CSEA can also be used for day case surgery with early discharge criteria. Availability of the epidural catheter for a rescue anaesthesia in CSEA allows the use of minimal doses of spinal local anaesthetic agent with resultant rapid recovery and discharge. However, no current data is available to assess the relative cost benefit ratio versus decreased recovery time with CSEA. Continuous spinal anaesthesia (CSA) may also have applicability in an ambulatory setting, because it has the ability to use lower amount of local anaesthetic agent which can lead to faster recovery time, especially in the elderly who are less prone to PDPH. However, with the introduction of LMA and newer anaesthetic agents with faster and more pleasant recovery profiles such as propofol, remifentanil, sevoflurane, desflurane, etc. have reduced the stress of GA and shortened the length of stay in postanaesthetic care unit than that seen for CNB.

SUBARACHNOID BLOCK (SAB) OR SPINAL BLOCK VERSUS EPIDURAL BLOCK (EB)

Technical Aspect

From the technical point of view, SAB is easier to perform and has a definite objective endpoint, i.e. the flow of CSF through the spinal needle. Conversely, the EB is not easy to perform and there is no definite objective end point, i.e. location of epidural space is confusing. The end point of identification of epidural space is loss of resistance and the presence of negative pressure. The loss of resistance is proved by the sudden easy movement of piston within the barrel. And the presence of negative pressure in the epidural space is proved by the inward movements of a drop of fluid in the hub of the needle. This is called the hanging drop technique. But, neither of these methods of locating the epidural space gurantees the proper location of the needle tip in all the patients.

Another difference between the SAB and EB from the technical point of view is that SAB is administered through the lumbar site only. Whereas, EB can be administered through the multiple sites; like lumbar, thoracic, cervical or caudal.

Onset and Spread

The onset of anaesthesia is much more rapid in SAB than EB. The spread of level of anaesthesia is more predictable and controlled in SAB than EB. The level of anaesthesia in SAB can be controlled initially by using the baricity of anaesthetic solutions and then by adjusting the patient's position. However, neither of these factors is much helpful in controlling the level in epidural block (EB). The level of anaesthesia in EB is controlled only by the use of epidural

catheter and the volume of drug though the position of patient helps little.

Duration of Anaesthesia and Analgesia

The failure to produce anaesthesia and analgesia to a desired degree and level for limited duration are inherent deficiency of a single sort technique of SAB or EB. Whereas the epidural catheter technique provides prolonged anaesthesia and analgesia, removing the previous deficiencies. The catheter technique for CSA is also available. It requires 10 to 15 times less amount of local anaesthetic agent than is needed for epidural blockade and thus virtually eliminates the possibility of systemic toxic reactions of local anaesthetic agents. The other advantages of CSA over conventional SAB are the ability to prolong the anaesthesia for long surgical procedures or even for postoperative analgesia with fewer episodes of hypotension and less need for vasopressors. With the advent of 32 G catheter that can be threaded through 26 G needle, the incidence of PDPH has decreased. Though it is reduced, still there is potential for infection, haemorrhage and nerve trauma in CSA.

Depth of Surgical Anaesthesia

The SAB provides more profound depth of surgical analgesia and anaesthesia than EB. On the otherhand the requirement for supplemental parenteral analgesia or sedation is more for EB than compared to SAB. One of the advantages of SAB over EB is that its does not suffer from the patchiness of anaesthesia which is sometimes exhibited by EB.

Unilateral Block

The SAB can be manipulated to achieve predominantly a unilateral block by keeping the patient in lateral position for 5 to 10 minutes after administration of anaesthetic agent and by controlling the baricity of anaesthetic solutions. Unilaterality in SAB also can be maximised by using a side port spinal needle and small dose of local anaesthetic agent. This facility is not available in EB.

Haemodynamic Stability

Haemodynamic parameters are better preserved during EB, particularly when catheter is used than SAB. The degree of change in MAP, stroke volume, cardiac output and heart rate is quick and more following SAB than EB.

PDPH

The PDPH is a trouble some complication of SAB, whereas EB is completely devoid of this problem. However, the potential for accidental dural puncture by thick epidural needle ever present in EB and it results in severe headache, particularly in young patients. A higher incidence of PDPH is observed in parturients after SAB.

Systemic Toxicity

One of the main advantages of SAB over EB is that small amount of local anaesthetic agent produces the desired level and effective depth of anaesthesia. Thus, the potential for central nervous system toxicity and systemic cardiovascular toxicity is almost nonexistent in SAB. On the other hand, in EB as large amount of local anaesthetic solution is used, so there is chance of systemic toxicity. Also, accidental intravascular or intrathecal injection of large amount of local anaesthetic agent in EB can lead to severe systemic toxicity or total spinal block, respectively.

Blood Loss

SAB and EB both reduces the blood loss during surgery. But, EB reduces more blood loss than SAB and results in reduced number of tranfused blood units. With hypotensive epidural anaesthesia there is approximately 50% decrease in intraoperative blood loss as compared to SAB. Coagulation function is partly better preserved during epidural block than SAB. This is indicated by higher prothrombin time in SAB. This is mainly because blood loss, dilution of circulating coagulation factors, and fibrinogen activation are greater during SAB than EB.

Spinal Cord Injury

Both the SAB and EB are associated with spinal cord and nerve root injury from mechanical trauma. But in SAB, spinal cord and nerve root damage also may result from chemical injury by local anaesthetic solution which is not found in EB. Transient neurological symptoms (TNS) have been described after SAB with any local anaesthetic agent, but is found most commonly with lidocaine. However, the recent retrospective, prospective and closed claim studies report that the incidence of postoperative neurological injury in patients undergoing SAB is between 0.7 to 1%. It has been rarely seen after epidural block and general anaesthesia.

25 Paediatric Anaesthesia

INTRODUCTION

Strictly speaking, though all the patients who are below the age of 14 years fall in the paediatric group, but only the patients who are below the 5 years of age or with a weight of less than 20 Kg need specialised anaesthetic management. This is because the newborn and infant has a number of physiological features which differ from the adult. These differences are of much relevance to an anaesthetist and anaesthetic management to this later group of patient is known as the paediatric anaesthesia. The difference in anatomy and physiology between the paediatric and the adult group of patients have many important consequences on anaesthesia, mainly with babies of 27 weeks gestation (birth weight as low as 600 gm) with some pecularities which may persist longer than the defined period after birth. Some of the peculiarities result from the fact that the infant at birth has to possess all the machineries which are required to adapt the changes from one environment in the mothers womb to a totally different one outside of it. Another important peculiarity is that such a small creature requires very special protective mechanisms to meet the hostile world outside. Other peculiarities are merely the result of adult functions being as yet underdeveloped. Thus, the neonate should not be regarded merely as an incomplete small adult, but rather, as a totally different organism. So, the provisions of a safe paediatric anaesthesia depends on the clear understanding of the anatomical, physiological, pharm ocological and psychological differences between the paediatric and the adult group of patients.

A full term neonate is one whose gestational age at birth is 37 weeks or more, whereas a preterm neonate is one whose gestational age at birth is lesser than 37 weeks. But with the passing of days, the medical and technological advances have pushed the gestational age closer and closer to 20 weeks at which the preterm neonates can be made viable (Table 25.1).

THE NORMAL WEIGHT GAIN

During the first few days after birth, the newborn infant loses upto 10% of its original birth weight. This is because of the loss of extracellular fluid. However, then the most full-term infants regain this lost weight by the age of 10 days after birth. Subsequently, they gain weight at the rate of 25 to 30 gms/day for the first 3 months of life. Thereafter, they gain about 400 gm of weight by every month for the remaining part of their first year. An infant usually doubles its birth weight by the age of 6 months and triples at the end of 1 year. Subsequently, the birth weight becomes four times at the end of 2 years and 5 times at the end of 3 years of age. At 5 years the expected weight of child is calculated by multiplying the birth weight with 6 and at 10 years with 10, respectively.

Table 25.1: Classification of paediatric patients according to their ages

Premature	:	< 37 weeks
Neonate	:	First 4 weeks after birth
Infant	:	From 5th week after birth up to 1st year
Toddler	:	1 to 3 years
Preschool	:	3 to 6 years
School age	:	6 to 10 or 12 years
Prepubescent	:	10 to 12 years (Girl), 12 to 14 years (Boy)
Pubescent	:	12 to 14 years (Girl), 14 to 16 years (Boy)

Here, there is an another easy formula for calculating the weight of a baby :

Weight = [Age (in years) + 4] × 2 in Kg, for 1 to 6 years and,

Weight = [Age (in years)] × 3 in Kg , for 7 to 12 years

(There are also many other formulae described in different books).

The most important difference between the paediatric and the adult age group of patients is the size of the body, which varies with age. But the weight is the most important determinant factor for any therapies and drugs are always prescribed as the 'doses per Kg'. Although it is rational to express the body size and therapies in terms of weight, but many physiological processes are measured in relation to surface area. But, the surface area to weight ratio of an infant is approximately twice than that of an adult. So, the metabolic rate, water and electrolyte requirement and requirements of ventilation are proportionately greater in paediatric age group of patients than that of an adult when expressed on the basis of weight. But, gradually these differences decrease, as the neonate and infant passes through the childhood (Table 25.2).

Table 25.2: The normal important milestones

4 to 6	Weeks	:	Social smile.
3	Months	:	Head holding.
6	”	:	Sits and supports, transfers object from one hand to other.
8 to 10	”	:	Crawls.
9	”	:	Stands holding furniture.
12	”	:	Walks holding furniture, says one word.
13	”	:	Walks without much support, says 3 words with meaning, feeds itself.
15 to 18	”	:	Joins 2 to 3 words into a sentence.

CARDIOVASCULAR SYSTEM

Foetal Circulation and its Changes After Birth

In foetal life blood is oxygenated in the placenta and is then returned back to the foetal heart by umbilical vein. The umbilical vein enters the foetus at the umbilicus through the umbilical cord, and then-courses through the the liver to join with the left portal vein.There is another vein called the ductus venosus, which connects the left portal vein with the inferior vena cava (IVC), and provides a low resistance pathway (bypass) between the left portal vein and the IVC. Thus, the oxygenated blood coming from the placenta through the umbilical vein has two pathways, before entering the right atrium. Most of the oxygenated blood coming from the placenta shunts through the ductus venosus to the IVC, and only a small portion of the oxygenated blood passes through the portal vein, liver parenchyma, hepatic vein and ultimately reach to the IVC. Thus, the blood of IVC comprises of blood coming from the liver parenchyma through hepatic vein, blood coming directly from the placenta through ductus venosus and blood coming directly from the lower extremities. On reaching the right atrium, the oxygenated blood of IVC is divided into two portions or streams by the inferior margins of the septum secondum, which is called the crista dividens. About 1/3rd of this total oxygenated blood of IVC enters the left atrium through the foramen ovale, and the remaining 2/3rd of the blood of the IVC mixes with the deoxygenated venous blood coming from the superior vena cava (SVC), and enters the right ventricle (Fig. 25.1).

The oxygenated blood reaching the left atrium from right atrium through foramen ovale again mixes with the small amount of blood coming from the lungs through pulmonary vein without any oxygenation, and passes to the left ventricle. The left ventricle then pumps out this oxygenated blood into the ascending aorta for distribution to the coronary arteries, head, neck and upper extremities (Fig. 25.2).

The deoxygenated blood coming to right atrium from the head, neck and superior extremities through SVC, after mixing with 2/3rd of the IVC blood, passes almost directly into the right ventricle. Then the right ventricle pumps out this deoxygenated blood into the pulmonary trunk. A small amount of this blood (10%) of pulmonary trunk enters the pulmonary circulation, and returns to the left atrium through pulmonary veins without taking any oxygen from the lungs.The rest of the blood (90%) of the pulmonary trunk passes through the ductus arteriosus into the descending aorta, and mixes with the small amount of blood reaching the descending aorta from the aortic arch. The largest branch of the descending aorta is the umbilical artery. So, 80% of the blood of descending aorta flows through the umbilical artery to the placenta through umbilical cord for oxygenation. This is favoured by the low resistance of the circulation of placenta and the remaining portion of the blood of descending aorta flows to the lower extremities.

Therefore, in foetal circulation there are two right to left shunts. One is at the level of ductus arteriosus and the other is at the level of foramen ovale. This is due to the higher pulmonary vascular resistance (PVR) than the systemic vascular resistance (SVR). It is also because the pressure developed in the right atrium and the right ventricle exceeds than that of the

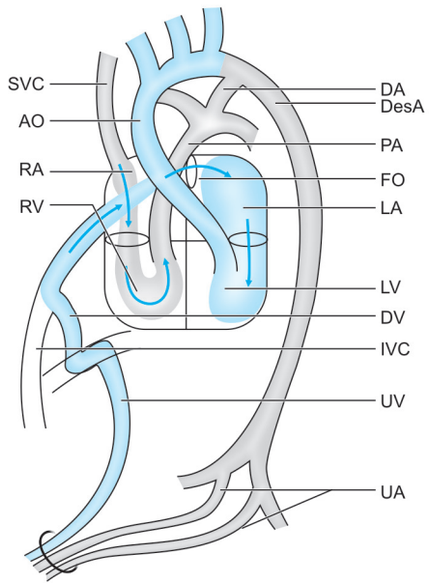

Fig. 25.1: Foetal circulation. UV-Umbilical vein, UA-Umbilical artery, DV-Ductus venosus, DA-Ductus arteriosus, IVC-Inferior vena cava, SVC-Superior vena cava, RA-Right atrium, RV-Right ventricle, LA-Left atrium, LV-Left ventricle, FO-Foramen ovale, AO-Aorta, DesA-Descending aorta, PA-Pulmonary artery

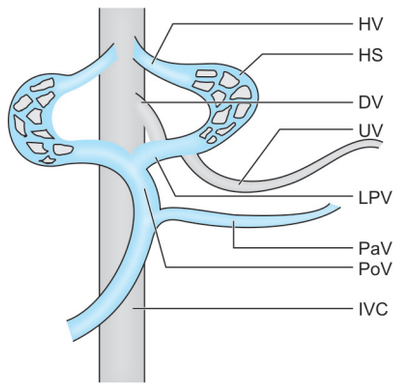

Fig. 25.2: IVC-Inferior vena cava, PaV-Pancreatic vein, PoV-Portal vein, LPV- Left portal vein, UV-Umbilical vein, DV-Ductus venosus, HS-Hepatic sinusoid, HV-Hepatic vein

left which is due to the handling of large amount of blood by the right side of the heart than the left.

As a result of this pressure difference between the two ventricles, the wall-thickness of them may be the same, or the right ventricle may be thicker than that on the left. This is in contrast to the adult situation, where the wall-thickness of right ventricle is about one-quarter of the left. As a consequence, the ECG pattern of the neonate and infant is comparable to that of an adult who has right ventricular hypertrophy.

The summary of major differences between the foetal (pre-delivery) and the neonatal (post-delivery) circulation. In this difference the foetal circulation is characterised by:

i. The presence of placental circulation which acts like adult pulmonary circulation and provides the gas exchange for foetus.
ii. The absence of gas exchange in a collapsed lung.
iii. There is very little flow of blood to the lungs, and consequently very little pulmonary venous return to the left atrium. So, the left side of the heart is a low pressure system.
iv. The presence of ductus venosus, which joins the portal vein with the IVC provides a low resistance bypass for the umbilical oxygenated blood to reach the IVC.
v. The presence of crista dividens and widely open foramen ovale provides a route for the oxygenated blood to reach the left atrium and the left venticle from the umbilical vein and the IVC for distribution to coronary arteries and the brain.
vi. The presence of a widely open ductus arteriosus which allows the right ventricular blood to reach the descending aorta and the umbilical arteries for further oxygenation, bypassing the non-functioning lungs.

After clamping of the umbilical cord and after the first breath, the high pulmonary vascular resistance which was present during foetal life falls, and at the same time the SVR rises. This causes the pressure at the right side of the heart to become less than that of the left side of the heart. This change stops the flow of blood through the foramen ovale and the ductus arteriosus, which was still maintained upto the period of birth due to the higher pressure at the right side of the heart than the left. The rise in SVR after birth is due to the elimination of the low resistance placental vascular bed from the systemic circulation, because of the clamping of the umbilical cord.

The factors responsible for the fall in PVR after birth are:

i. The unfolding of the pulmonary vasculature due to the expansions of lungs.
ii. The development of negative interstitial pressure arising from the surface tension forces.
iii. An increase in arterial oxygen tension associated with decreased CO_2 tension, following the onset of breathing which causes diminished hypoxic pulmonary vasoconstriction and reduced pulmonary vascular resistance.

The maximum decrease in PVR occurs rapidly during the first day of life and then continues to decrease gradually during the next several years, as the architecture of the pulmonary vessels change slowly.

After the first breath, lungs become inflated and PVR falls. This causes sudden increased pulmonary blood flow and subsequently increased left atrial pressure. This change in right and left atrial pressure causes the stoppage of blood flow through the foramen ovale and ductus arteriosus, and subsequently closes these right to left shunt in most cases.

As the functional or the physiological closure of ductus arteriosus results from the fall in PVR and the increase in SVR, but it is also caused by the contraction of the smooth muscles of ductus arteriosus. This is due to the increase in P_aO_2 after the first breath. The sensitivity of the contraction of the smooth muscle cells of ductus arteriosus to the P_aO_2 depends on the gestational age of neonate, and is parallel. Thismeans as the gestational age of foetus and neonate will increase, the sensitivity of contraction of the smooth muscle cells of ductus arteriosus to P_aO_2 will also increase. This closure of ductus arteriosus is completed within 10 to 15 hours after birth. But, during this period, the closure of the ductus arteriosus is reversible as it is physiological. Its anatomical closure is delayed by another 2 to 3 weeks. This closure of the ductus arteriosus is also influenced by prostaglandin E, which relaxes the ductal smooth muscles and contraction occurs with inhibition of prostaglandin synthesis. The prevention of ductal closure by the administration of prostaglandin E is used therapeutically in certain congenital heart lesions, where there is reduced pulmonary blood flow such as pulmonary atresia. In these circumstances, deliberately delaying of the ductal closure serves to maintain an increased pulmonary blood flow, until a surgical aorto-pulmonary anastomosis is established. Contrary, prostaglandin inhibitors are sometimes used to induce early ductal closure, where continued ductal shunting is undesirable.

The neonatal circulation is usually labile and sometimes may revert from the neonatal to the foetal type of circulation, with blood flowing from the right to the left side of the heart, through the functionally closed (not anatomically) ductus arteriosus or foramen ovale. So, this circulatory state of neonate is called the transitional circulation and the reverse from post delivery to predelivery state is initiated by hypoxia, hypercarbia, acidosis, anaesthesia induced changes in pulmonary or peripheral vascular tone, etc.This reversal state is caused by either an increase in PVR, or decrease in SVR in response to hypoxia, hypercarbia and acidosises. It is especially important in patients with hyaline membrane disease or congenital diaphragmatic hernia

which are responsible for the above mentioned conditions. Thus, a vicious cycle is set up between hypoxia, hypercarbia, acidosis and right to left shunt, leading to cyanosis, more hypoxia, gradual fall of cardiac output and subsequently death. This explains why the hypoxaemic events in infants during anaesthesia is dangerous and often prolonged, despite when the treatment appears to be adequate.

The risk factors that prolong this transitional circulatory state include prematurity, infection, acidosis, hypothermia, hypoxia, congenital heart diseases, etc. So, care must be taken to keep the infant warm to maintain the normal arterial O_2 and CO_2 tension and to avoid the anaesthetic-induced myocardial depression. The myocardial structure of heart, particularly the volume of the ventricular cellular mass which is responsible for myocardial contractility and cardiac output is significantly underdeveloped in neonates and infant than adults. So, the ventricles are less compliant in neonates and infants. This developmental ventricular myocardial immaturity of the paediatric group of patients account for the early tendency to cause biventricular failure. This also accounts for the high sensitivity of neonatal myocardium to volume overload, poor tolerance to an increase in afterload and heart-rate dependent cardiac output.

SUMMARY OF FOETAL CIRCULATION AND CHANGES AT BIRTH

The circulation in the foetus is essentially the same as in an adult, except for certain special differences. Here the foetal circulation is summarised with some differences from an adult.

i. The source of oxygenated blood in the foetus is not the lungs, but instead the placenta.
ii. Oxygenated blood from placenta, comes to the foetus through the umbilical vein, which joins the left branch of the portal vein, then the ductus venosus joins the left branch of the portal vein with the IVC. So a large portion of the oxygenated blood from placenta, passes through the left branch of the portal vein, ductus venosus and IVC and a small portion of the oxygenated blood passes through the substance of liver. Then it passes to the inferior vena cava through hepatic vein.
iii. The oxygen-rich blood reaches the right atrium through the inferior vena cava. It also carries the deoxygenated blood from the gut and lower limbs. Then the blood of the IVC is directed by the valve of IVC towards the foramen ovale. After that the oxygen-rich blood reaching at the foramen ovale is divided into two portions by the lower edge of the septum secundum (crista dividens).
    1/3rd of the oxygenated blood of the IVC passes through the foramen ovale into the left atrium.
    2/3rd of the oxygenated blood of the IVC gets mixed up with the deoxygenated blood returning to the right atrium from the upper limbs, head and neck, through the superior vena cava (SVC) and passes into the right ventricle.
iv. From the right ventricle, the blood (mostly deoxygenated) enters the pulmonary trunk. From the pulmonary trunk, only a small portion of this blood reaches the lungs and passes through it to the left atrium by pulmonary vein, without oxygenation. The greater part of the blood from the pulmonary trunk is short circuited by the ductus arteriosus into the aorta.
v. We have seen that the left atrium receives mainly oxygenated blood from the placenta through the right atrium and foramen ovale, and a small amount of deoxygenated blood from the lungs. The blood in the left atrium is, therefore, fairly rich in oxygen. This blood passes into the left ventricle, and then into the aorta. Some of this oxygen-rich blood passes into the carotid, coronary and subclavian arteries from the aorta and supply the brain, heart, head, neck and the upper extremities. The rest of the blood gets mixed up with poorly oxygenated blood coming from the ductus arteriosus, and supplies the trunk placenta and lower extremities. Therefore, the parts of the body that are supplied by the branches of the aorta, distal to its junction with the ductus arteriosus receive blood with only a moderate to less oxygen content.
vi. Much of the blood of the aorta, after its junction with the ductus arteriosus is carried by the umbilical arteries to the placenta where it is again oxygenated and returned to the heart through the umbilical vein, ductus venosus and the IVC.

Soon after birth, several changes take place in the foetal blood vessels, which lead to the establishment of the adult type of circulation.

The changes in the foetal blood vessels leading to the establishment of the adult type of circulation after birth are:

i. The muscles in the wall of the umbilical arteries contract, immediately after birth and occludes their lumen. This prevents the loss of foetal blood into the placenta.
ii. The lumens of the umbilical veins and the ductus venosus are also occluded. But this takes place a few minutes after birth, so that all the foetal blood in the placenta gets time to be drained back in the foetus. Though the umbilical artery, umbilical vein and the ductus venosus occlude immediately or a few minutes after birth,but this closure is physiological. Anatomical closure takes about 2 months. A patent ductus venosus decreases the delivery of the drugs to the liver, and may prolong their elimination half life.
iii. The ductus arteriosus is occluded, so that all the blood from the right ventricle now flows to the lungs where it can be oxygenated.

iv. The pulmonary blood vessels increase in size after birth due to unfolding of this pulmonary vasculature and consequently a much larger volume of blood reaches the left atrium through the lungs.

As a result the pressure inside of the left atrium is greatly increased. Simultaneously the pressure in the right atrium is diminished, because the extra amount blood from placenta no longer reaches it. The net result of these pressure changes causes the pressure in the left atrium to exceed than that of the right atrium and closure of the foramen ovale.

The vessels that are occluded soon after birth are in due course replaced by fibrous tissue and form ligaments.

The ligaments formed by the occlusion of foetal vessels are :

i. Umbilical arteries → Medial umbilical ligaments
ii. Left umbilical veins → Ligamentum teres of liver
iii. Ductus venosus → Ligamentum venosum
iv. Ductus arteriosus → Ligamentum arteriosum

THE DIFFERENCES IN CVS BETWEEN THE PAEDIATRIC AND THE ADULT GROUP OF PATIENTS

The CVS of the paediatric and the adult group of patients differ enormously. The right and the left ventricles are similar in size and thickness at birth. But, within first few days of life after birth the thickness of the left ventricular wall starts to increase gradually in response to the increased SVR and workload. On the other hand, the right ventricular wall thickness remains unchanged. So, by 3 months after birth, the mass of the left ventricle exceeds than that of the right and approaches the relative proportions of an adult. The weight of the heart of an infant doubles in the first year of life, while the body weight triples.Again, the weight of the heart doubles between the age of 4 to 5 years and between the age of 12 to 13 years of life. Thus, it gradually reaches the adult weight.

The myocardium of a newborn contains less contractile tissue and more connective tissue than that of an adult. This is reflected by the less active contraction of ventricular myocardium and a decreased compliance of the paediatric heart. It is also suggested that the limitation of myocardial contractility of paediatric heart is due to the decreased intracellular calcium influx and decreased calcium sensitivity to the contractile proteins. All these limitations of myocardial contractility in the paediatric patients tend to decrease or fix the size of stroke volume and maintain the cardiac output (CO), depending on the heart rate (CO = stroke volume × HR). In neonates and infants the resting stroke volume remains fairly constant at about 1 ml/Kg. Shortly after birth, the resting cardiac output is about 200 ml/Kg/minute depending mainly on the heart rate which declines gradually to 100 ml/Kg/minute by pubescent.

The cardiac output (CO) and cardiac index (CI = Cardiac Output divided by the body surface area) in paediatric patients are higher than that of adults and this is due to the high metabolic rate. So, the O_2 and other nutrients can be delivered easily to the actively growing tissues by increased circulation according to their increased metabolic need. In paediatric patients, this high CO and subsequent high CI is dependent mainly on the heart rate than the ventricular filling and the force of myocardial contraction, because ventricles of neonates and infants are poorly compliant. So, even though, the ventricles of a paediatric heart follow the Frank-Starling law, but the main determinant of CO is the heart rate. Thus, the neonates and infants can tolerate the higher heart rate (even 200/min) with ease. Therefore, during paediatric anaesthesia, the bradycardia should be avoided at any cost, because it represents a fall in CO (as cardiac output is heart rate dependent). So, sudden decrease of heart rate from 200/min to 50/min in an infant should be considered as cardiac arrest or as a severely compromised CO.Therefore, it should be treated immediately with cardiac massage, O_2, atropine and adrenaline. In paediatric patients, cardiac arrhythmias are rare in the absence of any persisting cardiac diseases and the most common form of cardiac arrest in such age group of patients is an asystole or EMD (not VT or VF).

Afterload is determined by the resistance of large arterial blood vessels and the tone of systemic peripheral vascular bed. As the sympathetic tone is poorly developed in a neonate and an infant, so afterload or SVR is usually low. But, it increases in parallel with the increase in systemic blood pressure with age. So, the systemic arterial pressure of neonates and infants tends to be lower than adults due to ↓SVR. The standard arterial pressure in neonate during the first day of life is about 70/50 mm of Hg, although immediately after delivery, it is slightly greater than this. Then, it rises gradually over the first week to approximately 90/50 mm of Hg and to the normal adult value of 120/70 mm of Hg by the age of 14 to 16 years. In asphyxiated neonates, the arterial pressure at birth may be higher. The rate of increase in blood pressure during the first week of life will be lower. In the preterm neonate, between 27 to 30 weeks of gestational age, the systolic pressure ranges between 45 to 55 mm of Hg. The ability of an infant to maintain his blood pressure in response to various circulatory stress is more difficult to assess than in adults. It is, therefore, not surprising that the CVP is raised even by head-up tilt of the neonates and this is reflected by the rise in aortic pressure in some infants and never by a fall (difference from adults).

The response of the neonates and infants to blood loss is perhaps that aspect of circulatory physiology, which is of greatest interest to an anaesthesiologist. All the evidences suggest that the human neonates and infants have a less active baroreceptor system, which normally

helps in the compensatory mechanism to blood loss. Also, it has been suggested that the liver serves as a buffer in the face of an increase in blood volume load in neonate. It is evidenced by the fact that gross liver enlargement may occur with little or no rise in CVP after over-transfusion which would indicate the ability of liver to take up large volume of blood from the venous system without increasing the blood pressure and manifesting heart failure.

The sympathetic system is also less developed in the neonates and infants and venodilatation occurs at rest. Thus, the sympathetic system cannot be blocked further, causing more venodilatation which is maximum at rest. So, paediatric patients who are normovolaemic at the start of anaesthesia do not exhibit a fall in the arterial pressure when spinal anaesthesia is administered. Moreover, they do not require preloading like an adult to avoid hypotension, as the further venous pooling does not occur and the venous capacitance does not further increase much from sympathectomy by spinal or epidural anaesthesia.

At birth, the autonomic innervation of heart is primarily parasympathetic, with sparse contribution from the sympathetic nervous system. But this balance of autonomic innervation matures as the child grows with the parallel increase in innervation from the sympathetic nervous system. Thus, the infant's cardiovascular system maintains a lower catecholamine store, and displays a blunted response to exogenous catecholamines. Hence, due to this reason the paediatric vascular tree is less able to respond to hypovolemia and vasoconstriction than the adults.

The decreased sympathetic neural output also explains the normally reduced BP in neonates, infants and children, and their increased susceptibility to reflex bradycardia and hypotension. Again, the diminished baroreceptor acitivity in infants may reduce their ability to adapt hypotension by an increase in the heart rate. So, the hallmark of the intravascular fluid depletion in neonates and infants is profound hypotension without tachycardia.

The potent causes of reflex bradycardia and hypotension in paediatric age group of patients during anaesthesia include easy vagal stimulation by laryngoscopy, tracheal intubation, tracheal suctioning and traction on the eye muscles, viscera, etc. This is due to the high parasympathetic tone in the paediatric group of patients. Bradycardia may also easily be caused by a variety of anaesthetic drugs, such as suxamethonium, halothane, neostigmine, etc. These effects can be successfully treated by IV atropine (20 µg/Kg).

The immature neonatal and infantile heart is also more sensitive to the calcium channel blocking properties of the volatile anaesthetic agents and opiod-induced bradycardia (Table 25.3).

HAEMOGLOBIN AND BLOOD VOLUME

Postdelivery haemoglobin (Hb) concentration of a neonate ranges from 13 to 20 gm/dl (average 18 gm/dl). Then, the concentration of Hb decreases gradually during infancy, reaching a level of 10 gm/dl by 10 to 15 weeks in full term neonates and 8 gm/dl by 4 to 8 weeks in preterm neonates. This decrease in Hb concentration in early infancy is due to the decreased erythropoiesis and shorter lifespan of the red cells. This is called the 'physiological anaemia of infancy'. Then, after reaching its plateau the Hb concentration again increases steadily throughout the infancy, touching the adult value by the end of first year. A preoperative Hb concentration of less than 10 gm/dl is abnormal and should always be investigated. Normally, the concentration of foetal haemoglobin (HbF) at 30 weeks of gestation is 95%. But, at birth this foetal haemoglobin (HbF) constitutes about 80% of the total haemoglobin. By 4 months, this falls to 10 to 15% and by 6 months this HbF disappears completely from circulation which is replaced by HbA. The synthesis of adult haemoglobin (HbA) is fully established by the age of 6 months. The differences between HbF and HbA are :

i. A higher affinity of HbF for O_2 than HbA
ii. A reduced affinity of 2, 3 – DPG to HbF than HbA
iii. The left ward shifting of the oxygen dissociation curve of HbF.

The higher affinity of HbF for O_2 in paediatric group of patients is due to the poor affinity for binding of 2,3-DPG to the Y-chain of HbF, allowing O_2 to bind strongly with it.This is reflected by low P_{50} value of the foetal Hb-O_2 dissociation curve, which is only 20 mm of Hg in a full term neonate. This low P_{50} value helps the foetus to optimise the uptake of O_2 from the placenta.It also prevents the release of O_2 from the haemoglobin at the tissue level, due to the left ward shifting of the O_2 dissociation curve. The other factors that shift the O_2 dissociation curve to the left (i.e. low P_{50}) include alkalosis, hypothermia and hyperventilation, which also limit the availability of O_2 at the tissue level. However, these demerits of HbF are removed by the increase in haemoglobin concentration, increase in the cardiac output, expanded blood volume, etc. On the other hand, the low PO_2 and increased metabolic acidosis at the tissue level due to hypermetabolic state of the paediatric patients help in the downloading of O_2 into the tissues and shift the

Table 25.3: The pulse rate and BP of paediatric patients at different ages

Age		*Heart rate*	
< 1	Months	110-160	per minute
2 to 5	"	90-140	"
5 to 12	"	80-120	"
>12	"	90-100	"
		Blood Pressure	
		S (mm of Hg)	*D (mm of Hg)*
< 1	Years	70-90	45 - 50
2 to 5	"	80-100	50 - 60
5 to 12	"	90-110	60 - 65
> 12	"	100-120	65 - 70

the oxygen dissociation curve to the right at the tissue level. Hence the leftward shifting of the O_2 dissociation curve prevents the O_2 downloading, while the rightward shifting helps in the same, thus compensating each other. Hyperventilation produces alkalosis and discourages the downloading of O_2 at the tissue level. So, hyperventilation should be avoided and normocapnia should be maintained during paediatric anaesthesia.

The normal blood volume of neonate at birth is about 90 ml/Kg. It gradually decreases to 80 ml/Kg in infants and young children. By the age of 6 to 8 yrs, an adult level of 75 ml/Kg is attained. The decision to transfuse blood in paediatric group of patients should be balanced against all other risks. In case of blood loss, usually the children can tolerate haematocrit value upto 25%. Blood loss of more than 10% of the total red cell mass should be replaced by transfusion of blood, especially if the initial haemoglobin is less than normal and further losses are expected. However, otherwise the most children who have a normal Hb concentration at the beginning of surgery can tolerate losses of upto 20% of their total red cell mass.

RESPIRATORY SYSTEM

During intrauterine life, the lungs begin to develop from the 4th or 5th week of gestation. By the 6th week of intrauterine life, lobar or secondary bronchi are developed. By the 7th week, segmental or tertiary bronchi develop and by the 8th week, subsegmental airways grow. By the 16th week of gestation, the tracheobronchial tree undergoes division upto the 16th order, terminating into terminal bronchioles and acini. At 16th week of intrauterine life, the number of airways and the number of pulmonary blood vessels in the foetus is similar to that of an adult, but the number of alveoli are less in number, and this number gradually increases towards term. From 16 weeks of gestation the lungs begin to mature as a potential gas-exchange organ, because after that onwards the pulmonary capillaries start interdigitating among the alveoli (Fig. 25.3).

Type II pneumocytes then begin to appear. It is nothing, but the differentiated epithelial cells of alveoli. The type I pneumatocytes are derived from these Type II cells. In the mature adult lungs, the Type I cells cover 25 times more surface area of the alveoli than the Type II cells. At birth, the total number of alveoli is 20 to 50 millions and each terminal bronchiole opens into a single alveolus, instead of a fully developed cluster of alveoli.In neonates, the alveoli are thick-walled and it number constitute only 10% of that of an adult. Then, the alveoli increase in number by multiplication and also increase in size until the child reaches the age of 8 years. Thus, at the end of 8 years, the total number of alveoli in children is 300 million which is equal to that of an adult. Subsequently, the growth of the lung occurs by an increase in only of the alveolar and airway size, but without any increase in number by multiplication. The granules of surfactants are produced and appear in the alveolar lining cells as early as at 24 weeks of the intrauterine life. So, after 24 weeks an independent life outside the uterine cavity becomes possible. Surfactants are lipoproteins in nature and reduce the surface tension of alveoli below 10 to 15 dynes/cm.

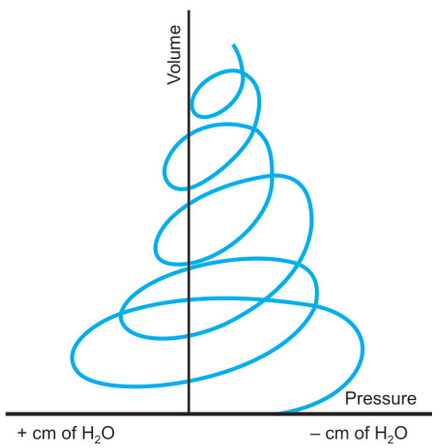

Fig. 25.3: The first few breaths of a neonate, where there is a high negative intrapulmonary pressure and low tidal volume.This is followed by a gradual reduction of this negative intrapulmonary pressure and an increase in the tidal volume

The fluid-air interface at the surface of alveoli which develops after the first breath of a newborn cannot be maintained without this surfactant. So, the lungs are unable to retain air within the alveoli without surfactant and collapses. If the pressure is measured within the alveoli of different sizes without surfactant, then it is found that the smaller alveoli have higher intra alveolar pressure than the larger ones which is explained by the Laplace law.

The Laplace law says that the pressure in each sphere or alveoli varies inversely with the radius of it (if the tension of the wall is constant). If the lung is considered as a large cluster of bubbles or alveoli in communication with each other, then it is expected that the smaller alveoli without surfactant would expand less readily on inspiration and empty more completely on expiration, than the larger ones.This is due to the high inward collapsing surface tension force of the smaller alveoli than the larger ones. Thus, the larger ones would become overdistended and the smaller ones would collapse, because smaller alveoli gradually drain into the larger ones. But, fortunately, this does not happen due to the presence of surfactant at the alveolar fluid-air interface, which reduces the surface tension to a degree, that is inversely proportional to the surface area of alveoli. Thus, the reduction of surface tension in smaller alveoli is greater than the larger ones and they remain distended or open, giving rise to a stable condition.

This Laplace phenomenon is not restricted to the consideration of just the surface tension of alveoli. But it is applicable to other hollow viscus of the body also. For example, a smaller heart does not have to develop the same tension in its wall as a larger one in order to produce the same given pressure within its cavities. A small diaphragm with a small radius can produce a larger negative intrathoracic tension, despite its paper-thin musculature which

is found during the first breath, and this negative intrathoracic pressure is as high as in the adults (-70 mm of H_2O).

The active constituents of this intra-alveolar surfactant are phospholipids, 85% of which is lecithin. Lecithin appears in the amniotic fluid towards the term. This terminal increase of lecithin in the amniotic fluid is greater than that of sphingomyelin, which is another phospholipid surfactant and is present in the amniotic fluid from the 24th week of gestation. When the ratio of lecithin to sphingomyelin is above 2, then the risk of collapse of the alveoli is less. If the child is born prematurely and these surfactant phospholipids are insufficient, then respiratory failure may follow. Glucocorticoids accelerate the production of these pulmonarysurfactant. This is proved by the fact that neonates who develop hyaline membrane disease have a low blood cortisol level, than the neonates who have a pulmonary disease.

The lungs in utero are filled with fluid. However, the composition of this fluid differs from both the amniotic fluid and the serum, since the pH is lower and the chloride content is higher than the both. This alveolar fluid is formed by an active secretory and absorption process of the alveolar epithelial cells. In the course of delivery, this alveolar fluid is expressed out of the lungs by the force exerted on the chest wall of the foetus by the birth canal and presumably it is replaced by air when the chest wall expands during first breath or first cry. The volume of fluid expressed in this way from lungs may be as much as 42 ml. With the first forceful respiratory effort after birth, most of the alveoli are recruited. Then gradually more and more alveoli are recruited in the subsequent respirations and they are expanded. Then the residual fluid in the lung is readily absorbed, as it has an extremely low colloidal osmotic pressure. This absorption of alveolar fluid takes nearly about 24 to 72 hours after birth and occurs through the transcapillary and translymphatic routes.

Within one minute of clamping of the umbilical cord, the first breath of neonate is established. For establishment of this first breath, many sensory factors such as sound, touch and temperature are needed. But, the major factor for the establishment of this first breath in newborn is sudden resetting of the respiratory centre to the new level of PaO_2 and $PaCO_2$, and the hypercapnia and hypoxia had pronounced effect in this resetting. During establishment of first respiration the sensory impulses first strike on the reticular system of brain, and cause a resetting of the respiratory centre to the new level of arterial O_2 and CO_2 concentration, so that the levels of O_2 and CO_2 tension, which had no effect on respiration before, now start effecting. The ventilatory response to CO_2 tension increases with increasing age. The ventilatory response to hypoxaemia in the neonate is more complex than its response to CO_2. The tension of O_2 in the carotid blood rises after the first few breaths from 35 mm of Hg to more than 60 mm of Hg and the CO_2 tension falls from 65 mm of Hg to 35 mm of Hg.

The tidal volume of first breath in newborn is about 20 to 80 ml and generates an extremely negative intrapleural pressure which as about – 70 cm of H_2O during inspiration. The first expiration is also active and assists in the expulsion of lung fluid. Then, progressively, each respiratory cycle shows a smaller pressure-volume loop, with steadily decreasing effort of breathing and retention of air in alveoli with every inspiration. The normal functional residual volume which is about 70 to 80 ml in a neonate is established within 60 minutes of birth.

The respiratory system of neonates and infants is less efficient and has low reserve than adults. But its O_2 consumption is 2 to 3 times as high as an adult. The two respiratory reflexes are seen in a neonate: Paradoxial Reflex of Head and Hering-Breuer Reflex. The first one is the inspiratory response which occurs after a partial inflation of the lungs. The second one is the passive expiratory response, that occurs after inflation. The respiratory pattern of some premature neonates is described as 'periodic', characterised by occasional episodes of apnoea, extending for 5 to 15 seconds. When apnoea is prolonged for more than 15 seconds, then there is bradycardia and haemoglobin desaturation (<90%). The frequency of apnoea is directly related to the degree of prematurity and 70% of preterm neonates show such periodic respiration. Among this, 50% have prolonged apnoeic episodes (>15 secs). Between apnoeic episodes, there is normal respiratory rate or tachyponea. The management of this apnoea of prematurity is theophylline. Periodic breathing and apnoea may be associated with full term neonates, but they are rarely associated with perioperative complications.

Causes of Less Efficiency and Low Reserve of the Respiratory System in the Neonates and Infants

Compared to older children and adults, the neonates and infants have less efficient system for ventilation. This is because of the weak intercostal and diaphragmatic musculature which is again due to the paucity of mature adult Type I muscle fibres, horizontal and more pliable ribs, and a protuberant abdomen. The protuberant abdomen of neonates and infants pushes the diaphragm upwards, beyond its optimal curvature for maximum contraction. This increases the total load against which the diaphragm has to work, and reduces its efficiency. So, the respiratory system of the paediatric group of patients is less efficient, with a low reserve than adults (Table 25.4).

