally after the negative aspiration test while applying pressure by fingers distally on the femoral sheath. By 20 ml drug femoral and lateral femoral cutaneous nerve block can be predicted. But obturator nerve block may require minimum 30 ml of drug.

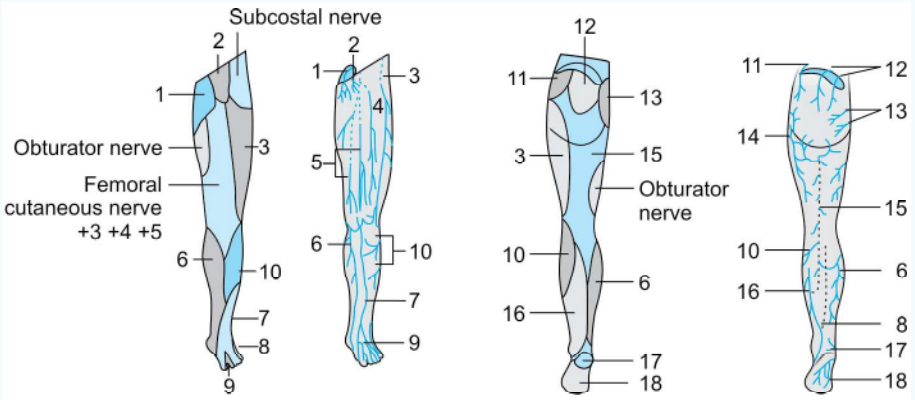
INDIVIDUAL NERVE BLOCK OF LOWER EXTREMITY

Femoral Nerve Block (Fig. 23.31)

After formation with in the substance of psoas major muscle, the femoral nerve emerges from the lateral border of it. Then the femoral nerve descends downward lying in the groove between the iliacus and psoas muscle. Here, the nerve innervates both the psoas and the iliacus muscles. Then, it enters the thigh passing beneath the inguinal ligamant lateral to the femoral artery. Here, the nerve also lies in the groove between the iliacus and the psoas muscle. At this point femoral nerve divides into anterior and posterior divisions which then subsequently break into multiple branches and supply the motors to the quadriceps group of muscles and the sartorious muscles and sensory over the skin of anterior thigh from inguinal ligament to knee and as saphenons nerve (sensory) on the medial side of leg from knee to the big toe and supplies articular branches to hip and knee joint. Beyond the inguinal ligament, the femoral nerve does not represent as a discreet structure, but has split into a bundle of spaghetti strands.

Practical Application

The only femoral nerve is blocked for virtually some minor specific surgical procedures on the upper part of thigh and for any lower extremity procedure where immobility of the knee joint is necesary or the use of pneumatic tourniquet are essential. Practically the isolated femoral nerve block is primarily used in combination with other peripheral nerve block. It can be used alone for: (i) small surgical procedures limited only on the anterior thigh, for example muscle biopsy, skin grafting, etc. (ii) knee arthroscopy and any operation on patella, (iii) surgical repair of the midfemoral shaft fracture, e.g. acute pain relief, reduction and traction placement in the setting of an acute fracture of shaft of femur, (iv) postoperative pain



1. **Ilioinguinal nerve (L_1):** It escapes through the lateral part of superficial inguinal ring—most of its branches go to scrotum or libia majora—some of its branches supply skin over the medial adjacent part of thigh.
2. Femoral branch of genitofemoral nerve ($L_{1,2}$): It pierces the deep fascia 2cm below the inguinal ligament and slightly lateral to the saphenous opening—supplies an area of skin, about size of the palm of hand, immediately below the inguinal ligament.
3. Lateral (femoral) cutaneous nerve of thigh ($L_{2,3}$): Discussed in the text.
4. Intermediate femoral cutaneous nerve ($L_{2,3}$): It is a branch of femoral nerve-pierces the deep fascia in the midline of thigh—extends up to the knee.
5. Medial femoral cutaneous nerve ($L_{2,3}$): It is a branch of femoral nerve—pierces the deep fascia on the medial side of thigh—divides into two—anterior and posterior branch—extends upto the knee.
6. Saphenous nerve ($L_{3,4}$): Discussed in the text.
7. Superficial peroneal nerve ($L_{4,5}$ S_1): Discussed in the text.
8. Sural nerve: It supplies the lateral part of the dorsum of the foot.
9. Deep peroneal nerve: It supplies the adjacent sides of 1st and 2nd toes.
10. Lateral cutaneous nerve of calf: It arises from the common peroneal nerve on the lateral head of gastrocnemius—pierces the deep fascia almost at once and descends to supply the skin over the lateral and anterior surface of upper part of leg.
11. Lateral cutaneous branch of subcostal and iliohypogastric nerve: They supply the upper and lateral gluteal region of thigh.
12. Lumbar nerves: They are the branches of dorsal rami of L_{1-3} lumbar spinal nerves and supply the upper medial region of thigh.
13. Sacral nerves: They are the branches of dorsal rami of S_{1-3} sacral spinal nerves and supply the upper medial region of thigh.
14. Lateral (femoral) cutaneous nerve of thigh: (it is the same nerve numbered in figure as 3). It supplies the lower lateral region of thigh.
15. Posterior cutaneous nerve of thigh ($S_{1,2,3}$): It arises from sacral plexus—comes out of pelvis through greater sciatic foramen under coverage of gluteus maximus muscle—lies on the medial border of sciatic nerve—leaving the gluteal region it enters the back of thigh—runs downwards under the deep fascia—pierces the deep fascia at the back of knee—terminal branches descend downwards upto halfway of the back of leg—supplies gluteal region, perineal region, back of thigh and upper part of the back of the leg.
16. Peroneal (sural) communicating branch: It arises from common peroneal nerve in popliteal fossa together with lateral cutaneous nerve of calf-pierces deep fascia—passes downwards to join sural nerve—supplies skin over proximal 2/3 of the back of the leg with sural nerve.
17. **Medial calcaneal branch:** It arises from tibial nerve at ankle-pierces the flexor retinaculum-supplies the skin of the posterior and lateral surfaces of the heel.
18. **Medial and lateral plantar nerves:** They are the terminal branches of posterior tibial nerve-supply the whole sole and planter surface of digits.

relief for surgical procedures on leg or knee (Fig. 23.32).

Technique

For the classical individual femoral nerve block the important anatomical landmark is the point which is situated below the inguinal ligament and immediately lateral to the pulsation of the femoral artery. After a proper antiseptic skin preparation a skin wheal is created by LA agent just 1 to 2 cm lateral to the femoral pulse, at the level of femoral crease. It is to be noted that the femoral crease is located 2 to 4 cm below the inguinal ligament. For 'single shot femoral block', a short (< 1 inch) blunt-bevel needle is usually used and it will allow the good appreciation of needle's entry into the femoral sheath. The needle is first inserted lateral to the femoral artery and is then directed parallel to the artery in a cephalad and posterior direction, within the sheath at an angle of 45° to the skin. The proximity of the needle to the nerve can be confirmed by the feeling of entry of needle into the sheath. An alternative to this technique is the field block by injection of LA agent at multiple sites.

The confirmation of the proximity of nerve to the needle is also done by the elicitation of paresthesia or by the use of nerve stimulator by eliciting the motor-evoked response in the quadriceps group of muscles. The ultimate goal is to obtain twitches in quadriceps muscle or patella at the minimal voltage of 0.4 mA or less. Success

with nerve stimulator technique requires differentiation between the evoked motor response and the direct stimulation of muscles due to the immediate vicinity of the tip of the needle from where the current is discharged directly to the muscle. When the sartorius twitches are obtained first as motor evoked response, then the needle should be redirected which subsequently and promptly results in the stimulation of quadriceps muscle. Injection of local anaesthetic agent only after stimulation of the sartorius muscle may result in failure to achieve the femoral block. For isolated femoral nerve block, 10 to 20 ml of local anaesthetic drug within the femoral sheath at the femoral triangle will accomplish the complete block, whereas larger of LA agent volume with technique modification results in '3-in-1' block (Fig. 23.33). The advantages of performing the isolated femoral nerve block at the level of femoral skin crease over performing the block at the level of inguinal ligaments are: (i) more superficial position of the femoral artery and nerve, (ii) greater width of the femoral nerve, (iii) more consistent femoral nerve-artery relationship and (iv) more consistent results of block. The isolated femoral nerve block is a superficial one and does not result in significant patient discomfort. Thus, light premedication is usually sufficient.

Because of the proximity of femoral artery and vein, the most likely complication of attempted femoral nerve block would be haematoma due to the puncture of vessels. Intravascular injection is also very likely. Intraneural injection is also possible, but unlikely because of the extensive branching of the nerve at the site of the attempted block. Poor site preparation or poor care of the continuous catheter (if it is used) would make the infection of injection site common and it is due to its proximity to the groin.

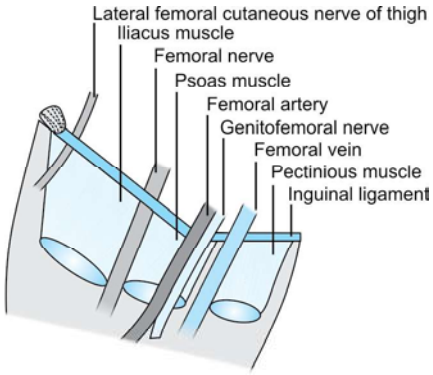

Fig. 23.33: Anterior aspect of high showing different site for injection of different nerve block

The femoral nerve is fully enclosed in a sheath which is extended downwards up to orjust below the inguinal ligament. This is an ideal site for catheter placement within the sheath for continuous femoral blockade. The most common technical approach to this procedure is the Seldinger technique. In this method, a smaller pliable, non-traumatic catheter is inserted through a larger, non-permanent catheter. Proper intra sheath placement of catheter is most commonly confirmed by motor evoked response using a nerve stimulator. However, ideal confirmation of placement is accomplished with injection of LA agent through the catheter, while the stimulation is still performed where augmentation followed by extinction of muscular contraction is observed.

The continuous femoral nerve block by catheter has an unique place for long-term postoperative pain relief after surgery. Low concentration local anaesthetics can provide pain relief without motor block. Bupivacaine of 0.125% concentration is ideally suited for only pain relief with minimal resultant toxicity or motor block. Due to close proximity to groin. The site of insertion of needle and catheter for femoral nerve block mandates sterile procedure and proper dressing to avoid infection. Like other catheter technique, nerve trauma and catheter breakage are also potential complications here.

Lateral (Femoral) Cutaneous Nerve Block

Lateral (femoral) cutaneous nerve of thigh (L2 L3) is a pure sensory nerve and originates from the dorsal branches of ventral rami of 2nd and 3rd lumbar spinal nerve. It provides only sensory innervation to the lateral side of the thigh above the knee. After its origin, it moves ventrally and laterally through the psoas compartment between the psoas and iliacus muscle, immediately caudal to the ilioinguinal nerve. Then after emerging from the lateral border of the psoas muscle it descends over the iliacus muscle but under the iliac fascia. Then it enter the thigh deep to the inguinal ligament, 1 to 2 cm medial to the anterior superior iliac spine. Distal to the inguinal ligament, the nerve divides into anterior and posterior branches in the thigh. The anterior branch becomes superficial after piercing the deep fascia about 10 cm distal to the anterior superior iliac spine and supply the skin over the anterior and lateral side of the thigh as far as upto the knee. The posterior branch pierces the fascia lata at higher position than the anterior branch and directly supply the skin over the lateral surface of thigh extending from the greater trochenter to about the mid thigh. This nerve has no motor supply, so stimulation of this nerve by stimulator does not produce any motor evoked response and is not helpful (Fig. 23.34).

The site of injection for the block of this nerve is 2 cm medial and 2 cm caudal to the anterior superior iliac spine. After proper antiseptic skin preparation, for the block of this nerve a 22 G and 4 cm long needle is inserted perpendicular to the skin until a sudden loss of resistance is felt which indicates the passage of needle through the fascia lata. Then the needle is gently advanced just slightly beyond this resistance and a volume of 10 to 15 ml of LA solution is injected fanwise below and above the fascia. This procedure is again repeated for second time with a slightly different direction of the needle. Multiple injection sites make this field block technique successful. This nerve block is indicated only for the superficial minor surgical procedures which require sensory

but no motor block of the lateral side of the thigh, for example simple muscle biopsy from vastus lateralis, skin graft harvesting from upper part of lateral thigh, meralgia paresthetica, etc.

Obturator Nerve Block

The obturator and the genitofemoral nerves are rather large branches of the lumbar plexus. They provide sensory innervation over the inguinal area, femoral triangle, medial part of the thigh, knee joint, hip joint and as well as the motor fibres to the adductors of thigh such as adductor longus, adductor brevis, adductor magnus, obturator, internus, obturator externus, etc. This relatively large area of sensory and motor coverage by this nerve has proved the potentiality or wide applications of block of this nerve in surgical anaesthesia, postoperative analgesia and chronic pain management over this area (Fig. 23.35).

Anatomy

The obturator nerve arises from the ventral division of anterior rami of L_2, L_3, L_4 spinal nerves. It descends first through the substances of psoas major muscle upto the sacroiliac joint where it pierces out the medial border of this muscle and passes down behind the bifurcation of common iliac vessel. It then descends over the fascia covering the obturator internus muscle and subsequently runs on the periosteum of ischium bone. Then, it descents through the pelvis, along its lateral wall and in close proximity to the inferolateral wall of bladder, bladder neck and lateral wall of prostetic part of the urethra. Here, it accompanies the obturator artery and vein. Finally, it reaches the obturator canal through the obturator foramen and exits into the thigh from pelvis after dividing into anterior and posterior divisions.

The anterior branch of obturator nerve provides: (i) sensory supply to the skin over the inner part of the thigh, hip joint, (ii) cutaneous branch to the subsartorial plexus and (iii) several motor branches to the adductors of the thigh (pectineus, adductor longus and the adductor brevis). The posterior branch supplies the motor to the posterior group of adductors of thigh (adductor brevis, adductor magnus and obturator externus) and an articular branch to the knee joint.

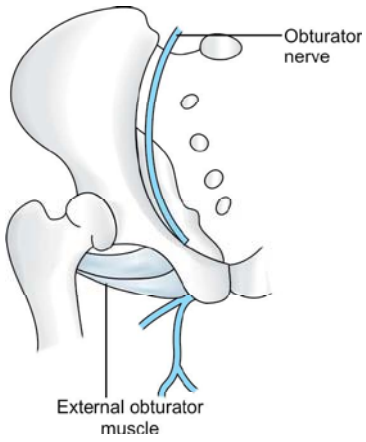

Fig. 23.35: The site of obturator nerve block

Clinical application

The obturator nerve can most easily be blocked with other nerves by using the same approach for the block of lumbosacral plexus. But it can also separately be blocked the for following procedures such as:

i. for superficial surguries over the medial part of the thigh,
ii. to relief spasm of adductors of the hip joint which causes relaxation of the medial thigh,
iii. to relieve intractable hip pain due to osteoarthritis,
iv. as a diagnostic aid for pain syndromes in the hip joint, inguinal area, or lumbar spine,
v. muscle biopsy and tendon transfer or release from medial thigh,
vi. any lower extremity procedure requiring the prolonged use of a pneumatic tourniquet.

The individual block of obturator nerve is very difficult for any anaesthesiologist and very uncomfortable for the patient, even under ideal conditions. Usually the obturator nerve block is combined with other nerve block in the following conditions such as: (i) superficial surgery of thigh (combined with femoral and lateral femoral cutaneous block), (ii) knee surgery (combined with femoral, lateral femoral cutaneous and / or sciatic nerve block).

Technique

The patient is placed in the supine position and the anaesthesiologist should stand at the patient's side which is to be blocked. The leg should be flexed at the knee joint and should be slightly abducted to make the adductor longus tendon prominent, close to its attachment to the pubic bone i.e pubic tubercle. The site of injection or the needle's entry point is 2 cm lateral and 2 cm caudal to this pubic tubercle. At this point the needle will enter medial to the

femoral artery and above the tendon of the adductor longus, but midway between the pubic tubercle and femoral artery and 2 to 3 cm below the inguinal ligament.

To avoid patient discomfort, a skin wheal should be created which is followed by injection of local anaesthetic agent at deeper level. Once the tissues have been prepared, the needle used for the block is first directed from the skin surface toward the inferior pubic ramus until contact is made with the bone. When the contact with bone is made, then the needle should be 'walked off' the inferior ramus in a dorsal and distal direction until it begins to slip into the obturator canal. Then the proximity of the needle tip to the nerve can be confirmed by three ways : (i) creating field block with relatively more volume of drug and repositioning the needle, (ii) eliciting paresthesia on the medial part of the thigh and (iii) using a nerve stimulator to elicit the movement of adductor group of muscles. Any of these strategies requires 10 to 20 ml of drug.

The complications of obturator nerve block are same as that of others such as nerve damage, intravascular injection, haematoma, sepsis, etc. The most common complication of attempting this block is excessive patient discomfort. The failure rate for successful block of this obtutator nerve is also and high this is because of the location of it. Higher infection rate may also be a concern with this nerve block than with others.

Sciatic Nerve Block

Combined with other nerves, the sciatic nerve block is also required for most of the surgeries over the lower extremity and for all the procedures requiring application of pneumatic tourniquet. The nerve can be blocked at the hip both from the anterior and posterior approach and this is known as the sciatic block. The terminal branches of the sciatic nerve also can be blocked isolatedly at the knee and below of it. At the knee, the block of the component of the sciatic nerve is called the popliteal block. Individual peripheral branches of the sciatic nerve also can be approached such as the common peroneal nerve near the fibular head and the other branches at the ankle as a component of ankle block (Fig. 23.36).

Anatomy

The sciatic nerve is the thickest and the largest nerve in our body, with root value of L_4, L_5, $S_{1,2,3}$. Its width is 2 cm. It leaves the pelvis with the posterior femoral cutaneous nerve of thigh (a branch of sacral plexus) through the greater sciatic foramen below the pyriformis muscle but within the sciatic notch. Then, it descends between the greater trochanter of the femur and the ischial tuberosity and passes distally under the gluteal muscles in the sciatic groove, running just over the lesser trochanter of the femur. Then, it becomes superficial at the lower border of the gluteus maximus muscle and descends downwards along the posterior aspect of the thigh lying on the adductor magnus muscle up to the popliteal fossa. At the popliteal fossa, the common trunk of the sciatic nerve splits into two distinct entities—the tibial and the common peroneal nerve, although they run together within a fibrous sheath until just above the knee.

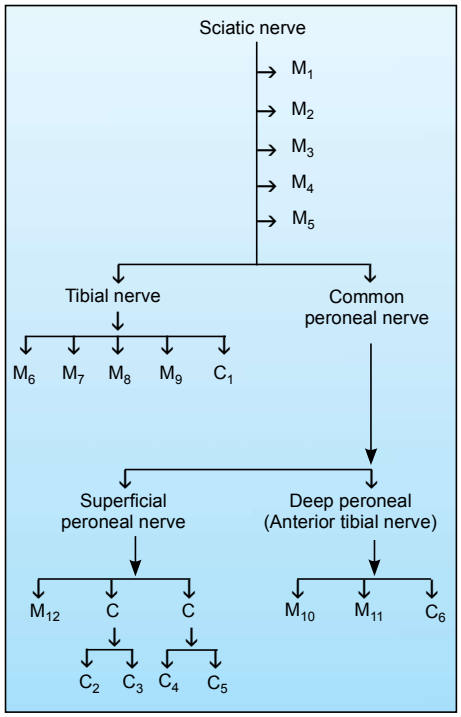

Fig. 23.36: M_1 = Semi-membranosus, M_2 = Ischial fibres of adductor magnus, M_3 = Semi-tendinosus, M_4 = Long head of biceps femoris, M_5 = Short head of biceps femoris, M_6 = Both heads of gastrocnemius, M_7= Plantaris, M_8 = Soleus, M_9 = Popliteus, M_{10}= Tibialis anterior, M_{11} = Extensor digitorum longus and brevis, Extensor hallucis longus, 1st and 2nd interossei, M_{12} = Peroneus longus and brevis, C_1 = Sural nerve, C_2 = Adjacent sides of 3rd and 4th toes, C_3 = adjacent sides of 4th and 5th toes, C_4 = Medial side of great toe, C_5 = Adjacent sides of 2nd and 3rd toes, C_6 = Adjacent sides of great toe and 2nd toe

The sciatic nerve block provides paralysis to the hamstring group of muscles, sensory anaesthesia over the posterior aspect of the thigh and sensory anaesthesia of the entire leg below the knee except a medial strip of skin which is innervated by the saphenus nerve, a branch of the femoral nerve. Since the branches to the hamstring muscles depart the sciatic nerve significantly below the level of the blockade, therefore the twitches of these muscles can be accepted as a sign of reliable localization of the sciatic nerve by the nerve stimulator.

Clinical Application

Sciatic nerve block together with the femoral or saphenons nerve block can be used for any surgery below the knee that does not require toruniquet. Toruniquet can not be applied in this type of combination of block because sensory supply of thigh remains intact. This type of combination of peripheral nerve block avoids sympathectomy and its complication which are common consequences of central neuraxial block So, this type of combination of sciafic, femoral, and raphenous nerve block can be taken as alternative to central neuraxial block. Therefore, its use may be advantageous in cases in which any shift in haemodynamics may be deleterious, such as patient with significant aortic stenosis. Sciatic nerve can be blocked by two

approaches; posterior approach and anterior approach.

Technique

Posterior approach

The patient is positioned laterally with the leg to be blocked should be up and both the hip and knee is flexed. At first a line is drawn connecting the posterior superior iliac spine to the greater trochanter of femur (line A). Then, a perpendicular line (line B) is drawn bisecting the line A. After that another line is drawn from the greater trochanter to the sacral hiatus (line C). Thus intersection of line B and line C is the point of needle entry. After proper antiseptic skin preparation a 22 G and 12 cm long needle is introduced perpendicularly through the skin, till the paresthesia is elicited or bone is contacted. If bone is encountered, then the needle is redirected in lateral or medial direction. Nerve stimulator may also be useful in locating the nerve (Fig. 23.37).

For nerve stimulator, a 100 mm long insulated needle which is connected to a stimulator (initial current 1.5 mA, 2 Hz) is gradually inserted perpendicularly to the skin at the site of injection which is described above. As the needle is gradually advanced to the deeper plane, then a twitch of the gluteus muscles are observed first. This is due to the direct stimulation of muscle by current. Once the twitching of gluteus muscle disappear with the further needle advancement, then the stimulation of sciatic nerve is obtained. The stimulation of sciatic nerve is recognised by the contraction of hamstring group of muscles supplied by the tibial and common peroneal nerve. Typically, the twitching of hamstrings group of muscles are observed first. Then, with the minimal further advancement of needle the twitches of foot are also readily observed. When this maneuver fails to localize the sciatic nerve, the needle is withdrawn up to the skin and is again redirected. The sciatic nerve is typically located at the depth of 5 to 8 cm from skin in an average size adult patient. Once the stimulation of foot is obtained by 0.2 to 0.4 mA or less amount of current then it is thought that the needle is in correct position and 20 to 30 ml of local anaesthetic agent is injected. The sciatic nerve block is of very deep in nature. So, adequate analgesia and sedation is necessary during this procedure to ensure the patient's satisfaction and comfort.

Anterior approach

This approach is applicable when the patient cannot be positioned laterally due to pain or lack of cooperation. The another advantage of anterior approach for sciatic nerve block is that this approach is very convenient and also allows the performance of femoral nerve block in the same position which subsequently shortens the time required to complete the block of both the nerves. With patient in supine position, a line is drawn over the inguinal ligament from the anterior superior iliac spine to the public tubercle (line A). Then, a second line is drawn parallel to the previous line begining at the tuberosity of greater trochanter (line B). After that a third line is drawn perpendicular to line A at the juncture of lateral 2/3 and medial 1/3 (line C). Then, intersection of line B and line C is the point of needle entry for the block of sciatic nerve through anterior approach. After proper antiseptic skin preparation a 22 G and 12 cm long needle is advanced perpendicular to the skin till it contacts with the bone which is lesser trochanter. Needle is then redirected medially passing the femur and paresthesia is sought. At that position, 20 ml of LA drug is injected incrementally after the negative aspiration test (Fig. 23.38).

If nerve stimulator is used, then the proper position of needle is recognised by stimulation of the sciatic nerve which results in rhythmic movements of the foot (simultaneous plantar or dorsi flexion).

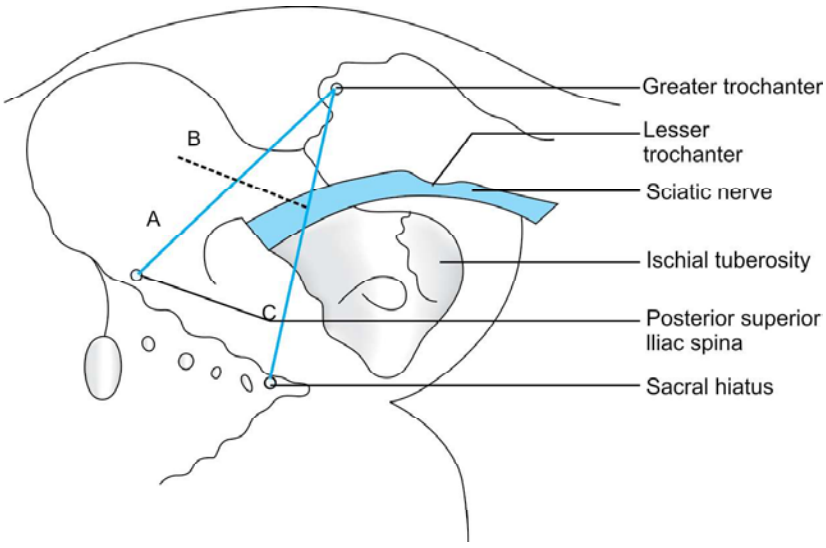

Fig. 23.37: Sciatic nerve block. Posterior approach

NERVE BLOCK AROUND KNEE

Just as the terminal branches of the nerves of brachial plexus can be blocked distally around the elbow and wrist joint, similarly

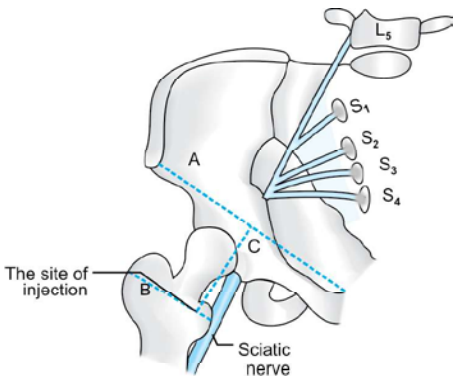

Fig. 23.38: Sciatic nerve block, anterior approach

the individual terminal branches of the nerves of lower extrimity arising from the lumbosacral plexus can be blocked around the knee, ankle and foot depending on the objective.

Popliteal Block

By this technique the components of the sciatic nerve such as the tibial and the common peroneal nerve can be blocked together in popliteal fossa behind the knee. With the saphenous nerve block this popliteal block can also be used for (Fig. 23.39) any surgery at any site on leg, ankle and foot. The popliteal fossa is formed above by the semi tendinosus and semi- membranosus tendon medially and biceps tendon laterally and below by the two heads of gastrocnemious. Within the fossa, from medial to lateral are situated popliteal vein, popliteal artery and sciatic nerve. Proximal to the flexion crease of knee, the terminal branches of sciatic nerve, i.e. the tibial and common personal nerves are bundled together and this is the site for the injection of LA agent for popliteal block. This posterior approach of popliteal block is performed with the patient in prone position and the leg is fully extended. Two inches proximal to the flexion crease of knee the pulsation of popliteal artery is identified first. Then the site 1 cm lateral to this pulsation is the needle entry point for popliteal block. After proper antiseptic skin preparation a 22 G and 4 cm long blunt bevelled needle is inserted perpendicular to the skin first and then it is advanced till the paresthesia or motor evoked response (if nerve stimulator is used) is elecited which is plantar flexion or dorsiflexion of foot. Then, 10 to 20 ml of local anaesthetic drug is deposited.

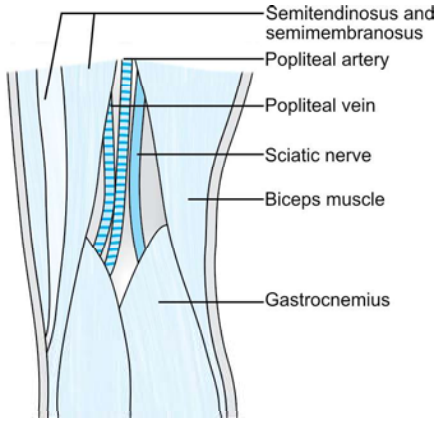

Fig. 23.39: The popliteal block (right leg)

Tibial Nerve Block

It is one of the two terminal divisions of the sciatic nerve (another division is common peroneal nerve) and comes out of it at the level of junction of the upper 2/3 and lower 1/3 on the back of the thigh. But they (the two terminal division of sciatic nerve) lie side by side in a common fibrous sheath. After that it descends on the popliteal fossa along the lateral side of the popliteal vein. Then it crosses superficial to the vein and artery at the back of the knee and descends on the fascia covering the popliteus muscle lying medial to the popliteal vein and artery. It then continues downwards finally as the posterior tibial nerve (PTN) from the lower border of the popliteus muscle on the back of the leg, with the posterior tibial artery within the posterior compartment of the leg. At the ankle, it reaches the midpoint between the medial malleolus and calcaneus under the flexor retinaculum and divides into lateral and medial plantar nerves. The posterial tibial nerve (continuation of tibial nerve) innervates all the muscles of the posterior compartment of the leg and supplies sensory to the ankle joint, and skin over the heel. The medial and the lateral plantar nerves which are the terminal branches of PTN innervate all the intrinsic muscles of the sole and supply sensory to the entire sole and many of the tarsal and metatarsal joints.

Common Peroneal Nerve Block

It is one of the two terminal divisions of the sciatic nerve. It runs downwards and laterally on the popliteal fossa along the medial margin of the biceps femoris muscle. It then comes in direct contact with the lateral surface of the neck of the fibula between the two heads of the origin of peroneus longus muscle. Here it divides into superficial peroneal (or musculocutaneous) and deep peroneal (or anterior tibial) nerves.

The superficial peroneal nerve is the nerve of the lateral (peroneal) compartment of leg. It supplies the peroneus group of muscles and the skin over the lower part of the leg. After supplying the peroneal group of muscles, it pierces the deep fascia at the junction of the medial and lateral third of the lateral surface of the leg and becomes a superficial sensory nerve. Then, it passes to the front of the leg and divides into medial and lateral cutaneous branches. Both of these divisions then reach the dorsum of the foot in front of the superior and inferior extensor retinaculum and then is distributed as follows. The medial division sends two digital nerves: (i) one goes to the medial side of the great toe upto its tip, (ii) the other divides to supply the adjacent sides of the 2nd and 3rd toes. Nailbed of any toe is not supplied by the digital branches of the nerves of the dorsum. Nailbeds are supplied by the plantar digital nerves. The lateral divisions again divides into two dorsal digital nerves. One divides to supply the adjacent sides of the 3rd and 4th toes. Other divides to supply the adjacent sides of the 4th and 5th toes (Fig. 23.40).

The deep peroneal or anterior tibial nerve is one of the branches of the common

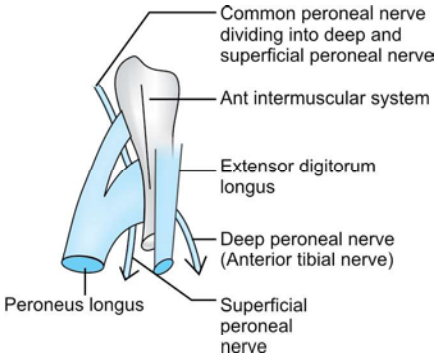

Fig. 23.40: Block at the level of fibular head

peroneal nerve and originates at the lateral surface of the neck of the fibula. It first enters the anterior compartment of the leg and then descends on the interosseons membrane. It innervates all the muscles of the anterior compartment of the leg. On reaching the front of the ankle, it divides into lateral and medial branches. The lateral branch supplies the tarsal joints, metatarsophalangeal joints and interossei muscles. The medial branch runs along the lateral side of the arteria dorsalis pedis and supply motor to the 1st dorsal interosseous muscle and sensory to the adjacent sides of the great toe and 2nd toe.

The block of this common peroneal nerve is appropriate only for surgery on the lateral side of the foot, when popliteal block is difficult. The site of injection or block is just distal to the head of the fibula below knee, where this nerve crosses the head of the fibula from posterior compartment to lateral compartment of leg. The nerve can be blocked by field block technique or with the help of nerve stimulator. Relatively a small volume of 5 to 10 ml of drug is required for this block.

Saphenous Nerve Block

It is one of the branch of the posterior division of the femoral nerve and purely sensory. It descends through the femoral triangle lateral to the femoral artery and then enters the adductor canal. Here, it superficially crosses the femoral artery from lateral to medial side and pierces the aponeurotic roof of the adductor canal. It then descends along the medial side of the knee where it pierces the deep fascia between the sartorius and gracilis tendon. It now descends over the deep fascia along the medial surface of the tibia with the great saphenous vein, but in front of it. At lower 1/3 of the leg, it divides into two branches: one descends along the medial border of the tibia to end over the skin of the ankle. The other enters the foot in front of the medial malleolus and then runs along the medial border of the foot up to the ball of the great toes. Thus, the saphenous nerve is the terminal sensory continuation of femoral nerve in the leg and foot. It can be blocked by infiltration of subcutaneous tissue with local anaesthetic agent in a straight line, perpendicular to the course of the nerve at any one of the several easily identified sites such as: (i) at the medial side of the knee joint, over the femoral condyle by a transverse skin infiltraton with 5 to 10 ml of local anaesthetic agent, which can be confirmed by testing by pinprick between the first and second toes on the dorsal surface of the foot, (ii) over the medial prominence of tibia just distal to the knee joint, and (iii) as a routine part of full block around the ankle.

NERVES BLOCK AROUND THE ANKLE

The complete anaesthesia of foot (both motor and sensory) requires the blockade of five nerves supplying it around the ankle. These are: posterior tibial and sural nerve (branch of the tibial nerve), superficial and deep peroneal nerve (branch of the common peroneal nerve), and saphenous nerve (branch of the femoral nerve). Depending on the site of surgical procedure, it may also be possible to block less than five nerves with accurate knowledge of their sensory and motor supply.

Ankle block is selected especially in patients who are too sick for central neuroaxial block, or unable to handle higher volume of local anaesthetic agent required for the other regional anaesthetic techniques for the block of lower extremity, but need surgery on the foot distal to the malleoli (Fig. 23.41).

Posterior Tibial Nerve Block

At the ankle, behind the medial malleolus, posterior tibial artery pulsation is the landmark for the block of this nerve. Here, the nerve lies lateral (behind) to the artery. After a proper antiseptic skin preparation a 22 G and 3 cm long blunt bevelled needle is inserted perpendicular to the skin but posterior to artery at the level of medial malleolus. Paresthesia may be encountered, but should not be sought. The tip of the needle must be under the covered edge of medial malleous and drug is administered like field block technique and 5 ml drug will accomplish the block. Then, the needle is withdrawn back from the posterior aspect of tibia. The blockade of posterior tibial nerve provides anaesthesia of the heel, plantar aspect of the toes, the medial aspect of sole (lateral aspect of sole is supplied by the sural nerve) and as well as some motor block supplied by it.

Sural Nerve Block

It is the cutaneous branch of tibial nerve and arises from it in the popliteal fossa. It is also joined by a sural communicating branch coming from the common peroneal nerve. The sural nerve pierces the deep fascia at the level of lower 1/3 on the back of the leg. Then, it passes behind the lateral malleolus along with the small saphenous vein and goes along the lateral border of the foot upto the tip of the little toe. At the level of the ankle, it is located superficially between the lateral malleolous and

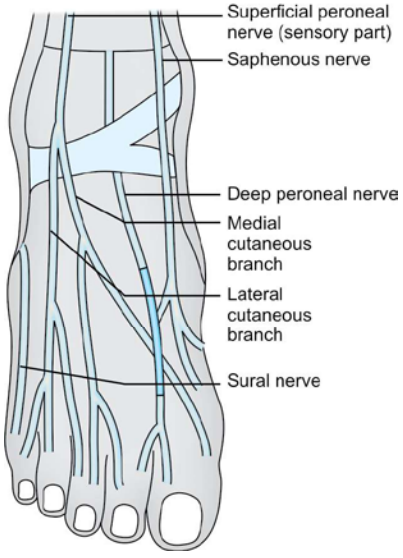

Fig. 23.41: Ankle block

the Achilles tendon. After proper antiseptic skin preparation a 25 G and 3 cm long needle is inserted lateral to the tendon directing towards the lateral malleolus and then 5 ml of LA solution is injected subcutaneously. This block provides anaesthesia of the lateral aspect of the foot and the lateral aspect of the proximal part of the sole.

Deep Peroneal, Superfacial Peroneal and Saphenous Nerve Block

These three nerves can be blocked through a single needle entry point at the inter malleolar line (between medial and lateral malleolus) in front of the ankle. At the intermalleolar line, the tendon of extensor hallucis longus is identified first by asking the patient to dosiflex his big toe. At this intermalleolar line, the tendon of extensor digitorum longus can also be palpated easily on the lateral side of the extensor hallucis longus tendon. Between this two tendons the anterior tibial artery is situated and is palpable at this level. The needle is inserted perpendicular to the skin on the intermalleolar line by the side of the anterior tibial artery between these two tendons and 5 ml of LA drug is deposited under the extensor retinaculum. This will block the deep peroneal nerve and anaesthetize the skin between the first and second toes.

During withdrawal of the needle, it is again directed laterally along the intermalleolar line through the same entry site of skin and 5 ml of LA drug is deposited subcutaneously blocking the superficial peroneal nerve resulting in anaesthesia of the dorsum of foot, excluding the fist interdigital cleft which is already anaesthetized by the block of deep peroneal nerve. The same maneuver can now be performed in the medial direction along the intermalleolar line anaesthetizing the saphenous nerve, supplying a strip of skin along the medial aspect of the foot.

ILIOHYPOGASTRIC, ILIOINGUINAL AND GENITOFEMORAL NERVE BLOCK

Indications

Iliohypogastric (L_1), ilioinguinal (L_1) and genitofemoral (L_1L_2) nerves are the branches of lumbar plexus and lies in the muscular layers of abdominal wall. They mainly supply the groin and the genital areas. So, blockade of these nerves is used for surgical procedures on inguinal and genital areas, such as herniorrhaphy, orchidopexy, chronic pain, postoperative pain relief over this area, etc. The block of these three nerves is also done along with femoral nerve block for long saphenous vein stripping. The block of these nerves has also been used to diagnose and treat pain due to nerve entrapments, neuralgias, neuromas, etc. on their site of sensory supply (Fig. 23.42).

Anatomy

The ventral ramus of the first lumbar spinal nerve (L_1) after receiving a twig from ventral ramus of T_{12} spinal nerve divides into two branches, the upper and the lower. The upper branch again divides into two branches. These are : ilihypogastric and ilioinguinal nerve. The lower branch unites with a branch from the second lumbar ventral ramus (L_2) and form the genitofemoral nerve.

After formation, the iliohypogastric nerve first emerges from the lateral border of the psoas major muscle by piercing it. Then, it runs downwards and laterally in front of the quadratous lumborum and transversus abdominis muscle, but behind the kidney. Here the nerve is embeded in the fascia covering the quadratus lumborum. Now the nerve pierces the transversus abdominis muscle and runs obliquely forwards between it and the internal oblique muscle of the anterior abdominal wall. Here, it supplies both the muscles. Then, the nerve divides into lateral and anterior cutaneous branches. The lateral cutaneous branch pierces the internal and external oblique muscles above the iliac crest and supplies the posterolateral area of the gluteal skin. On the otherhand, the anterior cutaneous branch runs further forward between the transversus abdominis and internal oblique muscles, and pierces the internal oblique muscle 2 cm medial to the anterior superior iliac spine and runs between it and the external oblique aponeurosis towards the inguinal region. Then, it pierces the external oblique aponeurosis 3 cm above the superficial inguinal ring and supplies the skin over the suprapubic region.

The ilioinguinal nerve after its formation also runs like iliohypogastric nerve but below it. It is smaller in size (Fig. 23.43) than the previous one and pierces the internal oblique muscle close to the anterior superior iliac spine. Then, the nerve runs medially on the internal oblique muscle and enters the inguinal canal from

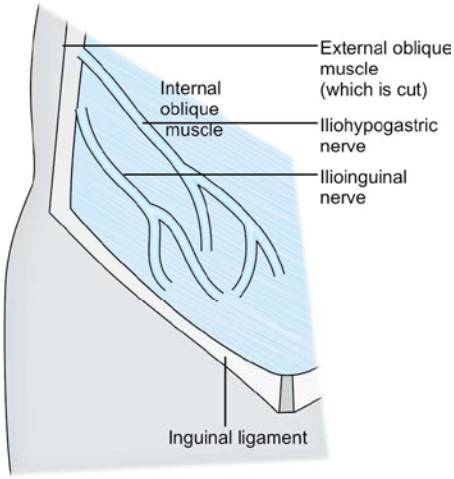

Fig. 23.42: Iliohypogastric and ilioinguinal nerve block

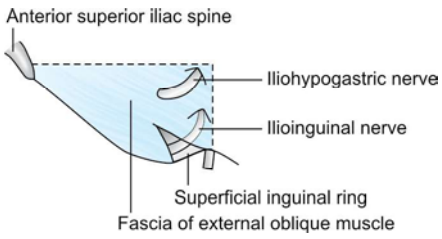

Fig. 23.43: Iliohypogastric and ilioinguinal nerve

above. This nerve is the only content of the canal which does not pass through the deep inguinal ring. It then traverses along the medial part of the canal to come out through the superficial inguinal ring and supplies: (i) the skin over the symphysis pubis, (ii) the skin over the root of the scrotum and penis in male or libia majora in female, and (iii) the skin over the superomedial angle of the femoral region.

After its formation the genitofemoral nerve pierces the psoas major muscle and emerges from its abdominal surface at its medial border, opposite to the body of L_3 or L_4 vertebra. It then descends subperitoneally on the psoas major muscle behind the ureter. Here it devides into genital and femoral branches above the inguinal ligament at variable distance. Then, the genital branch enters the inguinal canal through the deep inguinal ring and becomes the content of spermatic cord. In the spermatic cord it is also known as the nerve to cremaster, supplying the cremaster muscle and scrotal skin (in male). In female, the genital branch in the inguinal canal accompanies the round ligament and supplies the skin of labia major and mons pubis. The femoral branch of the genitofemoral nerve descends lateral to the external iliac artery. It then passes behind the ingiunal ligament and enters the femoral triangle lateral to the femoral artery, but within its sheath. It supplies the skin of the upper part of femoral triangle, but below the inguinal ligament.

Technique

Iliohypogastric and ilioinguinal nerve block

For the block of these two nerves the patient is first positioned in supine and then the anterior superior iliac spine is identified. After that an imaginary line is drawn from it to the umbilicus. From this line a point is marked which is 2 cm medial and 2 cm cephalad to the anterior superior iliac spine. This is the entry point of needle to block the above mentioned nerves. After proper skin preparations, a 22 to 25G needle which is 3.5 inch long is inserted perpendicular to the skin until it just pierces and cross the external oblique aponeurosis below which these nerves lie. Then, 8 to 10 ml of local anaesthetic agent is injected fanwise at that site to block both the iliohypogastric and ilioinguinal nerves.

Genitofemoral nerve block

For the block of this nerve the patient is first positioned supine and then hips are extended. The genital branch of genitofemoral nerve is first blocked by infiltrating 3 to 5 ml of local anaesthetic agent just lateral to the pubic tubercle below the inguinal ligament. Similarly, the femoral branch of genitofemoral nerve is blocked by injecting 3 to 5 ml of local anaesthetic agent subcutaneously just below the inguinal ligament at the lateral border of the femoral artery, after a negative aspiration test.

These three nerves also can be blocked together by a new transpsoas approach or technique, described by Hartrick. But, there is no scope to discuss it here.

Contraindications

The absolute contraindications of block of these nerves are: Sepsis, local infection, coagulopathy, lack of consent, etc. If there is coagulopathy but presence of strong indication, then the procedure can be executed very cautiously using a 27 G fine spinal needle.

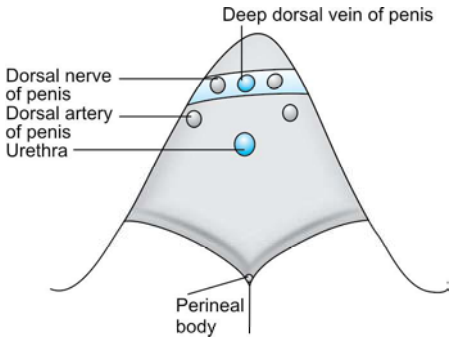

Fig. 23.44: Perineal membrane (in male)

PENILE BLOCK (FIG. 23.44)

The penile block is performed for any surgical procedure over the penis or for postoperative pain relief after any surgery over the penis under general anaesthesia. Penis is actually innervated by the dorsal nerve of penis or clitoris. It is the branch of pudendal nerve and gives this branch while it runs in the pudendal canal. Then the dorsal nerve of penis enter into the penis deep to its Buck's fascia under the symphysis pubis and divides into dorsal and ventral branches. The genital branch of the genitofemoral nerve and the terminal branches of the ilioinguinal nerve also supply the skin over the root of the penis near symphysis pubis (Fig. 23.45).

Bilaterally, the dorsal nerve of penis is blocked by injecting 2 to 3 ml of local anaestheitc agent under the Buck's fascia at 10 and 2 o'clock position using 25 G needle which is one inch long. The whole penis also can be anaesthetized by giving

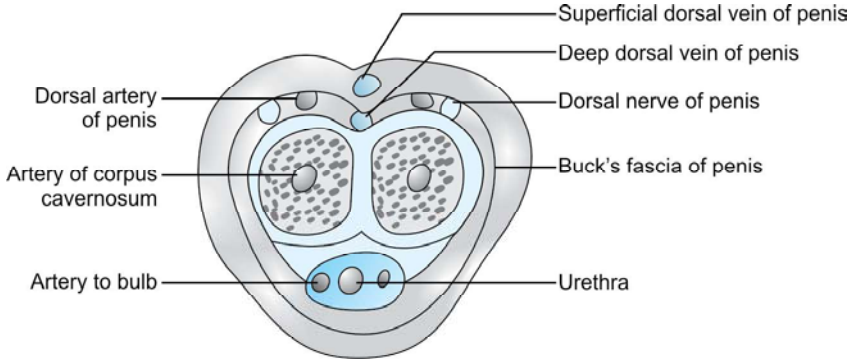

Fig. 23.45: Transverse section through the body of penis

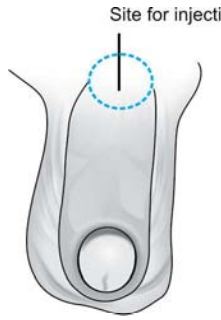

Fig. 23.46: Penile field block

a fan shaped (triangular or rounded) field block around the root of the penis with 10 ml local anaesthetic agent. For penile block epinephrine or any other vasoconstricting agents mixed with the local anaesthetic solution always should have to avoid to prevent the end artery spasm, leading to ischaemic injury of penis (Fig. 23.46).