The other causes of less efficiency of respiratory system in the paediatric group of patients are:

i. The diameter of the airways in neonates and infants is smaller. This increases the resistance to air flow, which is inversely proportional to the radius of the lumen and raised to the power of five (r^5). The airway resistance in

Table 25.4: Causes of low respiratory reserve in neonates and infants

1.	High respiratory rate.
2.	Narrow airways and high resistance to airflow.
3.	High compliance of airways and chestwall.
4.	Low compliance of lung.
5.	Sole reliance on diaphragmatic function due to weak, underdeveloped intercostal muscles.
6.	High O_2 consumption and metabolic rate.
7.	High dead space to tidal volume ratio.
8.	Infantile configuration of respiratory muscles (Type I fibres).
9.	Alveolar ventilation twice than adult.
10.	Large physiological shunt.
11.	Small lung volume.
12.	Low vital capacity (half of an adult).
13.	Weak intercostal and diaphragmatic muscles.

neonates is 30 cm of H_2O/L/sec, whereas in adults it is only 2 cm of H_2O/L/sec. Thus, the narrow airway in paediatric group of patients result in an increased resistance to the flow of air upto the age of 8 years. In children, the nasal resistance represents almost 50% of the total airway resistance. So, it accentuates the problem in children with nasal congestion, as they are obligatory nasal breathers.

ii. In children the compliance of airways and the chest wall is high and this is due to the poorly development of these structure. Thus, the high compliance of the chest wall provides little support to the lungs, and so the negative intrathoracic pressure is poorly maintained during inspiration. Hence it reduces the efficacy of the respiratory system. High compliance of airways also causes early closure of it, and the closing volume occurs within tidal breathing, i.e. functional airway closure occurs during each breath (FRC ≤ CC). Therefore, it causes an increase in alveolar and arterial O_2 tension difference ($P_{A-a}O_2$). This explains why PaO_2 in neonates and infants is lower than that of adults, and children are more at the risk of respiratory failure. On the other hand, lung compliance in neonates and infants is also very low. This is only about 6 ml/cm H_2O (adult value is 100 ml/cm H_2O) and is due to the poor development of elastic tissue in alveoli. This also accounts for greater closing capacity (CC) of the lungs and thus, predispose the neonate to increased intrapulmonary shunting of blood and higher P_aCO_2.

iii. In neonates and infants there is also high O_2 consumption and metabolic rate, which need increased ventilation. So to fulfill this high metabolic and O_2 consumption rate and to achieve adequate alveolar ventilation, neonates and infants have to maintain a high respiratory rate and subsequently increased work of breathing. High respiratory rate increases the alveolar minute ventilation. Alveolar minute volume is therefore rate-dependent, but not the tidal volume-dependent in neonates and infants. Thus the normal resulting increased respiratory rate in neonates and infants is approximately double than that of adults In neonates the average respiratory rate is 30-40 per minutes which is already at the higher limit of respiratory reserve. While in adult it is just 15 per minutes with much reserve. This explains the cause of low efficiency and low reserve of respiratory system in neonates and infants. The high alveolar minute ventilation in neonates and children also explains why the induction and emergence from inhalational anaesthesia are relatively rapid in small children. Also, a high metabolic rate explains why desaturation occurs very rapidly in children.

iv. Until the infant reaches the 2 years of age, the fibres of the main respiratory muscles, (diaphragm and intercostal) donot achieve the configuration of the adult Type 1. The adult Type 1 muscle fibres have an ability to perform repeated exercise without fatigue. As the newborns and infants are some what deficient in this adult Type 1 muscle fibres, so any factor that increases the work of breathing, results in an early fatigue of respiratory muscles and causes respiratory failure.

v. In neonates and infants there is already higher dead space to tidal volume ratio (Vd / Vt). So, any modest increase in the dead space (Vd) by equipments, such as facemasks, breathing tubes, humidifiers, etc., (or due to any cause) may have a disproportionately greater effect and reduces the efficiency of respiratory system in this group of patient.

vi. In children ventilation is solely reliant on the diaphragmatic function. This is because the ribs are soft, horizontal (i.e. perpendicular to the vertebral column), noncalcified and the intercostal muscles are poorly developed. Due to the horizontal disposition there is no bucket-handle type of movement of the ribs in children as in the adults. So, there is less expansion of chestwall and less ventilation. Diaphragm is also more horizontally attached to the ribs, reducing its mechanical advantages during contraction. Furthermore slight abdominal distension may easily cause splinting of the diaphragm, resulting in less efficient contraction of it leading to easy respiratory failure in paediatric patients.

vii. Alveolar ventilation per kilogram of body weight is twice than that of an adult in neonates. Thus it deplets the reserve and reduce the efficiency of respiratory system in neonates and infants. The normal alveolar ventilation in neonates is 150 ml/Kg/min, whereas alveolar ventilation in adults is 60 ml/Kg/min.

viii. Another important cause for less efficiences of respiratory system in the paediatric group of patients is a large physiological shunt, the value of which is nearly 20% on day-one.

ix. The lung volume in infants and neonates is disproportionately smaller in relation

to their body size in comparison to adult. But the metabolic rate is nearly twice than that of an adult. Therefore, the ventilatory requirement for per unit volume of lung is enormously high in neonates and infants. Thus, they have far less reserve for gas exchange than adults.

x. The normal O_2 consumption, CO_2 production and tidal volume (ml/Kg) of the neonate is almost double than that of an adult. The neonatal O_2 consumption is 7 ml/Kg/min as compared to 4 ml/Kg/min of an adult. Whereas, the neonatal CO_2 production is 6 ml/Kg/min as compared to 3 ml/Kg/min of an adult. Tidal volume of a neonate is 6 ml/Kg whereas in an adult it is 3ml/Kg. All these datas explain how the respiratory system of neonate and infant is using its reserve and depletes it and is less efficient than adult.

xi. The vital capacity of a neonate is half than that of the adult, i.e. only 35 ml/Kg. for neonates, whereas 70 ml/Kg for an adult.

xii. The FRC of a neonate is 30 ml/Kg, whereas the adult has an FRC of 35 ml/Kg.

xiii. Morever, hypoxic and hypercapnic ventilatory drives are not well developed in neonates and infants. Infact, unlike adults, hypoxia and hypercapnia depress the respiration in these group of patients (Table 25.5).

The different lung volumes of the neonates and infants differ from the adults. It is definitely smaller in neonates and infants than adults, but when compared with respect to their body weight and metabolic rate it is higher than that of the adult. The gas exchange area of neonatal and infantile lungs is 50 times less than that of the adults. The gas exchange area of the neonatal lung is only 3 m^2 in comparison to that of an adult, which is 150 m^2, though the metabolic rate of neonates is twice than that of the adult. The functional residual capacity (FRC) per Kg of body weight reaches the adult value during the first 48 hours after birth, but still the closing volume exceeds the FRC during normal breathing and explains the cause of low PaO_2 in neonates. When normalized for body weight, the tidal volume for both the groups is same. Dead space volume per Kg of body weight is also same for both the groups and it is about 30% of the tidal volume.

Table 25.5: Comparison of respiratory parameters between neonates and adults

Parameters	*Adult*	*Neonate*
Tidal volume (ml/Kg, in spontaneous respiration)	7-10	7
Dead space (ml/Kg)	2	2
Respiratory rate/min	15	30
V_D: V_T	0.3	0.3
Compliance (ml/cm H_2O)	100	6
Airway resistance (cm H_2O/Lt/S)	2	30
Time constant (S)	1.1	0.5
O_2 consumption (ml/Kg/min)	4	7

Spontaneous respiratory rate decreases, as the age increases. This reflects the age related decrease in ventilatory requirement which is parallel to the decrease in metabolic rate with age. This is explained by the O_2 consumption rate in neonates which is about 7 ml/Kg/minute, and is twice than that of the adult. The normal adult value is 3.5 ml/Kg/minute. Although respiratory rate of neonates and infants is high, alveolar ventilation is still inefficient than adults. Consequently, when the trachea is intubated and ventilation is constituted by mechanical ventilator, the normocapnia is only maintained by the high tidal volume of 10 to 15 ml/Kg and a low respiratory rate of 20 to 25 bpm in the healthy neonates and infants. This explains why in neonates and infants, the energy is mainly utilised for spontaneous respiration and is the major source of CO_2 production. To maintain normocapnia and a normal PaO_2 in neonates with poor respiratory gas exchange, higher respiratory rate (>15 to 25 bpm) is required. The neonatal and infantile lungs continue to grow and mature throughout there childhood and adolescence, and reach the adult value by 16 years of age.

xiv. Respiratory Rate (RR):It varies with age (Table 25.6).

The airway of the paediatric patients differs from the adults in the following ways:

i. The tongue of the paediatric group of patients is relatively larger than adults in relation to oropharynx. So, there is every likelyhood of an upper airway obstruction by this large tongue in this group of patient. It also causes technical difficulties during laryngoscopy and intubation.

ii. The larynx of the paediatric age group of patients is located highup in the neck. In neonates and infants it is situated at the level of C_{3-4} vertebrae. Whereas in adults, it is situated at the level of C_{5-6} vertebra. This is because, the neck is short and the hyoid cartilage lies in close proximity to the thyroid cartilage in paediatric patients. So, a straight blade of a laryngoscope, behind the epiglottis, becomes frequently successful to expose the vocal cords.

iii. The epiglottis of neonates and infants is long, floppy and acutely angled over the laryngeal inlet. It projects posteriorly at an angle of 45° to the base of the tongue. Whereas, the epiglottis of an adult is short, broad, flat and projects posteriorly at an angle of only 15 to 25° to the base of the tongue. So, the control of epiglottis and the exposure

Table 25.6: Respiratory rate and age in children

Preterm neonate	:	40-70	BPM
Neonate	:	40	”
2 to 5 years	:	25-30	”
5 to 12 years	:	20-25	”
> 12 years	:	15-20	”

of larynx by the blade of laryngoscope is more difficult in paediatric group of patients than the adults (Fig. 25.4).

iv. The paediatric larynx is funnel shaped and the position of cricoid cartilage in the larynx marks its narrowest portion. In contrast, the adult larynx is tubular in shape and narrowest at the level of the vocal cords, which is much above the cricoid cartilage. So, in adults an endotracheal (ET) tube which passes the vocal cord (glottic opening) will readily pass into the trachea without any hindrance at the level of cricoid cartilage. But, in neonates and infants an ET tube that easily passes the vocal cords, may be tight in the subglottic region at the level of cricoid cartilage and may not pass into the trachea. This is due to the maximum narrowing of larynx at this level, due to the presence of the cricoid cartilage from where the trachea begins. Hence, the uncuffed endotracheal tubes are preferred in patients less than 10 years of age.

The cricoid cartilage is covered with loose pseudostratified columnar epithelium. So, it is susceptible to oedema, when traumatized and inflamed by cuffed or tight tubes. As the epithelium of cricoid cartilage swells due to trauma, it occludes the lumen of the cricoid ring and severely obstructs the airflow. The resistance of airflow through a pipe is inversely proportional to the fifth power of the radius of the lumen of this tube. So, a small amount of swelling will cause a little decrease in the radius of lumen, but will tremendously increase the resistance to airflow. For example, when the radius of the cricoid lumen decreases two-folds, the resistance to airflow increases by 32 folds (i.e. $2^5 = 32$).

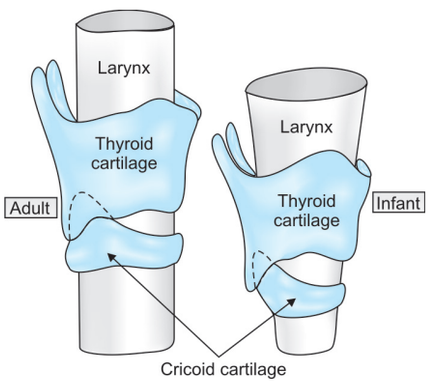

Fig. 25.4: Adult and infant larynx

v. The head of the neonates and infants is relatively large in comparison to their body size than adult. The occiput of it is most prominent and the chin is retrognathic. So, the prominence of occiput and largeness of the head of paediatric group of patient keeps already it in a 'sniffing' position without pillow which facilitates the tracheal intubation. Therefore, any pillow under the head during intubation may disturb this sniffing position and may make intubation difficult in neonates and infants.

vi. The nasal passage of the neonates and infants is relatively narrow and accounts for more than 50% of the total airway resistance. On the otherhand, neonates and infants are obligatory nasal breathers. So, they are highly predisposed to obstruction in the presence of even a very small amount of secretion in the airway.

vii. The trachea of the neonates and infants is made up of soft (compliant), short (4 to 5 cm), noncalcified, cartilaginous rings. Whereas the trachea of an adult person is long (10 to 11 cm) and made up of noncompliant cartilaginous ring which may be calcified. So, it does not easily collapse during any airway obstruction like paediatric patients.

Thus, the combination of these two characteristics, i.e a high compliance of the chestwall and the airway and a low compliance of the lung tissue in neonates and infants (opposite to that of an adult) promotes the chestwall to collapse easily during inspiration and maintain a relatively low residual lung volume at expiration,which results in a decreased FRC and low oxygen reserves (Table 25.7).

Table 25.7: Characteristics of the paediatric airway

1.	Relatively large tongue
2.	High up larynx
3.	Long acting acutely angled epiglottis
4.	Funnel shaped larynx
5.	The narrowest part of larynx is the cricoid cartilage
6.	Obligatory nasal breathers
7.	High compliance and easy to collapse chest wall and airway
8.	Retrognathic chin
9.	Short trachea and neck
10.	Prominent adenoids and tonsils

TEMPERATURE REGULATION AND MAINTENANCE IN PAEDIATRIC PATIENTS

The neonates and infants are particularly vulnerable to hypothermia. This is due to the (i) large body surface area to weight ratio, (ii) poor insulation due to thin skin and limited fat stores, (iii) immature sweat function, (iv) initial low BMR, and (v) the inability to move away from adverse thermal environment. This hypothermia causes early arterial desaturation by increasing the cellular metabolism and O_2 consumption. Previously, it was thought that this vulnerability to hypothermia is due to the ill-developed temperature regulating mechanism in paediatric patients. But, this is incorrect. Because actually, they donot have a well developed system for increasing the heat production in response to cold. The infant is able to raise the heat production in response to cold only upto 70 cal/Kg/min, as compared to an adult, who can achieve the heat production upto 90 cal/Kg/minute. Again, the vulnerability to hypothermia in neonates and infants is due to the greater heat losing surface area, than the mass of heat producing tissues i.e. larger body surface area (heat-losing) to body weight (heat-producing) ratio than adult. The premature infant is even more susceptible to hypothermia. This is because of their very thin skin and limited fat stores than mature infant and so losing more heat.

The three process of thermogenesis, producing heat in infants are:

i. Voluntary muscle activity
ii. Involuntary muscle activity
iii. Nonshivering (by cellular metabolism) thermogenesis.

The minimal ability of the neonates and infants to shiver (voluntary muscle activity) during the first three months of life makes the metabolism of brown fat (cellular thermogenesis) the principal method of heat production for this age group of patients. Brown fat is a specialised adipose tissue, capable of metabolising fat *in situ,* and is present in the newborn of most species. It develops between 25 to 30 weeks of gestation and constitutes about 25% to 30 % of the total body weight. The distribution of this brown fat varies from species to species, but in humans it is mainly found largely around the kidneys, the adrenal glands, between the scapulae, in axilla and around the blood vessels of the neck, mediastinum and the loin. The differences between brown and white fat are:

i. The blood supply is copious in brown fat
ii. In brown fat the nerve supply is abundant
iii. The cells of brown fat are multinucleated and judiciously equipped with mitochondrias.

The activities of tissues in brown fat to produce heat are mediated by catecholamines and can be abolished by sympathetic blockers. The substrate used for heat production in brown fat is mainly the fatty acids and the temperature of this tissue rises markedly, when the subject is exposed to cold. The metabolism of brown fat is severely limited in premature infants, and sick neonates who are deficient in fat stores. Furthermore, volatile anaesthetics inhibit thermogenesis in the brown adipocytes.

Newborn infants, however, cannot maintain their temperature only at the expense of brown fat consumption, but also burn their carbohydrate reserve for thermogenesis. At birth, the liver, cardiac, and skeletal muscle's glycogen content is much higher than that of an adult. Of these reserves, only the liver-carbohydrate contributes directly to the maintenance of blood sugar, and consequently to the production of heat and energy by its metabolism. However, the muscle glycogen may do so indirectly by conversion of it to lactic acid which may then become a source of glucose in the liver. Newborn infants in an adverse thermal environment tend to deplete their stored liver-carbohydrate and subsequently become hypoglycaemic and hypothermic. Hypoglycaemia which in the neonates is defined as glucose levels below 30 mg/dl may lead to grave brain damage, if untreated.

If the neonates are allowed to become hypothermic during anaesthesia, then unlike adults they try to maintain their temperature only by non-shivering thermogenesis, i.e. by cellular metabolism. Therefore, as the metabolic rate increases, O_2 consumption also increases. Then this increased O_2 consumption puts an additional burden on the cardiopulmonary system and this may become critical in neonates with a limited reserve. On the otherhand, the release of norepinephrine in response to cold stress causes vasoconstriction, which in turn causes further tissue hypoxia and lactic acidosis in the face of increased O_2 consumption and demand. This acidosis in turn favours an increase in right to left shunt, which further causes hypoxaemia. As a result, a vicious positive feedback loop of hypoxaemia and acidosis is set up.This problem of hypothermia is further compounded by cold operating room enviornment, wound exposure, intravenous fluid administration, dry cool anaesthetic gases and the direct effect of anaesthetic agents on the temperature regulatory mechanism. Thus, hypothermia is a serious problem during perioperative period of anaesthesia that has been associated with delayed awakening from anaesthesia, cardiac irritability, respiratory depression, increased PVR and altered drug response.

The Homeothermic animals have the ability to generate and lose heat, thus maintaining the core temperature in a fixed range. Heat loss from body occurs by one of the four following processes: radiation, convection, evaporation and conduction. Enviornment around a patient controls the loss of heat by this four process. The neutral thermal enviornment is defined as the range of ambient temperature at which the loss of temperature by evaporation does not occur. In this neutral thermal environment the metabolic rate is minimal. The temperature of such an enviornment is 34ºC for the premature neonates, 32ºC for the term neonates, and 28°C for an adult. These are also the temperature settings of an incubator.

Among the four processes of heat loss: radiation, convection and evaporation are the most important processes, responsible for heat loss in the OT. Radiation accounts for about 60% of the heat loss from a neonate or a infant placed in a 21°C room temperature. If the room temperature is raised to a thermoneutral environment of 34°C, the loss of heat by radiation will decrease to about 40% of the total heat loss. The reason for this is that the heat loss by radiation is a function of the difference between skin and the room temperature. So, if room temperature is raised, then the heat loss by radiation is minimum. The second major source of heat loss in the neonate is convection and this also can be reduced by increasing the room temperature to the skin temperature. Evaporative loss also can be reduced by keeping the environmental temperature at a neutral level. The neonate possesses minimum subcutaneous fat that cannot act as thermal insulation.

Many procedures and precautions can be undertaken in OT to maintain the body temperature of a neonate and an infant, mainly by reducing the heat loss. Thus the procedures taken to maintain the body temperature of a neonate and an infant by heat loss are:

i. The neonate should be transported to the theatre wrapped up by an insulator or in an incubator, set at thermoneutral temperature. Ideally, few hours before surgery the theatre should be warmed to the thermoneutral temperature. This causes the walls and the equipments of the theatre to warm up and reduces the net heat loss by radiation. Heat loss by radiation is a two-way process. The child loses heat by radiation to the walls and equipments and it also gains heat from the walls and equipments provided they are properly heated previously.
ii. All the body parts of a child that are not needed for surgical and monitoring purposes should be covered. Overhead radiant heaters should be used, if the child has to be exposed.
iii. During surgery, the child should lie on a thermostatically controlled heated blanket.
iv. Forced air-warming system by blowing filtered warm air into quilted blankets with perforations are effective in maintaining the child's temperature during surgery. This allows warm air to come into direct contact with the child.
v. Other measures such as using bonnets, to reduce heat loss from the exposed head is very effective. IV fluids and fluids used for lavage of the body cavities should be warmed to the body temperature. Anaesthetic gases should be humidified and warmed, in order to reduce the heat loss from lungs. The new born in the cold OT or Labour Room is very vulumerable to cold stress, because some heat loss is inevitable. This also can be reduced by warm wrappings, heated mattresses, overhead heaters, alluminium covers, etc.

RENAL FUNCTION AND FLUID BALANCE

The kidneys and subsequently all its functions are immature at birth. The maturation of the renal tissue occurs by hyperplasia during the first six weeks of life and then by hypertrophy during the next first year of life.

However, the complete maturation of renal tissue occurs by about two years of age. Due to low perfusion pressure and immaturity of the glomerular and tubular functions, both the glomerular filtration rate (GFR) and subsequently the renal tubular reabsorption rate are low in neonates and infants. At birth the GFR is only about 45 ml/min/1.7m^2, which increases rapidly to about 65 ml/min/1.7 m^2 by 6 months. Then, gradually it approaches the adult value of 125 ml/min/1.7 m^2 by the age of 2 years. Thus, the kidneys of neonates and mainly of premature are unable to handle the excessive water and solute load, especially Na^+ and K^+. The half life of medicines that are excreted by glomerular filtration are also prolonged. Hence, there is more chance of overtransfusion which may lead to pulmonary oedema and cardiac failure in this age group of patients. Because of the low glomerular filtration rate, poor capacity to concentrate urine, and no diuretic response to water load the infant's kidney is also less well-equipped to deal with the effects of dehydration (Table 25.8).

At birth in neonate the urine volume is about 25 ml/Kg/day. This gradually rises to about 100 to 120 ml/Kg/day by the end of 1st week. The insensible loss in normal babies is about 25 to 30 ml/Kg/day. To maintain the normal serum electrolyte concentration, the neonates and infants require about of 3 to 5 mmol/Kg of Na^+ and an equivalent amount of K^+ per day. The ability of an immature kidney in neonate and infant to eliminate excess Na^+ is limited. So, an extra load of Na^+ in the absence of loss easily results in hypernatraemia and its sequelae. The premature neonates often possess multiple renal defects including decreased creatinine-clearance, increased glucose-excretion, decreased bicarbonate-reabsorption and poor diluting-concentrating ability.

A great difference exists in the distribution of water in the body as a percentage of body weight among the neonates, infants and adults. In premature infants the water constitutes about 85% of the total body weight. In neonates, infants and adults, this percentage is 80%, 75% and 65% respectively. In neonates most of the total body water is in the extracellular compartment in contrast to adults, where most of the total body water is in the intracellular compartment. The plasma volume in percentage of body weight remains constant throughout the life and this is at about 5% of the total body weight (Table 25.9).

The approach to IV fluid therapy in paediatric group of patients should be considered in the light of their high metabolic rate, high O_2 demand and a high body surface to weight ratio. In the first week of life the requirement of fluid for maintenance increases everyday. When we relate the daily water requirement with the metabolic or caloric demand, then the general rule is that 100 ml of water is required for each 100 calories of spent energy.

On the other hand, when we relate the fluid requirement to body weight, then in infants with body weight upto 10 Kg, the fluid requirement is 100 ml/Kg/day or 4 ml/Kg/hour. For neonates and infants

Table 25.8: Distribution of water as percent of body weight

	ICF	*ECF*	*Plasma*	*Total*
Premature	30	50	5	85
Neonate	40	35	5	80
Infant	40	30	5	75
Adult	40	20	5	65

ICF= Intracellular fluid, ECF = Extracellular fluid

Table 25.9: Fluid requirements in the first week of life

Rate (ml/Kg/day)	*Day*
0	1
50	2, 3
70	4, 5
100	6
125	7

with body weight between 10 Kg and 20 Kg, this calculation requires an addition of water of 2 ml/Kg/hour for each Kg increase in body weight (Table 25.10).

As for example, for a neonate with a body weight of 15 Kg, the fluid requirement is (10×4) + (5×2) = 50 ml/hour or 1200 ml/day. Between 20 to 30 Kg, the daily fluid requirement needs an addition of 1 ml/Kg/hour, for each Kg increase in body weight above 20 Kg to the previous requirement. As for example, for a neonate or infant of 25 Kg , the fluid requirement is (10×4) + (10×2) + (5×1) = 65 ml/hour or 1600 ml/day. Of the total deficit, 50% is replaced in the first hour and 25% in each of the next 2 hours. However, this calculation does not include the previous deficit, third space loss due to surgical procedures, hyperthermia, hyperventilation, etc. Third space loss depends on surgical procedures and may vary from 1 ml/Kg/hour for a minor surgical procedure to as much as 15 ml/Kg/hour for major surgical procedures.

We also have to think about the composition of the IV fluid. There is still some controversy regarding the requirement of glucose in the IV fluid. Some reports of hypoxic brain damage have been published, due to high blood glucose levels. So, some anaesthesiologists do not recommend the routine use of glucose-containing solutions as IV fluid. This is also true that unrecognised hyperglycaemia, ketosis and high metabolic rate of neonates and infants are the motivating factors for discarding the routine use of glucose containing solutions in paediatric patients. But, this is not always true for those who have not food or fluid for a long time and also those who have a diminished glycogen store. The neonates who are at greater risk of hypoglycaemia are: premature babies or babies of small for gestational age babies receiving hyperalimentation and babies born to diabetic mothers. So, the current practice is to avoid the risk of hypoglycaemia. But, routine use of only 5% dextrose or lactated Ringer's solution is discouraged. Instead, 5% dextrose in 0·45% normal saline is used in a piggy-back infusion at maintenance rates with lactated Ringer's solution (or any balanced salt solution) for all deficits and third space losses. The IV fluids should also be administered by using a system that allows small volume to be given accurately. Anaesthesiologists usually perform this by injecting fluid using a syringe, or by a microprocessor-controlled syringe-driven infusion pump. The later method is preferable, as fluid is given at a slow but steady and accurate rate.

The Anaesthesiologists must assesses the blood loss during surgery. In minor surgical procedures the loss is minimal and the assessment is performed by visual inspection of the surgical field, swabs, mops and suction bottle. But for major surgeries where blood loss is more, then weighing of swabs and colorimetry is helpful. The estimated circulating blood volume in neonates, infants and children is near about 70-80 ml/Kg. In general, the blood loss less than 10% of the total blood volume either requires no replacement or can be replaced by crystalloid solutions. Loss between 10% to 20% should always be replaced by colloids or blood. But, over 20% of the loss must always be replaced by blood. The adequacy of blood replacement should always be assessed on the background of blood pressure, pulse rate and the central venous pressure (Table 25.11).

Table 25.10: Calculation of the fluid requirement (only for maintenance) in paediatric patients

Weight (Kg)	*Hourly requirement (ml/Kg/hour)*	*Daily requirement (ml/day)*
Upto 10 Kg	4 ml/Kg/hour	100 ml/Kg/day
10 to 20 Kg	10 × 4 + 2 (Wt in Kg – 10) ml/hour	1000 + 48 (Wt in Kg – 10) ml/day
Above 20 Kg	(10 × 4) + (10 × 2) + 1 (Wt in Kg – 20) ml/hour = 60 + 1 (Wt in Kg – 20) ml/hour	1000 + 48 × 10 + 24 (Wt in Kg – 20) ml/Day = 1480 + 24 (Wt in Kg – 20) ml/Day

HEPATIC FUNCTION

The maturity of liver function is somewhat incomplete during the birth at term.The ability to detoxify the drugs and the carbohydrate metabolism system in the liver are both poorly developed during birth. But, the capability of synthesis of albumin and coagulation factors are normal at birth. By the 6 weeks of age, the enzyme systems of liver function develops as per the adult levels, though they are not induced (stimulated) by agents which they metabolise. The conjugation reactions are often impaired in the neonates, resulting in jaundice. Because of the low glycogen stores and hepatic immaturity, hypoglycaemia (defined as blood glucose level of 30 mg/dl or less) in a term baby is common. In low birth weight or premature babies, hypoglycaemia (defined as blood glucose level 20 mg/dl or less) is more common. The condition of hypoglycaemia is usually without symptoms, unless the level is very low when the apnoeic attacks or convulsions may occur. Hypothermia also causes hypoglycaemia and vice versa. The plasma levels of albumin and other plasma proteins (necessary for binding of drugs) are low in term newborns and even more low in premature infants. This is responsible for the greater level of free drug in the plasma and neonatal coagulopathy (e.g hence the need for vit K at birth). As the infant gradually grows, the function of the liver matures in two ways: (i) The enzyme system slowly develops. (ii) The hepatic blood flow increases delivering more blood to the liver.

Table 25.11: Some important parameters of a newborn weighing 4 Kg

Heart rate	120-140 minutes
Mean blood pressure	70 mm of Hg
Respiratory rate	35-40 /minutes
Tidal volume	16 ml
Alveolar ventilation	400 ml/minute
Hb concentration	18-20 gm/100 ml
Urinary output	20-30 ml/Kg/24 hours
Fluid requirement	100 ml/Kg/24 hours

Hypocalcaemia

This condition commonly ocurrs during the first 2 days of life and this is mainly due to the immaturity of parathyroid glands and high phosphate content of some milk formulae which are usually marked. Nonspecific neurological signs, such as irritability causing tetany or convulsions etc, due to the low level of blood calcium is usually treated by intravenous infusion of 2% solution of calcium gluconate at the dose of 5 mg/Kg/hour.

GI System

Gastric secretion begins from the second trimester of pregnancy or 16 weeks of intrauterine life. Gastric pH is alkaline at birth. Then, it decreases approximately to pH 4 by 8 hours after birth. On the second day of life, the gastric pH reaches within the range of an adult. Till 4 to 5 months of age after birth, coordination between the respiration and swallowing does not develop. So, it frequently causes gastro-oesophageal reflux, laryngeal aspiration and coughing. The upper intestinal developmental abnormalities often manifest as vomiting and regurgitation, but the lower intestinal developmental abnormalities manifest as distension of abdomen and failure to pass meconium. Any developmental anomaly of the gastrointestinal tract manifests as early as 24 to 36 hours after birth.

CENTRAL NERVOUS SYSTEM

The anatomical developments of nervous system in a newborn are complete at term. But the functional development of nervous system, including myelination, synaptic connections, synthesis of neurotransmitters, etc, continues for 2 years after the commencement of extrauterine life. The cranium of the newborn is soft and pliable. It has many nonfused cranial sutures, two open fontanels (the posterior fontanel closes by 6 to 9 months and the anterior fontanel closes by 18 months of postnatal life), poorly developed cerebral cortex, fragile subependymal blood vessels, a spinal cord that ends at L_4, etc. All these peculiarities that differ from adult's CNS have important implications in the management of paediatric anaesthesia. Water is the predominant constituent of the neonatal and infantile brain tissue. Then, due to more and more myelination and dendritic proliferation water content of the brain tissue of the paediatric group of patient gradually decreases and the fat content increases, throughout the infancy and childhood. The modern inhalational anaesthetic agents are less soluble in water than fat. So, their partition coefficient is lowest in premature and newborn babies. This gradually increases with the passage of time after birth and this is due to the decrease in the concentration of water as body constituent. This explains the more rapid wash-in (induction) and washout (recovery) of inhalational anaesthetic agents from the brain tissue of the neonates and infants, when compared to adults and hence the altered requirements of it for this age group. The blood-brain barrier is immature and more permeable in the neonates and infants. So, barbiturates, opioids, antibiotics, bilirubin etc. cross this barrier more rapidly. In asphyxiated neonates and also in preterm babies, the autoregulation of cerebral blood flow is compromised, i.e. the cerebral blood flow varies directly with the systemic mean arterial pressure. But, still it is autoregulated over a wide range of change in arterial blood pressure in healthy neonates and infants. The neuro-endocrine axis of stress for pain and surgery, and the mechanism responsible for perception of noxious stimuli are well developed in neonates and infants like the adults. So an inadequate level of analgesia and anaesthesia in the perioperative period can result in marked stress response and its consequences in this paediatric group of patients.

PHARMACOKINETIC AND PHARMACODYNAMIC STATUS IN PAEDIATRIC PATIENTS

The pharmacodynamics of different drug in paediatric patients differ from that of the adults in following aspects. These are :

i. Composition of the body fluids and tissue, relative difference in tissue volume and solubility.
ii. Cardiac index and distribution of CO to different tissues.
iii. Protein-binding capacity of the blood.
iv. Maturation of blood-brain barrier.
v. Functional maturity of liver and kidneys.

In neonates and infants the total body water content (due to the large extracellular fluid and large blood volume) is disproportionately higher. Then, it gradually decreases with increasing age and this is due to the increase in fat and muscle content in body. So, the water-soluble highly ionised drugs have a larger volume of distribution and requires a larger initial dose on a weight basis in neonates and infants to achieve the desired blood level, e.g. succinylcholine. In premature babies and neonates, there is much less fat and muscle tissue than the adults. So, the drugs which depend on redistribution into fat and muscle for termination of their action (e.g. thiopentone and fentanyl) has a longer duration of action.

Thus, in general when compared to an adult, the potency of many drugs is greater in neonates and infants, requiring a lower does but this potency is lesser in children, requiring a higher dose and vice versa. Similarly, many drugs have a prolonged elimination half life in neonates and infants requiring a lower dose, but shorter half life in children over 2 years requiring a higher dose than an adult. This difference gradually equalises, as the children march towards their adulthood.

In premature babies and neonates, there is lower plasma concentration of albumin. Therefore, the ability of albumin to bind with drugs is also lower than in an adult. So, most of the IV drugs in these group of patients remain in a free-active form, requiring a lower dose. The concentration of α_1 acid glycoprotein which is the major binding protein in plasma for opioids and

local anaesthetics is also lower in paediatric patients, resulting in exaggerated and prolonged actions of these two groups of drugs in this age group of patients.

At birth the blood-brain barrier is immature and it gradually matures with increasing age. Again, the neonate's brain receives a large proportion of CO than the adult brain. So, the brain is exposed to more drugs and the concentration of drugs in the brain is higher in neonates and infants than in adults.Thus, it explains why narcotics should be used with caution and in reduced amounts in this age group of patients (Fig. 25.5).

In older children the renal functions reach an adult level by the age of 3 months and by that time the clearance of most of the drugs by kidney reaches the adult values. The activity of the liver function reaches the adult value by 6 weeks after birth. But, the volume and the weight of liver and kidney is disproportionately more than an adult, and hence receives more percentage of CO. This explains why most medications have a shorter half-life in children older than 2 years than in neonates and adults. In general, most medications will have prolonged elimination halflife in premature and term infants, shorter halflife in children and again prolonged of half-life in those approaching adulthood.

Some special characteristics of the pharmacodynamics of children during inhalational anaesthesia are:

i. Higher alveolar and minute ventilation (due to high respiratory rate) in relation to FRC.
ii. High CI. i.e. high cardiac output in relation to body weight, increases the rate of equilibrium of anaesthetic agents in the tissues.
iii. Preponderance of vessel-rich tissues (e.g. brain) and greater proportional distribution of CO to these vessel-rich organs.
iv. Reduced water solubility of inhaled anaesthetic agents in blood, i.e. blood/gas coefficients of volatile anaesthetics are lower in neonates and infants than in adults. All these cause alveolar and brain concentration of inhalational anaesthetic agents to increase and fall rapidly.

This increased rate of equilibration in neonates and infants correlates well with the earlier development of cardiovascular side effects and explains why induction and recovery by inhalational anaesthetic agents are more rapid in children.

MAC values of anaesthetic agents change with age. It is lower for premature infants and increases to a peak value at the age of 3 months. Then, it gradually declines again, until the adult value is reached. So, infants are known to have a greater anaesthetic requirement than the older children and adults. Hence, infants are in a precarious condition between the higher requirement of inhaled anaesthetic agents (say, for endotracheal intubation) and anaesthetic overdose (from cardiovascular standpoint). Use of narcotics and muscle relaxants usually widen this gap.

The blood pressure of neonates and infants tends to be more sensitive to volatile anaesthetics agents. This is probably because of the incompletely developed compensatory mechanisms (e.g. vasoconstriction and tachycardia) and an immature myocardium that is very sensitive to myocardial depression.

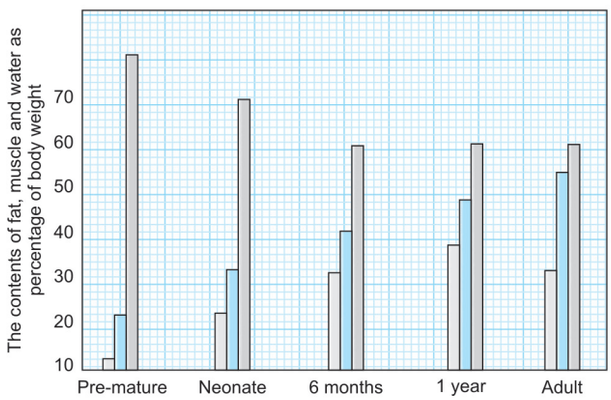

Fig. 25.5: Changes in the body composition from a premature neonate to an adult.The high water content in the body of the premature neonate causes a large volume of distribution of water soluble drugs and thus an increase in the dose requirement. Whereas a low fat and muscle content provides less redistribution of fat soluble drugs and hence prolongs their duration of action (as their effects are terminated by the redistribution of water)

VARIOUS ANAESTHETIC AGENTS USED IN PAEDIATRIC ANAESTHESIA

Volatile Anaesthetic Agents

Halothane

Although the use of halothane in western countries has declined gradually, but is still the gold standard volatile anaesthetic agent for induction of anaesthesia in the paediatric patients in most of the other underdeveloped countries, due to its least pungent odour (it is less pungent than sevoflurane). It also allows a very smooth induction, maintenance and emergence from anaesthesia. The low blood-gas solubility coefficient (2.3) of halothane and its high potency also permits a rapid onset, as well as a rapid recovery from anaesthesia. But, many anaesthetists now consider sevoflurane as the gold standard for this purpose. Airway related problems like coughing, laryngospasm, secretions, etc. occur less frequently with halothanes and sevoflurane than with other volatile anaesthetic agents, such as: enflurane, isoflurane and desflurane. Thus, halothane like sevoflurane is the anaesthetic agent of choice for induction by mask with airway problems in paediatirc group of patients.

As most vaporisers allow high concentration like 5 × MAC of any volatile anaesthetic agent to be administered if needed, so it can be given with almost 100% O_2 without any N_2O. This is very helpful in children with an airway problem. The potency of halothane varies with age. In neonates, the MAC value of halothane is about 0·9%. But, it increases rapidly to a maximum of 1.2% at 6 months of age and, thereafter, declines gradually to the adult value of 0·8%. The lower MAC value of halothane in neonates in comparison to infants is due to the immaturity of CNS in neonates. The higher value of MAC in infants compared to older children and adults is due to the increase in brain water content in the previous group of patients. Prolonged duration of action of halothane than the other newer volatile agents (sevoflurane, desflurane) makes it simetimes specially useful in paediatric anaesthesia, as the plane of anaesthesia does not quickly lighten during intubation or instrumentation of airway.

Halothane depresses the myocardium, reduces the heart rate and decreases the CO. The hypotension produced by halothane is primarily due to its direct myocardial depression effects and bradycardia. It is, therefore, prudent to give an anticholinergic, prior to halothane administration. Another concern with halothane is that it sensitises the myocardium to exogenous and endogenous catecholamines, causing arrhythmia. But, most arrhythmias associated with halothane in paediatric anaesthesia is due to either hypoxia, hypercarbia or inadequate level of anaesthesia. Thereafter, a prudent paediatric anaesthetist must controls hypercarbia, prevents hypoxia and maintains adequate level of anaesthesia. The maximum recommended dose of epinephrine with local anaesthetic solutions during halothane anaesthesia is 5 to10 µgm/Kg. The effect of LA agent is also aggravated in paediatric anaesthesia by hypercarbia, and an inadequate level of anaesthesia.The potent myocardial depressant effect of halothane can have a profound effect on neonates and children with congenital heart diseases. It is also responsible for the occasional inability to give sufficient concentration of halothane to critically ill patients to provide anaesthesia without inducing severe hypotension. In these circumstances, the smaller concentrations of halothane and liberal doses of short acting newer narcotics generally provide a better response.

Approximately, 20% of the absorbed halothane is metabolised in liver, mainly by oxidation and produce its higher degree of metabolites. This higher degree of metabolism in liver appears to be an important factor for the aetiology of halothane hepatitis. So, repeated administration of halothane within a period of less than 3 to 6 months may be associated with hepatic dysfunction and occasionally with fulminant hepatic failure. Though the exact mechanism of this hepatitis induced by halothane is not known, but it is speculated that the oxidative metabolites of halothane acts as an antigen and are responsible for this hepatitis. These oxidative hepatic metabolites of halothane are poorly developed in children and this explains the extreme rarity of halothane-induced hepatitis in paediatric patients, though the incidence of halothane hepatitis in adults when exposed to the drug is 1:10,000 to 1:30,000. However, if a child needs a second anaesthesia within 3 to 6 months of the first halothane anaesthesia, then a risk-benefit assessment has to be undertaken (Table 25.12).

Isoflurane

Isoflurane is one of the important agent in the series of halogenated volitle ether compound and chemically it is a halogenated methyl ether. It was originally developed in the place of ether in order to improve its molecular stability and also to reduce its metabolism in liver, when compared to halothane. The metabolism of isoflurane in liver is about 1/100th of that of halothane (0·2%) and therefore there is no report of hepatotoxicity in children.

Like ether, isoflurane has an irritant and pungent odour. Thus, it is associated with an increased incidence of airway problems, such as: coughing, secretions, laryngospasm, etc. during induction, maintenance (with or without muscle. relaxant), and recovery from anaesthesia. So, despite the low blood-gas solubility coefficient (1.4) of isoflurane, when compared to halothane which dictates a rapid induction and recovery from anaesthesia, the speed of induction of anaesthesia by this agent is significantly lower in clinical practice. Recovery characteristics of isoflurane is poorer than halothane. But, the advantage of isoflurane over halothane is that an equipotent concentration of isoflurane produces similar reduction of blood pressure, without reducing the heart rate and myocardial contractility like halothane. The

Table 25.12: Physical characteristics and physiological effects of volatile anaesthetic agents

	Ether	*Halothane*	*Sevoflurane*	*Isoflurane*	*Desflurane*	*N_2O*
Odour	Most pungent	Sweet	Minimum pungent	Markedly pungent	Markedly pungent	Nil
MAC	2	1.2	2.5	1.9	9.9	105
Blood gas partition coefficient	12	2.1	0.7	1.2	0.4	0.47
Myocardial depression	↑↑	↓↓	↑↓	↓	↓	↓
Vdilation	↑↑	↓	↓↓	↓↓	↓↓	↑
Respiratory depression	↑	↓	↓↓	↓↓	↓↓	Nil
Rate of metabolism (%)	4	20	2	0.2	0.02	Nil

reduction of arterial blood pressure during isoflurane anaesthesia is due to the decrease in peripheral vascular resistance, rather than myocardial depression (like halothane). This suggests that despite similar reduction in BP, isoflurane is associated with greater cardiovascular reserve than halothane, especially in neonates, infants and children where heart rate and myocardial contractility is more important to maintain CO.

Like halothane, the MAC value of isoflurane also varies with age. It is about 1.6% in neonates, 1.9% in infants (1 to 6 months) and declines gradually to approximately 1.2% in adults.

Sevoflurane

Like isoflurane, sevoflurane also belongs to the series of halogenated volatile ether anaesthetics agent, but it is halogenated solely by fluorine. The presence of only fluorine reduces the solubility of sevoflurane in the both fat and blood. Thus, this reduces the anaesthetic potency of sevoflurane, while increases the rate of uptake and elimination. So, as an anaesthetic agent, it has the property of causing very rapid induction and recovery, due to its very low blood-gas partition co-efficient (0.68) but is a less potent volatile anaesthetic agent. The eye lash reflex is lost within 60 to 90 seconds after beginning of administration of sevoflurane at 5-6%. The blood-gas partition co-efficent of desflurane is 0.42, which also suggests that induction of anaesthesia by desflurane should be more rapid than sevoflurane. But this not so true, because the desflurane is also very irritant to the upper airway, causing breath holding, cough, laryngeal spasm, etc. just like isoflurane which results in a delayed induction.

Sevoflurane's smell is least pungent (but according to some, halothane is least pungent) than all the other currently available volatile anaesthetic agents. So, higher concentrations of sevoflurane upto a maximum of about 8% can be given to the paediatric patients without cough, increase in secretion, breath holding, laryngeal spasm and other airway problems. There is little to be gained by adding N_2O with sevoflurane during induction, as the MAC sparing effect on sevoflurane is not as great as with other agents. The MAC value of sevoflurane also changes with age. In neonates it is 3.3%, in infants it is 2.5% and in adults it is 2%. The incidence of cardiac depression, bradycardia and arrhythmias are minimal during induction and maintenance of anaesthesia by sevoflurane than halothane. So, all these favourable points of sevoflurane makes it the anaesthetic agent of choice for induction and maintenance in paediatric patients. But only the higher cost of sevoflurane restrains its use and this economic consideration dictates that sevoflurane should mainly be used for induction, followed by other cheaper halogenated agents such as halothane, isoflurane, etc. for maintenance.

The other areas of concern with sevoflurane during anaesthesia, regarding its lesser safety are: higher rate of metabolism of sevoflurane in liver which is about 2% (isoflurane 0.2%) and its instability with sodalime. It is found that after 60 to 90 minutes of anaesthesia with sevoflurane, the peak concentration of fluoride ion in plasma rises from 1/3 to 2/3 of the proposed nephrotoxic level (50 mmol/litre). With sodalime sevoflurane also produces a compound A, which is nephrotoxic and is mainly found during the use of circle absorber system with lowgas-flow anaesthesia (0·5 to 1 litre/minute, in experimental animals). But, fortunately the formation of compound A in humans is much lower than in the experimental animals with the above mentioned flow and there is no reported cases of nephrotoxicity in humans. So, the use of sevoflurane with sodalime in low-flow circle system is still debatable, but not totaly condemned (above 2 litre/minute of fresh gas flow).

Desflurane

Desflurane is another halogenated volatile ether anaesthetic agent, where a single chlorine atom of isoflurane is replaced by fluorine. So, like isoflurane it has a markedly pungent odour and is unsuitable for induction of anaesthesia, due to high incidence of airway complications such as laryngospasm, cough, increased secreion, etc. Blood-gas partition coefficient of desflurane is lowest (0.4) among all the inhalational anaesthetic agents (N_2O − 0.47). Thus, the induction and recovery is fastest with desflurane when compared to that of other inhalational anaexthetic agents. The drug is stable in sodalime and the haemodynamic responses are similar to that of halothane. But, unlike halothane the metabolism of desflurane in liver is very minimum which is approximately 0.02% (halothane 20%) and so have no incidence of hepatotoxicity. This advantage clearly sets it apart from the other currently available potent volatile anaesthetics agent. The MAC value of desflurane also changes with age such as in neonates it is 9.2%, in infants it is 9.9% and in adults it is 6%. As desflurane is stable in sodalime and provides a rapid recovery, so it is also a suitable agent for maintenance of anaesthesia in paediatric patients, using close circuit with sodalime. But, its high cost bars its use which can be mitigated by the use of low-flow rates in a circle system.

The rate of emergence from anaestheisa is fastest, following desflurane and sevoflurane. But, both the agents are associated with an increased incidence of agitation or delirium after rapid emergence, particularly in young children. So, many anaesthesiologists switch over to either isoflurane or halothane for maintenance of anaesthesia, following an induction by desflurane or sevoflurane.

Nitrous oxide

N_2O is a very less potent (MAC 105%), non-irritant, non-inflammable, sweet smelling inhalational anaesthetic agent. Due to its low potency, it is used as an adjunct with other potent anaesthetic agents and is not used as a sole anaesthetic agent. It is

very stable with little biotransformation and produces rapid induction as well as recovery, due to its low blood-gas partition coefficient (0.47).

At the equipotent anaesthetic concentrations, it is half as potent as halothane in depressing the myocardium. So, in premature babies and neonates the N_2O should not be used. In such cases, air may be substituted as a carrier gas for O_2 and other inhalational agents. N_2O also should not be used in some paediatric surgeries such as bowel obstruction, diaphragmatic hernia, lobar emphysema, eustachian tube obstruction, etc. and the cause of which is given in relevant chapter.

Intravenous Inducing Agents

All the commonly used intravenous inducing agents, like thiopentone, propofol, benzodiazepine, ketamine, etc. can also be safely used in paediatric group of patients.

Thiopentone

It produces smooth induction of anaesthesia in one arm-brain circulation time and the termination of effect occurs through distribution and redistribution of it in the muscle, fat and different tissue compartments. Termination of effect of thiopentone does not occur through quick metabolism like propofol, but gradually accumulates in different body compartments with increasing doses. So, it cannot be used as a continuous infusion for maintenance of anaesthesia and should be used very cautiously in premature neonates and malnourished infants who have less muscle and low fat stores.

The dose of thiopentone varies with age. In neonates the dose is only 3.5 mg/Kg. But it increases rapidly to 6-7 mg/Kg in infants and then it again declines gradually throughout the childhood to an adult value of 4 to 5 mg/Kg. The increased requirement of thiopentone in infants and early childhood is due to the increased cardiac output which reduces the first-pass concentration of thiopentone arriving at the brain. The reduced requirement of thiopentone in neonates is explained by the decrease in plasma protein binding capacity of them. The induction doses of thiopentone also can be reduced by 50%, with the use of other different sedative premedications. The most important drawback of thiopentone in paediatric use is its cardiovascular and respiratory depression effect. The cardiovascular depression effect of thiopentone includes reduction of myocardial contractility and it brings down the arterial blood pressure by about 15-20%. So, it should be avoided in paediatric group of patients who are dehydrated, have significant amount of blood loss or have heart failure. The other side effects of thiopentone are hiccup, cough, laryngospasm, etc.

Propofol

It also produces a rapid and smooth induction of anaesthesia in paediatric age group of patients with low incidence of serious side effects. Chemically, it is an alkyl phenol compound and marketed as 1% emulsion in a white soyabean oil base with egg phosphatide and glycerol. Like thiopentone, it is highly lipophilic and protein-bound without any analgesic properties. The dose requirement of propofol for paediatric patients is higher than adults. This is because the volume of central compartment which is responsible for distribution and redistribution of propofol is 50% larger than adult and the clearance rate of it is 25% higher than thiopentone.

The beauty of propofol in paediatric anaesthesia lies in its use as both for induction by bolus doses and maintenance by continuous infusion. Propofol is now licensed for use as an induction agent in children over 1 month, but not for use as an infusion below 3 years. Till now, the TCI (target control infusion) pump for propofol is not configured for paediatric use like that of adult use. The children upto 8 years may require almost double the adult dosage (3 to 5 mg/Kg) of propofol. The dose of propofol for continuous infusion is 100 to 300 µg/Kg/minute. Pain may occur during bolus injection of propofol for induction. But, this can be minimised by using a larger vein, injecting the solution slowly and administering IV lignocaine in the dose of 0.2 mg/Kg before the administration of propofol. There is reduction in heart rate with propofol, particularly below 2 years of age and this is due to the attenuation of baroreceptor reflex. There is also a larger fall in blood pressure, compared to equipotent doses of thiopentone. Respiratory depression and the incidence of apnoea is greater with propofol than thiopentone, although laryngeal mask insertion is easier due to more depression of the laryngeal reflexes by propofol.

Propofol is not contraindicated in epilepsy, though involuntary movements may be seen during induction with propofol. They are usually caused due to the inadequate induction dose and early stimulation. Because of its prompt wake-up characteristic, antiemetic effect, usability as continuous infusion and low incidence of serious side effects, propofol is gradually displacing the short acting barbiturates, as the induction agent of choice for paediatric out patients. It is particularly useful for maintenance of sedation during radiotherapy, or in children undergoing a radiological diagnostic procedures. Although not common in paediatric anaesthetic practice, still the technique of TIVA using propofol is very useful in children who are prone to malignant hyperthermia or children with history of porphyria. Strict aseptic technique is recommended during handling of propofol, as contamination of its intralipid and preservative free preparation produces sepsis.

Propofol is not recommended for prolonged maintenance of sedation of critically-ill paediatric patients in the NICU (neonatal intensive care unit). Because, this drug has been associated with higher rate of mortality in NICU, compared to other agents and a controversial 'Propofol

Infusion Syndrome' which is responsible for there NICV deaths has been described. The essential features of this syndrome are metabolic acidosis, haemodynamic instability, hepatomegaly, rhabdomylosis, multiorgan failure, etc. Although seen primarily in the critically ill children, but this rare syndrome has also been reported in adults and in patients undergoing long-term propofol infusion (> 48 hours) for sedation at high doses (> 5 mg/Kg/hour).

Ketamine

It is also very helpful as an inducing and an analgesic agent for paediatric anaesthesia. Intravenous administration of ketamine in the doses as low as 1 to 2 mg/Kg produces adequate analgesia and sedation. The lack of cardiovascular depression effect of ketamine allows it to be used for induction of anaesthesia in very sick children. So, it is widely used as a sole anaesthetic agent in many developing countries. The dose of ketamine should be reduced in neonates, and this is because of the reduced clearance and prolonged metabolism of it in them. Emergence phenomenon from ketamine anaesthesia are less common in children, especially when it is used in combination with midazolam. But, the incidence of PONV and salivation is higher with ketamine than other inducing agents. Increased production of both bronchial and salivary secretion by ketamine is a major side effect, and usually requires prior administration of an antisialogogue.

During ketamine anaesthesia, even though the upper airway reflexes are relatively well preserved, but still aspiration of gastric contents may occur and so it should not be used as a sole anaesthetic agent for infants with full stomach or with hiatus hernia. Emergence phenomenon from ketamine anaesthesia is accompanied by hallucination and unpleasant dreams, but this is not so well marked in paediatric patients, as children are almost always dreaming. The current available formulation of ketamine in the market is a racemic mixture of the S (+) and R (−) enantiomers. Though, it is possible to separate the two enantiomers, but there is no such commercially viable technology which can separate them for their iosolated clinical use. The aim to separate these two isomers of ketamine and to make it commercially available is : the S (+) enantiomer of ketamine is twice potent, recovery is quicker and the incidence of emergence reaction is also low in comparison to the R (−) enantiomer of it.

The contraindications for the use of ketamine in paediatric patients include : presence of active URTI, increased ICP, open globe injury, seizure disorders, etc.

Narcotics

Due to the immaturity of blood-brain barrier in neonates and infants, the high lipophilicity and lower clearance of newer narcotics and its congeners have made the neonates and infants below 6 months of age very sensitive to this group of drugs. So, narcotics should be used with caution in premature neonates, term infants and infants below 6 months who are not in the intensive care unit and whose ventilation need not be controlled postoperatively. Infants older than 6 months probably have a response to narcotics similar to that of adults.

Morphine

It is least lipophilic than meperidine and all other members of this group of drugs. So, the entry of morphies in CNS is mainly controlled by the maturity of the blood-brain barrier. Hence, in an immature blood-brain barrier morphine enters the CNS most readily than all other narcotics. In contrast, meperidine is more lipophilic than morphine and therefore is able to cross the blood-brain barrier more readily, but only after its maturation because its penetration in CNS does not depend on the maturity of blood-brain barrier, but depends on the lipophilicity of this drug. Thus, the effects of an immature blood-brain barrier would be much less significant for meperidine than for morphine, but lipophilicity would be much more significant for meperidine than morphine. When the question of entry of these two drugs in CNS will arise. On the other hand, in case of morphine this is reverse. Meperidine may not be appropriate for long term administration in paediatric group of patients. This is due to the accumulation of its active and toxic metabolites such as normeperidine.

Morphine and other narcotics (except remifentanil) are metabolised mainly in liver and their actions are terminated by conjugation of their metabolites with glucuronide. But other than metabolism in liver which is responsible for the termination and short duration of action, the very high lipid solubility of some other newer narcotics have a shorter duration of action and it is due to their rapid distribution and redistribution in the tissues, like thiopentone and propofol. So, deficiency of the microsomal enzymes responsible for glucuronide conjugation may be responsible for prolongation of the clinical effects of these oldernarcotics like morphine and others whose termination of actions depend only on the conjugation of their metabolites with glucoronide in neonates and infants. The newborns and the infants have a lower clearance rate of morphine. Therefore, a standard dose will result in higher plasma values due to longer elimination half life. In spite of all these disadvantages, still morphine remains the most commonly used opioid for the management of severe pain in children and is the gold standard with which other potent analgesics are compared. In neonates and infants who are below 6 months old and undergoing relatively brief procedures (near about 1 hour), a single dose of 25 µg/Kg of morphine usually provides adequate intraoperative and postoperative analgesia. After a more prolonged and complex surgery, the postoperative analgesia is supplemented with a continuous infusion of morphine of 5 to 10 µg/Kg/hour. For children and infants above 6 months, the adult

doses of morphine are recommended. For continuous infusion or patient-controlled analgesia, due to its long half life morphine in a loading dose of 100 µg/Kg/hour is used first (if not used intraoperatively, which is usually done), followed by a maintenance dose of 25 µg/Kg/hour.

Fentanyl

It is a synthetic, highly lipid-soluble pure opioid agonist, and is 100 times more potent than morphine. Because of its high lipid solubility and a large volume of distribution, a single dose of fentanyl has a more rapid onset and a shorter duration of action than morphine. The termination of effects of a low bolus dose of fentanyl is due to redistribution in peripheral tissues, whereas the termination of effects of a high or continuous dose of fentanyl depends on its elimination through the liver and kidney when the redistribution site is saturated. So, if fentanyl is used as an infusion or in multiple doses, then progressive saturation of the peripheral tissues by it lead to a prolonged duration of action of it as clearance of it by metabolic process in liver is slow like morphine.

Due to the rapid onset and a brief duration of action, fentanyl now is the most commonly used narcotic in paediatric anaesthesia in short bolus doses, but not by infusion. As fentanyl is more lipophilic than morphine and meperidine, so its CNS action does not depend on the maturity of blood-brain barrier. The maturity of blood-brain barrier dictates the entry of water soluble (hydrophilic) narcotics only, such as morphine. Immature blood-brain barrier of neonates and infants permits only the entry of hydrophilic morphine, but not lypophilic fentanyl. Thus, this explains fentany's lesser sensitivity in premature infants and neonates than the older ones. The volume of distribution of fentanyl in infants is similar to that of adults, but the plasma clearance and elimination half life is greater. This is due to the high hepatic blood flow in infants than adults. The dose of fentanyl producing an anaesthetic state, also produces a stable cardiovascular response. Fentanyl can be used in the dose of 2 to 10 µg/Kg with other anaesthetic agent mainly volatile agent in a surgery where postoperative ventilation is not needed. Usually, it is administered in the dose of 1 to 2 µg/Kg at the start of anaesthesia which is followed by further bolus doses as clinically indicated, or by a continuous infusion in the dose of 1 µg/Kg/hour. Higher doses of fentanyl, such as 30 µg/Kg, can be used only in a surgery (e.g., cardiac surgery). where postoperative ventilation is mandatory or to produce a full state of anaesthesia with stable haemodynamic conditions without other anaesthetic agent mainly volatile agent. Since, the cardiac output of neonates is determined by the heart rate, fentanyl-induced bradycardia may require concomitant administration of vagolytic drugs, such as : atropine or pancuronium. Fentanyl is sometimes associated with chest wall rigidity, impairing adequate ventilation.

Remifentanil

It is the newest of all the synthetic narcotics. It is an ultra-short acting drug, and its methyl ester linkage makes the drug susceptible to metabolism by non-specific plasma and tissue esterases. The pharmacokinetic profile of remifentanil in children between 2 to12 years of age is similar to that of an adult. It has rapid distribution phases, small volume of distribution, and an elimination half life of only 2 to10 minutes. The dose of remifentanil is 1 µg/Kg, followed by infusion of 0·25 µg/Kg/minute.

Still now there is very few data regarding the use of remifentanil in neonates and infants. At present, it is not licensed for use in children under the age of 2 years (Table 25.13).

Muscle Relaxants

The use of neuromuscular blocking drugs has a definite place in paediatric anaesthesia. But the responses of these group of drugs differ markedly from those in adults. All the muscle relaxants generally have a shorter onset of action (upto 50%) in paediatric patients. This is because of the shorter circulation time than adults and it is due to increased cardiac output in proportion to body surface area in neonates and infants. In general, due to this increased cardiac output in proportion to body surface area the neonates and infants are also resistant to depolarising drugs, but sensitive to non-depolarising agents.

Succinylcholine

Because of its high water solubility, succinylcholine is widely and rapidly distributed into the extracellular fluid volume of the neonates and infants containing more water which is greater than adults. This accounts for decreased sensitivity of succinylcholine in neonates and infants than the older ones and needs higher doses in the former. So, the dose of succinylcholine required for muscle relaxation and intubation in neonates and infants is approximately twice than that of the children and adults. Thus, the dose of succinylcholine for neonates and infants is 2 mg/Kg IV and for adults it is 1 mg/Kg IV. This dose of succinylcholine will produce 95% neuromuscular block within 30 seconds which is followed by 90% recovery within 5 to 10 minutes. Children are more susceptible than adults to cardiac arhythmias, hyperkalaemia, rhabdomylosis, myoglobinaemia, masseter spasm and malignant hyperthermia after administration of succinylcholine. Succinylcholine frequently causes cardiac arrhythmia in paediatric patients, mainly when used with halothane. Sometimes, severe bradycardia and sinus arrest may follow the first dose

Table 25.13: The advantages of remifentanil

1. It is metabolised by non-specific esterases in plasma and tissues.
2. The metabolites of remifentanil are inactive.
3. Half-life of this drug is short and is independent of the duration of infusion.
4. Lack of cumulative effect.

of succinylcholine. But, it is more common after repeated bolus doses. So, atropine (20 µg/Kg) should be given IV prior to the first dose of succinylcholine in children. If a child unexpectedly experiences cardiac arrest, following the administration of succinylcholine, then immediate treatment for hyperkalaemia should be instituted. However, prolonged and heroic cardiopulmonary resuscitative efforts may also be required.

There is always a tendency to develop phase II block in neonates and infants with succinylcholine. It is also one of the most potent triggering agent for development of malignant hyperthermia. The incidence of malignant hyperthermia increases, if succinylcholine is preceded by halothane induction. Fatal cardiac arrest may also occur in a small number of patients following administration of succinylcholine. It is presumed that, these patients may have unsuspected muscular dystrophies and the drug causes massive breakdown of muscle cells causing hyperkalaemia and cardiac arrest. It is also not possible to predict this group of patients who are prone to exhibit this response. So, all these complications make the routine use of succinylcholine in paediatric patients controversy. On the other hand, succinylcholine is the only commercially available short acting muscle relaxant that provides a dependable and a very rapid onset of action. So, the present status of succinylcholine in paediatric anaesthesia is that it should only be reserved for patients with full stomach, necessitating rapid sequence intubation in emergency cases or in cases of difficult intubation or for the treatment of intractable laryngospasm causing severe hypoxia and impending cardiac arrest. For the later, intramuscular succinylcholine in the dose of 4 to 6 mg/Kg is also used if IV line is not already secured. In this situation, atropine in the dose of 20/Kg IM should be administered at the same time to prevent bradycardia. Some anaesthesiologists also advocate intralingual administration of succinylcholine (2 mg/Kg in the midline), as an alternate emergency route if IV line is not available.

In contrast to depolarizing muscle relaxants (e.g. succinylcholine), the nondepolarizing muscle relaxants show higher sensitivity in neonates and infants than children and adults. So, full neuromuscular blockade occurs at a lower blood concentration and this is true for all nondepolarizing muscle relaxants. The probable explanation of this fact is immaturity of the neuromuscular junction in neonates and infants, or the difference in the bioavailability of the drug or the lesser binding of nondepolarizing muscle relaxant with the plasma proteins whose concentration is less in neonates and infants than adults. On the other hand, the clinical significance of this sensitivity may not be great, owing to the larger volume of distribution of these nondepolarising neuromuscular blocking drugs, due to the large extracellular fluid volume in neonates and infants than adults. The immaturity of renal and hepatic function in neonates and infants also cause slower excretion of non-depolarizing drugs, and hence the prolongation of the blocking effect of these agents. Only the action of non-depolarizing drugs that are metabolized in the plasma (e.g atracurium, mivacurium) doesnot vary greatly with age. So, the specific choice of a non depolarizing muscle relaxants in neonates and infants depends on the onset of action, duration of action required and the desired or undesired side effects of the relaxant. If a prolonged action and tachycardia is desired, then pancuronium is best choice, otherwise atracurium is still the chosen one for the shorter procedures. Hoffmann elimination and ester hydrolysis of atracurium make it particularly useful in newborns and infants.

Atracurium

After a standard dose of 0·5 mg/Kg through IV, atracurium produces 95% depression of the twitch-response of voluntary muscles and intubating condition occurs within 0.9 minutes in neonates and infants. But, recovery to 10% of the control twitch height after administration of atracurium occurs with in 20 minutes. The volume of distribution of atracurium in neonates and infants is 0.18 litre/Kg in contrast to adults which is 0.14 litre/Kg. The plasma clearance of atracurium has also been found to be greater in neonates and infants (9 ml/Kg/minute) than that of the adults (5 ml/Kg/minute). The adverse effects associated with atracurium is related mainly to the release of histamine. These are probably hypotension, tachycardia and or bronchospasm. The cardiovascular changes caused by atracurium are dose related, and usually occur at doses greater than 2 ED_{95} value.

Vecuronium

Vecuronium is also chosen in paediatric patients for surgical procedures which are of longer duration and also where tachycardia is not desired. This is because vecuronium induced neuromuscular block is characterised by the lack of histamine release and marked cardiovascular stability in all the age groups of patient. It is a very long acting nondepolarising muscle relaxanat in neonates and infants than adults. Vecuronium in a standard intubating dose of 100 µg/Kg maintains over 90% neuromuscular blockade for almost an hour in neonates and infants, compared to just 30 to 40 minutes in adults.

Mivacurium

Mivacurium is another very short acting nondepolarizing muscle relaxant which offers the advantage of producing satisfactory surgical conditions for brief surgical procedures like succinylcholine. But vary rapid intubating conditions as produced by succinylcholine is not provided by it. Mivacurium has the shortest duration of action among all the currently available non-depolarising drugs and its action is terminated like succinylcholine by plasma pseudocholinesterase. So, like succinylcholine, very occasionally a patient may be cholinesterase deficient,

when its duration of action may be prolonged. In a dose of 0.2 mg/Kg IV, mivacurium provides excellent relaxation within 2 minutes. Then, 20% recovery of the twitch-response occurs after 8 to 9 minutes and spontaneous 95% recovery of twitch response occurs within 20 minutes. Mivacurium is also an ideal nondepolarising muscle relaxant which can be administered by constant infusion, since there does not appear to be any accumulation of drug. As mivacurium is structurally similar to atracurium, so it has significant histamine releasing properties, which may be evident even at therapeutic doses. So, the standard dose of mivacurium which is 0.2 mg/Kg should not be exceeded.

Rocuronium

Rocuronium has the most rapid onset of action among all the currently available nondepolarising muscle relaxants. A IV dose of rocuronium in 0.6 mg/Kg produces 90% depression of the twitch-response and an intubating condition within 30 seconds like succinylcholine, but without significant changes in blood pressure and heart rate. So, it may therefore be used as an alternative to succinylcholine, when rapid tracheal intubation is desired and succinylcholine is considered as contraindicated. Whereas, the duration of clinical effects of rocuronium following a standard intubating dose (0.6 mg/Kg) is longer and is near about 40 minutes.

Therefore, atracurium, rocuronium and vecuronium, have a short, intermediate and long duration of action, making them the most commonly used muscle relaxants in paediatric anaesthesia.

Rapacuronium

Rapacuronium is a currently used new amino-steroid non depolarising muscle relaxant agent, is being evaluated in paediatric practice. Data suggest that its onset of action is similar to that of succinylcholine and its duration of action is comparable to that of mivacurium.

The general rule for the use of non depolarising muscle relaxants in neonates and infants is the careful titration of dose due to extreme variability of response. So, the intitial dose of nondepolarising muscle relaxants should be one-third to one-half of the calculated total dose for the paediatric patient. The antagonism of neuromuscular blockade in all the neonates and small infants is mandatory, even if recovery is complete clinically. This is because any compensatory increase in the work of breathing due to residual neuromuscular block may cause fatigue and respiratory failure. The useful signs of reversal of neuromuscular blockade in neonates and infants are the ability to lift the legs and arms and recovery of the train-of-four response to peripheral nerve stimulation (Table 25.14).

PAEDIATRIC ANAESTHETIC RISK FACTORS

The paediatric anaesthetic risk is best assessed from the database of a register, made by an investigating group. This register was made on reports, based on approximately one million paediatric anaesthetic cases, administered since 1994. From this register, all the cardiac arrests and deaths were investigated and analysed to find out the possible causes during anaesthesia with these incidents. It was found that approximately 300 cardiac arrests had occured, and among them 150 arrests were directly related to anaesthesia. Thus, the incidence of risk of cardiac arrest in paediatric anaesthesia is 1·5 in 10,000 cases and among these the mortality rate is 30%. Another 6% patients suffered from permanent injury. But, the majority 64% patients either did not suffer from any injury or only temporary injury. It is also important to note that age is responsible for 50% of all the anaesthesia related cardiac arrests. Among them less than one month age babies, i.e. neonates have the highest risk. About 40% babies with a physical status of ASA 3-5, suffered anaesthesia-related cardiac arrest. So like adults, the major predictors of mortality in cases of paediatric anaesthesia are: age, ASA physical status, and emergency surgery.

Among all the cardiac arrests, 80% occured during the induction of anaesthesia and is most frequently preceded by: bradycardia, hypotension, and low SPO_2 levels. The most common cause of cardiac arrest during induction is cardiovascular depression due to medications. Among the medicines, halothane alone or in combination with other drugs is believed to be responsible in 60% of cases. In another 10% cases, inadvertant intravascular injection of the local anaesthetic agent during

Table 25.14: Guidelines of doses of muscle relaxants and their antagonists in paediatric patients

Agents	*Dose for tracheal intubation ($2 \times ED_{95}$) (mg/Kg)*	*Maintenance dose (mg/Kg)*	
		N_2O/O_2	*Halothane*
Succinylcholine	2	–	–
Atracurium	0.5-0.6	0.3	0.2
Rocuronium	0.6-0.7	0.4	0.3
Pancuronium	0.1-0.15	0.08	0.06

Edrophonium	0.3 mg/Kg + Atropine (10 - 20 µg/Kg)		

caudal injection (still following a negative aspiration test) is blamed. In about 50% cases of cardiac arrest in paediatric anaesthesia, patients have cogenital heart disease. The respiratory causes for cardiac arrest is most often due to laryngospasm, airway obstruction and difficult intubation (in a decreasing order). In most cases, laryngospasm occurs during induction.

SOME IMPORTANT CONSIDERATIONS IN PAEDIATRIC ANAESTHESIA

Preoperative Assessment

A preoperative visit to an anaesthetic clinic and preoperative preparation for surgery of children in all ages by the anaesthetist, is very crucial. Prior to surgery, the baby's condition should be properly evaluated to determine (i) any abnormality in the CVS, (ii) the degree of respiratory distress, if any, (iii) airway problems in respect to intubation, (iv) metabolic disturbances, (v) temperature variations, (vi) the extent of planned surgical procedure matching with patient's condition, etc. Among these a detailed history and physical examination of the patient, with special emphasis on the assessment of cardiovascular and respiratory functions is most important. The neonatal history should also include problems during delivery, the severity of prematurity, the history of admission in intensive neonatal care unit after birth, etc. The infants born prematurely, especially those with history of apnoeic periods are more likely to develop apnoea following anaesthesia. So, they should not be accepted for day case procedures, until they are at least 60 weeks of gestational age. The respiratory history includes asthma, frequent colds, obstructive sleep apnoea, etc.

The cardiovascular assessment for paediatric group of patients mainly includes cyanosis, heart murmur, and whether dyspnoea is present during exercise or not. The majority of pathological murmurs are diagnosed neonatally and these children are already under the care of a cardiologist. The previously unreported murmurs were commonly heard at the age of 2 to 4 years and the majority of them were functional. Mild murmurs in a child with normal heart sounds and normal oxygen saturation, and without any limitation in exercise tolerance can be assumed to be innocent, if they are not pansystolic. Most asymptomatic patients with murmurs do not have significant cardiac pathology. Innocent murmurs may occur in more than 30% of normal children. They are usually soft, short systolic ejection murmurs and are best heard along the left lower or left upper sternal borders, without any significant radiation. The innocent murmurs at the left upper sternal border are due to the flow of blood across the pulmonary valve. Whereas, those at the lower left sternal border are due to the flow of blood from the left ventricle in to the aorta (Still's vibratory murmur). In case of any doubt, surgery should be deferred until a formal assessment has been made by a paediatric cardiologist. The paediatrician and possibly a cardiologist should carefully evaluate the patients with a newly diagnosed murmur, particularly in infancy. An echocardiogram or a colour Doppler should be obtained if (i) the patient is symptomatic (e.g. poor feeding, failure to thrive, or easy fatiguability), (ii) the murmur is a harsh, loud, holosystolic-diastolic and radiates widely or (iii) if the pulses are either bounding or markedly diminished.

The previous family history regarding anaesthesia is also important which includes malignant hyperpyrexia and prolonged apnoea caused by suxamethonium. The problems during previous anaesthesia like PONV, poor pain relief or difficult venous access are also important. The laboratory tests required for surgery depend on the severity of the existing illnesses and also the preexisting diseases (outlined from history and full clinical examination). For example, if a healthy neonate or infant is scheduled for just a minor elective surgery, such as repair of an inguinal hernia, then only a routine blood count with Hb and serum glucose estimation is needed. Some paediatric centres require no preoperative laboratory tests in healthy children undergoing minor procedures. However, obviously, this puts more responsibility on the anaesthetist, surgeon and paediatrician to correctly identify the patients who require preoperative testing or not for anaesthesia and surgical procedures. On the other hand, if the patient presents with some chronic illness or any congenital defect, then extensive investigations including complete blood count, blood biochemistry, electrolytes, coagulation profiles, etc, are required, according to the defect and surgery planned.

Mere failure to urinate within 24 hours of birth which is a very common event for a neonate usually should not direct any renal function testing. However, in the presence of other concurrent anomalies such as presence of some congenital renal anomalies then this absence of urine output should be considered as serious. In such circumstances, extensive investigations should be undertaken including serum potassium, blood urea nitrogen, creatinine, ultrasound, etc.

If children suffer from upper and lower respiratory tract infection, surgery should be delayed. The standard recommendation for this delay is 4 to 6 weeks after an episode of acute RTI, however bearing in mind that some children have frequent RTI (5 to 10 times per year). In such circumstances, each case should be dealt on the basis of its own merits, for example, whether the child has nasal discharge, inflamed tonsil, infected eardrums, fever, etc. In rare cases, the viraemic phase of illness may be associated with myocarditis. So, children who have active viral illness or children who have recently been immunized using live vaccines should not have elective anaesthesia and surgery, as these children may develop a viral myocarditis. In such circumstances,

surgery should be avoided for a week, especially following DTP and Haemophilus Influenzae Vaccination and for 2 weeks after MMR. A diagnosis of bronchiolitis and measles warrants a delay of at least 6 weeks.

However, a child with a mild cold possesses maximum difficulty in taking decisions by an anaesthetist. The history in such cases is crucial. Because it is important to decide whether the child is at the beginning or at the end of the process of URTI. A child who is apyrexial, has no chest signs and constitutionally well is probably at the end of an attack of URTI and fit for surgery too, even with a running nose. Actually, the decision to anaesthetise children with RTI remains controversial and depends on the presence of other coexisting diseases, the severity of symptoms of RTI and the urgency of surgery. If the surgery cannot be deferred, then much consideration should be given to an anticholinergic agent and branchodilator during premedication, mask ventilation, humidification of inspired gases and a longer than usual stay in the recovery room. Anaesthesia in the presence of RTI is associated with higher incidence of laryngospasm, bronchospasm, postoperative croup, pneumonia and hypoxaemia. All these are due to increased incidence of secretions and airway obstructions in the presence of RTI. These risks are increased five-folds using an LMA, and by a factor of 10 if the child is intubated. But, still some anaesthetists prefer to use ET tube considering that it is wise and easy to control the airway using an endotracheal tube which will minimise the risk of cough or laryngospasm during anaesthesia. However, generally, for minor procedures where muscle relaxants are not needed, then LMA is the better choice according to my view.

During preoperative assessment of the paediatric group of patients the anaesthetist should also keep in mind the possible intubation difficulties due to recent trauma, inflammation, tumour, etc like adult patients which are discussed in details in respective chapter. The other possible conditions and syndromes which are common to paediatric group of patients and responsible for difficult intubation should also be looked for. Patients also may present with respiratory distress which can only be alleviated by surgery and for which this surgery is proposed. These include choanal atresia, laryngeal cysts or webs, congenital diaphragmatic hernia, oesophageal atresia with or without tracheo-oesophageal fistula, pulmonary cysts producing lobar emphysema or compression of lung tissues, etc. On the other hand, patients may present with respiratory distress due to concomitant causes which are not related to the proposed surgery. But, whatever may be, the degree of this respiratory distress should always be evaluated clinically by observing the colour of mucuous membrane, the degree of intercostal and sternal recession and auscultation of the lung fields before starting anaesthesia. Radiological examination of the chest should always be undertaken in such conditions and the blood-gas status is estimated, (if needed) by using blood from an arterial puncture preoperatively. Pneumothorax, which is often present in severe cases of diaphragmatic hernia on the contralateral side (or in the cases of severe respiratory distress) should always be drained before anaesthesia by inserting a cannula into the pleural space through second intercostal space and connected to an underwater drain. Metabolic disturbances due to hypovolaemia, hypoglycaemia, acidosis, etc, should also be corrected preoperatively by the intravenous infusion of appropriate solutions.

All children should be accurately weighed after admission, because body weight is the simplest and the most reliable guide to drug doses. Haemoglobin estimation should be performed routinely. A perioperative Hb of less than 10 gm/dl does not necessarily entail cancelation of surgery, if the child is otherwise fit and the surgery is not much blood-losing. All children above 3 months of age, coming from Africa or Mediterranean countries, are likely to be the carriers of sickle-cell disease. So, they should be screened by sickle cell test and then haemoglobin electrophoresis should be undertaken, if the screening test is positive.

A nasogastric tube should always be passed in all the sick paediatric patients, because gastric distension occurs readily which may jeopardise normal respiratory function and cause regurgitation with subsequent pulmonary aspiration leading to acidosis and pneumonia (Table 25.15).

Fasting

The purpose of fasting of any patient before anaesthesia and surgery is to decrease the risk of aspiration pneumonitis from regurgitation of gastric acidic juice and asphyxia from the presence of solid food in vomitus. Aspiration pneumonitis occurs if the pH of gastric fluid is < 2.4 and the volume aspirated is greater than

Table 25.15: Some common congenital syndromes associated with difficult intubation

Syndrome	*Clinical features*
Down	Small mouth, large tongue, small subglottic area, congenital heart diseases.
Pierre-Robinson	Small mouth, retrognathia, large tongue, cleft palate, subglottic stenosis.
Turner	Short and webbed neck, narrow and high arched palate, small mandible, epicanthic fold.
Klippel-Feil	Cervical vertebral fusion, less number of cervical vertebra, rigid and short neck.
Goldenhar	Cervical spine abnormality, mandibular hypoplasia.
Treacher-Collins	Hypoplasia of the malar bone, micrognathia, coloboma, preauricular ear tags, cleft palate, malocclusion of the teeth, deformity of the middle auricles causing deafness.

0.8 ml/Kg. Neonates scheduled for surgery within 24 hours after birth are usually not fed by mouth and so they do not need any fasting protocol. But, the neonates or infants who are presented for surgery after feeding, need a fasting protocol which is extensively reviewed and different from the previous protocol. Recently, a number of studies have shown that there is no difference between the residual gastric volume and pH in children who are allowed to fast for 2 to 3 hours prior to induction of anaesthesia, and those who are allowed to fast overnight or a standard fasting for 6 hours. It is also demonstrated that fasting for more than 2 hours after oral, clear fluid ingestion does not decrease the risk of pneumonitis, if aspiration occurs. Again, the half-life of water in the stomach is only about 12 minutes which implies that 95% of ingested water leaves the stomach within 1 hour. The half-life for breast milk is about 25 minutes and that for formulated milk is 51 minutes. So, the breast milk leaves the stomach more rapidly than formulated milk. Hence, a moderate approach of allowing the children to drink clear fluid (water, apple juice, etc.) 3 hours before induction of anaesthesia has several advantages.

The advantages of allowing the children to drink clear fluid three hours before induction of anaesthesia are :

i. From psychological point of view, this approach is more human and is also more satisfactory to both the parents and children, without increasing the risk of pulmonary aspiration of gastric contents and pneumonitis.
ii. As paediatric patients have higher metabolic rate and larger body surface area / weight ratio than adults, therefore there are more chances of dehydration and metabolic acidosis in prolonged fasting. But, 2 to 3 hours fasting decreases the chances of dehydration, hypoglycaemia and acidosis.
iii. There is less chance of hypovolaemia during induction of anaesthesia.

Table 25.16: Pre-operative fasting guidelines for paediatric patients (Fasting time in hours)

Age (months)	*Clear fluid*	*Breast milk*	*Cow / formulated milk*	*Solid*
< 3	2	4	4	6
3-6	2	4	4	6
6-36	3	6	6	6
> 36	3	6	6	8

A clear fluid is defined as a fluid through which a newspaper can be read.

iv. The incidence of aspiration is very low and is reported to be approximately 1:1000 in paediatric patients. So, prolonged fasting does not necessarily decrease this risk.

However, these recommendations are only for healthy neonates, infants and children, without the risk factors of decreased gastric emptying or aspiration.

The formulated milk should be considered as solid food. So, for any form of milk other than breast the standard fasting of 6 hours or more is advised. But, there is also some evidence that infants less than 3 months may safely be given infant formula feed or cow's milk upto 4 hours, preoperatively. Infants who are breast-fed may have their last feed 4 hours prior to the anaesthetic induction. In emergency settings, e.g in a child who has sustained trauma shortly after having food, it is probably best (if possible) to wait for 6 hours before induction of anaesthesia. Clearly in this situation risk-benefit judgement has to be made, especially if the surgery is a dire emergency (Table 25.16).

Premedication

The aim of premedication in paediatric anaesthesia is to produce a calm and cooperative child before induction of anaesthesia. Premedication is also used to reduce the stress of anaesthesia and surgery and also to reduce the risk of postoperative nasusa/vomiting and behavioural disturbances. Psychological preparation is an important aspect of preoperative care, especially for younger children. So, preoperative counselling is the best form of premedication. The anaesthesiologist should avoid wearing a white coat and will explain in great details to the family and the child, how anaesthesia is administered to children and what will be done to ensure the utmost safety. The more the information the parents and the child have, the more easily they can be dealt with the stress of surgery and hospitalization. Presurgical programs, such as: videotapes, literature, booklets are also very helpful and make easy the preoperative counselling and physiological preparation. After admission in the hospital, but before anaesthesia and surgery every effort should be made to help the child to adjust the new environment by friendly interior design, availability of toys, collection of photographs, etc.

But, unfortunately, outpatients and morning-of-admission surgery, together with a busy operating room schedule often make it difficult for an anaesthesiologist to have enough time for this preoperative counselling and psychological preparation. For this reason, premedication in the form of medicine can be extremely helpful.

Sometimes, sedative premedication is required, especially in children who in spite of good preoperative counselling remains apprehensive. They include the excessively upset child, children with previous unpleasant experiences of anesthesia and surgery, and certain children with developmental delays such as with cerebral palsy, Down syndrome, etc. The preschool children are mostly at risk. They are more vulnerable to separation anxiety in a strange enviornment, but without the ability to reason himself. Older children or adolescents may request premedication. Sometimes, even when the anaesthesia and surgery are uneventful, still there may be a disturbingly high incidence of postoperative psychological problems which include: nightmares, sleeping disturbances, bed-wetting, eating disorders

and behavioural changes etc. The use of local anaesthetic cream such as EMLA, Ametop, or tetracaine gel, etc. has some advantages and reduces the necessity of sedative premedications for establishment of an IV cannula. The availability of these above mentioned topical local anaesthetic creams reduces the pain of venipuncture and greatly facilitates the intravenous induction. Emla cream is a eutectic mixture of 5% lignocaine and 5% prilocaine in a 1:1 ratio. It should be applied at least 40 to 50 minutes before any needle prick and can produce vasoconstriction. Emla cream should be avoided in children below 1 year and this is because of the risk of methaemoglobinaemia from absorbed prilocaine, due to the reduced levels of methaemoglobin-reductase in infants. Ametop is a 4% gel formulation of amethocaine. It is licensed to be used above the age of 4 weeks and has the vasodilating property. It has a shorter onset of action which is about 30 minutes and a prolonged duration of action which is about 4 hours. But, it has a higher incidence of allergic reactions.

Sedative premedication should not be used at the expense of respiratory depression. Sedative premedication is contraindicated (not absolute) in patients with respiratory insufficiency or airways obstruction. In some surgeries like cleft palate, neurosurgery, tonsillectomy, etc. sedative premedication are usually not used, because it delays the recovery of laryngeal or other reflexes which is not at all desirable for these type of surgeries for the paediatric group of patients. But this rule is not mandatory. However, much less sedation is required if the child has been carefully prepared by preanaesthetic counselling.

Sedative premedication is not used in neonates and infants usually below 6 months of age, as separation anxiety is not a concern in this age group and this group of patient is more sensitive to the respiratory and cardiovascular depressant effects of the sedative agents. But, this protocol is not followed by some group of anaesthesiologists, because the time interval between the last feed and the scheduled timing for surgery cannot be controlled properly in a busy hospital. So, the children usually cry and disturb their parents. Hence, to reduce the anxiety of parents some anaesthetists break the protocol and premedication is given to make the baby sleep.

Atropine or glycopyrrolate is sometimes used as an antisialagogue during premedication, because increased secretion in narrow paediatric airways may cause airway obstruction and respiratory distress in the paediatric group of patients. Though the vagal tone is low in neonates, but in some centres atropine is given IV routinely during induction of anaesthesia, particularly if suxamethonium and halothane is used. But, atropine is also omitted in some centres because of low vagal tone, especially in the newborns and also because of the danger of increasing the viscosity of the bronchial secretions, particularly in babies with dehydration or mucoviscidosis which may lead to the plugging of the bronchioles or even the main bronchi with inspissated mucus. They also do not use atropine routinely, because modern anaesthetic agents do not require the antisialogogue (anticholinergic) agent due to their minimal irritating and secreting effects. The absorption of orally administered atropine (40 µg/Kg) is variable. So to ensure efficacy atropine (20 µg/Kg) or glycopyrrolate (10 µg/Kg) is administered intramuscularly, 30 minutes before OT. Many anaesthesiologists prefer atropine IV at or shortly after induction. If the baby is pyrexial and toxic, then atropine should be used in small doses or may even be omitted, balancing between the risk of febrile convulsions and necessity.

Almost all the sedatives are effective as premedication. But, the choice depends on the individual anaesthetist and the protocol of the institution. The need for sedative premedication must be individualised, according to the underlying medical conditions of the patients, the length of surgery and the desired induction procedures of anaesthesia. Sedative premedications may be administered orally, IM, rectally, sublingually, nasally or IV and doses are based on the body weight of child. Among them the oral route is mostly preferred in paediatrtic patients. The disadvantage of rectal route is that the effect of such administeration is likely to be unpredictable. IM route provides accuracy of doses and certainty of actions, but very few children welcome this route.

For sedation as premedication midazolam, given orally (0·5 mg/Kg) is gaining widespread popularity. The effect of this oral preparation of midazolam occurs within 10 minutes and the peak effect reaches 20 to 30 minutes after oral administeration. However, it does not influence the discharge time in day-case surgeries as one of the disadvantages of sedative premedication is that it prolongs the discharge time. Though there is oral preparation of midazolam, but it is not available in all countries. Hence, Parenteral preparation of midazolam can also be given orally, but it has a very bitter taste. This can be eliminated by diluting it in concentrated sweet fruit juice. The paracetamol elixir is also suitable for mixing with injectable form of midazolam for oral administeration, and has the merit of incorporating an analgesic component to the premedicant. As an alternative to midazolam, in some centres the parenteral ketamine preparation is also used orally in a dose of 3 to10 mg/Kg as premedication. But, ketamine causes excessive salivation and increases PONV. So, an antisialagogue and an antiemetic should always be used with ketamine premedication. If a profound degree of sedation is required during preoperative preparation of patient, then it is also possible to combine midazolam with ketamine. A relatively new route for administration of midazolam and ketamine as premedication is the intranasal route. But, at this

stage it is still unknown how much of the drug applied through the intranasal route is absorbed directly into the CNS through the cribriform plate, and how much is absorbed through nasal mucosa. But it will have to keep in mind that preservatives present in injectable preparations of these two drugs (as preservative free special preparation for use through nasal rouse is not available) are neurotoxic when passes directly to the neural tissue through cribriform plate. So, it is better not to use this preservative added preparation of these two agents through this route at present.

The nasal and rectal doses of midazolam are respectively 0·2 to 0·3 mg/Kg and 0·4 to 0·5 mg/Kg. The nasal and rectal doses of ketamine are respectively 3 mg/Kg and 6 mg/Kg. Because of the decrease in bioavailability of the drug through the oral and rectal route, the doses of these agents must be significantly higher when using these routes than with other routes.

The use of fentanyl as premedicant through oral transmucosal route is very popular, though it can also be used through any other routes. For absorption through buccal mucosa. It is prepared by incorporating fentanyl in a lozenge like lollipop and children are allowed to suck it. It is available in doses of different range. Swallowing of saliva decreases its efficacy, because first-pass metabolism of fentanyl through the liver is high. Onset of action of fentanyl through transmucosal route is 20 to 30 seconds and duration of action is 30 minutes for a dose of 10 to 15 µg/Kg of fentanyl. The disadvantages of fentanyl as premedication are : pruritus, nausea, vomiting respiratory depression and frequent oxygen desaturation. Respiratory rate decreases within 10 minutes. So, constant observation and monitoring is required and it should be administered only in a monitored clinical setting. The principal advantage of fentanyl as premedication is decrease in the intra- and postoperative analgesic requirement, but it does not delay the discharge of patient from the hospital.

Sufentanil also can be used as a premedicant like fentanyl. But it is most successful when used through the intranasal route. However, the intranasal dose of sufentanyl is 1·5 to 3 µg/Kg and it sedates the child within 10 minutes. However, the disadvantages of sufentanil are same as fentanyl. Traditionally children undergoing cardiac surgery need heavy premedication. Naturally, the choice is morphine, because it can prevent the spasm of the right ventricular infundibulum in uncorrected Fallot's tetralogy.

There are many other drugs which also can be used for sedative premedication. These are : diazepam (0.4 mg/Kg orally), lorazepam, trimeprazine (vallergan, 3 to 4 mg/Kg orally), chloral hydrate, promethazine (1 ml/Kg), etc. Injection of Vit K_1 in the dose of 1 mg should always be given through IM to all the newborns in view of the immaturity of hepatic production of prothrombin. The longer duration of action makes lorazepam unsuitable as premedicant for day-care surgery. Chloral hydrate and triclofos are used as more for sedation than premedication. The oral doses of chloral hydrate and triclofos are 25 to 50 mg/Kg and 50 mg/Kg respectively.

Induction

The method of induction of anaesthesia in paediatric group of patients is most colourful and is determined by a number of factors, such as : age of the patient, behaviour or psycological setup of the child, ability of the child to cooperate with the anaesthetist, medical conditions of the patient, the proposed surgical procedure, the presence or absence of full stomach etc. But among these the last and the most important factor is the anaesthetic procedure with which the anaesthesiologist is most convenient or competent.

When the infants are younger than 10 to 12 months of age, then induction of anaesthesia by volatile anaesthetics agents through face masks is the procedure of choice. Fortunately, the modern, potent, volatile anaesthetic agents can render the small children unconscious within minutes. This is also usually easier in children who have been sedated prior to entering the operating room and who are sleepy enough without ever knowing what his happening (steal induction). There are also some other healthy alternatives to the above mentioned inhalational technique for induction of anaesthesia without frightening the children and these are described in table (Table 25.17).