As the penis is a very vascular structure, so careful aspiration before every injection is mandatory to avoid any inadvertant intravascular administration of LA agent.

INTERCOSTAL NERVE BLOCK

Indication

The intercostal nerve block is very useful in many circumstances, though it has some disadvantages. The bilateral blockade of 6th to 12th intercostal nerves provides motor block and sensory anaesthesia of anterior abdominal wall extending from xiphoid process to symphysis pubis. Bilateral blockade of intercostal nerve is necessary, because there is some overlap of innervation over the midline from each side. Anterior abdominal muscles are relaxed, but there is no anaethesia of visceral peritoneum. So, light general anaesthesia or supplemental bilateral celiac plexus block is necessary if any intra-abdominal procedures is attempted by only intercostal nerve block. This combined technique (bilateral intercostal block plus celiac plexus block) is ideally suited for upper abdominal surgery such as cholecystectomy, gastrectomy, splenectomy, etc. But for mid-abdominal surgery this intercostal block and celiac plexus block is further supplemented by paravertebral block of the first and second spinal nerve roots. In a similar fashion, intrathoracic surgery also can be performed by combination of upper intercostal nerve block and stellate ganglion block, with or without light general anaesthesia. However,though these are not generally used, but very useful for severe debilitated patients. Thus, intercostal nerve block with plexus or ganglionic block provides an alternative approach to spinal and epidural anaesthesia for intra-abdominal or intrathoracic surgical procedures, if the central neuroaxial blocks are contraindicated. On the otherhand, only intercostal nerve block without plexus or ganglion block also can replace the spinal or epidural anaesthesia for surgical procedures performed only on the abdominal or chest wall without the price of sympathectomy, which is associated with central neuroaxial block (Fig. 23.47).

The unilateral intercostal nerve block of three or more ribs at a time provides an excellent pain relief for fractured ribs, herpe zoster, pleurisy, chest tube insertion or replacement, percutaneous biliary drainage, etc. This technique is also useful to relieve the acute post-thoracotomy pain, midline abdominal surgical incision pain, subcostal incisional pain, etc. It improves ventilatory function and reduces the narcotic requirements. But, intercostal nerve block does not provide analgesia as effective as continuous epidural infusions. On the otherhand, it needs frequent and repeated injection to relief the pain.

Anatomy

Each intercostal nerve is the continuation of the ventral ramus of a thoracic spinal nerve. They are twelve in number on each side. Among these the 3rd to 6th intercostal nerves are accounted as the typical intercostal nerves. Because they are only confined to the thoracic wall. The major portion of the first (Fig. 23.48) thoracic spinal nerve (first intercostal nerve) joins with the C_8 spinal nerve and forms the lower trunk of brachial plexus. The lateral cutaneous branch of the second intercostal nerve remains undivided. Rather, it becomes the intercostobrachial nerve and supply the medial side

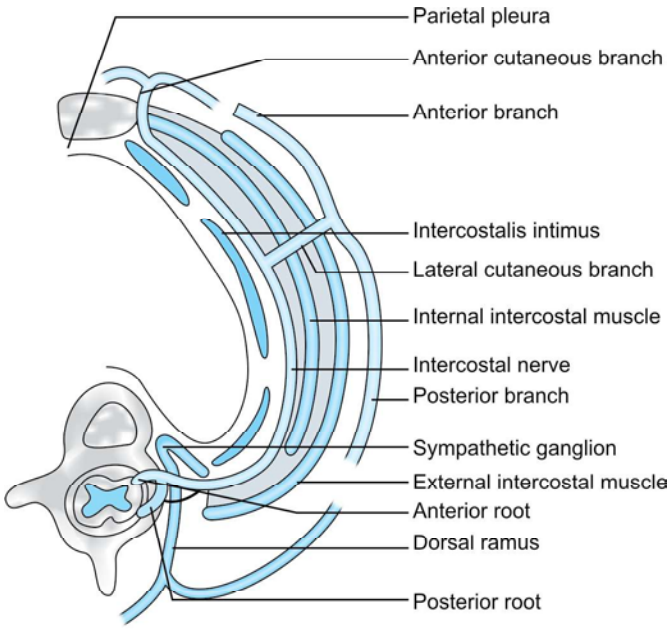

Fig. 23.47: The intercostal nerve—its origin and branches

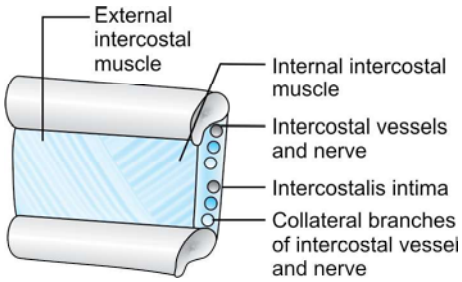

Fig. 23.48: Contents of intercostal space

of the upper arm and arm pit. The 7th to 11th intercostal nerves pass to the anterior abdominal wall. They enter the intercostal space through the digitation between the costal origin of the diaphragm and the transversus abdominis muscle.

After its origin in the vertebral canal each intercostal nerve comes out though the respective intervertebral foramen and appears in the posterior part of the intercostal space. It then runs upwards and laterally behind the sympathetic trunk to reach the undersurface of the respective ribs. Here, it lies inbetween the costal pleura and the posterior intercostal membrane (which is the posterior membranous part of internal intercostal muscle). Then, each nerve runs in the costal groove along the inferior edge of each rib which provides a channel for the nerve and its companion artery and vein. The overhanging outer external edge of the lower border of each rib protects these fellow travelers from direct external assault. In the costal groove the arrangement of these travelers from above down wards are vein, artery and nerve (VAN). When these neurovascular structures run under the lower edge of respective rib in the costal groove, then it runs between the external intercostal and internal intercostal muscle lying externally, and intercostalis intima muscle and parietal pleura lying internally. On reaching the angle of respective rib, each nerve gives off a lateral cutaneous branch. Then the main trunk of the nerve passes forwards along the costal groove between the internal intercostal muscle and intercostalis intimus. Near the midaxillary line the costal grove becomes less well defined and the nerve migrates away from the rib. Because of these two factors, reliable block of intercostal nerve is more difficult beyond the anterior axillary line (Fig. 23.49).

In the anterior part of the intercostal space, the nerve passes in front of the sternocostalis muscle and crosses the internal thoracic artery. Then, it pierces the intercostalis internus, anterior intercostal membrane (membranous part of intercostalis externus), pectoralis major and comes out as the anterior cutaneous nerve to supply the skin of the anterior chest (T_2-T_6) and abdomen (T_7-T_{12}) wall.

The ventral ramus of the first thoracic spinal nerve is not entirely the intercostal nerve. It divides into upper and lower branches. The large upper branch crosses the neck of first rib and joins with C_8 nerve to form the lower trunk of brachial plexus. The smaller lower branch is continued as the first intercostal nerve.

The 12th intercostal or subcostal nerve is unique in that it is not closely associated with its corresponding rib. The branches of it depart early and join with L_1 spinal nerve to form the iliohypogastric and ilioinguinal nerve. So, the standard subcostal injection technique is less likely to produce anaesthesia of this nerve.

The lateral cutaneous branch of each intercostal nerve arises near the angle of each rib and pierces the muscle in the midaxillary line. After being cutaneous, this branch again divides into two branches–anterior and posterior. The anterior branch runs anteriorly and unites by the side of the sternum with the terminal anterior cutaneous branch of each main intercostal nerve. Posterior branch runs posteriorly and unites with the cutaneous branch of the dorsal ramus of the same thoracic nerve which also supply the paravertebral muscles and the skin over it. Both these branches supply the skin over the corresponding area. A collateral branch also arises from the each intercostal nerve near the angle of each corresponding rib. It also passes forwards in the same intermuscular plane like the main nerve, but along the upper border of the next lower rib. Anteriorly, it terminates as additional anterior cutaneous nerve by piercing the muscle like the terminal part of main nerve.

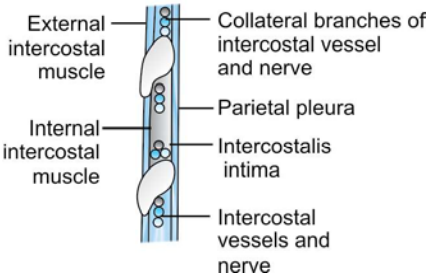

Fig. 23.49: Vertical section through an intercostal space

Each intercostal nerve is connected with the corresponding sympathetic ganglion of the sympathetic chain by white and grey rami communicantes. White ramus carries the preganglionic sympathetic fibres. While the grey ramus carries the postganglionic sympathetic fibres from the ganglion.

Technique

The anatomy of ribs may themselves vary. Posteriorly by the side of the midline all the ribs are well protected by paravertebral group of muscles. The lower six ribs are broad, flat and more superficial than the upper six ribs. So, they are easily palpated lateral to these paravertebral muscles. The upper ribs are narrower, deeper and more protected by scapula and paravertebral muscles. So, they are not easily palpated and technically more difficult to reach by the needle. As the upper ribs are protected laterally by the scapula, so paravertebral approach is more practical in this region.

The intercostal nerves can readily be blocked at the angle of the rib, just lateral to the sacrospinalis group of muscles. The patient may be placed in the lateral, sitting, supine or prone position. But, prone position is more practical and technically easy to block the intercostal nerve. In prone position a pillow is placed under the

abdomen to provide slight flexion of the thoracic spine. The arms will hang over the edge of the operating table, so that scapulla falls away laterally from the angle of the rib. First a line is drawn along the thoracic vertebral spines. Then, the ribs are identified along the line of their most extreme posterior angulation. For the 12th rib, this is usually 7 cm from the midline. Whereas for the 6th rib, this is usually 5 cm from the midline. Thus, a line is drawn connecting the posterior angles of these two ribs which will run upwards lying 3 to 5 cm away from the midline and is angled medially at the upper level. The posterior angles of the rest of the rib will come on this line and inferior border of each rib is marked on this line.

Then, after appropriate skin preparation, sedation and analgesia, a 22 G and 4 cm long needle is inserted perpendicular to skin until it rests on the rib. Then, the needle is walked in a caudal direction until it pass below the inferior border of the rib, where 3 to 5 ml of local anaesthetic agent in injected. This process is repeated at each rib, starting with the lower most and moving gradually upward.

The six or seven designated ribs on each side are blocked in this process. The ribs on the opposite side also can be blocked in a similar manner. Alternatively, intercostal block can also be performed on a supine patient at the midaxially line. In practical situation, the lateral cutaneous branch of intercostal nerve is not targeted for block. Because, in reality, CT studies show that injected solution spread several centimeters along the costal groove and block this lateral cutaneous branch.

If intercostal nerve block are to be supplemented by somatic paravertebral nerve blockade and sympathetic celiac plexus blockade, then these should be performed at the completion of intercostal anaesthesia. But care should be taken to adjust the total dose of the LA drug, so that the maximum recommended doses does not exceed.

COMPLICATIONS

The probable complications are: pneumo thorax (most common), respiratory inadequacy, systemic toxicity, hypotension, etc.

24 Spinal, Epidural and Caudal Anaesthesia or Central Neuroaxial Block

HISTORY

It was 1855, when Friedrich Gaedcke (FG) of Germany had first isolated cocaine (alkaloid) from coca plant (Erythroxylon coca), which usually grew as bush in Bolivia and Peru. Before that discovery, the plant was well-known to the local Indians as an euphoriant and stimulant. But, the modern local or regional anaesthesia began with the introduction of cocaine into the medical practice in September 1884 by Karl Koller (Fig. 24.1) after its isolation from plant by FG. Karl Koller was then a 27 years old trainee ophthalmologist in Vienna. He was also the first medical man who used and publicised the analgesic and local anaesthetic properties of cocaine by applying it as topical drop in ophthalmic surgery.

Before the discovery of analgesic and local anaesthetic property of cocaine Karl Koller was working under professor, named Carl Ferdinand who was then considerably dissatisfied with the standard and condition of general anaesthesia for ophthalmic surgery during that period. Karl Koller also soon began to share the same dissatisfaction with his professor, regarding the restlessness, coughing, vomiting, etc. during operative and postoperative period after general anaesthesia. So he began to realise that this problem would only be solved, if any local anaesthetic agent could be invented which when instilled into the conjunctional sac would abolish pain. With this aim, Koller also tried with morphine and other sedatives, by instillating them in the conjunctival sac. But, he was unsuccessful and turbulent ophthalmic operating conditions under general anaesthesia continued.

Sigmund Freud, a friend and contemporary of Karl Koller was also working as his junior colleague in the neurology department of the same hospital. He later achieved world fame as the originator of psychoanalysis. In a fine summer in 1884, Freud was working with cocaine what was then a fairly new drug and had reached Europe from South America in and around 1860. As cocaine produced euphoria and CNS stimulation, so it led Freud to believe that cocaine might be a remedy for morphine addiction and as well as can be used as a tonic for his psychoneurotic patients. He also knew that cocaine deadened mucous membrane. But, Sigmund Freud never thought that it was due to the local anaesthetic property of cocaine. He was also not clear about the effects of cocaine on muscular contraction. Then, once Freud went on a holiday, asking Koller to do some experiments on cocaine and to elucidate the problem.

Fig. 24.1: Karl Koller

Thus when Freud was on holiday, Koller had started same experiments by applying cocaine on his own tongue. But he was astonished by cocaine's strange power to deaden all the sensation of tongue. In a flash, he realised that this might be that agent, he had been looking for long period to act as a local anaesthetic in his eye operations. Then, he started serial experiments to investigate the analgesic and local anaesthetic properties of cocaine in his experimental laboratory on animals. Later, Koller used cocaine on his friends and lastly on his patients. He was extremely satisfied with his work and had lost no time in making his discovery public. Then, he wrote a short preliminary report and asked his friend, Dr Josef Brettaver, to read it for him at the forthcoming meeting of German Ophthalmological Society which is to be held in Heidelberg where Koller himself was not be able to attend it. In 15th September 1884, Brettaver's paper made a sensation. After that Koller had given many lectures on the local anaesthetic property of cocaine. He also gave many clinical demonstrations on the local anaesthetic property of 2% cocaine solution in the outpatient clinic. In the following months, Koller read two full papers on the local anaesthetic property of cocaine before the Imperial Medical Society. But Freud, whose interest in surgical anaesthesia was minimal, made no claim to this discovery by Koller.

However before Koller's work, in 1849 Simpson had also recorded some history of local anaesthesia and some experiments of his own. But between 1849 to 1884 and before Koller's discovery, ether spray was used for local anaesthesia and it acts by freezing the skin. Later ethylchloride spray was also used for the same purpose in 1880 by Rothenstein.

After Koller's work in 1884 and in the early part of 1890, Reclus in Paris and Karl Ludwig in Berlin had first popularised the infiltration anaesthesia using cocaine. But, the first direct nerve block with cocaine had been employed by WS Halsted and RJ hall and the mandibular nerve was their first nerve. Then, Halsted extended his work on this concept by blocking other nerves. Subsequently, he was the first surgeon to block the nerves of face, brachial plexus, internal pudendal nerve and posterior tibidal nerve using cocaine. He also first showed that the reduction of circulation in any part of a body by an Esmarch bandage would prolong the effects of local anaesthetic agent. Then, when the use of cocaine was popularised, gradually its toxicity became evident due to the use of its higher doses. These were: CNS stimulation, addiction among the general surgical patients, and clouding of cornea when used as topical anaesthesia in ophthalmic surgery.

So, subsequently the relatively less toxic substitutes for the highly toxic cocaine as local anaesthetic agent was searched for. Hence in 1890, in dentistry, oil of cloves (eugenol) was first used as a local analgesic and anaesthetic agent in stead of cocaine. Then, gradually Giesel's tropococaine appeared in 1891 and subsequently Fourneau's stovocaine was marketed in 1904. Einhorn's novocaine (procaine) was described in 1899, but was first used clinically in 1904. Then, it was popularised by H Braun in 1905. Subsequently, Miescher and Uhlmann introduced nupercaine (cinchocaine) in 1929. Amethocaine was first described in 1931. Then first important milestone about local anaesthetic agent came when Lofgren and Lundqvist first synthesised lignocaine in 1943. But Gordh was the first to use it clinically in Stockholm in 1948. Then the local anaesthetic agents which were appeared chronologically are: Chlorprocaine in 1952, mepivacaine in 1956, prilocaine in 1959, bupivacaine in 1963, etidocaine in 1972 and ropivacaine in 1993.

H Braun first introduced adrenaline in 1902 (which was first isolated in pure form in 1897) with cocaine to retard the absorption and to prolong its effect. The term 'block' was first used in 1897 by Crile and the term 'regional anaesthesia' was first used by Cushing in 1901.

The cerebrospinal fluid (CSF) was first discovered by Domenico Cotugno in 1764. But, its circulation was first described by F Magendie in 1825, who gave its name as CSF. In 1885, when J L Corning was experimenting with cocaine on the spinal nerve of his dog, he accidentally pierced the dura and gave first spinal anaesthesia. Later, he deliberately had repeated the intradural injection and called it as spinal anaesthesia. Then, he suggested that this type of anaesthesia might be used in surgery. After that this lumbar dural puncture was standardised as clinical procedure by HI Quincke in Germany in 1891 (Fig. 24.2).

The first planned spinal anaesthesia on human for surgery was performed by August Bier on 16th August in 1898. The patient was a 34-year-old parturient and Bier courageously injected 3 ml of 5% cocaine solution in CSF through the lumbar spinal route. However, this experiment became a great success. Then, subsequently Mr Bier had used spinal anaesthesia on 6 patients. After that, to prove his faith on his method Bier and his assistant each injected 2 ml of 1% cocaine into each other's subarachnoid space. The name of assistant was Hildebrandt. The procedure was actually first attempted on Bier by his assistant. However, after successfully locating the subarachnoid space of Bier, Hildebrandt was unable to attach the syringe to the needle and a considerable amount of CSF was lost on the floor. So, in order to salvage the experiment, Hildebrandt volunteered himself as the research subject to Bier. This time the intrathecal injection of cocaine was successfully completed by Bier. Then, Bier and Hildebrandt celebrated their achievement with wine and cigars. Unfortunately, on the next day Bier complained of severe headache which resolved only after nine

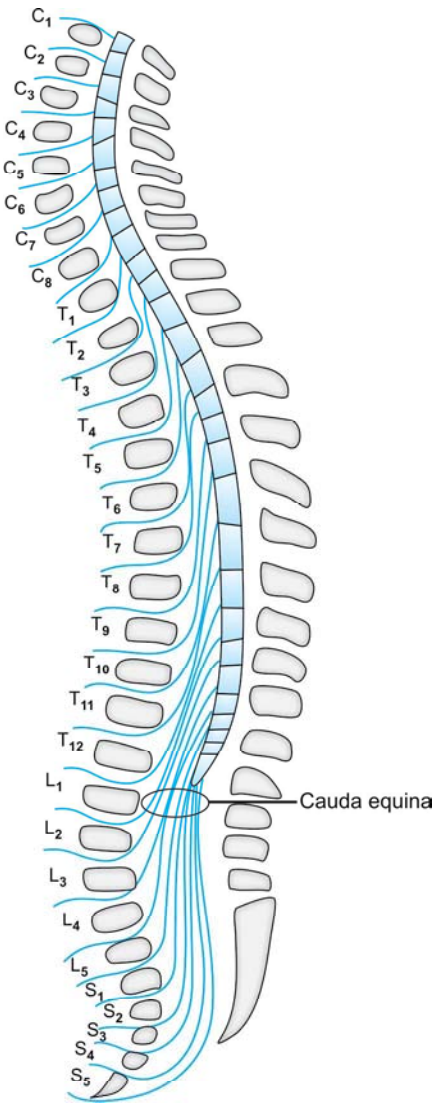

Fig. 24.2: The longitudinal section of vertebral column

days. However, Hildebrandt had also suffered from headache significantly more. While anaesthetised, their degree of analgesia and anaesthesia had been tested and monitored by being kicked on their shin bone and pinched with instruments. As a result, they not only developed a postdural puncture headache, but also suffered from severe bruises over their legs due to the repeated assessment of their sensory block. Then this work was published in April 1899 under the title 'Research on the cocainisation of the spinal cord' and the popularity of spinal anaesthesia had quickly spread. August Bier had also described in this book that his own post spinal headache is due to the excessive leakage of CSF. Bier also advised spinal anaesthesia for operation on legs. But, later he gave it up, owing to the toxicity of cocaine.

Soon after that, Tuffier and Sicard of Paris extended the scope of spinal anaesthesia in the field of surgeries, including the external genitalias and the lower abdomen. In 1903, adrenaline was introduced with local anaesthetics to increase the duration and to reduce the toxicity of cocaine used in spinal anaesthesia. Due to the toxicity of cocaine, stovocaine was first used in spinal anaesthesia in 1904 and novocaine (procaine) in 1905, soon after their discovery. In 1907, A E Barker, a surgeon of London, was the first to realise the importance of the curves of vertebral column and the use of gravity in controlling the level of spinal anaesthesia. He first introduced 'heavy' or hyperbaric solution of stovocaine in 5% glucose. Contrary Babcock of Philadelphia was the first to use the hypobaric solution. His hypobaric formula was stovaine containing alcohol, lactic acid, etc.

G Labat, in 1921 first used novocaine crystals which was dissolved in CSF for barbatose technique. In the mean time, during 1923 ephedrine was introduced in the practice of medicine and spinal anaesthesia had also gained popularity. So, ephedrine was first used to control the hypotension and to maintain the blood pressure in spinal anaesthesia in 1927.

For surgery on the head, neck and thorax spinal anaesthesia was also first used in 1909. After discovery of nupercaine in 1929, it was used as hyperbaric solution by McLelland of New York in 1930 with great success. It was partly due to the longer duration of action of it. At that time nupercaine was also used as hypobaric solution. Then gradually amethocaine (tetracaine), lignocaine and bupivacaine was used in spinal anaesthesia, shortly after their discovery.

In UK, spinal anaesthesia was under cloud for many years though it was used rampantly worldwide during that period. It was partly because of the tendency for litigation, if complication occurred. A burning example of this was the Wolley and Roe case, in early 1950, in which paraplegia had occurred followed by spinal anaesthesia in two patients, operated upon the same day. At that time, it was thought that this complication was due to the contamination of anaesthetic solution by phenol which entered the ampoles through a minute crack in the glass. But after prolonged investigation, a much more likely explanation was that the used needle and its accessories was sterilised by boiling in a steriliser which had been contaminated with acid substances, used to prevent scale formation.

In 1901, F Cathelin and A Sicard in Paris were the first to use sacral approach for the epidural space independently. This was some years before the lumbar route for the epidural space came into use. Sacral block was then employed in Germany in 1909 and was popularised by G Labat, in 1923 by his book. The use of sacral analgesia in infants was first described by Campbell in 1933. The method of continuous caudal analgesia by catheter was developed by Hingson in 1943.

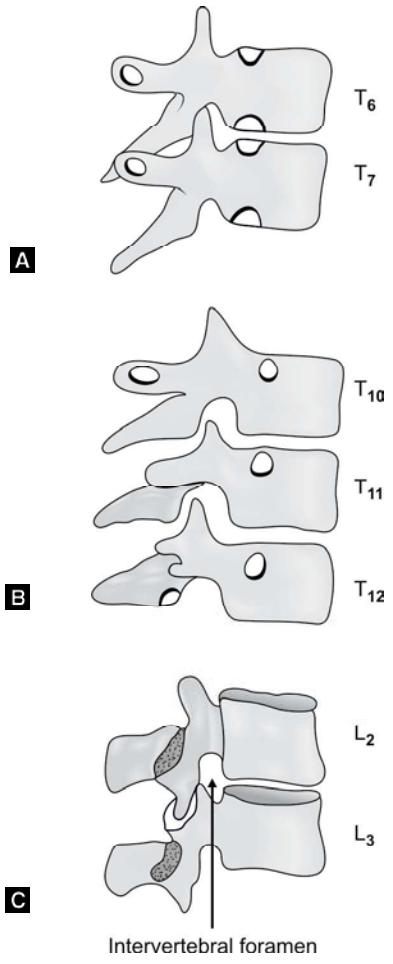
The history of lumbar epidural block is somewhat cloudy. It was not certain, whether Corning had deposited cocaine into the intradural or extradural space, in 1885. Although the interspinous approach for the epidural space has also been demonstrated at the beginning of the century, but Pages of Madrid in 1921 was the first to describe the practical application of lumbar epidural anaesthesia. Later, in 1931, Dogliotti of Italy had popularised this lumbar epidural technique. This is followed by other clinical exponents such as Hess (1934), Odom (1936), Harger and his associates (1941). Curbelo of Cuba was the first to insert a ureteric catheter into the epidural space to introduce the continuous epidural block, using the Tuohy needle. This needle was first designed for intrathecal use and later was adapted to allow the passage of smaller bore catheter. The first report of the injection of opiates into the epidural space came from Jerusalem in 1979.

INTRODUCTION

The central neuroaxial block (spinal or epidural anaesthesia) results in chemical sympathetomy, sensory block, and motor paralysis. The spinal anaesthesia is devoid of any systemic pharmacological effect of the anaesthetic drug due to its small volume. On the other hand, epidural block is not always devoid of the systemic effect of used local anaesthetic agent as it needs large volume. Both the individual spinal and epidural or continuous epidural block have their own advantages and disadvantages. But the combined spinal and epidural (CSE) anaesthesia blurs the difference between the two, covering the disadvantages of each other and added flexibility to the wide range for clinical use.

Cocaine was the first drug used in spinal anaesthesia. But Gorton had first promoted the high spinal anaesthesia for head and neck surgery. However, Koster first used total spinal block for intrathoracic and intracranial procedures (Figs 24.3A to C).

In previous days, spinal block was also used for medical therapy, e.g. pulmonary



Figs 24.3A to C: A. Lateral view of 6th and 7th thoracic vertebrae, B. - Lateral view of 10th, 11th and 12th thoracic vertebrae, C - Lateral view of 2nd, 3rd lumbar vertebrae

oedema due to its hypotensive effect. During that period anaesthesiologists continued to face the confusion regarding the balance between the risks and benefits of spinal anaesthesia, especially those involving continuous spinal anaesthesia or the use of 5% xylocaine. In USA, the FDA withdrew the very fine spinal catheter and 5% xylocaine due to the perceived association between them and cauda equina syndrome. It seems likely that more spinal and epidural block have failed due to inadequate IV sedation and anxiolysis, rather than due to the technically flawed blocks. The continuous epidural block for the postoperative analgesia decreases the length of hospital stay and allows the more efficient use of ever increasingly stretched health care service. There is a common believe that in epidural block there is less reduction of BP and is slower in onset. But, this is not always correct. Ephedrine which is used to check the hypotension due to regional anaesthesia is a mixed adrenergic agonist and is preferred than a pure adrenergic agonist. Gradually the days are coming, when the infusion of large amount of crystalloid solution as preload to minimise the spinal or epidural hypotension should be rethinked. Sometimes, during epidural anaesthesia due to large amount of drug, the level of anaesthetic agent in blood may reach a concentration (toxic level) which is sufficient enough to produce the systemic effects.

ANATOMY

In the vertebral column multiple vertebrae are arranged in a column. So, it is thus named. The vertebral column consists of 23 fibrocartilaginous discs and 33 vertebrae of which 7 are cervical, 12 are thoracic, 5 are lumbar, 5 are sacral and 4 are coccygeal. The cervical, thoracic and lumbar vertebrae are called the free vertebrae and each of them presents regional characteristics. On the otherhand, the next sacral and coccygeal vertebrae are called the fixed vertebrae. This is because the five sacral vertebrae are fused to form the sacrum and the four rudimentary coccygeal vertebrae are united to form the coccyx (Fig. 24.4).

Functions of the vertebral column are:

i. Support of trunk.
ii. Transmission of body weight.
iii. Protection of spinal cord, spinal nerves, and its menings.
iv. Attachment of muscles and ligaments for various movements of the trunk.

There is very slight movement between the two adjacent vertebrae. But a very wide range of movements of vertebral column are possible when the entire column and the small movement between the two vertebrae are considered as a whole.

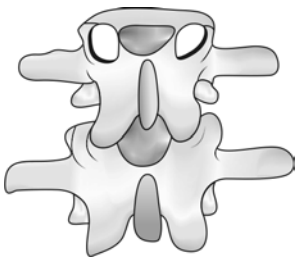


Fig. 24.4: Lumbar vertebrae and its posterior view

The Parts of Vertebra

1. Body

The body of a vertebra transmits body weight and is connected to the bodies of adjacent upper and lower vertebrae by the intervertebral discs, forming the secondary cartilaginous joints. The body of a vertebra is enclosed by a shell of compact bone, except at the upper and lower surfaces, where it is composed of spongy bone and is covered by a plate of a hyaline cartilage. The front and sides of the body of a vertebrae are somewhat concave in shape and pierced by blood vessels. The posterior surface of the body of a vertebra presents one or more centrally placed basivertebral formina, through which the basivertebral vein and some nutrient arteries pass. Along the entire mobile part of the vertebral column, the anterior and the posterior surfaces of the body of each vertebra are connected respectively by the continuous flow of anterior and posterior longitudinal ligaments of which the anterior ligament is stronger than the posterior (Fig. 24.5).

2. Vertebral arch

It is situated behind the body of each vertebra and is composed of 2 pedicles and 2 laminas. This predicle and lamina of each side of a vertebra joins together posteriorly at the midline to form a vertebral arch which forms the boundary of vertebral foramen laterally and posteriorly. This vertebral foramen is also bounded anteriorly by the posterior surface of the

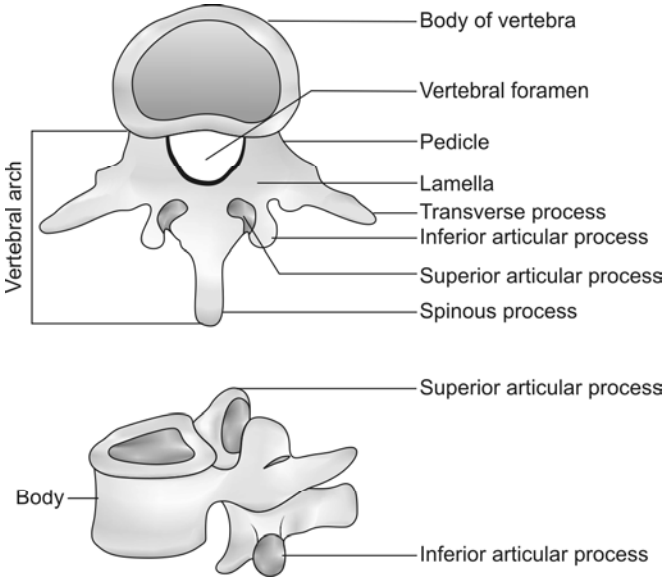

Fig. 24.5: Typical lumbar vertebra

body of respective vertebra. Thus, both the body and vertebral arch complete a vertebral foramen. The vertebral forminas of the adjacent upper and lower vertebrae join continuously to form a vertebral canal for the lodgement and protection of spinal cord, spinal nerve, its meninges and CSF. In the cervical region, the vertebral canal is triangular in shape and more roomy for the accommodation of cervical enlargement of spinal cord. However, in the thoracic region, the vertebral canal is comparatively smaller and circular. In the lumbar region this vertebral canal is again some how more larger and triangular in shape to accommodate the lumbar enlargement of the spinal cord. In adults the spinal cord ends usually at the level of the lower border of L_1 vertebra and the subdural and the subarachnoid spaces (containing CSF) end at the level of S_2 vertebra. After the end of the spinal cord the vertebral canal contains a bunch of spinal nerves called the cauda equina and a non-nervous pial thread known as the filum terminale interna. This pial thread (filum terminale interna) is nothing but the continuation of the pial membrane as a thread after the end of the spinal cord.

An area called the epidural space (or extradural space) intervenes between the periosteum of vertebral canal and the dura mater, covering the spinal cord. This epidural space extends from the foramen magnum above to the sacral hiatus below and contain loose fibro fatty tissue with valveless internal vertebral venous plexus. This epidural space is also traversed by the roots of spinal nerves with their covering meningeal sheaths after coming out from the spinal cord and crossing over the subarachnoid space. Two deficiencies are present at the lateral and posterior walls of the vertebral column. The former is being the inter vertebral foramen and the later is being the interlaminar foramen.

3. Pedicle

Each pedicle springs from the posterolateral surface of the vertebral body, and is situated at somewhat midway between its upper and lower surfaces. It projects backward with slight lateral inclination. Each pedicle is grooved above and below and is called as the superior and inferior vertebral groove or notch, respectively. Inferior groove is more deeper than the superior. Each groove together with the groove of the pedicle of the vertebra above and below form the intervertebral foramen. Thus, each intervertebral foramen is bounded above and below by the pedicles of the adjacent vertebrae, behind by the interarticular joint, and in front by the lower part of the body of upper vertebra and the intervertebral disc. The intervertebral foramina are smallest in the cervical and upper thoracic regions. It gradually increases in size and becomes largest in relation to the 5th lumbar vertebra. Along with the gradual increase in size of the intervertebral foramina, the thickness of the spinal nerves are also increased in craniocaudal direction. So, the lower lumbar nerves are more vulnerable to compression within the intervertebral foramina (Fig. 24.6).

The intervertebral foramen contains (a) both the ends of the anterior and posterior nerve root with dorsal root ganglia, (b) the beginning of mixed spinal nerve, (c) the beginning of two rami of spinal nerve – anterior and posterior, (d) a spinal artery, and (e) an intervertebral vein. In cervical region the superior vertebral notches transmit the numerically corresponding cervical nerves and the inferior notches transmit the immediately succeeding cervical nerves. But in rest of the vertebral column, however, the superior notches transmit the immediately precceding spinal nerves and the inferior notches are occupied by the numerically corresponding spinal nerves.

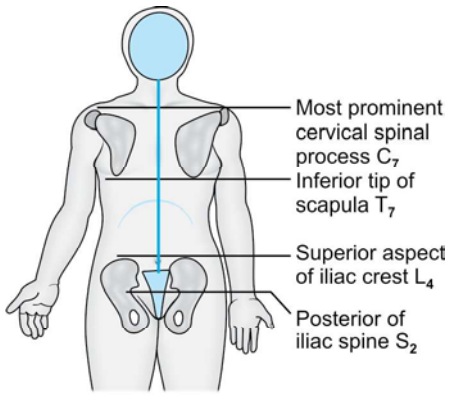

Fig. 24.6: The surface landmarks for identifying the spinal vertebral levels

This is because cervical vertebrae are seven in number, whereas the cervical spinal nerves are arranged in eight pairs.

4. Lamina

The each lamina arises from the dorsal or posterior end of the each pedicle. Then, it passes medially and backwards and fuses with the fellow of the opposite site at midline. From the fused laminae an elongated spinous process projects backward with a slight downward inclination. The laminae of the adjacent vertebrae are connected by a series of fibroelastic membrane called the ligamentum flavum. In the mid thoracic region the laminae partially overlap with one another. The space between the laminae of two adjacent vertebrae and the interarticular joint is called the interlaminar foramen. So, the interlaminar foramen is bounded above and below by the adjacent laminae and at the sides by the inner aspect of articular process of the vertebra of above and below. During the extension of vertebral column it is small, but during flexion it enlarges and provides an access to the spinal or epidural needle (Fig. 24.7).

5. Processes

They are 7 in numbar, such as 2 transverse, 1 spinous and 4 articular arising from each vertebra. The transverse and spinous processes give attachment to the different ligaments and muscles acting on the vertebral column.

Transverse process

The transverse process project laterlly from each side of the vertebral body at the junction of pedicle and lamina. In cervical vertebrae the transverse processes present a foramen, called the foramen transversarium which transmits: the 2nd part of vertebral artery (except in the seventh cervical vertebra), a plexus of vertebral veins and a plexus of sympathetic nerves. In thoracic vertebrae the transverse processes present a costal facet (except the last two thoracic vertebrae) on its anterior surface close to the tip for articulation with the tubercle of numerically corresponding rib, forming costotransverse joint. In lumbar vertebrae the transverse processes are relatively slender. The transverse processes of all the free vertebrae are connected to one another by inter transversus muscles. In some regions these transverse processes give attachment to erector spinae and paravertebral group of muscles which help in flexion, extension and rotation of the trunk.

Spinous process

The unpaired spinous process of each vertebra projects generally backwards in the midline from the fused laminae of both sides. In the cervical region these spines are horizontal, short and present a bifid tip, except the 2nd and 7th cervical spine which are elongated and prominent. The 7th cervical spine is called the cervical prominence. The tip of the spinous process of cervical vertebrae are connected to

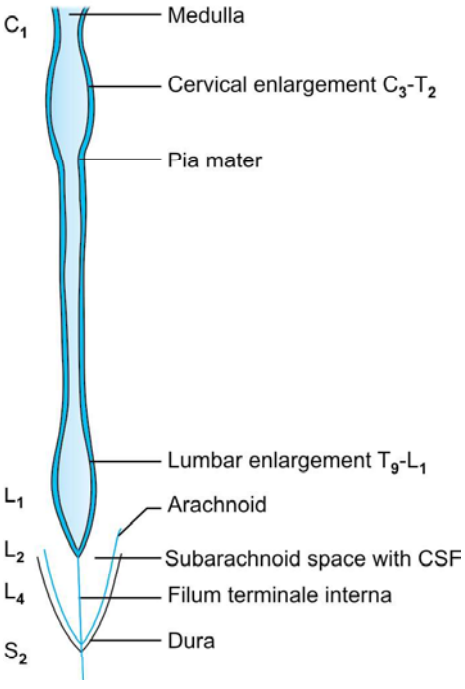

Fig. 24.7: Important vertebral levels in relation to the spinal cord. Blue covering is the pia mater, black covering is the arachnoid mater and red covering is the dura mater

one another and to the external occipital crest (with its protuberance) by a fibrous band, called the ligamentum nuchae. This ligamentum nuchae at its lower end is attached to the C_7 spinous process. The the thoracic spines are more elongated with pointed tips and is inclined backwards and downwards. The first four thoracic spines slope obliquely downwards but does not overlap on one another. While the fifth to eighth thoracic spines overlap on one another. The lower four thoracic spines from eighth to twelveth are almost horizontal. The lumbar spine are broad, quadrilateral and horizontal in direction. All the thoracic and lumbar spines are connected to one another by the interspinous ligament along their shaft and supraspinous ligament along their tip. They also provide attachments to the posterior layer of thoracolumbar fascia and extensor muscles of the trunk. Since, considerable spaces are available in the interval between the horizontally directed lumbar spines, so the spinal or epidural anaesthesia is often made through the lumbar puncture. This lumbar subarachnoid puncture is usually performed distal to the caudal end of spinal cord (below L_1) to avoid its injury.

Articular process

There are 4 articular processes arising from each vertebra. Among these each pair of superior and inferior articular processes project respectively above and below from the junctions of pedicles and laminae. These articular process are meant for articulation with the vertebra immediately above and of a particular vertebra of a particular vertebra. When viewed from behind, it is shown that the vertebral spines occupy the median plane and the two vertebral grooves, each lie lateral to the spines. Bilateral vertebral grooves are occupied by the deep extensor muscles of the back. In the cervical and the lumbar regions the grooves are shallow and formed by the laminae. In the thoracic region they are deep, wide and formed by the laminae and transverse processes also.

Some landmarks of vertebral column are:

i. T_3 spine corresponds with the level of scapular spine.
ii. T_7 spine coprresponds with the inferior angle of scapula.
iii. L_4 spine corresponds with the summits of iliac crest (useful for lumbar puncture).
iv. S_2 spine corresponds with the posterior superior iliac spine (end of the spinal subarachnoid space).
v. The upper end of the natal cleft between the two buttocks corresponds with sacral hiatus useful for sacral epidural anaesthesia.

Ligaments

The vertebrae are hold together by a series of overlapping ligaments. These ligaments not only bind the vertebrae together, but also assist in protecting the spinal cord. These ligaments are:

(i) Anterior and post longitudinal ligaments

It runs in front and behind of the bodies of vertebra, extending from the axis or second cervical vertebra to the sacrum.

(ii) Ligamentum flavum

As this name says, it is made up of yellow elastic fibres. Above, it is attached above to the anterior and inferior aspect of the lamina of the upper vertebrae and below it is attached to the superior and posterior aspect of the lamina of the lower vertebrae. It blends medially and posteriorly with the interspinous ligaments and the ligamentum flavum of the opposite side. Laterally and anteriorly it blends with the capsule of interarticular joint of that side.. It is thinnest at the cervical region and thickest at the lumbar region. These ligaments are muscle sparers and assist in straightening of the vertebral column after bending forward. It also helps in maintaining the erect posture of body. It comprises half of the total length of the posterior wall of vertebral column (Table 24.1).

Table 24.1: Characteristics of ligamentum flavum at different level of vertebral column

Site of vertebral column	*Distance from skin to ligament (cm)*	*Thickness of ligament (mm)*
Cervical	2 - 3	2 - 3
Thoracic	3 - 5	3 - 5
Lumbar	3 - 8	5 - 6

(iii) Interspinous ligaments

It extends forwards from the tip of spinous process where it fuses with supraspinous ligaments to the point where the two laminae of opposite sides fuses in the midline. Here it blends with the ligamentum flavum. Above it is attached to the inferior border of spine of the upper vertebra and below is attached to the superior border of spine of the lower vertebra. In the lumbar region it is most wide and dense.

(iv) Supraspinous ligament

It extends from the tip of the 7th cervical spine to the sacrum joining the tip of all the thoracic and lumbar spinous processes. From 7th cervical spine and above it is continuous with the ligamentum nuchae. It is thickest and widest in lumbar region.

Curvature of Vertebral Column

There are 4 curvatures in the vertebral column – two concave ventrally one at thoracic and one at sacrococcygeal regions, and two concave dorsally one at cervical and one at lumbar regions. Thoracic and sacral curvatures are the remnants of flexion attitude of the foetus in uterus. So, they are called the primary curvature. Whereas the cervical curvature appears after birth when the child lifts his head and lumbar curvature appears at the end of 1st year when the child learns to stand. So, they are called the secondary curvatures. The cervical and the lumbar curvatures (secondary curvature) are caused by the inequal thickness of the intervertebral discs (thicker anteriorly) and the primary curvatures are caused by the bony configuration. The accentuated pathological ventral concavity of vertebral column at the thoracic region is called the Kyphosis and the accentuated dorsal concavity at the lumbar region is called the lordosis. Scoliosis is the exaggerated form of lateral curvature of the vertebral column. The cervical curvature extends from the atlas to the 2nd thoracic vertebra. The thoracic curvature extends from the second to the twelfth thoracic vertebrae. The lumbar curvature extends from the L_1 to L_5 vertebra and the pelvic curve or the sacrococcygeal curvature extends from the lumbosacral joint to the tip of the coccyx and faces downwards and forwards.

Intervertebral Disc

The intervertebral discs connect the upper and lower surfaces of the adjacent vertebral bodies and is present from axis (2nd cervical vertebra) to sacrum. They actually intervene between the plates of hyaline cartilages which cover the upper and lower surfaces of the adjacent vertebral bodies. Each intervertebral disc is made up of a central gelatinous part, called the nucleus pulposus and a peripheral fibrocortilaginous part, called the annulus fibrosus. It accounts for 1/4 to 1/5th of total length of the vertebral column. It is thicker at cervical and lumbar region where the vertebral column needs more mobility and is thinner at thoracic region where the vertebral column needs less mobility. In cervical and lumbar regions it is more thickened anteriorly than posteriorly. So it also gives rise to the ventral convexity of vertebral column. It also functions as a shock absorber when placed between the two vertebral bodies and connects the vertebrae strongly. The intervertebral disc also provides resiliency to the vertebral column and ensure even distribution of compressive forces on the upper and lower surfaces of the bodies. If during spinal block, the needle hits the annular fibrosus, then the nucleus pulposus may prolapse through it and may cause sciatica (Fig. 24.8).

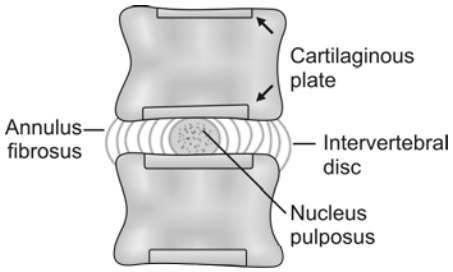

Fig. 24.8: Intervertebral disc

The annulus fibrosus is composed of a series of concentric laminae of fibres. These fibres in each lamina of annulus fibrosus are arranged in parallel to each other, but run obliquely between the body of two adjacent vertebrae. The posterior fibres of the laminae are predominantly vertical which predisposes to herniation of nucleus pulposus. The peripheral fibres of the annulus fibrosus consists of collagenous tissue and the inner fibres are made of fibrocartilages which blend with the nucleus pulposus without any demarcation. At the front and behind of the vertebral bodies the annulus fibrosus blends with the anterior and posterior longitudinal ligaments respectively. Some fibres sink deeply into the bone and the others are attached to the epiphyseal ring of the vertebral bodies.

The nucleus pulposus is a gelatinous mucoidal mass containing abundant water, cartilage cells and a few multinucleated notochordal cells in children. In young persons the water content of the nucleus pulposus is about 90%. This produces great turgor or fullness of the disc. In healthy young adults, the intervertebral discs are so strong that the vertebrae may break before the discs are ruptured during a fall. By the end of the first decade, the notochordal cells disappear and the mucoidal materials are replaced by fibrocartilage. The water content of the discs also diminishes with the advancement of age.

The contents of vertebral canal from outwards to inwards are:

i. Epidural space (or extradural space),
ii. Spinal dura mater,
iii Subdural potential capillary space,
iv. Arachnoid mater,
iv. Subarachnoid space with (CSF),
v. Pia mater (arachnoid and pia together from leptomenings),
vii. Spinal cord, spinal nerves and cauda equina.