Typically, during inhalational induction the child coax for breathing an odourless mixture of N_2O (70%) and O_2 (30%). Sevoflurane or halothane is added to this anaesthetic gas mixture graduatly in increasing concentration of 0·5% after every three to five breaths. Many, if not most, paediatric anaesthetists consider sevoflurane as the agent of choice for inhalational induction rather than halothane, because sevoflurane has a wider therapeutic safety window in terms of cardiovascular depression and has no unpleasant smell. Desflurane and isoflurane are not used for induction, because they have more pungent smell and are associated with increased coughing, breath holding and laryngospasm etc. during induction. Some clinicians use a single – breath induction technique with sevoflurane of 7 to 8% concentration to speed up induction. It produes unconsciousness after 4 to 6 breaths without any excitement, But this single-breath technique should not be used with halothane, as it has severe cardiodepressant effects. When single breath technique using high concentration

Table 25.17: More healthy options of induction without frightening the child

1. Insufflation of anaesthetic gases over the child's face.
2. Substituting a clear, scented face mask in the place of the traditional black one.
3. Placing a drop of food flavouring oil inside the mask (e.g. oil of orange).
4. Allowing the child to sit during the early stages of induction.

of halothane and svofalurane in not used, then patients typically pass through an excitement stage during which period any stimulation by premadure attempt of laryngocopy or even IV cannulation can induce laryngospasm.

In older children who allow an IV line before induction of anaesthesia then in such circumstances. IV induction is preferred. Intravenous induction is also preferred if the patient comes to the operating room with a previously inserted intravenous catheter due to other reasons. Patients with full stomach always need IV rapid induction and intubation with or without succinylcholine. In such situation induction by in halational agents even by single breath technique in never tried to prevent aspiration of gastric contents. For IV induction of anaesthesia thiopentone, propofol, ketamine, midazolam, diazepam, etc, can be used. Induction with intramuscular ketamine (5 to 10 mg/Kg) is only reserved for some specific situations, such as (i) handling of a very violent child who will not take any oral pre-medicant and (ii) refuse to co-operate during induction by volatile inhalational agents and (iii) the patient is younger and healthy enough who requires many assistant to apply force for inhalation of volatile anaesthetic agents and also (iv) there is no IV line before hand for IV induction.

The child should be accompanied by parents (or someone with whom he or she is comfortable) to the anaesthesia room. The person accompanying the child should be informed beforehand what to expect in the anaesthesia room. He should be made aware of the excitation state of the child, when inhalational induction by mask is initiated or he should be made aware of how to assist the anaesthetist when IV induction is planned by distracting the child. During mask induction by volatile anaesthetic agents, breath holding by the patient is very common and if so, then one should not attempt to assist respiration by squeezing the bag because this often elicits cough and laryngospasm. Breath holding should be differentiated from airway obstruction or laryngospasm by an anaesthetist by observing the movements of bag, chest wall and abdomen. Airway obstruction, most commonly due to the falling of tongue, can be managed by extension of the neck and by an upward thrust of the mandible, applied at the angle. But if laryngospasm occurs, then closing of the pop-off valve of anaesthetic circuit and creation of positive airway pressure of about 10 cm H_2O approximately (while allowing the child to breathe spontaneously) will often allow the gas exchange and helps to overcome the laryngospasm. If this procedure is ineffective, then administration of positive pressure ventilation avoiding inflation of stomach often disrupts laryngospasm. However in very emergency conditions, the intravenous muscle relaxant is the only answer. But if IV line is not yet instituted, then only the cricothyroid puncture can save the life of the child.

In children where difficult airway is anticipated, the induction by mask should be done very slowly, gradually increasing the concentration of the inhalational anaesthetic agent and maintaining a spontaneous respiration. As the level of anaesthesia deepens, then gentle manual assistance of ventilation by anaesthetist corraborating with spontaneous respiration, may be done. This allows an anaesthesiologist to assess whether he will be able or not to ventilate successfully by mask, when muscle relaxant is used and intubation fails. Muscle relaxant should be used only if an anaesthetist feels that he can ventilate the patient successfully by mask, if intubation fails too. A child with an airway obstruction should have a slow and prolonged induction of anaesthesia, before allowing laryngoscopy and endotracheal intubation. In some emergency conditions when the patient presents with full stomach and airway problem, then the issue of full stomach is secondary to the airway problem. Rapid sequence induction of anaesthesia and intubation is indicated in these patients. A surgical team should be prepared to perform an emergency tracheostomy, if the total airway obstruction occurs and mask ventilation or endotracheal intubation fails.

Induction of anaesthesia through rectal route is also an unique techniques in the paediatric group of patients and have many advantages over the oral route. Many different medications are used rectally for induction of anaesthesia. The main advantage of this approach is that the child falls asleep in the parent's arms and hence separation of patient from the parent is atraumatic. This technique is no more intimidating than taking a rectal temperature. Oxygen desaturation is usually not a problem, unless the child's head flexes forward causing airway problem.

Other than inhalational, IV, and rectal route many medications are also used intramuscularly for induction of anaesthesia, like premedication. But here the only difference between the induction of anaesthesia and premedication is the dose of drugs used. The main advantage of this route of administeration over the rectal and oral route is its reliability but its main disadvantage is being a painful procedure.

A child with a full stomach should be treated like an adult with full stomach. As metabolic rate is much greater, so O_2 desaturation occurs more rapidly in neonates and infants than children and more rapidly in children than adults. However, the added problem in this group of patient is that the children are usuallyunco-operative and refuse to breathe 100% O_2 prior to induction (pre-oxygenation) for denitrogenation. Like an adult all the steps of rapid induction and intubation should be followed in paediatric patients with full stomach. During induction of paediatric group of patients with full stomach, injection of atropine is mandatory. This is because atnopine will to prevent anaesthesia induced reflexes, succinylcholine induced bradycardia and delay the bradycardia due to hypoxaemia. During

induction and intubation of a patient with full stomach, cricoid pressure is also mandatory and is applied gently after the child loses consciousness.

Unlike adult practice, it is not possible to have all the necessary monitoring devices placed on the child before induction. So, the appropriate monitoring should be placed as soon as possible, after the induction of anaesthesia.

For mask induction, different types of face masks are also used. Face masks with different size and different flavours and scents are now also available to reduce the noxious smell of the anaesthetic vapours. Scented transparent silicon or plastic masks are much more acceptable to little children than the traditional Rendell-Baker or Soucek masks which are made up of black rubber or PVC. But the advantage of these later masks is that they have very small dead space of only 4 ml. On the otherhand, the transparent clear plastic masks allow an anaesthetist to observe the presence of vomitus, though they have high dead space volume. In fact, the Rendell-Baker mask was originally developed to fit around the facial anatomy of the child in an attempt to minimize the equipment dead-space. But, the flow of fresh gas in a clear mask is such that the advantage of using a Rendell-Baker mask has nowbecome minimal. On the otherhand, these Rendell-Baker masks are much more difficult to use than the transparent ones with pneumatic cushion. An alternative to use a facemask is cupping of the anaesthesiologists hand over the face of a child, while holding and directing the T-piece carrying anaesthetic gases towards the nose of the patient.

Airway Management

The ratio of the dead space and the tidal volume (V_d / V_t = 0·4) remains constant throughout the life of a healthy patient. But any increase in the dead space by anaesthetic apparatus, connectors, humidifiers, etc, also significantly increases the V_d and V_t ratio and this has significant effect on ventilation. Therefore always this should be kept at a minimum level. This is very important for a child who breaths spontaneously and has a compromised cardiovascular and respiratory systems. The anaesthetic circuit which is most commonly used in children under 5 years of age or below 20 Kg of body weight throughout the world, is the Jackson-Rees modification of Ayres T-piece. This is also called the Mapleson F system. The original Ayre's T-piece was made up of a light metal T-tube with a main lumen of 1 cm in diameter. A smaller side tube was attached at right angles to the main lumen through which the anaesthetic gas mixture was introduced. Then a length of a rubber tube was attached to the open end of the T-piece, and it acts as a reservoir of anaesthetic gases. This is the modification of Ayre's T-piece to the Mapleson E circuit. To prevent the dilution of fresh gas flow by air and to avoid rebreathing, the capacity of the expiratory limb must be greater than the tidal volume, and the fresh gas flow must be twice than the minute volume of the patient. In 1950, Jackson Rees again modified this system by attaching an open-tailed breathing bag to the reservoir tube in order to facilitate the controlled ventilation and to observe the spontaneous ventilation. This is called the Mapleson F circuit. The reservoir bag in the Mapleson F circuit helps (i) to observe the respiration, (ii) to assess the tidal volume of patient and compliance of lung, (iii) to reduce the dead space during spontaneous ventilation (as the fresh gas flow washes out the expired gas during the pause after each expiration), and (iv) allows the application of continuous positive airway pressure in a spontaneous ventiliation or PEEP in controlled ventilation which helps in improving oxygenation. The main advantages of this valveless circuit are: simplicity, light weight, low resistance, minimal apparatus dead space and helping in manual ventilation (if needed) by the open-ended reservoir bag. This circuit may be used both for spontaneous and controlled ventilation. Controlled ventilation (manually or by a ventilator) is the most satisfactory mode of ventilation for neonates and infants, because any changes in compliance, air leak or tube displacements can easily be detected. For mechanical ventilation, the bag is removed and an appropriate ventilator is attached to the expiratory limb. Scavenging system may be connected indirectly to the circuit which prevents the possibility of blockage of the expiratory flow. The disadvantage of this circuit is the absence of a pressure relief valve. It is popular for induction of anaesthesia and maintenance of short duration. The recommended fresh gas flow (FGF) to maintain normocarbia in Mapelson F circuit, during spontaneous respiration is 200 to 300 ml/Kg. But, only 70 ml/Kg produces normocarbia during controlled ventilation. Fresh gas flow (FGF) approximately equal to the normal minute volume is also sufficient to maintain normocapnia in controlled ventilation. This is because CO_2 rebreathing has no consequence during controlled ventilation and the anaesthetist can control P_aCO_2 by increasing the ventilation (Fig. 25.6).

Another recommendation for FGF rate, necessary to prevent rebreathing:
2.5 times the minute ventilation, for spontaneous breathing or 1000 ml + 200 ml/Kg in controlled ventilation.

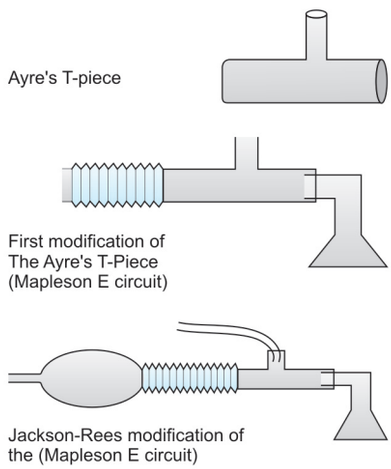

Fig. 25.6: Ayre's T-piece and modification over it

This discrepancy of recommendation of the FGF rate is dependent on the respiratory pattern. A rapid respiratory rate with minimal expiratory pause allows no time for the FGF to flush out the expired gases through the expiratory limb, before the next breath starts. This causes rebreathing of expired gases and so a higher FGF is required. Contrary, an end expiratory pause during controlled ventilation will help to flush out the expired gases in the expired limb and thus prevents the rebreathing and reduces the FGF. Most of the children require a minimum FGF of 3 litres/minute which can then be adjusted to achieve normocapnia and an inspired carbon dioxide concentration of less than 0.6 kPa. The measurement of end tidal CO_2 concentration by a capnometer may be underestimated in children below 10 Kg and this is due to dilution of the expired gases. So, sampling should be as distally in the circuit as possible. Partial rebreathing also allows conservation of heat and humidification in ventilators.

The minute volume (MV) should be calculated by:

MV = tidal Volume (10 ml/Kg) × RR

After tracheal intubation, controlled ventilation (if it is decided) can be conducted either manually or mechanically. Traditionally many institutions still prefer manual ventilation, because it allows a breath-by-breath estimation of the changes in chest compliance. But, gradually the need for manual assessment of chest compliance is pushed back and to assure adequacy of ventilation the modern non-invasive monitoring techniques such as: oximetry, capnography, pressure-volume loops, etc, are now in widespread. Moreover, the manual ventilation limits the activities of an anaesthetist, and may provide a false sense of security in detecting changes in compliance by hand. But, still the ability to hand-ventilate using the Ayre's T-piece (Mapleson F circuit) is essential in paediatric practice and such circuit should always be available in case of ventilator failure (when patient is mechanicaly ventilated) or unexpected desaturation. In a baby with gastroschisis or exomphalos, the manual ventilation can be used to assess the changes in lung compliance and can determine the volume of abdominal contents that can be reduced back into the abdominal cavity. Manual ventilation during repair of tracheo-oesophageal fistula can be timed properly, which allows the surgeon to get maximum exposure and time for the repair.

Standard adult ventilators are also suitable for paediatric patients with weight more than 20 Kg. But, below 20 Kg a paediatric version is needed with the ability to deliver small tidal volumes, rapid respiratory rate, variable inspiratory flow rate and different I:E ratio. However, the always measurement of this small inspired tidal volume is meaningless. Because, the compression of gases in the ventilator tubing and variable leaks around the endotracheal tube gives a false security. But, more sophisticated ventilators may, however, be capable of measuring expired tidal volume which is of more practical value.

Two modes of controlled ventilation are commonly used for neonates and infants.

(i) Volume controlled / time cycled.

(ii) Pressure controlled / time cycled.

The volume controlled / time cycled ventilation deliver a fixed tidal volume which is based on the inspiratory time and inspiratory flow, but is independent of the peak inspiratory pressure. It makes an allowance for changes in lung compliance, but at the potential cost of high peak airway pressure. With decrease in compliance of lungs, the tidal volume does not change, but the peak airway pressure changes. However, in contrast to volume controlled/time cycled ventilation, a pressure controlled/time cycled ventilation delivers a variable tidal volume under a fixed inspiratory peak pressure. Here, the tidal volume or minute volume varies directly with the compliance of chest and lung, and is indicated by the bellow movement or on the panel screen. As the compliance decreases, the tidal volume also decreases and vice versa. Both these ventilatory mode should be used with caution when there are chances of marked variation in the lung's compliance, due to surgery or pathological conditions such as: bronchoconstriction, pulmonary oedema, etc. To account for the changes in lung compliance when using a pressure controlled ventilation, the adequacy of alveolar ventilation can only be assessed by using a breath-by-breath capnography.

The ultimate setting of a ventilator's parameters depends on the clinical observation and the results from monitors. Inspiratory flow by changing pressure or volume can be gradually increased or decreased, until the optimum chest movement is observed. Measurement of capnography and pulse oximetry confirms normocapnia and adequate oxygenation. The peak airway pressure should always be kept at minimum level and an alarm at both the upper and lower limit side is mandatory in all ventilators. Most children are ventilated adequately with a respiratory rate between 20 to 30/minute and inspiratory pressure between 15-20 cm of H_2O. The respiratory rate should be adjusted accordingly to achieve the normocapnia.

In a ventilator the respiratory rate is set electronically between 20 to 30/min and inspiratory : expiratory ratio varies from 1:1 to 1:3. The gas flow rate required to produce a given minute volume is obtained by using a nomogram. This takes into account the voloume of gas which is lost during the expiratory phase. PEEP may be applied to the expiratory limb of the ventilator. This can also be used as a constant pressure device (CPAP) by incorporating a pressure-limiting relief valve (Fact file- I).

Non-rebreathing valves are also used in paediatric anaesthesia. But they tend to stick and produce more resistance and dead space. Circle absorber is used in paediatric anaesthetic circuit in some countries (e.g. USA). They have light tubings,

FACT FILE - I

The tidal volume of neonates is only 20 ml and the physiological dead space is just its 1/3rd. So, the amount of alveolar ventilation in neonates is only 14 ml. Hence, the addition of even a very small dead space from the anaesthetic apparatus (even a few ml) represents a very large proportional increase in dead space and tidal volume ratio. Masks are not suitable for neonates and infants for prolonged periods, because they usually require intubation. However, good fitting of the face mask is more important than its low dead space, because the latter can be reduced by increasing the FGF within the mask. The Rendell-Baker and Soucek masks do not make a good air seal on the face, though their dead space is very low.

silicone rubber valves, low gas flow with efficient humidification, warming and scavenging systems.

For the older children, over 20 Kg, it is satisfactory to use the Bains, Humphrey ADE or the circle absorber system. The ADE circuit is a hybrid system, incorporating Mapleson A, D and E types of circuits in one breathing system. Here, the E mode behaves similar to the T-piece. The A mode is efficient in children over 10 Kg of weight. Both D and E modes are suitable for controlled ventilation. The circle absorber system offers economic advantages, because a low fresh gas flow required in it. It also conserves warmth and moisture, as the reaction of CO_2 with sodalime is exothermic, producing heat and water. While using the circle absorber system in completely close circuit, then the ability to monitor the inspiratory and expiratory levels of O_2, N_2O, CO_2 and volatile anaesthetic agents is mandatory. The unidirectional valves may increase resistance to breathing and shouldnot be allowed to become damp. Paediatric circle system using a 15 mm light-weight hose, is suitable for children over 5 Kg. Till now there is no evidence of nephrotoxicity in children due to compound A, formed by the action of sevoflurane with sodalime.

In the past, much interest had been given to the resistance of the breathing system and the dead space volume of the apparatus during the use of circle CO_2 absorber system which led the paediatric anaesthesiologists to use nonabsorber (Mapleson F circuit) systems mainly. However, recently the attitude has changed and there is renewed interest in the use of circle system with CO_2 absorber in paediatric anaesthesia practice (Table 25.18).

The recent research works do not support the opinion that circle system with CO_2 absorber imposes more resistance to the breathing in infants and children during controlled ventilation. In contrast, it appears that the mechanical dead space imposed by some T-piece connectors, can be excessive during spontaneous respiration. Some problems, such as muscle fatigue, inefficient ventilation, tendency for lung collapse, etc. which were observed previously with the circle absorber system, were due to spontaneous breathing with this system. So, it can be advised that if ventilation is either controlled or assisted in neonates or infants, then a standard adult circle system which is fitted with low dead space connectors, small bore tubings and a reduced capacity reservoir bag, is appropriate for the maintenance of anaesthesia in paediatric patients of all ages.

Again, it is easy to scavenge the waste gases from all these systems with the resultant benefit of reducing the pollution of the theatre environment (Table 25.19).

An appropriately sized Guedel's airway is an important and useful adjunct in maintaining the airway when a child is being anaesthetised, but not intubated. A too small airway is ineffective and a too large airway may obstruct the larynx itself. So, an airway of correct length in used and this length is measured which is equivalent to the distance from the angle of the mouth to the angle of the mandible.

Table 25.18: Reasons for a renewed interest in the use of circle system with the absorber in paediatric practice

1.	Increased concern about economy.
2.	Enviornmental pollution.
3.	Improvement in the design of anaesthetic machines and ventilators.
4.	Use of the small bore anaesthetic circuits, reducing the anatomical dead space.
5.	Increase in availability and use of multi gas analyzers.
6.	The desire to use standard anaesthetic breathing circuits for patients of all ages.

Table 25.19: Estimation of LMA size in paediatric patients

Size of LMA	*Weight (Kg)*	*Cuff volume (ml)*
1	0-5	2-5
1.5	5-10	5-7
2	10-20	7-10
2.5	20-30	12-14
3	Large child > 30	15-20

Depending on the surgical and patient requirements, anaesthesia in the paediatric group of patients can be maintained with a face mask, tracheal tube or a laryngeal mask airway (LMA). But, the introduction of LMA offers a healthy alternative to face mask anaesthesia with Guedel's airway in patients scheduled for minor surgery. Both the indication and insertion technique of LMA for prediatric patients are similar to that of an adult. For preterm neonates who require G.A, spontaneous ventilation with face mask or LMA is avoided, because they are more prone to periodic breathing and apnoea during general anaesthesia. Neverthless, the role of LMA in neonatal surgery is limited. This is because in most instances the neonatal airway should be secured to prevent aspiration and to facilitate positive pressure ventilation, but neither of which can be properly assured with a LMA. Infants are also poor candidates for anaesthesia with spontaneous ventilation by LMA, and higher doses of volatile anaesthetics. It is because of poor pulmonary mechanics causing early respiratory failure and increased susceptibility to the cardiovascular depressant effects of volatile anaesthetic agents. These group of patients are likely to be benefited best from balanced anaesthesia offered by full dose

of muscle relaxant, intubation, controlled ventilation, minimum concentration of volatile anaesthetic agents and optimum doses of opioids. Balanced anaesthesia should also be applied to older children, undergoing surgeries for more than 45 minutes duration. Surgery lasting for less than 30 to 40 minutes of duration may be allowed to continue in children under spontaneous ventilation by LMA with a mixture of N_2O, O_2, and volatile anaesthetic agents, which is supplementated by appropriate doses of opioids, and local or regional block, where necessary.

For the maintenance of anaesthesia and the airway (from falling of tongue on the larynx), the LMA is one step ahead of face-masks with Guedel's oropharyngeal airway, but one step behind the ET tube. So, it is in an intermediate position between the face mask with oropharyngeal airway (Guedel) and the ET tube. In the maintenance of an anaesthetised airway, the LMA has certain advantages over the face mask with Guedel's airway, but also has some disadvantages when compared to the ET tube. The LMA is generally used only when spontaneous breathing is planned in a child during surgery, though controlled ventilation can be performed with LMA when necessary. It does not protect the airway against aspiration of gastric contents like ET tube. So, it is unwise to use the LMA in a patient with full stomach. The LMA is also displaced easily, causing airway obstruction. So, the present status of LMA is that it can be used in a variety of operations with spontaneous respiration or controlled ventilation, where the airway pressure is kept below 15 to 20 cm of H_2O. LMA is available in different sizes to fit all the children, including neonates. But the neonatal (size 1) LMA is not popular for different reasons such as difficulty to insert, easy displacement and increased apparatus dead space resulting in rebreathing and hypercapnia. On the other hand, due to the large cross-sectional area of the LMA tube, airway resistance increases very little. The success rate for insertion of LMA in the neonates and infants is less. In 70% unsuccessful cases it is seen that the epiglottis is not in the normal anatomical position. In most instances, the epiglottis is downfolded over the laryngeal inlet or within the bowl of the LMA. This is because the LMA used for neonates and infants is not designed according to their airway. Actually, LMA designed for the adult airway is simply scaled down in size to fit the neonates, infants and children.

Endotracheal Tube (ET Tube)

Though previously it was mandatory to intubate the trachea during artificial ventilation in neonates and infants, but now with the advent of LMA it is no more mandatory. Intubation with controlled respiration has several advantages. By intubation bronchial toileting becomes easy. It protects the lungs against aspiration of gastric contents, although when the patient is properly prepared and premedicated, then the incidence of aspiration is very low. Hence, LMA is no longer contraindicated medicolegally from the points of view of aspiration when the patient is prepared properly. However, operations in the oral cavity are not possible without tracheal intubation and with or without controlled ventilation. Even for operations outside the oral cavity, it becomes very difficult to maintain the airway of a neonate by only using airway devices and a face mask, even for the shortest surgical procedures requiring general anaesthesia. So, it is usually wise to intubate the trachea electively in most situations. But intubation results in the reduction of cross sectional area of the airway. For example, a 3·5 mm ET tube causes an increase in resistance by a factor of 16. So, tracheal intubation should not be followed by spontaneous ventilation. It always should be followed by controlled ventilation in order to reduce the work of breathing in paediatric patient.

There are different types of ET tubes which are used for paediatric patients. These are cuffed/uncuffed/Magill/Oxford/Preformed (RAE − Ring-Adair-Edwin)/Armoured/Ctole, etc, and may be made of different materials such as: PVC, silicone, rubber, plastic, etc. The RAE tubes are not recommended routinely for infants, because of the frequent inadvertent bronchial intubation caused by it. They are frequently used to facilitate the surgery around the head and neck. In RAE tube, there is a preformed bend that may be temporarily straightened during intubation.Both cuffed and uncuffed versions of nasal and oral RAE tubes are also available in various sizes. As the diameter of RAE tube increases, the total length and the distance from the distal tip to the curve of the tube also increases. Frequently, there is a mark at the bend. In majority of cases when this mark is at the level of teeth (in oral version) or naris (in nasal version), then the tip of the tube will be satisfactorily positioned in the mid-trachea, provided the proper size of the tube for the patient is selected. However, this is just a guideline and should not be used as the sole criteria for judging the correct positioning of the tube (Fact file -II).

The curvature of the nasal RAE tube is opposite to the curvature of the oral RAE tube, so that when in place the outer portion of the tube is directed over the patient's forehead. This helps to reduce the pressure

FACT FILE - II

After endotracheal intubation the controlled ventilation is the choice in neonates and in all babies upto 5 Kg of body weight, even for minor surgical procedures. This is because :

(i) Small babies are very sensitive to the respiratory depressant effects of the anaesthetic agents,

(ii) Controlled ventilation provides adequate alveolar ventilation,

(iii) Controlled ventilation maintains the normal residual lung volume.

The ventilation rate is maintained at 30 to 40/minute with a pressure of 15 to 20 cms of H_2O, PEEP of 5 cm of H_2O and FGF of 4 litres/minute to preserve the FRC. For babies above 5 kgs of body weight the spontaneous respiration with or without intubation may be allowed if the surgical procedure permits.

on the nares. This tube may also be useful for oral intubation of patients who are to be operated in prone position. The oral RAE tubes are shorter than the nasal ones. The external portion of the oral RAE tube is bent at an acute angle, so that when in place it rests on the patient's chin. These tubes are easy to secure and their use may reduce the risk of unintended extubation. The curvature of the RAE tube allows the breathing system and its connections to be placed away from the surgical field during operations, especially around the head and neck without using special connectors. The disadvantages of RAE (preformed) tubes include: difficulty in passing a suction catheter down them and these tubes offer more resistance than the comparable sized conventional ET tubes.

The spiral embedded armoured tube has a spirally winded reinforcing wire which is made up of metal or nylon and is covered internally and externally by rubber, PVC or silicone. Spirally embedded or armoured tubes are especially useful in situations where bending or compression of the ET tube is likely to occur.

The ET tubes may be either disposable or reusable. The reusable red rubber ET tubes, though possibly more irritant to the mucosa, are less liable to kinking and are easier to insert. Generally uncuffed tubes are used in children below the age of 10 years. This is because cuff pressure may cause ischaemic injury to the underlying tracheal mucosa which subsequently may lead to post-intubation croup or severe post-intubation laryngeal oedema leading to obstruction. This post-intubation laryngeal oedema may also require further intubation or even tracheostomy.

Another crucial point of paediatric anaesthesia by intubation is the determination of the size or internal diameter (ID) of the ET tube, appropriate for the given patient.

The general formula to calculate the ID or the appropriate size of tube is:

ID (in mm) = Age (years) ÷ 4 + 4.5

When using the above formula, any fractional sizes should be rounded up. This formula is only used as a rough guide to determine the size of a tracheal tube in children aged 2 years or above. But, the determination of tube sizes for neonates, infants and children who are less than 2 years of age is guided by the body weight. It is better to recall that a neonate weighing ±3 Kg will require a 3 mm (ID) tube. Low birthweight or premature babies need a 2.5 mm (ID) tube. The remainig sizes below 2 years should then be interpolated. It is advisable to keep in hand the tubes of one size both larger and smaller (0.5 mm larger or smaller) than the selected tube during intubation. For neonates, the best guide in choosing the ET tube is weight. In paediatric patients, the ideal size of a tube will be like that when it is in place there should have a small air leak around it to prevent the damage of mucus membrane of the rigid subglottic region, i.e the cricoid ring, which is the narrowest part of the child's airway. A correctly sized tube is one in which ventilation is adequate, but a small audible leak of air is present when the positive pressure is applied at 20 cm H_2O. However, this view has recently been challenged. But whatever may be the debate, it is clear that an appropriate sized tracheal tube should pass easily through the cricoid ring and there should not be excessive air leak in the working range. An alternative rough guide for the determination of the size of an ET tube is to use a tube with an external diameter similar to that of the child's little finger. As the children have a relatively short trachea, so the tube may easily enter either the right or the left main bronchus, or may even come out of the trachea easily when the neck is extended.

Certain care to be taken during intubation:

i. After intubation and intermittently during operation auscultation of both the lungs is mandatory,
ii Tube should be well secured by adhesive tapes with the immobile maxilla, rather than the movable mandible
iii The length of the tip of a ET tube from the alveolar margin (i.e. the length of the tube in the air passage) should be calculated from the formula: Age/2 + 12 cm.

This above formula is applicable only for the patients who are more than 2 years of age. However, the length of a orotracheal tube from the aveolar ridge (in cm) to the tip of the tube for patients aged less than 2 years is produced in the table below and should be memorized. But, whatever may be the length, it should allow the tip of the tube to reach the midtracheal point, while 2 to 3 cm of the tube should protrude out from the mouth for fixation. Some disposable tubes have a special marking 2 cm away from the patient's end to indicate the adequate insertion of tube into the trachea, passing below the vocal cord. Correct positioning of the tracheal tube should also always be checked by capnography and auscultation of the lung fields. The ET tube is connected with the anaesthetic machine by a connector. However, a paediatric 8.5 mm connectors are usually used, instead of the standard 15 mm connector. The catheter mount should be avoided in paediatric anaesthesia because a large dead space is involved. An alternative calculation for the length of the tube measured from the alveolar margin to the mid-trachea point is three times the internal diameter of the tube and for nasal intubation this measurement of length is : [Age (Years) ÷ 2 + 15] cm (Table 25.20).

If intubation is preceded by a period of difficult mask ventilation, then it is

Table 25.20: Estimation of endotracheal tube size in neonates and infants

Weight or age	*Length from alveolar ridge*	*Internal diameter*
1-2 Kg	7 cm	2.5 mm
2-4 Kg	8 cm	3 mm
Term neonate	9-10 cm	3.5 mm
3 months- 1 year	10-12 cm	4 mm
2 years	11-12 cm	5 mm
Over 2 years	—	Age ÷ 4 + 4.5

very common for the stomach to become inflated by ventilating gas. The inflated stomach decreases the tidal volume of the lungs, causing arterial desaturation. So, in this situation the stomach should be deflated by passing a nasogastric tube and removing it after operation.

In the first year of life a straight blade infant size Magill's laryngoscope, placed behind or posterior to the epiglottis, is more helpful for visualisation of the larynx and vocal cord. Because, in paediatric patients the larynx lies more anteriorly and is situated highup in the neck, opposite to the C_{3-4} vertebral body (in older children and adults it lies opposite to C_{5-6} vertebral body) and is covered by a large, soft and floppy (as the cartilagenous support is not yet fully developed) epiglottis, inclined at an angle of 45° to the glottis. So, visualisation of the vocal cord with a curved blade (Mackintosh) laryngoscope is difficult.The straight blade Magill's laryngoscope flattens out the curvature of the epiglottis and can be used to lift it by pushing forward directly and thus to expose the larynx. Paediatric version of Polio and McCoy blades are also available for paediatric laryngoscopy and intubation in difficult cases. For visualisation of the larynx, an anaesthesiologist has to align the three imaginary axes : one through the trachea, one through the pharynx and one through the mouth. In adults and older children this is usually achieved by placing a pillow under the head (familiar 'sniffing the morning air position') and putting the laryngoscope into the valecula in front of the epiglottis. But, in neonates and infants due to a larger head and shorter neck relative to the body, instead of placing the pillow under the head, it is usually necessary to place it under the shoulder. Laryngoscopy should be done very gently in paediatric group of patients and proper care should be taken to avoid the trapping of lips between the teeth and the laryngoscope blade which will cause injury and bleeding and distract the concentration of anaesthetist. The blade of laryngoscope also should not be levered against the upper teeth which may cause dislodging or even breaking them.

Certain considerations prior to ET intubation are:

i. Whether an awake, atraumatic intubation is possible and can be achieved easily.
ii. The possible presence of conditions making intubation difficult or impossible (e.g tracheo-oesophageal fistula).
iii. The difficulty in maintaining the airway with a face mask after induction and difficulty of maintaining ventilation by face mask after muscle relaxants.
iv. The presence of intestinal obstruction.
v. A very poor general condition of the patient (Table 25.21).

It should be noted that the concept of conscious intubation depends entirely on the clinical state of the patient and bears no relationship with age. However, in a vigorous infant and provided there is no possibility of aspiration of pharyngeal content, anaesthesia always should be induced prior to intubation. After intubation of an uncuffed tube, the laryngopharynx is lightly packed with a ribbon gauze which is slightly moistened with water or liquid paraffin to stabilise the ET tube and to prevent its kinking as well as leaking of gas.

Monitoring

The best monitoring device during paediatric anaesthesia is that which increases the contact between an anaesthetist and the patient. So, there is no substitute for an experienced and vigilant anaesthetist observing the child, and it is complimented by instrumented monitoring by modern electronic devices. Hence, for this instrumental monitoring of the paediatric group of patients the conventional adult methods of monitoring by electronic gadgets is applicable but with some special modifications for the smaller infants and neonates. With the electronic monitoring the colour changes, the movement of the chest and bag, the changes of respiratory pattern, the peripheral arterial pulses, etc, should also closely be observed clinically. It provides information about the present status of patient's oxygenation, ventilation and circulation (Fig. 25.7).

The routine instrumental monitoring of a paediatric patient should always include a precordial or oesophageal stethoscope, a blood pressure cuff of suitable width, pulse oximeter, ECG, temperature, end-tidal CO_2 tension and a peripheral nerve stimulator if muscle relaxants are administered. A precordial stethoscope and pulse oximeter should always be attached after induction, if not possible before. The precordial stethoscope should be changed to an oesophageal one, after the trachea has been intubated. The precordial or oesophageal stethoscopes assist in monitoring the heart rate, the quality of heart sounds and the pulmonary ventilation. The oesophageal stethoscope is also used for a qualitative measurement of the cardiac output, because a volume-depleted infant has soft

Table 25.21: Suggested size (ID) and length of the oral ET tube with age 72 years

Age	*Length from alveolar ridge*	*Internal diameter*
2 years	11-12 cm	4.5-5 mm
4 years	12-13 cm	5-5.5 mm
5 years	13-14 cm	5.5 mm
6 - 7 years	14-15 cm	6 mm
8 - 9 years	15-16 cm	6.5 mm
10 years	16-17 cm	7 mm
11-12 years	17-18 cm	7.5 mm
13-14 years	18-19 cm	8 mm

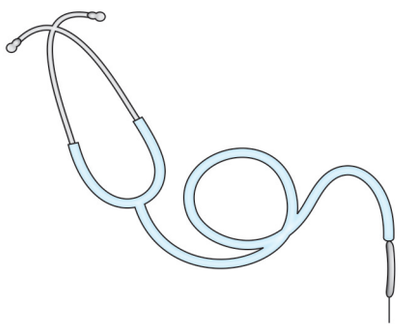

Fig. 25.7: Anaesthesia monitoring tool

heart sounds and an increase in the intensity of heart sounds after volume repletion may be recognised easily.

The sphygmomanometry method of determining BP in a small baby is difficult, and this is because of the inaudibility of Korotkoff sounds. But, the BP can be measured by automatic devices accurately, provided the width of the cuff covers at least 2/3rd of the upper arm and surrounds at least 3/4th of the limb. Many of the mechanical automatic sphygmomanometer devices are calibrated to the size of the patient, so it is important to select the proper 'neonate' mode for accurate measurement of BP.

The greatest advancement of this century in the sphere of monitoring in paediatric anaesthesia is the development of pulse oximeter by which O_2 saturation of haemoglobin can be measured continuously and noninvasively by a transcutaneous method. It is an extremely sensitive apparatus giving very early warning signs of impending hypoxia, long before clinical signs appear. The beauty of pulse oximeter lies in the simplicity of its principles upon which it works. The oximeter sensor can be attached to any site of the patient like finger, earlobe, nose, tongue, forehead, etc, and even in the medial aspect of the hand or lateral aspect of the foot in neonates. In neonates the pulse oxymeter probe should preferably placed on the right side of the body to measure the preductal oxygen saturation. The accuracy of this monitor is unaffected by the presence of foetal Hb, hyperbilirubinaemia, anaemia, etc. However, accuracy is affected by several other factors, such as the presence of met-and carboxy haemoglobin, nail polish, extraneous infrared lights (from radiant overhead heaters), hypothermia, hypotension, etc. Sometimes, the pulse oximetry results may not be accurate in cold neonates with poorly perfused extremities due to vasoconstrictions. In such situations, the application of the oximeter probe to the earlobe or nose may yield an accurate result. In addition, the use of an overhead radiant light for warming the baby may result in inaccurate oximeter results. So, the oximeter sensor should be shielded from the radiant light. The artefacts due to movement always give inaccurate measurement of O_2 saturation in neonates and infants during anaesthesia. But, now, newer algorithms have virtually eliminated motion artefacts and enables the accurate measurement of HbO_2 saturation in paediatric patients in spite of spontaneous movement.

The ECG monitoring is used in almost all the paediatric patients. The direct monitoring of arterial and central venous pressures are also easily achieved after cannulation of the radial artery and the internal jugular vein. However, such invasive direct arterial and central venous pressure monitoring are only be used in paediatric patients when such monitoring are absolutely necessary for the management of safe anaesthesia, during complicated surgery or in high-risk patients. During central venous and/or arterial cannulation all air bubbles should be removed from the pressure-tubings and only small volume of flushes should be used to prevent air embolism and circulating overload respectively in paediatric group of patient. The right radial artery is often chosen for cannulation in the neonates, because its preductal location mirrors the actual oxygen content of the carotid and retinal arteries. A femoral artery catheter or may be a suitable alternative in very small neonates when radial artery is not easily arressed. The critically ill neonates may still have an umbilical artery catheter in situ. The anaesthetists should not use these monitors simply because the patient is small or he is inexperienced. If these monitors are needed, then it can be inserted by an anaesthetist or a surgeon or even a cardiologist or a neonatologist. Pulmonary artery catheter is rarely indicated in paediatric patients, as the pressures of the right and left side of the heart are almost identical.

The end tidal CO_2 tension correlates well with the alveolar and subsequently arterial CO_2 tension. So, the measurement of end tidal CO_2 tension using a capnograph with a paediatric cuvette is mandatory in paediatric anaesthesia. Thus, the end tidal CO_2 analysis allows the assessment of the adequacy of ventilation, confirmation of ET tube placement and early warnings of malignant hyperthermia. The CO_2 partial pressure in blood can also be estimated noninvasively by transcutaneous methods. But, this technique of measurement of CO_2 tension by transcutaneous route is not commonly used in the OT, because it requires a long calibration period, responds slowly to the changes of CO_2 partial pressure in blood and does not provide breath-by-breath analysis like the end tidal CO_2 tension. For the measurement of alveolar CO_2 tension which correlates well with the arterial CO_2 tension, two types of capnometers are available. These are : sidestream and mainstream capnometers. The accuracy of capnometer reading depends on several factors such as : type of capnometer, the location of the end-tidal gas sampling port in the anaesthetic circuit, the type of anaesthetic circuit being used and the cardiopulmonary dysfunction of the patient. The sidestream capnometer aspirates gas continuously from the breathing circuit through a fine bore tubing and the main analyser lies at a distance. So, for an accurate result this side stream analyser must aspirate gas at a sufficient rate, compared to the respiratory rate and the gas should be sampled from within the tracheal tube. For this purpose, a 18 G or a 20 G IV catheter may be inserted into the 3 or 3·5 mm ID endotracheal tube.

On the other hand, the mainstream capnometer is placed directly at the junction between the ET-tube and the patient end of anaesthetic circuit and analyzes the expired gas as it passes through the sensor of it. Hence, it does not need to aspirate the gas continuously. These capnometers provide more accurate results about the end tidal CO_2 tension than the side stream capnometers. But, these are heavier than

the light-weight paediatric circuits and add more dead space. Neverthless, the small tidal volume and the rapid respiratory rate of small infants can present difficulties with both the capnograph models. Flow-through (mainstream) analysers are usually less accurate in patients weighing less than 10 Kg. Even with aspiration (side-stream) capnographs, the inspired (baseline) CO_2 can appear falsely elevated and the expired (peak) CO_2 can be falsely low. The end tidal CO_2 tension which is similar to the alveolar CO_2 tension does not correlate well with the arterial CO_2 tension in the presence of right to left cardiac shunt. But, in contrast the end tidal CO_2 tension accurately reflects arterial CO_2 tension in the presence of left to right shunt. Also, the end tidal CO_2 tension does not accurately reflect the arterial CO_2 tension in lung diseases. In such situations, the end tidal CO_2 tension should not be relied upon for accurate assessment of the adequacy of alveolar ventilation. Here the arterial blood gases should always be analysed to document the actual gas tension.

The temperature should always be measured during the surgery of small babies by nasopharyngeal, oesophageal or rectal probes due to their increased susceptibility to iatrogenic hypothermia and hyperthermia and also for early detection of malignant hyperthermia. Hypothermia can be prevented by maintaining a warm operating room environment (26° C or higher), warming and humidifying the inspired gases, using a warm blanket and also by warming all the IV fluids. The room temperature required for a neutral thermal environment varies with age. It is highest with premature newborns. However, it should also be kept in mind that during the maintenance of temperature of the paediatric patients outmost care also must be taken to prevent unintentional skin burns and iatrogenic hyperthermia from overzealous warming efforts.

Among all these routes, the nasopharyngeal probe provides an accurate reflection of the body core temperature. The oesophageal temperature may not accurately reflect the core temperature. Because, it is usually affected directly by the temperature of the inspired gases. The rectal temperature also can reflect accurately the core temperature, but it changes very slowly. The body core temperature also can be measured accurately from the external auditory meatus. But, it is not commonly used, because of the risk of trauma to the tympanic membrane. Axillary temperature does not provide the actual core temperature of body and it is very difficult to maintain the probe position over the axillary artery.

EXTUBATION AND POSTOPERATIVE CARE

At the end of the surgery when extubation is planned, then the administration of volatile anaesthetic agents should be stopped and the neuromuscular block should be anatagonised if they are used at all. The neuromuscular block should be antagonised in all paediatric group of patients, especially in neonates (preterm or full term) and infants. Because, even with the use of modern short acting neuromuscular blocking agents, the recovery from muscular paralysis in the neonates and infants remain unpredictable and any residual neuromuscular blockade may quickly lead to respiratory failure. Following anaesthesia with spontaneous ventilation under volatile anesthetics for short surgical procedures, extubation should be performed under deep anaesthesia. It is not advisable to extubate this group of patients under light anaesthesia, as severe laryngospasm is very frequent. Therefore, to maintain the level of deep anaesthesia volatile anaesthetics are continued till the child has been extubated successfully. The ET tube is extubated after thorough oropharyngeal suctioning and then the child is given 100% O_2 to breathe.

During the reveral of neuromuscular block by neostigmine (40 to 50 µg/Kg) and atropine (20 µg/Kg) or glycopyrolate (10 µg/Kg), the patients tend to follow three phases. In the begining the patient begins to breathe irregularly and tries to strain on the endotracheal tube. Next, the patient beathholds for a variable period. At that time they are at the greatest risk of hypoxia. Then, finally the regular respiration is resumed. After that the patient begins to gag on the endotracheal tube, move his limbs and contract the rectus abdominis muscle. Extubation is done after thorough oropharyngeal suctioning at this phase and 100% O_2 is administered with utmost attention for further occurrence of laryngospasm

After extubation the postoperative management of paediatric patient depends on the grade and the complications of surgery and anaestheisa and the associated medical conditions of the patient. After any surgery the patients should be monitored with a pulse oximeter, apnoea monitor and ECG in the recovery room, because the neonates are very prone to post-anaesthetic apnoea. 20% of preterm neonates may develop postoperative apnoea after general anaesthesia and the risk of which increases in the presence of anaemia and decreases with increasing postconceptual age. The risk of post anaesthetic apnoea is also high in the presence of congenital heart disease, severe respiratory distress, intracranial haemorrhage and any other major organ dysfunction. This post-operative apnoea usually occurs within 6 hours after discontinuation of anaesthesia. Though the process of maturation of respiratory centre is a dynamic process, still due to individual variations it is not surprising to face postoperative apnoea even in full term neonates. Caffeine is recommended for the management of post anaesthetic apnoea. A single dose of caffeine of 10 mg/Kg is sufficient for 18 to 24 hours to prevent postoperative apnoea. However, all patients who are prone to post anaesthetic apnoea are observed with an apnoea monitor for 24 hours or at least 12 hours after the last apnoeic episode.

NEONATAL ANAESTHESIA

Children, younger than 1 year, have a higher incidence of complications in anaesthesia than older children.

Reasons for higher incidence of complications in anaesthesia of children younger than 1 year are:

i. Usually, the neonates who are presented for surgery are of ASA 3 and 4 grade.
ii. The cardiovascular and respiratory system of the neonates, particularly the premature ones, function between the adult or extrauterine and the foetal or intrauterine type. So, any type of surgical stress or hypoxia can convert this adult to foetal type of circulation and as a consequence worsen the hypoxaemia, acidosis and cause death unless the cycle is broken immediately.
iii. Immaturity of organ systems (especially the cardiovascular, pulmonary, renal, hepatic and nervous system), high metabolic rate, high ratio of body surface area to weight, miscalculation of drug doses, etc, make taking care of these neonates and premature babies technically very difficult.
iv. The care of neonates is also always confronted with sudden changes, unexpected responses and the some unknown congenital problems.

Most of the complications that arise during neonatal anaesthesia are due to the lack of understanding of their special considerations prior to the induction of anaesthesia. So, the neonatal anesthesiologist has to be prepared for these unexpected situations and has to be ready with a variety of equipments and of proper sizes to provide highest level of care.

The controlled ventilation after endotracheal intubation is the technique of choice for neonates and for most of the babies upto the 5 Kg of body weight, even for minor procedures. The small babies are very sensitive to the respiratory depressant effects of inhalational anaesthetic agents. So, controlled ventilation ensures adequate alveolar ventilation and maintains a normal residual lung volume. But, recently many operations are done under spontaneous respiration with the LMA. During spontaneous ventilation, even the low resistance of the circle system can become a significant obstacle for the sick neonate. Unidirectional valves, long breathing tubes and absorbers account for most of this resistance. For patients weighing less than 10 Kg some anaesthesiologists prefer the Mapleson D circuit because of their low resistance and lightweight. Neverthless, as the resistance of breathing circuit can easily be overcomed by positive pressure ventilation, so the circle system can safely be used in patients of all ages if ventilation is controlled. Monitoring of airway pressure may provide an early evidence of obstruction caused by a kinked ET tube or advancement of the tube into the mainstem bronchus.

For controlled ventilation in neonates, a respiratory rate of 30 to 40 per minute with inspiratory and expiratory ratio of 1:2 (it is occasionaly necessary to reverse the inspiratory: expiratory ratio from 1:2 to 2:1 to improve gas exchange) is used with a peak inflation pressure of 25 to 30 cm of H_2O (but not more than 30 cm of H_2O). PEEP of 5 cm of H_2O (not more than 10 cm of H_2O) is also used to preserve the FRC with a fresh gas flow of 4 litres/min. Using PEEP and peak inflation pressure upto 30 cm of H_2O we should keep the inspired O_2 concentration as low as possible to maintain a P_aO_2 just between 60 to 80 mm of Hg. Early application of PEEP to the patients with hyaline membrane disease improves the gas exchange and may also decrease the severity of the disease by reducing the surfactant consumption. The net effect of PEEP on tissue oxygenation depends on the degree to which the cardiac output is reduced (PEEP than 10 cm of H_2O reduces cardiac output). For the babies over 5 Kg of body weight, anaesthesia by spontaneous breathing without intubation is possible, but only if the surgery permits and is of very short procedure.

Every effort should be made to maintain the neonate's temperature by minimising thermal loss. Operation theatre should be warmed. Electric warmer, warming blankets and heated humidification of inspired gases, particularly when nonbreathing circuit is used, minimises the heat loss.

Pulse oximeter is extremely important, not only to prevent hypoxia but also to prevent hyperoxia and retinopathy of prematurity (ROP). Oxygen saturation should be maintained between 93 to 95% (P_aO_2 between 60 to 80 mm of Hg), which keeps the patient on the steep side of oxy-heamoglobin dissociation curve. Keeping the O_2 saturation at this level, an anaesthetist will maintain a delicate balance between the potential rapid O_2 desaturation due to the absence of any reserve, and the potential development of ROP due to higher inspired O_2 concentration. So, an anaesthesiologist should be extremely vigilant and should respond quickly to any changes in O_2 saturation.

Premature neonates are deficient in surfactant production, which results in alveolar instability and atelectasis. This results in an increased intrapulmonary shunting and decreased compliance of lungs. Mild cases can be treated conservatively with humidified O_2. But, severe cases require tracheal intubation and mechanical ventilation. The decision to provide mechanical respiratory support is always made on clinical grounds such as : apnoeic attacks, respiratory rate above 60/min, signs of increasing work of breathing (nasal flaring, subcostal recession), increasing O_2 dependence (needs increased inspiratory O_2 concentration to maintain normal arterial O_2 saturation) and failure to clear secretion. Such babies are unable to maintain an arterial O_2 tension between 50 to 80 mm of Hg with increasing inspired O_2 concentration and the CO_2 tension rises above 50 mm of Hg. On the other hand, high pressure and high inspired O_2 concentration which is sometimes required for mechanical ventilation may result

in retrolental fibroplasia and damage to lung parenchyma. Factors that cause this progressive destruction of lung architecture and function (with fibrosis and cyst formation) due to high pressure and high O_2 concentration are: pulmonary hypoplasia, surfactant deficiency, the presence of L-R shunt, high ventilatory pressures (more than 30 cm of H_2O), high inspired O_2 concentration (> 60%), chronic infection and poor mucociliary function. This condition is progressive and vicious in cycle, as increased V/Q mismatching demands higher inspired O_2 concentration and falling lung compliance needs even higher inflation pressure. This high peak inspiratory pressure causes more shear injury of the lung parenchyma, creating a viscious cycle. This can be reduced only by the judicious use of PEEP and other ventilatory modes. A significant number of children who have had this type of treatment develop chronic lung disease of prematurity (previously termed bronchopulmonary dysplasia). So, the measurement of cutaneous O_2 and CO_2 tension is increasingly important and satisfactory, and is particularly helpful even when it may be difficult to obtain arterial blood for blood gas analysis. A reasonable correlation exists between the transcutaneous and arterial gas levels, when the peripheral circulation is good. But significant discrepency may occur in patients with poor tissue perfusion and with arterial O_2 tension at extremes of hypoxia and hyperoxia.

Weaning from the ventilator takes place after achievement of the cardiovascular and biochemical stability with inflation pressure of less than 25 cm of H_2O, P_aCO_2 of less than 50 mm of Hg and P_aO_2 of more than 80 mm of Hg at FiO_2 of 0·5 (i.e., the inspired oxygen concentration being 50%). Neonates must never breathe through an endotracheal tube without PEEP. Because, the zero-end expiratory pressure allows the small lungs to collapse progressively, so that the closing volume comes closer to the FRC in subsequent respirations with increased R-L intrapulmonary shunting and hypoxia. As the lung volume falls, the airway resistance to gas flow rises, so that the work of breathing and oxygen consumption also rises. With the ET tube in place, the normal mechanism is lost, whereby the glottis generates 2 to 3 cm H_2O pressure in terms of respiratory distress.

SOME SPECIAL PAEDIATRIC SURGICAL CASES

Congenital Diaphragmatic Hernia

In this condition which occurs 1 in 4000 live births abdominal visceras herniate through a defect in the diaphragm, most commonly through the Foramen of Bochdalek of the left side. Another name for this Foramen of Bochdalek is the persistent pleuroperitoneal canal. It is a free communication between the peritoneal and pleural cavities, causing a posterolateral hernia of abdominal visceras into thorax. It is due to the failure of diaphragm to develop from the lateral arcuate ligament on one or both sides, forming a triangular gap. So, a congenital diapragmatic hernia takes place through that opening and abdominal visceras herniate into the thorax, due to positive intra-abdominal pressure. In severe degree of congenital diaphnagmatic hernia almost all the abdominal visceras including stomach, intestine, liver and spleen, may be above the diaphragm and impair the development of lungs, causing hypoplasia of it. The intrauterine gestational age at which herniation begins to occur determine the severity of hernia which in turn determines the degree of lung hypoplasia. So, along with congenital diaphragmatic hernia there is also concomitant pulmonary hypoplasia associated with ↑PVR, ↑PAP and pulmonary hypertension. If the defect starts at an early gestational age, then the mediastinum is also shifted to the right and the growth of the contralateral lung is also stunted. The degree of respiratory distress at birth is related mainly to the degree of associated pulmonary hypoplasia which is indirectly related to the degree of herniation of abdominal visceras into the thoracic cavity. Infants who present with respiratory distress soon after birth, indicates severe degree of herniation and severe degree of lung hypoplasia. Usually they do not survive as they have inadequate amount of lung tissue to sustain life. After birth the midgut starts to fill with air, causing further distension of gut and compression of lungs which further increases the respiratory and cardiovascular distress. The diagnosis of congenital diaphragmatic hernia is suspected by respiratory distress after delivery and a scaphoid empty abdomen, this is confirmed by a chest X-ray.

Repair of diapragmatic hernia is not an emergency one and the child should be managed medically first. Surgery is considered only when the child's condition is optimized medically. Pulmonary hypertension should be treated with tolazoline and PGE-inhibitor before administration of anaesthesia for better result (Table 25.22).

Intraoperative P_aCO_2, reflected as $ETCO_2$ tension, reflects the severity of lung pathology and the chances of survival. It is the anaesthesiologist's duty to control the P_aCO_2 to improve the hypoxaemia and to check the hypotension.

The defect of diaphragmatic hernia is usually repaired through an abdominal incision Use of muscle relaxant and ventilation of patient by mask and bag before intubation may cause inflation of stomach and more herriation of gut in to thorax. So, an awake intubation without bag and mask ventilation is ideal (only if possible) and prevents over distension of the gut which

Table 25.22: Problems faced by an anaesthetist during perioperative management of congenital diaphragmatic hernia

1. Hypoxaemia, due to pulmonary hypoplasia, gut distension and pulmonary hypertension.
2. Acidosis due to hypercapnia.
3. Hypotension caused by kinking of major blood vessels, particularly those of the liver.

cause further herniation of abdominal visceras into the thoracic cavity. N_2O also should not be used for the same reason, as it overdistends the gut and increases the herniation of abdominal viscera into thoracic cavity. An intraarterial line is helpful in this type of sugery for blood gas analysis and continuous monitoring of the BP. Anaesthetic agents that depress the myocardium should always be avoided and stress response should be blunted by narcotics such as : fentanyl or remifentanil, which helps to establish a stable haemodynamic system. It is not always possible to introduce back all the viscera totally from the thorax into the peritoneal cavity. In such cases, a silastic silo may be used to introduce the contents gradually into the abdomen. Postoperative ventilation is essential for management of such patients.

Oesophageal Atresia and Tracheo-oesophageal (T-E) Fistula

The oesophageal atresia with or without tracheal fistula with oesophageous occurs in about 1 out of 3000 live births. It should be suspected when hydramnios complicates the pregnancy.

The infants suffering from this disease are of low birth weight and this anomaly may be the part of a larger constellation of many other congenital anomalies of structure such as vertebrae (V), anus (A), trachea (T), oesophagus (E) and renal (R) which are abbreviated shortly as VATER. Among these the cardiovascular anomalies such as : septal defects and coarctation of aorta most often coexist with this condition. So, echocardiography should always be performed before surgery of such patients. Other anomalies described above should also be excluded by thorough clinical examination and full investigations. Usually, after birth a baby who is suffering from oesophageal atresia and associated T-E fistula presents with respiratory distress or symptoms of choking during feeding and distended abdomen. Usually six types of tracheo-oesophageal fistulae with oesophageal atresia (from A-E) are described, and most of them present with an inability to swallow because of oesophageal atresia except type E. The diagnosis of this congenital anomaly is confirmed only by passing a nasogastric tube, which cannot be passed into the stomach. The main risk of life in T-E fistula comes from the soiling of lungs with saliva or gastric contents, causing pneumonitis and lack of nutrition (Table 25.23).

Table 25.23: The major issues for the management of safe anaesthesia in TE fistula repair.

1. Aspiration pneumonities.
2. Over distension of stomach by air coming through the fistula.
3. Ventilatory problems, as gases pass through the trachea and fistula to further distend the stomach.
4. Problems due to other concomitant congenital anomalies.

After birth, the corrective surgery for TE fistula should be performed as an one-stage repair and as soon as possible. Delay usually results in more soiling of the lungs, causing more pneumonitis which makes the patient gradually inoperable.

Preoperatively the child should not receive any feeding and a large bore catheter is placed in the blind oesophageal diverticulum in the A, B, C and D types of T-E fistula. It will help to drain the saliva continuously, so that the child does not swallow it. The child should be nursed in prone position with head-up tilt to prevent the soiling of lungs by gastric fluid in B, D and E types of T-E fistula. If the lungs are soiled and the child has pneumonia or pneumonitis, then the operation should be postponed until the pneumonitis improves by antibiotic and physiotherapy. Operation should be performed as soon as the child's condition is optimized medically. Sometimes, if operation is delayed for a long time due to severe illness of the baby, then initially a palliative gastrostomy should be performed to provide the means of nutrition during recovery from pneumonities and to prevent further pneumonitis (Figs 25.8A to E).

Awake intubation or inhalational induction by volatile anaesthetic agents followed by intubation is the choice of anaesthesia. Intubation after an adequate

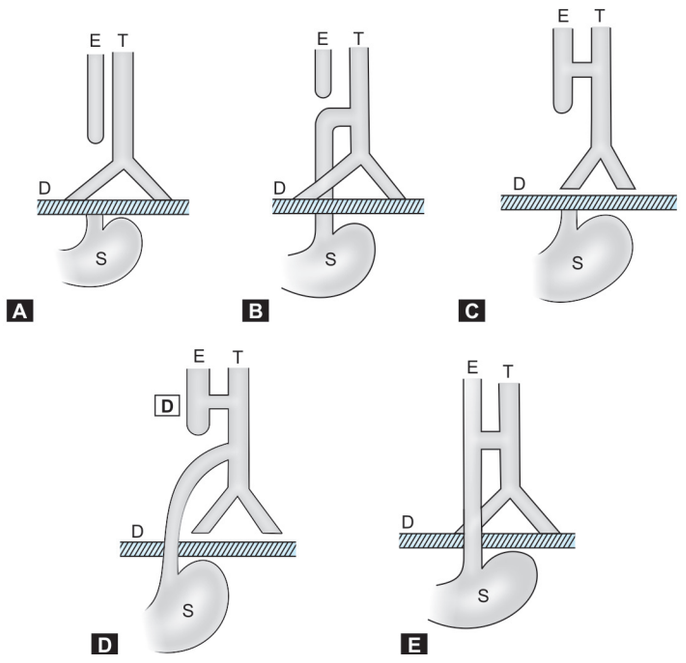

Fig. 25.8A to E: Varieties of tracheo-oesophageal fistula. E-Oesophagus, T-Trachea, S-Stomach, D-Diaphragm

dose of a muscle relaxant and followed by IPPV is contraindicated, as positive pressure ventilation causes huge distension of stomach due to passage of gas through the trachea and fistula, and subsequent compression of the diaphragm and lungs. Initially the ET tube should be inserted intentionally to deeper level beyond the fistula than predicted in any main bronchus, right or left. Tube is then withdrawn slowly, until the breath sounds are heard equally on both sides. This technique usually ensures that the tip of ET tube is placed beyond the level of fistula, but proximal to the carina. The leak of gas into the stomach caused by the placement of ET tube proximal to the fistula is easily diagnosed by auscultation of abdomen with a precordial stethoscope. The endotracheal tube should be inserted with the bevel facing up, so that the posterior wall of the tube occludes the fistula. This is because the fistula is usually situated on the posterior wall. After inhalational induction by volatile anaesthetic agents and intubation by muscle relaxant the controlled ventilation is always recommended for the surgical repair of tracheo-oesophageal (T-E) fistula. After intubation, the determination of O_2 saturation by pulse oximeter is the most useful monitoring, because any intraoperative change in the position of ET tube, as little as 1 to 2 mm from the previous position may determine whether the anaesthesiologist is ventilating the both lungs, or the one lung or the fistula. The ventilation must be monitored very carefully during surgical dissection of the fistula, as the trachea may kink during traction or manipulation and the ET Tube may be dislodged during traction. Postoperatively the neonates, especially the premature ones may have repeated apnoeic spells and this is may be due to the residual effect of anaesthesia, hypoxia, hyperglycemia, anaemia, hypocalcemia or hypothermia. Therefore, the patient should not be reversed to spontaneous respiration postoperatively for at least 12 hours.

The postoperative care of a neonate after surgical repair of T-E fistula should be given in a neonatal intensive care unit with full monitoring facilities.

Pyloric Stenosis

The incidence of pyloric stenosis is about 1 in 400 live births and males are affected in about 80% cases. It presents usually during the first 4 to 6 weeks of life after birth and is not a surgical emergency. The pathology of pyloric stenosis is the gross thickening of pyloric circular smooth muscle like a hard tumour, causing obstruction to food with increased vomiting. If untreated, the infant loses weight and becomes severely dehydrated with hypokalaemia, hypochloraemia and metabolic alkalosis. This is due to repeated vomiting of gastric secretions containing H^+ and Cl^- ions. As the obstruction is at the level of pylorus, so there is no loss of alkaline intestinal secretions. Body is thus loaded with bicarbonate and the kidney has to take this load. Bicarbonate load on the kidney at the glomerular level, exceeds its absorption power at the tubular level. Thus, the urine becomes alkaline and indicates compensatory phase. If the dehydration remains uncorrected, then hypovolaemia activates renin-angiotension-aldosterone axis to preserve the circulating volume by absorbing Na^+ and water from renal tubules. This results in an exchange of Na^+ for H^+ and K^+ (Na^+ enters, H^+ and K^+ released), which leads to the paradoxical acidic urine with worsening of hypokalaemia and metabolic alkalosis. This indicates decompensatory phase.

The surgery for pyloric stenosis (pyloromyotomy) is not an emergency one. So, it should be preceded by complete correction of fluid and electrolyte imbalance. The initial management of pyloric stenosis is gastric suction through a nasogastric tube and IV cannulation for parenteral therapy. The nasogastric suction is very important, because the stomach is always filled up with food, debris, barium sulphate (used for radiological diagnosis), etc. The initial intravenous infusion of fluid should be 5% dextrose in 0.45% saline to which 40 m.mol/L of KCl is added (2 ml/Kg of 0.9% NaCl raises the serum chloride by 1 m.mol/L). Usually, the rate of infusion of fluid is 6 ml/Kg/hour. During the preoperative preparation of patient the gastric residue is drained off continuously by nasogastric suction and stomach is washed with 0·9% saline every 4 hourly, until the aspirate is clear and odourless. Surgery should not take place until the plasma chloride level is at least 90 mmol/L and the potassium bicarbonate concentration is 25 mmol/L.

Usually, the child becomes ready for surgery within 24 to 48 hours after the commencement of treatment. Before induction of anaesthesia stomach should always be aspirated and as the children are sick but lusty, so awake intubation is not possible. However, the induction should be smooth by either the inhalation or IV route, according to the experience of the anaesthesiologist. Cricoid pressure must be used, which should be as effective in infants as in adults to prevent the aspiration of gastric contents in the lungs if there is any, even after aspiration by nasogastric tube. The postoperative oral feeding is usually re-established immediately after the patient returns to the ward. The postoperative analgesia is provided by wound infiltration with local anaesthetic agents and rectal or oral paracetamol, depending on when the surgeon decides to feed the child.

Omphalocele and Gastroschisis

It is the protrusion of a part of intestine through a defect in the anterior abdominal wall at the level of umbilicus, resulting in exposure of the viscera that are either covered (omphalocele) or uncovered (gastrochisis) by peritoneum. Whereas exomphalos is the herniation of the abdominal viscera into the unbilical cord of varying degree without any defect in the anterior abdominal wall. However, omphalocele or gastrochisis and exomphalus are embryologically two separate conditions, but present similar challanges to the anaesthesiologist.

These conditions are surgical emergencies. It is imperative that the abdominal contents should be placed in a clear sterile polythene bag, as soon as possible after birth to prevent infection, heat loss and fluid loss. Adequate intravenous access and extensive intraoperative invasive monitoring are usually necessary. This is because hypotension secondary to tension on major organs or caval compression during surgical manipulation is common. N_2O should be avoided during maintenance of anaesthesia. Muscle relaxants should be used liberally to provide optimal surgical conditions and relaxation for closure of the defect on the abdominal wall through which herniation was occurred. Nasogastric tube should be in place to decompress the stomach which will help in reduction of viscera and easy closure of the anterior abdominal wall. Postoperative controlled ventilation is mandatory, because of the reduction in compliance of the lungs, due to increased intra-abdominal pressure caused by the return of the viscera in the peritonial cavity and to provide adequate time to the abdominal wall to stretch and accommodate the viscera slowly. Intravenous alimentation play a vital role for the rapid recovery of these patients. Sometimes, it is not possible to close the defect in one sitting, then staged surgical procedures may be planned (Table 25.24).

Table 25.24: The challenges in management of omphalocele and gastrochisis

1. Massive fluid loss and dehydration. It results from the exposed visceral surfaces and from the third space loss, caused by partial bowel obstruction.
2. Heat loss.
3. Infection.
4. Difficulty in surgical closure without causing severe increase in the intra-abdominal pressure and severe compression on the lungs.
5. Frequent association of this condition with prematurity.
6. Other associated congenital defects with this condition.

Meningomyelocele

It is the herniation of a part of the meninges and the spinal cord through a defect in the vertebral column. It is a common neonatal congenital abnormality and requires an emergency surgery (Table 25.25).

Cleft Lip and Cleft Palate

Though in some centres, the total repair of both the cleft lip and cleft palate is carried out in the neonatal period, but usually the primary repair of a cleft lip is performed during the first few weeks of life and that of a cleft palate between 1 and 3 years of age. The cleft lip and cleft palate are also often accompanied by other congenital anomalies. Among them the defects of cardiac and central nervous system are of particular relevance to the anaesthesiologist. These conditions are also often associated with Pierre-Robin syndrome (micrognathia, cleft palate and glossoptosis), Treacher-Collins syndrome (cleft palate and hypoplasia of the first bronchial arch) and Klippel-Feil syndrome (fused cervical vertebrae). These may cause incipient or actual respiratory obstruction and make intubation very difficult. In Pierre-Robin syndrome, the periodic episodes of respiratory obstruction occur due to a relatively oversized tongue, blocking the airway. So, they have to be nursed in the prone position in order to overcome the obstruction. Failure to thrive as a consequence of difficulties in feeding and repeated respiratory infections is common in this group of patients.

The ideal collaboration of surgeon, paediatrician and anaesthesiologist is very much desirable in treating preoperative anaemia, malnutrition, respiratory infection, etc., which are commonly associated with these congenital anamolies and also in judging the optimal time for operation of this group of patients.

Table 25.25: Points to be kept in mind during anaesthesia of meningomyclecele

1. Possible association of meningomyelocele with hydrocephalus.
2. Possibility of cranial nerve injury during surgery.
3. Possibility of brain herniation during and after surgery.
4. Possibility of underestimation of fluid and blood loss.

Sedative premedication should be avoided during surgery of cleft palate. Induction by inhalation of N_2O, O_2 together with halothane or sevoflurane is simple and effective, although some anaesthesiologists prefer an intravenous induction. Once the child is asleep by inhalational anaesthetic agents, then an intravenous infusion line can conveniently be set up. Intubation can be performed under deep inhalational anaesthesia, but the use of muscle relaxants intravenously provide an optimum condition. But before giving relaxants of any sort, it is wise to ensure that the facial configuration of the patient will allow effective artificial ventilation with a bag and mask. It is particularly important to avoid trauma to the lips or gums in children waiting for repair of cleft lip during intubation. So, a 'tooth guard' made of several layers of sticking plaster or a custom made soft plastic mould is used. It will not only protect the gums, but also prevents the laryngoscope blade from falling into the maxillary defect. Sometimes, the use of a wad of gauze placed in the roof of the mouth will prevent the blade of the laryngoscope from slipping into the cleft.

There should be a wide range of ET tubes available to the anaesthesiologist for intubation during surgery of cleft lip and cleft palate. The surgeon requires the tube to be as unobtrusive as possible, while the anaesthesiologist requires a non-kinkable secure airway. During operation the use of one of the various modifications of the Dott-Gag will allow a good access to the surgeon, and the ET tube is retained in position by the lower (tongue) blade. But, care must be taken to check the patency of the tube after insertion of the gag, as the latter may occlude the tube by pressing it on the mandible. A preformed endotracheal tube, such as: Oxford tube is

preferred in these cases. Its strengthened proximal segment and built in pharyngeal curve offers greater resistance to kinking than the standard Magill's tube. The Oxford tube is, however, more difficult to introduce than the gently curved Magill's tube. But using a fine gum elastic bougie, threaded inside the tube as an introducer, greately facilitates intubation. The Oxford tube is tapered at the patient's end. It is, therefore, possible to force an overlarge tube through the glottis and through the narrowest part of the trachea at the cricoid cartilage unintentionally which may give rise to laryngeal oedema and postoperative croup. So, particular care must be taken to select a well-fitting tube with minimal gas leak. A small gas leak is of no significance, particularly as a pharyngeal pack is invariably used in such cases to protect against inhalation of blood.

Many anaesthesiologists allow spontaneous ventilation during surgery and maintain anaesthesia by N_2O, O_2 with any potent inhalational anaesthetic agent. Provided, the concentration of halothane is kept low and hypercarbia is not allowed to occur, then an infiltration of local anaesthetic with 1:200000 adrenaline is not a concern. Controlled ventilation using N_2O, O_2 and nondepolarising relaxants and / or opioids is a useful alternative, particularly when an anaesthesiologist is reluctant to use halothane.

With completion of surgery after pharyngeal suction, extubation should be done carefully in an awake and semiprone position which will protect against aspiration of slightly oozed blood from the operation site. Prior to extubation, auscultation of chest is mandatory which may reveal any retained secretion and occasionally a poorly expanding or blocked segment of the lung. In such conditions, careful suction of the endotracheal tube followed by gentle hyperinflation of the lungs is usually all that is needed. Children who are accustomed to breathe through the large defects in the palate have little time to accommodate the diminished airway, following operative repair. So, a bag, mask and an airway should be ready to treat any temporary obstruction of the airway, following extubation. An anaesthetic technique which will ensure rapid recovery of pharyngeal reflexes should be selected. Blood should be cross-matched as the surgical loss may exceed 10% of the total blood volume.

Postoperative airway problems after surgical correction of cleft palate are not infrequent, particularly in cases of a small mandible where the effectiveness of the genioglossus muscle is lost and the tongue falls back, partially or completely blocking the airway. In such circumstances nursing of child in the prone position is usually sufficient, although forward traction of the tongue by means of a tongue stitch may be required in refractory cases.

Inguinal Hernia

This is one of the commonest operations like circumscision in the paediatric age group of patients. At present regional anaesthesia (spinal, epidural or caudal) combined with light GA is the chosen mode of anaesthesia for repair of inguinal hernia in paediatric patients. Only general anaesthesia is indicated where regional anaesthesia is absolutely contraindicated. Regional anaesthesia combined with GA has several advantages over only GA.

The advantages of regional anaesthesia combined with GA are:

i. Decreased dose of the general anaesthetic agent required for surgery.
ii. Rapid pain free recovery.
iii. Early ambulation.
iv. Early discharge.

For RA the type of blocks and techniques chosen should have minimal side effects and should not interfere with the motor function. All the techniques of RA such as spinal or caudal or lumbar epidural with or without catheter and with or without adjunct may be applied. The child should have an IV cannula in place before the RA applied. But unlike the adult practice the volume preloading is not needed. Administeration of vasoactive drugs such as ephedrine is also not required. Spinal anaesthesia has a very quick onset of action with profound muscle relaxation, but duration of action is short. Caudal anaesthesia and analgesia has a slower onset, but lasts for a longer time. Therefore, under GA combined with caudal bilateral hernia can also be repaired and can provide postoperative analgesia too. Combined spinal-epidural (CSE) anaesthesia has both the advantages of spinal and caudal anaesthesia. Hence, in conclusion it can be said that all types of regional anaesthetic techniques adopted in adults can be administered safely in paediatric patients, combined with GA. But only strict attention has to be paid to the route of administeration, the dose of the local anaesthetic agent and the size of the proper equipment (e.g. miniature needle, fine catheter, etc.).

Caudal block with 0.25% bupivacaine in a dose of 0.75 to1 ml/Kg with or without catheter is effective for inguinal hernia repair or orchidopexy. For circumcision or hypospadious repair the caudal dose of bupivacaine is 0.5 ml/Kg as 0.25% solution. For the volumes over 20 ml the bupivacaine is diluted to 0.15%. For all the above mentioned percentage and doses of bupivacaine, analgesia lasts for 4 to 6 hours. Bupivacaine concentration higher than 0.25% offers no added advantage about sensory blockade, except adverse motor blockade. Also 0.125% bupivacaine solution is reported to produce the same quality and duration of intraoperative and postoperative analgesia as 0.25% solution and the lower concentration resulted in lesser motor blockade. For inguinal hernia repair and orchidopexy the ilioingninal and iliohypogastric nerve block which is achieved by infiltrating 0.25% bupivacaine medial to the anterior superior iliac spine also has been used successfully in paediatric patients. The penile nerve block for circumscision or hypospadius operation or any other surgical procedure on the

penis which is achieved by infiltration of 1 to 3 ml adrenaline-free 0.25% bupivacaine or adrenaline-free 1% lignocaine provides excellent intraoperative and postoperative analgesia.

The direct local infiltration of the surgical wound by long acting local anaesthetic agents is another effective method of providing pain relief (postoperative analgesia) in all children. In most institutions it is now rare for a paediatric patient to awaken from anaesthesia without some form of regional block. Parents are advised to start analgesia (oral or parenteral) when the child begins to become irritable, but prior to the complete dissipation of the block. This procedure usually provides a smooth transition and a pain free postoperative period.

POST-OPERATIVE PAIN RELIEF IN CHILDREN

Many adverse pathophysiological changes occur in children due to the acute postoperative pain. These are increase in anxiety, avoidance, certain adverse somatic signs and symptoms such as: ↑HR, ↑BP, ↑metabolic acidosis, ↑RR causing respiratory alkalosis, ↑catecholamines, etc, and the increase in parent's distress. But, unfortunately the acute pain experienced by children is often inadequately assessed and treated, inspite of our sincere efforts.

This is because pain in children had been often underestimated and undertreated. This is due to an exaggerated fear of respiratory depression caused by narcotics which are used as post-operative analgesics and other misconceptions (Table 25.26).

But, modern paediatric anaesthesia asserts on the controlling and decreasing the postoperative pain, as far as possible, without causing any harm to the child. The severity of the pain dictates the choice of the analgesic. Mild pain is treated with non-opioids, whereas the moderate and severe pain is treated with opioids and/or regional anaesthesia.

Table 25.26: Misconception governing the post-operative pain relief in children

1. Due to immaturity of the nervous system, children experience no or little pain than adults. But the nerves responsible for pain are fully developed by 27 weeks of gestation.
2. Paediatric patients, especially neonates and infants, have no memory of pain.
3. Pain is not a character building for children, which is incorrect.

The adequate pain management in paediatric patients requires the following methodical approach.

i. Pain evaluation
ii. Route of administeration
iii. Selection of drugs

Pain Evaluation

The pain in paediatric patients can be assessed by using self-report, behavioural observation and psychological changes, depending on the age of the child and his or her communication skills. In the school-going age the children can give the verbal description of severity of their pain, but it is more difficult to evaluate it in a preverbal child. So, different ages demand different methods of evaluation of pain. However, the behavioural and physiological scales are important for newborns, infants and preschool children. Their score is based on the changes in physiological parameters such as heart rate, blood pressure, respiratory rate, sweating, crying, patient's position and facial expressions, etc. The most popular scales for assessment of pain in preverbal children are : the Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), the Objective Pain Scale (OPS) of Hannallah Broadman and the Children and Infants Post-operative Pain Scale (CHIPPS). In older children, the self-evaluation scores are much more suitable. Therefore, Visual Analogue Scales (VAS) can be used for this group of patient. The 'Smiling Facies' scale (from smiling to sad and then to crying facies corresponding to increasing pain) and 'The Colour's Scale' (from red to green – no pain to highest pain) are also routinely applied according to the age, verbal communication skill and intelligence of patient.

Routes of Administration

Oral analgesia is always desirable for children, whenever is possible. The standard doses of analgesics and adequate intervals through oral route provide excellent analgesia in the majority of patients. The intravenous route of administration of drugs provides rapid onset of analgesia with the advantage of incremental intravenous titration, but with no discomfort to the child. The intramuscular injections should be avoided, as children often deny repeated intramuscular injections and also because of unpredictable pharmacokinetics.

Patient Controlled Analgesia (PCA) also provides excellent analgesia for paediatric group of patients. However, preoperative education is valuable for children using PCA. This is because the patient needs the control of button to self-administer the bolus of analgesics and before using PCA adequate intravenous loading dose of the opioid is required to achieve the adequate blood levels. The two modes of PCA are used. These are (i) bolus only and (ii) bolus with continuous infusion. Various nerve blocks and epidural block are also often can be used for postoperative analgesia (Table 25.27).

Selection of Drugs

The non-steroidal anti-inflammatory drugs (NSAIDs) are taken as the first line of therapy for analgesia in paediatric group of patients. This is followed by the opioids and then local anaesthetics. Recently,

Table 25.27: Common routes of administration

Oral	:	Transmucosal preparation Fentanyl lollipop (8 to 10 µg/Kg)
Rectal	:	Paracetamol (80 to 170 mg)
	:	Diclofenac (12.5 mg)
Parenteral		Intramuscular
	:	Intravenous
		Bolus, continuous infusion, PCA, epidural, subcutaneous

the local anaesthetic agents have become the drug of choice. Recently a multimodal approach using a combination of drugs provides effective analgesia with a lower doses than any single drug.

Among the NSAIDs, paracetamol is the agent of first line management for paediatric pain control. Their action is linked to their anti-inflammatory, antipyretic and analgesic effects by inhibiting cyclo-oxygenase and thus reducing the production of pain mediators like thromboxanes and prostaglandins. Their main efficacy is in mild to moderate pain. But, they also have an opioid-sparing effect. They are metabolized in the liver and excreted by the kidneys. They should be used with caution in newborns, because their organs are still immature. Other side effects of NSAIDs are: gastric irritation and inhibition of platelet function. They also have a ceiling effect which means that above a certain higher dose there is only an increase in the side effects without increasing the analgesic effect. NSAIDs must be avoided in infants less than 1 year. Most NSAIDs can be administered by the oral or rectal route, while ketorolac and propacetamol can be used through IV. Paracetamol is the most commonly used paediatric analgesic in daily practice. A recent paper recommends the following doses of paracetamol in children: 40 mg/Kg as rectal suppositories (PR) initially, followed by 20 mg/Kg orally, followed by 30 mg/Kg orally at every 8 hours interval. The 90 mg/Kg/day dosage is not always sufficient for pain relief and 100 to 200 mg/Kg/PR may be necessary, keeping in mind that the toxicity is connected with the cumulative action of repeated doses. In the newborn the dosage of paracetamol is reduced to 40 mg/Kg/PR, followed by 30 mg/Kg/12 hours orally. Propacetamol, the injectable water soluble prodrug of paracetamol is useful for faster onset of analgesia. The recommended IV dose of Ketorolac, another NSAID whose effectiveness has been demonstrated successfully in acute pain management is 0.75 mg/Kg and provides analgesia similar to 0.1 mg/Kg of morphine. Diclofenac is used as 0.5 to 1 mg/Kg/rectal and Ibuprofen as10 mg/Kg orally, every 8 hours.

The opioids are the basis of postoperative treatment for moderate to severe pain. Their action is at the specific receptors along the CNS, inhibiting the release of neurotransmitters. The major concern for the use of narcotics in the paediatric age group of patients is the proportional increase in side effects with increased doses. These are respiratory depression, nausea, vomiting, pruritus, urinary retention, delay in gastrointestinal function, etc. The respiratory depression can occur even several hours after the administration of opioids. So, the accurate monitoring of all the vital parameters such as respiratory rate and oxygen saturation is mandatory. The evaluation of sedation score is also important for paediatric group of patients because a slight overdose of narcotics may easily cause deep sedation which is not desirable. Morphine is the gold standard opioid with which all other opioids are compared and is frequently used for postoperative pain relief in children. The doses of morphine depend on the route of administration, for example, SC → 0.01 to 0.02 mg/Kg, IV → 0.02 to 0.1 mg/Kg, continuous infusion : loading dose of 0.1 to 0.2 mg/Kg followed by 0.01 mg/Kg/hour; Epidural→ 0.03 mg/Kg/8hours. However, the above mentioned doses of morphine must be reduced in newborns and infants. Fentanyl is 100 times more potent than morphine. It has a rapid onset and shorter half life. So, it is useful for short-term therapy in acute pain in the dose of 1 to 4 μg/Kg IV. Fentanyl also can be administered epidurally at the dose of 1 to 2 μg/Kg. Remifentanyl is the most recent synthetic opioid which is mainly metabolised by a specific plasma esterase. It has a very short elimination half-life of 3 to 5 minutes. Alfentanil and sufentalil are two other important synthetic opioids. The commonly prescribed adjuvant drug for opioid's complication is naloxone (5 to 10 μg/Kg − IV) and ondansetron (0.1 to 0.2 mg/Kg /8 hourly − IV or PO).

Table 25.28: Common regional block

Caudal	: 0.5 to 1.2 ml/Kg of 0.25% bupivacaine for sacral or lumbar nerves
Penile block	: 0.1 ml/Kg of 0.25% bupivacaine on each side
Ilioinguinal block	:
Lumbar epidural	: 0.5 ml/Kg of 0.5% bupivacaine
Brachial plexua block	: 0.3 ml/Kg of 0.25% bupivacaine

The regional anaesthesia has a wide application for the management of postoperative pain in paediatric group of patients. The regional analgesia can involve epidural block, subarachnoid block, different plexus block, different peripheral nerve block wound infiltration and topical application. Blocks are safe and effective in children with the use of different local anaesthetic agent with or without adjuvants like clonidine, opioids, etc, in both as single shot or as continuous infusion technique, according to the type of surgery and the quality and intensity of the post-operative pain. It is the best technique for reducing the surgical stress. All local anaesthetics used for adults may be applied in paediatric practice too, provided the appropriate dosing regimens are followed. The lignocaine and mevacaine are suitable for short time surgeries and mild postoperative pain, while bupivacaine is used for long-term analgesia. Ropivacaine is the new aminoamide local anaesthetic agent with lesser cardiac and central nervous system toxicity than bupivacaine (Table 25.28).

To conclude for the postoperative pain management in paediatric patients, we can always say that the presence of a tender and loving care of mother by the side of the child reduces the pain to a great extent. The anticipation of pain and its pre-emptive intervention is very helpful. Using the multimodal (pharmacological, cognitive, behavioural and physical) and the multi disciplinary approach for the relief of pain, whenever possible, offers the best post-operative pain relief in children.

26 Perioperative Arrhythmia and its Management

INTRODUCTION

The incidence of perioperative cardiac arrhythmia varies from centre to centre and it depends on many factors. These factors are:

i. Types of arrhythmia (because all the types of arrhythmia are not taken into account or its incidence, as all are not potentially so harmful).
ii. Types of surveillance. Extensive surveillance increases the incidence of arrhythmia and less sensitive survilence decreases the incidence of arrhythmia.
iii. Patient's characteristics and underlying diseases.
iv. The nature of surgery.
v. The nature of anaesthesia itself with its different variabilities.

The perioperative arrhythmias are nothing different or special in type. These are the same arrhythmias that we see in everyday cardiologycal practice. But these are just named such (perioperative arrhythmia), because they are associated with operative procedures. Even the management of these arrhythmias remains more or less the same, except stoppage or alterations of some anaesthetic drugs. and stoppage of some surgical procedures such as traction on viscera, muscles (specially ocular), peritoneum, etc. The incidence of perioperative arrhythmias in cardiothoracic surgery with extensive monitoring exceeds 90% and in most of these cases requires no treatment. Whereas this incidence of perioperative arrhythmia in elective caesarean section is very low. The factors that determine how a patient tolerates perioperative arrhythmias include: heart rate, the specific type of arrhythmia, duration of arrhythmia, the presence and severity of any underlying cardiac disease, the effects of that specific cardiac rhythm on the cardiac output and the possible interaction of antiarrhythmic drugs with the drugs which are administered to produce and maintain the anaesthesia.

Fig. 26.1: ECG with sinus rhythm at heart rate of 100/min, because there are 3 large squares between two QRS complexes

HEART RATE

The measurement of heart rate and the identification of cardiac arrhythmia go hand in hand. This is because many abnormalities of heart rate measurement results from arrhythmias and also any wrong measurement of HR may seem arrhythmia. However, to begin with, I shall describe ways how to measure the heart rate from ECG tracing and how to diagnose the abnormalities that can affect it. It will have to remember that when there is talk of measuring the heart rate, it will mean the ventricular rate which corresponds to the patient's pulse and not the atrial rate.

Measurement of Heart Rate

Measurement of heart rate from an ECG tracing is simple and can be done in several ways.

i. When the paper speed is 25 mm/sec, then 1 sec ECG tracing covers 25 mm length of paper or 25 small squares, or 5 large squares (every small square is 1 mm and every large square containing 5 small squares is 5 mm) (Fig. 26.1). Therefore, 1 minute ECG tracing covers 1500 small squares or 300 large squares (60 sec × 5 large squares). If patient's cardiac rhythm is regular, then that have to do is to count the number of large squares between two QRS complexes and divide 300 by this number which will give the heart rate.
For example, if there are four large square between two QRS complexes, then the heart rate is 300 ÷ 4 = 75 per min. The explanation is like that 300 large squares mean 1 minute and the number of large square between two QRS complexes mean the interval between two heart beat. So, the division of 300 (i.e. 1 minute) by the interval (time in second) between two heart beat will give the heart rate.
ii. When the rhythm is irregular, this method does not work well because the number of large square between two QRS complexes varies from beat to beat. Here, that have to do is to count the number of QRS complexes within the total duration of 30 large squares which indicates the number of QRS

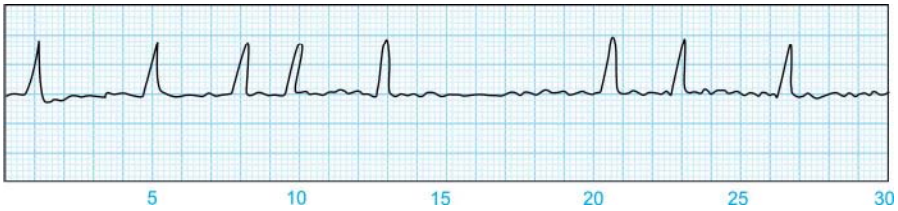

Fig. 26.2: This graph shows irregular cardiac rhythm. Here heart rate is calculated like this: We know 5 large square is 1 sec, or 1 sec = 5 large square, So 60 sec or 1 min = 60 × 5 = 300 large square, 30 large square contain 8 QRS complexes. So, 300 large square contain 8 × 10 = 80 QRS complexes. Thus, the heart rate is 80/min

complexes in 6 sec. (1 sec means 5 large squares) (Fig. 26.2).

Now, the heart rate can simply be workout by multiplying the number of QRS complexes in 6 sec (which is equivalent to 30 large square) with 10. As for example, if the number of QRS complexes within 30 large squares is 6, then the heart rate is 6 × 10 = 60 per minute.

iii. When the ECG paper speed is 25 mm/sec (i.e. 25 small squares per sec because every small square is 1 mm or 0.04 sec), then within 1 minute the tracing covers 1500 small square. Then the heart rate can easily be calculated by dividing 1500 with the number of small squares between two R waves. As for example, let the number of small squares between two R waves is 20. Then the heart rate is 1500 ÷ 20 = 75 per minute (Fig. 26.3).

These above methods of measurement of ventricular rate also can be used to measure the atrial or P-wave rate and to match the atrial rate with the ventricular rate. Usually, the two rates are same. But, in some situations the P waves are prevented to originate or are originated but are incapable of activating the ventricle and the two rates differs. This situations will be discussed later on (Fig. 26.4).

After the measurement of heart rate, one have to decide is whether: (i) it is regular or irregular, (ii) bradycardia or tachycardia, (iii) QRS complex is narrow or broad and (iv) supraventricular or ventricular in origin. As a general rule, a regular cardiac rhythm with heart rate between 60 and 100 beats per minute is considered normal. If the heart rate is regular but below 60/min, then it is called bradycardia and if the heart rate is regular but above 100/min, then it is called tachycardia.

Sinus Rhythm

Sinus rhythm is the normal cardiac rhythm in which the SA node acts as the natural pacemaker and discharging impulses at the rate of 60 to 100 times per minute (Fig. 26.5).

Sinus Arrhythmia

It is the normal physiological variation of heart rate with respiration, i.e. increase in heart rate during inspiration and decrease in heart rate during expiration. Heart rate increases during inspiration as a reflex response to the increased blood volume returning to the heart during inspiration. But during expiration reverse occurs and heart rate decreases. It is harmless and no treatment is necessary. It is uncommon after the age of 40. The characteristics of sinus arrhythmia in ECG tracing are that every P-wave is followed by QRS complex and the heart rate varies with the respiration (Fig. 26.6).