Epidural Space (Extradural Space)

It is a space between the spinal dura mater and the periosteum of vertebral bone which is also called the periosteal dura. Therefore, it is bounded on one side by the spinal dura mater and on another side by the bodies of vertebrae with posterior longitudinal ligament (anteriorly), pedicles and intervertebral foramen (laterally), lamina and ligamentum flavum (posteriorly). Superiorly, it is closed by the fusion of the spinal dura mater with the periosteum of the skull and the vertebral bone (periosteal dura) at the foramen magnum. The periosteum of the vertebral canal is nomenclatured as the periosteal dura and the true dura mater of spinal cord is known as the spinal dura. As the spinal dura mater extends only up to the S_1 level inferiorly, so the subarachnoid space extends up to that level, but the epidural space is extended beyond that up to the sacral hiatus where it is closed by sacrococcygeal ligament (Fig. 24.9).

Through the intervertebral foramen epidural space communicates with the paravertebral space outside the vertebral canal. The fibrous strands, anchoring the spinal dura mater posteriorly with the periosteum partly divide the epidural space into two half in the midline. Actually in undisturbed

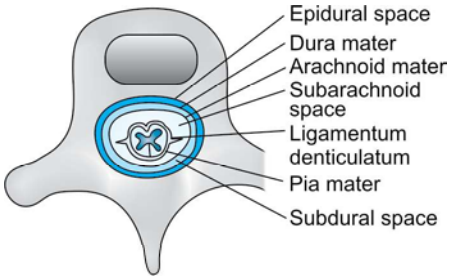

Fig. 24.9: Relationship of spinal cord to the meninges and vertebra

state the epidural space is a potential one with some loose areolar tissue in the midline and the epidural venous plexus by the side of the midline. The spinal dura or the investing layer of dura is in contact with the ligamentum flavum (where periosteum is absent) or with periosteum (where bone is present) but is not adhere to it. After an inflammatory disease, the spinal dura is adhered to the periosteum (periosteal dura) of vertebral bone and the epidural space is oblitered. When an epidural needle passes through the ligamentum flavum the blunt edge of the needle can contact with spinal dura and push it away. Thus, pushing away the spinal dura from the periosteum or periosteal dura creates a negative pressure which can be used to verify the placement of the needle in the epidural space. It also creates a space which can accept the local anaesthetic agent or a catheter. The epidural space at each vertebral level must be filled with local anaesthetic agent to ensure a complete anaesthesia while the general rule is that 1 ml of anaesthetic agent is required for each vertebral segment. But the range for a normal human being is wide which may vary from 0.8 to 2 ml for each segment while a catheter with a titrated dose is most commonly used.

The contents of epidural space are:

i. Loose areolar tissue,
ii. Liquid fat,
iii. 31 pairs of spinal nerve with their dural cuff on their way to intervertebral foramen,
iv. Sacral and coccygeal nerves,
v. Spinal arteries, arising from different sources at different levels enter the epidural space through the intervertebral foramen and supply the spinal cord, spinal nerves, meninges, periosteum and ligaments.
vi. Vertebral venous plexus: It forms a network of veins running vertically in epidural space. It can be divided into the anterior venous plexuses and

the post venous plexus. The anterior venous plexus lies anteriorly on the other side of midline and basivertebral veins empty into it. The posterior venous plexus lie posteriorly on other side of the midline. These venous plexuses communicate above with the intracranial venous sinuses and below with the pelvic, portal and caval system of veins. They also connect with the intervertebral veins which pass out through the intervertebral foramina and so communicate with the vertebral ascending cervical, deep cervical, intercostals, iliolumbar and lateral sacral veins. These venous plexuses have no valves. So, these epidural veins become distended during coughing, straining, pregnancy, etc. when the venous pressure rises. Through the valve less veins blood also can flow in opposite direction during increased intrathoracic and intra-abdominal pressure.

Meninges

The brain and the spinal cord are enveloped by three connective tissue membranes which are called meninges. These are named from outside inwards as dura mater, arachnoid mater and pia mater. The space outside this dura mater is called the epidural space. It is bounded between periosteum where bone (lamina) is present and ligamentum flavum where bone is not present on one side and and the dura mater on another side. A potential subdural space which is filled with a capillary layer of fluid, intervenes between the dura mater and the arachnoid mater. A subarachnoid space appears between the arachnoid mater and the pia maters and is filled with the CSF. In some parts of the brain and spinal cord, the subarachnoid space is significantly enlarges forming the cisterns. These three meninges primarily support and protect the soft tissues of the brain and spinal cord. Hence, they are surnamed by the word 'mater' which means mother for protection (Fig. 24.10).

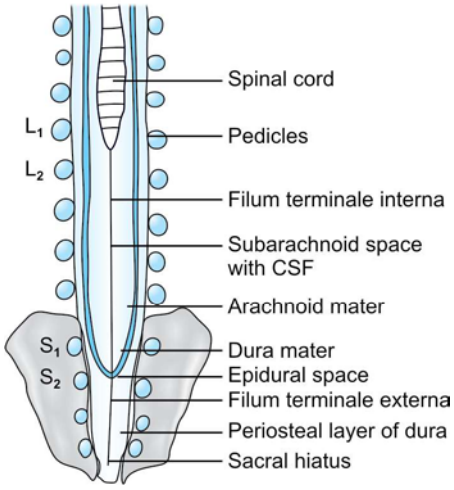

Fig. 24.10: Diagrammatic longitudinal section through the lower end of the vertebral column

Dura mater

It is a thick, fibrous and non-elastic membrane. In the cranial cavity the dura mater is arranged in two layers called the periosteal and the investing layer. Here, the periosteal layer of the dura mater represent the inner periosteum layer of the skull bones and adhere firmly with the investing layer of the dura mater, except where they split to enclose the venous sinuses of cranium. So, in the cranial cavity there is no epidural space (as the periosteal and investing layer adhere firmly). In the vertebral column, this periosteal layer of dura mater represent the inner periosteum layer of the bony part of the vertebral canal and the investing layer represent the dura mater of the spinal cord or spinal dura mater and the space between them is called the epidural space. The investing layer of dura is continued from the cranium into the vertebral canal as spinal dura, but is firmly adhered at the margins of the foramen magnum with the periosteal layer. Hence, the epidural space of the vertebral column is closed above at the level of the foramen magnum and local anaesthetic solution deposited in epidural space of vertebral canal can never enter into the cranial cavity. Below, the investing layer of dura or spinal dura mater ends with the arachnoid mater as a tube at the level of the 1st or 2nd sacral vertebra, so that CSF is not found below this level. At S_2 level the investing layer of dura or spinal dura mater ends with arachnoid mater by giving an covering layer to the filum terminale interna. This filum terminale interna is now known as the filum terminale externa with the coverings of dura and arachnoid mater and goes down to blend with the periosteum on the back of coccyx. The anterior and the posterior nerve roots, issuing from the spinal cord pierce the dura and carry a tubular prolongation of dural sheath (dural cuffs) which blends ultimately with the perineurium of mixed spinal nerve. In the vertebral canal the spinal dura is loosely attached anteriorly by fibrous stands to the posterior longitudinal ligaments and thus anchors its place anteriorly. Similarly, it is loosely attached posteriorly by fibrous strands to the vertebral arch and thus anchors its place posteriorly.

Arachnoid mater

The word arachnoid mater owes its name from the Greek word 'arachnes' which means a spider. In the cranial cavity and vertebral canal this meningeal layer is so named, because the numerous spider like trabeculae extend between the arachnoid and the pia mater. It does not follow the pia mater so intimately to line the every indentation of the brain and spinal cord which the pia mater does. The arachnoid mater is a thin, delicate and transparent structure. It constitute the middle of the three investing membranes (dura, arachnoid and pia), covering the brain and spinal cord. Spinal arachnoid mater is the continuation of the cerebral arachnoid mater and closely applied (but not yet attached) to the dura. The subdural space (between dura and arachnoid) is a potential capillary interface, containing little serous fluid, but not the CSF and possibly such a thin film of fluid exerts a negative force of traction which prevents the arachnoid mater from projecting inwards. The space between

the arachnoid mater and the pia mater is called the subarachnoid space and contain CSF. It is divided by an incomplete mid-line septum along the dorsal surface of the cord. The arachnoid mater is adhered (but not applied) to the dura only where some structures pierce both the membranes and where the ligamentum denticulata is attached to the dura.

Pia mater

It is made of two layers: (a) the outer epi-pia layer containing large blood vessels, and (b) the inner pia – intima layer (or pia-glia) lying in close contact with the nervous tissue. The blood vessels run between these two layers of pia mater. The epi-pia layer is lined by the flattened mesothelial cells and is connected to the overlying arachnoid mater by a number of trabeculae. The blood vessels extend through these trabeculae from the arachnoid mater to the pia mater and ramify between the epi-pia and pia-glia layer. The intercommunicating space around the arachnoid trabeculae (i.e. subarachnoid space) contains the CSF. The pia intima or pia-glia layer covers intimately the surfaces of the brain tissue and spinal cord. It consists of mesothelial cells held in a mesh work of reticular, elastic and collagen fibres and rests on a basement membrane which is lined internally by the foot plates of the astrocytes. Posteriorly the pia mater is adherent to the posterior median septum of the spinal cord and is also connected to the arachnoid mater by a fenestrated subarachnoid septum. Anteriorly the pia mater is folded into the anterior median fissure of the spinal cord. On each side, between the ventral and dorsal root of spinal nerve, the pia mater form a narrow vertical ridge with tooth like processes, projecting from its lateral free border. This is called the ligamentum denticulatum and attached through the arachnoid to the dura mater between the two roots of spinal nerves. These processes help to suspend the spinal cord in the middle of the subarachnoid space. The blood vessels going to the brain and spinal cord lie in the subarachnoid space before piercing the pia. They carry with them a sleeve of pia mater in the brain tissue and spinal cord.

Filum terminale (FT)

It starts as a thread like structure at the level of L_1 or L_2 vertebra from the terminal end of spinal cord (conus medullaris) and is named as FT interna. Filum terminale interna is composed of only pia mater and its length is of 15 cm. It then end by piercing the dura and arachnoid at the level of S_2 vertebra and continues below as the filum terminale externa, which ends eventually by blending with periosteum at the back of coccyx. FT externa is 5 cm in length and is composed of dura, arachnoid and pia mater.

SUBARACHNOID SPACE

It is a CSF filled wide space lying between the pia and arachnoid mater and surrounds the entire CNS like water bath. The spinal subarachnoid space is wider than its cerebral counter part. In spinal canal it is widest below the L_1 vertebra where spinal cord ends and continues as cauda equina (Fig. 24.11).

Cerebrospinal Fluid (CSF)

CSF is a clear, colourless liquid with pH of 7.4. Average volume of CSF in adult is near about 135 ml, of which 35 ml is in the ventricule, 25 ml is in the cerebral subarachnoid space and 75 ml is in the spinal subarachnoid space. Choroid plexus in the ventricles secrets CSF at a rate of 0.3 to 0.4 ml/minute. The normal glucose content of CSF is 2.5 to 4.4 mmol/litre (45 to 80 mg/dl) and protein content is 20 mg/dl. The normal albumin and globulin ratio in CSF is 1:1. After spinal anaesthesia the albumin level in CSF rises and becomes double of the normal value on the 18th day. The normal CSF pressure varies from 70 to 180 mm of H_2O in lateral position to 375 to 550 mm of H_2O in vertical posture. During epidural anaesthesia the increased pressure in the epidural space is transmitted to the subarachnoid space and hence the sensation of dizziness is felt by the patient. The specific gravity of CSF at body temperature, compared to water is 1.007. Whereas the specific gravity of 10% dextrose which is commonly used to make the anaesthetic solution hyperbaric is 1.034.

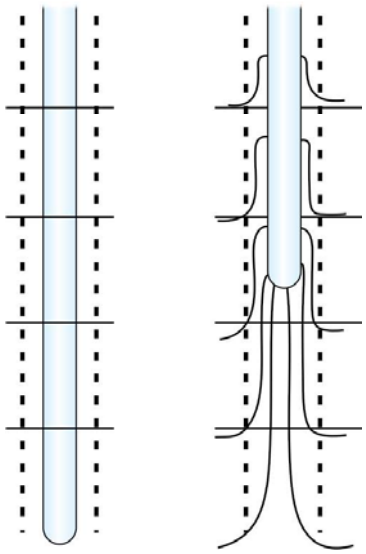

Fig. 24.11: The effect of recession of the spinal cord, during development, on the course of the spinal nerves

SPINAL CORD

The spinal cord as a part of CNS is a continuation of brain. It is an elongated and cylindrical neural structure and is contained within the upper two-third of the vertebral canal. Although cylindrical, it is some what flattened ventrodorsally. It retains actually the primitive form of CNS which is present in all the animals. The spinal cord is mainly concerned with the reception of different modalities of sensory impulse, integration and association of these information, and production of reflex response of basic characters. It is the direct continuation of medulla oblongata of brain. Spinal cord

begins at the upper border of atlas and ends, in adult, as a conical structure named conus medullaris at the level of the lower border of L_1 vertebra or upper border of L_2 vertebra. The apex of conus meduladris is continued down as filum terminale interna.

The length of a spinal cord is 42 to 45 cm in an adult. Sometimes, it extends up to the second or even, more rarely, up to 3rd lumbar vertebra. In newborn the spinal cord extends up to the 3rd lumbar vertebra and in foetal life the cord extends the entire length of the vertebral canal. At the third month of foetal life, the length of the spinal cord is as long as the vertebral canal and each spinal nerve arises from the cord at the level of the corresponding intervertebral foramen. During subsequent development the spinal cord does not grow as fast as the vertebral column. Therefore, the lower end of the spinal cord gradually ascends to reach the level of the third lumbar vertebra at the time of birth, and the lower border of the first lumbar vertebra in the adult. As a result of this relative upward migration of the spinal cord, the roots of the spinal nerves have to follow an oblique and downward course to reach the appropriate intervertebral foramen. This obliquity is most marked in the lumbar spinal nerves and many of these roots occupy the vertebral canal below the level of the spinal cord. So, below the 1st lumbar vertebra the vertebral canal is occupied by the leash of lumbar, sacral and coccygeal spinal nerve roots, termed the cauda equina. Another result of this upward recession of the spinal cord is that the spinal segments do not lie opposite to the corresponding vertebrae. In estimating the position of spinal segment in relation to the surface of the body and spine of vertebra, it is found that the later is always lower than the corresponding spinal segment. As a rough guide, it may be stated that in the cervical region there is a difference of one segment (e.g. the 5th cervical spine overlies the 6th cervical spinal segment), in the upper thoracic region there is a difference of two segments (e.g. the 4th thoracic spine overlies the 6th thoracic spinal segment), in the lower thoracic region there is a difference of three segments (e.g. the 9th thoracic spine lies opposite the 12th thoracic spinal segment). The spinal cord has two enlargements cervical and lumbar, corresponding to the increased nerve supply to the upper and lower limbs. The cervical enlargements extends from C_3 to T_2 spinal segment and the lumbar enlargement extends from T_9 to L_1 spinal segment.

Blood Supply (Fig. 24.12)

The spinal cord is mainly supplied by two posterior and one anterior spinal arteries. The posterior spinal artery, one on each side of the midline, arises from the posterior inferior cerebellar arteries at the base of the skull. It supplies the posterior horn and the posterior columns and is reinforced by the numerous posterior radicular arteries arising from the ascending cervical artery, deep cervical artery, intercostal artery and the lumbar artery. The single anterior spinal artery arises by the union of two small branch each of which arise from each vertebral artery at the level of the foramen magnum (Fig. 24.13).

The reinforcement of anterior spinal artery is few and irregular. But, one radicular artery, reinforcing the anterior spinal artery at the level of T_{11} segment,

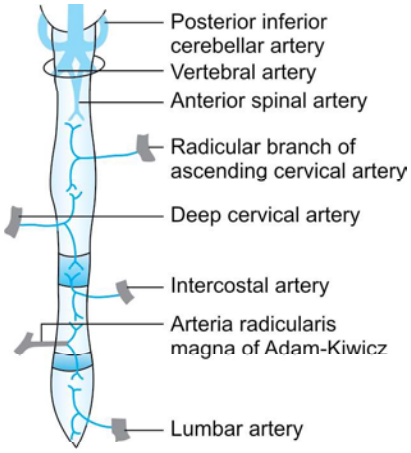

Fig. 24.12: Anterior arterial trunk of the spinal cord

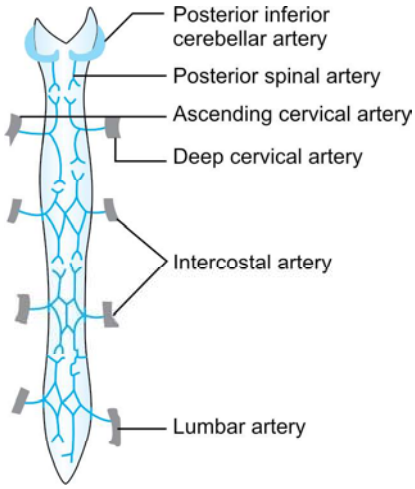

Fig. 24.13: Posterior arterial trunk of the spinal cord

supply the lumbar enlargement of the cord and is constant. This is called the radicular magna or artery of Adam-Kiewiez. Anterior spinal artery supplies the anterior and the lateral columns of white matter and most of the grey matter. The anterior and posterior spinal arteries do not anastomose with each other and thus creates three distinct vascular areas of the cord, with no anastomoses between them. Hence, this arrangement make the cord more prone to the damage by hypotension, thrombosis, vasoconstriction, aortic clamping, etc. (Fig. 24.14).

Anterior spinal artery syndrome

It is due to the thrombosis of anterior spinal artery and is manifested as paraplegia, but the retention of sensation of post column

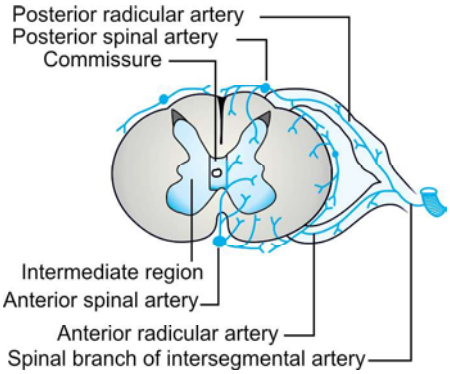

Fig. 24.14: Arterial supply of the spinal cord

which includes joint position, vibration, pain, touch, etc.

Venous drainage of spinal cord

It is done by anterior and post venous plexuses which again drain through the intervertebral foramina into the vertebral, azygos and lumbar veins. The normal intraspinal capillary pressure is 30 mm of Hg. Deprivation of blood supply for 2 minutes may result in infarction of cord.

SPINAL NERVES

The spinal cord gives attachment on either side of it to a series of 31 pairs of spinal nerves. These are 8 cervicals, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. Each spinal nerve arises from spinal cord by two roots—anterior (or ventral) and posterior (or dorsal). Again each nerve root is formed by the aggregation of a number of rootlets that arise from the cord over a certain length. The length of the spinal cord, giving origin to the rootlets for one spinal nerve constitutes one spinal segment. So, the spinal cord is made up of thirty one such segments: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and one coccygeal. The anterior or ventral roots contain motor fibres (both intrafusal and extrafusal) to the skeletal muscles of trunk and limbs and in some places preganglionic autonomic sympathetic (motor) fibres to the glands, smooth muscles of internal organs and blood vessels. The dorsal or posterior or sensory roots convey the sensory fibres from the peripheral general exteroceptive receptors of the internal organs, skin and subcutaneous tissues carrying sensation of pain, temperature, touch, pressure, etc. and general proprioceptive sensations from the muscles, bones and joints. Some fibres convey, in addition, general visceral sensations including visceral pain from internal organs and blood vessels (Fig. 24.15).

Both the roots of spinal nerve receive a tubular prolongations from the spinal menings and enter the corresponding

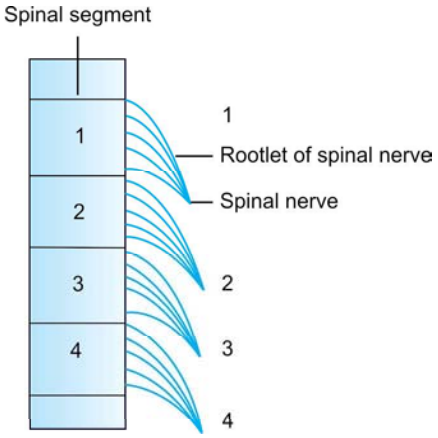

Fig. 24.15: Scheme to illustrate the concept of spinal segment and spinal nerve

intervertebral foramen. There they unite to form the mixed spinal nerve trunk. Just before joining with the ventral root, the dorsal root presents a spinal ganglion (dorsal root ganglion) which usually lodges in the corresponding intervertebral foramen. After coming out of the spinal cord and piercing the pia mater within the vertebral canal, the spinal nerve roots run in the subarachnoid space and carry a sleeve of CSF within the tubular prolongation of meninges (arachnoid mater and dura mater) up to the intervertebral foramen where they pierce the arachnoid and dura mater. After piercing the arachnoid and dura mater in the intervertebral foramen, when the spinal nerves come out, then the arachnoid covering blends with the perineurium and the dura mater with the epineurium of the spinal nerves. Each spinal ganglion which is present on the dorsal root contains 50,000 to 1,00,000 unipolar neurones. The axon of each neurone of the spinal ganglion sends a peripheral process into the mixed spinal nerve which carry the sensory impulses from the periphery and a central process into the dorsal horn of spinal cord through the dorsal root. It is roughly estimated that the number of sensory fibres in a dorsal nerve root is about 50,000 to 1,00,000 whereas the motor fibres in the ventral nerve root is about 5000. In more than half of the population, the first cervical and the coccygeal spinal nerve present no dorsal root.

The upper seven cervical spinal nerves leave the intervertebral foramina above the pedicles of the respective vertebrae. The eighth cervical nerve emerges below the pedicles of the 7th cervical vertebra. Then, eventually all the thoracic, lumbar and sacral spinal nerves emerge below the pedicles of the corresponding vertebrae. Due to the cranial shift of spinal cord during development with increased age, the spinal nerve roots become progressively oblique from above downwards. In the lumbosacral regions, the roots of the spinal nerve descends almost vertically and form a bunch of nerves, known as the cauda equina. It is so named because it resembles to the tail of a horse. This cauda equina is formed around the non-nervous pial filament called the filum terminale interna by the roots of five pairs (below L_1 or L_2) of lumbar, five pairs of sacral and one pair of coccygeal spinal nerves.

After emerging from the intervertebral foramen each mixed spinal nerve divides immediately into the dorsal and ventral primary rami. Each ramus receives fibres from both the roots, i.e. each ramus has both the sensory and motor fibres. Immediately after division, the dorsal primary ramus passes backwards and supplies the muscles and the skin of the back. It is to be noted that the C_1 nerve has no cutaneous branch and the dorsal rami of C_7, C_8, L_4 and L_5 nerves do not supply the skin. In the neck the dorsal ramus supplies the splenius muscle and the other muscles deep to it. After piercing and supplying the muscles, the dorsal ramus again divides into medial and lateral branches to supply the skin segmentally. In general, the extensor muscles of the vertebral column (motor), the scalp and the varying extent of skin over these muscles (sensory) are supplied by the dorsal ramus.

The ventral ramus supplies the prevertebral flexor group of muscles of the neck and trunk, the muscles of the thorax and

abdominal wall, the muscles of the upper and lower extremities (motor) and the skin of the sides and the front of the neck and trunk and extremities (sensory). The prevertebral flexor group of muscles include the longus capitis, longus colli, scalene, psoas, quadratus lumborum, etc. and piriformis. In the trunk the ventral ramus of 12 thoracic and first lumbar spinal nerves supply the intercostal muscles and the overlaying skin segmentally. The ventral rami of upper eleven thoracic spinal nerves form the intercostal nerves and that of the twelve thoracic spinal nerve form the subcostal nerve. The ventral ramus of first lumbar spinal nerve is distributed via the iliohypogastric and ilioinguinal nerve. Each intercostal nerve supplies the muscles of intercostal space. But the lower six intercostal nerves pass beyond the costal margin to supply the flat muscles of anterior abdomen and rectus abdominis. Moreover, the ventral rami of spinal nerves (which are also called the roots of plexus) form the cervical, brachial, lumbar and sacral plexuses at their respective places. The skin and the muscles of the upper limbs are supplied from the brachial plexuses and those of the lower limbs are supplied from the lumbosacral plexuses.

Out of the 31 pairs, only 14 pairs (12 thoracic and 2 lumbar) of spinal nerve have connection by the white rami communicans with the sympathetic chain. While all the spinal nerves are connected with the sympathetic chain by grey rami communicantes containing postganglionic fibres. The white rami communicantes contains the preganglionic sympathetic fibres, arising from the lateral horn cells of spinal cord extending between T_1 and L_2 segment of it. After arising from the lateral horn cells of spinal cord the preganglionic sympathetic fibres reach the sympathetic chain by the white rami communicantes and make connection with the postganglionic fibres at the corresponding ganglion in the sympathetic chain or passes uninterruptedly to the upper or lower ganglion of the sympathetic chain where they make synapses with the postganglionic fibres. Thus, the postganglionic fibres arise from all the sympathetic ganglion situated on the sympathetic chain and is then carried by the grey rami communicantes to all the spinal nerves. Thus, the sympathetic chains get its inflow from only the 14 pairs of white rami communicantes from 14 pairs of spinal nerves ($T_1 – L_2$), but have 31 pairs of grey rami communicantes for outflow to all the spinal nerves. Hence, each of the 31 pairs of spinal nerves receive the grey rami communicantes from the sympathetic trunk and conveys the postganglionic sympathetic fibres (non-myelinated) to supply throughout the whole body, except the abdominal and thoracic visceras and the structures head and neck supplied by cranial nerves. The thoracic visceras get their sympathetic supply through pulmonary and cardiac plexus and abdominal visceras get their sympathetic supply through splanchnic nerves. Thus, the sympathetic system innervates the entire body wall and all the four limbs through 31 pairs of spinal nerves.

DERMATOMES

The area of the skin supplied by a single segment of spinal cord through its ventral and dorsal nerve root is called the dermatome. As because the dorsal root of 1st cervical nerve (C_1) conveys only the proprioceptive fibres, so it does not present any dermatome. The front and the sides of the neck is represented by the C_2, C_3 and C_4 dermatomes. This is because the C_2 to C_4 spinal nerves supply this area of skin through the branches of cervical plexus such as great auricular (C_2, C_3), lesser occipital (C_2), transverse cervical cutaneous (C_2, C_3), and supraclavicular nerves (C_3, C_4). The upper limit of cervical dermatome involves the skin overlaying the angle of mandible, most of the auricle and occipital region of the scalp. Above that limit, the cervical dermatome meets with the sensory area supplied by the vth cranial nerve (trigeminal N). Below, the cervical dermatome extends up to the sternal angle in front, and over the rounded shoulder laterally (Fig. 24.16).

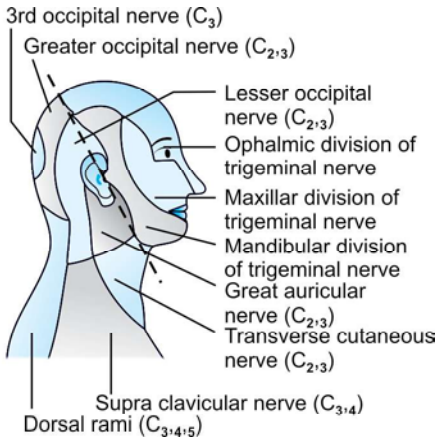

Fig. 24.16: The segmental innervation of scalp, neck and face. One side of the dashed line is supplied by cranial trigeminal nerve and another side is by spinal nerves

The dermatomes of trunk are represented by T_2 to L_1 spinal nerves and are arranged in regular series like strips. On the body the adjacent dermatomes overlap on each other considerably. So, the interruption of a single dermatome does not produce any effect on regional anaesthesia. At the level of sternal angle, the C_4 and T_2 dermatomes meet. This is because the missing of C_5, C_6, C_7, C_8 and T_1 dermatomes are carried over by the branches of brachial plexus to supply the upper limb which develops as a lateral outgrowth from the body wall.

The upper limb is supplied by the nerves of brachial plexus which is formed by the spinal nerves arising from the cervical enlargement of the spinal cord. The brachial plexus is formed by the ventral rami (which form the root or starting point of plexus) of C_5, C_6, C_7, C_8 and T_1 spinal nerves. The brachial plexus consists of roots (ventral ramus of the spinal nerve), trunks and cords. The five roots which extend from C_5 to T_1 emerge through the interval between the scalenus anterior and scalenus medius muscles.

The anterior division of brachial plexus supply the flexor compartment and the posterior division supply the extensor compartment of muscles. The flexor group of muscles possess richer innervation than the extensor group of muscles, because their actions are more powerful and precise. This explains why the most caudal root of the brachial plexus which is derived from T_1, is distributed entirely to the muscles of flexor compartment. This same principle is also applicable to lumbosacral plexus where S_3 root supplies only the muslces of the flexor compartment (Fig. 24.17).

The extreme peripheral end of the upper limb is supplied by the central dermatomes. Thus, the radial side of the arm is supplied by C_5, the radial side of the forearm is supplied by C_6, the middle three fingers with their adjacent palmar and dorsal surfaces is supplied by C_7, the little finger with the ulnar side of forearm is supplied by C_8 and the ulnar side of the arm is supplied by T_1 segments. The dermatomes overlaying the deltoid and bottom of the axilla are borrowed from the neck and trunk and are supplied respectively by the C_4 and T_2 spinal segments.

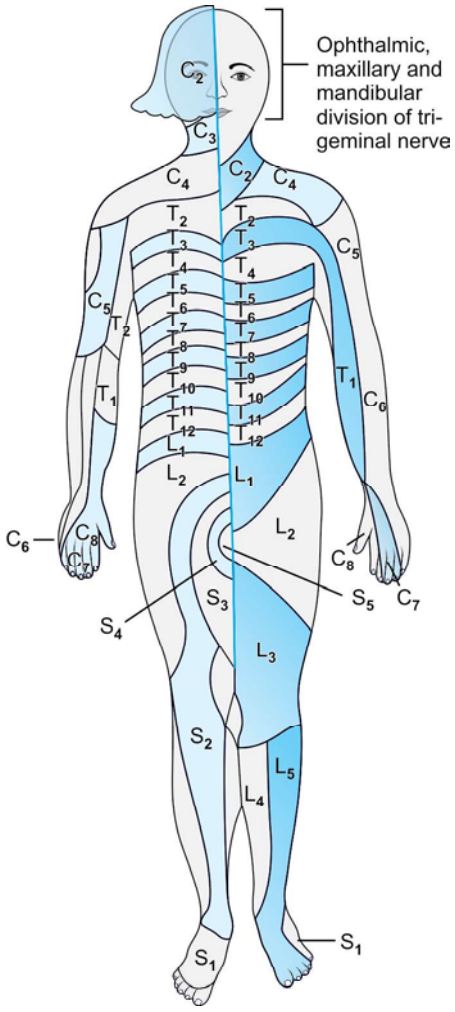

Fig. 24.17: The illustration of dermatomes

Each lower limb is supplied by the lumbar and sacral plexus which is formed by the spinal nerves arising from the lumbar enlargement of the spinal cord. The lumbar plexus is formed by the ventral rami of the upper three lumbar spinal nerves and the larger upper part of the ventral ramus of the 4th lumbar spinal nerve (L_1 to L_4). These are called the roots of the lumbar plexus. The smaller lower part of the ventral ramus of fourth lumbar spinal nerve joins with the ventral ramus of the 5th lumbar spinal nerve to form the lumbosacral trunk. Then, this trunk enters in the formation of sacral plexus. So, as the L_4 nerve makes connecting link between the two plexuses, it is called the nervous furcalis. Thus, the lumbar plexus is formed by the anterior rami of 1st, 2nd, 3rd and ascending part of 4th lumbar spinal nerve, assisted by a twig from the anterior rami of T_{12} nerve ($T_{12,}$ $L_{1,\ 2,\ 3,\ 4}$). On the otherhand, the sacral plexus is formed by the ventral rami of the 4th and 5th lumbar (lumbosacral trunk) spinal nerve and upper three sacral spinal nerves ($L_{4,\ 5}$ $S_{1,\ 2,\ 3}$) with a contribution from the upper part of 4th sacral spinal nerve.

Since, the lower limb buds grow as the lateral outgrowth from the body wall, opposite to the lower four lumbar and upper three sacral segments of spinal cord (at the level of junction of the ventral one third and dorsal two-third of genital labiosacrotal swelling), so the overlaying skin of each lower limb is supplied by $L_{2,\ 3,\ 4,\ 5,}$ $S_{1,\ 2,\ 3}$ spinal nerves through the lumbosacral plexus.

The consecutive dermatomes, involving the front of thigh (in front of the anterior axial line) are arranged in the following sequence from above downwards L_1, L_2 and L_3. In front of the leg, L_4 dermatomes lies on the tibial side and L_5 area on the fibular side. S_1 dermatomes lies along the lateral side of the dorsum and sole of the foot. The S_2 segment forms a narrow strip which extends up between the anterior and posterior axial lines along the middle of the calf and back of the thigh. The S_3 segment involves a wide semicircular area around the anus and between the axial lines. The S_4 segment supplies the adjacent perianal skin.

MICROSCOPIC STRUCTURE OF THE SPINAL CORD

On cross-section the spinal cord presents a white matter at the periphery and a butterfly like grey matter in the centre.

Grey Matter

The grey matter consists of nerve cells, neuroglia and blood vessels. In the centre of the spinal cord they are arranged in H-shaped manner. So, it is butterfly in shape. All the nerve cells in this area is non-myelinated, so it is grey in colour. Grey matter presents a pair of ventral horns, a pair of dorsal horns, an intermediate region which intervenes between the ventral and dorsal horns, and a commissure which connects the symmetrical halves of grey matter of each side across the midline. The ventral horns are broad than the dorsal horns and are more broad in the cervical and lumbar region than the thoracic region to accommodate numerous motor neurones, suppling the muscles of the upper and lower limbs. The dorsal horn consists of apex, head, neck and base. The base is continuous with the intermediate region of grey matter. The apex of dorsal horn is caped with a translucent mass of nerve tissue, called the substantia gelatinosa of Rolando which allows the entry

of sensory impulses through the dorsal nerve roots. The intermediate region of grey matter intervenes between the bases of ventral and dorsal horns and lies lateral to the commissure. In thoracic and lumbar regions, this intermediate region forms a lateral projection, called the lateral horn which is the centre of sympathetic output (Fig. 24.18).

The grey commissure is longitudinally transversed by a central canal, containing CSF. It is lined by ependymal cells and is continuous above with the cavity of the fourth ventricle, through the central canal of medulla oblongata. Within the conus medullaris of spinal cord the central canal is dilated to form the terminal ventricle. It may also extend for a distance of about 4 to 5 mm into the proximal part of the filum terminale interna. The central canal is surround by neuroglial tissue, called the substantia gelatinosa centralis.

The anterior or ventral horn of grey matter contains motor neurones and interneurones (internuncial or connector neurones). Motor neurones send axon fibres to the muscles. Interneurones or internuncial neurones possess small cell bodies and their processes are confined within the grey matter. They connect between the axons of sensory neurones in the dorsal horns and the cell body of motor neurones in the ventral horn, and is responsible for reflex activities. Their reflex activities may be intrasegmental or inter segmental, and ipsilateral or contralateral. Sometimes, the axons of sensory neurones in the dorsal horn make the direct connection with motor neuron of the ventral horn, without intervention of internuncial neurones. This is called the monosynaptic relays. The interneurone or internuncial neurones may be excitatory or inhibitory. But a particular interneurone cannot act in both ways. The Renshaw cell is classical example of inhibitory interneurone. The neurochemical transmitter substance of inhibitory synapses within the spinal cord is usually glycine. While the inhibitory neurotransmitter substance in the brain in GABA.

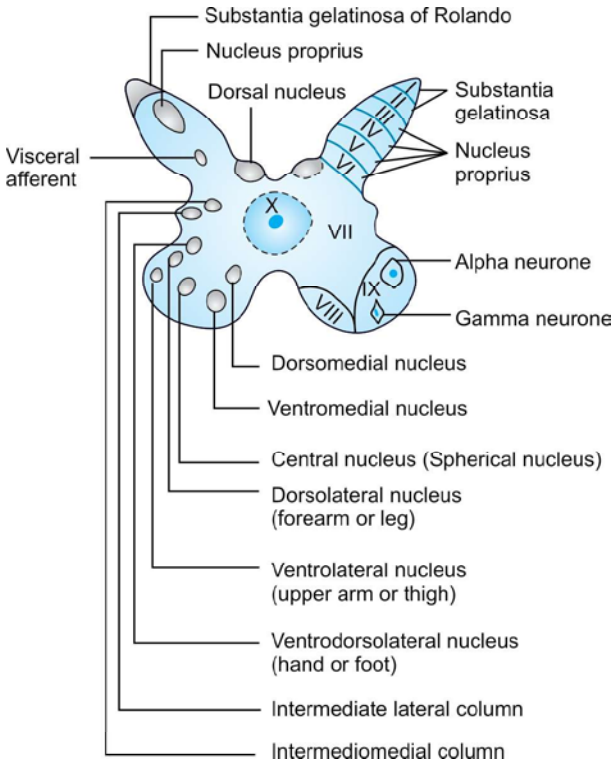

Fig. 24.18: Schematic representation of grey matter

The motor neurones in the anterior horn of grey matter is of three types—α, β and γ. Axons of these motor neurones leave the spinal cord through the ventral roots of mixed spinal nerve and then reach the effector striated muscles through the ventral and dorsal ramus which are the branches of this mixed spinal nerve. The cell bodies of α-neuron is large and their axons are thickly myelinated, conducting at a velocity of about 15 to 120 metres per second. These axons end on striated muscles by forming motor end plate over the individual muscle fibre (extrafusal fibre). The number of muscle fibres or muscle cells supplied by a single α (alpha) neuron is known as the motor unit, which may be large or small. The larger motor unit includes 100 to 200 muscle fibres or more (supplied by one motor neurone) and is concerned with gross movements. The smaller motor unit is comprised of 5 to 10 muscle fibres and appears in skillful movements, such as movements of the fingers of hand and eyeballs. On the otherhand, a single α-neurone may receive one thousand or more synaptic connections from the interneurones or from the fibres of dorsal roots with cells lying at the dorsal root ganglia or from the descending fibres of upper motor neurones. These synapses may be excitatory or inhibitory. The α-motor neurones also receive connections from the muscle spindles, corticospinal tract and vestibulospinal tract. Sometimes, the axons of α-neurones provide collateral branches which make synapses with the cell body of Renshaw cell type of interneurones situated in the anterior grey column or (ventral horn). In turn, the axons of Renshaw cells send impulse to inhibit the corresponding α-neurones and prevent excessive alpha firing. On occasions the Renshaw cells also inhibit the adjacent α-neurones and suppress the action of antagonistic muscles at the same time (Fig. 24.19).

The γ (gamma) neurones are small in size and their axons are thinly myelinated, conducting at velocity of 10 to 45 metres

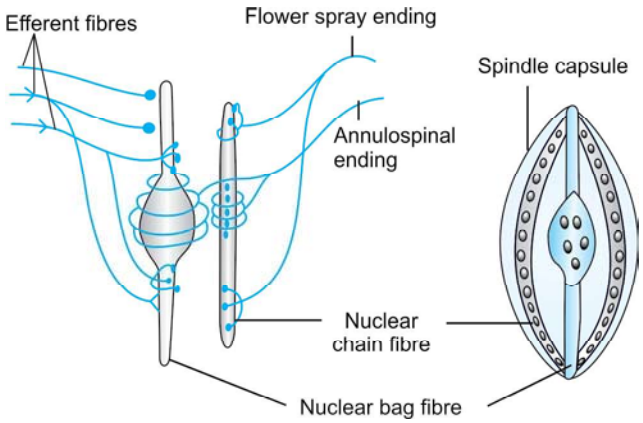

Fig. 24.19: Neuromuscular spindle

per second. The simple act of picking up a pencil from table not only employs the α-motor pathways, but also engage some afferent pathways which reach the spinal cord from the sensory endings of the skin, joints and the muscles spindle of hand and the fingers muscle to control the total muscle movement of hand and to pick up the pencil. In fact, the muscles spindles are the sensory end-organ of the skeletal muscles and are responsible for signaling the degree of shortening or lengthening of the whole muscle. In this way, they can provide information, so that only the exact amount of muscle activity which is required for the task is used. Histologically, the muscle spindle is an elongated and encapsulated structure which lies in parallel with the skeletal muscle fibres and shares its attachment. This latter point is of particular importance, as its principle function is to signal the exact length of the skeletal muscle fibre. Within the capsule of muscle spindle, small specialised intrafusal fibres can be recognised as the nuclear bag fibre and the nuclear chain fibre. γ-neurone (motor) supplies to the contractile polar regions of both the nuclear bag and nuclear chain type of intrafusal fibres of muscle spindle. The non-contractile equatorial region of intrafusal fibres are supplied by the general sensory nerve endings which act as stretch receptors and convey the sensory impulses when the polar regions contract, subsequent to the excitation of gamma neuron or when the entire muscle is passively stretched. The cell bodies of both the sets of afferent fibres are located in the dorsal root ganglia of posterior root and their central process reach the spinal cord through the dorsal nerve root and make monosynaptic connection directly or through internuncial neurones with the α-neurones which supply the extrafusal fibres of the corresponding muscle. Therefore, the α-neurones are excited and the whole muscle is thrown into contraction, until it shortens to equal with the degree of contraction of muscle spindle controlled by the γ-neurone. This method of control of contraction of a voluntary muscle by the gamma reflex loop maintains its residual length, even in resting condition and without any influence from the higher centre. The gamma loop acts as a servo mechanism and forms the basis of the reflex control of the residual muscle tone. The function of the intrafusal fibres is to inform the central nervous system through the gamma loop about the length and the rate of change in length of the extrafusal fibres. Whereas the α-neurones, on stimulation produce the final shortening of the muscles without limit, but the gamma neurones cause the muscle to contract to a predetermined length. The activities of gamma neurones are controlled by both the pyramidal and extrapyramidal fibres which may be excitatory or inhibitory. Considerable control of these motor neurone is exerted directly by the reticular system and indirectly by the cerebellum and basal ganglia.

The cell body and the axon of β-neurone is intermediate in size and diameter. Their axons supply both the extrafusal muscle fibres and the intrafusal fibres of the muscle spindle (Fig. 24.20).

There are four sets of neuronal column in the dorsal horn of grey matter. From apex to base they are named as follows: Substantia gelatinosa of Rolando, nucleus proprius, Clarke's column (nucleus dorsalis) and visceral afferent nucleus. The substantia gelatinosa (SG) is composed of cell body of sensory neurones and the small and medium sized cell body of interneurones. It extends along the entire length of

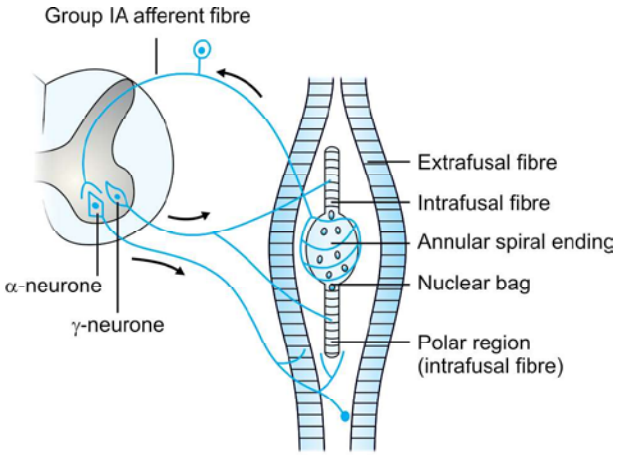

Fig. 24. 20: Pathways of active stretch reflex

the spinal cord. Traced above, it is continuous with the nucleus of the spinal tract of trigeminal nerve. The SG is traversed by the fibres of the dorsal nerve roots which are the axons of neurones situated in the dorsal root ganglia and carry the peripheral sensation. Some of these fibres make synapses with the SG cells, while others pass more deeply to the cells of nucleus proprius. The nucleus proprius (NP) lies deep to the SG and constitutes the head and neck of the dorsal horn of grey matter. It extends along the entire length of the spinal cord and is composed of the cell body of interneurones and tract cells. The axons of tract cells contribute to form the ascending tracts of the anterolateral white funiculi. The sensory fibres of the dorsal root which passes through SG and does not make synapses there, make synapses in NP or make tract. The nucleus dorsalis (Clarke's column) occupies the base of the dorsal horn and extends from C_8 to L_2 segments of the spinal cord. The nucleus dorsalis is also consist of interneurone and tract cells. The SG and NP is responsible for pain and temperature sensation, whereas the Clarke's column or nucleus dorsalis receives the proprioceptive afferent (i.e. muscle (Fig. 24.21) and joint sensation), touch and pressure sensation. Axon's of cell body of dorsal nucleus or Clarke's column pass ipsilaterally and form the posterior spinocerebellar tracts. The visceral afferent nucleus is situated at the base of the dorsal horn and extends from T_1 to L_2 and S_2 to S_4 segments of spinal cord. The cell bodies situated within this visceral afferent nucleus (VAN) receives visceral afferents fibres from the dorsal nerve roots and projects fibres to the preganglionic visceral efferent nuclei of the autonomic system which are located in the lateral horn of the corresponding segments of the spinal cord.

The lateral horn of the intermediate region of grey matter extends from T_1 to L_2 segments of the spinal cord. It is composed of intermediolateral and intermedio medial columns of cells and act as preganglionic motor neurones of sympathetic system (thoracolumbar outflow). The preganglionic fibres arising from these sympathetic motor neurones are thinly myelinated and pass successively through the ventral roots, mixed spinal nerve trunk and reach the corresponding ganglia of sympathetic chain via the white rami communicate. So, T_1 to L_2 spinal nerves have white rami communicantes in addition to grey rami communicantes which is present in all the spinal nerves, carrying the postganglionic sympathetic fibres which arises from the sympathetic chain. The intermedio medial group of cells reappears in the sacral region without any lateral projection. It extends from S_2 to S_4 segments of the spinal cord. These cells also act as the preganglionic motor neurones for the sacral outflow of parasympathetic system. Their axons pass through the ventral roots of corresponding mixed spinal nerves and then they leave the spinal nerves to form the pelvic splanchnic nerves (parasympathetic) (Fig. 24.22).

Recently, the entire spinal grey matter is mapped out by Rexed into ten laminae, according to the cytoarchitecture and packing density of neurones. Laminae I to VI are confined in the dorsal horns. Among these lamina I and II corresponds with the substantia gelatinosa (SG) and lamina III to VI corresponds with the nucleus proprius. Lamina VII occupies the intermediate region of grey matter. It includes nucleus dorsalis, intermediomedial and intermediolateral nucleus of autonomic system. Lamina VIII is located in the medial part of the ventral grey column in the cervical and lumbosacral enlargements of the spinal cord. In the other segments of the spinal cord, lamina VIII is located at the base of the ventral horn. Lamina IX is located in the lateral part of ventral horn at the enlarged segment of spinal cord for the limbs. Whereas in the rest of the segments of spinal cord (except the enlarge segment of spinal cord for limbs – such as cervical and lumbar segment), it occupies the head of the ventral horn. Lamina X occupies the area around the central canal which consists mostly of neuroglial cells (Fig. 24.23).