Fig. 26.3: This graph indicates 20 small squares between two R waves. So, 20 small squares indicate one heart beat. Therefore, 1500 small squares (or 1 minute) indicates 1500 ÷ 20 = 75 heart beat

Fig. 26.4: This graph shows different P-wave and QRS complexes. To calculate the P-wave and QRS complex rate separately, we have to take the help of 30 large square

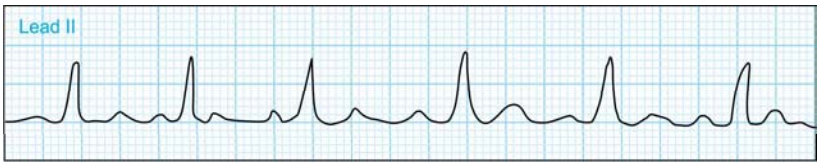

Fig. 26.5: This is a graph of sinus rhythm which is characterised by: (i) regular heart beat by any rate, (ii) P waves are upright in lead II and (iii) QRS complex after every P waves

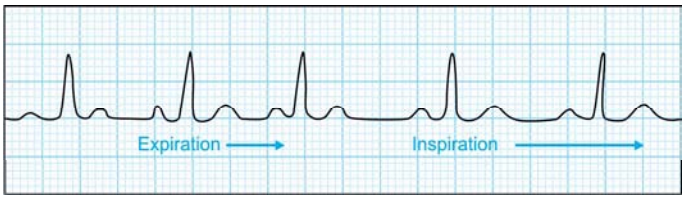

Fig. 26.6: This is a graph of sinus arrhythmia, characterised by: heart rate 100/min during inspiration and 75/min during expiration

PERIOPERATIVE DIFFERENT TYPES OF CARDIAC RHYTHM

The following types of cardiac rhythms (normal or abnormal) are usually encountered during the perioperative period.

Rhythms Arising from SA Node

Sinus rhythm, sinus arrhythmia, sinus bradycardia, sinus tachycardia, sick sinus syndrome, sinus arrest.

Rhythms Arising from Atrial Musculature

Atrial tachycardia – (supraventricular tachycardia, paroxysmal supra ventricular tachycardia) atrial flutter, atrial fibrillation.

Rhythms Arising from AV Node

AV nodal re-entry tachycardia, AV re-entry tachycardia (W-P-W syndrome), AV nodal or junctional rhythm, AV junctional tachycardia.

Ventricular Rhythms Arising from Ventricular Musculature

Ventricular extra-systoles, ventricular tachycardia, accelerated idioventricular rhythm, torsades-de-pointes, ventricular flutter and ventricular fibrillation.

Rhythm Due to Conduction Disturbance

Escape rhythm, ectopic beats (RBBB or LBBB are not varieties of rhythm. These are only due to conduction defects).

Following questions should be asked for diagnosis or identification of various types of cardiac rhythms:

The diagnosis of various types of cardiac rhythm from the tracing of ECG are not usually difficult. But, sometimes it becomes difficult. Then the following questions should be asked which will facilitate the diagnosis of different arrhythmias. These are:

(i) From where the impulses are arising?

SA node, atria, AV node or ventricles. (Table 26.1).

(ii) How the impulses are conducted?

Normal conduction, accelerated conduction (W-P-W syndrome) or blocked conduction.

(iii) If the rhythm is regular or irregular?

To determine whether the cardiac rhythm is regular or not, the distance between the two consecutive R waves is measured. If the RR interval varies, then the rhythm is irregular. The causes of irregular rhythm is sinus arrhythmia, atrial flutter with varying degree of blocks, atrial fibrillation (AF), any supraventricular rhythm with intermittent block, escape rhythm, ectopic beats, ventricular fibrillation.

(iv) If the rhythm is supraventricular (including the AV junction) or ventricular?

The supraventricular rhythm means when it originates from the site above the ventricle. All the supraventricular rhythms produce narrow QRS complexes, provided there is no conduction defects. If supraventricular rhythm is associated with bundle branch block or an accessary pathway, then the QRS complexes will be broad. The ventricular rhythm by itself originating from ventricular musculature are associated with broad QRS complex (>3 small squares). This is due to the conduction of impulses through ventricular musculature, instead of through the specified high conducting Purkinje fibres which takes less times.

Table 26.1: Different types of cardiac rhythms

1.	**SA nodal rhythms**
	Sinus rhythm
	Sinus arrhythmia
	Sinus tachycardia
	Sinus bradycardia
	Sick sinus syndrome
	Sinus arrest
	Sinus block
2.	**Atrial rhythms**
	Atrial tachycardia
	Paroxysmal atrial tachycardia
	Atrial flutter
	Atrial fibrillation
3.	**Atrioventricular rhythms**
	AV nodal or junctional rhythms
	AV junctional tachycardia
	AV re-entry tachycardia
	AV nodal re-entry tachycardia
4.	**Ventricular rhythms**
	Ventricular tachycardia
	Accelerated idioventricular rhythm
	Torsades-de-pointes
	Ventricular fibrilation
5.	**Conduction disturbances**
	RBBB, LBBB, LAHB, LPHB,
	Bifasicular block
	Complete block
6.	**Escape rhythms**
7.	**Ectopic beats**

(v) If the P-waves are present or not?

The presence of P-waves indicates atrial activity. So, careful examination of P-waves and QRS complexes gives an idea of the relationship between atrial and ventricular activity. The shape of P-wave also provides an idea of the origin of atrial depolarisation. For example – if it is upright in lead II, then it is sure that the atrial depolarisation origins in or near the SA node. On the contrary, inverted P-waves in lead II suggest its origin closer to or within the AV node. This is because here impulses pass from AV node to SA node whose direction is upwards and opposite the direction of lead II. If all the P-waves are followed by QRS complexes, then it indicates that conduction from atrium to ventricle is normal and there is no AV block. If there are more P-waves than QRS complexes, then conduction between atria and ventricles is being either partly blocked or completely blocked or atrial activity is such increased that it is beyond the normal conduction capability of AV node. More QRS complexes than P-waves indicate AV dissociation with higher ventricular rate than atrium. During the identification of P-wave always it have to bear in mind that sometimes the P-waves may be difficult or even impossible to identify clearly. Therefore, it can be difficult to say firmly that atrial activity is present or absent.

(vi) If there is bradycardia or tachycardia?

CAUSES OF PERIOPERATIVE BRADYCARDIA AND ITS MANAGEMENT

In the previous page all the arrhythmias are classified according to the site of their origin. But here from the aspect of management all the arrhythmias are classified under the two broad headings — arrhythmia causing bradycardia and arrhythmia causing tachycardia.

The common causes of perioperative bradycardia are:

i. sinus bradycardia
ii. sinus arrest
iii. sinoatrial block
iv. sick sinus syndrome
v. conduction defects – second and third degree AV block,
vi. Escape rhythm – AV junctional escape rhythms, ventricular escape rhythm,
vii. ectopics
viii. asystole

Sinus Bradycardia

Sinus bradycardia is defined as a type of sinus rhythm where the heart rate is less than 60 beats per minute. In physiological conditions it is usually found in normal persons, athletes, during sleep, etc. and is not harmful. It is unusual for the sinus bradycardia to be slower than 40 beats/min, otherwise alternative causes like heart block, drug effect, etc. should be considered. The probable pathological causes of sinus bradycardia are: drugs (digoxin, β-blockers, antiarrhythmic agents, adenosine, verapamil, diltazem, anaesthetic drugs etc.), ischaemic heart disease, M1-leading to conduction defects, sick sinus syndrome, hypothyradism, hypothermia, electrolyte imbalance, obstructive jaundice, uraemia, raised ICP, etc.

The characteristic features of sinus bradycardia in ECG are :

i. Heart rate less than 60 beats per minute.
ii. Every P-wave is followed by a QRS complex.
iii. The P-wave is upright in lead II and inverted in lead AVR (Fig. 26.7).

Fig. 26.7: This is a graph of sinus bradycardia, characterised by : heart rate 50/min, upright P-wave in lead II and QRS complex after every P-wave

If bradycardia is severe i.e. less than 40 beats/min, then one have to consider – sinus arrest, sino-atrial block, sick sinus syndrome and complete heart block, etc. If sinus bradycardia is severe, then escape beats or escape rhythm from the AV node or ventricles may also occur as a safe guard mechanism.

For sinus bradycardia due to physiological conditions no treatment is needed. But for the management of symptomatic severe bradycardia, the first step is to asses the urgency of situation such as syncope, falls, dizziness or breathlessness, etc. This is usually done by proper history taking, careful examination and further investigations (e.g. thyroid function, plasma electrolytes, etc.). It will also help to identify the underlying pathological causes of bradycardia and to correct it where possible by discontinuation or reduction of the dose of responsible drugs, by identification of abnormal cardiac rhythm and its management, by identification and treatment of hypothyroidism etc. When the bradycardia is severe and symptomatic with evidence of severe haemodynamic disturbance, then more urgent treatment is instituted immediately such as:

(i) Inj Atropine – 300 to 600 µg given slowly intravenously and or (ii) Inj Isoprenaline – 0.5 to 10 µg/min by intravenous infusion.

However, insertion of temporary pacemaker, later on permanent if indicated, is preferred than the prolonged infusion of isoprenaline. So, isoprenaline infusion should only be used as a short-term measure, while arranging for temporary or permanent pacing. Chronic severe bradycardia due to any cause may be an indication for a permanent pacemaker, particularly, when it is causing symptoms or haemodynamic disturbance even after removal of the aetiologies.

Sick Sinus Syndrome

The sick sinus syndrome refers to some conditions which are characterised by the combination of abnormal impulse generation and conduction problems related to the dysfunction of sinus node. As the name (syndrome) suggests, it is a collection of symptoms such as dizziness, fatigue, confusion, syncope and congestive heart failure. Any of the following ECG findings can be seen in patient with sick sinus syndrome with different combination. These are sinus bradycardia, sino-atrial block, sinus arrest and brady-tachy syndrome.

Sino-atrial block

Here, the SA node depolarises as normal rate, but some impulses fail to reach the atria from the SA node. Here, the pathology lies in the junction between the SA node and atrial muscle. The sino-atrial block may be of three degrees.

i. *First degree SA exit block*: It denotes a prolonged exit time of all impulses from SA node to the surrounding atrial tissue. It cannot be diagnosed by standard surface ECG, but requires invasive intracardiac recording.
ii. *Second degree SA exit block*: It denotes the intermittent failure of exit of impulses from the SA node to the atrium. It is manifested in ECG as the intermittent absence of P-wave. This is because the P-wave fails to appear in

the expected place. But the next usually appears exactly where it is expected.

iii. Third degree SA exit block or complete SA block. Here, all the impulses originating from SA node are blocked and fails to pass to atrium. So, it is characterised by complete lack of SA node activity in ECG and the presence of a subsidiary ectopic atrial or AV junctional pacemaker (Fig. 26.8).

Sinus arrest

Here the SA node fails to depolarise itself, but there is no abnormality of passing the impulses from SA node to atrium once it originates. So, all the manifestations of sinus arrest are like third degree SA exit block. Looking at the ECG strip we can find that a P-wave will suddenly fail to appear in the expected place and there is a gap of variable length, until the sinus node fires again which is irregular and a P-wave appears (Fig. 26.9).

Brady-tachy syndrome

It refers to a combination of sinus bradycardia, sinoatrial block, sinus arrest (all the components of sick sinus syndrome) with PSVT. In this syndrome the tachycardia often emerges as an escape rhythm in response to an episode of bradycardia and then it usually terminates with prolonged sinus pause. So, there is alternate periods of tachycardia and bradycardia. Moreover, any atrial tachycardia during which the atrial ectopic site is activated may cause overdrive suppression of the sinus node resulting in clinical appearance of this syndrome (Fig. 26.10).

The sick-sinus-syndrome usually coexists with atrial fibrillation, atrial flutter, atrial tachycardia, AV conduction disorder, etc.

Degeneration and fibrosis of SA node and conducting system due to ageing is the most common cause of sick-sinus-syndrome. The probable other causes of sick sinus syndrome are – IHD, drugs (antiarrhythmic), cardiomyopathy, myocarditis, etc. The diagnosis of this syndrome usually requires 24 hours holter monitoring. While looking at the ECG strip, a P-wave will suddenly fail to appear in the expected place and there is a gap of variable length until the sinus node fires again and a P-wave appears. The conduction problems become apparent when a patient with brady-tachy syndrome develops atrial fibrillation. During tachycardia the AV node fails to conduct all the atrial impulses at this unusual high atrial rate. Thus, AV block precipitates and the ventricular rate remains slow (Table 26.2).

An asymptomatic patient with SSS does not require any treatment. But, symptomatic patients need consideration for permanent pacemaker. This is particularly important if they also have paroxysmal tachycardia that require antiarrhythmic drugs (which can worsens the episodes of bradycardia). On the other hand, paroxysmal tachycardia which arise as escape rhythm in response to episodes of bradycardia may improve as a consequence of pacing and thus the vicious cycle is cut.

Fig. 26.8: This is a graph of sinoatrial block, characterised by: two P-waves fails to appear and next P-wave appears where it is expected

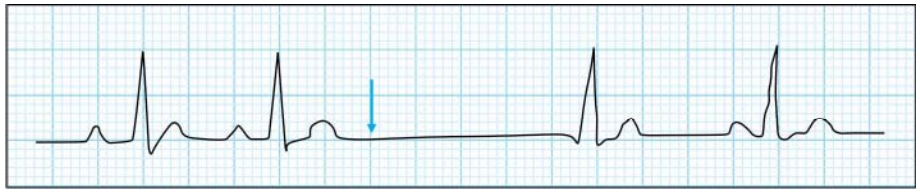

Fig. 26.9: This is a graph of sinus arrest, characterised by: P-wave fails to appear and next P-wave does not appear where expected

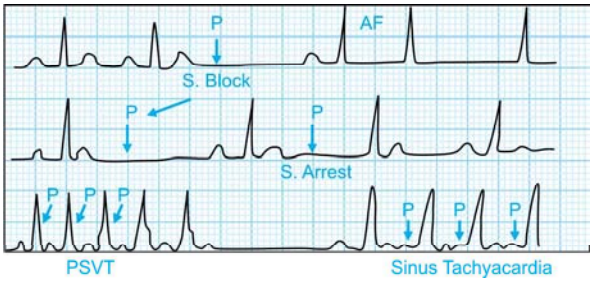

Fig. 26.10: This is a graph of sick sinus syndrome, characterised by: sinus block, sinus arrest, atrial fibrillation (AF), PSVT and sinus tachycardia

Atrio-ventricular Conduction Defects

Introduction

The specialised conducting system (AV bundle, bundle of His, Purkinje fibres) running between the atrium and the ventricle ensures smooth conduction of sinus impulses from the atrium to the the ventricle resulting in synchrous contraction of these two chambers. Hence any abnormalities of this conducting system may lead to incomplete or complete block of passage of impulses from atrium to ventricle

Table 26.2: Common features of sick sinus syndrome

Sinus bradycardia
Sinus arrest, sinoatrial block
Paroxysmal atrial fibrillation
Paroxysmal supraventricular tachycardia
Atrioventricular block

causing cardiac stand still or escape ventricular beat. Discussion on this conduction abnormalities has three significant clinical points :

i. Detection of the site of conduction disturbance.
ii. The chance of risk of progression of incomplete block to complete block.
iii. The probability of electrophysiological and haemodynamic stability of the subsidiary escape rhythm, arising distal to the block.

This last point is very important, because the symptoms which will develope depend on the stability of this escape rhythm. After AV block, the subsidiary escape beat can arise from the bundle of His or distal to the bundle in the Purkinje system. The difference between these two types of escape rhythm is that the impulse arising from the bundle of His is of 50 to 60 beats/min, whereas the impulse arising from the distal Purkinje system is 30 to 40 beats/min and unstable with broad QRS complex.

Classification

AV conduction defects or block can be classified into three degrees.

First Degree AV Block

It is also called the prolonged AV conduction defect which is characterised by a PR interval > 0.2 sec. The PR interval is the period that extends from the beginning of P-wave to the beginning of R-wave and includes the time for atrial depolarisation, the time for impulse passing through the AV node with physiological delay and the time for impulse passing through the His-Purkinje conducting system. The delay in passing of impulses through any of the structure can contribute to the prolonged PR interval (Fig. 26.11).

Delay in atrial depolarisation has no clinical significance. Delay within the AV node results in prolonged PR interval (> 0·24 sec) with normal QRS complex. Delay in His-Purkinje system results in prolonged QRS duration or broad QRS complex in addition to a prolonged PR interval. The first degree heart block does not usually need any management.

Second Degree AV Block

This is also called the intermittent AV block, as some but not all the atrial impulses fail to conduct to the ventricles through AV node. The second degree AV block is again of two types such as Mobitz type I and Mobitz type II.

In Mobitz type I (Wenckebach block) variety of second degree AV block, there is gradual prolongation of PR interval, followed by a complete block of conduction of an atrial impulse to the ventricle. This type of second degree AV block is almost always localised in the AV node and associated with normal QRS duration. This type of AV block is usually found with inferior wall infarction, β-blockers, calcium channel antagonists, drug intoxication particularly digitalis, normal individual with high vagal tone, etc. So this phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults. Sometimes this Mobitz type I category of second degree AV block can progress to third degree complete heart block, but it is uncommon except in acute inferior wall myocardial infarction. But still, if the Mobitz type I category of AV block progress to complete block, it is well tolerated, This is because the escape pacemaker usually arises in the proximal bundle of His and provides a stable rhythm. So, the Mobitz type I block rarely necessitates any aggressive therapy. If the ventricular rate as a consequence of Mobitz type I block is adequate and the patient is asymptomatic, then only observation is sufficient (Fig. 26.12).

In Mobitz type II variety of second degree AV block, there is sudden complete block of conduction of impulses from the atrium to the ventricle through AV node, without any previous warning of prolonged PR interval. In some varieties of this type of conduction defect, block is localized in the His-Purkinje system, but not in the AV node and is associated with prolonged QRS duration. Clinically, it is very important, because it has high incidence of progression to complete AV block with unstable escape pacemaker rhythm below the block. So, cardiac pacing is necessary in this type of block (Fig. 26.13).

Third Degree AV Block

In third degree AV block no atrial impulse propagates to ventricles from atrium. So,

Fig. 26.11: This is graph of first degree AV block. It is characterised by: long PR interval (0.32 sec)

Fig. 26.12: This is graph of Mobitz type I AV block. It is characterised by: progressive lengthening of PR interval (0.16 sec, then 0.28 sec, then 0.32 sec) followed by a P-wave fails to be conducted with no QRS complex and then PR interval resets with repeated cycle

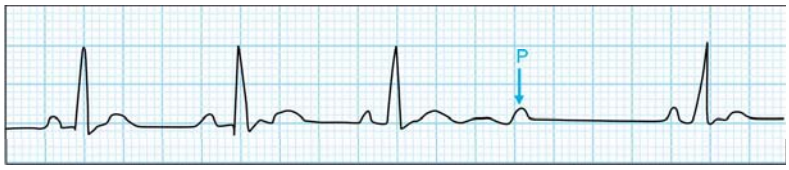

Fig. 26.13: This is a graph of Mobitz type II block. It is characterised by: all the normal and constant PR intervals and occasional P-wave fails to be conducted

the escape beat may arise from the AV node or His-Purkinje system. When the escape beat arise from AV node, the block is proximal to the origin of this escape beat in AV node and this block is called the AV nodal block. In such situation the escape ventricular beat is of normal QRS complex (as it passes through the normal Purkinje fibres) with 40 to 50 beats/min and is responsive to exercise or atropine. This is usually of congenital type. If the block is situated in the His-Purkinje system, then the escape rhythm arises from the ventricular musculature and is unreliable. It is characterised by broad QRS complexes with rate < 40/min and is usually unresponsive to atropine and exercise. This type of complete AV block mandates pacemaker implantation (Fig. 26.14).

Adams-Stokes attacks
(Adams-Stokes syndrome)

The episodes of ventricular asystole in the absence of escape beat may complicate the complete heart block or Mobitz type II second degree AV block or the sick sinus syndrome. This may be recurrent and cause syncope which is called the 'Adams–Stokes' attacks. A typical episode of Adams–Stokes syndrome is characterised by sudden loss of consciousness which frequently occurs without warning and may result in sudden fall of patient on ground. Convulsions (due to cerebral ischaemia) can occur if there is prolonged asystole. There is also death like appearance during the attack. But when the heart starts to beat again, there is characteristic regain of consciousness and flush. In contrast to epilepsy, the recovery in Adams-Stokes attack is rapid. Other diseases like the hypersensitive carotid sinus syndrome and the malignant vaso vagal syndrome may also cause similar symptoms and should be differentiated from Adams-Stokes attacks.

AV Dissociation

AV dissociation is said to be present when the atria and the ventricle are under control of two separate pacemakers. It occurs in the following three different conditions:

i. When there is complete AV block – discussed before.
ii. There is no AV block, but due to severe sinus bradycardia escape AV junctional rhythm starts. In such case, when the sinus rate and the escape rate is same, then the P-wave occurs just before the following QRS complex. This is called isorhythmic AV dissociation. Treatment of this condition is removal of causes of bradycardia. These are: (a) discontinuation of anaesthetic drugs, digitalis, β-blockers, Ca-antagonist etc, causing severe bradycardia (b) use of vagolytic agents and (c) pace making, only if patient becomes symptomatic due to severe bradycardia.
iii. There is no AV block, but enhanced lower pacemaker rate (VT, accelerated idioventricular tachycardia, etc.) which competes with normal sinus rhythm coming through AV node and frequently exceeds it. Due to rapid lower pacemaker activity in ventricle, the bombardment of the AV node by impulses arising from ventricle in a retrograde fashion, renders it refractory to the normal sinus impulse. Thus, the atrium and the ventricle beats independently. This is called interference AV dissociation, and is usually happened during myocardial ischaemia, infarction, after cardiac surgery, etc. Treatment of such condition is antiarrhythmic agent, removal of offending drugs and the correction of metabolic abnormalities or ischaemia.

Fig. 26.14: This is a graph of third degree AV block. It is characterised by : P-wave (atrial) rate is 100/min, QRS complex (ventricular) rate is 42/min, broad QRS complexes and no relationship between P-waves and QRS complexes. There is no relationship between P-wave and QRS complex because no P-wave is conducted to ventricle through AV node due to complete AV block. QRS complexes are broad because they arise from the ventricular musculature

Role of Intracardiac ECG in diagnosis of AV conduction defects

The main indication for performing intracardiac ECG or His-bundle ECG is to determine the proper indication of pacing or to select the proper patient who will be benefited from pacing.

i. *A symptomatic third degree AV block*: In such patient the His-bunle ECG will be helpful to assess the stability of the junctional pacemaker, if it is present. If His-bundle escape rhythm is unstable, then pacing is indicated, though the patient is asymptomatic.
ii. *Patient with syncope and bundle branch or fascicular block*: If such patient shows infra-His-bundle conduction disturbance then they are indicated for pacing. But nodal conduction

disturbance are not indication for pacing. Bifascicular block with asymptomatic patient are not indicated for intracardiac ECG as these group of patients are very unusually associated with AV conduction disturbances.

iii. *Symptomatic 2nd and 3rd degree AV block* are always indication for pacing without intracardiac ECG.

iv. *Asymptomatic 2nd degree AV block* is always indicated for intracardiac or His-bundle ECG. If the block is established at the intra or infra His-bundle level, then pacing is indicated though the patient is asymptomatic.

Management of AV Conduction Defects

Pharmacological therapy

It is only indicated in acute situations of AV conduction defect. Atropine in the dose of 0·6 to 2 mg IV and isoprenaline in the dose of 1 to 4 µg/min by infusion increases the heart rate, by removing the AV block. But, they have insignificant effect only if the block is below the AV node. Moreover, the result of pharmacological therapy is not always consistent and long-term. So, pacing is the only answer for long-term management of conduction defect.

CAUSES OF PERIOPERATIVE TACHYCARDIA AND ITS MANAGEMENT

Tachycardia is defined as heart rate above 100 beat/min. Sinus tachycardia is sinus rhythm, (i.e. regular impulses arising from SA node) with heart rate above 100 beat/min. Non-sinus tachycardia means tachycardia where impulses do not arise from the sinus node, but from anywhere else. The physiological causes of sinus tachycardia are anxiety, pain, fever, exercise, etc. It is rare for sinus tachycardia to exceed 180/min, except in fit athlete. At this heart rate, it may be difficult to differentiate the P-waves from the previous T-waves, as they march on each other and then this the rhythm can be mistaken for an atrioventricular nodal re-entry tachycardia or PSVT.

Some pathological causes for sinus or nonsinus tachycardia are: (i) drugs – atropine, adrenaline, etc. (ii) heart failure, (iii) fluid loss, (iv) anaemia, (v) hyperthyroidism, (vi) MI, (vii) pulmonary embolism etc (Fig. 26.15).

The characteristic features of sinus tachycardia in ECG are:

i. Heart rate is greater than 100 beats/min.

ii. The P-wave is upright in lead II and inverted in lead AVR.

iii. Every P-wave is followed by a QRS complex, though sometimes it is very difficult to identify the P-wave. (Fig. 26.16)

The management of sinus tachycardia is the management of cause. When a patient has a compensatory tachycardia such as in blood loss, fluid loss, anaemia, low BP, etc. in such situations slowing of the heart rate with β-blockers can lead to disastrous decompensation. However, if the sinus tachycardia is inappropriate or non-compensatory in nature, as in anxiety, heart failure or hyperthyroidism, etc. then treatment with β-blockers maybe helpful or life saving.

Tachycardia also can be classified into

i. Narrow QRS complex tachycardia (<3 small squares)

ii. Broad QRS complex tachycardia (>3 small squares).

In narrow complex tachycardia impulses alway arises from above the ventricular level, i.e. they are supraventricular in origin. The QRS complexes formed by impulses arising from the supraventricular level are narrow, because these impulses pass after their origin through the normal fast conducting tissues such as AV node, bundle of His, and lastly through the Purkinje fibres. But when any impulse arise from the ventricular level and does not pass through these normal conducting path, instead goes through the myocardium then QRS complexes become broad. This is because the conduction through myocardium is not as fast as the normal conducting tissues. The causes of narrow complex tachycardia are – sinus tachycardia, atrial tachycardia, AV nodal re-entrant tachycardia, AV re-entry tachycardia, AV junctional tachycardia, atrial flutter with high AV conduction, atrial fibrillation with high AV conduction, W-P-W syndrome, etc.

In broad complex tachycardia impulses always arise below the level AV node, except supraventricular origin with bundle branch block. The causes of broad QRS complex tachycardia are: ventricular tachycardia (VT), accelerated idioventricular tachycardia, torsades-de-pointers,

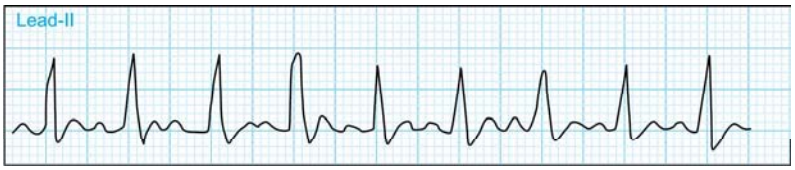

Fig. 26.15: This is a graph of sinus tachycardia. It is characterised by: heart rate 150/min, QRS complexes after every P-wave and upright P waves in lead II

Fig. 26.16: This is a graph of sinus tachycardia with P-waves hidden within the previous T-waves

ventricular flutter, ventricular fibrillation, supraventricular tachycardia with bundle branch block, etc.

Narrow Complex Tachycardias and its Management

Paroxymal supraventricular tachycardia (PSVT) or (atrial tachycardia)

It is not sinus tachycardia as impulse originates from an ectopic focus, somewhere within the atrial myocardium, except the SA node. The characteristic features of PSVT in ECG are:

i. Heart rate greater than 100 beats/min.
ii. Abnormally shaped P-waves (Fig. 26.17).

The atrial rate (P-wave) in PSVT is usually 150 to 250 beats/min. But, when the atrial rate is above 200/min, then the AV node struggles to keep up with the conduction of impulses through it and AV block may precipitate.

The management of PSVT depends on the urgency of the situation, i.e. evidence of any haemodynamic disturbance such as hypotension, cardiac failure, poor peripheral perfusion, etc. However, the general rule is that the supraventricular tachycardia causing haemodynamic disturbance requires urgent diagnosis and treatment. Initially, carotid sinus massage (vagal stimulation) reduces the heart rate by increasing the degree of AV block and in 80% of cases it is effective. When hypotension is present with PSVT, then IV phenylephrine in the dose of 0·1 mg in incremental rate may correct hypotension and subsequently tachycardia (alone) or in combination with carotid sinus massage which correct tachycardia (Fact file -I).

FACT FILE- I

Supraventricular tachycardia (SVT)

The term SVT is often misused. So it frequently leads misunderstanding. Literally, it refers to any tachycardia which originates above the ventricle (supraventricle). Thus it encompasses : sinus tachycardia, atrial tachycardia, AF, AV re-entry and nodal re-entry tachycardia etc. But some people use this term specifically to mean only AV nodal re-entry tachycardia. So, now it is recommended that all the arrhythmias should be diagnosed as specifically as possible and the term SVT should be reserved only for those whose are not diagnosed specifically but origin is above the ventricle.

If this fails, then verapamil in the dose of 2.5 to 10 mg IV or adenosine in the dose of 6 to 12 mg IV is used as second step of management. Adenosine is preferred than verapamil, because of its extremely short half-life and without any side effects. Adenosine should not be used if patient has asthma or obstructive airway disease. Verapamil should not be used, if patient has recently taken β-blocker, otherwise severe bradycardia can result (Figs 26.18 A and B).

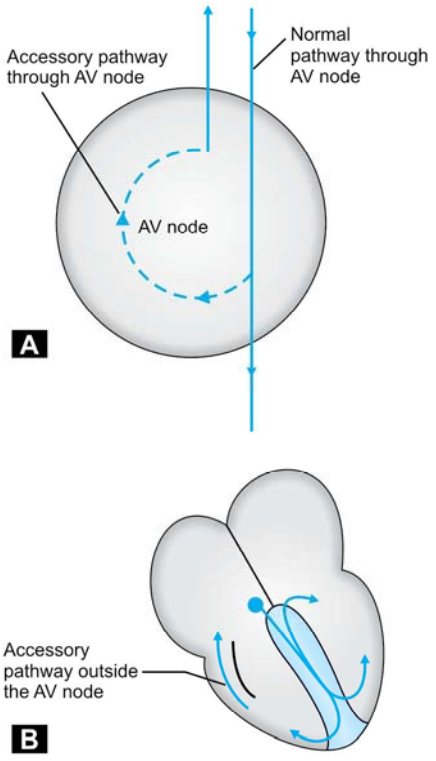
The β-blockers can also be used to slow or terminate the tachycardia of PSVT, but these are the agents of third choice. Digitalis also reduces the rate of atrial tachycardia but produces slower onset of action and has no role in acute therapy of tachycardia of PSVT.

If pharmacological treatment of PSVT fails or when tachycardia is recurrent, in spite of good pharmacological treatment, then temporary pacing may be used to terminate the arrhythmia. In the last resort, if severe ischaemia and / or hypotension is caused by tachycardia then DC cardioversion should be considered.

Fig. 26.17: This is a graph of atrial tachycardia. It is characterized by: heart rate 150/min and abnormally shaped P waves

AV re-entry tachycardia

AV reentry tachycardia may arise when there is a second alternate pathway for passing of impulses between the atria and the ventricles. This is in addition to the normal route for conduction of impulses other than the AV node. The presence of two different routes for conduction of impulses from atrium to ventricle creates the possibility that impulses can travel down through one route (anterograde conduction) and then return back through other route (retrograde conduction). In doing so, an impulse thus can enter into a repeated cycle of activity which circles round the two pathways continuously. Thus, it repeatedly re-enters and activates the atria and ventricles in rapid succession causing tachycardia. The extra connection between the atria and ventricles can either be an accessory pathway which is anatomically separate from the AV node (AV re-entry tachycardia, e.g. WPW syndrome) or through the AV node itself in which both the pathways lie in the AV node but are different



Figs 26.18A and B: This figure shows accessory pathway through the AV node A. and also through outside the AV node B

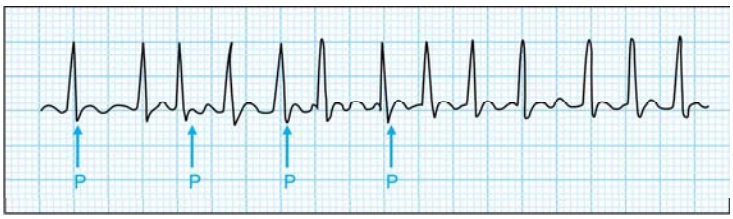


Fig. 26.19: This is a graph of AV re-entry tachycardia in WPW syndrome. It is characterised by: ventricular rate is 225/min, narrow QRS complexes and inverted P waves after QRS complexes

from their electrical activity (AV nodal re-entry tachycardia) (Fig. 26.19).

When the accessory pathways are found (like in W P W syndrome) not in the AV node, then the patients are susceptible to the episodes of AV re-entry tachycardia with anterograde conduction via the AV node and retrograde conduction via the accessory pathway. So, during the tachycardia by this type of circuit delta wave is lost. Because delta wave is only formed when anterograde conduction occurs through the accessory pathway and retrograde conduction occurs through the AV node. An AV re-entry tachycardia taking this route i.e. down the accessory pathway and up the AV node is very rare. Hence, when it does occur, then only the delta waves are seen.

Patients with AV nodal dual pathway, i.e. when both the pathway (accessory and normal) exist within the AV node, are also at the increased risk of AV re-entry tachycardia. This is called AV nodal re-entry tachycardia in which anterograde conduction usually occurs down the normal AV nodal pathway and and retrograde conduction occurs via the abnormal additional pathway within the AV node.

Both the AV re-entry and AV nodal re-entry tachycardia have the following characteristics:

i Heart rate is 150 to 250 per minute.
ii There is one abnormal P-wave (P^1) per QRS complex (although P-waves are not always clearly seen).
iii. There are regular QRS complexes.
iv. QRS complexes are narrow (in the absence of aberrant conduction).
v May have delta waves or not. Delta wave is present in the AV re-entry tachycardia where accessory pathway is present outside the AV node and anterograde conduction occurs through this accessory pathway and retrograde conduction occurs through the AV node. Delta wave is absent in AV re-entry tachycardia if anterograde conduction occurs through AV node and retrograde conduction occurs through the accessory pathway which is situated outside the AV node. Delta wave is also absent in the AV nodal re-entry tachycardia, where the accessory pathway is present within the AV node (Fig. 26.20).

In AV re-entry tachycardia the inverted P^1-waves are often seen in the middle between two QRS complexes. But, in AV nodal re-entry tachycardia the inverted P^1-waves are often difficult or impossible to find out as they follow the QRS complexes closely or are burried within them. Although the actual position of the P^1-waves may be helpful to distinguish between AV re-entry tachycardia and AV nodal re-entry tachycardia, but an ECG in sinus rhythm (i.e. when tachycardia is not present) is more diagnostic as it may reveal a short PR interval or delta wave, suggesting W P W syndrome. Truely speaking, the definite diagnosis of AV re-entry and AV nodal re-entry tachycardia is very difficult and need electro-physiological studies.

Management of AV nodal re-entry and AV re-entry tachycardia

The AV nodal re-entry tachycardia can be prevented by increasing the block within the AV node and thereby breaking the repetitive cycle of electrical activity by β-blocker or by Valsalva manoeuvre. Valsalva manoeuvre works by increasing the vagal inhibition on AV nodal conduction. Alternative of this manoeuvre is carotid sinus massage.

AV nodal re-entry can also be prevented by the use of drugs. The drugs with degree of preference are adenosine, digitalis, β-blocker and Ca-channel antagonist such as verapamil. Adenosine should not be used, if the patient suffers from asthma or any other obstructive airway disease. In emergency situation when the patient is haemodynamically compromised, then urgent DC cardioversion or overdrive atrial pacing is done.

The management of AV re-entry tachycardia is also same like AV nodal re-entry tachycardia. The patient with AV reentry tachycardia who requires pharmacological agents for chronic therapy should also be considered as the candidates for radio-frequency catheter ablation of the by-pass tract.

Wolff-Parkinson-White (WPW) Syndrome

Normally in most people impulses pass from atrium to ventricle through a distinct normal path such as AV node, bundle of His and Purkinje fibres. But, some people have additional or accessory conducting path between the atria and ventricles. This accessory path is called the bundle of Kent and the conduction of impulses through this pathway is more faster than the AV node. So, the wave of depolarisation reaches the ventricle from atrium more quickly (when it only passes anterogradely through this

Fig. 26.20: This is a graph of AV nodal re-entry tachycardia. It is characterised by: ventricular rate 150/min, narrow RS complexes and invisible P-wave

Fig. 26.21: This is a graph of WPW syndrome, characterised by: ventricular rate 75/min, short PR interval (0.08 sec) and delta waves shown by arrow

accessory pathway) than usual and thus the PR interval becomes short. A part of the ventricle is activated first by the accessory path, giving rise to Delta wave – the first part of the QRS complex. Shortly after that the rest of the ventricle is depolarised rapidly with the arrival of the normally conducted wave of depolarisation via the AV node from atrium and complete the rest of the QRS complex (Fig. 26.21).

The key diagnostic point of WPW syndrome in ECG is the short PR interval and the delta waves.

The WPW syndrome without tachycardia is found incidentally and may be asymptomatic. In these cases no action is needed. Some patients with WPW syndrome have symptoms of palpitation due to tachycardia or arrhythmia. If a symptomatic patient with WPW syndrome due to tachycardia require surgery of any kind, then the anaesthetist must be informed of the ECG finding.

The protocol of management of tachycardia in WPW syndrome is similar to PSVT. The pharmacological aim of therapy is the increase of refractoriness and reduction of conduction velocity through the components of re-entrant circuit. If there is life threatening rapid ventricular rate in response to WPW syndrome, then DC cardioversion is carried out. Alternatively, lignocaine (3 to 5 mg/kg) or procainamide (15 mg/kg) can be used, slowly intravenously over 15 to 20 min to reduce the ventricular rate. Sometimes, WPW syndrome is associated with AF. Then, IV verapamil or digitalis should not be used and if used then it should be given very cautiously, because these drugs decrease the refractoriness of accessory path and increase the ventricular rate causing VT. In chronic therapy, verapamil is not associated with increased risk. In patient with WPW syndrome and AF, the use of β-blockers are of no utility in controlling the ventricular response, when the conduction proceeds through the by pass tract. In patient with WPW syndrome and PSVT, atrial and ventricular pacing almost always terminate the PSVT immediately and regularise the ventricular rate.

The radio-frequency catheter ablation of by pass tract offers a permanent cure of WPW syndrome and is effective in 90% patient. It is the treatment of choice of WPW syndrome in patient with symptomatic arrhythmias (Fact file-II).

FACT FILE - II

Atrial fibrillation and WPW syndrome

Not only the AV re-entry tachycardia complicates the WPW syndrome, but also the AF may be precipitated. In AF due to AV re-entry tachycardia, conduction to the ventricle can occur via either the accessory pathway (commonest) or the AV node or both. When the conduction through accessory pathway takes place, it causes rapid and potentially lethal ventricular rate. Therefore, the drugs such as verapamil, adenosine, etc, which block the AV node are detrimental in such patient and increase conduction through accessory pathway. In such circumstances, DC cardio version is the treatment of choice. These conditions also can be treated by drugs which slow the conduction through accessory pathway such as sotalol, disopyramide, amiodarone etc. Ablation of accessory path also can be thought.

AV Junctional Tachycardia

The AV node is divided in three regions: (i) The central N region, (ii) the peripheral AN region where the atrial fibres enter the AV node, and (iii) the peripheral NV region where the AV node extends into the bundle of His. It had been said that the central N region show the absence of diastolic depolarisation (phase 4) and therefore automaticity does not exist in this area. So, the cells proper in the AV node cannot act as pacemakers or originate ectopic discharges. In contrast, the junctional AN zone or NV zone are the zones of automaticity and can act as pacemakers or be the site of ectopic discharges. Hence, the older terminology of AV nodal rhythms had been replaced by AV junctional rhythms. However, the more recent studies also have demonstrated the diastolic depolarisation in the N regions of AV node. Therefore, the older designation of AV nodal rhythms can be justified (Fig. 26.22).

In junctional beat the ectopic impulse arises from any junctional sites (AN or NV zones) of AV node. The impulse then spreads upward into the atrium and downward into the ventricle. This usually produces an upright P^1 wave in aVR and high oesophageal leads, and an inverted P^1 wave in aVF and low oesophageal leads. This P^1 wave can be burried in the QRS complex during tachycardia and may not be visible. The atrium is activated in a retrograde fashion prior to activation of the ventricle. This produces a normal or short P^1R interval. Such a beat is not distinguishable from an atrial ectopic beat arising from a low atrial focus near AV node and therefore is best referred to as a supraventricular beat. The finding of a short P^1R interval (less than 0.12 second) with an inverted P^1 wave in lead aVF may favour junctional origin of impulse. A P^1R

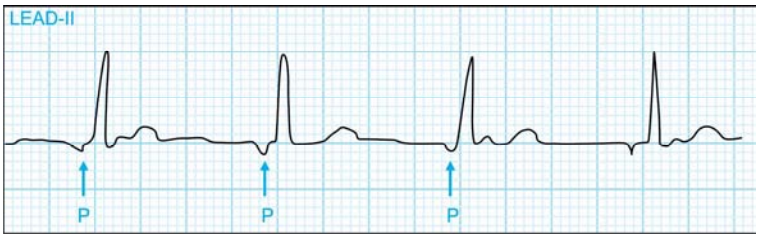

Fig. 26.22: This is a graph of AV junctional rhythm characterised by: inverted P waves in lead II, abnormally short PR interval, and narrow QRS complex

interval longer than 0.12 second with an inverted P^1 in aVF may favour ventricular excitation (Fig. 26.22A).

In AV junctional rhythm and tachycardia the QRS-T complexes are of normal configuration. The junctional beats may be either premature, i.e. occurring earlier than the next anticipated sinus beat or escape beats. The previous one occurs when increased automaticity of the junctional sites develops (e.g. digitalis toxicity) and the later occurs when the sinus rate slows. When the junctional beats act as escape rhythm, then it is regular and the rate may vary from 40 to 80 per minute (Table 26.3).

Table 26.3: Causes of inverted P waves

1. Incorrectly positioned electrodes
2. Change of axis of heart
3. Dextrocardia
4. Abnormal atrial depolarisation
   a. Atrial ectopics
   b. AV junctional rhythm
   c. Retrogradely conducted ventricular ectopic
   d. Retrogradely conducted ventricular tachycardia

The junctional escape rhythms are the form of safety net for heart. Without escape rhythms, complete failure of impulse generation from SA node and its conduction through AV node at any moment would lead to ventricular asystole and death. So, the heart has a number of subsidiary pacemaker site that can take over the responsibility if normal impulse generation from SA node or its conduction fails. The subsidiary pacemaker site are located in the AV junction or in the ventricular myocardium. If the AV junction fails to receive impulse, as a result of SA arrest or block or even during severe sinus bradycardia, then it will take over as the cardiac pacemaker. The QRS complexes generated from ventricular depolarisation by AV junctional rhythm will have the same morphology as normal, but at a slower rate of around 40 to 60 beats per minute. AV junctional pacemaker will continue until it is inhibited by impulses from the SA node. If the AV junctional pacemaker fails or its impulses are blocked to pass to ventricle then a ventricular pacemaker (from ventricular myocardium or Purkinje fibre) will take over the responsibility and this QRS complexes will be broad (Figs 26.23 and 26.24).

The AV junctional rhythm may be transient or permanent. The transient AV junctional rhythm may sometimes be seen in normal people. It may be produced by carotid sinus pressure (protective escape phenomenon) or may result form digitalis (increased automaticity of junctional site) or quinidine administration. Transient or permanent junctional rhythm also results from variety of organic heart diseases, e.g. rheumatic fever, coronary artery disease, other acute infectious myocarditis, etc. (Fig. 26.25).

In AV junction tachycardia (which is due to increased automaticity of AV junctional rhythm) the rate can vary from 120 to 200 per minute. The ventricular rhythm is regular. The P^1 waves may precede or be burried in or follow QRS complexes. The ECG pattern of QRS complex is identical with that of a junctional premature beat. With a rapid rate it is impossible to tell whether any given P^1 wave is related to the preceding QRS complex or to the following complex. Actually one can not differentiate the ECG pattern produced by junctional tachycardia from that produced by an atrial tachycardia arising from a low atrial ectopic focus near AV node. Therefore, the general term such as supraventricular tachycardia is more applicable than the specific term AV junctional tachycardia.

Thus, management of AV junctional tachycardia is like that of atrial tachycardia.

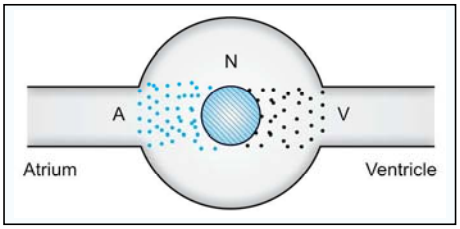

Fig. 26.22A: AV node

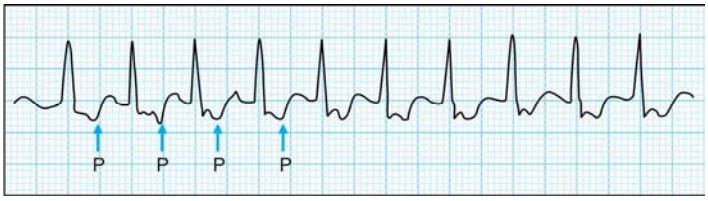

Fig. 26.25: This is the graph of AV junctional tachycardia. It is characterised by: heart rate 150/min, narrow QRS complexes, P waves hidden within the ST segments

Atrial fibrillation (AF)

Atrial fibrillation is much more common than atrial flutter. It affects 5 to 10% of elderly people and may be permanent or paroxysmal. The electrophysiological characteristic of AF is local multiple rapid chaotic depolarisation of atrial musculature which divides the atria into multiple small islands. Hence, no P-waves are seen in ECG. Instead the baseline of ECG consists of low amplitude oscillations representing chaotic electrical activity of atrium which is called the fibrillatory or F waves. Usually, the 400 to 600 atrial impulses reach the AV node per minute, but among them only 120 to 150 of these will reach the ventricles to produce tachycardia of narrow QRS complexes. This is due to the block of AV node with the traffic jam of impulses. However, due to this traffic jam and block of AV node conduction of atrial impulses through AV node is erratic which makes the ventricular rhythm irregularly irregular.

The characteristic features of AF in ECG are:

i. Absence of atrial P-waves
ii. Irregularly irregular ventricular rhythm with narrow QRS complexes. This is because transmission of atrial impulse through AV node is erratic which makes the ventricular complexes irregularly irregular (Fig. 26.26).

Once AF has been diagnosed perioperatively, then the cause of it should always be sought with careful patient's history and examination. This is because AF may be the first manifestation of many forms of organic heart disease, particularly those that are associated with enlargement or dilatation of the atria. The common causes of AF are: hypertension, 1HD, hyperthyroidism, sick-sinus-syndrome, consumption of alcohol, rheumatic mitral valvular disease, cardiomyopathy, ASD, pericarditis, myocarditis, pulmonary embolism, pneumonia, cardiac surgery, etc. When such factors are present, then the therapy of AF should be directed toward the primary abnormality.

The aims of treating AF are:

i. To control the ventricular rate.
ii. To reduce the risk of thromboembolism.
iii. If possible, restoration of sinus rhythm. (Table 26.4).

If patient's clinical status is severely compromised perioperatively by atrial fibrillation due to high ventricular rate, then electrical cardioversion is the treatment of choice. In the absence of severe cardiovascular compromised state, the slowing of ventricular rate in AF can be achieved by β-blockers, verapamil or digitalis. Both the β-blockers and verapamil prolongs the refractory period of AV node and thus slows the conduction through it. Where increased catecholamine levels or increased sympathetic tone is likely to be the cause of AF, then β-blockers are also always favoured. Digitalis is less effective in controlling ventricular rate in AF, because it takes longer time for onset of action and associated with more toxicity. Pharmacological cardioversion to sinus rhythm in AF also can be attempted by quinidine, flecainide, sotalol, propafenone or amiodarone. Among them amiodarone is probably more effective than other agents, but can lead to troublesome side effects. If medical cardioversion fails, the electrical cardio version is useful. The DC cardioversion for AF is successful when it is not long-standing and atrium is not enlarged. In patient when cardioversion is unsuccessful or in whom AF is likely to recur, then it is better to allow the patient to remain in AF and to control the ventricular response only with β-blockers or verapamil. Anticoagulation therapy appears to decrease the incidence of systemic embolization, associated with AF and cardioversion. Some advocate transesophageal echocardiography to locate the clot in atrium before cardioversion who is suffering from AF. In absence of clot, cardioversion can be undertaken and anticoagulation started immediately.

The risk of stroke due to thrombi in AF can be reduced up to 60% by anticoagulant therapy using warfarin. The use of anticoagulant in non-rheumatic AF is controversial. Patients without risk factors for thromboembolic events (previous thromboembolic episode, age > 75 yrs, hypertensive, diabetes mellitus, heart failure, large left atrium, impaired left ventricular function) may require only aspirin. In patients, below the age of 65 yrs, no anticoagulation therapy is required. The use of warfarin is most controversial in the elderly who have both the highest risk of stroke and the highest risk of bleeding when taking warfarin. The benefits and risks of anticoagulant therapy for AF must always be weighted up before initiating treatment.

Resistant atrial fibrillation can also be treated by electrical AV nodal ablation (to

Fig. 26.26: This is a graph of atrial fibrillation. It is characterised by : absent P waves, irregularly irregular QRS rhythm as AV node fails to pass all the impulses coming from high atrial activity (>300/min)

prevent conduction from atria to ventricle) with insertion of permanent ventricular pacemaker.

Atrial Flutter

The characteristic features of atrial flutter in ECG are:

i. Atrial rate is around 300 per minute. This is in between atrial tachycardia and atrial fibrillation.
ii. *Sawtooth base line*: This is because of undulating P-wave due to the rapid atrial rate which gives a characteristic undulating appearance to the baseline of the ECG. This is also called the flutter waves (Fig. 26.27).
iii. AV block, usually of 2:1, 3:1, 4:1.

Atrial flutter differs from atrial tachycardia. The difference is that atrial rate or P-wave is higher (usually 250 to 350 per minute) in flutter than tachycardia and is often, almost, exactly 300 per minute. The AV node cannot keep up with such high atrial rate. So, AV block occurs. This is most commonly 2:1, although 3:1, 4:1 or other variable degrees of block may also occur. Thus, the ventricular rate is less than atrial rate and may be 150, 100 or 75 per minute.

The causes of the atrial flutter are the same as those of atrial fibrillation. The most effctive treatment of atrial flutter in emergency condition is Direct Current (DC) cardioversion. In patient who develop atrial flutter following an open heart surgery or recurrent flutter in the setting of acute MI, then atrial pacing can usually convert the atrial flutter to sinus rhythm. Atrial pacing may also convert atrial flutter to AF which allows for easier control of the ventricular response. If immediate control of atrial flutter is not mandated by patient's clinical status, then the ventricular response should first be slowed by blocking the AV node with β-blockers, or Ca-antagonist (verapamil). Once, AV nodal conduction is slowed with any of these drugs, then an attempt to convert the flutter to sinus rhythm using sotalol, flecainide, propafenone or amiodarone should be tried. The doses of these drugs which are selected are gradually increased, until the rhythm converts or side effects occur.

Broad QRS Complex Tachycardia and its Management

The causes of broad complex tachycardia are: ventricular tachycardia, accelerated idioventricular rhythm, idioventricular tachycardia, ventricular fibrillation, ventricular flutter, torsades de poindes, supra ventricular tachycardia with bundle branch block.

Ventricular Tachycardia (VT)

It is defined as broad, abnormal QRS complexes with rate more than 100 per minute (usually between 140 to 220 per minute). Usually, the episodes of VT can be self limiting. But sometimes it may be sustained or can degenerate into ventricular fibrillation. From the managemental point of view VT can be classified into sustained and non-sustained type. Sustained VT is defined as ventricular tachycardia that persists more than 30 sec with severe haemodynamic compromise. It generally accompanies with some form of serious underlying cardiac pathology such as acute MI, IHD, cardiomyopathies, myocarditis, congenital heart diseases, metabolic disorders, drug toxicity and prolonged QT syndrome, etc.

The non-sustained VT is defined as 3 or more successive ectopic ventricular beats and is sustaining less than 30 sec. It is usually not associated with any serious underlying cardiac diseases and does not produce any symptoms, i.e. without any haemodynamic compromise. (Fig. 26.28).

The ECG diagnosis of VT is suggested by tachycardia with broad QRS complexes (rate exceeding 100 beats per minute). The QRS configuration may be uniform (monomorphic) or it may vary from beat to beat (plymorphic) as in 'torsades-de-pointes'. Bidirectional VT refers to ventricular tachycardia that shows an alternation in QRS amplitude and axis, e.g VT with RBBB with alternating superior (leftward) and inferior axis (rightward).

Sometimes, the onset of ventricular tachycardia is generally abrupt and this paroxysmal VT is usually initiated by sudden multiple ventricular premature contraction (VPC). In non-paroxysmal tachycardia the onset is gradual.

The supra-ventricular tachycardia (SVT) with RBBB or LBBB may also resemble VT due to the broad QRS complex and increased heart rate. But it shoud be distinguished from original VT. Because the clinical implications and management of these two arrhythmias are totally different.

These two conditions (true ventricular tachycardia and supraventricular

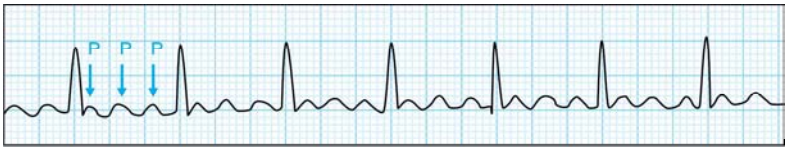

Fig. 26.27: This is a graph of atrial flutter with 3:1 AV block. It is characterised by: flutter P waves at a rate of 300/min, QRS complexes at a rate of 100/min, and 3:1 AV block (when atrial rate is above 200/min, AV node struggles to keep up with the impulse conduction and AV block may occur)

Fig. 26.28: This is a graph of ventricular tachycardia (VT). It is characterised by: Broad complex tachycardia at a rate of 200/min, QRS duration > 0.14 sec (3.5 small squares) and concordance (same QRS direction) in all the leads from V_1 to V_6

tachycardia with bundle branch block) can be differentiated apparently by :

i. Observation of intermittent canon waves in the tracing of central venous pressure monitoring and varying intensity of first heart sounds suggests AV dissociation and presence of VT.
ii. Close observation of 12 lead ECG may also be helpful.
iii. Pharmacological maneuvers such as IV administration of verapamil or adenosin (these agents terminate only the supraventricular tachycardia, but not the VT) to differentiate them can be hazardous and should be avoided. (Table 26.5)
iv. It is always useful to have a 12 lead ECG during sinus rhythm or non-tachycardia condition (i.e before development of VT) for comparison with that during tachycardia. If the QRS morphology during tachycardia is same with the previous QRS complex in ECG, i.e. when there is no tachycardia, then the diagnosis of PSVT with conduction defect is favoured.
v. An infarction pattern on the sinus rhythm tracing suggests the potential presence of VT

A characteristic feature of VT due to ventricular cause is the presence of independent atrial activity with it. This is suggested by :

• Independent P-wave.
• Fusion beats.
• Capture beats (Fact file-III and IV).

In supreventricular tachcardia the normal atrial activity is usually disturbed. So independent P-wave is absent. Whereas, in VT the independent atrial activity is indicated by the presence of independent P waves, but occurring at a slower rate than the QRS complexes. So, these QRS complexes bear no relationship to P-wave. Thus through theoretically there is definite P-ware, but, it can be difficult or even impossible to find out P waves in the jungle of multiple broad QRS complexes, originating from ventricle during VT (Fig. 26.29).

The fusion beats occur when the ventricles are activated and contracted by an atrial impulse and by an ectopic ventricular impulse at a time arriving simultaneously. The capture beats occur when an atrial impulse manages to 'capture' the ventricles for a normal contraction, causing a normal QRS complex in the jungle of broad, rapid, QRS complexes. This may be preceded by a normal P-wave (Fig. 26.30).

The characteristics of ECG that suggest tachycardia of ventricular origin (VT) are :

i. Broad complex QRS > 0.14S or 3 small squares, in the absence of antiarrhythmic therapy.
ii. Presence of AV dissociation (independent atrial and ventricular activity).
iii. Similar QRS pattern or axis in all the precordial leads.
iv. Left axis deviation with RBBB morphology or northwest axis deviation (extreme left axis deviation) with LBBB morphology.
v. Capture / fusion beat.

FACT FILE- III

Capture beat :

When there are both independent sinus and ventricular rhythm, then their impulses meet at the AV node and there interfere each other's mutual progress. So, the AV node always remains in a state of refractoriness and this is due to the prior passing of either the sinus impulses from SA node or the ectopic impulses from ventricles. But sometimes, with critical timing and due to slow ventricular ectopic rate, a sinus impulse may reach the AV node during a non-refractory phase of it and is conducted to the ventricle. Thus, it immediately activates or captures the ventricle for that beat only. This conducted sinus impulse resulting in ventricular contraction and normal QRS complex during continuous ectopic broad QRS ventricular rhythm is known as a capture beat. The QRS complex of capture beat is easily recognised, because it resembles a normal narrow sinus conducted ventricular beats inbetween the broad QRS complexes originating from ventricular ectopic site. Furthermore, the capture beat is always related to a preceding sinus P-wave.

FACT FILE - IV

Fusion beat:

Sometimes, the captured sinus impulse invades the ventricle through AV node when the ectopic ventricular impulse also tries to invade the whole ventricle, originating from ventricle. Then, each impulse will activate part of the ventricles and the resulting QRS complex will have a configuration which is in between that of the pure sinus conducted ventricular beat and the pure ectopic ventricular beat. Thus, the combination or summation of these two types of beats is known as the ventricular fusion beats. A ventricular capture and fusion beat are the most reliable diagnostic pointer to the ventricular origins of the basic ventricular tachycardia.

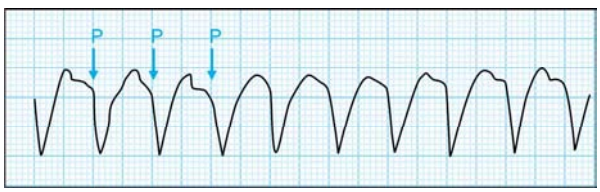

Fig. 26.30: This is a graph of fusion beat VT. It occurs when atrial and ventricular impulses arrive simulataneously

vi. No response to carotid sinus massage or IV adenosine.

The symptoms resulting from VT depend on the cardiac output which again depends on the ventricular rate, the duration of tachycardia, and the presence and extent of the underlying cardiac pathology. When the tachycardia is very rapid and is associated with severe myocardial dysfunction, then CO tremendously decreases producing hypotension, syncope, and unconciousness. Contrary, it will have to keep in mind that the presence of haemodynamic stability does not preclude the diagnosis of VT. Decrease in CO during VT may also be attributed by the loss of atrial contribution to ventricular filling (especially if atrial fibrillation is present) and by the abnormal sequence of ventricular activation.

VT without heart disease has a good prognosis with extremely low risk of sudden death. On the other hand, VT within first 6 weeks of MI have poor prognosis.

The episodes of VT can be terminated by using : (i) DC cardioversion, (ii) drugs and (iii) pacing. But the management of VT depends mainly on the risk-benefit ratio, because the antiarrhythmic agents can also produce or exacerbate the ventricular arrhythmias when they are given to prevent it. A patient with non-sustained VT without any organic heart disease and without any symptoms should not be treated, because the prognosis will not be affected. However, the patient with sustained VT, but without any heart disease may become symptomatic and require treatment (due to very low cardiac output producing hypotension and symptoms).

These tachycardias respond well to β-blockers, verapamil, procainamide, sotalol, amiodarone etc. For pharmacological termination of VT, the procainamide is the most effective agent. If it cannot terminate the tachycardia, it will always at least slow the rate. For the selection of appropriate antiarrhythmic pharmacological agent to prevent recurrence, programmed stimulation is the most effective way. In stable patients when pharmacological therapy fails, a pacing catheter can be inserted percutaneously into the right ventricular apex and the ventricular tachycardia can be terminated by overdrive pacing. Ventricular pacing to terminate VT is effective, but may sometimes also precipitate ventricular fibrillation. The VT caused by severe sinus bradycardia should also be treated by pacing at first hand. A patient with sustained VT with organic heart disease and severe haemodynamic compromise, the rhythm should be promptly terminated by DC cardioversion. Automatic implantable cardioverter defibrillation (AICD) devices can be implanted to deliver low energy shocks for recurrent episodes of VT or VF.

The development of endocardial catheter, intraoperative mapping and localization of the site of origin of arrhythmia by electrophysiological testing and then subsequent surgical ablation can better cure the ventricular tachycardia.

Some specific types of V T

Torsades-de-pointes (twisting points)

It is an unusual form of VT which is associated with long QT interval and undulating pattern of ECG with variations (polymorphic) in the direction of QRS axis. The ECG shows rapid, irregular and broad QRS complexes that oscillate from an upright to an inverted position and seem to twist around the baseline. So, it is named as the twisting point because the mean QRS axis changes. The arrhythmia is usually non-sustained and repetitive, but may degenerate into VF.

It can occur during the treatment with certain antiarrhythmic drugs (quinidine, phenothiazines, tricyclic antidepressent etc.), electrolyte abnormalities (particularly hypokalaemia and hypomagnesemia), hereditary syndromes (Jervell and Lange-Nielsen Syndrome, Romano-Ward syndrome), intracranial events and bradyarrhythmias particularly third degree AV block (Table 26.6).

Table 26.6: Causes of long QT interval and Torsades-de-pointes

Electrolyte disturbances
Hypokalaemia
Hypocalcaemia
Hypomagnesaemia
Bradycardia
Complete heart block
Sinus node disease
Drugs
Class Ia antiarrhythmic drugs (e.g disopyramide)
Class III antiarrhythmic drugs (e.g solatol, amiodarone)
Tricyclic antidepressants (e.g amitriptyline)
Phenothiazines (e.g chlorpromazine), erythromycin and other macrolides
Congenital syndrome
Jervell and Lange - Neilson's syndrome
Romano - ward syndrome (autosomal dominant)
(autosomal recessive associated with congenital deafness)

The hallmark of torsades-de-pointes in ECG are:

i. Broad complex tachycardia with polymorphic QRS complexes.
ii. Marked QT prolongation.
iii. Variation in QRS axis (Fig. 26.31).

These patients with torsades-de-points often have multiple episodes of sustained or non-sustained VT with recurrent syncope and risk of development of VF with sudden cardiac arrest. So, urgent assessment is warranted with identification and withdrawn of causative drugs prolonging QT interval and correction of electrolyte

Fig. 26.31: This is a graph of torsades-de-pointes. It is characterised by : broad complex tachycardia (300/min) and variations in QRS axis

abnormalities. The management is like that:

i. The drug induced torsades-de-pointes is treated by atrial or ventricular pacing which increases the heart rate and thereby shortens the QT interval.
ii. For patients with congenital prolonged QT syndrome, β-adrenergic blocking agent is the mainstay of therapy.
iii. Cervicothoracic sympathectomy is also indicated as a form of therapy in Torsades-de-pointes by interrupting the sympathetic supply to heart.

Idioventricular Tachycardia

The idioventricular tachycardia results from the accelerated ventricular depolarization originating from ectopic foci situated in ventricle. The heart has many potential pace maker cells. These are situated in the SA node, AV node, atria, His bundle and the ventricles. But, only one of these sites with highest automaticity controls the heart rate. It is because the impulses arising from the pace maker cells of higher automaticity reaches the lower potential subsidiary pacemaker's site and abolishes their immature impulses before they have the time to fire. Thus, the subsidiary pacemaker centre with lower automaticity enjoys protection by the impulses from the fastest pacemaker centres. But, when the inherent rate of AV nodal pacemaker site is increased than SA node and goes above 100/minute, then it is called the idionodal tachycardia. Similarly, when the inherent discharge rate from the ectopic ventricular pacemaker site is increased more than SA node, and goes above 100/minute then it is also called the idioventricular tachycardia. But when the discharge rate from the idioventricular pacemaker site is below the rate of SA node, then it is called the accelerated ventricular rhythm. So, it is commonly found in incomplete atrioventricular dissociation or found in the presence of causes which decrease the sinus rate or increase the expression of nonspecific ventricular pacemaker site such as fever, carditis, etc. It is not a sudden, precipitous, dramatic event like VT and does not precipitate in VF. The idioventricular tachycardia whose rate varies around 100/m is not so pathognomic and rarely cause much decrease in cardiac output and haemodynamic embarassment. The only difference between the idioventricular tachycardia and VT is the ventricular rate (in VT the heart rate is 150 to 220/min) (Fig. 26.32).

Fig. 26.32: This is a graph of idioventricular tachycardia. It is characterised by: broad QRS complexes and heart rate is 100/min. When broad QRS complex rate is <100/min, but >40/min, it is called the accelerated idioventricular rhythm. When broad QRS complex rate is <40/min, it is called the escape ventricular rhythm

The diagnosis of idioventricular tachycardia is based on the following criteria :

i. Evidence of ventricular origin — broad, bizarre QRS complexes
ii. Presence of captured beats — the captured beats are due to the relatively slow rate of idioventricular tachycardia than VT and the relatively long cycle of ventricular ectopic action potential which permits adequate recovery time and therefore a greater opportunity to capture a sinus beat. With very fast ventricular rates, as occur in VT, the refractory period frequently occupies the whole ventricular cycle and therefore, the opportunity to capture a sinus beat becomes minimal or absent.
iii. As the rate of idioventricular tachycardia is not so high, so the ectopic ventricular rhythm also begins with several consecutive fusion beats. This is also called the incomplete capture beat. Since, the rate of two rhythms (atrial and ventricular) are close to each other, so the idioventricular tachycardia tends to terminate after few successive fusion complexes.
iv. AV dissociation may be present or not. If it is present fusion or captured beats will not be found.
v. The ectopic pacemaker site for idioventricular tachycardia has great protection. This is evident from the fact that it is abolished when the sinus rhythm regains its dominance. This is in contrast to VT, where the ectopic rhythm is not abolished by the faster sinus rhythm.

Ventricular flutter

The Ventricular flutter is the expression of:

i. a very rapid and regular ectopic ventricular discharge like ventricular tachycardia but the rate is higher than VT.
ii. grossly abnormal intraventricular conduction (Fig. 26.33).

In ECG the QRS and T deflexion of ventricular depolarisation are very wide and bizarre, one merging with the other. So, that it is difficult to define or separate the QRS complex, ST segment and T wave. This is the difference between V. flutter and V. tachycardia. In V. tachycardia this separation is possible. This results in the appearance of a continuous sine like wave form in V. flutter.

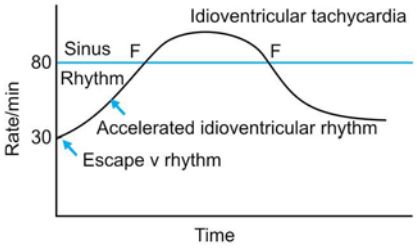

Fig. 26.33: This diagram illustrates the mechanism of ventricular tachycardia. A potential ventricular escape rhythm (beginning of red line) is enhanced to accelerated idioventricular rhythm. When it exceeds the sinus rhythm, then it becomes manifested as an ventricular tachycardia. At points F both the sinus and idioventricular rhythm will be at the same rate. Thereby, after that ventricular beat results in ventricular fusion beats. Before point F, ventricular beats are captured

The bizzare sine like wave of v flutter also may result from the abnormal intraventricular conduction alone. In ventricular flutter the coordinated activation of ventricular myocardium and sufficient contraction of it to produce a stable haemodynamic condition by giving some cardiac output is still present. However, the change from ventricular tachycardia to ventricular flutter is associated with a fall in BP and cardiac output.

Ventricular flutter is uncommon in clinical practice. It acts as a phase of tramition lying between VT and VF. So, only few examples are recorded, since the condition usually progresses or changes rapidly from ventricular tachycardia to ventricular fibrillation. Ventricular flutter differs from ventricular fibrillation in the uniformity, constancy, regularity and relatively large amplitude of QRS deflexions. Whereas the deflexions of ventricular fibrillation are small and completely chaotic and irregular.

It is well-known that V flutter and V tachycardia are the expressions of same mechanism. So their separation may nevertheless serve a useful purpose, since a diagnosis of V flutter immediately connotes a very rapid ventricular rate and / or grossly abnormal intraventricular conduction and reflects an ominous clinical state with a drop in blood pressure and a low cardiac output.

Ventricular fibrillation (VF)

Ventricular fibrillation (VF) is a very fatal condition and so it requires an immediate diagnosis and treatment. The onset of this type of arrhythmias is rapidly followed by loss of conciousness as cardiac output falls tremendously or becomes nil and if untreated, then death ensues. The 3/4th of all cardiac arrest are in the form of VF.

VF is most commonly seen after acute MI, in severe ischaemic heart disease, following administration of antiarrhythmic drugs, after electrical accidents, in severe electrolytes and acid-base imbalance, etc. (Fig. 26.34)

Genesis of VF:

i. The non-ischaemic VF begins after a short run of very rapid VT which is again initiated by subsequent multiple VPC (Ventricular Premature Contraction). The VT ultimately breaksdown into multiple wavelets of reentry circuit within the ventricular myocardium, leading to VF.
ii. In infarction or in ischaemia the VF is usually precipitated by a premature, single, early ventricular depolarisation or complex falling on T-wave (vulnerable period), which produces a rapid VT that degenerate into VF. Onset of VF within 48 hours of infarction is called primary VF and has a good long-term prognosis. Because once corrected by DC shock, this primary VT does not require prophylactic treatment (i.e low rate of recurrence). On the other hand, the onset of VF after 48 hours of infarction is called secondary VF and it merits bad prognosis due to high recurrence rate.

Electrocardiographically VF is recognised by grossly irregular undulation of waves (ventricular complexes) in ECG which is of varying amplitudes, contours and rates. The management of VF is as cardiac arrest i.e. institution of CPR immediately.

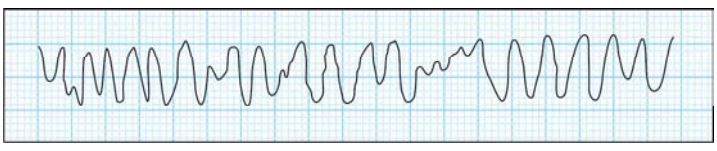

Fig. 26.34: This is a graph of ventricular fibrillation. It is characterised by: chaotic ventricular activity

CARDIAC ARREST AND CARDIO-PULMONARY RESUSCITATION (CPR)

Cardiac arrest is defined as the sudden and complete loss of cardiac function. In this condition the patient immediately loses consciousness, pulse is not palpable and respiration ceases quickly. So, death is virtually inevitable, unless an effective treatment is provided promptly. Therefore, any effective treatment which is tried immediately to start the cardiac function is called the cardio-pulmonary resuscitation.

Most frequently many cardiac arrests are managed very poorly. This is because there is lack of immediate organisation of an efficient team, lack of proper knowledge about the recommended procedures, immediate lack of proper equipments and drugs, and very frequently, different types of arrhythmias that occure during cardiac arrest are incorrectly diagnosed and treated. So, the management of cardiac arrest which is called CPR is described in a stepwise manner to prevent the haphazard way of working.

Step – I

If it is seen that a patient has been suddenly collapsed and becomes unresponsive or unconscious due to cardiac arrest, then immediate help is sought. This is because chances of successful outcome from CPR decline rapidly with the passing of time. The cardiac arrest which is manifested as unresponsiveness or unconsciousness should be confirmed first by shaking the patient and asking the questions loudly while keeping the fingers on pulse (first on radial, then if not palpable on brachial or carotid artery) and examining the eyelash or corneal reflexes. Simultaneously, the respiration should also be checked, when unresponsiveness is confirmed and pulse is not palpable. If respiration is not felt then cardiac arrest is confirmed clinically and immediate help is sought and precordial thump is delivered. If precordial thump

is started within 30 sec of confirmation of cardiac arrest, then the energy delivered by precordial thump is sufficient enough to restore an effective rhythm in 2% cases of VF and up to 40% cases of VT (provided the cardiac arrest is presented in the form of VF or VT).

If precordial thump fails to work, (usually fails) then next steps of CPR are:

i. Basic life support (BLS).

ii. Advanced life support (ALS) (Fig. 26.35).

Step – II

Though the BLS itself very rarely restores the cardiac function or patient's own breathing and circulation, still it is regarded as the cornerstone of CPR. This is because it works as stop-gap procedure to maintain the patient's minimum oxygenation and circulation until the efficient personnels, drugs and equipments needed for ALS are made available.

BLS procedure stands on : A – Airway, B – Breathing, C – Circulation.

Airway

Airway should be maintained by :

i . opening the mouth,

ii. removing or loosing any clothing around the patient's neck,

iii. removing foods, blood, froth, etc, from the mouth and cleaning the airway,

iv. lifting the chin in order to lift the tongue from the back of the throat.

Breathing

Breathing of the patient should be assessed by looking at the chest and/or by listening the mouth of the patient for breath sound and/or by feeling the patient's exhaled air on the dorsal surface of the examiner's hand. This is actually the part of the diagnosis of cardiac arrest. If the patient does not breathe, then immediate mouth to mouth artificial breathing should be started or artificial ventilation should be started by any device which is available at hand. The different types of devices which are in use for artificial ventilation has been discussed in separate chapter.

Circulation

When breathing of the patient is assessed, then peripheral pulse (brachial, carotid) also should be palpated simultaneously without wasting any time. If there is no palpable peripheral pulse then the diagnosis of cardiac arrest in confirmed and immediately full basic life support is started i.e. with mouth to mouth breathing, the cardiac compression is given. Classical cardiac compression is performed by placing the heal of one hand on the middle of the lower half of the patient's sternum and placing the heel of other hand over the first and then interlocking the fingers. After that pressure should be given vertically downwards, so that sternum is depressed by 4 to 5 cm. The rate of the chest compression should be maintained at 100 per minute. The time taken for each chest compression should be equal to the time taken to release the pressure. Every 15 chest compression should be followed by two ventilations at a ratio of 15:2. The idea behind this chest compression is that the cerebral blood flow of at least 20% of normal is needed to be maintained for a full neurological recovery and this is possible by this type of properly performed cardiac compression and artificial ventilation. Recovery of spontaneous respiration and peripheral pulse should be checked after every 10 breaths.

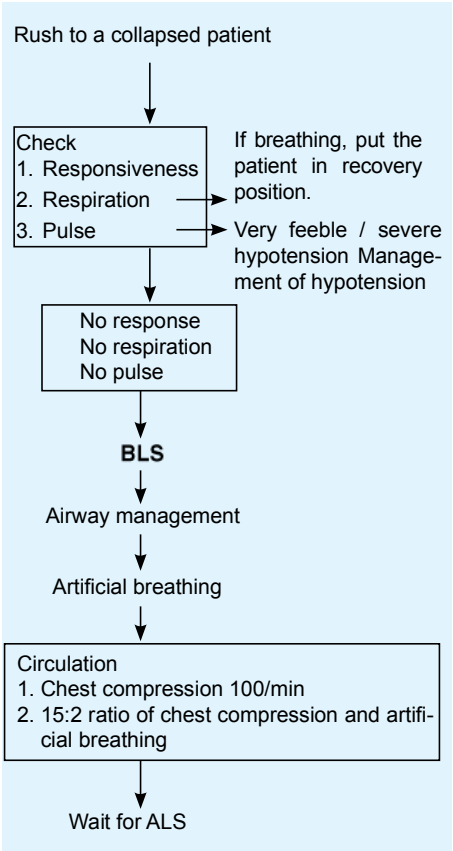

Fig. 26.35: Algorithm of adult basic life support (BLS)

Step – III

ALS is the main part of this step. ALS is commenced as soon as there is availability of proper equipments such as intubating aids, monitors, defibrillator, ventilating equipments, drugs and trained cardiac arrest management team. BLS should be continued till ALS is available and applied. Now, as the part of ALS, the defibrillator or cardiac monitor should be attached and the cardiac rhythm disorder should be studied by the other members of the team, when BLS is going on.

There are four types of arrhythmias that are usually encountered during or shortly after cardiac arrest. These are:

i. Ventricular fibrillation.

ii. Pulseless VT or sustained VT with no CO (Cardiac Output).

iii. Asystole.

iv. Electro Mechanical Dissociation (EMD).

VF

It is the most commonest form of arrhythmia in cardiac arrest and appears as a chaotic rhythm on ECG. If the monitor is faulty or the gain is turned too low, then it can also be mistaken as asystole.

Pulseless VT

It appears as broad complex rapid ventricular complexes (QRS complex) with severe haemodynamic compromise characterised

by nil or very low CO (pulseless). In such type of arrhythmia causing cardiac arrest DC shock is very helpful to convert VF and VT to normal cardiac electrical activity or to such an cardiac electrical activity which is capable of maintaining a workable cardiac output.

Asystole

It implies that there is no electrical cardiac activity and thus the ECG is simply shown as a flat or straight line. DC shock is not helpful in asystole rather it potentiates asystole (Fig. 26.36).

Electromechanical dissociation

In such condition the cardiac electrical activity is normal and the heart contract normally. But it fails to produce any CO or any effective circulation. This is mainly due to severe reduction of preload. The DC shock is also not helpful in EMD. (Fig. 26.37).

Management of VF and VT in cardiac arrest

Defibrillation converts the abnormal cardiac rhythm i.e. VF and VT (which is the most commonest > 95%) to sinus rhythm or at least to a rhythm that restores some cardiac output. So the first step of ALS is defibrillation even before the diagnosis of specific electrical activity in cardiac arrest. Defibrillation is also the coice of management for VF and VT in ICU. In addition, defibrillation can also be used if there is asystole because it cannot be entirely confirmed that it is not due to the small complex (fine) VF. So, in doubt of benefit, defibrillation should be used even in asystole as VF and VT is the most commonest (in more than 95% of cases) and treatable form of cardiac arrest. However, there is no reason in defibrillating a patient if it is confirmed that there is asystole. Because defibrillation just changes one type of cardiac rhythm to another, but it will not restart the heart where there is no initial electrical activity as in asystole. In case of EMD, defibrillation also has no role, because by definition of EMD the heart is working normally electrically, but without any CO due to some mechanical reasons such as reduction of preload.

During defibrillation the following steps should be taken. These are:

i. All nitrate patches should be removed from the patient's body.
ii. The paddles always should be placed at least 15 cm away from the permanent pacemaker.
iii. Electrode jel or gelly always should be used on the skin below the paddles.
iv. Electorde jel should not spread between the paddles as this can cause a short circuit.
v. Every body attaining this patient should stand clear of the patient and his bed just during discharging of electrical energy (Fig. 26.38).

Then, in rapid succession (i.e one after another, not measuring the time interval between the two) three DC shocks are given with the energy of 200J, 200J and 300J respectively. After that a brief pause is given to assess the patient's cardiac rhythm on monitor's screen and/or pulse and to recharge the defibrillator. These three successive DC shocks should be delivered within 45 seconds and it is not necessary to resume the basic life support as a part of ALS (i.e ventilation and chest compression) between each of these three successive shock.

After the 1st round of 3 DC shock, BLS is again started for a minute and the cardiac rhythm and pulse is assessed at the end of this minute. At this point the IV line is instituted and patient is intubated by others. BLS should not be interrupted for more than 15 sec due to any reason, when attempting intravenous line and / or intubation. If access to the IV line and intubation fails in first attempt, then it should not be tried again, till the end of the next set (2nd round) of 3 DC shocks. In between the failed attempt for IV line and intubation and DC shock, BLS should be continued for another 1 minute. The second set of 3 DC shocks should be with energy of 300J each. Before the second set of DC shock 1 mg adrenaline is given intravenously (if line is procured) or through endotracheal tube. It is not necessary to give time to adrenaline to circulate before giving the second set of DC shocks, because adrenaline does not aid in defibrillation. But it only improves the cerebral and coronary circulation by constricting the peripheral vasculature and reducing the blood flow to the skin and skeletal muscle. If adrenaline is used by endotracheal route, the total dose should be diluted to 10 ml in isotonic saline and should be used by five ventilations.

After adrenaline and the second set of DC shocks, BLS should be continued again for a minute and at the end of this minute the patient's cardiac rhythm and pulse should be assessed again. If still satisfactory cardiac rhythm has not been restored, then third set of three DC shocks should be delivered with energy of 360 J, each.

Thus, each loop [DC shock → BLS (it means chest compression and ventilation) → assessment → drug] should take no

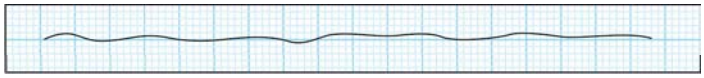

Fig. 26.36: This is a graph of asystole. It is characterised by flat line in ECG (no spontaneous electrical activity)

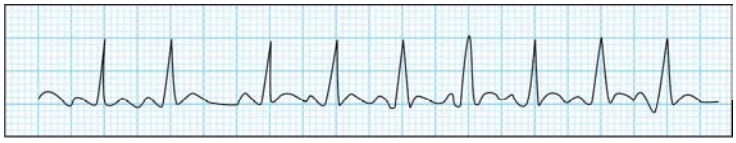

Fig. 26.37: This is a graph of electromechanical dissociation. It is characterised by normal QRS complexes in the absence of a cardiac output

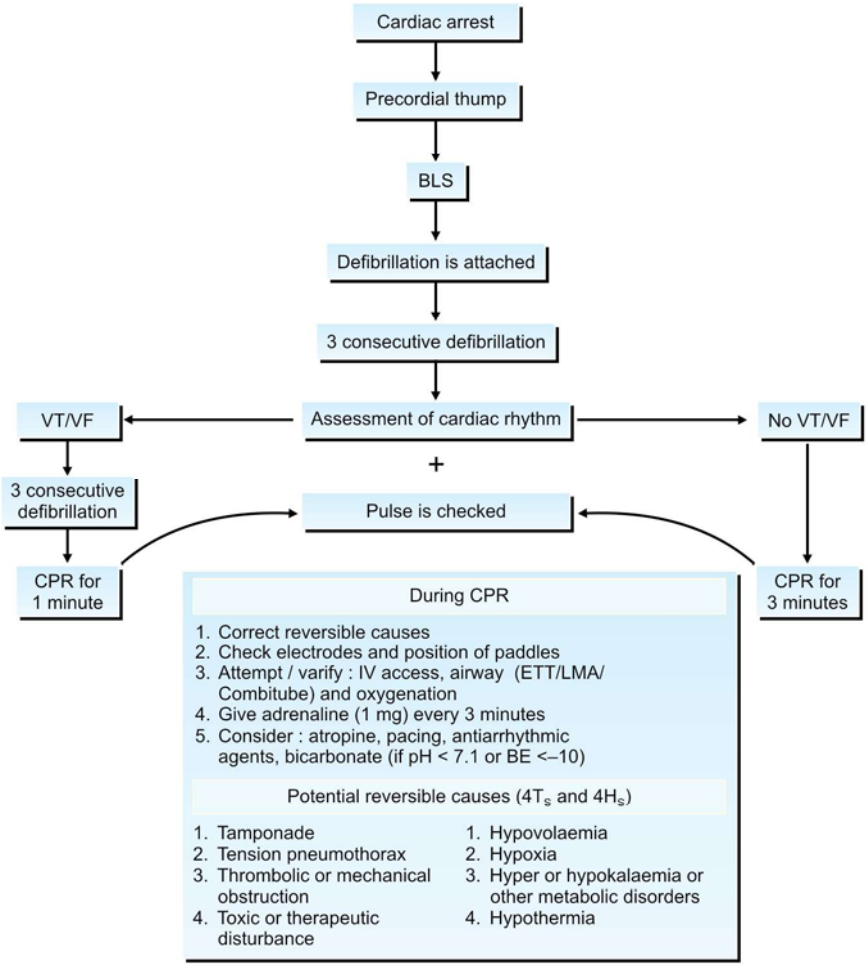

Fig. 26.38: Algorithm of adult life support

more than 2 or 3 minutes and should be repeated, untill either a effective cardiac rhythm maintaining some cardiac output is restored or it is decided that CPR would be abandoned.

After the third set of DC shocks, if VF is still continuing, then the following things can be done:

i. antiarrhythmic agents such as lignocaine, bretylium or amiodarone can be started.
ii. K^+, Ca^{2+}, magnesium should be checked and corrected.
iii. Paddle position should be changed.

Actually the benefit of the use of antiarrhythmic drugs are lacking in the management of CPR. Again the routine use of sodium bicarbonate to correct acidosis following cardiac arrest is not recommended, because paradoxically it worsens the intracellular acidosis and does not improve the final outcome. If bicarbonate is to be used then dose should be calculated from arterial pH and blood gas analysis that is discussed in acid-base balance chapter.

Management of asystole in cardiac arrest

Following cardiac arrest BLS is started immediately, while looking for ALS and if possibel the causes should be treated simultaneously with BLS and ALS. Management of aystole in cardiac arrest is not the DC shock, because DC shock does not regenerate any electrical cardiac activity. But, sometimes very fine (VF) may be misdiagnosed as aystole due to the faulty equipment or too low gain setting on the monitor. So, this wrong diagnosis is very dangerous and if there is any doubt, then for benefit of doubt three DC shocks at energy level of 200J, 200J and 360J each should be given successively to avoid missing of a potentially reversible VF. On the otherhand, application of DC shock in a confirmed asystole has no adverse effect.

Following DC shocks, the BLS and ALS should be continued again like the management of VT or VF in CPR. Intubation and access to the IV lines should be tried. Cardiac rhythm should be diagnosed as confirmed asystole. Adrenaline 1 mg should be administered intravenously and BLS should be maintained for 3 minutes with chest compression to ventilation ratio of 15:2. Then 2nd dose of adrenaline is given and patient's cardiac rhythm and pulse is again assessed. If asystole persists, 3 mg atropine in a single bolus dose is given IV. The cycle should be repeated, maintaining BLS and giving further doses of adrenaline every 3 minutes. After 3 repeated cycle, if the patient is still asystolic, pacing should be done using transvenous pacing wire or transthoracic pacing. In the mean time all the causes for cardiac asystole are searched for and removed.

Management of EMD in Cardiac Arrest

In cardiac arrest, if rhythm is diagnosed as EMD, then always the underlying remediable cause should be immediately looked for and treatment is started. The few causes of EMD are cardiac tamponade, drug overdose, electrolyte disturbance, hypothermia, hypovolaemia, pulmonary embolism, tension pneumothorax, etc.

Immediately BLS is started, while looking for ALS and if possible treating the causes. After intubating the patient and

gaining the intravenous access, the adrenaline in the dose of 1 mg is administered IV in bolus and then BLS is continued for 3 minutes with chest compression to ventillation ratio of 15:2. After that cardiac rhythm and pulse is assessed. If still EMD persists then one bolus dose of 3 mg of atropine is given IV. Cycles should be repeated, maintaining BLS and ALS and giving further doses of adrenaline after every 3 minutes interval.

Although high doses of adrenaline (5mg IV), alkalizing agents, calcium and pressor rising agents can be given, still there is no confirmed evidence for their routine use and better prognosis.

Non Drug Therapy of Arrhythmia

External defibrillation or cardioversion

The cardioversion is the process of restoration of normal electrical rhythm of heart by electrical shock and the device by which this process of cardioversion is accomplished is known as the defibrillator. This process of cardioversion can be accomplished by passing sufficiently large amount of direct electrical current through the heart from an external or internal sources. The mechanism of action of DC shock is that it will completely depolarise the heart for a fraction of a second and will temporarily interrupt any arrhythmia. Thus, it will produce a brief period of asystole which is usually followed by the resumption of normal sinus rhythm. The defibrillator usually delivers a high energy direct current of short duration via two metal paddles or gel pad, positioned over the upper right sternal edge and the apex of the heart. When this technique is used to treat organised rhythms such as atrial fibrillation or ventricular tachycardia, then the shock should be synchronised with the ECG and is normally given at 0.02 seconds after the peak of R wave. Otherwise, if energy is applied during a critical period around the peak of T wave then it may provoke ventricular fibrillation. But this precise timing of discharge of shock is not important in ventricular fibrillation as it is not an organised electrical cardiac rhythm.

In ventricular and other emergencies, the energy of the first shock should be minimum of 200 J. There is no need for anaesthesia, if the patient is unconscious such as VF in cardiac arrest. But, usually an elective cardioversion requires a general anaesthesia or sedation for conscious subject such as for correction of atrial arrhythmia. High energy shocks may cause the myocardial damage also. So, if there is no urgency, it is appropriate to begin with a low amplitude shock i.e. 50 to 100J and gradually going to larger shocks, if necessary.

Digoxin toxicity increases the risk of untoward arrhythmias after cardioversion. So, it is conventional practice to withhold the drug for 24 hours, before any elective cardioversion. Patients with long-standing atrial arrhythmias such as AF are at the increased risk of systemic embolism before and after cardioversion. So, it is wise to ensure that the patient is adequately anticoagulated for at least 4 weeks on either side of the procedure.

Implantable Cardioverter – Defibrillators (ICDs)

These are expensive and sophisticated devices which can automatically sense and terminate the life- threatening different types of ventricular arrhythmias by pacing or synchronised cardioversion with low energy shock or defibrillation with high energy shock. But, this automatic high energy shock can be painful, if the patient is still conscious. These devices also can pace the ventricles in the event of severe bradycardia and asystole. ICDs are implanted transvenously like a permanent pacemaker and are subject to similar complications. Clinical trials among the high risk patients have shown that the devices are more effective than antiarrhythmic drugs in preventing sudden death from severe cardiac arrhythmia. An ICD is used to treat the patient who present with cardiac arrest due to VT or VF or sustained VT causing syncope or severe haemodynamically compromised VT associated with poor left ventricular function (LVEF < 35%). These devices may also be used prophylactically in selected patients who are thought to be at the high risk of sudden cardiac death such as long QT syndrome, hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysplasia, etc.