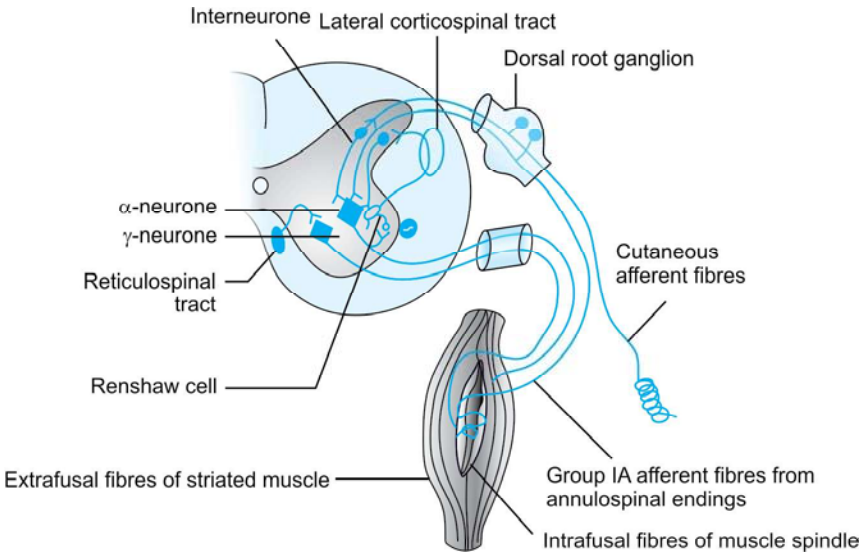

Fig. 24.21: Neurones of the anterior grey column and their functional role

White Matter

The white matter of spinal cord consists of nerve fibres (but not the nerve cell bodies), neuroglial cells and blood vessels. It is white due to the myelination

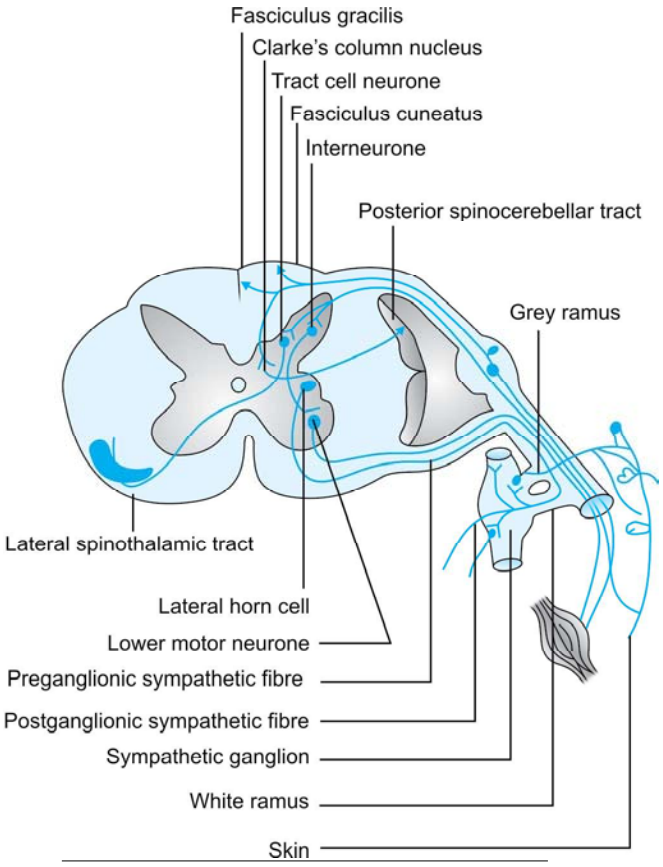

Fig. 24.22: Neurones of the posterior grey column and lateral horn cells with their functional role

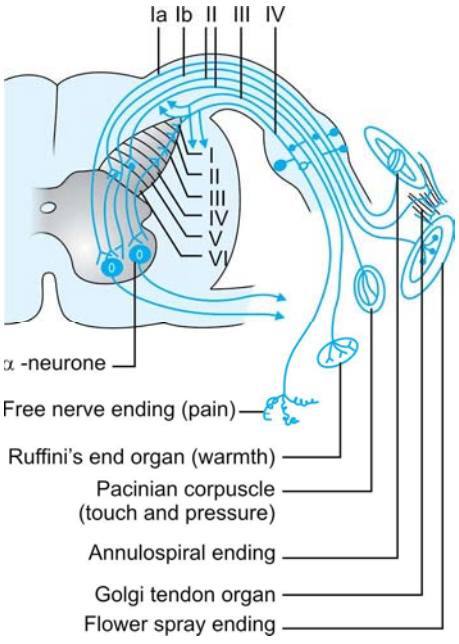

Fig. 24.23: Arrangements of sensory fibres at the root entry zone and their immediate termination

of nerve fibres. In the spinal cord the white matter occupies the periphery of the butterfly shaped central grey matter and is arranged into three pairs of funiculi—anterior, lateral and posterior. Usually all white funiculi are essentially composed of longitudinal nerve fibres which are grouped into different functional tracts and runs upwards or downwards on the same side of the spinal cord. But, some fibres of the white matter dicussate horizontally or obliquely across the grey matter and white commissure and pass to the opposite side of the spinal cord.

Fibres of Dorsal Nerve Roots and their Termination

All types of sensation such as exteroceptic, proprioceptive, and interoceptive, reach the spinal cord through the dorsal nerve root. Each dorsal nerve root has a ganglion near the intervertebral foramen and each ganglion contains 'T' shaped bipolar neurones with peripheral and central processes. Distal to the ganglion, dorsal root (sensory) meets with the ventral root (motor) to form the mixed spinal nerve which then comes out through the respective intervertebral foramen. The peripheral processes of the T-shaped ganglion cells which are situated in the dorsal root ganglion reach (i) the exteroceptive sensory receptor organs in the skin, (ii) proprioceptive receptors in the muscles, bones and joints, and (iii) interoceptive or visceroceptive receptors in the blood vessels and viscera. The central process of these T-shaped ganglionic cells form the dorsal nerve root and fans out centrally into six or eight root lets and reach the spinal cord. At the entry zone of root each rootlet presents medial and lateral divisions or bundles.

The medial divisions consist of thickly myelinated group I and group II fibres. Group I fibres are again subdivided into Ia and Ib. Ia fibres convey primary afferents from the muscle spindle. Ib fibres carry afferents from Golgi tendon organs, touch and pressure. Group II fibres convey secondary afferents from the muscle spindle, touch and pressure receptors and vibratory receptors (Pacinian corpuscles). All the fibres of the medial division enter into the posterior fasiculi and joint with the ascending tracts.

The lateral divisions consist of thinly myelinated group III and unmyelinated goup IV fibres. Group III fibres conduct fast and discriminative pain and temperature sensation. Group IV fibres are concerned with slow (aching) pain and visceral sensation. On reaching the spinal cord, the fibres of lateral division divide into short ascending and descending branches in the dorsolateral tract of Lissaur. Then, it extends one or two segments cranially and/or caudally and provide collateral and terminal branches which enter into the dorsal horn of grey matter.

BLOOD-CSF AND BLOOD-BRAIN BARRIER

The projection of vascular pial fringes into the ventricles of brain such as lateral, third and fourth ventricle is called the choroidal plexus. Ependyma is the simple layer of ciliated columnar cells. This lines the ventricles of brain including the choroidal plexus and the central canal of spinal cord. The ependyma, lining the choroidal plexuses of ventricles, helps actively in the formation of CSF. Actually, it also presents the blood − CSF barrier. The choroidal plexus presents numerous villi like projection on the ventricular aspect of the ependyma. Each villus contains capillary plexus. It is formed by afferent and efferent vessels, a small amount of connective tissue stroma derived from pia mater, and few nerve fibres. This aforesaid structure of the choroidal villi are enveloped by the ependymal cells which are simple ciliated columnar resting on the basement membrane and are connected to one another by tight junction (Fig. 24.24).

Thus, the blood - CSF barrier consists of the following:

i. Fenestrated endothelium of choroid capillaries resting on a basement membrane,
ii. A tissue space intervening between the vascular endothelium and the pial membrane,
iii. A continuous layer of ependymal cells connected by tight junctions.

The ependymal cells are actually the cells which is derived from the germinal layer of primitive neural tube and give rise to the development of neuroblasts and spongioblast. The spongioblast differentiates into astrocyte and oligodendrocytes.

The arterial blood of choroidal plexus is derived from the anterior and posterior choroidal arteries. The former are the branch of internal carotid artery. The latter are usually three or four in number and are derived from the posterior cerebral artery. The venous blood from the choroid plexus is assembled on each side to form a single choroid vein. The choroid veins join with the thalamostriate veins and ultimately drain into the straight sinus through the internal cerebral and great cerebral veins. The mechanism of the control of circulation of blood through the choroidal plexuses is not yet established.

The ependymal cells on ventricular surface exhibits microvilli. The structures of ependymal cells suggest that they are concerned with the transcellular and bi-directional transport of solvents and solutes between the choroidal capillaries and the ventricular cerebrospinal fluid. The total surface area of choroidal plexuses ranges from 150 to 300 sq cm. The active transport through the ependymal cells provides higher concentrations of Na and Cl ions and lower concentrations of other substances in the CSF than that of the plasma.

It is important to mention at this stage about the existence of two more brain barrier. These are CSF-brain barrier and blood-brain barrier. The CSF brain barrier intervenes between the CSF and the extracellular (neurone or glial cells) space. It includes extrachoroidal ependymal cells of the ventricles which have gap junctions between them, basement membrane and subependymal glial cell membrane. The blood-brain barrier includes the tissues that intervenes between the blood in the capillaries and the neurones.

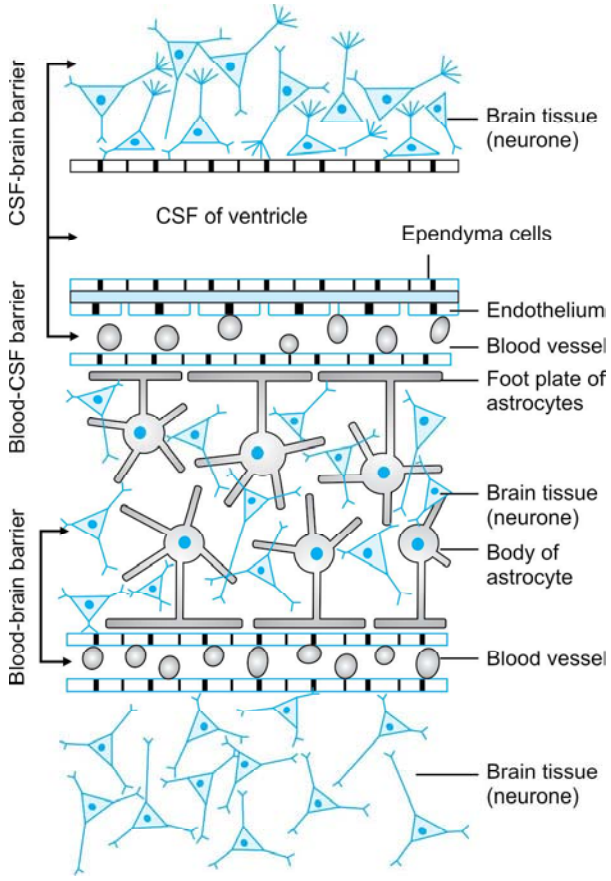

Fig. 24.24: The blood-CSF, CSF-brain, and blood-brain barrier

The blood-brain barrier consists of the following:

i. Nonfenestrated endothelium of the capillaries connected by tight junctions,
ii. A basement membrane for vascular endothelium,
iii. Perivascular feet and cell bodies of the astrocytes,
iv. A network of intercellular spaces between the astrocytes and the neurones, having an

interval of about 200A wide. The blood-brain barrier permits the entry of water, O_2, CO_2, some drugs like sulphadiazine and erythromycin, etc. readily into the brain. But proteins, bile salt, catecholamines and drugs like penicillin, etc. cross the barrier to a limited extend.

The CSF-brain barrier is weaker than the blood-brain barrier. This is because vital dyes and isotopes injected into the CSF gain quick access into neurones and neuroglia. In general, substances possessing high lipid solubility, such as CO_2, volatile anaesthetics and barbiturates, etc. pass from the blood to the brain and ultimately to the CSF. On the otherhand substances with limited lipid solubility, such as electrolytes, sugar and amino acids, etc. pass from the blood to the CSF and ultimately to the brain.

SELECTION OF THE PATIENT FOR REGIONAL ANAESTHESIA (RA)

Psychological Factors

During the training period many anaesthetists have the experience of successfully placing the block, but the effect of regional anaesthesia fails. In such circumstances, one of the most common reason for this unfortunate event is that the regional technique selected was not suitable for that patient. These patients are easy to identify. So, it is a mistake from the side of an anaesthetist to try to coerce with such patients to accept the regional anaesthesia without heavy sedation or GA. Because it is likely to be very difficult to manage these patients in the OT room, only with regional anaesthesia. So, regional anaesthesia without heavy sedation or GA is impossible or rarely provided to children. The patients of adolescent age group can be difficult to evaluate. Patients with psychiatric diseases, e.g. schizophrenia, manic depression, claustrophobia, Alzheimer's, dementia, etc. are not suited for regional anaesthesia.

Some orthopedic surgeries require special position during operation. This does not cause problems for short surgeries. But this can become extremely uncomfortable over long period of time, specially for patients who are suffering from body arthritic changes. Then, the gradual movement of patient that result from the restlessness during lengthy procedures can require excessive sedation and spoil the advantage of RA. Some procedures, e.g. shoulder surgery, surgery over head and neck area, etc. requires the patient to be drapped over the head for considerable period of time. But some patients may not be able to tolerate this situation and RA is not suitable for these group of patients. Another problem of RA is if the patient does not understand the principal language which is used in the OT by stuffs and the anaesthetists is not fluent with the language of the patient. Sometimes, RA without supplement of sedation or GA is also probably not wise. Some surgeons prefer to work with RA and modify his surgical techniques to accommodate it. So, to make RA successful, he also explains to the patient about the benefits of RA over GA, before the patient meets the anaesthetists. Contrary, some surgeons are uncomfortable to work with RA. So, he becomes reluctant to convey to the patient regarding the benefit of RA. Then, the preparation for RA may become more complicated or even impossible by anaesthetist.

Physical Factors

i. Regional anaesthesia should not be attempted when patient has any signs of systemic infection. So, general sepsis should be considered as absolute contraindication.
ii. Psoriasis and hidradenitis are two conditions in which although the skin is not infected, but this area must be avoided for needle prick. So, another site for regional technique should be selected, otherwise general anaesthesia is preferred.
iii. Herpes, found at preoperative examination, may pose problems. Secondary and subsequent recurrence of this disease is not contraindicated for RA. But, primary herpes is often associated with viraemia and so is a contraindication for RA.
iv. Chronic osteomyelities does not show any evidence of bacteraemia and so RA is not contraindicated. However, presence of bacteraemia in acute case is a contraindication for RA and should be avoided.
v. Pelvic infection presents controversy when RA is considered. The confluence of lymphatic drainage from the pelvis and the epidural space make placing of a needle (a potential nidus for infection) in vertebral canal during such infective condition controversial.
vi. For regional anaesthesia to be considered – no systemic signs of sepsis or clinical signs of pyelonephritis should be present.
vii. Many of HIV positive patients are severely ill, and might be considered ideally suited for RA due to severe illness. However, invasion of CNS by the HIV virus is of particular concern for RA. This is because the virus has property to cause demyelination. So, it is now generally agreed that any disease state which cause demyelination is an absolute contraindication for RA, since local anaesthetic agent too accelerates this demyelination. Here, the risk benefit ratio must be calculated.

Neurological Diseases

i. For diseases with central demyelination, such as, amyotrophic lateral sclerosis, Guillain-Barrè syndrome, etc. the RA is an unwise choice.
ii. The diabetic peripheral neuropathy is an area, where there is less consensus between RA and GA. Patient with this type of peripheral neuropathy often have other endorgan diseases which make them ideal for RA. But, however

due to medicolegal issues for postoperative changes in the extent of neuropathy due to diabetes (but not due to anaesthesia) some anaesthetists are reluctant to use regional anaesthesia in such cases. So, though mechanism of diabetic neuropathy is unknown and unaffected by action of local anaesthetics, still proper preoperative evaluation for any neurological deficit of such patient by thorough physical examination and risk/benefit analysis of the situation should be clarified before taking the decision for RA.

iii. An history of old stroke, especially an old embolic event, is not a contraindication for RA. The patient requiring urgent surgery in the period immediately after a haemorrhagic stroke, RA is strongly contraindicated. It is also contraindicated for any patient with a potential for increased intracranial pressure. The grey zone is the time interval between an acute condition and a chronic one. So, risk/benefit analysis and complete documentation of patient status is mandatory.

Coagulopathy

The actual incidence of neurological dysfunction associated with central neuroaxial block, resulting from cord compression by haemorrhagic complications such as haematoma paraplegia, abscess, etc. is unknown. But, the incidence which is cited in different literature vary from 1 in 1,50,000 in epidural to less than 1 in 2,20,000 in spinal anaesthesia. Among these complications the epidural haematomas is most common and, 68% patients have the history of coagulation abnormality due to intravenous heparin, antiplatelet medication, oral anticoagulants intake, dextran 70, administration, etc. Like the introduction of needle and/or catheter, the epidural haematoma also can occur immediately after the removal of the epidural catheter. These suggest that catheter removal is not entirely atraumatic. So, determination of patient's coagulation status at the time of catheter removal is perhaps as critical as that at the time of catheter placement. Neurological outcome is good only in 38% of the patients who underwent laminectomy within 8 hours of diagnosis of epidural haematoma. But, routine screening for coagulation profile in healthy patients, who are not taking any medicine that influences the coagulation cascade, is no longer advised before RA. But, practitioner of RA must take proper history of symptoms and signs of any coagulation defect. History of taking any anticoagulants, antiplatelets (aspirin, NSAIDs), a prior history of surgical bleeding diathesis, etc. should not be excluded from indication of RA, but should be evaluated carefully. The most valuable tools to detect potential bleeding problems during RA are bleeding time (BT), prothrombin time (PT) and partial thromboplastin time (PTT) which are the gold standard indicators of the integrity of an intrinsic and extrinsic pathways of coagulation. Salicylation of platelet by antiplatelet aggregating factors such as aspirin is irreversible and effect is not resolved till new generation of platelets are synthesised. Thus, two weeks withholding of aspirin and NSAID makes preoperative choice easier. However, not every patient could be prepared in this manner. Coagulopathy from this medication should be considered unusual. Prophylaxis of deep vein thrombosis (DVT) may involve low dose heparin/warfarin / coumarin, etc. and should be titrated against a defined prolongation of PT/PTT ratio. In such cases of prophylaxis, coagulation cascade is usually not altered, keeping in mind that a small percentage of patient will always have abnormal coagulation test. So, laboratory testing should be minimal for preoperative preparation of anesthesia. Withholding the medication for a period and documenting their normal coagulation tests after withdrawal is best choice. Preparing a risk / benefit ratio for these patients is mandatory. For a patient with clinically documented embolism and in need of urgent surgery of stopping the anticoagulant must be a joint decision by surgeon and anaesthesia team. Rarely, an indication for RA is so strong that active reversal of anticoagulation is executed with blood component therapy (fresh frozen plasma, cryoprecipitate, vit K) to allow anaesthetists to use RA technique. Resumption of heparin is decided by surgeon when surgical bleeding is stable in postoperative period.

Regional anaesthetic management of the patients who are on oral anticoagulants (warfarin)

The anaesthetic management of patients who are orally anticoagulated preoperatively with warfarin is dependent on the dosage and timing of initiation of therapy. The PT and INR valve (normal value of PT − 9.6 to 11.1 S which correspons to an INR value of 1.4) of patients on chronic oral anticoagulation will require at least 3 to 5 days to become normal after discontinuation of the anticoagulant therapy. Therefore, except in extraordinary circumstances, the spinal or epidural needle or catheter placement and removal of it should not be performed in dully anticoagulated patients. It is, therefore, recommended that documentation of the patient's normal coagulation status should be achieved prior to the implimentation of neuroaxial block.

Patients who are getting warfarin as thromboprophylaxis preoperatively have significantly higher PTs and complication rate. On the otherhand, many orthopaedic surgeons administer the first dose of warfarin on the night before surgery. For these patients, the PT and INR have should be checked prior to the neuroaxial block, if the first dose was given more than 24 hours earlier or a second dose of oral anticoagulant has been administered.

Patient receiving low dose of warfarin therapy for long period should have their PT and INR monitoring during

central neuroaxial block on a daily basis and checked before the removal of catheter specially if initial dose of warfarin is more than 36 hours before hand. There is a large variability in patient's response to warfarin. For example, usually the mean PT, by low dose (5 mg) of warfarin given postoperatively, does not increase beyond the normal range until 48 hours is passed. Again average therapeutic value is not achieved until the seventh postoperative day have passed. But few patients have PT value greater than 12.8 S after a single dose of warfarin. Higher dose of warfarin may require more intensive monitoring of the coagulation status. Reduced doses of warfarin should be given to patients who are likely to have an enhanced response to the drug. An INR > 3 should prompt the physician to withhold or reduce the dose of warfarin in patients with indwelling neuroaxial catheters. There is no definitive recommendation for removal of neuroaxial catheters in patients with therapeutic levels of anticoagulation status during a neuroaxial catheter infusion. But caution must be exercised in taking decision about the removing and maintaining these catheters.

Regional anaesthetic management of the patients who are receiving heparin

The safety of central neuroaxial block with intraoperative heparinization is well documented, provided no other coagulopathies are present. But the concurrent use of other medications that affect the coagulation status may increase the risk of bleeding complications for patients receiving standard heparin.

Intravenous heparin administration should be delayed for at least 1 hour after needle placement. Indwelling catheter should be removed 1 hour before a subsequent heparin administration or 2 to 4 hours after the last heparin dose. Evaluation of the coagulation status may be appropriate or mandatory prior to the placement of catheter or removal of it in patients who have demonstrated enhanced response to anticoagulants or are on higher doses of heparin. Although the occurrence of a bloody or difficult needle placement may increase the risk, but there are no data to support the mandatory cancellation of a schedule dose. If the decision is made to procede for central neuroaxial block in a patient who is receiving heparin, then a full discussion with the surgeon and careful postoperative monitoring are warranted.

There is no contraindication to use of spinal or epidural block after administration of subcutaneous standard dose of heparin provided coagulation parameters remain within recommended level and close monitoring is performed.

Regional anaesthetic management of the patients who are receiving LMWH (Low molecular weight heparin)

The patients on preoperative LMWH should be assessed to have altered coagulation profile at the time of spinal or epidural needle or catheter placement. A single short spinal anaesthesia may be the safest neuroaxial block in patients receiving preoperative LMWH. In these patients, needle placement should occur at least 10 to 12 hours after the last LMWH dose. Patients receiving higher doses of LMWH will require longer delays (24 hours). Neuroaxial block should be avoided in patients where a dose of LMWH is administered two hours preoperatively. This is because needle placement coincides with the peak anticoagulant activity of LMWH. Antiplatelet, oral anticoagulant, standard heparin or dextran administered in combination with LMWH may increase the risk of spinal haematoma.

Patients who are not receiving any anticoagulant, heparin or LMWH at present, but with proposed postoperative initiation of LMWH for thromboprophylaxis may safely undergo single dose and continuous catheter techniques. But the first dose of LMWH should not be administered earlier than 24 hours postoperatively. In addition, it is recommended that the indwelling catheter should be removed at least 24 hours after last dose of LMWH.

The decision to implement LMWH therapy in the presence of an indwelling catheter must be made with care. Extreme vigilance of the patient's neurological status is warranted. A minimum dose of opioid or very dilute local anaesthetic solution which does not block the motor is recommended in these patients in order to allow frequent monitoring of the neurological function. If epidural analgesia is anticipated to continue for more than 24 hours, LMWH administration may be delayed or an alternate method of thromboprophylaxis may be selected based on the risk profile for the individual patient. These decisions should be made preoperatively to allow optional management of both postoperative analgesia and thromboprophylaxis.

Regional anaesthetic management of the patients who are receiving antiplatelet medication

The antiplatelet medications are seldom used as primary agents for thromboprophylaxis. The only antiplatelet drugs, by themselves, appear to represent no added significant risk for the development of spinal haematoma in patients having epidural or spinal anaesthesia. Several large studies have demonstrated the relative safety of neuroaxial blockade in both obstetric and surgical patients receiving these medications. However, the concurrent use of medications that affect the other components of clotting mechanisms, such as oral anticoagulants, standard heparin and LMWH, may increase the risk of bleeding complications for patients receiving antiplatelet agents. Assessment of platelet function prior to performance of neuroaxial block is not recommended.

Ticlopidine and clopidogrel are also used as platelet aggregation inhibitors. These agents interfere with the platelet

fibrinogen binding and subsequent platelet – platelet interactions. The effect is irreversible for the whole lifespan of the platelet. Ticlopidine and clopidogrel have no effect on platelet cyclo-oxygenase and act independently of aspirin. The risk of spinal haematoma in patients receiving ticlopidine and clopidogrel in unknown.

EQUIPMENT REQUIRED FOR REGIONAL ANAESTHESIA

A failure of an anaesthetist to provide basic resuscitation, immediately after development of any complication due to toxicity of LA agent from any regional block, may accentuates this LA toxicity. This is because the toxicity of LA agent is magnified by hypoxia, hypotension and acidosis and a vicious cycle may set up. The LA agent induced grandmal seizure should also be promptly identified and treated by securing the patients airway, and giving a dose of thiopental intravenously. It is followed by a intubating dose of succinylcholine and subsequent intubation and ventilation. This prevents hypoxia and meet the excessive demand of O_2 for skeletal muscles due to seizure. By the time, the action of drugs used for induction wear off, the seizure precipitated by local anaesthetic agent used for RA will also be resolved.

So, the minimum requirements for a safe performance of regional anaesthesia (both peripheral nerve block and central neuroaxial block) are:

i. Emergency resuscitation drugs,
ii. Appropriate needles, syringes, IV cannulas, etc.
iii. Access to circulation and IV fluids,
iv. Thiopental, succinylcholine, atropine, adrenaline and other emergency drugs,
v. Oxygen and device for assisted positive pressure ventilation,
vi. Suction, laryngoscope and tracheal tubes,
vii. Monitoring devices,
viii. All facilities for general anaesthesia,
ix. Trained assistance.

Many anaesthetists do not routinely wear the sterile gown or face mask for regional techniques. But, it is mandatory to wear gown and mask for central neuroaxial blockade and introduction of catheter. However, this may not be mandatory for other regional blockade such as plexus block or field block. There is some controversy regarding the routine monitoring during the injection of any regional block. But, this is mandatory during central neural blockade.

INDICATIONS AND CONTRAINDICATIONS OF CENTRAL NEUROAXIAL BLOCK (CNB)

As a general rule, the central neuroaxial block is only indicated for the surgical procedures which can be accomplished on the awake patient with the sensory and motor block that is appropriate for this surgical procedure and the level of block does not produce adverse patient's outcome. Therefore, low spinal or epidural anaesthesia (block up to T_{10} spinal level or below it) carries different implication than the high (block up to T_5 spinal level or below it) spinal or epidural anaesthesia. Neuroaxial blocks may be used alone usually for the procedures on the lower half of body or in conjunction with GA usually for the procedures on the upper half of the body (upper abdomen, thorax and neck). Indeed in some European centres, cardiac surgery has also been routinely performed under thoracic epidural anaesthesia, typically with light GA.

Indications

Spinal anaesthesia may be an especially good choice than any other regional anaesthetic procedure. This is because the total dose of local anaesthetic drug to achieve up to the level of T_{10} block is quite small and will not push the total dose, as given during the epidural anaesthesia or different plexus blocks, close to the toxic level. The central neuroaxial block as a primary anaesthetic procedure is most commonly used to provide surgical anaesthesia for all procedures, carried out on the lower half of the body. Hence, the usual indications for CNB include surgeries on the lower limb, pelvis, genitals, perineum, obstetrics and most urological procedures. Regional anaesthesia in the form of central neuroaxial block (CNB) is also used for upper abdominal surgery, but in combination with GA or sedation. It is less commonly used as a sole anaesthetic procedure for upper abdominal surgeries. Recently, the RA technique has found in favour of analgesia in obstetric practise and provide anaesthesia for both elective and emergency obstetric procedures. Patients with respiratory diseases may definitely get benefit from regional anaesthesia by avoiding GA but only if the block does not extent beyond the level of T_{10} spinal segment. So, caution should be exercised in patients with severe respiratory and cardiac diseases if the level of block extends high up above the T_{10} level. Because, in acute respiratory disease the motor block of accessory respiratory muscles may impaired the pulmonary mechanics and aggravate the impairment of ventilation. Except lumbar approach, other approaches for spinal block such as thoracic and cervical approach are not used for the fear of damage to the spinal cord. So, the dural puncture for spinal block is usually performed below the level of first lumbar vertebra to prevent the damage of spinal cord which terminates at this level. But this is not true for epidural anaesthesia which can be approached through any route such as cervical, thoracic, lumbar and sacral. A relatively uncommon, but useful indication for spinal anaesthesia is elective surgical procedures over spine, especially lumbar such as laminectomy, spinal stenosis revision, lumbar fusion, etc. Usually majority of these cases are performed under GA, but there have been a number of reports of successful application of spinal anaesthesia for the above mentioned surgical procedures on spine. The reluctance to use spinal anaesthesia for lumbar spine surgery is based on several factors which

are discussed later. Many surgeons are unaccustomed to perform spine surgery on an awake patient. Occasionally, patient's movement and change in pattern of ventilation of an awake patient can be very disturbing. Many anaesthetists are also reluctant to employ any regional technique on a prone patient. This is because if GA is needed intraoperatively, then intubation of such patient in the prone position is difficult and potentially very dangerous. So, some anaestheologists prefer to have control over patient's airway under GA before the patient is placed in the prone position. On the otherhand, surgery on lumbar spine requires sensory block up to T_{12} segment. And an awake patient with block up to T_{12} level is capable of safely positioning their upper part of body with head and neck and can maintain his or her own airway unless oversedated or sensory level of spinal block is too high. If the duration of operation is too prolonged and the effect of original spinal anaesthesia receeds, then the dura will be in view and an enthusiastic surgeon can perform another second subarachnoid injection of LA agent. But except periosteum, rest of the spinal tissue where surgery is going on is insensitive. So, the need for supplementation of anaesthesia is confined to infiltration of skin only for wound closure.

Contraindications

The contraindication for spinal and epidural anaesthesia are grouped under two headings – absolute and relative. But at some point the demarcation between these two groups is blurred.

Absolute contraindications

i. Patient's refusal and proved allergy to local anaesthetic agent.
ii. Patient's inability to maintain stillness due to any medical causes.
iii. Lack of co-operation and understanding from patient's side.
iv. Intracranial lesion due to any cause resulting ↑ICP. It is a very important contraindication for spinal anaesthesia, because it may result in brain stem herniation due to excessive lea age of CSF. Epidural is also contraindicated (relative) in such patient because inadvertent intrathecal puncture during the procedure of epidural anaesthesia may result in a sudden fall in CSF pressure with herniation of brainstem through the foramen magnum.
v. Coagulopathy and untreated clotting defect.
vi. Skin infection at prick point of needle.
vii. Severe spinal and neurological abnormality, causing it technically impossible.
viii. Fixed cardiac output states, e.g. severe MS, MI, AS, etc. with very low left ventricular ejection fraction.
ix. Absence of resuscitation equipment and no intravenous access to meet emergency.

Relative contraindications

i. Coagulopathy – Intrinsic or idiopathic. In a patient taking anticoagulant, the risk must be weighed against the benefit. Well controlled anticoagulant treatment is not always a contraindication for spinal or epidural anaesthesia.
ii. Fever − General sepsis is an absolute contraindication for spinal or epidural anaesthesia, because infection may become settled at the point of injection, if there is any haematoma. But simple fever without any general sepsis is not an absolute contraindication.
iii. Severe hypovolaemia or continuing rapid blood loss.
iv. Lack of anaesthetists experience.
v. The potential for major blood loss during surgery.
vi. Previous laminectomy is not an absolute contraindication for spinal or epidural anaesthesia. It may be relative contraindication.

Heparin for deep vain thrombosis (DVT): APTT ratio up to 2 and in case of coumarin, INR up to 2 is safe ground for epidural or spinal anaesthesia.

Spinal or Epidural

The choice between the spinal and epidural anaesthesia for a patient depends on the following multiple factors:

a. Predictability of the length of surgery – epidural with catheter is preferred for prolonged surgery.
   Spinal anaesthesia is preferred where the duration of surgery is highly predictable.
b. Need for prolonged postoperative analgesia, epidural (with or without catheter) is preferred.
c. Where both spinal or epidural is applicable – chances of post spinal headache should be considered.
d. If patient is discharged immediately – single shot epidural without catheter is preferred.
e. For short surgical procedures waiting for epidural to take effect makes spinal more practical.
f. For more sick patient epidural block with catheter is preferred than spinal, because it avoids the sudden physiological changes which occurred during spinal anaesthesia.
g. For obstetric analgesia (not anaesthesia) subarachnoid block has no role.

PHYSIOLOGICAL EFFECTS OF CENTRAL NEUROAXIAL BLOCK (SPINAL AND EPIDURAL)

The central neuroaxial block is associated with certain physiological changes in the body and these are described below. When these physiological changes in our body cross their limits, then complications occur. For example, the physiological effects of neuroaxial block such as hypotension is not a complication. It becomes a complication when the hypotension is severe and produces damage, because complications imply damage to the patient.

Cardiovascular Effects

The central neuroaxial block, i.e. spinal or epidural anaesthesia produces pharmacological sympathectomy. The effect of this pharmacological sympathectomy due to spinal or epidural anaesthesia is similar to that of the α and β adrenergic blocking agent. However, the level of this sympathectomy and its effects depends on the height of block. In spinal anaesthesia the level of sympathectomy is 2 to 4 dermatomes above the level of the sensory block and in epidural anaesthesia it is at the same level of sensory block. Sympathetic block, i.e. sympathectomy causes both venous and arterial dilatation. But the venodilatation effect predominates as 75% of total blood volume is on the venous side. In general, the dilatation of arteries and resistance vessels cause reduction of the after load and increase in CO (if preload is maintained). Whereas, the dilation of venous capacitance vessel cause reduction of preload and decrease in CO. But the resultant effect of this arterial (resistance vessels) dilatation against venous dilatation in spinal or epidural block is decrease in CO and hypotension. This is due to the prepondarance of venodilatation. The decrease in myocardial contractility and heart rate also lead to decrease in CO and hypotension in a high spinal or epidural block. This happens when the block extends above the level of T_1 spinal segment and there is blockade of the cardioaccelerator sympathetic fibers which arises from the T_1 to T_4 segment of spinal cord (sympathetic outflow is from T_1-L_2). This causes decrease in compensatory outflow from the cardiac spinal sympathetic centre in response to the afferent impulses from the intrinsic chronotropic stretch receptor of the right atrium and great veins which in turn decreases the chronotropic and inotropic drive of heart, leading to further reduction of CO and hypotension. Thus, a vicious cycle starts.

There is also decrease in the coronary blood flow. This is because the coronary blood flow parallels with the mean arterial pressure. The myocardial O_2 consumption rate also varies. When there is fall of systemic vascular resistance and mean arterial pressure without tachycardia, then there is also reduction of after load and subsequent reduction of O_2 consumption rate by heart. But when there is compensatory tachycardia, O_2 consumption tremendously increases. Usually, there is no change in blood flow in organs, when sensory block extends only up to T_{10} level. This is because reduction of preload due to venodilatation causing decrease in CO and simultaneously reduction of afterload due to arterial dilatation causing increase in CO balance each other. But, when the block extends above the T_{10} level, then the balance tilts towards hypotension and the blood flow in different organs are impaired. Till up to 20% fall of mean arterial pressure (MAP) cerebral blood flow does not fall. But untill now it is still controversial and unanswered that up to which level the decrease of mean arterial blood pressure is acceptable. However, the reduction of blood pressure below 30% of mean arterial pressure is not advisable.

In summary, the sympathetic outflow to the capacitance vessels of the whole body originates from the T_1-L_2 segments of spinal cord. Among these the sympathetic cardioaccelerator fibres arise from the T_1-T_4 segment of spinal cord. The degree of compensatory sympathetic response to the central neuroaxial block is proportional to the number of segments blocked. In spinal and epidural block due to pharmacological sympathectomy the decrease in venous return decreases cardiac preload and hence cardiac output. In response to this change there is a compensatory increase in the heart rate (provided the cardioaccelerator fibres are not blocked) which tries to maintain the cardiac output and BP. This is mediated by the sinoaortic baroreceptors. On the otherhand, the decreased afterload due to dilatation of arteriolar resistance vessels due to pharmacological sympathectomy in spinal or epidural block may improve the performance of LV (provided preload is maintained by fluid) CO, BP and visceral perfusion. But the ultimate result regarding the CO, BP and organ perfusion depends on the severity of the reduction of preload and afterload which again depend on the extent of block of sympathetic outflow. Coronary flow increases as long as CO and pressure head in aorta is maintained. If CO and pressure head is not increased, then vasopressor agents are required to maintain BP, tissue perfusion and patient's well-being by constricting the capacitance vessels and the arteriolar resistance vessels. Compensatory increase in heart rate to maintain CO and BP requires intactness of the sympathetic efferent fibres to the heart which originate from the T_1 to T_4 segment of spinal cord. If sympathetic block extends above this height, then the compensatory increase in heart rate and myocardial contractility will not occur and this will result in severe hypotension. It is also possible in such situation that increased unopposed dominance of vagal tone to heart may drive the heart rate slow causing bradycardia and hypotension. So, to counteract this increased vagal tone anticholinergic agents (atropine) are also needed.

Respiratory Effect

The spinal or epidural anaesthesia with sensory block up to a certain level, i.e. more or less around T_{10} level have little clinical significance on the mechanics of respiratory system. Up to this level of block tidal volume remains unchanged. But, vital capacity may decrease due to the reduction in inspiratory and expiratory reserve volume. This is again due to the paralysis of some accessory respiratory muscles of abdomen. Rarely, respiratory arrest occurs and if it occurs it is due to the hypoperfusion and hypoxia of respiratory centre in brainstem due to severe hypotension. This occurs when the block extends up to a very higher level or due

to total spinal block. Hence, central neuroaxial block should be used catiously in comprised (respiratory system) patient because unintentional extension of block to the higher level causes paralysis of accessory respiratory muscles and further deterioration of pulmonary function even respiratory arrest due to hypoperfusion and hypoxia of central respiratory centre.

As the level of block rises an increasing proportion of the muscle, involved in respiration, are affected. The principal muscle of respiration, i.e. the diaphragm, usually remains unaffected, except in extreme cases of high spinal anaesthesia extending to cervical region or total spinal block. As the block ascends, gradually more and more intercostal muscles become paralysed after the paralysis of abdominal muscles. But most healthy patients should be able to maintain normal ventilation by the remaining unaffected muscles. Although the subjective feeling of immobility of chest wall and suffocation may be alarming, if they are not informed in advance. In such situation mild sedation may be needed to increase the tolerance of the patient. But the subjective distress may be early and greatly magnified in patients suffering from respiratory disease and if heavy sedation is used. So, the panicky sense of suffocation may sometimes make the central neuroaxial blockade a poor choice of anaesthesia for some patients. The degree of sedation necessary for the patient to tolerate anxiety could cause further respiratory depression in a patient who has limited respiratory reserve. In order to achieve the goal of avoiding instrumentation of the airway (i.e. intubation) by using spinal or epidural anaesthesia, the general rule is to keep the sensory level of blockade below T_7. If higher block is necessary for surgical procedure, then the selection of general anaesthesia with controlled airway should be considered, with or without combination of central neuroaxial block.

Gastrointestinal Effect

The sympathetic supply to GI tract originates from the T_5-L_1 segment of spinal cord. So, when the spinal anaesthesia extending up to T_5 segment results in sympathectomy, then vagal tone over the GI tract dominates and sympathetic tone disappears. This results in hyperperistalsis and early emptying of GI tract. So, gastric emptying is facilitated. Nausea and vomiting also results due to the hyperperistalsis of gut and vagal stimulation. Hence, atropine is effective in treatment of this type of nausea and vomiting by blocking the vagus. The spinal or epidural anaesthesia provides excellent surgical condition of GI tract due to contracted gut. Hepatic blood flow decreases in proportion to decrease in MAP. But its function remains unaffected and there is no hepatic ischaemia. Hepatic function is less impaired in central neuroaxial block than GA. In postoperative stage of epidural analgesia and anaesthesia, intramucosal pH of stomach remains high and provides a protective effects from gastric ulceration.

Renal Effects

Due to wide physiological reserve, the decrease of renal blood flow for reduction of BP following central neuroaxial block, have little physiological importance. But neurological block is a frequent cause of urinary retention, causing delayed patient discharge from the hospital and frequent catheterisation. Urine production is unaffected by the spinal or epidural block, as long as the mean arterial pressure is not significantly reduced. During regression from spinal or epidural block, it starts from the higher level and the thick nerve fibres are freed first. Hence, as the centre of bladder innervation is situated at $S_{2\text{-}4}$ spinal segment and some of the nerve fiber involved in urination are thin and easily blocked, so they may be the last to regress. Therefore, the passing of urine may be one of the last effects of regression of spinal or epidural anaesthesia.

Neurological Effects

Preoperative anxiety before surgery leads to sympathetic stimulation and increased release of catecholamine that results in gluconeogenesis amd myocardial stress. Sympathetic stimulation also causes increased heart rate and increased myocardial oxygen demand. But, sympathectomy resulting from spinal anaesthesia interrupts this catecholamine release and causes reduction of its level. The plasma level of ACTH varies from unknown to decrease, in the presence of sympathetic block.

PREOPERATIVE PREPARATION, PREMEDICATION AND INTRAOPERATIVE MANAGEMENT OF PATIENT FOR REGIONAL ANAESTHESIA

The patients scheduled for regional anaesthesia should also be prepared like general anaesthesia. Because all the regional techniques have a certain failure rate, (though small) and patients may require GA at any moment. Therefore, all the protocols regarding history, fasting, premedication, preoperative investigation, etc. are the same for regional and general anaesthesia. Reassurance is the corner stone of the successful outcome of a regional anaesthetic technique. Many patients prefer to go to sleep during operation. These patients should be reassured that sedation will be available, if required. Some patients have the fears of development of backache or neurological complications, particularly paralysis in future following spinal and epidural anaesthesia. These patients should also be reassured regarding the safety of this technique.

The risks and benefits of the proposed regional anaesthetic technique should also be discussed in advance with the patient. This discussion and written consent should be recorded in the patient's chart. There is always considerable anxiety in patients regarding the outcome of proposed surgery and the procedure of spinal or epidural

anaesthesia. Hence, mild anxiolytic premedication is very essential. If the patients have previous back pain, it increases when the patient is positioned for spinal or epidural anaesthesia. So, this pain can be relieved by any narcotics given in small doses. This will help in better positioning of patient and facilitate anaesthetist to give spinal or epidural block easily. But whatever may be given, it has to keep in mind that over-premedication does not allow the patient to maintain the needed position for extradural or dural puncture, particularly if sitting position is selected. Anxiolysis to the point of disinhibition should also be avoided, because it can lead to sudden untowards movements and agitation of patient, resulting difficulty for RA. The site of injection or block must be cleaned with an appropriate antiseptic agent according to the local hospital or institution policy. The anaesthetists must wear sterile gown and face mask especially during the central neuroaxial block. If the patient is awake the procedure can be made more tolerable by subcutaneous infiltration of small amount of local anaesthetic agent by a very fine 30 G needle or by applying eutectic local anaesthetic mixtures on the skin, before pricking by needle. Care must be taken to avoid inadvertent intravenous injection of local anaesthetic agent. So, prior to injection, aspiration must be performed to detect any blood in the syringe. Aspiration should also be repeated when large volume of drug is used in epidural technique. At the end, the whole procedure should be appropriately documented.

Aspects, other than the regional block, must be carefully considered to ensure that the overall experience of the patient regarding regional anaesthesia should be as much pleasant as possible. Most patients, except those undergoing minor surgical procedure, expect to be sleepy or unconscious. So, attention must be paid to the patient's overall comfort and warmth feeling while lying on a hard table and the provision of a relaxed enviornment. The patient should be protected from viewing the operation by the use of screens and towels, if needed. In some operations the position of the patient may itself give rise to some discomfort and embarrassment due to exposure. So, adequate sedation may make such procedures more tolerable.

Supplementation of Regional Anaesthetic Technique may be Done by the Following Methods

(i) By distraction of mind

The diversion of patient's attention from surgery is the major adjunct of regional anaesthesia. This can be performed by the use of personal stereos. Alternatively, a member of the operating room staff may engage the patient's mind by continuous chating.

(ii) By use of sedation

Properly titrated sedation can be used to supplement the regional anaesthesia. The provision of amnesia and hypnosis for the events in the operating room can be an advantage for many patients. But, the extensive use of sedation in conjunction with regional anaesthesia is illogical at best, and dangerous at worst. In such situation, anaesthesiologist must justify the use of excessive sedative drugs. Theoretically, the choice of sedative drugs during RA appears to be wide. But, in practice only a few drugs are used. Among all the sedatives, benzodiazepine is the first choice. Midazolam, the water soluble benzodiazepine, offers considerable advantages over its predecessor diazepam. It may be administered by intravenous bolus (0.15 to 0.17 mg/kg) or by continuous infusion (0.25 mg/kg/hour) technique. There is wide variation of dose – response relation with midazolam. The above mentioned dose is for guidance only. So, care and caution are required during the use of midazolam.

The newer anaesthetic agent propofol can also be used in place of midazolam. Continuous infusion of propofol is probably the best method of administration of sedation with RA throughout the whole surgical procedure. An infusion of propofol at the rate of 2 to 4 mg/kg/hour will provide sedation with rapid recovery. Now, some newer methods of administration of propofol are also of interest. For this a software algorithms is attached within the infusion pump with the aim to maintain the blood levels of propofol at the selected level (target controlled infusion). By this technique precise degree of sedation may be maintained. Another method of administration of propofol is to allow the patient to self-administer it in anxiolytic doses. This is called the patient controlled sedation and is analogous to the patient controlled analgesia (PCA). The advantages of propofol over midazolam are that the drug is easier to titrate. Over sedation is probably less common and recovery is more rapid, though the amnestic effect of propofol is not as powerful as that provided by midazolam. Care and caution with regard to cardiorespiratory system should be maintained like midazolam.

Small doses of short-acting opioids such as fentanyl (1 to 2 µg/kg) or sufentanyl (0.2 to 0.6 µg/kg) also can be used for analgesia in addition to or instead of sedative drugs. Supplementary analgesia have synergestic action with sedatives and may help to relief the discomfort. During the use of sedatives and analgesics, it is mandatory to monitor the saturation of oxyhaemoglobin and to administer oxygen, whenever necessary.

(iii) By use of general anaesthesia

It may seem unlogistic to render deliberately a patient insensible, when the central neuroaxial block (CNB) is providing perfect operating condition. But, sometimes the anxiety or doubt concerning the efficacy of block provided, or inadequate block may force the anaesthetist to apply general anaesthesia in addition to CNB. In such circumstances very light plane of general anaesthesia is needed. The combination of GA with CNB will give excellent

operating condition, as well as prolonged postoperative analgesia. But while combining GA with CNB, an anaesthetis must keep in his mind that this combination may sometimes produce a potential problem in which sudden onset of sympathetic block from CNB and cardiac depression effect of GA together can cause considerable haemodynamic compromise.

Awake versus Asleep

There has been recent controversy regarding the performance of central neuroaxial blockade in the awake, sedated or anaesthetised patient. The reason of controversy evolves from the fact that awake patient will tell and warn the anaesthetist when neural tissue is deemed to be damaged by a needle or catheter or injecting solution. But, there is no clear cut evidence that always CNB or any other plexus and peripheral nerve block should be performed with the patient awake. Because, there are multiple reports when neural damage has occurred in an awake patient and the patient did not complain at the time of institution of regional block. On the otherhand, there is no doubt that warning signs such as paraesthesia and pain, associated with nerve damage will be masked by sedation or anaesthesia. Again, it is easier to perform regional anaesthesia on a patient who is asleep or anaesthetised, particularly in children. Thoracic epidural blockade with or without catheter is the most difficult situation to resolve. The technique of thoracic epidural anaesthesia is very challenging and success is more likely when the patient is asleep. So, the careful use of nerve stimulators (when a nerve with motor function is to be blocked) is imperative during regional anaesthesia in the anaesthetised patient. But, this cannot be performed when the nerve to be blocked is purely sensory. So, at the conclusion, it can be said that the question regarding the use of spinal, epidural or any regional block in awake and sedated patient is still remain unresolved. But always we will have to keep in mind that if any damage occurs in sedated or anaesthetised patient, then it may be very difficult to defend in the court, though it is widely used all over the world.

Position of Patient

Usually, three positions of patient are used for spinal or epidural anaesthesia. These are lateral, sitting, and prone. Before positioning, to lateral or prone it is mandatory to secure an intravenous line with a large bore indwelling cannula and monitoring devices are connected. The preintervention administration of 0.5 to 1 litre of intravenous crystalloid or colloid solution as bolus to limit the hypotension, induced by central neuroaxial block is considered as standard practice. But, care may be required for those patients with severe pulmonary disease, heart disease, renal disease, etc. Treatment with vasoactive drugs is an alternative approach to IV fluid loading. But, controversy surrounds this topic (Fig. 24.25).

Lateral position

It is the most common position which is practised now for CNB and does not need any well trained assistant. It is useful for more sedated patient also. Patient should be positioned with head slightly tilted down or up, so that the spread of hypo, iso or hyperbaric anaesthetic solution to operative site is optimised. The spinal column has two ventral concavity – thoracic and sacral. So, when the patient is placed in supine after lateral position, the movement of hyperbaric local anaesthetic solution within the spinal subarachnoid space is not always towards the dependent part, if the injection is given at the mid lumbar region. This is because the thoracolumbar kyphosis, moves cephalad from the maximum lumbar prominence situated at the level of L_2-L_3 vertebra towards the most dependent part of the thoracic curvature in supine position, situated at about T_4 or T_5 vertebra level.

If the dural puncture is performed in lateral position and this position is maintained for few minutes, then there is a slight tendency for the dependent limb to be more influenced or paralysed by unilateral manner, although due to CSF mechanics both sides are ultimately affected equally. Leaving the patient on lateral position for 5 to 10 minutes after the injection of hyperbaric solution, there is more likely to produce a unilateral denser block on the dependent side, but not the complete unilateral block. Only at the higher spinal segmental level there is preferential unilateral blockade. With regard to cephalad and caudal spread the lateral position functions in the same way as the supine position. In any position, lateral, sitting or prone few moments should always be spent for careful identification of the most appropriate interspinous space for the dural puncture or EA which may save much time, increases the chances of successful block and will ensure that the procedure is as speedy and comfortable as possible for the patient.

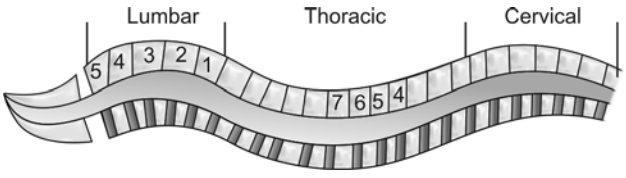

Fig. 24.25: The most prominent part of the lumbar lordosis and the most dependent part of the thoracic curvature in supine position

Sitting position

It is chosen only when the lower lumbar and sacral levels of anaesthesia are required or is adequate for surgical procedure such as perineal, lower urinary tract, vaginal, etc. Sometimes obesity and

scoliosis make identification of spinous process and interspinous spaces at midline more difficult in lateral position. So, if for only obesity and scoliosis, sitting posture is chosen but higher sensory anaesthesia is needed, then the patient should be made supine immediately after the procedure in sitting position. Some anaesthetists also prefer the sitting position than lateral position for routine spinal anaesthesia. This is because the sitting position has the advantages that generally the vertebra column remain in a straight line in such position and the identification of the interspinous spaces and so the technique of block is easier to perform. On the otherhand, some patients may find it is difficult to sit for the lumbar puncture (e.g. fractured neck of femur) and in such situation the lateral position will be more appropriate. Care may be required if premedication has been administered and there should be an assistant for positioning of the patient. After giving block at L_{2-3} interspinous space, if sitting position is maintained for 5 to 10 minutes, then it blocks the lower lumbar (below the puncture site) all sacral (S_{1-4}) and coccygeal spinal nerves, i.e. cauda equina only, which is called the saddle block. It also depends on the lumbar level where dura is punctured. If dura is punctured at higher thoracic level and sitting position is maintained for 5 minutes then more higher spinal segments will be blocked.

Prone position

This position is chosen only when the patient is to be maintained in that position during surgical procedure. Paramedian approach is more indicated and helpful in that position. For confirmation of subarachnoid block, we have to aspirate CSF, because CSF pressure is minimum in that position. In some circumstances the spinal or epidural anaesthesia is given in lateral position and then patient is make prone. In such situation. If the patient is placed in prone position before fixation of drug, then the movement of drug in CSF is determined by the same factors such as change the compliance of the subarachnoid space, tilting of vertebral column and as well as the gravity of the drug. As the thoracolumbar kyphosis is reversed when the patient is prone and the degree of flexion – extension achieved by prone position influences the location of the most dependent site as well as the movement of drugs, so the placement of patient into prone position with the downward direction of head before the onset of a gravity dependent spinal anaesthesia could result in dangerously high cephalad spread.

SPINAL ANAESTHESIA

Technique of Intrathecal Anaesthesia Through Lumbar Puncture Route

Worldwide, the intrathecal (spinal or subarachnoid) anaesthesia is the most commonly performed regional anaesthetic technique. Whereas extradural (or epidural) blockade is used to provide the labour analgesia and postoperative analgesia, in addition to any surgical anaesthesia. For intrathecal anaesthesia thoracic or cervical route are not used for fear of spinal cord injury, except when the dura is inadvertently punctured during the thoracic or cervical extradural analgesia/or anaesthesia. So, for intrathecal or spinal anaesthesia only the lumbar puncture is conducted under strict aseptic technique with all the required equipment for resuscitation.

Once, the anaesthetist is happy with the patients positions, then the skin of the back should be cleaned with an antiseptic solution or spray, guided by the protocol of that institution and allowed to dry. Then the patient should be drapped properly. After that the skin and the deeper structures over the lumbar spines can be infiltrated with local anaesthetic agent prior to the insertion of spinal needle but this will depend on the anaesthetist's choice. Some anaesthetists do not infiltrate the skin by LA agent prior to the main technique. Now the anaesthetists has choice for several types of needle for lumbar puncture, i.e. from the traditional cutting (Quincke) to the more recently introduced pencil tip (Whitcare and Sprotte) needles. However, the pencil tip needles are now the first choice of many anaesthetists for intrathecal anaesthesia, as it is associated with reduced incidence of PDPH.

Most anaesthetists perform intrathecal lumbar puncture in the midline and the space is selected between the spine of L_3 and L_4 or L_2 and L_3 vertebrae. First the vertebral spinous processes is selected and identified. Then, the spinal needle is inserted through the area of an anaesthetised skin, making an angle cranially to compensate for the (Fig. 24.26) angle of the spinous process. The needle will pass gradually through the skin, subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum and finally through the epidural space, dura mater and arachnoid mater before entering the subarachnoid space. There is often a characteristic 'give', when the tip of the needle passes through the dura and arachnoid layer. The successful intrathecal puncture of needle is confirmed, when the removal of the stylet is followed by the appearance of CSF at the hub of the needle. The appearance of CSF may be delayed if a very fine needle such as 27G is used. Again if there is any doubt regarding the authenticity of the fluid, then the use of a bedside glucose testing strip may be helpful. If a cutting tip spinal needle is used, then it is recommended that the needle should be inserted with the bevel parallel to the fibres of the ligamentum flavum and dura mater, so that the fibres are parted away rather than cut by the needle tip, as it is advanced. Inserting the needle in this fashion also reduces the chances of postdural puncture headache (PDPH). The lateral or paramedian approach to the subarachnoid space is also

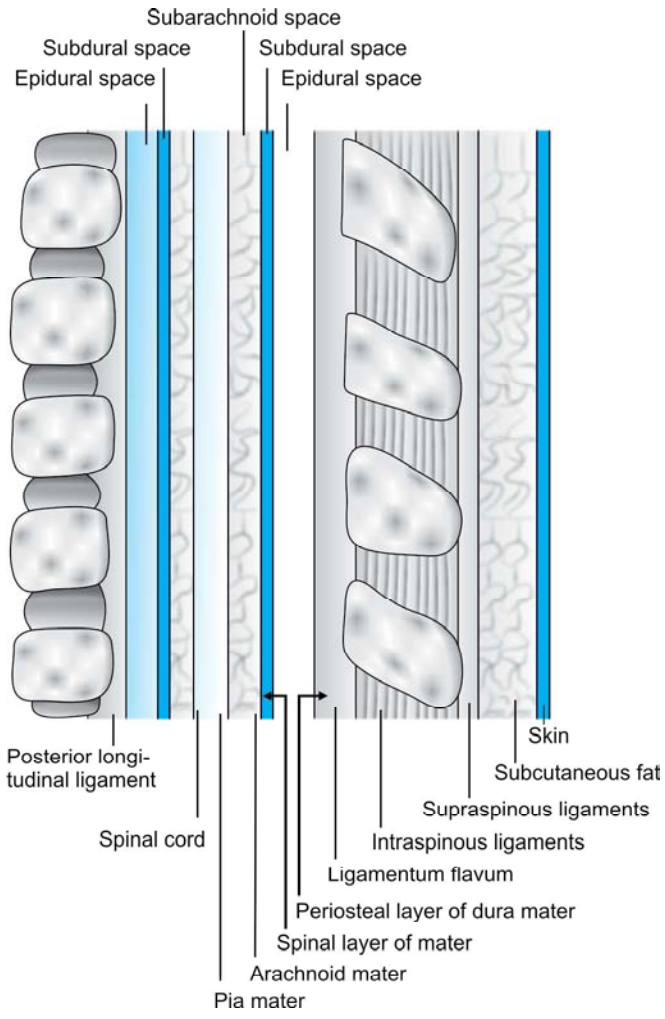

Fig. 24.26: The sagittal section through lumbar vertebrae

useful when the midline approach is difficult due to some scar tissue or arthritic changes. Once, the tip of the needle is confirmed to be lying in the subarachnoid space, then the local anaesthetic solution is injected. It is a good practise to confirm that the tip of the needle has not moved during aspiration of CSF or at some point during the injection of LA agent. Once the block has been established, then the upper level of anaesthesia should be identified with the loss of sensation to pin prick (a common measurement), although some would suggest that the touch is a more reliable method for the assessment of the level of block.

Choice of Local Anaesthetic Agent for Spinal Anaesthesia

In spinal or subarachnoid anaesthesia various drugs with different volumes, concentration, doses, baricity, sites, and position of patient are used to meet the aim. There are multiple studies regarding all these variables. Comparison of these multiple studies is also very difficult as different parameters for the measurements of neural block (both sensory and motor) have been used. The most important factor for the choice of local anaesthetic drug in spinal block is its duration of action which also varies according to the concentration, volume and total dose (in mg) of drug and the, site of injection and the position of patient. Among these the most important factor for duration of action is the drug itself. Till now, many different drugs have been used, but only a few drugs remain in current practise. In the recent years the choice of drug, available to anaesthesiologist, has been reduced only to the most commonly used 0.5% bupivacaine in 8% dextrose. Other drugs that are available in other countries (not in India) include procaine, lignocaine, mepivacaine and tetracaine. The duration of action of these drugs varies, (the reason of which is described above) but in general, procaine has a short duration of action, lignocaine and mepivacaine have a moderate duration of action and tetracaine, bupivacaine have a longer duration of action. The action of hypobaric solution persists for longer period than that of the isobaric solutions which in turn have a more prolonged action than that of the hyperbaric solutions. Sometimes, the epinephrine is added to the local anaesthetic agents to extend the duration of action. It doubles the length of duration of action of LA agents. The epinephrine may also have a direct antinociceptive effect on the spinal cord by the direct activation of descending inhibitory systems that modulate the dorsal horn neural activity. If patient plans to go home after outpatient surgical procedure, then the short acting LA drug is preferred.

Three drugs are commonly used for spinal or epidural anaesthesia. These are lignocaine, tetracaine and bupivacaine (Table 24.2).

Lignocaine

It has wide application in regional anaesthesia, mainly in spinal anaesthesia as hyperbaric or isobaric solution and provides a short to intermediate duration of action. It is chosen for the procedures that can be completed within 1 hour or less. The commonly used concentration of lignocaine in spinal block is 5% solution in 7.5% dextrose (hyperbaric). For the standard spinal anaesthesia 50 to 100 mg of lignocaine is used at L_2-L_3

Table 24.2: Specific gravities of some spinal anaesthetic agents

Agent	*Specific gravity*
1. Bupivacaine	
0.5% plain	0.99 - 1
0.5% in 8.25% dextrose	1.02 - 1.03
2. Lignocaine	
2% plain	1
5% in 7.5% dextrose	1.02 - 1.03
3. Tetracaine	
0.5% in water	0.99
0.5% in dextrose	1.01 - 1.02
4. Procaine	
10% plain	1.01
2.5% in water	0.99

interspinous space to achieve block up to mid thoracic level for a duration of 60 to 90 minutes. The onset of action of hyperbaric lignocaine is vary rapid and the upper level of block can be pushed higher by different physical intervention within 5 minutes after administration of LA drug or within 10 minutes, if epinephrine is added. The hyperbaric lignocaine solution is also an excellent preparation for the saddle block in sitting position. And in these cases dose can be reduced if the patient can be kept sitting for 5 minutes after injection. In such situation the dense motor and sensory block below the level of dural puncture is expected. If the patient is placed supine rapidly from sitting position after injection, then it will be not a saddle block and higher sympathetic, motor, and sensory block is anticipated due to the cephalad spread of LA agent. It was found in different studies that there is higher incidence of transient radicular irritation with the use of 5% lignocaine in subarachnoid space. But the relation between 5% lignocaine and transient radicular irritation is controversial. So, the reduction of concentration of lignocaine in hyperbaric spinal preparation is under trial.

Till now, there is also some controversy regarding the use of vasoconstrictor with different local anaesthetic drugs, like lignocaine, tetracaine and bupivacaine during spinal anaesthesia. The addition of 0.1 to 0.2 mg epinephrine or 5 mg phenyl ephedrine prolonges the duration of lignocaine and its efficacy, during the central neuroaxial block. Here two segment regression is the measurement of duration of neuroaxial block. But the addition of adrenaline in spinal drug to increase the duration of action of it may increase the risk of anterior spinal artery syndrome and cord ischaemia, particularly if associated with hypotension.

The subarachnoid block by isobaric solution is also possible by using 2% plain solution of lignocaine without added preservative. But the standard dose of isobaric lignocaine solution in subarachnoid block is 3 cc to 4 cc with or without 0.2 mg epinephrine. It provides anaesthesia up to T_{10} level for 60 to 90 minutes if drug is administered at L_3-L_4 space in supine horizontal position. However, the level of anaesthesia by isobaric lignocaine solution does not depend on the physical position of the patient after injection. But the level of anaesthesia in isobaric solution depends only on the volume, total dose, direction of needle-bevel and the speed of injection of local anaesthetic drug. Mixed with sterile water, preservative free 2% lignocaine also can be used as hypobaric solution for subarachnoid (SA) block.

The allergy caused by LA agent is commonly due to PABA (para-aminobenzoic acid) which is the breakdown product of ester linked LA agents such as procaine by plasma enzymatic cleavage. It is thought to trigger an allergic reaction in certain individual. This is because that patient may have previous immunological sensitisation to PABA as it is a common ingredient in many fragrances and cosmetics. Thus, I_gG or I_gM mediated anaphylaxis is a possibility of some ester linked LA agent. True allergy to amide local anaesthetic agent is uncommon, except in multiple-use preparations that have methylparaben as preservative. Methylparaben is a common allergen and is related to PABA. Even skin testing conducted under optimum circumstances to identify allergy of LA agent does not totally eliminate this concern. So, reasonable caution is mandatory.

The dose, concentration and volume of lignocaine used in epidural anaesthesia is discussed in separate section.

Bupivacaine

Like lignocaine it is also very commonly used LA agent for spinal anaesthesia and in some country it is the only available drug for subarachnoid block. Commonly used hyperbaric concentration of bupivacaine for subarachnoid block is 0.75% and 0.5% in 8.25% dextrose. The 2 cc of these hyperbaric bupivacaine solution, injected at L_3-L_4 interspinous space in supine horizontal position can block sensory level up to T_4 or T_6 spinal segment. However, lower dose is used in some extreme age group of patient due to the reduced compliance of subarachnoid space. The expected duration of action of 2 cc hyperbaric bupivacaine in subarachnoid space is average 2 hours. This duration of action can be reduced if the drug is made to spread over a wide area and diluted with CSF by the change of physical position of patient. However, as the spread of LA agent reduces the duration of action, but it increases the level of block of spinal segment. Isobaric form, i.e. 0.5% and 0.75% bupivacaine in plain aqueous solution are also used in spinal anaesthesia. Different studies indicate that there is no difference in the duration of action over a wide range of concentration from 0.25 to 0.75% as long as the total dose (in mg) of isobaric bupivacaine is kept constant. Below 0.25% the intensity and the duration of motor block is decreased. With isobaric solutions the onset of action of bupivacaine is also slow, with full sensory and motor block evolving only after 10 minutes. As with other isobaric techniques, the level of block is typically up to T_{12} segment and the haemodynamic alterations are minimal due to the lower level and slow onset of

anaesthesia which allows adequate time for endogenous compensation. When the isobaric form of bupivacaine is used, then the injected total dose of drug (i.e. total dose in mg) is more important in determining the height of block than the volume of drug and position of the patient. The action of bupivacaine lasts for 2 to 2.5 hours. The typical subarachnoid dose of bupivacaine is 15 to 20 mg. Addition of epinephrine with bupivacaine for spinal anaesthesia has minimal clinical significance.

(Epidural dose of bupivacaine is further discussed in separate chapter).

Tetracaine (Amethocaine)

It is available in package as both crystal (20 mg) and 1% solution (20 mg) which can be drawn in sterile water (hypobaric), dextrose solution (hyperbaric), or in CSF (isobaric). Thus, an anaesthetist will prepare their own solution (baricity) of tetracaine according to their need. The onset of action of tetracaine is 5 to 10 minutes and the duration of action is 2 to 3 hours with epinephrine. It may persist for 5 hours in lower extremity. It is the most commonly used agent for spinal anaesthesia in USA. In some country premade tetracaine with different baricity is also available. Premade tetracaine spinal kits contain 1% tetracaine solution in 2 cc ampoule which is mixed with 10% dextrose for hyperbaric solution. Some anaesthesiologists do not prefer premade preparation. Instead, they constitute the solution themselves immediately before their use. Because as tetracaine is an ester local anaesthetic, it loses its potency in premixed solution after exposure to heat, which explains occasional failure of block after the use of premade tetracaine. The usual dose of hyperbaric tetracaine is 6 to 20 mg, depending on the patient's height, weight, age and other factors that decrease the compliance of subarachnoid space. The level of sensory and motor block usually extends up to the level of T_4-T_6 spinal segment after lumbar spinal of 20 mg tetracaine at L_2-L_3 interspinous space in supine position. The onset of action of tetracaine is relatively rapid than bupivacaine, but some what slower than lignocaine. The addition of 0.2 mg epinephrine with tetracaine increase the duration of action by 20 to 50%. The classic isobaric tetracaine solution can be prepared by mixing its crystal with CSF, drawn from patient after dural puncture. Like other isobaric solutions the speed of injection, total dose, orientation of the bevel of spinal needle, etc. influences the level of block, but not the patient's position or posture (physical condition).

The dose of isobaric tetracaine solution is same as in hyperbaric.

Choice of Needle for Spinal Anaesthesia

1. The first question about the choice of spinal needle is if it should be disposable or reusable. But, the most anaesthetists accept the disposable tray, though there is no indication that the disposable set shifts the risk-benefit equation in patient's favour.
2. The second question regarding the choice of needle is cutting or noncutting pencil tipped. Cutting tipped needle like Quincke or Babcock, cut the dural fibre during their introduction causing more leakage of CSF and more incidence of post spinal headache. Whereas, the noncutting conical pencil tipped needle like Greene / Whitacre / Sprotte, etc. do not cut the dural fibres and are associated with decreased incidence of PDPH, when the needle sizes are compared.
3. The third question regarding the choice of needle is if it should be fine or thick. Fine needles such as 25-gauge or above are preferred for less incidence of post spinal headache. But, the introduction of these fine needles is technically difficult and the incidence of failure rate is high. Very fine needles may be inserted through an introducer or a 20 G needle. The introducer aids the passage of fine spinal needle through the tough ligamentous structure of the vertebral column. In older patients in whom the ligamentous structure of the vertebral column become calcified, it may be impossible to insert a fine tip pencil point needle in the subarachnoid space without the use of an introducer. The introducer has an additional advantage that spinal needle does not touch the skin and so also reduces the chance of infection.
4. The fourth question regarding the choice of needle is if it should be long or short bevelled and sharp or blunt pointed. The standard sharp pointed long bevelled needles are suitable for many blocks and may permit smooth passage of needle through the tissues. This enables fine control of the needle tip, but less recognition of the tissue plane. Whereas, the short bevelled blunt needle (e.g. Sportte needle) may enable tissue planes to be identified more easily, but the passage of needle through the tissues is not so smooth. The nerve damage caused by the type of needle is controversial. It is assumed that the standard sharp long bevelled needles cause less nerve damage if it is pierced accidentally but there is more chance to pierce the nerve by this type of needle. On the other hand, the blunt short bevelled needle has less chance to pierce the nerve, but if happens cause more damage. The less nerve damage by the sharp long bevelled needle is due to the fibres being separated rather than torn.

Needle

The standard hypodermic needle has a sharp pointed tip with bevel less than 20°. This is called the 'A' bevel type of needle. But a needle which is used for nerve block in regional anaesthesia is designed to be less traumatic to the nerve tissue. So, it is made slightly blunt with the bevel greater than 45° and is called the 'B' bevel type of needle. Depending on the purpose of

needle the bevel can be either sharp, polished or dull. The usual site for exit of drug from the needle is at the tip of it. But for some special applications the exit site is sometimes kept not exactly at the tip of the needle, but slightly proximal to the tip of the needle. Some other needle's modifications may also improve the dexterity of the operator. These are wings that can be attached to the hub of the needle. This allows the two handed better grip of the needle and enable the operator to feel the tissues better during its passage through it. Some needles have alternating polished and dull surface along the shaft of it for better tissue feeling. The shape, sharpness, bevel and hole at the tip of the needle are all variable that can be manipulated to suit the special needs. The Touhy and Huested modification are such examples of altering the tip of needle for special task such as epidural anaesthesia. The 2 to 4 mm area at the tip of Touhy needle is gently curved, which is designed to pass it through the soft tissue smoothly and make contact with dura without penetrating it (Fig. 24.27).

The spinal needles are also classified (i) according to the size of the needle, and (ii) according to the shape of the needle tip. According to the size, the type of spinal needle extends from 20 to 30 G. Thicker needle helps to feel the tissue structures better during its passage through it and after piercing the dura the flow of CSF through wide bore needle is faster. So, it helps in easy recognition of proper placement of needle in subarachnoid space. Another advantage of thicker needle is less failure rate in compare to finer needle. But PDPH incidence is high in case of thicker needles due to the large dural hole and significant CSF leak. On the otherhand, these advantages of thick needle becomes the disadvantages of fine needle. So, in fine thin needle there is less feeling of tissue structure during its passage through it and the flow of CSF through needle is not easy. So recognition of placement of it in subarachnoid space is difficult, and failure rate is high. But one distinct advantage of fine needle is less incidence of PDPH. Sometimes very fine spinal needles (25 to 30 G) need introducer (18 to 20 G) to facilitate their insertion through skin, ligaments and other structures. The introducer also prevent needle deflection, bending or breaking while passing through the tissues. The introducer also helps to keep the spinal needle sterile as it does not come in contact with skin and other structures.

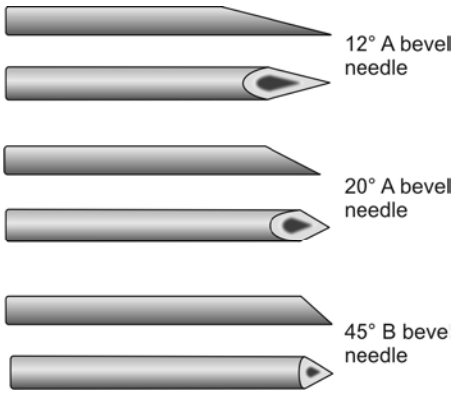

Fig. 24.27: The different types of A and B needle used for regional block

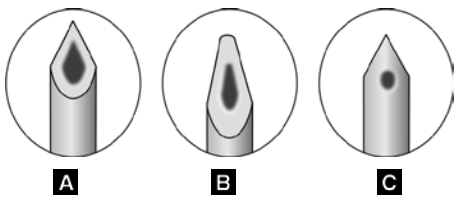
According to the shape of the tip of spinal needle, it is again subclassified into: (a) cutting tip spinal needle, and (b) noncutting pencil tip spinal needle (Figs 24.28A to C).

(a) Cutting tip spinal needle are

i. Pitkin needle – It has short, cutting bevel, and eccentric sharp pointed tip.
ii. Howard Jones – It is metallic spinal needle with cutting tip, available in size ranging between 20 to 24 G.
iii. Quincke-Babcock – It is the most widely used spinal needle with a cutting tip and long sharp bevel. It has exit point at the tip and available from 16 to 30 G.



Figs 24.28A to C: Spinal needle. A. Quincke, B. Sprotte, C. Whitcare

iv. Atrucan – It is cutting tip needle with double bevel.

(b) Noncutting pencil tip spinal needles:

i. Green needle – Long sharp bevel and rounded tip with orifice at end.
ii. Whitcare needle – Solid pencil tip with small lateral orifice, 2 mm proximal to the tip – proximal injecting needle.
iii. Sprotte needle – Solid pencil tip with large lateral orifice whose diameter is equal to the internal diameter of the needle with proximal injecting point.

Factors Affecting the Height of and Duration of Block in Spinal Anaesthesia

1. Density

The density of any solution is the weight of solute in gram per 1 ml of solvent. Concentration is nothing but density, but concentration in w/v means weight of solute in gram per 100 ml of solvent. Increased concentration of any local anaesthetic solution in CSF increases the duration and the height of block. It influences the duration more than baricity. But baricity influences the height of block more than the concentration.

2. Specific Gravity

It is the ratio of density of a solution compared to the density of water. It also influences the duration and the height of block like the baricity of solution of a LA drug by influencing the spread.

3. Baricity

Baricity is the ratio of comparing the specific gravity of one solutions to another. Baricity of LA solution is classified as hyperbaric, isobaric and hypobaric in reference to the specific gravity of CSF which varies between 1.003 and 1.005. The plain LA solutions such as 2% lignocaine and 0.5% bupivacaine which is available commercially for local infiltration are prepared

at a specific gravity nearly identical to CSF (isobaric) at room temperature and hence they are isobaric. When they are warmed to body temperature before injection, then they become slightly hypobaric. The classic isobaric LA injection can also be prepared from crystal of local anaesthetic agent such as tetracaine after mixing it in patient's CSF. Hypobaric solutions are also can be made by mixing the crystal of local anaesthetic agent in preservative free sterile water. Hyperbaric solution are created by mixing the LA agent with 7.5 to 10% dextrose (in order to achieve a gravity of 1.02 or above) (Table 24.3).

Hyperbaric Solution

The hyperbaric solution of LA agents are made by adding 5 to 10% dextrose with it. They move downward in CSF and block the roots of nerve below the puncture level. In sitting position and if it is maintained for 5 to 10 minutes after the administration, of LA agent, then the LA agent moves caudally and blocks the coccygeal, sacral and lumbar spinal nerves (below the puncture site) only. This is called the saddle block. The hyperbaric solution of LA agent also moves to the dependant side in lateral position and cephalad up to the midpoint of thoracic curvature in supine position if the site of dural puncture is at the height of the lumbar lordosis and the patient is in slightly Trendelenburg position. Otherwise, (if the patient is in anti-Trendelenburg position and the site of dural puncture in at the height of the lumbar lordosis) the drug will accumulates caudally in the sacral hollow and will produce inadequate height of block. In supine position the hyperbaric solution causes more higher block than the isobaric or hypobaric solution. In lithotomy position baricity have little effect on the height of the block. The hyperbaric solution acts in a more predictable manner than the hypobaric or isobaric plain solution of LA agent. The peripheral nerve toxicity of local anaesthetic agents is increased in the presence of dextrose. But it is uncertain, whether this is a direct effect of dextrose on nerve or whether the presence of dextrose enhances the toxic effect of local anaesthetic agent.

Table 24.3: Factors affecting the level of spinal anaesthesia (arranged according to their importance from more to less)

i.	Site of injection
ii.	Baricity of anaesthetic solution
iii.	Position of patient
	– During injection
	– Immediately after injection
iv.	Drug dose
v.	Drug volume
vi.	Patient height
vii.	Curvature of spine
viii.	Pregnancy
ix.	Needle direction
x.	Age
xi.	Intra-abdominal pressure

Isobaric Solution

They are the simplest solutions of LA agent. They are commonly marketed for infiltration anaesthesia such as 2% xylocaine and 0.5% bupivacaine in vial with preservative and are also used in epidural block. The spread and consequently the height of block by isobaric local anaesthetic solution in spinal anaesthesia does not depend on the position or the posture of the patient. So, the effects are somewhat unpredictable. Tetracaine (amethocaine) isobaric formulation is made by diluting the tetracaine crystal (20 mg) in CSF. The distribution of isobaric local anaesthetic solution and consequently the height of block produced by it mainly depends on the volume of drug, the temperature and the direction of injection (Table 24.4).

Hypobaric Solution

They are usually used and most useful in prone positions for anorectal procedures or in lateral positions for hip surgery. Theoretically, 2% lignocaine has been investigated as a 'clinically' hypobaric spinal drug. But, practically physiochemical properties of 2% lignocaine is more isobaric than hypobaric. Still some anaesthesiologists find it more useful in situations reserved for hypobaric techniques.

Table 24.4: Factors that probably do not affect the height of spinal block

- Rate of injection
- Addition of vasoconstrictor
- Barbotage technique
- Cough or any strain, like bearing down during labour
- Bevel of needle
- Weight of patient
- Gender

4. Lipid and Water Solubility of Drug

More lipid soluble anaesthetic agent such as fentanyl spreads less than the less lipid soluble anaesthetic agent such as morphin in spinal anaesthesia. This is because when an agent becomes more and more lipid soluble, then it is absorbed more and more quickly by the lipid rich nervous system impairing the spread it.

5. Volume of Anaesthetic Solutions

Like baricity, position of patient and site of injection, the volume and the total dose of drug (in mg), has same effect on the height of spinal anaesthesia. But increased dose in mg certainly prolongs the duration of block. On the otherhand, the greater spread of a large volume of local anaesthetic agent may briefs its duration of effect due to quick absorption by the blood vessels of large area. So the spread increased by baricity, posture or other means curtailed the duration of effect of LA agent.

6. Barbotage

This term is derived from the French word named 'barboter' which means to paddle or mix. Repeated aspiration of CSF (Table 24.5) by syringe and injection of LA in the subarachnoid space cause mixing and dispersing of the original dose of local anaesthetic agent in it. Thus, the spread of a given dose of local anaesthetic drug and

Table 24.5: Dosages and duration of action of commonly used spinal anaesthetic drugs

Drug	Preparation	(Doses in mg)			(Duration in minute)	
		Perineum and lower limbs	Lower abdomen (up to T_{10})	Upper abdomen (up to T_4)	Plain	With adrenaline (0.1 to 0.2 mg)
Lignocaine	5% in 7.5% dextrose	20 - 50	50 - 70	70 - 100	60 - 90	90 - 120
Bupivacaine	0.5% in 8.25% dextrose	5 - 10	10 - 15	15 - 20	90 - 120	120 - 150
Ropivacaine	02 - 1% solution	6 - 12	12 - 16	16 - 18	90 - 120	90 - 120
Tetracaine	1% in 10% dextrose	5 - 10	10 - 15	15 - 20	90 - 120	120 - 150

subsequently the height of anaesthesia can be increased by barbotage, which is now hardly used.

7. Site of Injection

Any site (or interspinous space) for injection can be chosen for the administration of local anaesthetic agent for spinal or epidural anaesthesia. But, obviously the higher will be the site of injection, the higher will be the height of block. This is applicable to both the spinal and epidural anaesthesia. But in spinal anaesthesia the higher will be the site of injection, the higher will be the chance of cord injury and severe hypotension. The L_{3-4} / L_{4-5} is the safer intervertebral space to restrict the dural puncture for spinal block, in order to avoid the possible damage of spinal cord. But, epidural block can be given at any site such as cervical, thoracic, lumbar, and sacral.

8. Position of Patient during and Immediately after Injection

Like the above mentioned factors, the position of patient during and immediately after injection in subarachnoid or epidural space is also very important in determining the height of block. But the Baricity of LA solution, concentration and volume of drug, position of the patient and the site of injection are all interrelated and can be modulated according to the necessity of the height of block. After placement in subarachnoid space the local anaesthetic agent is very rapidly taken up by the nerve tissues of spinal cord and disappears from CSF. So, the first 5 minutes after administration of drug are very crucial for the local anaesthetic agent for tissue fixation. In lateral position, the vertebral column is more or less horizontal. However in lateral position in some women, the vertebral column is inclined towards the head and it is due to increased width of pelvis relative to the shoulder. In some men the vertebral column is inclined towards the coccyx because of the increased width of shoulder relative to the pelvis. So, the operating table should be inclined during CNB in lateral position according to the necessity, keeping all the factors in mind.

For anorectal, perineal, genital and bladder neck surgeries, 1 ml hyperbaric solution in sitting position (maintained for 5 minutes) at L_{4-5} space is useful which blocks only the sacral, coccygeal and L_{4-5} spinal nerve with little or no fall of blood pressure. This is known as the saddle block. Increasing the volume and concentration of LA agent the duration of this type of block can be increased according to the duration of surgery. But for lower abdominal surgery 1.5 to 2 ml drug (hyperbaric) at L_{3-4} space is injected in lateral position and the patient is turned immediately in supine position. This is sufficient for 45 minutes to 1 hour surgery in lower abdomen. L_{3-4} interspace forms the apex of the lumbar curvature. So, administration of heavy drug in that space in supine position spreads up to the mid thoracic segment as T_5 is the most dependent part of the thoracic (Fig. 24.29) curvature in supine position. Sometimes, after injection drugs may fall in the hollow of the sacrum, leading to block of only sacral and coccygeal spinal nerve roots. For upper abdominal operations block up to T_4 or T_5 spinal segment is required. This is obtained when 2 to 3 ml of hyperbaric LA drug is injected at L_{2-3} interspace with slight head-down position. For upper abdominal surgery the level of anaesthesia is needed up to T_4 segment, along with the greater splanchnic nerve ($T_{4, 5, 6, 7, 8}$) block supplying the omentum and mesentry. So, intraoperative paraoesophageal vagus block is also given by surgeon for upper abdominal surgery, along with the spinal or epidural anaesthesia.

Some landmarks of segmental supply which is very useful for spinal anaesthesia are: perineum – S_{2-4}, groin – L_{1-2}, umbilicus–T_{10}, xiphoid – T_7, nipple – T_{4-5}, 2nd intercostals space – T_2, clavicle – $C_3 - C_4$, subcostal arch – T_{6-8}. Factors that decrease the size of subarachnoid space also cause the compression and the decrease of the compliance of subarachnoid space. For example, increased intra-abdominal pressure transmitted via intervertebral foramen to epidural space cause compression and reduction of subarachnoid space. Thus pregnancy, obesity, ascities, huge ovarian tumour or any other factors that increase

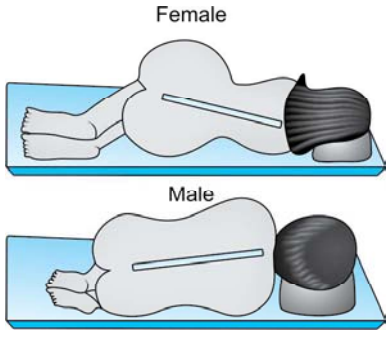


Fig. 24.29: The natural tendency of inclination of vertebral column in lateral position of male and female patient

the intra-abdominal pressure cause reduction of the volume of subarachnoid space and increase in the height of block with the same volume of drug. Age decreases the compliance of subarachnoid space and increases the height of block also. The decrease of compliance of subarachnoid space with increase of age is due to the increase of stiffness and decrease of the size of subarachnoid space.

9. Pregnancy

Pressure over inferior vena cava by gravid uterus causes dilatation of the epidural veins which in turn decreases the volume of the epidural space and increases the epidural pressure. Thus compession of subarachnoid space from increased epidural pressure causes lower volume of it and higher spread of LA solution. Progesteron also potentiate LA action, which is also responsible for the increase in spread of action of local anaesthetic agent in pregnancy.

10. Ascites

It has also the same effect as gravid uterus on inferior vena cava and in turn on epidural vessels and space. Also increased intra-abdominal pressure from ascities is transmitted directly into the epidural space through the intervertebral foramen and thus increases the epidural pressure which in turn decreases the size of subarachnoid space and increases the spread and action of local anaesthetic agent in spinal anaesthesia.

11. Obesity

Obese patients also have decreased subarachnoid compliance, particularly when the patient is in supine position, where the weight of abdominal pannus acts much in the same way as a gravid uterus or ascitis.

12. Spinal Stenosis

For the same reasons, decreased compliance of subarachnoid space in spinal stenosis causes wider spread and increased action of local anaesthetic agent (LA) in spinal anaesthesia.

13. Age

The age influences the conduct and outcome of subarachnoid anaesthesia to some extent. Geriatric patients have the decreased compliance of subarachnoid space and reduced CSF volume which causes greater spread and increased extent of the level of spinal anaesthesia with same volume of drug. This is applicable to hyperbaric, as well as to isobaric and hypobaric anaesthetic solutions.

Geriatric patients rarely develop PDPH. So, the use of fine, noncutting spinal needle to minimise this complication is not necessary. On the otherhand, the thick and cutting sharp spinal needle have advantage for geriatric patients, since these patients have difficult dural puncture due to the calcification of the ligaments such as supraspinous, interspinous, etc. and may offer greater dexterity. The low incidence of spinal headache in geriatric patient is probably related to the advanced degenerative arthritis which is common in the geriatric spine and makes the continued leak of CSF unlikely due to inflammation that induces sealing of the dural puncture.

14. Temperature

It also acts for movement of the drug.

Height of block necessary for few common operations

Prostate, bladder, thigh – block up to T_{10}
Inguinal hernia – block up to T_{10}
Umbilical operation – block up to T_{6-7}
Lower abdominal operation – block up to T_7
Upper abdominal surgery (cholecystectomy gastrectomy, transverse colectomy) – block up to T_4

For gut surgery, some afferent stimuli pass through the vagus nerve. So, such type of surgeries require para oesophageal block of vagus nerve or GA along with spinal or epidural block. Here the central neuroaxial block helps by producing an ischaemic field, gut retraction, good relaxation, reduction of stress and postoperative analgesia.

Fate of Local Anaesthetic Agent in CSF

Anatomically, it is likely that the exposure of spinal cord and its nerve roots to local anaesthetic agent which is injected in the CSF, results in blockade of conduction of impulses through them, before they exit through the intervertebral foramen. However, though there is also exposure of spinal cord to local anaesthetic agent, but the conventionally used concentration and doses of LA drug make penetration of it into the deeper parts of intact spinal cord unlikely. Termination of action of LA agent after spinal anaesthesia is likely to occur by dissociation of drug into the spinal fluid from the cord and its roots first and later by absorption of it into the vascular space. The principal site of action of epidural block is also the spinal nerve roots while they are passing the epidural space. The direct injection of local anaesthetic agent into CSF for spinal anaesthesia allows a relatively small dose and volume of local anaesthetic agent to spread over an wide area and to achieve dense sensory and motor blockade. In contrast, the same concentration but much higher volumes of local anaesthetic agent is injected in epidural space as there is no influence of spread of drug by CSF. Moreover, the injection site (level) for epidural anaesthesia must generally be close to the nerve roots that must be anaesthetised. The termination of action of LA agent after epidural block is likely to occur by the absorption of drug by epidural venous plexuses and partly by passing of the drug into the subarachnoid space.

First very quick, then gradual fall of concentration of local anaesthetic drug in CSF is seen in spinal block. The first steep fall in concentration of local anaesthetic agent in CSF is due to the mixing of drug with CSF and then rapid intake of drug by the nerve root and spinal cord. The second

gradual decrease of drug concentration is due to the vascular absorption of drug from CSF and nervous tissue. The CSF flow into venous sinuses via arachnoid villi may also contribute to some extent in the clearance of local anaesthetic agent. The lymphatic drainage has also contribution in the clearance of drug. Local anaesthetic acts both on the spinal cord and nerve roots, but opioids act only in the substance of the cord.

ORDER OF BLOCKING OR SENSITIVITY OF DIFFERENT NERVE FIBRES TO LOCAL ANAESTHETIC AGENTS

All types of fibres within a nerve are affected by local anaesthetic agents during spinal or epidural anaesthesia. But, within one mixed nerve there is a tendency for the smaller (thin) and slow conducting fibres (sensory) to be more readily blocked than the larger (thick) and fast conducting fibres (motor), though always this rule does not hold good. Because it is well established that myelinated autonomic preganglionic sympathetic B fibres which are larger and have a faster conduction time are about three times more sensitive to local anaesthetic agent than the thiner and slower conducting non-myelinated postganglionic C fibres (Fig. 24.30).

The preganglionic autonomic B fibres are the most sensitive of all the nerve fibres, causing early vasodilation and consequent hypotension which is a well recognised early sequel to epidural, spinal or paravertebral block. Large (or thick), rapid conducting, motor A fibres are the most resistant to local anaesthetic agents. It is probable that A-δ fibres, responsible for pain and temperature sensation are more sensitive than the C pain fibres, although it is larger and more rapid conducting than C fibres. This explains why sometimes the pathological pains, such as impending uterine rupture or placental separation, conducted by C fibres, may break through an epidural block which is relieving the physiological labour pain conducting through A-δ fibres. This is called the 'epidural sieve'. Sensory (proprioceptive) A-α fibres appear to be more sensitive to blockade than motor A-α fibres, although both have the same conduction velocity. This is because sensory fibres conduct at a higher frequency (Fig. 24.31).

All the local anaesthetic agent block the small and slow conducting sensory fibres more rapidly than motor fibres. The varying ability of different LA agents to produce the sensory and motor block would appear to be related largely to their epidural use. Thus, bupivacaine, the most selective for sensory fibres on epidural use, produces profound motor block on peripheral and intrathecal use. In summary, starting from the most sensitive, the order of sensitivity of nerve fibres to blockade is like that: preganglionic, pain and temperature, touch, proprioception and motor fibres.

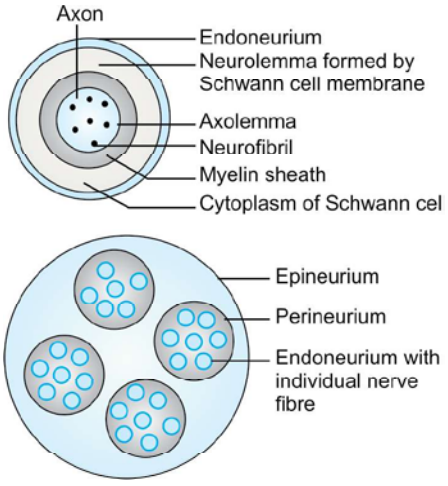

Fig. 24.31: Organisation of a trunk of peripheral nerve

Explanation of feeling of some pain or failure of RA after technically correct procedure

The probable explanation of failure after a technically good spinal or epidural block are:

i. A given concentration of local anaesthetic solution may block the fine fibres carrying the ordinary or sharp pain sensation, but may not be adequate to block some large fibres, responsible for carrying pressure and dull pain sensation. Increasing the concentration of local anaesthetic agent will solve this problem.
ii. Some pain fibres pass via sympathetic nerve and then via sympathetic chain to reach the spinal cord at higher level than the site of injection and may be the cause of failure.
iii. Dura can be punctured in the midline as well as laterally and even possibly at the dural investment of nerve root resulting in false feeling of placement of needle tip in the subarachnoid space.
iv. The tip of the needle may be moved further during pushing of injection after proper placement of it in the subarachnoid space and the local anaesthetic agent has not been deposited into the proper CSF.
v. Rarely, fluid-filled cyst in the subarachnoid space where the needle tip is entered may be responsible for failure. The membrane of the cyst limits the spread of the local anaesthetic agent.
vi. A problem with the potency of local anaesthetic solution may be responsible and possible (Table 24.6).

Sometimes, the local anaesthetic agent accumulates in the sacral hollow from the highest injecting point at the lumbar lordosis during dural puncture in supine position through lumbar route due to antiTrendelenberg position of the patient. In such

Table 24.6: Characteristic features of various nerve fibres

Fibre type	Diameter (μm)	Conduction velocity (m/sec)	Function	
			Sensory	Motor
A-α	13-20	70-120	Proprioception	Somatic
A-β	5-12	30-70	Touch, pressure	–
A-γ	4-11	15-30	–	Muscle spindle
A-δ	1-4	12-30	Pain, temperature	–
B	1-4	3-15	–	Preganglionic sympathetic
C	0.5-1	0.5-2.5	Pain, reflex	Postganglionic sympathetic

situation, inadequate level of anaesthesia up to the groin results.

The partial failure is a more common problem than the complete failure and is mainly due to insufficient dose and improper position of patient rather than individual variation. In partial or complete failure, the block can be repeated. But often general anaesthesia is more appropriate.

During spinal anaesthesia before injecting drug. It is wise to verify that the spinal needle is surely located in the subarachnoid space and is freely communicating with CSF. To confirm this the needle should be rotated 360°, with observation of free flow of CSF in all quadrants. If dural puncture is oblique or at the dural sleeve, there may be one or more quadrant where free flow of CSF does not occur. This may signal inadequate or partial dural puncture and needle should be removed and placed again correctly. Failure to replace the needle correctly results in two adverse outcomes. In an oblique puncture, an inadequate level of spinal anaesthesia may result. If injection is into the dural sleeve, hydrostatic injury to the nerve root may occur. Intense searing paresthesia at the time of CSF withdrawal during test may signal the nerve root damage and is early enough to avoid morbidity.

CONTINUOUS SPINAL ANAESTHESIA (CSA)

Continuous spinal anaesthesia (CSA) is a comparatively newer concept of regional anaesthesia and is performed by the introduction of microcatheter into the spinal subarachnoid space. But, it is always remained in controversy due to many neurological complications. The history of CSA can be dated back to 1907 when Dean, a British surgeon, first used this technique to prolong the duration of spinal anaesthesia. He performed CSA by the repeated injection of local anaesthetics into the subarachnoid space through a lumbar puncture needle which was left *in situ* after its successful entry. But, the needle breakage and spinal cord trauma were some of the ominous complications of this procedure. Then, in 1940, Lemmon introduced malleable needle and split mattress technology for this procedure. After that in 1944, Edward Touhy used a malleable spinal catheter, i.e. a No. 4 ureteral catheter for CSA and had popularised this technique. But during that period PDPH due to large needle and thick catheter was very rampant in CSA, which led to the introduction of microcatheters in 1990. Then, different sizes of microcatheters, varying from 27 to 32 gauges were made available and could be introduced into the subarachnoid space via 22 to 27 gauges spinal needle for CSA. But surprisingly, this did not reduce the incidence of PDPH. On the contrary, it causes increased neurological complications, termed the cauda equina syndrome. Hence, in 1992, FDA in USA banned CSA with spinal catheters, thinner than 24 gauge.

Before discussing more about CSA, let us first innumerate its various advantages and disadvantages.

Advantages of CSA

i. Reduced failure rate as CSF flowed into the catheter can be visualized.
ii. Prolonged anaesthesia which further can be extended even in the postoperative period for adequate analgesia.
iii. Requires low doses of local anaesthetic agent, especially when compared to CEA (continuous epidural anaesthesia).
iv. Extreme haemodynamic and cardiovascular stability due to the use of low and gradual incremental dosage of local anaesthetic agent.
v. May be used for prolonged pain relief, as in cancer patients by allowing subarachnoid narcotic administration for long duration.

Disadvantages of CSA

i. Increased incidence of PDPH.
ii. Increased incidence of nerve injury causing sensory loss, or motor loss or both.
iii. Increased chances of infection and haemorrahage.
iv. Increased incidence of cauda equina syndrome.
v. Very fine spinal needles (27 G and 29 G) and very fine catheters (30 G and 32 G) have made the technique possible without the risk of severe PDPH. But, these sizes of needles and catheters make the successful lumbar puncture more difficult.

Haemodynamic Stability in CSA

Perhaps the most undisputable indication for CSA is very elderly or critically ill patients who are put up for surgeries on lower abdomen or inferior extremities. Elderly patients generally have some cardiovascular compromise due to hypertension, ischaemic heart disease, heart failure, etc. or respiratory compromise due to low respiratory reserves or both. Critically ill patients are also similarly compromised. Hence, they require very good haemodynamic stability during anaesthesia, which is offered best only by CSA. The CSA offers a very good haemodynamic stability because very low dose of local anaesthetic agent is given at a time which prevents very rapid

and wide spread of drug and thus causes slower onset of action. This helps in gradual slow sympathetic block and easy gradual cardiovascular adaptability. It also gives enough time to an anaesthetist for adequate fluid infusion and vasopressor therapy if required. The low incidence of hypotension, low requirement of vasopressors, low failure rate are some of the indications of haemodynamic stability in CSA.

Postdural Punctural Headache in CSA

Though it was first thought that the incidence of PDPH was low with microcatheters in CSA, yet now the topic is still very controversial. The various studies at various times have proved that the microcatheters not always lower the incidence-PDPH. In fact, one study also showed that severity of PDPH was more in microcatheters and maximum patients required epidural blood patch for treatment of it. Also PDPH was observed to be more in younger age group of patients. Hence, it was inferred that PDPH was more frequently seen in lower age group patients (especially parturients) with microcatheters and with longer duration (especially for postoperative analgesia by microcatheter).

Cauda Equina Syndrome

Microcatheters for CSA was initially introduced for decreasing the incidence of PDPH. But, in reality it hardly did so. On the contrary, it more commonly causes neurological deficit, termed as the 'cauda equina syndrome'. A local anaesthetic agent, when introduced into the CSF through a conventionally used spinal needle, then it causes a turbulance which helps in mixing of the drug in CSF. But, when microcatheters are used, then lack of this turbulance causes improper mixing of drug in CSF. Hence if there is no turbulance and proper mixing, then the hyperbaric local anaesthetic agents thus will settle at the bottom of the spinal theca depending on the position of the patient. Hence, higher concentration of local anaesthetic agent is found near the caudal portion of the spinal cord, exposing the nerves of cauda equina long enough to the high concentration of these drugs which sometimes become toxic to the nerve fibres. This causes serious neurological defects, known as the cauda equina syndrome.

Failure of CSA

One of the causes of the failure of CSA is its technical difficulty during the introduction of catheter in the subarachnoid space through the needle successfully. Inability to inject local anaesthetic agent, knotting of the catheters inside the spinal canal, broken catheters, etc. are the other major causes of frequent inability of producing adequate anaesthesia by CSA. Therefore, very thin microcatheters, like 32 G, are also supplied by a steel wire stylet to help in threading it through 25 to 27 G spinal needle. These catheters would bend very easily during their introduction in the spinal canal. Then straightening or even removing of them, would often pose a problem. Sometimes, threading of the catheter becomes difficult even though the spinal needle is in place. This is due to the dura which may cover the opening of the spinal needle or needle touches the lateral or anterior wall of the spinal cord. In such cases, little withdrawal of the needle may help in threading of microcatheter through it into the CSF. The spinal microcatheters should not be introduced more than 2 to 3 cm inside the dural sac. More than 4 cm insertion often changes the direction of the microcatheter caudally, causing frequent cauda equina syndrome. 22 G Sprotte spinal needle prevents caudal migration of 28 G spinal microcatheters. Often the spinal catheter may also get entangled in the nerve roots or may even enter the intervertebral foramen with the nerve roots causing low backpain, radicular pain or even transient paraesthesia during the procedure. This may result in transient or permanent neurological damage.

During any failure or difficulty in threading catheter through the fine spinal needle, the procedure should be reassessed or abandoned. In such situation general anaesthesia is better option than facing the grave neurological defects in postoperative periods.

Present Status of CSA

For very elderly or compromised patients with severe systemic complication, CSA may still be the best and safest opted technique. It gives a stable haemodynamic platform, and thus decreases both morbidity and mortality of patient. As small, slow and gradual incremental doses of LA agents are given in CSF, so haemodynamic status remains almost unaltered. Hence, high risk patients with chronic bronchitis, emphysema, hypertension, coronary artery diseases, myocardial ischaemia, myocardial infarction, congestive cardiac disease, etc. tolerate this method of CSA much better. PDPH is the main disadvantage of CSA with an incidence of 6 to 9% with 20 G catheters. But, it is more common in younger age group of patients and incidence becomes almost nil after 60 years of age. Neurological injuries are more common with microcatheters. But by abandoning the technique, whenever there is some techical difficulty during insertion (as discussed before), the possibility of neurological trauma can be avoided.

Thus, it can be concluded that CSA is the choice of anaesthesia in elderly and very high risk patients with many systemic complications, or a severly compromised state. It is best avoided in young and obstetric age group of patients where continuous epidural anaesthesia (CEA) is still the choice. The ultra thin microcatheters need not be used as they have no added advantages. The anaesthetist should be well prepared to abandon the technique and goes for a general anaesthesia, whenever there is some problem in insertion and threading of a microcatheter through the fine spinal needle, especially if patient complains of radial pain or paraesthesia.

This shall avoid neurological damage and postoperative neurological deficits.

EPIDURAL ANAESTHESIA

Though epidural anaesthesia and analgesia had lead its journey from a small arena like labour ward and/or the obstetric operating room but now it has spread a strong foot hold over a wide area and become a common practice in surgical patients including neck, thoracic, abdominal and cardiothoracic surgeries. Recently, it has also made its strong presence in the pain clinic. However, at present epidural analgesia and anaesthesia for obstetric surgery has been superseded by spinal anaesthetic technique in some underdeveloped countries. But, painless labour by walking epidural anagesia and subsequent obstetric surgery (if needed) by epidural anaesthesia is still the routine practice in many developed countries. On the other hand, the postoperative epidural analgesia following major surgery is now the best means of analgesia in the modern postoperative care.

Epidural anaesthesia is provided by the effect of local anaesthetic agent on the spinal nerve roots as they pass from the spinal cord to the intervertebral foramen through the extradural or epidural space. Some part of the local anaesthetic agent which is deposited in the epidural space also (Table 24.7) penetrates the dura and arachnoid mater and passes into the CSF to act directly on spinal cord and the spinal nerve roots, bathed by CSF. Epidural analgesia provided by low concentration of LA agent also acts by the same mechanism as epidural anaesthesia. But, the addition of other drugs such as opioids, clonidine, benzodiazepine, etc. acts only through the receptors on the spinal cord which proves that the drug placed in the epidural space diffuses through the CSF.

The indications and contraindications for epidural anaesthesia and analgesia are similar to those of intrathecal anaesthesia. But, the commonest indication for epidural technique is where the duration of surgery is prolonged, the patient is very ill and high quality postoperative analgesia is needed which can be provided only by intermittent bolus injections or by continuous infusion of LA agent or narcotics using an epidural catheter.

Table 24.7: Indications of epidural block

A. *Surgical, obstetric, diagnostic, prognostic*
- Surgical anaesthesia and analgesia
- Obstetric anaesthesia and analgesia
- Differential neural blockade to evaluate pain
- Prognostic indicator before destruction of nerve

B. *Acute pain*
- Palliation of acute pain in any emergency
- Patients with multiple fractured ribs by thoracic epidural
- Management of pain due to acute pancreatitis
- In cervical epidural
  - To evaluate head, neck, face, shoulder and upper extremity pain
- In lumbar epidural
  - To evaluate lower abdominal, back, groin, pelvic, bladder, perineal, genital, rectal, anal and lower extremity pain
- Postoperative pain
- Pain due to acute herpes zoster
- Pain due to vascular insufficiency of the extremities

C. *Prophylactic and pre-emptive pain*
- Before amputation of ischaemic limbs

D. *Chronic benign pain*
- Radiculopathy
- Spinal stenosis
- spondylosis
- Vertebral compression fracture
- Diabetic polyneuropathy
- Postherpetic neuralgia
- Reflex sympathetic dystrophy
- Phantom limb syndrome
- Peripheral neuropathy

E. *Cancer related pain*
- Pain secondary to malignancies
- Pain due to bony metastases
- Chemotherapy-related peripheral neuropathy

Some Important Characteristics of Epidural Anaesthesia and Analgesia

i. It needs more skill.

ii. Sitting position is only preferred when it is absolutely necessary. Otherwise, increased pressure of CSF in sitting position increases the risk of dural puncture, leading to spinal anaesthesia.

iii. Absolute stillness of the patient's posture during the procedure is very necessary.

iv. Movement, cough, cry etc; cause increased CSF pressure and enhance the chances of dural puncture.

v. The intervertebral space like L_{2-3}, L_{3-4}, L_{4-5} is preferred for epidural anaesthesia and analgesia, though any interspinous space can be chosen. The choice of site for the introduction of Touhy needle or any epidural needle is determined by the surgical incision site. The insertion of needle should be at the level of the middle of the dermatomes that innervate the area of the skin in which the incision will lie. During difficulty, the best interspinous space may be one vertebra above or below the ideal level. The anaesthetist should balance the practical problems of a potentially difficult space against the benefit of a successful first time identification of the epidural space which is one or two vertebra below or above. In difficulty of flexing spine or lumbar lordoris, upper spaces can be chosen. Thoracic approach for epidural block is generally used by skilled person for upper abdomen and thoracic surgery and / or postoperative analgesia.

vi. Prior application of eutectic LA mixture or skin infiltration by local anaesthetic agent is very important for the use of thick 16 to 18 G Tuohy needle or any epidural needle in awake patient.

vii. In lumbar approach of epidural anaesthesia the depth of ligamentum flabum from the skin for most of the patient is 3.5 to 6 cm (average 4 cm). On the other hand, ligamentum flabum is itself 5 to 6 mm thick in midline.

viii. Patient with the history of previous spinal surgery at the site of planned epidural anaesthesia have more chance of failure or partial block. It is either due to technical difficulty in identifying the

space or an anatomical distortion of the space by scaring, haematoma, adhesion, etc. which prevents the spread of local anaesthetic agent in the epidural space. Even in patient without previous spine surgery or disease, repeated epidural anaesthesia at the same site becomes less effective with each application. Explanation of this failure is that repeated entry of needle and injection of local anaesthetic agent into the same small epidural space cause anatomical changes (due to bleeding, haematoma, inflammation and scar formation) and obliterate some parts of epidural space.

ix. One of the probable causes of one-sided epidural anaesthesia is migration of catheter into the dural sleeve or moving out of the epidural space with outgoing nerve root through the intervertebral foramen.

x. Another important characteristic of the epidural anaesthesia and analgesia is that there is relatively large absorption of LA agent from this space due to large absorption area, dense epidural venous plexus, and large volume of drug (Fig. 24.32).

Needle of Epidural Anaesthesia

Most commonly the Tuohy needle is used for epidural anaesthesia and analgesia. The important feature of this needle is the rounded Huber point tip which is curved and blunt. The curvature of this tip directs the passage of the catheter and bluntness of the tip reduces the risk of dural puncture. The large caliber of the Tuohy needle helps in easy detection of the epidural space, particularly by the loss of resistance. The Tuohy needle is graduated in centimeter and so it can also help to assess the depth of epidural space. For single shot epidural technique where catheter is not used, Crawford epidural needle is also very much appropriate. It is a modification of Tuohy needle with a small sharp area at the tip.

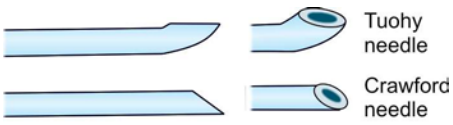

Fig. 24.32: Epidural needle

Approach for Epidural Space

Our approach for epidural space may be in the midline or from the lateral side (paramedian). In midline approach, once the tip of the needle is in supraspinous ligament after crossing the skin and subcutaneous tissue, then considerable resistance during the advancement of needle and injection of fluid is felt. This resistance is due to the advancement of needle through the interspinous ligament and ligamentum flavum. After that as soon as the tip of the needle enters the epidural space, then there is feeling of sudden loss of resistance. The advancement of the needle just under and parallel to the spinous process of the vertebra above will yield easiest entry of it into the epidural space in the midline. Contact with bone close to the skin usually suggests obstruction due to spinous process, whereas contact with bone at deeper level suggests obstruction due to lamina or pedicle and signals the possibility that needle has perhaps strayed from the midline or is angled too cephalad or caudal.

During lateral or paramedian approach of epidural space the sacrospinal and other paravertebral group of muscles are encountered first after the skin and subcutaneous tissue and offer a doughy feeling, as supraspinous and interspinous ligaments are bypassed. Strong resistance only felt when the paravertebral group of muscles are crossed and the tip of the needle hits the ligamentum flavum. The key to successful insertion of needle in epidural space in this approach is the change from doughy soft feeling to tough gritty feeling, due to the change from the muscle to ligamentum flavum. Too abrupt advancement of the needle in any approach may result in accidental dural puncture and subdural block. The chances of traumatic damage to the nerve roots and epidural vein is more during epidural anaesthesia in lateral approach because the two posterior epidural venous plexus lie by the side of the midline. Like spinal anaesthesia, lateral approach for epidural block is also applicable only when the interspinous space is narrow and there is difficulty to approach the epidural space through midline due to any cause.

Methods of Identifying Epidural Space

The epidural space can be identified by different methods. These are as follows:

1. By feeling the loss of resistance

The feeling of loss of resistance when the tip of the epidural needle enters the epidural space can be tested by two ways, either by fluid-filled syringe or by air-filled syringe with epidural needle.

(i) Advantage/disadvantage of fluid-filled syringe (glass or plastic) for detection of epidural space

The question between the glass or plastic syringe for detection of epidural space by the feeling of loss of resistance depends on the individual anaesthetist's choice and experience. The loss of resistance is less clear by plastic syringe, because there is more friction between the plunger and the barrel. But glass syringe is always of low friction syringe. On the other hand, plastic syringe is more consistent in its behaviour than the glass syringe. The advantage of fluid-filled syringe over an air filled syringe for the detection of epidural space by the feeling of loss of resistance is that the needle can be advanced by (Fig. 24.33) pressing on the plunger and not by pushing the barrel. When the epidural space is entered, the movement of the needle and barrel is halted automatically and the plunger moves forward injecting the fluid in the epidural space, and pushing the dura away from the tip of the needle and creating an actual space. This also reduces the chances of dural puncture. The advancement of the needle must be at the right

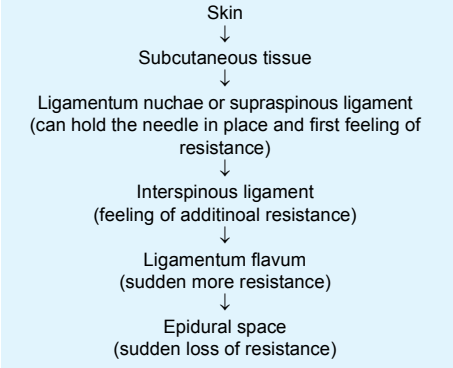

Fig. 24.33: Resistance offered to the needle during passage to epidural space

angle to the hip and shoulder. However, being parallel to the floor has no importance. The hole at the needle tip pointing cephalad will minimise the angle at which the needle tip encroaches the epidural space and thus will reduce the chances of dural puncture. The advancement of needle should be smooth and continuous. The disadvantage of fluid-filled syringe is that sometimes a few drops of fluid drips back from the needle hub after proper entry in the epidural space and can create confusion for CSF as dural puncture occurs.

(ii) Advantage/disadvantage of air filled syringe for detection of epidural space

Here, the epidural needle cannot be advanced by giving pressure on the plunger alone. But, the needle must be advanced step by step by holding the needle shaft or the barrel of the syringe, rather than in a continuous fashion like fluid-filled syringe, described before. Thus, the use of air-filled syringe needs the elicitation of the bounce of plunger with every millimetre of advancement of needle to feel the loss of resistance for detection of epidural space. It is a more slower process and there is more chance of dural puncture, because like fluid the air does not automatically remove the dura from the tip of the needle when it enters the epidural space. But, as no fluid drips back from the needle hub after entry of the tip of the needle in epidural space, no confusion is created for dural puncture. However, here is the more chances of emphysema and air embolism (if the needle enters into a vein). There are other many mechanical helps to feel the sign of loss of resistance by air-filled syringe. These are Macintosh's needle with spring-loaded stilette, Ilke's spring loaded syringe, Macintosh's ballon, etc. In spring-loaded stilette or syringe, the stilette or plunger is automatically pushed in due to the loss of resistance when the needle tip enters the epidural space. In Macintosh's balloon, it is automatically deflated when the tip of the epidural needle enters the epidural space. But they are usually not used now, because they are more complicated, produce more false negative and false positive result, and cause more distractions.

After entering the epidural space, the air or fluid-filled syringe is disconnected. If a small amount of fluid (in case of air-filled syringe) leaks back, it may raise concern about the partial dural puncture. But it can be resolved by two ways. If the fluid is of room temperature and flow is self-limiting, it is surely fluid of epidural space. Whereas, CSF would feel warm, if it is allowed to drop on the forearm of anaesthesiologist as it is coming from the core of the patient's body and flow is not self-limiting. The use of teststicks for glucose would also make the distinction between the CSF and other fluids, since CSF would contain some glucose, whereas other fluid such as fluid of the epidural space, saline or local anaesthetic agents would not.

2. By negative pressure sign

A negative pressure is detected in 50 to 80% of cases in the epidural space. There are three explanations which have been put forward to account for this negative pressure in epidural space.

i. The first theory is that the negative pressure which is normally present in the pleural cavity is transmitted from this cavity via the thoracic paravertebral spaces and through the intervertebral foramen to the epidural spaces.
ii. The second theory is that negative pressure is created by expanding the volume of vertebral canal and consequently that of the epidural space by the flexion of the spine.
iii. The third theory is that the negative pressure is simply created by indenting the dura with the tip of the needle. This is the most probable explanation of negative pressure in epidural space. The negative pressure is obliterated once the fluid is injected and then the epidural pressure may rise to as high as 30 cm of water during an epidural injection. Clinically the negative pressure in the epidural space has been demonstrated in a number of ways.

Hanging drop method

While the needle is progressing towards the epidural space a drop of fluid (saline or LA agent) is deposited at the hub of the needle, until the drop is hanging. Then, as soon as the tip of the needle reaches the epidural space, then due to the negative pressure created by pushing the dura away, fluid is sucked in the hub. However, this technique should be limited to the experienced hands, because heavy skill is required to interpret the feel of tissue during very slow approach to the epidural space and to see the drop movement simultaneously. This technique is further limited by the possibility of tiny bit of tissue or blood clot at the needle tip which may prevent the passive transmission of negative pressure from the epidural space to the hub of the needle. Very slow approach and the increased feel of tissue is mandatory, when the epidural anaesthesia is applied in thoracic or cervical spine.

Odom's indicator

A drop of fluid being contained in a small glass capillary tube is attached with the epidural needle. As the epidural space is entered by the tip of the needle, then the fluid moves inward to the negative pressure of the space. This is Odom's indicator. This

negative pressure sign has also the distinct advantage in lateral approach.

Technique of Epidural Anaesthesia

Usually EA is applied by two methods catheter single shot or continuous epidural by catheter.

Single shot epidural anaesthesia

The single shot epidural anaesthesia is rarely used nowadays, except for fewoutdoor or day-case surgery. It is unjustified if the epidural anaesthesia is used for any surgery, but the patient is not allowed to enjoy a good postoperative analgesia by repeated doses or by continuous infusion of local anaesthetic or narcotic agents in the epidural space through the epidural catheter later on.

Continuous epidural anaesthesia by catheter

The ability to insert a catheter safely into the epidural space allows slow injection of local anaesthetic agents and / or narcotics, intermittently as bolus or continuously as infusion to control the rate of neural blockade, to decrease the haemodynamic side effects and to reinject the drug when necessary and thus maintaining anaesthesia and / or analgesia indefinitely. There are multiple positive points about the epidural anaesthesia using catheter. The safe access to the epidural space in the thoracic and cervical regions also will create the possibility of selective block in limited dermatomes and thus will accomplish the only analgesic objective (pain control), minimizing the side effects of wide-spread motor block and wide-spread pharmacological sympathectomy. For orthopaedic anaesthesia the control of postoperative pain is valuable, especially where the orthopaedic surgical indication requires the excellent postoperative pain control for continuous passive or active motion of limbs (physiotherapy) after fracture repair, joint replacement, release of frozen joint, etc.

The obstetric analgesia and postoperative pain control, are the ideal conditions for continuous epidural analgesia. Here the surgical anaesthesia is not sought for as it will hamper the objective of obstetric analgesia by hindering the vaginal delivery. The ideal situation would be only analgesia in the restricted dermotomes of surgical site with no or minimal motor block. When used alone or in conjunction with a low concentration of local anaesthesic agent (e.g. 0.25% bupivacine) and a lipophilic narcotic (e.g. fentanyl, etc.) this catheter technique should make possible near total relief of postoperative and labour pain. It does not interfere with pulmonary mechanics (in COPD) and allows a patient of enough motor strength to take self-care. In instances, where complete motor function is essential, the use of only narcotic drug without local anaesthetic agent can achieve analgesia without even slight degree of motor block.

Epidural Catheter

The size of epidural catheter varies from 19 G wide bore to 30 G microbore. The wide bore large catheters are used for adult patients and fine microcatheters are used for the paediatric patients. The objective regarding the epidural catheter is to pass largest possible catheter through a given needle, since the tensile strength of a catheter decreases with the higher number (or fine bore). Impregnating the walls of catheter with a special substance or chemical which increases the tensile strength of it is an another approach to use the fine catheters, without decreasing the tensile strength. The goal is to minimize the risk of catheter loss under the skin or long-term follow-up for evaluation, if a part of a catheter is lost. The material selected for construction of catheter is determined by many factors. When catheter is made up of Teflon, then the advantages are : increased-firmness cause easy insertion, greatest possible resistance to kinking during continuous use, linear shear strength is maximal and does not soften when it reaches the body temperature. The disadvantage of Teflon catheter is increased rigidity and absence of increased flexibility at body temperature which increases the risk of trauma to nerves and blood vessels.

Spinal nerve roots are usually located in tight epidural compartment with minimal mobility. Thus, a rigid catheter which is inserted in this tight epidural space can lacerate or penetrate the surface of these rigid nerve roots. In that situation, if a catheter is left in place when the patient is mobile or in anticoagulant, the gradual softening of a catheter, made of polyvinylchloride (PVC) would be a distinct advantage. Teflon lacks this softening property. So, PVC catheters are thinked better for softness and flexibility during insertion and use. But, this material causes decreased resistance to breakage and increased kinking. The chance of breakage is even more for a catheter which has multiple exit ports at their tip and this is because of their inherent weakness at the ports.

The catheters with a single orifice at the most distal end are selected for accurate delivery of anaesthetic solutions at the exact site of placement of it. But, there is more chance of occlusion of this type of catheter with single distal orifice by blood clot or tissues. Whereas, the multiorificed catheter cannot deliver the injecting anaesthetic solution accurately at the site of its placement, but minimise the potential for occlusion of it by blood clot or tissues that can occur with single port catheter. The size of port around the diameter of the catheter also theoretically increases the area of spread of the solution at the site of injection, but at the cost of decreased shear strength of catheter. Some epidural catheters are designed with fine metal stylet inside it which makes them quite rigid, and helps to guide the catheter easily. In such situation besides potential nerve injury, there is higher risk of dural

puncture with stylet catheter, even after the successful placement of needle. This risk can be decreased by withdrawing the stylet so that the 1 to 2 cm tip of the catheter is free of stylet and is not rigid any more. But still the stylet gives the necessary rigidity to the catheter within the hub of epidural needle, during initial entry into the epidural space and helps its insertion. Epidural catheter increases the versatility and duration of the central neuroaxial block. Catheter tip emerges from the tip of the needle, if the 10 cm mark on the catheter disappear at the hub. Resistance may be felt at this point. If resistance during the passage of catheter is felt beyond this point, then it should never be withdrawn without needle, neither should it be forced onwards. Withdrawal of the catheter alone without the needle, once it has emerged from the tip, may cause the end of the catheter to be sheared off by the tip of the needle and remain in the epidural space. If a piece of an epidural catheter is accidentally left behind in the epidural space, then there has been some debate over whether the patient should be informed or not. It is probably best to be honest. So it should be explained what has happened. But the patient will be very anxious after this explanation. Hence, Patient should be reassured that the chances of adverse long term sequelae are remote.

The obstruction during passage of catheter through the epidural needle may be due to:

i. catheter tip hits against nerve root,
ii. catheter tip hits against blood vessel,
iii. it hits against the dura,
iv. the needle or the catheter tip is not in the epidural space at all.

Catheter tip should not be passed more than 15 cm from the needle hub. Once catheter enters into the epidural space in the midline, it will generally pass freely. If resistance is encountered well before this, the needle may be carefully rotated through 90 degree. If this still does not enable the catheter to pass, then increasing spinal flexion of the patient may be helpful. Sometimes catheter may run a short distance in the epidural space and then is curled back or pass out through the intervertebral foramen. The tendency for a catheter to pass in one side of the epidural space increases the likelihood of an asymmetrical or unilateral block which, if resistant to treatment, may necessitate removal and reinsertion of the catheter. If blood is aspirated, the catheter is slightly withdrawn. If flow of blood still persists, then another space is tried. As aspiration of blood or CSF does not give one hundred percent guarantee that if catheter is in blood vessels or in subarachnoid space or not, so a test dose is mandatory before giving the full clinical dose. Epidural catheter should be inserted only 2 to 3 cm in the epidural space from the tip of the needle. There is no advantages in passing the catheter for more than 4 or 5 cm from the tip of the needle into the epidural space. Migration of catheter in the ant. epidural space is the commonest misposition of it. The use of multi or uniport catheter depends on the anaesthetist's choice. Multiport catheter has less chances of unilateral and unblocked spinal segments than the single port catheter.

Epidural Test Dose

The epidural test dose procedure has in common the objective of decreasing the incidence of inadvertantly injecting a large volume of anaesthetic agent, scheduled for epidural anaesthesia into the intravascular or subarachnoid spaces. A variety of agents and strategies have been described for this test dose procedure, but the ultimate choice depends on the experience of the anaesthetist. Any evidence of epidural anaesthesia even partial signals an extremely low probability that the needle or catheter is fully within the subarachnoid space or within the lumen of a blood vessel. On the contrary, extended anaesthesia than expected by the test dose signals the probability that the needle or catheter is in the subarachnoid space. The 2 to 3 ml of local anaesthetic drug (a dose insufficient for epidural blockade, but sufficient for spinal effect and expected to occur within 2 minutes) is used as test dose, before giving the total dose scheduled for epidural anaesthesia. However, the correct period of timing between the test dose and the next principal injection is very important and is determined by the type of LA agent used. There is no reliability in this procedure, if correct time interval (2 to 3 minutes for lignocaine's onset of action) is not maintained prior to the next main injection. If bupivacaine is selected as the epidural agent, then the time interval between the test dose and the principal anaesthetic doses would need to be longer or initial test dose would have to be performed with another agent, e.g lignocaine. During continuous epidural anaesthesia and analgesia each subsequent epidural injection should also be preceded by aspiration and epidural test dose, because catheter migration into vessel or subarachnoid space does occur at any time.

The intravascular injection of LA agent during the administration of test dose or principal dose is identified by the systemic signs, based on the occurrence of cranial nerve paraesthesia and this is due to the disinhibition of limbic system of brain curved by LA agent. Thus, intravascular injection of LA agent can be identified by general ill feeling, unexplained fear, perioral paraesthesia, lingual paresthesia (metal taste), ocular paraesthesia (scotoma), aural events (roaring in the ear), etc. These symptoms are very obvious with 2-chloroprocaine, but less obvious with lignocaine and absent with bupivacaine, because of its very high protein- binding property. The CNS toxicity as signs of intravascular injection are reported being unreliable, following small doses of LA agent alone. So, vasoactive substances are often injected with LA agent as indicators or markers and their systemic effects are used as signs of intravascular injection of LA agent. The

classical choice of vasoactive substance as marker is epinephrine. The commonest test dose is 3 ml of LA agent with 15 µgm of epinephrine (adrenaline). This dose of epinephrine will produce 20 to 30% increase in patient's heart rate within 20 to 30 seconds of injection. It will last for a brief period (1 to 2 minutes) and is unlikely to harm patient. To detect the increase in heart rate caused by epinephrine which is used as test dose, ECG monitoring is mandatory and mere symptom like palpitation is unreliable. The use of epinephrine as test dose is contraindicated in cardiac patients and parturients (potential risk of uterine artery vasoconstriction).

At last, in conclusion it can further be told that a false sense of security does not develop, if a test dose has no adverse effects. Although it is rare, still it is not uncommon for epidural catheters to migrate into blood vessels or into the subarachnoid space after satisfactory test doses. Therefore, the anaesthetist must be vigilant at all times.

Drugs and Doses for Epidural Block

Lignocaine

For epidural anaesthesia initial 15 to 18 ml of 1.2 to 2% (commonly 1.5%) lignocaine hydrochloride is used with or without adrenaline in the dose of 5 µmg/ml. The action of this dose lasts for 1 to 1.5 hours. If adrenaline is used with LA agent, then some prolongation of local anaesthetic action occurs. Subsequent repeated doses of lignocaine cause tachyphylaxis and so it is impossible to maintain continuous analgesia and anaesthesia by lignocaine by infusion or repeated bolus doses, without ultimately producing any serious systemic toxicity of it. The 0.5% solution of lignocaine gives sensory block without affecting the motor and 1.5% solution of it gives both sensory and good motor block, while 2% solution causes intense motor and sensory block (Table 24.8). So, for epidural anaesthesia and analgesia the dose of lignocaine varies according to the volume, concentration, site of injection, and the desired effect.

Bupivacaine

The 0.5 to 0.75% solution of bupivacaine HCl is usually used in a dose of 2 mg/kg or 0.4 ml/kg for epidural anaesthesia. The action of surgical anaesthesia of this dose and concentration of bupivacaine lasts for 4 hours. However, the only analgesic or sensory action may last for 8 hours. A concentration of 0.125 to 0.25% bupivacaine is used only for postoperative analgesia, avoiding motor block and the analgesic action of this concentration lasts only for 4 hours. A concentration of 0.25% solution of bupivacaine is usually satisfactory only for sensory block, but the duration and reliability of 0.125% solution are not usually acceptable. On the other hand, in 0.25% solution of bupivacaine there may, however, be minor degrees of motor block and some risk of haemodynamic instability. So, such a concentration of bupivacaine would be unsuitable for upper abdominal or thoracic analgesia which may produce a high incidence of hypotension. Again in general, lower concentration (0.125%) of bupivacaine does not cause motor block by any degree, but necessiate larger volume of drugs and consequently increases the spread which may result in higher incidence of hypotension. Unlike lignocaine the epidural dose of bupivacaine can be repeated for indefinite period without producing tachyphylaxis and any risk of systemic toxicity. The 0.75% bupivacaine is not recommended in USA.

The dose of continuous epidural infusion by bupivcaine is 0.125 to 0.375% solution at the rate of 10 to 20 ml/hr. Levobupivacaine may be used in place of bupivacaine.

Table 24.8: Onset and duration of action of local anaesthetic agents administered epidurally in 20 to 30 ml of volumes

Drug	*Concentration (%)*	*Onset (min)*	*Duration of action*	
			Plain (min)	*Adrenaline 1:2,00,000 (min)*
Lignocaine	2	10-20	60-90	90-180
Bupivacaine	0.5	15-25	160-240	160-240
Chloroprocaine	3	10-15	45-60	60-90

Chloroprocaine

Preservative free 2 to 3% chloroprocaine is also used both for spinal and epidural block. But duration of action of chloroprocaine is very short and only 45 minutes. So, combining of chloroprocaine with catheter technique allows a good matching of surgical procedure with minimal recovery time. It is mainly used in USA. However, it antagonises the action of fentanyl.

Ropivacaine HCl

Ropivacaine has less CNS and CVS toxicity than bupivacaine, but more or less has same onset and duration of action like it. It causes better differential block, i.e. at lower concentration ropivacaine profoundly blocks only sensory, but completely preserve the motor. So, 0.05 to 0.1% solution of ropivacaine is used for only sensory block, but 0.3% for profound sensory and slightly motor block and 1% for both profound sensory and motor block. Therefore, it is best suited for obstetric anaesthesia and analgesia and postoperative pain by infusion technique.

Method of Injection of Anaesthetic Agent through Epidural Catheter

There are many methods or sequences for the injection of anaesthetic agent during continuous epidural anaesthesia using

catheter. Among these the first choice is after an appropriate test dose. The calculated first schedule dose of local anaesthetic agent is injected through the needle prior to the catheter placement. The advantage of this method is allowing the time for the onset of anaesthesia while the catheter is being placed and when the catheter placement is complete, then there is already enough anaesthesia to begin the surgical procedure without wasting any time. Also the bolus first dose of local anaesthetic agent, injected through the needle, will expand the epidural space and make the catheter placement much easier and successful.

But disadvantages of this method are found in those cases where even the correct placement of needle and injection of anaesthetic agent through this needle will not allow the subsequent successful insertion of catheter. In such cases, replacement of needle in another space is much riskier as local anaesthetic has already filled the epidural space, which may confuse the detection of epidural and subarachnoid space and once epidural anaestheisa has been set up, absence of paraesthesia does not indicate needle contact with neural tissue and cannot prevent the trauma of nerves.

The second choice is after the test dose through needle (which expands the epidural space) the catheter is inserted first. Then after positioning the patient, the first bolus dose of local anaesthetic agent is injected through the catheter, followed by subsequent doses or continuous infusion. Another choice is that some anaesthesiologists prefer to give the first dose of local anaesthetic agent through epidural needle before the catheter placement with patient in sitting position. This approach offers maximum bathing of large nerve roots (L_5-S_1) by gravitating down the anaesthetic agent for those cases where the dermatomes supplied by these nerve roots are a major part of surgery. Due to the downward movement of LA agent, subsequent insertion of catheter does not produce confusion like 1st technique. Although uncommon, it is also possible to thread a catheter caudally by directing the tip of the needle caudally. This is because the needle may be rotated caudally after entry into the epidural space. But, this entails more risk because the needle is directed against the dura and rotating the needle would cause a cork-screw like effect in which case the needle would advance either partially or completely from epidural space into the subdural or subarachnoid space.

Mechanism of Action and Fate of Local Anaesthetic Agent in Epidural Space

Till now this discussion is full of a controversy and unclear, but some postulated hypothesis exist. The principal site of action of LA agent in epidural anaesthesia is the portion of nerve roots which are present in the epidural space. Local anaesthetic agents injected in the epidural space also can pass out of the intervertebral foramina and act on the mixed spinal nerve in the foramina. As these foramina are generally occluded by spinal nerves and accompanying vessels, so with the increased age these foramina become narrower and thus confine the anaesthetic solution more in the epidural space and cause much higher block by increased spread with same volume of drug. Also the substantial amount of drug diffuses in the subarachnoid area from the epidural space for its action. But, the two modes of block, i.e. in the epidural space and in the subarachnoid space is different. This is explained by the fact that epidural block works segmentally, nearest to the injection site which would be impossible if intrathecal route of distribution was the only factor for mechanism of action of epidural anaesthesia. Local anaesthetic agent in epidural anaesthesia also penetrates the dural cuff to block the nerve roots and transmit centrally along the nerve to block the conduction in the spinal cord. Whatever may be the destination of the epidurally administered local anaesthetic agent, they must ultimately be absorbed into the bloodstream. Absorption of local anaesthetics into the circulation takes place more rapidly from the epidural than from the subarachnoid space. The speed with which they are absorbed depends upon the local vascularity, which may again be influenced by the injected adrenaline and by the characteristics of drug itself.

Epidural Anaesthesia using Catheter and CVS/RS

Epidural anaesthesia has unique effect on CVS. If the patient is properly prepared with volume expander and the level of anaesthesia is properly titrated by catheter, then the influence of epidural anaesthesia on LV performance is favourable, even in patients with cardiac disease with decreased cardiac output and decreased LVEF. Experimental work demonstrates the reversal of myocardial ischaemia with segmental thoracic epidural analgesia. This is because EA allows suitable placement of catheter and then proper titration of anaesthetic drug with the level of block which results in controlled rate and degree of sympathetic block, allowing adequate time for compensation for decreased venous return and reduced cardiac output by activating cardiac acceleration fibres.

Continuous epidural anaesthesia (EA) by catheter controls the respiratory mechanics more easily than the subarachnoid block. The decrease of pulmonary function is proportionate to the height of the motor block achieved. Even the lowest level of lumbar EA causes abdominal muscular paralysis which is only involved in active expiration. Impairment of active expiration has no clinical significance on respiration in the absence of COPD. As the level of motor block ascends, it effects the increasing amount of muscles involved in quiet respiration. Intercostal muscles act by stabilising and expanding bony thorax and thus help in respiration by creating

negative intrathoracic pressure. As more and more intercostal muscles are blocked then respiration becomes more dependant on diaphragm alone. Block of high sensory level in EA, blunts normal endocrine response to surgical stress and also the respiratory response to increased level of arterial PCO_2.

Factors Controlling the Spread of Epidural Block

The factors controlling the spread of epidural block are:

1. Volume and concentration of local anaesthetic agent

The volume and concentration of LA agent influence the epidural anaesthesia as spinal anaesthesia which has been discussed earlier.

2. Posture

Though 0.5% bupivacaine and 2% lignocaine is isobaric, still it tends to spread in epidural space according to the gravity, but not so reliably as hyperbaric solutions given intrathecally. As the fat has a lower specific gravity than the aqueous local anaesthetic solutions, but the very thin film of it in the epidural space is unlikely to be sufficient to account for such positive geotropism. Gravity is more effective for epidural spread in obese than in normal subject. This is because of more presence of fat in epidural space in obese than in a normal individual. The height of block is not so clinically predictable by position and posture changes in epidural anaesthesia, because gravity and baricity are not so intimately related to the spread of block in epidural anaesthesia. Still, it is apparent that tilting can determine the caudal and cephalad spread in epidural anaesthesia. Thus, lateral position produces a block which is significantly higher on the dependent side. In most subjects, it is possible to induce only sacral spread of local anaesthetic solution in epidural anaesthesia with the aid of sitting position. But it may be necessary to use a low space and / or a large volume.

3. Site of injection

Epidural anaesthesia mainly work segmentally at the roots, nearest to the injection site. So, the site of injection is very important for the level of anaesthesia in epidural procedure. As for example, during upper abdominal surgery where the dermatomes are supplied by thoracic spinal nerves, very large volume of drug (which may reach toxic level) is necessary to reach the thoracic segments, if epidural is given by lumbar route. So, in such cases higher interspinal space is preferable and idealy throcic epidural approach greatly reduces the dose requirement and unnecessary lumbar anaesthesia. For leg and perineal block, lower lumbar interspaces are preferred. For obstetric analgesia, a lower lumbar approach than L 2/3 interspinal space causes standard volume of solution to be ineffective and has too much effect on the legs.

4. Age

The total dose requirement of local anaesthetic agent during epidural anaesthesia is inversely related to the age. Age-related arteriosclerosis and osteoarthritis changes cause gradual closure of the intervertebral foramen and thus prevents the leak of anaesthetic solutions in the paravertebral space from epidural area through the intervertebral foramen, causing increased spread of it along the vertebral column and higher level of block with same volume of LA agent.

5. Pregnancy or intra abdominal tumours

Increased pressure on inferior vena cava by gravid uterus or any other intra-abdominal tumours or ascitis leads to the diversion of venous return from the lower part of the body through the vertebral and epidural venous plexuses. Therefore, distension of these venous plexuses causes reduction of epidural space and so higher spread by the same volume of LA drug results higher level of block and more hypotension. But some schools do not believe in it. They believe that pregnant patients are more sensitive to hypotensive effect of LA agents (by vasodilation) due to high level of progesterone. Thus, for pain relief in labour a small volume of drug is adequate (where very few segments have to be blocked) than obstetric anaesthesia.

6. Height and weight of patient

Obesity reduces and height of patient increases the dose requirement of local anaesthetic agent.

7. Nerve root size

S_1 nerve root is thickest of all the spinal nerves and is notoriously resistant to epidural block. So, S_1 dermatome has a very long latency and shorter duration of block.

INDIVIDUAL EPIDURAL BLOCK

Thoracic Epidural

The thoracic epidural space extends from the lower margin of C_7 vertebra to the upper margin of L_1 vertebra. The vertebral column in the thoracic area normally has a kyphotic curvature (concave ventrally) with its apex at the approximately T_6 level in supine position. The inclination of the spinous processes of thoracic vertebrae is different at different levels. The spines from T_1-T_4 vertebrae have very little inclination, whereas those of T_5-T_8 vertebrae tilt significantly downward, making a midline approach to the epidural space practically impossible in that area. The T_9-T_{12} spines direct dorsally without any significant inclination. So, the midline approach for epidural space is possible in that T_9-T_{12} spaces. The ligamentum flavum in the thoracic region is not as thick as in lumbar region. So, in the thoracic region the epidural space can be entered

without encountering much resistance. In thoracic area, the epidural space is only 3 to 4 mm wide and like other space contains loose areolar tisue, fat and vertebral venous plexuses. The lumbar enlargement of the spinal cord is situated within the thoracic vertebra between T_9-T_{12} segment. The pressure in the thoracic epidural space is approximately −15 cm of H_2O and is very close to that of the negative intrapleural pressure. It is more pronounced in the sitting position. However, the negative pressure in the epidural space is also considered to be secondary to the tenting of the dura by the blunt epidural needle during procedure. In 12% of cases, the pressure in the epidural space is not negative.

The cardiovascular effect of thoracic epidural anaesthesia depends on the level of block. The preganglionic sympathetic fibres as white rami communicans are present in all the thoracic spinal nerve. Sympathetic block up to T_{10} level, extending from L_2 produce minimal cardiovascular changes. The degree of hypotension due to sympathetic block up to that level will depend on the existing blood volume. The hypotension if occur usually will be partly compensated by vasoconstriction of the upper extremities and partly compensated by cardiac stimulation by tachycardia and increased myocardial contraction as T_1-T_4 cardiac (Fig. 24.34) sympathetic fibres are not blocked. If the block extends up to the segment T_6 from L_2 then hypotension will not be compensated and it will be revealed. This hypotension is primarily due to venodilatation, pooling of blood in venous side, and subsequently decreased right heart filling and decreased cardiac output. Blocking of the sympathetic fibres to the abdominal viscera, including those to the adrenal medulla, also can reduce the response to stress during the lower abdominal and pelvic surgical procedures. If the block extends up to the T_1 segment, the sympathetic fibres innervating the heart will also be affected. Therefore, the cardioaccelerator fibres, coming out of the

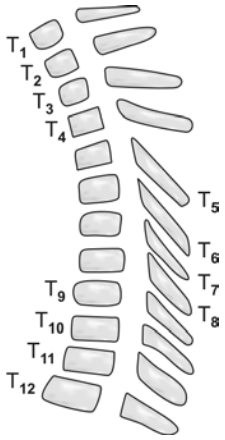

Fig. 24.34 : The inclination of spine of different thoracic vertebrae

T_1-T_4 segment will be blocked producing severe bradycardia and hypotension due to nonavailability of cardiac compensatory mechanism and also due to the unopposed action of the parasympathetic fibres derived from the vagus nerve. Sometimes, it results in cardiac standstill. So the response is manifested primarily by the combined effects of degree of sympathetic denervation and unopposed vagal nerve dominence. Sympathetic denervation produces arterial and more important, arteriolar dilatation. But this arterial or arteriolar dilatation is not complete, however, because vascular smooth muscle on the arterial side maintains a significant degree of autonomous tone which is not dependent on sympathetic system. The venous system has very little smooth muscle present within its walls and maintains no significant residual tone due to complete sympathetomy. Thus, venodilatation and severely reduced preload result in a reduction in cardiac output with severe hypotension, but without any compensation as the cardioaccelaratory fibres are blocked. Bradycardia or cardiac standstill also can occur after blockade of the cardioaccelaratory fibres arising from T_1-T_4 segment or failure of activation of the great vein and right artrial cardiac receptors which usually occurs due to the decreased venous return, and reflexly increase the heart rate (Bainbridge reflex). During sympathetic block below the T_4 level, the baroreceptors in the carotid sinus and aortic arch normally respond to a fall in blood pressure by producing a compensatory tachycardia (Marey's law), through vagal afferent and efferent pathways.

Bainbridge reflex

The venous engorgement of the right atrium and the great veins reflexly increase the heart rate. The afferent fibres, arising from the roots of the great veins and right atria pass along the trunk of the vagus to the cardiac centre. Engorgement of these parts stimulates the nerve endings and reflexly inhibit the vagal tone and also stimulates the sympathetic to some extent. Thus, the heart rate rises and cardiac output increases. This reflex is called the Bainbridge reflex or more appropriately the venous reflex.

Cardioinhibitory reflex (Sinoaortic or Marey's reflex)

There are the stretch receptors in the carotid sinus and aortic arch. When the blood pressure rises, these nerve endings become stimulated due to stretching, and cause sensory impulses to pass up through the sinoaortic nerves and increase the vagal tone. So that heart rate falls. When blood pressure falls, no inhibiting impulse passes up and heart rate rises. Thus the heart rate and blood pressure have an inverse relation. This is known as the Marey's law.

Paralysis of the intercostal muscles by thoracic epidural block can affect the respiratory volumes. When this block affects all the intercostal muscles, then normal ventilation and P_aCO_2 can still be maintained by the activity of the diaphragm only, since the phrenic nerve is not affected. But, patient suffers from a severe feeling of suffocation. So, sedation is very much needed which again reduces the central ventilatory drive. On the other hand, secondary to intercostal muscle paralysis increased diaphragmatic shortening improves the tidal volume. But, the

inspiratory reserve volume and functional reserve capacity are significantly decreased with the decrease of vital capacity.

Thoracic epidural with Tuohy needle and catheter can be performed by the patient sitting, lateral or prone position. Sitting position provides better alignment of the spine and facilitates better identification of landmarks. But a patient who is anxious may have a strong vasovagal and hypotensive reaction. So, for them lateral decubitus is preferred. Flexion of the patient contributes very little by expanding the interlaminar space in the thoracic region (Fig. 24.35).

Thoracic epidural space also can be approached from three directions—midline, paramedian and laminar. The midline approach is applicable in the upper part of the thoracic spine between C_7 and T_5 and in the lower part of the thoracic spine between T_9–T_{12}. Because in these areas the spinous processes are more or less horizontal and project directly to the posterior without inclination. In these segments, the level of the spinous process corresponds to the same level of vertebra.

The paramedian or lateral approach can be used at any level of the thoracic spine. In paramedian or lateral approach the epidural needle is advanced at a 45 to 55 degree angle towards the cephalad and at 15 to 30 degree angle toward the midline. Contacting the lamina with the epidural needle significantly increases the safety of this approach, because the epidural space can be entered by just walking off the superior margin of the lamina. Extreme angles can result in the needle passing between the spinous processes into the paraspinal muscles of paravertebral space of the opposite side. For laminar approach, the starting point is 1 to 2 cm lateral to the superior margin of the spinous process (like paramedian approach), but the needle is not angled toward the midline. It runs parallel to the spinous process and enters the interlaminar foramen medial to the interarticular process. Here, only the lateral portion of the epidural space is entered (Fig. 24.36).

The complications of the thoracic epidural technique or approach are similar to those of the lumbar epidural.

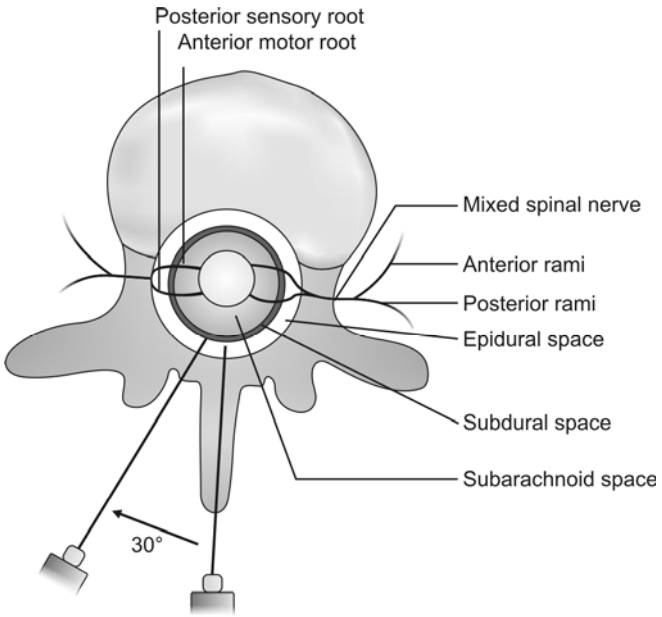

Fig. 24.35: Cross-section of median and paramedian approach to the lumbar epidural space. The red colour circle indicates the dura mater and the green colour circle indicates the arachnoid mater

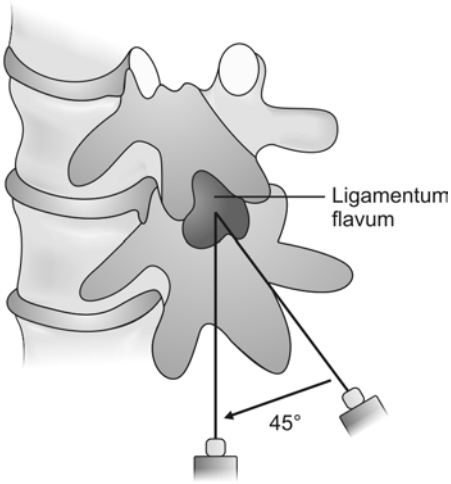

Fig. 24.36: The median and paramedian approach to the lumbar epidural space

There are many indications for thoracic epidural block. Among them a few are stated below. Thoracic epidural catheters are increasingly utilised for providing intraoperative and especially postoperative analgesia for thoracic and upper abdominal surgical procedures, such as mastectomy, cholecystectomy, gastrectomy, repair of diaphragmatic hernia, etc. It has also been utilized for thoracotomy and cardiac surgery in conjunction with light general anaesthesia. Patients with multiple fractured ribs get excellent analgesia by thoracic epidural with catheter at selected segments. Local anaesthetic, such as 0.125% bupivacaine and / or an opioid can be used without any motor block and hypotension. Catheters placed in the thoracic epidural space can also be used to provide only long-term analgesia using opioids, local anaesthetics, phenol or alcohol in alone or with combination for chronic pain due to many causes or acute pain in nonoperable malignancy. The catheter should be placed in the area of the involved nerve roots. If alcohol is used it should be injected through the catheter in 0.5 ml incremental doses to a maximum of 5 ml. The injection has to be repeated daily for at least 3 days. Phenol is used in concentration of 5% with dextrose or with normal saline.

Cervical Epidural

The cervical epidural space is bounded above by the fusion of the investing layer of drug (vertebral periosteum) and the spinal layers of dura at the foramen magnum and below it is continuous with the thoracic epidural space at the level of the T_1 vertebra. The cervical epidural space is bounded anteriorly by the posterior surface of the body of cervical vertebra with posterior longitudinal ligament and posteriorly by the vertebral laminae and ligamentum flavum. The ligamentum flavum is thin in the cervical region and gradually becomes thicker caudally. It is thickest at the lumbar region. This fact has direct clinical implication, because the loss of resistance felt during cervical epidural block is more subtle than it is in the lumbar and lower thoracic region. The vertebral pedicles and intervertebral foramina form the lateral boundary of cervical epidural space. The degenerative changes and narrowing of these intervertebral foramina associated with aging may be marked in the cervical region. Such changes reduce the leakage of local anaesthetic solution out of the foramina and account for the reduced anaesthetic dose requirement in elderly patients undergoing cervical epidural block. At the level of C_7, the distance between the ligamentum flavum and the dura is only about 1.5 to 2 mm. It is due to the presence of cervical enlargement of spinal cord, serving the upper extremities. Whereas, the distance between ligamentum flavum and the dura is greatest at the L_2 interspace, measuring about 5 to 6 mm in adults. It should also be noted that flexion of the neck moves this cervical enlargement more cephalad, resulting in widening of the epidural space to 3 to 4 mm at the C_7-T_1 interspace. This fact has important clinical implications for cervical epidural block.

Like other epidural space, cervical epidural space also contains loose areolar tissue, fat, epidural veins, arteries and lymphatics. Fat in the epidural space serves as a shock absorber for other contents of the space and as a depot for injected drugs. The amount of epidural fat varies in direct proportion to the amount of fat, stored elsewhere in the body. The epidural fat is relatively vascular and appears to change to a denser consistency with aging. This change in consistency may account for the significant variations in required dose of a drug in adults, especially with the cervical approach to the epidural space. The valveless epidural veins are concentrated principaly at the anterolateral portion of the epidural space and transmit both the intrathoracic and intra-abdominal pressures. When pressure in either of these body cavities increases such as during Valsalva's manoeuvre or compression of the inferior vena cava in the abdomen by a gravid uterus ascitis or a tumour mass, etc. then the cervical epidural veins distend and reduce the volume of this epidural space. This decrease in volume of the cervical epidural space can directly affect how much drug is needed to obtain a given level of neural blockade. Most of the epidural arteries with significant anastomoses lie in the lateral portions of the cervical epidural space. The arteries enter the epidural space via two routes: through the intervertebral foramina and via direct anastomoses from the intracranial portion of the vertebral arteries. Trauma to these epidural arteries can result in the formation of epidural haematoma and compromise the blood supply to the spinal cord itself.

Cervical epidural block can be carried out with the patient in the sitting, lateral or prone position and each position has its advantages and disadvantages.

1. The sitting position for cervical epidural block is most preferred, because (i) it enhances the operator's ability to identify the midline, (ii) it also ensures that the cervical spine is flexed which widens the lower cervical epidural space, (iii) the sitting positis avoids the rotation of the spine which is inherent in the lateral position and makes identification of the cervical epidural space difficult. But, sitting position is not always an option for patients with acute vertebral compression fracture or with the history of vasovagal syncope or sedated, where lateral position is preferred. For the patient's comfort lateral decubitus or position is more suitable and also for those who cannot assume the sitting position. If lateral position is selected, then care must be taken to ensure that there is no rotation of the patient's spine because it will make the cervical epidural block extremely difficult or impossible or produce complications. During cervical epidural it will have to-kept in mind that flexion of the cervical spine is mandatory to maximise the width of the epidural space. Another important point for cervical epidural anaesthesia is that the needle entry site should be exactly in the midline. Failure to accurately identify the midline is the most common cause of difficulty in performing the cervical epidural block. Prone position is selected in special cases, such as during placement of epidural catheters with spinal stimulation electrodes. However, prone position should be avoided if sedation is required, because access to the airway is limited.

For the purposes of diagnostic and/or prognostic cervical epidural block, 1% preservative-free lignocaine is most suitable as local anaesthetic agent. For therapeutic purpose, 0.25% preservative-free bupivacaine in combination with 80 mg of depot methylprednisolone is injected. Subsequent doses of methylprednisolone is 40 mg daily with or without local anaesthetic agent to treat the acute painful conditions. Chronic painful conditions such as cervical radiculopathy, diabetic neuropathy, etc. are treated by daily or every alternate day or once in a week injection through the catheter as the clinical situation dictates. Other indications for cervical epidural block are intractable pain, thyroidectomy, carotid end arterectomy, etc. During cervical epidural analgesia differential block is used to avoid

motor block of phrenic nerve. For this purpose drugs used are bupivacaine 0.125% or lignocaine 0.5%.

Like thoracic and lumbar epidural block, cervical epidural block can also be employed by Hustead or Tuohy needle which is advanced slowly at an angle of 30 degree cephalad. Catheter is advanced approximately 2 to 3 cm beyond the needle tip. The needle is then carefully withdrawn over the catheter. Under no circumstances only catheter should be withdrawn back through the needle, because it will cause shearing of the catheter at the needle tip and lost in the epidural space. If significant pain occurs during placement of the epidural needle or catheter or during injection of drug, then the physician should immediately stop the procedure and ascertain the cause of pain to avoid the possibility of neural trauma. So, intravenous sedation or GA before initiation of cervical or other epidural nerve block renders the patient unable to provide accurate verbal feedback, if the needle is misplaced. Like other central neuroaxial block, during cervical epidural block if an epidural needle or catheter is accidentally placed in the subarachnoid space and the problem goes unrecognised, then injection of a fraction of epidural doses of local anaesthetics solution will cause immediate total spinal anaesthesia and its consequences. So, implication of test dose in cervical epidural anaesthesia is not as helpful as thoracic and lumbar epidural anaesthesia.

The administration of opioids and local anaesthetic agents into the cervical epidural space may be associated with a greater incidence of urinary retention. This side effect is more common in elderly male and multiporous females whose bladders are prolapsed. Overflow incontinence may occur when such patients are unable to void or bladder catheterisation is not done. So, all patients must empty their bladder before their discharge from the pain clinic, if they get cervical epidural anaesthesia or analgesia.

Caudal (or Sacral) Epidural Anaesthesia

Anatomy of sacrum, sacral canal and hiatus

The sacrum represents the fusion of 5 sacral vertebrae. However, many variations of this fusion are common and have an important bearing on the incidence of failure rate of caudal epidural anaesthesia. The sacrum is triangular in shape. The apex of this triangle is directed below and is formed by the 5th sacral vertebra which articulates with the coccyx. The base of the triangle is formed by the first sacral vertebra and articulates with the body of 5th lumbar vertebra. The anterior surface of the sacrum is concave and is characterised by four anterior sacral foramina on both sides of the midline (4 pairs) through which the anterior primary rami of four sacral spinal nerves pass out. The posterior surface of the sacrum which has a greater interest for anaesthetist is convex. A bony ridge with three or four rudimentary spinous processes runs in the midline and is called the median sacral crest. On the both sides of this median sacral crest, there are 4 posterior sacral foramina, (total 4 pairs) corresponding with the anterior one, through which posterior primary rami of the four spinal sacral nerves pass out. The local anaesthetic solutions injected into the sacral epidural space or sacral canal can pass freely through these foramina and this is an important factor for the unpredictability of the height to which caudal anaesthesia may extend. The canal in the sacrum is called the sacral canal. It is also triangular in shape and continuous above with the lumbar portion of vertebral canal and terminate below at the sacral hiatus (Fig. 24.37).

The sacral canal contains:

i. the epidural space with venous plexus and fibrofatty tissue. This sacral epidural space is continuous above with the lumbar epidural space,

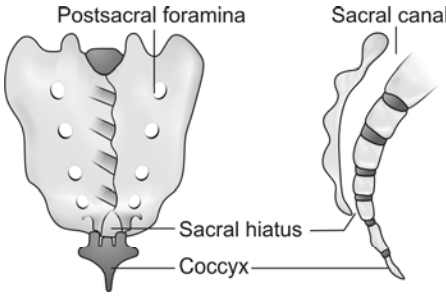

Fig. 24.37: The posterior and sagittal view of sacrum and coccyx

ii. the dural sac made of spinal dura mater and arachnoid mater contains CSF and ends between S_1 and S_3 vertebrae (usually at the lower border of S_2),
iii. the five sacral nerve roots,
iv. coccygeal nerve,
v. filum terminal externa.

The epidural venous plexus in sacral canal generally ends at S_4 level, but may also continue caudally. Most of these vessels are concentrated in the anterior portion of the canal. Both the dural sac and the epidural vessels are susceptible to trauma during the excessive cephalad advancement of the epidural needles and catheters used for caudal block through the sacral canal. The remainder of the sacral canal is filled with fibrofatty tissue which is subjected to age-related increase in density.

The sacral hiatus is actually a deficiency on the posterior wall at the lower end of the sacrum. It results from the failure of the fusion of laminae of 5th sacral vertebrae. It is triangular in shape. The apex of the hiatus is formed by the spine of 4th sacral vertebrae. The lateral margin of hiatus bears prominence called the sacral cornu which represents the articular process of 5th sacral vertebrae. Base of the hiatus is formed by the superior surface of coccyx and is covered by posterior sacrococcygeal mambrane. In surface marking, the sacral hiatus forms an equilateral triangle with the two posterior superior iliac spines. There may be multiple anatomical variations of sacral hiatus. Some of which are described below. The apex of hiatus may be formed by the spine of 2nd or 3rd sacral vertebrae due to the absence

of laminae of 3rd and 4th sacral vertebrae, respectively. Occasionally, the whole bony post wall of the sacrum remains deficient. On the other hand, when the lamina of 5th sacral vertebra is present, then hiatus may become very small with the diameter as narrow as 2 mm and makes the introduction of needle for caudal epidural anaesthesia almost impossible. There are many fibrous bands in the sacral canal which divide the sacral epidural space into multiple loculi, causing incomplete spread of local anaesthetic agents in the sacral canal and incomplete anaesthesia. Now a days caudal epidural anaesthesia is often combined with GA for paediatric patients to decrease the amount of intraoperative anaesthetic agents and/ or to provide postoperative analgesia for the surgeries on inguinal region, perineal region, lower extremities and sometimes lower abdomen.

Technique

It is better to see and practice than to read the technique of caudal epidural anaesthesia. Usually the needle, selected for caudal anaesthesia, should be malleable enough to adapt itself with the curvature of the sacral canal and will not break. A wide bore needle gives a better feel of the structures as it passes through the hiatus and canal, while a short bevel at the tip minimises the risk of puncturing the dura. However, nowadays many operators use an ordinary disposable hypodermic needle for caudal epidural block. The ideal position of patient for caudal block is prone or lateral. The sacral hiatus is identified first by sacral cornu. The needle then pierces the skin and sacrococcygeal ligament at right angle. After that needle should be depressed in the intergluteal fold and is advanced cranially in the sacral canal, maximum up to the line joining the two posterior superior iliac spine, where the dural sac (with the subarachnoid space) ends. Aspiration for blood or CSF is done. Blood through needle indicates puncture of epidural vein and in that case needle should be withdrawn for a few millimetre. If CSF comes through needle, then procedure should be abandoned or converted it to spinal block. For test dose (test for confirmation whether the tip of the needle has enter the dural sac or remains outside the dural sac in the epidural space), 2 ml of local anaesthetic drug is used first. If patient can move his toes then it is sure that the tip of the needle is in epidural space and not in subarachnoid area. Then rest of the drug is injected.

Problems

The needle may miss the sacrococcygeal ligament and may pass dorsal to the sacrum under the skin or may pass under the periosteum of the posterior surface of sacrum. This can be tested by injecting a few ml of air and palpating the crepitus under the skin. The needle may slip under the base of the coccyx and can pierce the rectum or foetal head (in pregnancy). The needle may run beneath the periosteum of the sacral canal causing marked resistance to injection and complain of severe backache. Any feeling of resistance during injection of LA agent indicate needles is not properly placed.

Doses

The level of block by caudal epidural anaesthesia depends on the volume of local anaesthetic solution, and the position of the patient. With the patient in horizontal position 20 to 30 ml of local anaesthetic drug is required to block up to $L_{4\text{-}5}$ level. It is used for operation on anus, perineum and vagina. 40 ml drug is needed for analgesia and anaesthesia up to the umbilical level. But, with the patient in horizontal position such a large dose may risk the systemic toxic reaction. However, Trendelenburg position helps in upward extension of the drug and reduces the dose.

Indications

The main indication of epidural anaesthesia through this caudal route is the production of conduction block of only the lower lumbar and sacral spinal nerve roots for procedures such as urinary bladder operation, anal-vulva-vaginal operation, operation on inguinal region, circumcision, etc. without affecting blood pressure and much systemic conditions. In some conditions where caudal-epidural is highly indicated due to severe illness of the patient, but sacral approach is technically very difficult, then it may be easier to perform lumbar epidural block in sitting position. Postoperative analgesia by caudal epidural block in conjunction with GA is a good choice, particularly in children and obstetric analgesia.

Continuous caudal epidural anaesthesia using catheters

An epidural catheter may be placed into the sacral canal in a manner, analogous to that of continuous lumbar, thoracic or cervical epidural anaesthesia, through an epidural needle placed in sacral canal though sacral hiatus. The epidural catheter is advanced through the needle approximately 2 to 3 cm beyond the tip and then the needle is carefully withdrawn over the catheter. But, under no circumstances, the catheter is withdrawn back through the needle to avoid the shearing of catheter tip. A test dose of 3 to 4 ml of local anaesthetic agent is then given via the catheter and the patient is observed for any sign of local anaesthetic toxicity due to intravascular injection or inadvertent subarachnoid injection. If no sign of side effects or toxicity of LA agent are noted, then intermittent boluses or continuous infusion of local anaesthetic agent with or without opioids are administered through the catheter. Because of proximity to the anus, the risk of infection limits the long-term use of caudal epidural catheters.

Paediatric caudal block

Though placement of an epidural catheter allows for continuous infusion of local anaeshtetic agent with or without opioid or opioid alone for continuous caudal block

for various reasons, till the single injection caudal or sacral block is one of the most popular paediatric regional anaesthetic techniques for intra and postoperative analgesia. A combination of caudal block, supplemented with light general anaesthesia allows for a quicker recovery due to lesser need of volatile and other general anaesthetic agent.

Technically, the caudal blocks are much easier to perform in children than adults. This is because in children:

i. landmarks defining the sacral hiatus are easy to palpate,
ii. limited amount of gluteal pad of fat,
iii. less subcutaneous fat over hiatus,
iv. gluteal musculature are poorly developed,
v. there is less fusion and less distortion of sacral hiatus,
vi. the sacrococcygeal ligament is not calcified.

In children dural sac ends in between the 2nd and 3rd sacral vertebrae which is generally much lower than that of adult and sacrum is smaller in proportion to the overall size of the body. So, there is much higher possibilities to pierce the dura during caudal block in children.

It is previously stated that when the caudal block is combined with GA, then it provides excellent perioperative analgesia. So, the common indication of paediatric caudal epidural block are: (i) sacral segment surgeries – circumcision, rectal operation, club foot repair, etc. (ii) groin surgeries – herniorrhaphy, orchidopexy and hydrocele, etc. (iii) urologic procedures, (iv) lower extremity orthopaedic procedures. By increasing the volume of drug, the level of caudal block can be increased high by which the different lower abdominal surgeries can also be performed.

For caudal epidural, 0.25% bupivacaine is the commonly used drug which provides minimal motor blockade with adequate sensory blockade. But the total dose of bupivacaine should not exceed 3 mg/Kg. An easy calculation of volume of 0.25% bupivacaine is: 0.5 ml/kg for only sacral blockade, 0.75 ml/kg for the blockade of lumbar segments and 1.25 ml/kg for the blockade of thoracic segments. Test dose is unreliable in children, so close observation, frequent aspiration, and fractionated injection of drug is the best safeguard against undetected subarachnoid and intravascular injection.

COMPLICATIONS OF SPINAL AND EPIDURAL BLOCK

As some complications are common for both the spinal and epidural anaesthesia, so they are discussed together.

Hypotension

Vasodilation and hypotension is a predictable and desirable feature of central neuroaxial blockade when the nerve roots above the L_2 levels are affected from where the preganglionic sympathetic fibres originate. Severe hypotension is more likely in the older patients, and in patients with higher level of block (T_5 and above). The definition of hypotension during CNB varies, but a systolic blood pressure of less than 90 mm of Hg is challengeable. It is more appropriate to consider a fall in BP of 25 to 30% from its preoperative mean arterial pressure (MAP) level as a practical guide to dictate the treatment. The incidence of hypotension following CNB has been reported to be 92% in an untreated control group undergoing caesarean section with spinal anaesthesia. It is a very serious problem in spinal anaesthesia and is due to its rapid onset and giving no time for adequate cardiovascular compensation. More quick acting anaesthetic drugs cause more fall of blood pressure. In continuous epidural, this incidence of hypotension can be reduced by giving the full dose of LA agent in multiple small incremental doses, when a extensive epidural block is needed and thus giving CVS the time for compensation. This complication can be managed by intravenous preloading with crystalloid (1 to 2 litres) or colloid solution. Colloid solutions are more effective in reducing the hypotension at lower volumes than the crystalloid solution. But, the colloids are more expensive and carry a slightly increased risk of allergic reaction. So, crystalloids are generally preferred for IV preloading as routine prophylaxis against hypotension. However, caution is required for the patients with cardiac disease where smaller volumes of IV fluids plus earlier use vasopressors is advisable. The administration of large volumes of IV fluid as the only treatment of persistent hypotension, produced by central neuroaxial blockade is potentially dangerous and is not recommended. Pressure-rising drugs like ephedrine or methoxamine are used where preloading fails to maintain MAP. Combination of preloading and vasoconstrictor had maximum effect and is the best in preventing spinal hypotension. This is followed by the sole use of vasoconstrictor which is the second choice. Preloading alone offers least protection against spinal hypotension.

The optimal treatment of hypotension induced by central neural blockade remains still unresolved. A correction of the fall of the systemic vascular resistance generally includes the treatment with α-adrenergic agonist such as methoxamine. Whereas the impaired venous pooling is corrected by IV fluids and β-adrenergic agonists. A slight head down tilt and elevation of legs encourage venous return. Methoxamine, as an α-adrenergic agonist, increases the peripheral vascular resistance and restores pressure, but perhaps at the expense of organ blood flow. This drug may produce or extend bradycardia and is preferable to ephedrine when tachycardia is present. So caution should be exercised when (Table 24.9) there is a normal or lower than normal heart rate, as more reflex bradycardia due to increase of vascular resistance may follow the administration of methoxamine. The initial intravenous bolus dose of methoxamine should be 2 mg. Ephedrine is a predominantly β-adrenergic agonist

Table 24.9: Complications of central neuroaxial block (CNB)

A.	**Related to needle and/or catheter introduction**
i.	*Trauma*
	Nerve root damage
	Spinal cord damage
	Cauda equina syndrome
	Dural puncture leak causing PDPH, tinnitus, diplophia, etc.
	Cranial nerve injury
	Backache
ii.	*Bleeding*
	Intraspinal haemorrhage
	Epidural haematoma
iii.	*Infection*
	Meningitis
	Epidural abscess
iv.	*Displacement of needle or catheter*
	Inadvertent intravascular injection
	Inadvertment subarachnoid block or total spinal (epidural block)
	Inadequate block
	No effect
	Shearing and retention of catheter
B.	**Exaggerated physiological responses**
	Total spinal anaesthesia (in case of epidural block)
	Higher block than expected
	Respiratory arrest, cardiac arrest
	Urinary retention
	Anterior spinal artery syndrome
	Horner's syndrome
C.	**Toxicity of drugs**
	Systemic toxicity
	Transient neurological symptoms
	Cauda equina syndrome

and has little direct effect on peripheral resistance. It mainly acts on heart. Thus, it maintains the blood pressure by increasing the heart rate with some effect on the venous pooling. Ephedrine is also advantageous over methoxamine in pregnancy, because here the preservation of uterine blood flow in the presence of hypotension is more important. It is administered in a bolus dose of 3 to 6 mg intravenously.

Sometimes, the simple treatment of bradycardia by atropine may restore the blood pressure to an acceptable level. Raising of legs to increase the venous drainage and thus to reduce the chance of hypotension may encourage further cranial spread of the local anaesthetic block, if this is under taken in the early stages of anaesthesia, and may cause more hypotension.

Postdural Puncture Headache (PDPH)

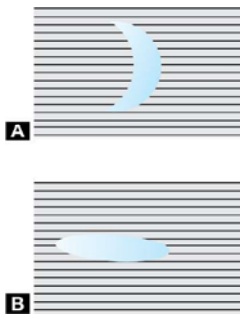
It is the complication of spinal block only and in epidural anaesthesia when the needle inadvertently punctures the dura. The principal cause of PDPH in spinal anaesthesia is low CSF pressure and it is due to its continuous seepage through the punctured hole on dura or aseptic meningeal irritation. It also may herald the onset of infective meningitis. The rate of leakage of CSF from subarachnoid space to epidural space, causing PDPH should be above 10 ml/hour. The loss of CSF up to 10 ml/hour has no symptom or headache. The healing of dural puncture usually takes 3 weeks. So, PDPH usually lasts for 1 to 2 weeks. But it may last for days, weeks or even months. In traumatic leakage the choroid plexus can form CSF maximum at the rate of 500 ml/day.

The mechanism of PDPH is when the rate of leakage of CSF exceeds its rate of formation then it leads to some change in hydrodynamics of CSF. This causes the loss of cushioning effect of brain and produce traction on vessels, basal dura, tentorium and other sensitive brain structure. Attachment of these structures to the cranium on one hand and meninges on the other hand leads to the stretching of meninges and blood vessels, causing pain. The PDPH is mainly posturally mediated and is being worse in upright position. This is due to the increase in downward traction of brain tissue by the gravity. Typical PDPH starts 6 to 12 hours after the puncture of dura and lasts for weeks. It is worse in sitting up position and disappears after lying down. The pain is typical and different from any other previously experienced headache. Usually the pain is experienced at the frontal region or behind the eye ball. Nausea and vomiting may accompany this pain. Tinnitus and deafness may also accompany the PDPH and is due to the low CSF pressure, resulting in fall of intra-labyrinthine pressure. The normal CSF pressure is 150 mm of water. When PDPH precipitates it drops to 50 mm of water. It is most common in obstetric patient, because during contraction of uterus and bearing down there is more leakage of CSF. The PDPH is also more commonly associated with young female patient, large bore spinal needle, cutting tip, passing of the bevel of needle tip at right angle to dural fibres etc. Other factors that increase the rate of PDPH are those that increase CSF pressure, e.g. obesity, ascites and pregnancy (Figs 24.38A and B).

Classification of postdural puncture headache (PDPH)

PDPH is classified into mild, moderate and severe form.

i. *Mild PDPH:* Here PDPH is slight and does not restrict daily activities. The patient is not bed ridden at any time during the day. There are no other associated symptoms like nausea, vomiting, etc. with PDPH.
ii. *Moderate PDPH:* Here PDPH is significant and restricts daily activities. The patient is bedridden for some part of the day. Associated symptoms may or may not be present.



Figs 24.38A and B: A. The apperture of hole in dura made by the bevel of spinal needle which is perpendicular to the direction of dural fibre. B. The apperture of hole in dura made by bevel of spinal needle which is parallel to the direction of dural fibre

iii. *Severe PDPH:* Here PDPH is very intense and forced the patient to stay in bed throughout the whole day. Associated symptoms are always present.

In one study, it is found that 86% of patients who developed PDPH have associated symptoms such as nausea (60%), vomiting (24%), stiffness of neck (43%), ocular (13%) and auditive symptoms (12%). Other symptoms associated with PDPH are:

Vestibular symptoms − nausea, vomiting, vertigo, dizziness, etc.

Cochlear symptoms − hearing loss, hyperacusis, tinnitus, etc.

Occular symptoms − photophobia, diplopia, difficulty in accomodation, etc.

Musculoskeletal symptoms − stiffness of neck, scapular pain, etc.

Prophylaxis and management of PDPH

Prophylaxis and mangement of PDPH are:

i. Use of more and more finer and pencil tipped needle.
ii. Bevel of the needle tip should be parallel to the dural fibre during its puncture.
iii. Lateral position of the patient during procedure is associated with less incidence of PDPH.
iv. Postoperative monitoring should be done in lying down position, at least for 24 hours in bed. In case of the use of wide bore needle postoperative rest in bed should be atleast for 72 hours. This rest will help in repair of hole of dural puncture and will reduce the incidence of PDPH.
v. Avoiding all types of straining activities and trying to lie down in prone position.
vi. Analgesics, adequate oral intake of water which ensure maximum production of CSF, use of DDAVP – 4 mg/day, etc. are other methods by which the incidence of PDPH can be reduced. Another conservative method for the management of PDPH is use of IV caffeine and sodium benzoate. Caffeine is a potent vasoconstrictor and may relieve the symptoms of PDPH by preventing the traction on blood vessel of brainstem. Rapid administration of 500 mg caffeine mixed in one litre of crystalloid solution has the dual effect of caffeine in bolus and aggressive hydration. Caffeine may be an adrenergic stimulant for some patients also.
vii. In most cases by the above simple measures PDPH can be avoided or treated. But, still when the headache persists with the above measure, an epidural blood patch by 10 to 20 ml of autologus blood is considered. Success rate of autologus blood patch is 90%. With the possible accumulation of CSF under ligamentum flavum, successful epidural placement of needle during the placement of blood patch may yield small amount of clear or straw coloured liquid and confuse. However, it may frequently produce mild headache, neckache and paraesthesiae. Also the introduction of infection by such a means would be disastrous. So, this procedure should be reserved only for the severe refractory cases of PDPH.

Sometimes excessive leakage of CSF can cause death due to herniation of uncus against the tentorium cerebellae. This is due to high ICP for any cerebral lesion which was present before dural puncture.

D/D of PDPH

Other causes of postoperative headache not related to dural puncture should be differentiated from PDPH. These are: migraine, meningitis, dehydration, hyponatraemia, neck muscle spasm due to stiffness of operating room table, withdrawal from caffeine, etc.

Cranial Nerve Paralysis

Any cranial nerve can be affected by central neuroaxial block. This is possibly due to the result of excessive spread of local anaesthetic agent in the brain, causing direct neural toxicity or as a result of downward traction of brain along with cranial nerves due to low CSF pressure from leakage. Among all the cranial nerves sixth cranial nerve is more prone to injury and it is due to its long and tortuous course. Due to the low CSF pressure from leakage, there is descent of medulla and pons which causes stretching of this nerve and injury between its origin at pons and anchoring site at cavernous sinus, over the apex of petrous temporal bone. Sixth cranial nerve injury causes photophobia and diplopia due to lateral rectus muscle paralysis.

Accidental Total Spinal Block

Total spinal block results when the full epidural dose of local anaesthetic solution is inadvertently placed in the subarachnoid space, during an attempted epidural anaesthesia. In total spinal the large doses of local anaesthetic solution, scheduled for epidural anaesthesia, spread all over the spinal and cranial CSF and blocks all the nerve roots including the cranial nerves, vital centres on the 4th ventricle and all the sympathetic outflows, causing complete cardiopulmonary shut down. Effects of these are severe hypotension, severe bradycardia, apnoea, aphonia, unconsciousness, dilatation of pupil and even cardiac arrest. Appearance of patient resembles like death even if cardiac arrest does not occur. Usually, it comes soon after the injection of drug in the wrongly diagnosed epidural space, but it may be delayed for 30 to 45 minutes.

The corner stone of management of this total spinal block is quick diagnosis, intubation, ventilation with 100% O_2, aggressive management of hypotension by pressure rising drugs, correction of bradycardia, IV fluids, etc. Patients usually recover completely after LA drug is withdrawn from the cranial CSF which usually occurs within 1 to 2 hours. Then surgery can also be carried out when the patient's condition becomes stable. Hypotension should not be allowed to persist for long time. Due to hypotension and ischaemia of neural tissue, or due to irritant effect caused by the large volume of drug in intrathecal space

(which is in direct contact with nerve tissue) prolonged neurological disturbances may occur.

Epidural analgesia for labour pain (obstetrics analgesia) can be made safely via adjacent interspinous space after an inadvertent dural puncture during the first epidural attempt. But, this cannot be applied for LUCS (obstetrics anaesthesia). Because large dose of LA agent is needed for caessarean section and this may cause total spinal block after passing through the previous dural hole which is made inadvertently by the epidural needle in previous attempt. If the level of block ascends high up, then consciousness is gradually lost as afferent impulses reaching cortex, become fewer and fewer.

Respiratory Failure

It is due to the higher spread of spinal or epidural block and may be due to the deliberate or inadvertent attempt. When the height of block reaches the level of T_1 spinal segment, then gradual progressive paralysis of all the intercostal muscles, reduction of voice to whisper, increased diaphragmatic activity, increased activity of accessory respiratory muscles of neck and tracheal tug, etc. are some of the common features of peripheral respiratory failure. But as the central respiratory drive persists and the cervical spinal segment from where the phrenic nerve originates is not blocked, so the patient continues the respiration, which is only accomplished by diaphragm. If local anaesthetic drug spreads in the cervical segment, then apnoea may also supervene due to phrenic nerve paralysis. There may be warning of this development, and this warning is patient will complain of tingling or numbness in the hands. This is due to the involvement of brachial plexus as it is formed by the cervical spinal nerve roots. This higher spinal anaesthesia causing peripheral respiratory failure is also associated with severe hypotension which causes reduced cerebral circulation. The apnoea may also be due to this hypotension and reduced blood supply to the cerebral respiratory centre, but may or may not be due to the direct spread of drug to the brain stem. So, the immediate restoration of BP is the primary physiological consideration during higher CNB. The management of complete respiratory failure is like the total spinal block. But, the speed is very vital in this treatment as the cardiac arrest may rapidly follows the respiratory arrest in cases of ischaemic medullary paralysis.

If respiratory difficulties are reported then the anaesthetist should be prepared to intubate and ventilate the patient. It is important to remember that, although the patient may be unable to breathe due to phrenic paralysis, he or she still may be conscious and a small dose of an intravenous anaesthetic agent is indicated to render the patient unconscious. Sometimes upper airway reflexes may also still be active and muscle relaxants may be needed to facilitate the intubation. The patient may require some form of general anaesthesia to maintain unconsciousness, untill the block wanes and spontaneous respiration returns. If the block is high enough then unconsciuosness will occur, but consciousness may return before the patient can breath spontaneously.

Back Pain

Back pain resulting from the spinal or epidural anaesthesia is mainly related to the needle puncture, causing tissue trauma and mild bleeding into the tissue. The tissues include supraspinous ligament, interspinous ligament, ligamentum flavum and intervertebral disc. With fine needle the backache is uncommon. Further potential changes due to injury in tissue is altered by the previous presence of any degenerative processes. The probability of back pain increases when the large bore needles are used and/or repeated attempts in same space or tissues are made. Patients with existing back pain should be made aware that a brief moderate increase in the back pain may occur.

However, any back pain after central neuroaxial block should be thought of as possible sign of more serious complication. For example, severe pain within the first several hours after resolution of anaesthesia should be considered as an early sign of accumulating haematoma. When a progressively worsening back pain is accompanied by further conduction blockade after returning from primary anaesthesia, then the possibility of neural compression by rapidly expanding epidural haematoma must be investigated. But severe back pain which begins after 24 to 48 hours of CNB and gradually progresses, then it must be evaluated as a possible sign of epidural abscess, especially if there are sign of systemic sepsis.

Previously, a local anaesthetic agent such as 2-chloroprocaine preparation had contained sodium bisulfite as preservative which has neurotoxic property. So, in the past many permanent neurological defects have been reported, following the inadvertent massive subarachnoid injection of this preparation, during attempted epidural anaesthesia. Therefore, in newer preparations of 2-chloroprocaine, sodium bisulphate is replaced by EDTA as preservative. Hence, the use of this newer preparation of 2-chloroprocaine sometimes cause severe persistent back pain and it is due to it's low pH and influence of EDTA on skeletal muscle which begin shortly after the resolution of epidural anaesthesia. This pain is described as severe muscle spasm of the paravertebral group of muscle mass and is thought to be caused by the backtracking of EDTA solution around the needle or catheter or through the intervertebral foramen to the paravertebral space.

During flexion of spine, the intervertebral disc is protruded in the spinal canal due to increased pressure on it by vertebral body. Thus, it becomes more prone to damage by the needle causing back pain due to cord compression by the prolapsed

disc. Backache also may be simply due to the musculoskeletal and sacro iliac strain which is common during obstetric delivery and if this patient has received central neuroaxial block then it is sometimes blamed. However, sometimes back pain is as common in patients who have not received spinal or epidural anaesthesia, as in those who have received it.

Haematoma

It results from the injury of epidural venous plexuses or subarachnoid vessels by needle or catheter. Damage to the epidural vessels is more likely to occur with an epidural catheter than with a needle. In patients with untreated clotting defects and 'unmonitored anticoagulant therapy', haematoma may be so large as to produce cord compression and neurological damage. So, a clotting defect should be considered as a contraindication to epidural or spinal block. This haematoma may be a nidus for infection in preexisting bacteraemia and may lead to abscess formation causing epidural abscess. Metastatic blood-borne infection may also occur, particularly in an small epidural haematoma, originating from some other focal source of sepsis. Large haematoma producing symptoms need early surgical intervention. Haematoma and abscess almost produce the same symptoms, but the differentiating point is that the symptoms of haematoma develops much more quickly than abscess. Laminectomy is urgently required to evacuate the haematoma or abscess and to avoid permanent neurological defect from cord compression.

Cord or Nerve Root Damage

Nerve roots or spinal cord can be damaged at any space during epidural or spinal anaesthesia by the needle or catheter. It may be temporary or permanent. In the distribution area due to this damage there may be pain, paraesthesia, numbness, etc. which may gradually recovers, if the injury is minor in nature and reversible.

Meningitis

Meningitis which means an infection of meninges is a very prognostically bad sequelae of spinal or epidural anaesthesia. It can be prevented by rigid aseptic technique during the procedure. On the otherhand, meningism which means aseptic meningitic reaction can also occur due to blood or injection of irritant agents in CSF. The irritant agents responsible for this aseptic meningitis (meningism) may be chemical antiseptics, starch powder from gloves, detergent, high concentration of drug, alcohol, phenol, preservatives, radio opaque agents, etc. which enter in the epidural space or CSF during the procedure. Blood responsible for meningism comes from punctured vessels present in subarachnoid space or epidural space.

Ischaemic Cord Damage

As spinal cord is supplied by end arteries, so it is more prone to ischaemic damage due to different causes. One of such cause is addition of adrenaline in local anaesthetic solution which produce vasoconstriction and ischaemia of cord. Ischaemic cord damage by adrenaline is also aggravated if it is associated with severe hypotension in arteriosclerotic subjects. Some space occupying lesion in spinal canal – such as haematoma, abscess, neoplasm, etc. also can cause compression of the functional end arteries and ischaemia of cord. When the anterior spinal artery which supplies the large part of the cord is obliterated or jeoparadised, then it produces anterior spinal artery syndrome. This syndrome is characterised predominantly by motor disturbance with sometimes loss of sphincter control and sensation. Hypotension from any cause may predispose to cord ischaemia. Preexisting arterial diseases (aorta / radicular arteries) may also aggravate this functional ischaemia of cord.

Paraplegia

After central neuroaxial blockade paraplegia has also been reported. This paraplegia can be caused by haematoma, abscess formation, chemical irritant, direct needle trauma, etc. Except CNB various anatomical abnormalities such as developmental laminar stenosis, narrow spinal canal, extradural spinal tumour, etc. may be the principal cause of paraplegia by compromising the circulation of cord. But when these are aggravated by spinal or epidural anaesthesia then regional block had to take the blame though it is merely a coincidence.

Adhesive Arachnoiditis

It may be due to the:

i. Injection of contaminated local anaesthetic,
ii. Mistaken injection of irritant solution in epidural and subarachnoid space instead of local anaesthetic agent,
iii. Injection of full epidural dose of LA agent intrathecally.

Cauda Equina Syndrome

It is due to the injury of cauda equina by the needle, catheter, or toxic effect of high concentration of local anaesthetic agent leading to:

i. Paraplegia, loss of leg reflexes,
ii. Incontinence of faces or retention of urine,
iii. Loss of sexual function,
iv. Paralysis of perineal nerve.

The causes of injury of cauda equina are the same as cord or root damage or paraplegia.

Nerve Damage due to Chemical Irritant

A number of chemical substances such as antiseptic, alcohol, phenol, preservatives, drugs, etc. cause definite nerve damage or irritation when injected in the epidural or intrathecal space. Pain is felt immediately and one is forced to abandon the procedure as soon as possible if analgesia or anaesthesia does not follow the spinal or epidural block which suggests that local anaesthetics or appropriate drugs has not

been injected. Also highly concentrated local anaesthetic agent in contact with nerve for a long time can also cause irreversible nerve damage, with histological change in nerve fibre. So, hypobaric or isobaric technique is largely abandoned because it causes deposition of large volume of drug around the nerves, displacing CSF, which is the normal enviornment of nerve roots. In total spinal, not only hypotension but also disturbances of pH, electrolyte and osmotic factors around the nerve fibres for longer time help to damage the nerve as large volume of drug has suddenly come in direct contact with the nerve.

Persistent Paraesthesia

Neurological defect should be evaluated after complete resolution of effect of the local anaesthetic drug, keeping in mind that in case of bupivacaine, the complete resolution may take 24 hours or longer. If resolution of neural blockade is followed by return of neural deficit, then a more aggressive approach is necessary. This complication first suggests the development of compressive damage to central axis. Evaluation should include predisposing factors (coagulopathy, antiplatelet medication, etc.), details of the procedure, (blood via needle/catheter, paresthesia during needle placement or catheter insertion, etc.) and history of the aggressive positioning of patient with catheter in place. Investigations should also look for the other possible aetiologies such as surgical procedure, positioning of patients devices and traction used during surgery or to position the patient. EMG before anaesthesia can detect the pre-existing neurological defects, but the exact location of defect from an acute injury of nerve is not possible with EMG, until axonal degeneration has occurred. Therefore, this is not valid until 3 weeks have elapsed.

An isolated, unilateral lesion of dermatome is more easily attributed to epidural anaesthesia than patchy multidermatomal lesion. Direct compression of cord often cross several dermatomes and causes multidermatomal lesion. Therefore, it can be differentiated from isolated nerve root injury. Absence of accompanying motor defect absolves epidural/spinal anaesthesia. Cauda equina syndrome is occurred due to either transverse chemical meningitis or vascular embarrassment of antispinal artery.

Epidural Abscess

The actual incidence of abscess after epidural or spinal anaesthesia is very low. It is unusual for an epidural abscess to form and accumulate enough to present symptoms with in 12 hours, except for unusually very virulent organisms. When excessive back pain after 24 to 48 hours of central neuroaxial blockade is accompanied by neurological irritation, focal deficit, systemic signs of toxicity, etc. then investigation is mandatory. Definitive diagnosis of abscess is made by CAT scan or MRI. Definitive treatment of it requires decompressive lamincetomy and aggressive IV antibiotic therapy to prevent the permanent neurological defect.

Wet Tap

During an attempted epidural anaesthesia, inadvertent passage of large epidural needle in subarachnoid space through the dura mater is called the wet tap. The response of an anaesthetist to possible wet tap should start immediately with confirmation and followed by next anaesthetic plan and strategies, with keeping in mind of severe PDPH. After wet tap there are several options. In first option the local anaesthetic agent with spinal dose can be injected in subarachnoid space to create a spinal anaesthesia, if it fit with the proposed surgical procedure. The second option is needle can be replaced at a different interspinous space and the epidural anaesthesia may be tried again. Second attempt of epidural anaesthesia at the same level might not be a wise choice, even if a clean reentry of an epidural needle into the epidural space through the same interspinous space is possible. This is because of the potential for massive subarachnoid deposition of local anaesthetic agent through the previous dural hole. After a wet tap, epidural anaesthesia can be followed by some manoeuvres to decrease the incidence of headache. These manoeuvres are injection of saline and blood patch through the catheter, prior to its removal, which will resist further leakage of CSF through the previous puncture site. Early epidural patch of blood is probably not indicated, because the success of this treatment is considerably higher even when applied after 24 hours.

Local Anaesthetic Toxicity

Despite proper safeguard, it is also possible to have a toxic blood level of local anaesthetic agent from a properly calculated dose in epidural anaesthesia, mainly in continuous form. For local anaesthetic agents, with low protein binding, signs of toxicity should be quite obvious and early. For example, symptoms of cranial nerve paraesthesia such as lingual paraesthesia or perioral tingling would likely to be reported rapidly by almost every patient who are given procaine (low protein binding). If the agent is of intermediate protein binding, for example, lignocaine and mepivacaine, then the gradual report of aura due to CNS toxicity could be missed, especially if the patient is not in constant communication with anaesthesiologist during dosing. Generally the signs of gradual accumulation of local anaesthetic agent in CNS include perioral numbness, gustatory paraesthesia, ringing in the ear, visual scotoma, etc. In agents with high protein binding, for example, bupivacaine and etidocaine, the aura may be very short or even absent.

Other Neurological Complication

Other than paraplegia, cord and root damage and ischaemic cord injury the other possible neurological complications

are: Pruritus, trigeminal nerve palsy, radiculitis, ascending myelitis, transverse myelitis, meningoencephalitis, intraocular haemorrage, Horner's sign, unmasking of spinal cord, neoplasm, etc.

Failed Epidural Anaesthesia

Sometimes, after successful location of epidural space and injection of full dose of local anaesthetic agent in this space, it may produce no result or anaesthesia. This is called the failed epidural anaesthesia. The speculation of such failure is that needle may pass off the midline into the muscle mass and simulate false loss of resistance during testing and injection of drug. Another speculation is that though the needle is placed correctly at midline, but any cystic degeneration in the epidural space (congenital or degeneratinve process) can create a false space where this phenomenon may occur. One way of indentification of such false space is that loss of resistance during the administration of initial dose of injection gives way to a rapid increase in resistance as the false space becomes filled, or the injection through the needle is easy but catheter placement is not possible.

Urinary Retention

Although the action of central neural blockade provided by single shot subarachnoid or epidural anaesthesia (not continuous postoperative epidural analgesia) usually lasts only for few hours, but urinary retention can sometimes be a problem, even after the block has been regressed. This retention of urine is a particular problem in the older male patients who may have pre-existing pathology, related to prostate enlargement. This problem is again exaggerated if large amounts of intravenous fluids have been administered as the part of the management of hypotension associated with central neural blockade. So, many anaesthetists routinely catheterise the bladder in patients having central neural blockade, either before or after the block has been instituted. But bladder catheterisation is often associated with a transient bacteraemia. This itself does not usually cause problems, but there are certain groups of patients in whom the administration of prophylactic IV antibiotics is advisable. These groups of patients include those having valvular heart disease and those having prosthetic joint replacements.

DIFFERENTIAL BLOCKADE

The concentrations of local anaesthetic agents required to achieve conduction blockade are different for each nerve fibre. These difference are influenced by the size of nerve fibre, myelination, and various tissue factors such as the rate of diffusion through the tissues, location of fibre within the nerve trunk (those on the surface are easier to block than those in the centre), fibrous diffusion barriers of the local anaesthetic agent and the ability of LA agent to move within the extracellular fluid. There is a general principle that the nerve fibres with smaller diameter will be blocked first than the nerve fibre with larger diameter and the nonmyelinated nerve fibres are blocked earlier than the myelinated nerve fibres. So the sensory fibres are blocked with lesser concentration of LA agents than the motors. Hence, there is only one type of nonmyelinated group C fibre which are theoretically most easier to block than the myelinated groups of comparable size nerve fibres. But, practically these C fibres are bundled in groups with significant amount of neural connective tissue (Schwann cells) around this bundle requiring higher concentration of LA agent to block these fibres than the comparable myelinated A-δ fibres.

The fibres earliest to be blocked are preganglionic B-fibres (though myelinated) that create pharmalogical sympathectomy and hypotension, associated with spinal or epidural anaesthesia. After the B group of fibres, the nerve fibres which are next sensitive to be blocked are the A group of fibres. Within the fibres of group A the concentration of local anaesthetic agent that is required to block the motor A-α fibres is double than that required to block the sensory A-δ fibres. If LA agent is injected at lower concentration or at a considerable distance from the site of action (i.e. nerve fibre), then it is found that the sensory fibres are blocked leaving the motor fibres. This explains the separation of motor block (A-α fibre) from sensory block (A-δ fibre) which thus can be elicited. So, at the edges of any area where regional anaesthesia is given due to the gradual fall of conentration of LA drug at the periphery, A-α fiber will not be blocked there, causing separation of motor block from sensory and autonomic block. This is called the differential blockade. Similarly in spinal or epidural block the injection of LA agent at the lumbar region delivers a relatively high concentration of it to the cauda equina which has very limited diffusion barrier. Hence, blockade at this level is uniformly dense for all types of fibres. Then as the agent spreads by gravity within CSF and as it moves cephalad, then the relative concentration of LA agent drops with increasing cephalad movement, and finally at a distance the agent reaches a concentration at which the myelinated largest and thickest A-α fibres are no longer blocked and no interruption of conduction of motor nerve is expected. But the fibres carring pain, touch, temperature and preganglionic sympathetic fibres are blocked. This is called the differential block. As the block precedes more cephalad, then the touch and pressure (A-β, γ fibres) are remain unblocked but the pain, temperature and preganglionic (A-δ, C, B fibre) fibres are blocked. This explain the common experience with spinal anaesthesia, when the patient retains a sense of pressure at the site of surgery, while having no feeling of sharp pain at the edges of the upper limit of block achieved. So, the classic teaching

is that there are different of two spinal segments between the motor, sensory and sympathetic block, depending on the local anaesthetic agent for spinal anaesthesia and the method of measurement of block. The simplest method of evaluation of block of different fibres which is generally used, usually brings similarity between the level of anaesthesia produced by the blckade A-δ and C-fiber. But to reflect the blockade of B fibre, the clinical tool for evaluation is patients sense of cold. If actualy sympathectomy is measured by thermography or galvanometry, the levels of it can be as much as five segments higher than the light touch.

i. A fibres
   A-α: 13-20 µm myelinated motor
   A-β: 5-12 µm myelinated touch, pressure
   A-γ: 4-11 µm myelinated muscle spindle
   A-δ: 1-4 µm myelinated pain, temperature
ii. B fibres
   1-4 µm myelinated preganglionic, sympathetic.
iii. C fibres
   0.5-2 µm nonmyelinated pain, temperature and postganglionic sympathetic.

COMBINED SPINAL-EPIDURAL ANAESTHESIA (CSEA)

This technique combines the advantages of both the spinal and epidural anaesthesia and thus makes it more versatile and flexible by removing the disadvantages of each other. This method of combined spinal epidural anaesthesia describe the placement of epidural needle in epidural space first, followed by an epidural catheter or a spinal needle through the previous needle. The history of combined spinal and epidural anaesthesia (CSEA) dates back to 1937, when Soresi, a New York surgeon, first performed an epidural block with a fine gauze needle and then he pushed the needle through the dura and arachnoid to make it a spinal block. There is no control of clinical trials at that time and Soresi had claimed that his technique had produced 24 to 48 hours postoperative pain relief from single injection of procaine both into the epidural and spinal spaces. But his claim was clearly over optimistic and failed to impress others.

Then CSEA was attempted by Curelaru, a Romanian anaesthetist, who performed both spinal and epidural blocks in a same patient, but through separate interspinous spaces. Almost simultaneously with Curelaru's work and unaware of it, Brownridge in Adelaide also performed combined spinal and epidural block for caesarean section using separate interspinous spaces by the spinal and epidural needles like Curelaru. But Brownridge's reasons for combining both the techniques were very much same as in keeping with the modern aims of combining the rapid onset, reliability and low toxicity of the spinal block with the ability of an epidural catheter to extend or prolong the block if necessary and use it for postoperative pain relief. In the following years, Coates was the first to describe the spinal needle through the epidural needle, using a single interspinous space. He used an available long spinal needle which could protrude past the tip of the epidural needle, the prototype for customised CSE sets, now provided by manufacturers. This variety of CSEA has now become the most popular. However, this needle through needle technique does not allow the placement and testing of the epidural catheter prior to the spinal injection. But when this is regarded as essential, then either a separate interspinous space may be used or another variety requiring spacialised equipment can be employed. This is the needle beside needle or 'double-barrel' needle. This equipment consists essentially of an epidural needle with a spinal needle channel guide which is soldered or incorporated in its wall. After the epidural needle has been placed and the catheter is inserted, the spinal needle is introduced through its guide channel into the subarachnoid space.

At present there are different technical combinations for combined spinal – epidural anaesthesia (CSEA). These are:

i. Use of separate intervertebral space for each epidural and spinal needles. Here catheter is negotiated through the epidural needle first and test dose is given. Then through another intervertebral space, dura is punctured by spinal needle and in subarachnoid space LA drug is deposited. The patient is then turned supine and according to the necessity of the height of block drug is injected through the epidural catheter. The same epidural catheter can be used for postoperative analgesia too.
ii. Use of the same intervertebral space for epidural and spinal needle. Here epidural needle is placed first. Then through the epidural needle a spinal needle is introduced (needle through needle) and dura is punctured. After the spinal drug is given through the spinal needle it is withdrawn and the catheter is introduced through the epidural needle in epidural space. Then the epidural needle is withdrawn and patient is turned supine (Fig. 24.39).

The disadvantages of this second technique are:

a. It does not allow the placement and testing of epidural catheter prior to the spinal injection. So, anxiety may arise about the movement of the heavy spinal LA solution which is already injected and may spread towards the cephalad or caudal

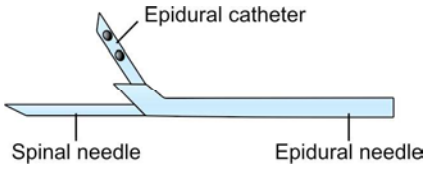


Fig. 24.39: The combined spinal epidural needle which allows the placement of 20 G epidural catheter through the modified Tuohy needle and placement of a 27 G spinal needle via an addition lumen

direction, especially if there is delay in positioning of the patient due to difficulties arising from the later insertion of catheter. This problem can be readily avoided by performing the CSEA in the Oxford position which had been introduced since 1984. Other ways of avoiding this problem are to perform the epidural first, using a separate intervertebral space or needle beside needle method. Where spinal injection is given after catheter is introduced.

b. There is controversy about the maximum possible protusion of the spinal needle beyond the tip of the epidural needle when the hubs are opposed. If spinal needle is too short it is less likely to puncture the dura, if too long it may transfix the dura and injure the cord.

c. Grazing of the tip of spinal needle against the bend of Tuohy needle.

d. Catheter may pass through the hole in dura, made by the spinal needle, in the subarachnoid space, though the possibility is very remote.

iii. To remove the above disadvantages, 'needle beside needle' technique is introduced. This equipment consists essentially of an epidural needle with a spinal needle guide channel, incorporated in its wall. After the epidural needle has been placed and catheter is inserted (also tested by test dose) spinal needle is inserted through its side channel.

Uses of CSEA

The advantages of CSEA include: Rapid onset, profound neuroaxial block, the ability to titrate the block with reduction of BP, prolongs blockade according to the necessary, postoperative analgesia and lower the total drug dose. The possible disadvantages of CSEA include: increased failure rate of SAB (approximately 5%), intrathecal migration of epidural drug and/or catheter and decreased ability and reliability of epidural test dosing. The CSEA has been most widely accepted in obstetric population. So, the concept of the 'walking epidural' has become popular among the patients, when intrathecal opioid allows the rapid onset of analgesia without motor blockade and extrathecal low concentration of bupivacaine (0.125 to 0.25%) allows prolonged analgesia. Lipid soluble opioids such as fentanyl or sufentanil are most commonly used for this purpose. Use of CSEA may reduce the incidence of instrumental vaginal delivery, lower anxiety and decreased the incidence of PDPH rate. It is demostrated that compared with lignocaine – fentanyl epidural block for caesarean section, CSEA with hyperbaric bupivacaine in subarachnoid space and fentanyl in epidural space provides more rapid onset, better motor blockade, decreased anxiety levels, decreased shivering and greater patient satisfaction.

The potential advantages of CSEA are now well known. The main uses of it are for orthopaedic and obstetric purposes. The great flexibility of CSEA has also provided its use in many other different situations.

Obstetrics

Today obstetrics is the most common indication for CSEA both as a method of pain relief during labour and for operative obstetrics. The introduction of CSEA as a pain relief during labour had lagged behind its use for caesareans section. The intrathecal use of local anaesthetics for relief of labour pain went back as early as 1900 and intrathecal use of morphine for relief of labour pain went back as late as 1980. However, a single short intrathecal local anaesthetics are only effective for limited period and a single short intrathecal morphine is only effective during first stage of labour and has a high incidence of side effects. However, continuous spinal anaesthesia (CSA) has always been associated with an unacceptably high incidence of severe PDPH. Consequently, the ability of CSEA to provide quick and reliable control of labour pain with the injection of local anaesthetic or more lipid soluble opioids than morphine or their combination in subarachnoid space and then continue the pain relief by epidural catheter provides distinct advantages of CSEA over a single shot spinal anaesthesia or continuous lumbar epidural analgesia and anaesthesia. There are two situations in which CSEA is particularly advantageous. The first of these is the delayed call for analgesia where pain relief by epidural block is slower on onset and requires high motor blocking concentrations of local anaesthetic. Secondly, CSEA has proved to be one of the most effective ways of providing analgesia with minimal motor block which is called 'walking epidural'.

The indication of CSEA for operative obstetrics essentially means caesarean section. Use of CSEA for caesarean section has two distinct advantages. The first is to use an adequate dose of spinal drug to achieve an adequate height and depth of anaesthesia for the operation and then to use the epidural catheter to modify or prolong the block, if the spinal is inadequate and/or to provide postoperative analgesia. The second is called as the 'sequential technique' in which in an attempt to reduce the hypotension a minimum amount of spinal dose which is intentionally made to be inadquate for surgery is used. The block is then deliberately extended cephalad with the epidural dose through catheter. In this two stage technique (sequential technique), the epidural catheter is not just act as a reserve for rescue anaesthesia or postoperative analgesia, but it served as a conduit for routine local anaesthetic to gradually raise the level of an intentional low subarachnoid block.

The epidural block has achieved wider acceptance as an alternative to SAB in obstetrial patients who are chronically hypovolaemic such as in pre-eclampsia. This is because incrementally giving the drugs through the epidural catheter increases the epidural sensory and motor

blockade in stages and thus minimizes the risk of hypotension. However, one large prospective study which compared the epidural and CSEA for severly pre-eclamptic patient undergoing LUCS had concluded that the changes in blood pressure are similar after epidural block or CSEA. Similarly, another study concluded that SAB produced reductions in blood pressure similar to epidural block in severly pre-eclamptic patients requiring LUCS. But, spinal anaesthesia is widely used for obstetrical surgery for technical simplicity, high success rate, minimal maternal and foetal drug exposure, minimal risk of maternal aspiration and an awake cooperative postoperative patient. However, recently many anaesthesiologist can place an epidural needle and catheter faster than they locate CSF with a small gauge spinal needle. So, subsequently administration of an epidural anaesthesia need not significantly expand operative room time.

Orthopaedics

Orthopaedic cases are the second most popular indication for the use of CSEA after obstetric cases. When CSEA is compared with individual epidural or spinal block for major orthopaedic surgeries, then it is found that CSEA has a quicker onset, better quality control and lower failure rate than the individual spinal or epidural anaesthesia alone. CSEA is also very useful for out-patient orthopaedic surgeries. It allows a minimal amount of spinal local anaesthetic agent to be used and thus hastens recovery, but with the ability of the epidural catheter to prolong the block if necessary.

Now, there are increasing number of indications for the use of CSEA other than obstetric and orthopaedic cases.

ADJUVENTS TO REGIONAL ANAESTHESIA

There was a time when our concept about pain was guided only by the simple 'door bell' theory. This theory expresses that press the switch, the bell rings and cut the wire, the ringing stops. But later, we have come to understand that such an old perception is a wrong guide to pain treatment and invariably leads to unsatisfactory results or frank failure of pain management. After the door bell theory, the 'gate control theory' of Melzack and Wall, and the concept of 'central sensitisation' has revolutionised the current management of pain. The preemptive analgesia, although proven and disproven by voluminus data, have stood the time, because clinicians have repeatedly shown satisfactory results of the preemptive analgesia from the points of view of patients and caregivers.

Based on the current datas, it is proved that the acute painful stimuli creates many changes, not only in the periphery at the site of origin, but also in the neurochemical and molecular milieu of the dorsal root ganglion and the dorsal horn cells of the spinal cord. Additionally, an increased neuronal metabolic activity in the other parts of central neurones system have been noted during acute pain, suggesting multiple dimension of pain. In 1993, Dikenson summarised the role of endogenous neurotransmitter systems in modulating and processing the pain coming from peripheral nervous system to the central nervous system and includes more than twenty-five such neurotransmitter systems in his summary. Then, if we multiply this formidable, but incomplete list of neurotransmitter by potential sites of action within the spinal cord, then a visionary can conjure up a wealth of potential ways to enhance the spinal analgesia. So inspired by the many rapidly changing knowledge of the peripheral, spinal and supraspinal responses to pain, investigators have reacted similarly by searching for the correct agonists or antagonists, and stimulants and inhibitors of pain. Thus, the drugs and pain control modalities are mixed and matched to achieve the optimal relief of pain with the least complications.

Acting directly on the proverbial door bell wire theory, regional anaesthesia is a mainstay in the armamentarium of an anaesthesiologist for the management of pain. In the last few years, several pain reliving drugs have been studied and combined with other drugs, with the objective of producing optimum analgesia and the least possible side effects. Combination of analgesic therapy in search of synergistic effect has been a common practice. Therefore, different neurotransmitter system were targeted with a combination of drugs to achieve the optimum therapeutic outcome with lower doses of drugs, thereby resulting in reduced side effects.

Hence, as adjuvents many things can be added with local anaesthetic agents in regional anaesthesia. These are: Narcotics, benzodiazepines, alpha-2-adrenergic agonists (i.e. clonidine), cholinesterase inhibitors (neostigmine) and phencyclidine (ketamine).

The aim of using adjuvents with or without local anaesthetic in spinal and epidural spaces are to:

i. Improve the analgesic intensity,
ii. Increase the duration of action,
iii. Achieve the faster onset of action,
iv. Achieve the acceptable analgesia with lower doses of drug and thus to reduce the risks and side effects.

Intraspinal or Epidural Opioids or Narcotics

Following the initial reports, in 1979, of clinical efficacy of intrathecal and epidural opioids, they have subsequently been used to control the pain following a wide variety of surgical procedures as sole analgesic agents or in combination with low dose of local anaesthetic agent. Bypassing the blood and blood-brain barrier the small doses of opioids, administered either in the subarachnoid or epidural spaces acts directly on the spinal cord to provide profound and prolonged segmental analgesia. This undoubtedly represents a major breakthrough in pain management.

Numerous studies have shown that spinal opioids can provide profound postoperative analgesia with less central and systemic adverse effects than the opioids administered systemically. Then, a large number of nonopioids analgesics have also been administered in epidural or subarachnoid space to achieve the pain relief without the risk of respiratory depression. This technique has been employed successfully to treat intraoperative, postoperative, traumatic, obstetric, chronic and acute cancer pain. Among these, management of postoperative and obstetric pain is the commonest indication for spinal opioid analgesia (Table 24.10).

The unique feature of spinal or epidural opioid analgesia is the lack of other sensory (except pain), sympathetic and motor block that allows the patients to ambulate without the risk of orthostatic hypotension or motor incoordination (walking epidural) which is usually associated with local anaesthetic agents, administered spinally or epidurally or opioids administered parenterally. These advantages of spinal or epidural opioids are particularly beneficial in high risk patients undergoing major surgery such as patients with severly compromised pulmonary or cardiovascular function, grossly obese patients and very elderly patients, etc.

For intrathecal or epidural administration, the analgesic doses of morphine are only 2 to 5% of the parenteral dose. Thus, patients can be expected to be less drowsy, more cooperative and more ambulatory. Intrathecal opioids are very easy for administration, either at the time of injection of local anaesthetic drug during spinal anaesthesia or as a separate technique when general anaesthesia is administered. With catheter the epidural route for opioids with local anaesthetic has been used much more extensively for intraoperative surgical analgesia and anaesthesia, and for postoperative pain control with or without local anaesthetic agents. The reasons for popularity of epidural opioids includes: Epidural opioids provide excellent analgesia alone or in combination with local anaesthetic agent with or without GA, willingness to leave an epidural catheter in place for extended periods to maintain analgesia and freedom from the risk of PDPH (only in epidural route).

The synergystic effect of opioid and local anaesthetic agent are best seen at the low doses of both. At higher doses the clinical synergistic effect becomes blurred and toxic effects superven. When the effects of IM or IV narcotics and epidural or spinal narcotics are compared in respect to analgesia, ambulation, GI motility, early and late pulmonary function, duration of hospitalisation and occurrence of deep vein thrombosis in the postoperative period, it is found that the average dose of IV or IM narcotics is seven times greater than that required by the epidural or spinal route. Patients, receiving epidural or spinal narcotics report superior analgesia, ambulate sooner, have fewer pulmonary complications, have earlier return of bowl function and are discharged from the hospital earlier than the patients receiving IM or IV narcotics. Mortality, overall complication, infection, time of extubation and hospital costs are all significantly lower when the narcotics are given intrathecally or epidurally than the parenteral group. Although, intraspinal or epidural opioid is not as effective as regional analgesia provided by local anaesthetic agents for controlling pain during vaginal delivery, but intraspinal or epidural only opioids for control of pain following caesarean section are widely used. These may be offered when spinal or epidural anaesthesia is chosen for surgery.

The rational for the combination of local anaesthetic agent with opioids for the relief of labour pain is that these two types of drugs eliminate pain by acting at two different distinct sites: The local anaesthetic act at the nerve roots and the opioids act at the receptor site of spinal cord. Spinal opioids alone provide good relief of pain at rest, but may not be adequet during physiotherapy and mobilisation. Although combination of local anaesthetic and opioids are used for postoperative and labour pain, but the results are more impressive in the relief of labour pain. Because it is well recognised that labour pain is different from postoperative pain as it is not relieved by epidural opioids alone. Patients receiving epidural injections of local anaesthetics combined with opioids report more rapid onset, more profound and long lasting relief of labour pain and less motor blockade than the patients receiving either drug alone. As a part of combined spinal epidural technique intrathecal opioids (e.g. fentanyl 25 µg, sufentanil 5-7 µg) combined with very small doses of local anaesthetic (e.g. bupivacaine 1 mg) provide almost instantaneous pain relief during labour and the

Table 24.10: Dose and duration of action of adjuvants to regional anaesthesia

	Single dose (mg)	*Rate of infusion (mg/h)*	*Onset of action (min)*	*Duration of action single dose (hour)*
A. *Epidural*				
Morphine	1-5	0.1-1	30	10-24
Meperidine	20-50	10-50	10	5-10
Diamorphine	5	-	5	12
Methadone	1-8	0.2-0.5	10	5-10
Fentanyl	0.025-0.1	0.025-0.1	5	2-6
Sufentanil	0.01-0.06	0.01-0.06	5	2-6
Alfentanil	0.5-1	0.2-0.5	10	1-2
B. *Intraspinal*				
Morphine	0.1-0.3	-	10	10-24
Meperidine	10-30	-	5	10-24
Fentanyl	0.01-0.025	-	5	3-5

epidural catheter is used if labour is prolonged. These low doses of narcotics and local anaesthetic agents through the both thecal and extrathecal route allow the parturients to ambulate which is called the 'walking epidurals'.

The only preservative free morphine preparations have been used epidurally or intrathecally in a wide range of concentrations with no apparent difference in efficacy. The addition of epinephrine to morphine is not recommended. The dose of intrathecal morphine is 0.1 to 0.2 mg. Epidural morphine can be used as intermittent injection or as continuous infusion. The effective doses of continuous infusion of epidural morphine may range from 0.1 to 1.5 mg/hour. Elderly patients may require remarkably small doses of epidural morphine. The relatonship between the age and the total dose of epidural morphine to achieve analgesia is: Effective 24-hour morphine dose (mg) = 18 − Age (0.15).

A more lipophilic drug such as fentanyl is also useful when rapid onset of epidural or intrathecal analgesia is important. The dose of intrathecal fentanyl is 20 to 25 µg. Intermittent boluses of 50 to 75 µg fentanyl through epidural route can also be used to achieve analgesia promptly in the immediate postoperative period, if the initial epidural dose of morphine is not adequate. Used as the sole opioid, 25 to 100 µg bolus of fentanyl in epidural space can be followed by continuous infusion of 25 to 100 µg/hr with an pump.

The adverse effects of central neuroaxial narcotics are: respiratory depression, pruritus (particularly face and upper trunk), urinary retention, nausea, vomiting and sedation (uncommon). The incidence of respiratory depression is about 0.3% at low doses of opioid which is usually used. At higher doses the incidence of respiratory depression may be higher. It results from the migration of these narcotic agent to the brainstem. So, it is more frequent with the more hydrophilic opioids than the more lipophilic opioids. This is because the more hydrophilic opioids are less absorbed by the nervous tissue which is rich in fat and remains in more water soluble form in CSF which help it to flow more to cephalad direction.

Therefore, high level of vigilance is mandatory during the use of intrathecal or epidural opioids. Intensive care facilities should be used for high-risk patients e.g. advanced age, serious underlying diseases, extensive surgery, etc. Early respiratory depression occurs within the first 2 hours following epidural narcotic injection. It is due to the result of vascular uptake from epidural and subarachnoid space and redistribution of opioid (i.e. the same mechanism that follows IV or IM injection). Delayed respiratory depression, occurring within 6 to 12 hours following spinal or epidural injection, is likely the consequence of rostral spread of opioid in CSF. Pruritus is common and sometimes becomes bothersome in few patients receiving central neuroaxial opioids. This incidence is particularly high in obstetric patients. The itching may be generalised or localised with the face being a common site. Although, pruritus caused by intrathecal or epidural opioid is probably not due to the release of histamine, still antihistamines often provide symptomatic relief.

Nausea and vomiting caused by intrathecal or epidural opioid is believed to be due to rostral spread of opioid through the CSF to the vomiting and CTZ centre, located superficially in the floor of 4th ventricle. This can be frequently treated by antiemetics.

Sedation, produced by epidural or intraspinal opioid rarely becomes a significant problem. It is due to the result of spread of the drug through CSF to the receptors in the thalamus, limbic system or cortex.

Mechanism of action of epidural or spinal opioids

The perception of pain and reaction to it are both altered by the opioids, so that pain is no longer taken as unpleasant or distressing sensation and patient tolerates it better. The analgesic action of systemic opioids have both the spinal and supraspinal components. But the central neuroaxial opioids have only spinal components. The intrathecal or extrathecal injection of opioids has been shown to cause segmental analgesia without affecting other modalities. This is because it acts only on the opioid receptors in the substantia gelatinosa (Lamina I and II) of dorsal horn and inhibit the release of excitatory neuro transmitters from the primary afferents carrying pain impulses. The action of opioid also appears to be exerted through the inter neurons which are involved in the gating of pain impulses. Release of substance P from the primary pain afferents in the spinal cord and its postsynaptic action on the dorsal horn neurones is also inhibited by the opioids. Normally, the action of systemic opioid at supraspinal sites such as in medulla, midbrain, limbic system and cortical areas is to alter the processing and interpretation of pain impulses as well as to send the inhibitory impulses through descending pathways along the spinal cord. Several other aminergic and neuronal systems appear to be involved in the action of systemic opioids and simultaneous action at spinal and supraspinal sites greatly amplifies the analgesic action of it.

When given through epidural or spinal route the uptake of opioids by the spinal cord is proportional to their lipid solubility. Highly lipid soluble opioids are quickly absorbed by the cord, resulting in lesser cephalad spread of it. So, highly lypophilic drugs have faster onset of action and quicker elimination than hydrophilic agents. Reversely, hydrophilic opioids are taken up by the spinal cord to a lesser extend and, therefore, show greater cephalad spread than the lipophilic opioids. It also shows delayed onset of action and elimination. Opioids from the subarachnoid or epidural space is eliminated by the vascular uptake.

Intrathecal Midazolam

GABA (Gamma Amino Butyric Acid) is a simple amino acid molecule which is

found as an inhibitory neurotransmitter in about 40% of the synapses – in both central and peripheral nervous system. Tissue trauma causes release of variety of chemical substances into the vicinity of the injury, such as P-substances, bradykinin, leucotrienes, 5HT, prostaglandins, etc. These substances sensitise the peripheral nociceptor, so that transduction threshold of sensitivity is decreased. Therefore, the peripheral C fibres tend to fire spontaneously and even fire in response to non-noxious stimulation, such as touching the skin. This causes a condition of primary hyperalgesia around the wound and subsequently the total spinal cord sensitisation. As a result, the pain perception gradually increases in strength even though the stimulus remains the same or absent. This phenomenon is called the 'wind up'.

Pain due to spinal cord sensitisation and wind up phenomenon is resistant to opioid. But, we know that GABA reduces this sensitisation and wind up phenomenon. GABA receptors are of two types: GABA-A and GABA-B. Among these the GABA-A receptors are present in presynaptic or primary afferent fibres and postsynaptic fibres. It is specially found in lamina II of dorsal horn of spinal cord. Whereas GABA-B receptors are found in the interneurons. So, inhibitions of selective GABA-A receptors would be ideal for analgesic action, causing powerful analgesia with no sedation. Benzodiazepines act on these GABA-A receptors and inhibit them.

Midazolam, a water soluble benzodiazepine when injected intrathecally, causes spinally meidated antinociceptive effects without any CNS effect, by combining with spinal cord GABA-A receptors. It also suppresses the visceral pain. Intrathecal midazolam probably also releases an endogenous opioid which acts on delta receptors of spinal cord and thus produces analgesia. Intrathecal midazolam causes segmentally cord level analgesia and has almost no neurotoxicity or major side effects up to the doses of 2 mg or continuous infusion of 6 mg/day. There is no significant nausea, vomiting, sedation, amnesia, itching, urinary retention, hypotension or bradycardia, etc. with intrathecal BZD.

Clonidine

Clonidine's analgesic property is known for centuries and is used extensively by veterinarians without proper knowledge of its mechanism of action. Initially it was used in humans for control of BP. Then, it was tested through epidural route on animals for analgesia with much promising results and no neurotoxicity. After that ice was broken when Tamson and Gordh first used clonidine epidurally on two chronic pain patients in 1984 and the result was very promising. The α-2 receptors are present on both pre and postsynaptically. Clonidine is α-2 adrenergic agonist and stimulation of presynaptic α-2 adrenergic receptors cause the inhibition of release of norepinephrine from the sympathetic terminals at periphery and noradrenergic neurones in CNS. These α-2 receptors are located on the superficial laminae of spinal cord and brainstem nuclei responsible for pain. So, analgesia may be produced at spinal and brainstem level. Clonidine like local anaesthetic agents also causes the blockade of conduction of nerve fibres. At spinal cord level, it also decreases the noxious afferent inputs through interaction with the α-2 adrenoreceptors. It also reduces the release of substance P and excitatory amino acid in spinal cord from peripheral nerve stimulation by noxious stimuli, suggesting presynaptic inhibitory mechanism. It also hyperpolarises the neurones in the dorsal horn and render them less responsible to afferent stimuli. In addition to brainstem and peripheral site of action, neuroaxial administration of clonidine inhibits the sympathetic preganglionic neurones in spinal cord resulting in hypotension. The sedative property of clonidine also reduces the requirement of hypnotics and is often a desirable feature.

Analgesic, hypnotic and haemodynamic effects of clonidine after central neuroaxial or systemic administration begins within 30 minutes and reaches maximum within 1 to 2 hours, but these actions last for 6 to 8 hours.

Dose

For regional anaesthesia and analgesia through epidural route the dose of clonidine with 0.5% bupivacaine is 0.5 to 1 µg/kg. It does not produce respiratory depression and does not suppress the neurohumoral secretion during stress, but produce analgesia. Postoperatively, 3 to 10 µg/Kg extradural clonidine as the sole agent results in 4 to 6 hours analgesia, but at the expense of bradycardia, hypotension and sedation.

Use

Clonidine may be used through intrathecal or extrathecal route for analgesia with or without local anaesthetic agents. It may also be used with bupivacaine, lignocaine, ropivacaine for peripheral nerve blocks, such as: molar extractions, intercostals block, brachial plexus block, etc. It gives early onset, prolonged duration of action and satisfactory analgesia and anaesthesia when used with local anaesthetic agent. In case of sympathetically maintained pain, prolonged relief of pain (9 to 10 times longer duration) is achieved by bupivacaine and clonidine combination than bupivacaine alone after stellate ganglion block.

Ketamine

Ketamine which is available in market is a racemic mixture of two enantiomer such as (R-) and (S-) form of it. Its α-elimination phase is few minutes, but the β-elimination phase is 2 to 3 hours. One of its metabolites, such as norketamine, is one- third to one-fifth as potent as the original drug and is responsible for the

prolonged analgesic effect of ketamine. It produces a dissociation state (catalepsy) in patient by electrophysiological inhibition of the thalamocortical pathways, and stimulation of the limbic system. It has good broncho-dilating and minimal respiratory depression effect. Protective airway reflexes are preserved by ketamine, but in noncoordinated way. It also increases oral secretion.

The analgesic and anesthetic properties of ketamine are mainly attributed by interaction of it with N-methyl D-aspartate (NMDA) receptors and other non-NMDA glutamate receptors. By blocking the action of other non-NMDA receptors, such as opioid receptors, cholinergic receptors, muscarinic and nicotinic receptors, adrenergic receptors and GABA receptors, etc. ketamine plays minimal role in analgesia. NMDA is the most abundant excitatory neurotransmitter causing pain sensation in CNS where ketamine acts. 'Wind up' phenomenon in dorsal horn is responsible for chronic pain and it acts through NMDA receptors where ketamine also acts.

The reduction of polysynaptic stimulation in the CNS by ketamine which is also responsible for analgesic effect of it acts through NMDA receptor at postsynaptic sites. Ketamine binds to the phencyclidine part of the NMDA receptor channel and thus inhibits the activation of glutamate and blocks NMDA receptor. NO (Nitric Oxide) plays important role in pain perception. NMDA and non-NMDA receptor activation stimulate NO synthesis. So, inhibition of NO synthesis by the blocking of NMDA and non-NMDA receptors by ketamine may be involved in its analgesic effect.

For the ubiquitous character of ketamine, it is suggested that the combination of systemic ketamine with regional or peripheral nerve block or combining ketamine with local anaesthetic agent for regional or peripheral nerve block may cause more optimal pain relief.

Neostigmine

The laboratory studies have suggested that the spinal cholinergic activation produces analgesia, because cholinergic receptors have been found in spinal cord and have been shown to have a potent antinociceptive action. So, considerable evidence exists to implicate the role of cholinergic agonists (acetylcholine) and anticholinesterase agents (neostigmine) which increases the level of ACh by inhibiting the break down of it in the spinal cord in inhibition of nociceptive transmission by stimulating these cholinergic receptors and cause analgesia. They do not act on opioid receptor, NMDA receptor or non-NMDA receptor. It does not cause axonal conduction blockade like local anaesthetic agent. It is also found that intrathecal analgesia by neostigmine is mediated through M1 and M2 muscrinic cholinergic receptor which can be blocked by atropine. Autoradiographic studies reveal the existence of muscarinic receptors such as both M1 and M2 in lamina II and III of the spinal cord. Neostigmine, as an anticholinesterase inhibitor, cause an accumulation of ACh at the muscarinic receptors in the dorsal horn when it entered into the CSF and thus cause analgesia.

Neostigmine is used both through intrathecal and epidural route with local anaesthetic agents where duration of analgesia becomes prolonged. The intrathecal dose of neostigmine is 50 µg. The 50 µg neostigmine in epidural route is less effective in prolonging the duration of analgesia. Neostigmine in a dose of 100 µg as an additive to epidural lignocaine is proved to be best in prolonging the duration of analgesia through this epidural route. The increased dose, 150 µg (epidurally) of neostigmine prolongs the duration of postoperative analgesia but at the cost of increased incidence of side effects. The common side effects of neuroaxial neostigmine are nausea, vomiting, hypotension, sweating, etc.

Epinephrine

When epinephrine is administered centrally it may potentiate the action of local anaesthetics. The mechanisms of action are:

i. Like clonidine, low doses of extradural epinephrine have direct α_2-activity on the dorsal horn cells.
ii. The vasoconstrictor properties of epinephrine reduce the vascular uptake of local anaesthetic agent and thus it helps to prolong their action.

CENTRAL NEUROAXIAL BLOCKADE (CNB) VERSUS GENERAL ANAESTHESIA (GA)

The CNB is less forgiving than GA for anything less than perfection. The choice of any anaesthetic technique such as CNB or GA is a complex medical decision which depends on many factors, such as, patient's characteristics, type of surgery, type of anaesthetic technique and its risks, anaesthetist's choice, surgeon's choice, etc. The assessment of anaesthetic risk both in CNB and GA include the consideration of anaesthetic technical factors, toxicities of anaesthetic agent, intraoperative or postoperative events, management of postoperative pain, etc. However, with proper planning and sufficient experience, it is possible to do CNB and GA with same risk and CNB as rapidly as GA. But there is one distinct advantage of CNB over GA is that the patient can be immdiately transferred to recovery room on completion of surgery after CNB. However, general anaesthesia cause prolonged emergence which can delay the next postoperative procedure.

Cardiorespiratory Effect

Many anaesthiologists think that CNB is preferable to GA for patients with pulmonary diseases. But, many published studies, comparing the pulmonary complications observed after CNB and GA have not extablished any consistent benefit of

CNB over GA. Some studies suggested beneficial effects of CNB over GA in patients with lung disease with respect to decreased morbidity from respiratory complication. However, other studies have not established superiority of either anaesthetic technique in the elderly and in patients with chronic lung disease. There is also definite evidence that excellent postoperative analgesia with continuous extradural analgesia leads to a reduction in respiratory complications. It is also possible that high quality analgesia from other than epidural (e.g. patient controlled analgesia) may also lead to a reduction in pulmonary complication. So, the provision of adequate analgesia may be more important than the method of analgesia employed.

CNB acts directly on the nerve pathway and avoids the surgical stress with its haemodynamic demands. Thus it directly avoids the myocardial depressant effect of inhalational agents of GA. Whereas GA acts indirectly through CNS to avoid the surgical stress with its haemodynamic demands. Hypotension following CNB is not always preventable and is not always without any adverse effects. So CNB is not always a safer alternative to careful GA for heart patient, particularly in inexperienced hands. CNB is particularly hazardous for patients who require well maintained preload (e.g. aortic stenosis). It is also very crucial in many cardiac patients (coronary disease) causing sudden fall in diastolic pressure with resultant fall in coronary perfusion. Conversely, reduction of afterload by CNB may be beneficial for patients with reguritant valves. But an epidural block with catheter and simultaneous intelligent use of IV fluids with vasoconstrictor can carefully titrate the fall of BP. So, always CNB may not be more hazardous in a patient then GA. Appropriate invasive monitoring of filling pressure, cardiac output and systemic vascular resistance sometimes may make CNB more safer than GA. Several studies have shown that CNB in comparison to GA is associated with less cardiac morbidity. This might be related to the reduction in thromboembolic manifestation, reduction in catecholamine levels in plasma and avoidance of cardiac depression. But, later studies concluded that CNB does not reduce the rate of cardiac complications than GA. Contrary still, many practitioner argue that individual subgroups of patients should benefit from CNB and so they continue to offer spinal or epidural anaesthesia, with or without catheter to their high-risk patients.

Metabolic and Endocrine Alterations

Surgical procedures performed under GA result in increased concentration of glucose, lactate, cortisol, aldosterone, renin, vasopresin, growth hormone, epinephrine, norepinephrine, etc. But these changes do not occur under CNB, because it completely abolishes the stress response to surgery by blocking the nerve pathway. It is observed that in CNB the markers for surgical stress, i.e. increase in protein degradation and decrease in protein synthesis were typically arrested as compared to GA. The mechanism by which CNB inhibits the metabolic and endocrine alterations during surgery is probably related to blockade of afferent and efferent pathways for nociceptive impulses. CNB also prevents central sensitisation and provides pre-emptive analgesia.

Blood Loss

In CNB decreased bleeding is observed during surgery, especially during the procedure on the lower abdomen and lower part of the body. But, there seems to be little reduction in bleeding associated with upper abdominal and thoracic surgery. Reduction of bleeding during surgery is probably due to hypotension caused by sympathetic block, reduction of venous pressure leading to reduced venous oozing, and relaxation of capillary sphincters causing reduction of arteriolar bleeding. This results in decreased requirement of transfusion and its related complications in CNB as compared to GA.

Nausea and Vomiting

Nausea and vomiting can occur with both the techniques. But, the incidence is more with GA than CNB. In CNB as laryngeal reflexes are intact (if the patient is not deeply sedated) there is less chance of aspiration if vomiting occurs. But in GA, if larynx is not properly guarded, there is every chance of aspiration if vomiting occurs. Another point is that during CNB if vomiting occurs then it is very much distressing, because abdominal and part of the thoracic muscles are paralysed.

Postoperative Pain Relief

CNB can easily be converted to postoperative analgesia. Hence, many of the prescribed benefits of CNB is actually due to this analgesia which can be extended into the postoperative period.

Thromboembolism

The CNB is associated with decrease in blood viscosity and less alterations in coagulations factors such as inhibition of coagulation and stimulation of fibronolysis which commonly occurs in GA. One can see inhibition of platelet aggregation from local anaesthetic drugs during CNB. In the postoperative period, CNB also limits the increase in factor VIII or von Willebrand factor. Thus, CNB increases the total limb blood flow, which is responsible for reduction in the incidence of thromboembolic events (mainly DVT and pulmonary embolism). This effect in CNB may be as great as 50% in reduction of thromboembolic incidence during hip surgery. In multiple studies, it is found that arterial inflow, venous emptying rate and venous capacitance are all higher in patients receiving CNB. Intraoperatively, the breathing pattern may also have a profound influence on the leg blood flow. Spontaneous breathing during CNB promotes the better venous return and this results in higher cardiac output and better blood flow in legs.

While intermittent positive pressure ventilation (IPPV) during GA impedes the venous return and this results in a low cardiac output and reduced blood flow in legs. Thus, CNB is associated with less incidence of thromboembolic phenomenon than GA.

Coagulation Profile

In GA, platelet aggregation and hypercoagulable state of blood is triggered by the neurohumoral changes which is due to stress responses during surgery. But, this is completely attenuated in CNB. On the otherhand, regional anaesthesia and analgesia also effectively attenuates the increase in plasminogen activity as compared to GA.

Hypothermia

Both GA and CNB impair temperature hameostasis. Hypothermia during CNB can nearly be as severe as that which is observed during GA. The thermoregulatory activity is reduced with advancing age during CNB, but no age related differences regarding thermoregulation were found during GA. On the otherhand, CNB decreases the vasoconstriction and shivering thresholds, possibly by producing a substantial increase in apparent leg temperature. This explains why CNB is associated with severe hypothermia.

Mortality

A number of large studies have been performed to evaluate the postoperative mortality rate following CNB or GA after major surgical procedures. The short-term mortality rate (up to one month postoperatively) is better after CNB as compared to GA. But, there is no difference in long-term survival rate (up to 1 year postoperatively) with both the techniques. Many of the deaths, occurring in GA group during the first postoperative month were related to the thromboembolic complications. However, large retrospective cohort study of elderly patients with hip fracture is unable to demonstrate that CNB is associated with better outcome than GA.

There is no general consensus that certain types of patient undergoing certain types of surgery benefit more from regional or general anaesthesia. The ultimate outcome of surgery depends on how a technique is performed rather than which technique is selected. The outcome also depends on the skill of the practitioner, patient's factor and the occurrence of side effects or complications. For many anaesthetists the benefits of regional anaesthesia appear to be self evident and worth attaining, while other practitioner virtually perform no regional technique throughout their whole life.

Discharge Criteria

The use of CNB for ambulatory surgery (or day case or out patient surgery) has gradually become more popular. The introduction of higher gauzes (more fine) pencil point spinal needles have reduced the incidence of PDPH to approximately 1% and have increased the discharge criteria. The ideal CNB for day case surgery would combine the rapid and adequate surgical anaesthesia with rapid achievement of discharge criteria, such as ambulation and urination.