Radiofrequency catheter ablation

The aim of this technique is to interrupt the re-entry circuit by selectively damaging the accessory path for conduction of cardiac impulses with endocardial tissue by radio frequency energy, delivered through a catheter that is passed into the heart through a peripheral artery or vein. This procedure is often time consuming and the patient may experience some discomfort during the time of ablation. But, it does not require any anaesthesia. Serious complications are rare and subject to similar of pacing. The radio frequency ablation eliminates the need for long-term drug therapy and is an attractive form of treatment for many arrhythmias offering the prospect of a lifetime cure. The technique has revolutionised the management of many cardiac arrhythmias and is now the treatment of choice for atrial tachycardia, AV nodal re-entry tachycardia, WPW syndrome and AF. The applications of this technique are now expanding. So, it has also been used to treat some forms of VT.

PACEMAKER

The artificial electrical depolarisation of heart is a valuable clinical means of therapies of different types of arrhythmias. So, its major uses include : (i) cardiac pacing for the control of rate and rhythm of heart and thus correcting some arrhythmias, and (ii) delivery of countershock by DC current (cardioversion) for correction of some arrhythmias which is already discussed.

The device by which the cardiac pacing for the control of rate and rhythm of heart is doen is known as the cardiac pacemaker. Anaesthesiologists must learn about pacemakers due to two reasons: (i) pacing is the mode of treatment of large number of cardiac arrhythmias facing emergencies, and (ii) pacing affects the appearance of ECG which may sometimes confuse an anaesthetist to diagnose a cardiac arrhythmia from ECG. Due to the advancement of technology more and more sophisticated kinds of pacemakers are coming out, so that a wide range of pacemaker with different mode of functions are now available. But, the two most basic functions of pacemakers for the control of cardiac rate and rhythm are

i. It provides a safety in patients who are at risk of bradycardia or asystole, and
ii. It terminates tachycardia.

There are three methods of pacing:

i. External pacing

It is effective only in very emergency situation, where internal temporary pacing is not available or if available but has no time to implant it. However, it becomes ineffective after several hours and it is painful to the conscious patient. So, patient must be sedated. Transthoracic pacing is the example of such an external pacing, and is also called the transcutaneous pacing. It functions by delivering an electrical stimulus that is sufficient to induce cardiac contraction from outside through two large adhesive gel pad or electrodes, placed over the apex and upper right sternal edge like defibrillation. These two electrodes also can be placed over the precordium and back of the patient. It has the advantage of being easy and quick to set up, but may cause discomfort and skeletal muscle contraction. Some sophisticated ECG monitor or defibrillator machines incorporate this type of transcutaneous pacing system which can be used as a temporary measure, until the temporary transvenous pacing is established.

ii. Internal pacing with power source outside the body

This is also called the temporary pacing. It can be accomplished by inserting an electrode into the heart through a large veins in neck, arm, leg or by direct puncture of the myocardium through the chest wall. These techniques are effective for emergency situations and short-term therapy. Its status lies between the external pacing and the permanent pacing. Here, the electrode placed within the cardiac cavity is connected to an external pulse generator (power source) which can be adjusted time to time to alter the energy output and pacing rate. The threshold of pacing is the lowest output that will reliably pace the heart and it should be less than 1 millivolt during initial period of implantation. It may require daily adjustment, because the threshold of myocardium tends to rise due to inflammation and oedema of cardiac tissue around the tip of the electrode.

iii. Internal pacing with power source implanted in the body

This is also called the permanent pacing. Again it can be of two types.

A. Left ventricular epicardial pacemaker : Here the electrodes are sutured directly into the left myocardium. This is done via thoracotomy or subxiphoid approach. The power source is embedded in the abdominal wall
B. Right ventricular endocardial pacemaker: Here the electrodes are introduced into the apex of the right ventricle via an axillary or subclavian vein and the power source is implanted at the pectoral or axillary area. Because of the relative simplicity and better efficacy of this procedure, insertion of this type of permanent pacemaker is preferred.

The temporary pacemaker provides pacing in an emergency situations, until a permanent pacemaker is implanted. In temporary pacing electrodes are introduced usually through the transvenous route. But transesophageal and transcutaneous temporary pacing also can be used. Here, the battery and the electronics part of the pacemaker remain outside the body. Whereas in permanent pacemaker the battery, electronics and electordes are all implanted within the patient's body. Both the temporary and permanent pacemakers are such set that it monitors the patient's cardiac activity continuously and provides impulses when necessary, because patients seldom need pacing impulse from pacemaker continuously. This helps to prolong the life of battery of pacemakers. This is called demand pacing.

All the pacemaker units mentioned above can function in an unipolar or bipolar manner. The unipolar circuit consists of a cathode end which is inserted into the myocardium and an anode end which is situated at a remote site, usually on the surface of the implanted power unit. But, the bipolar pacemaker has both the cathode and anode end within the heart which are usually at 1 to 2 cm apart.

Indications for Temporary Pacing

The indications for temporary pacing are :

i. Patients waiting for permanent pacing.
ii. Acute MI: In acute inferior wall MI complete heart block is usually developed due to the damage of artery which supplies the AV node. So, extensive infarction causes severe bradycardia or second and third degree AV block due to the damage of the bundle branches in the interventricular septum. In such situation mortality is high. So, immediate temporary pacing and inotropic support are very essential.
iii. Some tachycardia such as AV reentry tachycardia and ventricular tachycardia can be terminated by overdrive temporary pacing in emergency situations.
iv. Perioperative pacing.

Indications for Permanent Pacing

The indications for permanent pacing are:

i. Second degree AV block with an episode of symptomatic bradycardia

(syncope) regardless of whether it is Mobitz type I or II.
ii. Third degree AV block.
iii. Bi-fasicular block with a history of syncope or documented intermittent failure of the remaining fascicle. Asymptomatic patients with bifascicular block are not indicated for pacing.
iv. Sick sinus syndrome (SSS)with symptoms only. Asymptomatic patients with SSS are not indicated for pacemaker.
v. Malignant vasovagal syndrome.
vi. Carotid sinus syndrome.

DESCRIPTION OF PERMANENT PACEMAKER

The permanent pacemakers are usually described by internationally accepted code of 5 letters. Each letter describes an individual aspect of the pacemaker's different function that is shown in the table. There are different types of pacemaker available in the market. Among them some commonly available pacemakers are described here.

VVI

This pacemaker senses ventricle (V) by single lead placed within the ventricle (V). It also paces ventricle via the same lead when no cardiac electrical activity is detected. So this is also called the ventricular demand pacemakers. Otherwise, the pacemaker always senses and is inhibited (I) by normal ventricular activity and does not send impulses for ventricular contraction.

VVT

This is a triggered (T) type of ventricular pacemaker. During sinus conducted rhythm (or other spontaneous rhythm), the pacemaker also continuously discharges impulses approximately 0.04-0.08 sec after the onset of normal QRS complex. Thus, it can be seen as an artefact in the ECG and indicates pacemaker function. But it plays no role in ventricular depolarisation, because the artifact constantly falls in the absolute refractory period of the normal action potential of the ventricle. Whenever, the spontaneous sinus rhythm falls below the preset rate fixed by the pacemaker, then the pacemaker assumes its function. This is not a demand pacemaker.

AAI

The single lead of this pacemaker is situated in atrium (A) and senses atrial (A) activity. If normal atrial activity is detected, pacemaker becomes inhibited (I). But, whenever atrial activity is not detected, then it takes over the function by pacing the atria. It is also a type of demand atrial pacemaker.

AAO

This is not a demand pacemaker and the electrode is placed in the atrium. It is not a demand pacemaker, because it does not sense (O) the atrial electrical activity and in not inhibited. It continously sends impulses according to a prefixed rate for atrial depolarisation and subsequently ventricle contracts. If the patient's problem requiring pacing is due to the SA node or atrial disease, but AV nodal and His-Purkinje system conduction is normal, then this transvenously inserted atrial pacemaker is effective.

DVI

This unit paces both the atrium and the ventricle, but senses only the ventricle (V). As this pacemaker paces both the chambers of heart, so it is designated as double (D) chamber pacemaker. The pacemaker is inhibited (I) by an earlier spontaneous ventricular depolarisation. But since there is no atrial sensing, so atrial pace impulse will not be inhibited and atrial pace artefacts will appear regularly in the ECG at the programmed rate even though P-waves precede them. It cannot be used in the presence of atrial fibrillation.

DDD

This pacemaker has two leads, one in the atrium and one in the ventricle. So, it is called the dual chamber (D) pacemaker. It senses both the atrial and ventricular activity (D). It is inhibited if it senses activity in the ventricle. In complete AV block, if it senses atrial activity without ventricular activity, it can pace ventricle in sequence with atria. It can also pace the atria alone or atria and ventricle both in sequence (D). (Table 26.8)

AAIR, VVIR, DDDR

'R' indicates the rate of responsiveness. The rate of responsiveness means pacemakers adjust the HR or pacing rate according to the need of the patient during activity which mimic the physiological response. Here the patient's level of activity is continuously monitored by pacemaker through several parameters like vibration, respiration or temperature of blood. Thus heart rate is adjusted by pacemaker according to the activity.

Programmable pacemaker

The advancement of technology in the manufacture of pacemaker permit future modifications or change of many of its functions (programme) by external means, thereby sparing the need for an invasive procedure. Thus, the changes of different parameters can be made in the pacemaker from outside. These are pacing rate, sensing interval (rate hysteresis), pulse width, amplitude, etc. This facility allows the cardiologist to prolong the life of pacemaker by choosing the optimum settings and providing the means to overcome a wide range of pacing problems. For example, programming can be used to increase the output in the face of an unexpected increase in threshold or to alter sensitivity, if the pacemaker is inappropriately inhibited by electrical potentials, generated in the pectoral muscles.

The atrial pacing is appropriate for patients with sick sinus syndrome

Table 26.7: Letter codes for different functions of pacemaker

	Letter refers to	*Code*	*Meaning*
1	Chamber paced	V	Ventricle
		A	Atrium
		D	Dual or both the chambers
2	Chamber sensed	V	Ventricle
		A	Atrium
		D	Dual or both the chambers
		O	None
3	Mode of response or sensing	T	Trigeering of pacemaker (ventricular synchronus)
		I	Inhibition of pacemaker (ventricular demand)
		D	Inhibition or triggering
		O	None
		R	Rate responsiveness Reverse function: This pacemaker is silent at slow rates and activated by fast rates.
4	Programmable functions	P	Programmable for rate or output or both
		M	Multiprogrammable
		O	None
		E	External control
5	Special antitachy-cardia functions	P	Pacing of tachycardias
		S	Shock delivered
		D	Dual (pacing and shock)
		O	None
		B	Bursts of impulses

(sinoatrial disease) without AV block. Ventricular pacing is the only suitable mode for patients with continuous atrial fibrillation. In DDD (dual chamber pacing) the atrial electrode can be used to detect the spontaneous atrial activity and trigger the ventricular pacing. Thereby, it preserves the atrioventricular synchrony and allows the ventricular rate to increase together with the atrial rate during exercise and other forms of stress. Thus, though DDD is more expensive, but has many advantages when compared to only ventricular pacing. These include superior haemodynamics with better effort tolerance, a lower prevalance of atrial arrhythmias in patients with sick sinus syndrome (SSS) and the ability to prevent and cure the 'pacemaker syndrome'. The pacemaker syndrome consists of fall in BP and dizziness, precipitated by the start of ventricular pacing.

VVIMB

This is similar to VVI pacemaker but is multiprogrammable with pacing bursts for tachyarrhythmias.

DVIM

This is an atrio-ventricular pacemaker which paces both the atrium and the ventricle. It is ventricular inhibited and is multiprogrammable.

ECG FINDINGS in Pacemaker

The pacemaker depolarizes atrium and / or ventricle by electrical impulses which is generated within it and appear in the ECG tracing as 'pacing spikes'. In atrial pacing, the pacing spikes will be followed by P-wave and in ventricular pacing, the pacing spikes will be followed by broad QRS complexes (broad complex is due to the conduction of electircal impulse through the ventricular muscles like ectopic foci, but not through the normal conducting Purkinze tissue). Therefore, recognition of any specific disease state of myocardium and conducting system by ECG analysis during pacing is usually impossible. In only atrial pacing, the spikes are followed by P waves and normal QRS complexes (without ventricular spike) as the impulse conducts via the normal conducting pathway. In dual chamber pacing both the spikes will be seen. The failure of a pacing spike to be followed by depolarisation of heart indicates a problem with 'capture' (Fig. 26.39).

The ECG tracing also can help in localizing the site of electrode placement and in detecting the change of position by dislodgement of the electorde if it occurs. In right ventricular apical endocardial paceing, the depolarisation wave of heart will flow from right to left (R → L) and from apex to base. The resulting QRS vector, therefore, will be oriented to the left and superiorly. Thus the QRS complex in lead I will be positive and in lead II, III, and AVF will be negative. On the other hand, if the electrode is displaced from the apex

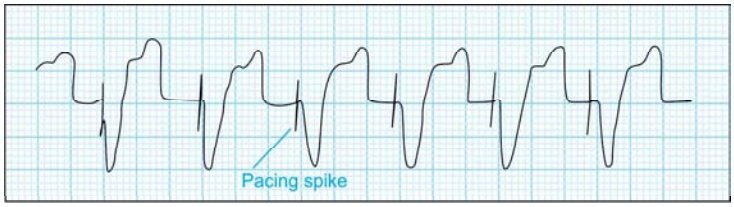

Fig. 26.39: Graph of the ventricular pacing, it is characterised by ventricular pacing spikes and followed by broad QRS complex

to the outflow of right ventricle, then the direction of depolarisation wave will be R → L, but from base to apex. So, the QRS complex remains upright in lead I, but now becomes upright in lead II, III and AVF.

Interpreting of an ECG of a patient with functioning pacemaker, the pacemaker rate should be accurately measured. Any change in rate indicates the early battery failure.

In unipolar pacemaker as the distance between the anode and the cathode is long, so the pacing spike will be large. But in bipolar unit due to the close position of anode and cathode, the spike (pacemaker artefact) will be small in ECG tracing.

For detection of any changes in the pacemaker position by dislodgement, the determination of spatial orientation of the pacing spike is also helpful. This is especially applicable to a bipolar right ventricular endocardial pacemaker. The cathode is usually distal to the anode. So, as a result of its position in the right ventricular apex, the vector of electrical artefact or spike will be oriented to the right and superiorly. Thus, it will produce negative artefact in lead I, II, AVF. If due to any cause the electrode becomes detached and floats into the right ventricular outflow tract, then the vector of artefact will be directed inferiorly. Then it will produce an upright artefact in II, III and AVF lead. The explanation is like that : the anode-cathode relation in the right ventricular pacemaker will be reversed i.e. the distal pole will be the anode. In this instance, the artefact for pacing will be oriented to the left and inferiorly, producing an upright signals in lead I, II and AVF (Fig. 26.40).

During the management of ventricular tachycardia when the antiarrhythmic drugs fail, then the ventricular pacing has been succesfully used to prevent the recurrent ventricular tachycardia and ventricular fibrillation. The mechanism is like that : when repolarization of ventricular muscle become asymmetrical due to some reason (ischaemia, infarction) leading to local potentiation of ectopic discharge, then pacing the heart at the rates of 130 to 150 per minute causes ventricular repolarization to become synchronous throughout the entire myocardium and eliminate the local potentials with arrhythmias. This type of pacing is called the 'over drive pacing'. In the treatment of refractory VT, ventricular pacing at rates slower than the tachycardia (under drive pacing) may also abolish arrhythmia by interrupting the reentry circuit that causes the tachycardia.

If the entire heart is depolarized for a moment by sufficient current, introducing in the myocardium, then the normal cardiac rhythm is re-established after depressing or breaking the cycle of arrhythmia. This countershock is delivered externally by defibrillation. This is called DC shock. But, it can be applied internally during cardiothoracic surgery or through pacemaker. It is a major life saving process by eliminating VF and VT during resuscitation process of cardiac arrest. In emergency the countershock or DC shock is also preferable to drug therapy to terminate the atrial flutter and fibrillation. This DC defibrillator introduces an electrical charge for 0·0025 sec (AC defibrillation introduces an electrical charge for 0·25 sec and due to this long duration, the charge could fall on supernormal phase of any rhythm and can produce any type of arrhythmia) and are now coupled with synchronizing device that prevent the discharge at the critical phase of cardiac cycle and thus avoides any serious arrhythmia.

Surgically implanted defibrillator are also now available which are programmed to recognize VT and VF spontaneously and discharge an internal DC shock automatically.

Fig. 26.40: This figure shows dual chamber pacing. The first three cardiac cycles show the atrial and ventricular pacing with narrow pacing spikes in front of each P-wave and QRS complex. The last three beats show spontaneous P waves with a different morphology and no pacing spikes. The pacemaker senses or tracks these P waves and maintain an AV synchrony by pacing the ventricle after an appropriate interval

Pacemaker and Surgery

The importance of pacemaker from anaesthetic point of view during surgery are :

i. The original indication for insertion of pacemaker should be known to an anaesthetist which may modify the mode and outcome of anaesthesia.
ii. The type of pacemaker also should be known which will help to diagnose the intraoperative arrhythmia.
iii. Checking of pacemaker before and after surgery for any 'capture beat'.
iv. To avoid interference with or damage to the pacemaker from diathermy.
v. Inappropriate pacemaker inhibition due to any intraoperative measures can cause bradycardia or even asystole.
vi. To minimize the pacemaker damage or inhibition the active diathermy electrode should be placed at least 15 cm away from the pacemaker generator box and the indifferent electrode as far from the box as possible.

Patients with certain cardiac conduction disorders who do not have a permanent pacemaker should be considered for a temporary pacemaker, if they are about to undergo general anaesthesia. These indications for temporary pacing are : (i) third degree AV block and (ii) second degree AV block. Pacing is not usually necessary for bifascicular block unless the patient has a history of syncope.

27 Ischaemic Heart Diseases and Anaesthesia

INTRODUCTION, AETIOLOGY AND PATHOPHYSIOLOGY

Ischaemia refers to the lack of O_2 which is due to inadequate perfusion. It may be absolute or relative and results from an imbalance between the O_2 supply and / or its demand. Therefore, myocardial ischaemia occurs either from a decrease in coronary blood flow (e.g. variant angina) and / or from a disproportionate increase in myocardial O_2 consumption (e.g. exertional angina). The myocardial O_2 supply is primarily determined by the coronary blood flow. The volume of coronary flow (supply) is related to both the perfusion pressure and the coronary vascular resistance which ultimately depends on the diameter of the lumen of the coronary artery. On the other hand, the four major factors which govern the myocardial O_2 demand or consumption are : ventricular wall tension, after load, heart rate and ventricular contractility. The another term such as 'double product' is a clinically useful index of myocardial O_2 demand or consumption. This is derived by multiplying the systolic blood pressure (after load) with the heart rate.

With increasing age, the people mainly suffer from cardiovascular diseases. On the other hand, cardiovascular diseases account for the majority of perioperative deaths. Therefore, the increased aging of population increases the likelihood of more and more patients undergoing surgery with co-existing cardiovascular diseases, among which ischaemic heart disease is the most common. The first and the most common presentation of ischaemic heart disease (IHD) is acute myocardial infarction (MI) in 50% of patients. The main cause of decrease in coronary blood flow (supply) causing ischaemia and infarction with increased age is the reduction of the diameter of lumen of coronary arteries by atherosclerosis. Atherosclerosis may cause an absolute decrease in myocardial perfusion in the basal state or may limit the appropriate increase in perfusion when the demand for flow is increased. The important factors for the development of atherosclerosis are: male gender, increasing age, hypercholesterolaemia, high plasma low density lipoprotein (LDL) and low plasma high density lipoprotein (HDL), systemic hypertension, cigarette smoking, diabetes, obesity, sedentary life style, and a positive family history. Coronary blood flow can also be limited by arterial thrombi, spasm, or ostial narrowing due to aortitis. The reduction of the O_2-carrying capacity of blood (e.g. severe anaemia, presence of carboxy-haemoglobin, etc.) is a rare cause of myocardial ischaemia and infarction. Myocardial ischaemia can also occur, if myocardial O_2 demands are abnormally increased, for example: exercise, tachycardia, severe myocardial (ventricular) hypertrophy due to hypertension, or aortic stenosis, etc. Not infrequently, two or more causes of ischaemia will co-exist, such as an increase in O_2 demand due to left ventricular hypertrophy and a reduction in O_2 supply secondary to coronary atherosclerosis. Often such a combination leads to early clinical manifestation of myocardial ischaemia.

The most common cause of myocardial ischaemia is the atherosclerotic disease affecting the epicardial coronary arteries. In healthy persons the epicardial coronary arteries serve largely as conduits. They undergo little constriction and relaxation. So, these vessels are referred to as the conductance vessels. On the contrary, the intramyocardial vessels normally exhibit striking changes in tone and their radius. Therefore, they are referred to as the resistance vessels. The normal coronary arterial circulation is controlled by the heart's own requirement of O_2 through these intramyocardial resistance vessels. This need is met by the ability of coronary arteries to vary its resistance (therefore blood flow) by itself, while myocardium extracts a high and relatively fixed percentage of O_2. Normally, the intramyocardial resistance vessels demonstrate an immense capacity of dilatation during needs, e.g. exercise, emotion, stress, etc. This manner of regulation of myocardial O_2 supplies is called the metabolic regulation. The coronary resistance vessels also adapt to the physiological alterations in blood pressure within certain range in order to maintain the coronary blood flow constant according to the myocardial needs. This is called the coronary autoregulation.

The atherosclerosis is caused by the dysfunction of vascular endothelium and the abnormal interaction of endothelium with blood monocytes and platelets. This leads to subintimal collection of abnormal fat,

debris and cells (i.e. atherosclerotic plaque) at different segments of the coronary artery (mainly epicardial), resulting in segmental reductions of cross sectional area. Once stenosis (of epicardial vessels) has reduced the cross-sectional area of the myocardial blood vessels by more than 70% (approximately), then the distal resistance vessels (intramyocardial vessels) dilate to reduce the vascular resistance and maintain the coronary blood flow. Thus, a pressure gradient develops across this stenosis. When the resistance vessels are maximally dilated, then the myocardial blood flow becomes dependent only on the pressure gradient in the coronary artery distal to the obstruction. In such circumstances, ischaemia in the region perfused by the stenotic artery can be precipitated by the increase in myocardial O_2 demands caused by increased physical activity. When stenosis reduces the cross-sectional area by approximately 75%, then a full range of autoregulation to increase the flow and to meet the increased myocardial demand against the increased physical activity is not possible causing ischaemia on exertion. When the luminal area is reduced by more than approximately 80%, then blood flow at rest may also be reduced and after that any further minor decrease in stenotic orifice can reduce the coronary flow dramatically, causing ischaemia at rest. Severe coronary narrowing and myocardial ischaemia are frequently accompanied by the development of collateral vessel. Usually this occurs, when the narrowing develops gradually. But when this collateral is well developed, then such collaterals can provide sufficient blood flow to sustain the viability of myocardium at rest. But, this is not possible during conditions of increased demand.

Ischaemic heart disease is often manifested as: angina pectoris, acute myocardial infarction, cardiac arrhythmias, heart failure or sudden death. Among these manifestations, angina pectoris is the most common symptom of myocardial ischaemia and is classified into the following clinical syndromes such as: (i) stable angina pectoris, (ii) variant angina (Prinzmetal's angina) (iii) mixed angina, (iv) unstable angina, (v) nocturnal, postprandial, and walk-through angina, (vi) silent angina.

DIAGNOSIS

History

The most important aspect of history, regarding the myocardial ischaemia which is an part and parcel of diagnosis is the patient's description of its own chest discomfort, i.e. its character, location, radiation, duration, precipitating and palliative factors etc. Typically, patients describe angina pectoris as a sensation of tightness or heaviness over his left precordium. The others commonly used adjectives of chest discomfort by the patient due to ischaemia include: squeezing, constricting, suffocating, crushing sensation, etc. Some patients make a tight fist over their chest to show what the pain or the discomfort is. The myocardial ischaemic pain may radiate to the inner aspects of left arm, or both arms, or shoulders, or neck and jaw. Radiation of pain to the lower abdomen is unusual and one should be caution about making this as diagnosis of angina. Chest pain which is sharp, stabbing, comes and goes in seconds, but not dull and continuous are unlikely to represent angina. The anginal syndrome usually begins gradually and goes to a peak before subsiding over several minutes. The resolution of ischaemic pain is usually due to the cessation of precipitating factors such as exercise, tension, cold exposure, etc, or use of nitroglycerine. Patients with the classical history of angina pectoris, male gender and old age increases the likelihood for the affection of left main coronary artery or multivessel disease.

Noncardiac chest pain is usually transient. It is exacerbated by the chest wall movement. It is also associated with tenderness over the involved area which is often a costochondral joint. The retrosternal sharp pain which is exacerbated by deep breathing, coughing or changing in body position suggests pericarditis. The oesophageal spasm can produce severe substernal pain. It may be confused with the angina pectoris. In such condition administration of nitroglycerine is also likely to relieve the pain, because oesophagus consists of smooth muscles.

From the severity of history, the patient's functional capacity can be determined and this has been shown to correlate well with the result of treadmill test. This patient's functional capacity is prognostically very important and can be quantified as MET (metabolic equivalents). One MET is defined as the rate of O_2 consumption by a normal person which is 3 to 5 ml/Kg/min. However, any mobility problems due to skeletal dysfunction limit this test or assessment. Patients who can exercise at 4 MET or greater present a low risk for perioperative morbidity due to ischaemia :

1. MET – eating and dressing
3. MET – light work or walk (3 to 4 Km/hour)
4. MET – climb a flight of stairs
6. MET – short run

A patient who had a CABG operation within 5 years and has no symptoms may be considered of normal perioperative risk.

Physical Examination

The physical examination is often normal in the patient with stable angina. Although frequently normal, but a careful examination may reveal some important contributory information regarding the prognostically significant co-morbidities, such as, hypertension, peripheral vascular diseases, dibetes mellitus, renal diseases, pulmonary diseases, xanthelasma, arcus senilis, etc. There may also be signs of associated anaemia, thyroid disease, etc. Physical examination by palpation can also reveal the thickened or absent peripheral associated arteries, signs of cardiac enlargement, etc. Examination of fundus of retina may reveal increased light reflexes and arteriovenous nicking as the evidence of

hypertension. Examination during an episode of chest pain may reveal a transient s_4 or s_3 heart sound and it is due to the altered left ventricular compliance or a murmur of mitral regurgitation resulting from papillary muscle dysfunction. Aortic stenosis, aortic regurgitation, pulmonary hypertension, and hypertrophic cardiomyopathy must be excluded, since these disorders may cause angina, even in the absence of coronary artery disease.

During physical examination the signs of left ventricular failure should be searched for. Peripheral oedema is usually a late finding in patients with LVF. It is often due to venous insufficiency. Examination of jugular venous pulse for abnormalities reflects right ventricular failure.

Laboratory Studies

Although the diagnosis of ischaemic heart disease (IHD) is made with confidence from typical history, but a number of simple laboratory tests can be helpful to correlate between the history and the diagnosis. The urine should be examined for evidence of diabetes mellitus and renal diseases, since both these conditions may accelerate the atherosclerosis and myocardial ischaemia. During laboratory investigations the examination of blood should include the measurement of lipids (total cholesterol, LDL, HDL), glucose, creatinine, haematocrit, thyroid function and any special test indicated by physical examination. A chest X-ray is important, since it may show the consequences of IHD, i.e. cardiac enlargement, signs of heart failure, etc. Calcification of coronary artery can sometimes be identified by X-ray (Table 27.1).

ECG

An ECG should be performed on all patients over 50 years of age who are scheduled for surgery and in younger patients who are with risk factors of IHD. Always the changes from previous ECG tracing should be investigated. The bundle branch block may predispose to brady arrhythmias or atrial fibrillation. But, 24 hours ECG monitoring is only necessary, if there is any history of palpitations or blackouts.

If patients with a known prior history of MI are excluded, then nearly 60% of patients presenting with the history of angina pectoris have a normal ECG. But, the absence of abnormalities in resting ECG does not eliminate the possibility of IHD. Repolarisation abnormalities, i.e. T-wave and ST-segment changes and intraventricular conduction disturbances at rest are suggestive of IHD. But they are nonspecific, because they can occur in any pericardial, myocardial, and vulvular heart diseases also. They are also found in anxiety, changes in posture, drugs, and oesophageal diseases. The more specific ECG changes associated with myocardial ischaemia is the ST-segment and T-wave changes which usually accompany the episode of angina pectoris and disappear thereafter. The characteristic of ST-segment changes in myocardial ischaemia is the displacement of its axis from the neutral electrical or base line. The ST-segment is usually depressed during angina, but may be elevated in its Prinzmetal's form. Along with ST segment, the T-wave changes in the ECG during ischaemia include symmetrical T-wave inversion which may be transient. In a patient with consistent inverted T-waves, in association with prior pathological Q-wave from previous myocardial infarction, may manifest a return of the T-wave to the normal upright position during ischaemic attack. This is called the pseudo-normalisation.

Exercise ECG (stress testing)

12 leads ECG before, during and after exercise on a treadmill is the most widely used test for the diagnosis of IHD. It is useful for establishing the patient's left ventricular functional reserve and thus the prognosis. The programme is usually symptoms limited. The test is discontinued with the evidence of chest pain, discomfort, severe shortness of breath, dizziness, fatigue and ST-segment depression of greater than 0.2 mV (Table 27.2). The test is also discontinued when there is fall in heart rate (exceeding > 10 beats/min), fall in systolic blood pressure (exceeding >20 mm of Hg) and development of ventricular tachycardia or arrhythmia. The significant diagnostic ischaemic ST-segment response is defined as the flat depression of it for more than 0.1 mV below the baseline and lasting longer than 0.08 second. The junctional or upsloping of ST-segment changes are not considered as diagnostic of myocardial ischaemia. It does not constitute a positive test. T-wave abnormalities alone is also not considered as diagnostic of ischaemia. This stress ECG test has a high negative, but a low positive predictive value. This test is useful for assessing the ischaemic patients, possessing high or intermediate risk than low risk group. Overall, false +ve or false −ve results is 15%. A positive treadmill test indicates that the likelihood of IHD is 98% in males over 50 years of

Table 27.1: Relation between areas of myocardial ischaemia and ECG leads

ECG leads	*Coronary artery*	*Area of ischaemia*
I, AVL	Circumflex artery	Lateral aspect of left ventricle
II, III, AVF	Right coronary artery	Right atrium, Right ventricle
V_3 - V_5	Anterior descending artery	Anterolateral aspect of left ventricle

Table 27.2: Indications of exercise ECG testing

Diagnosis of chest pain
Assessing of exercise tolerance
Assessing the response to treatment
Risk stratification of stable angina

Table 27.4: Relative contraindications to stress ECG

Myocardial infarction (after 7 days to 1 month)
Mild to moderate aortic stenosis
Known severe coronary artery disease
Significant left ventricular dysfunction
Known serious risk of arrhythmia

age with a history of typical angina pectoris (Table 27.3).

The likelihood of IHD decreases progressively, if the patient has atypical or no chest pain. The incidence of false +ve test is significantly increased in asymptomatic male under the age of 40 with no risk factor for premature atherosclerosis. False +ve also increases when there is (i) previous changes or abnormality of the ST-segment and T-wave at rest, (ii) patient taking drugs like digitalis, quinidine, etc, with intraventricular conduction disturbances (iv) myocardial hypertrophy and (v) abnormal serum potassium level. Since the overall sensitivity of exercise stressed ECG is only about 75%, a negative result does not exclude IHD. In negative result the likelihood of three vessels disease or left main coronary artery disease is extremely unlikely.

The normal response to exercise or stress induced ECG includes a progressive increase in heart rate and blood pressure. But an important adverse prognostic part of this test is failure of BP to increase with sign of ischaemia, because it reflects ischaemia induced global left ventricular dysfunction (Table 27.4).

The presence of chest pain or severe ST-segment depression (> 0.2 mV) at a low workload which persists for more than 5 minutes after the premature termination of exercise increases the specificity of the test. It suggests severe ischaemic heart disease and high risk with further adverse events. Exercise testing is not always possible or can not be performed because of the presence of many non-cardiac causes, such as peripheral vascular diseases and associated claudication, lung disease, arthritis, other orthopaedic causes, etc. In the presence of the following conditions, such as, artificially paced ventricular rhythm, pre-existing ST-segment depression, left ventricular hypertrophy, digitalis therapy, pre-excitation syndrome etc, which interfere the interpretation of exercise ECG test, it should not be performed.

Echocardiography

The exercise induced ECG test and associated ST-segment changes indicate the presence of ischaemic heart disease. But it can not locate the site of obstruction in coronary vessels and its associated ventricular wall motion abnormalities. So, an initial, without any stress, echocardiographic cardiac wall motion analysis, and then echocardiography performed after stressing the heart by dobutamine infusion (stress echocardiography), correspond to the site of myocardial ischaemia. Thus, it tremendously helps to localise the obstructive coronary lesion. The stress echocardiography also can be done by artificial cardiac pacing which enhances the accuracy of stress echocardiography and helps to localise the obstructive coronary lesion.

Nuclear Stress Imaging

The nuclear stress imaging is very useful for assessing the coronary perfusion. After administration the tracers, like – thallium, technetium, etc, can be detected and their concentration can be measured by proton emission computed tomography (PECT) in the myocardium that correspond to the coronary blood flow. When there is lesser tracer activity, it suggests a significant coronary obstructive lesion. Exercise or stress increases the difference in tracer concentration between the normal and the underperfused regions. This is because coronary blood flow increases markedly with exercise, except in regions which is distal to the obstruction in coronary artery. The magnitude of perfusion abnormality is most important prognostic indicator of ischaemia.

Both of these, i.e. echocardiography and nuclear stress imaging are indicated for the diagnosis of IHD when the exercise induced ECG is not possible or it is difficult to interpret the ST-segment changes on the ECG. The intravenous infusion of dobutamine or artificial cardiac pacing provide progressively adequate cardiac stress for patients who can not exercise. Alternatively, the effects of cardiac stress on the extent of coronary dilatation can be assumed by artificially producing coronary dilatation by administration of coronary vasodilator, such as, adenosine or dipyridamole which dilates the normal coronary arteries, but evokes minimal to no change in the diameters of atherosclerotic coronary arteries.

Coronary Angiography (or Arteriography)

Coronary arteriography is the most definitive investigation for diagnosis, localization, and quantitation of IHD. It provides the most important information about the condition of coronary arteries. The common indications for cardiac catheterisation and arteriography are: chronic stable or unstable angina, markedly positive exercise or stress induced ECG test, postinfarction angina, inconclusive noninvasive studies, frequent hospitalisation due to cardiac causes, unexplained cardiomyopathy, high risk of IHD, angina following

thrombolytic therapy, valve replacement in patient with high risk of IHD, etc. It is also helpful for establishing the diagnosis of nonatherosclerotic coronary artery disease, such as, coronary artery spasm.

Although coronary angiography is an invasive procedure, still the risk of this test is very low in relation to the potential information which is yielded from the study. The overall mortality of angiography is 0.2%. Patients > 55 yrs of age and with an ejection fraction < 30% or with left main coronary artery disease have the greatest risk for complications.

Treatment of IHD

Medically IHD is treated mainly by the following drugs, such as, antiplatelets, anti-thrombin, β-blockers, Ca^{2+} channel blockers and nitrates. So, the preoperative awareness of an anaesthetist about these drugs is important, because these drugs may exert potentially adverse effects during anaesthesia. The aim of medical treatment of IHD is to decrease the myocardial O_2 requirement or demand and to improve the coronary blood flow or supply. When optimal medical therapy fails to control the symptoms of IHD, then revascularisation of myocardium by CABG, PTCA or placement of coronary stenting is indicated. Among these, CABG is the most promising and is performed when the occluded coronary artery is of reasonable size, free of distal plaque and a high grade proximal stenosis. It is likely to improve the survival of patient with EF < 40% and multivessel disease. But, the presence of hypokinetic or akinetic area declares the poor prognosis.

If not contraindicated, then low dose aspirin as antiplatelet agent is recommended for all IHD patients. It is used in the dose of 75 to 325 mg/day and decreases the risk of cardiac events. Clopidogrel, inhibiting platelet aggregation acts more effectively than aspirin. Patients in whom placement of intracoronary stent is anticipated, plateled glycoprotein IIb/IIIa receptor antagonists is more useful. It acts by inhibiting the adhesion, activation and aggregation of platelet.

As antithrombin the unfractionated heparin is recommended for the treatment of unstable angina. But it has many disadvantages such as variability in dose responses relationship due to its binding with plasma protein. So, instead of unfractionated heparin the low molecular weight heparin (LMWH) provides a more predictable and long half-life pharmacological profile as antithrombin. It has also advantages that it does not need monitoring by APTT (activated partial thromboplastion time) measurement and can be administered easily by the subcutaneous route. During the weeks, following the initial presentation of unstable angina, the combination of warfarin and aspirin can be used. It is superior to monotherapy with aspirin or warfarin alone.

The β-blocker (mainly the cardioselective β_1-blocker) decreases the myocardial O_2 demand or consumption and thus supports its use in the management of unstable angina. Chronic administration of β_1-blocker also decreases the risk of MI and sudden death. Now, it has been used in low doses in patients in whom β-blockers have traditionally been considered to be contraindicated, such as congestive heart failure, pulmonary disease, advanced age, etc. The β_1-blocker induced decrease in heart rate and contractility is maximum during activity than at rest. The decrease in heart rate also increases the diastolic perfusion time which may contribute to improve the myocardial perfusion. β_2-blockers can increase the risk of bronchospasm in patients with reactive airway disease and can increase the manifestations of peripheral vascular resistance. So, it (β_2-blocker) is not used in IHD patients. The most common side effects of β-blocker therapy are fatigue and insomnia. It is contraindicated in heart block, but not in diabetes mellitus, though it may mask the signs of sympathetic nervous system acitivity during hypoglycaemia.

The use of long acting calcium channel blockers for IHD are not as effective as β_1-blockers for decreasing the incidence of M1, but are comparable to β-blockers in terms of relieving the frequency and severity of angina pectoris which is due to coronary artery spasm. The short acting Ca^{2+} channel blocker such as nifedipine are not recommended for the management of IHD as they increase the sympathetic activity with associated adverse cardiac events. So, only the long acting Ca^{2+} channel blockers are used. There is adverse interactions between the calcium channel blocker and the anaesthetic drugs. For example, myocardial depression and peripheral vasodilatation effect produced by volatile anaesthetic drugs could be exaggerated by the similar effects of calcium channel blockers. The calcium channel blockers may also potentiate the effects of depolarizing and non-depolarising muscle relaxants and exaggerate the diseased states associated with skeletal muscle weakness. The pharmacological antagonism of neuromuscular transmission may be impaired in the presence of Ca^{2+} channel blocker. This is because of diminished pre-synaptic release of acetylcholine.

Nitrates dilate the coronary and its collateral arteries and improve the coronary blood flow. It also decreases the peripheral vascular resistance, resulting in decrease in left ventricular outflow impedance and myocardial O_2 consumption. The venodilating property of nitrates decrease the venous return and thus preload also. Thereby, it decreases the left ventricular filling pressure, filling volume, force of contraction (Frank-Starling law) and myocardial O_2 consumption. All the above mentioned properties of organic nitrates thus help to decrease the frequency, duration, and severity of angina pectoris. It also helps to increase the amount of exercise needed, before the onset of ST-segment depression. Nitrates are relatively contraindicated in hypertrophic obstructive cardiomyopathy and

severe aortic stenosis. The sublingual tablet or oral spray of nitroglycerine is recommended for prompt relief of angina pectoris, but not for long-term therapy. For later, long acting nitrate preparation is effective and recommended. The therapeutic value of organic nitrate is compromised or dampened by the rapid development of tolerence during sustained therapy of it. So, for long-term use nitrates should be administered with one daily nitrate-free interval of at least 8 hours to prevent the development of nitrate tolerance.

ANAESTHETIC MANAGEMENT OF PATIENTS WITH KNOWN OR SUSPECTED IHD UNDERGOING NONCARDIAC SURGERY

Assessment

The goal of preoperative anaesthetic assessment of a patient with ischaemic heart disease is to identify the individuals with increased risk of adverse perioperative cardiological outcome. The risk of perioperative death due to cardiac complications is less than 2% for patients who do not have IHD. On the other hand, this risk is double or triple in patients with known or suspected coronary or other sclerotic vascular disease. The most reliable indicator for adverse perioperative cardiac events in patients who is suffering from IHD and undergoing noncardiac surgery is myocardial ischaemia during operation and within first 48 hours following surgery. The perioperative risk for patients with IHD is usually estimated on the basis of patient's exercise tolerence. Patients who can perform strenous activities like walking, running, climbing, etc, but without any cardiac symptoms have lower risk of cardiac complications than patients who are unable to perform such strenous exercise. The limited exercise tolerence in the absence of significant lung disease is the most striking evidence of decreased cardiac reserve. The patients should always be evaluated against the background of exercise, because symptoms of ischaemic heart disease may be absent at rest. In stable patients with angina pectoris undergoing elective major noncardiac surgery, there are few independent predictors of cardiac complications. These predictors are : current complaints of angina pectoris, use of nitrate therapy, history of positive exercise test, history of M1, Q-wave in ECG, history of congestive heart failure, history of pulmonary oedema, history of paroxysmal nocturnal dyspnoea, etc. The previous CABG surgery, preoperative ST-T wave changes on the ECG, presence of critical aortic stenosis, presence of abnormal cardiac rhythm, advanced age, etc, are also the valuable predictors. It is also important to recognise the presence of incipient congestive heart faiture preoperatively, as the added stress of anaesthesia, surgery, and post operative pain may convert this incipient preoperative congestive overt congestive heart failure.

Physical examination and investigations for preoperative assessment of patient with IHD are like physical examintion and investigation of an IHD patient who is not goging for any surgical procedure which is described before.

Preoperative Preparation and Medication

High risked myocardial ischaemic patients, undergoing noncardiac surgery is probably best benefited from optimal preoperative anti-ischaemic treatment which is described before. This preoperative anti-ischaemic treatment or preparation can be achieved by pharmacological and psychological method. The patient suffering from severe myocardial ischaemia can also be treated preoperatively by CABG operation or angioplasty with or without stent before any elective noncardiac surgery. Anxiety which is part and parcel of a surgery is an another important precipitating factor of ischaemia. It acts by evoking the activity of sympathetic nervous system with accompanying increase in systemic BP and HR. Both of these increase the myocardial O_2 demand which may manifest as the myocardial ischaemia in ECG and may be first recognised when these patients arrive in the OT. These ECG changes are usually taken as the silent sign of ischaemia, because they are not accompanied by angina pectoris or haemodynamic abnormalities. This silent ischaemia is not different from those that occur in the same patients during their normal daily activities.

Anxiety is managed by both psychological and pharmacological approaches. The psychological approach for the reduction of anxiety is attempted by preoperative visit of a patient to an anaesthetic clinic during which the fearless anaesthetic sequences are explained in details. The pharmacological approach for reduction of anxiety can be achieved by many drugs. But, the choice of drug depends on the personal preference and the experience of anaesthetist. The aim of premedication for a myocardial ischaemic patient is to produce maximum sedation and amnesia without any undesirable degree of circulatory and ventilatory depression. For this purpose benzodiazepine is a very useful drug. It can be combined with morphine (10 to 15 mg IM) plus scopolamine (0.4 to 0.6 mg IM). Because scopolamine produces profound sedative and amnestic effect without any undesirable changes in HR. So, it is very valuable as a premedicant for ischaemic heart diseased patients.

Drugs used for medical management of patients with ischaemic heart disease should not be withdrawn abruptly and are continued throughout the perioperative period. For example, the sudden withdrawl of antihypertensive agents, mainly β-blocker, may result in rebound increase in sympathetic nervous system activity. Nitrates should be given preoperatively, intraoperatively and postoperatively. In high risk patients they can be continued as IV also. Otherwise, oral and transdermal route for nitrate is sufficient for low risk groups. The calcium antagonist should be

given postoperatively. The dihydropyridine group of calcium antagonist (nifedipine), especially short acting, add to the risk of acute MI. Therefore, these should be substituted to another class such as phenyl alkylamine (verapamil) or benzothiazepine (diltiazem) group of Ca^{2+} antagonist. The ACE inhibitors improve survival in patients with left ventricle dysfunction due to IHD. So, they should be given preoperatively and also should be resumed postoperatively as soon as GI absorption resumes. If they have been stopped for several days, then restarting at a reduced doses may be prudent, as most of these drugs are associated with first dose hypotension. There is theoretical possibility of H_2 receptor antagonist to produce coronary artery vasoconstriction. Because, this is mediated by unopposed H_1 receptors activity. But practically it does not seem to produce any adverse side effects in IHD patients.

Induction of Anaesthesia

The anaesthetic technique for ischaemic heart diseased patient is aimed at to minimise the incidence and severity of myocardial ischaemia by preventing the factors which predispose it such as tachycardia, hypotension, hypertension, hypoxia, etc. Induction for patients with IHD can be achieved by intravenous administration of several common inducing agents such as propofol, thiopentone, BZD, etc. Among these, ketamine is not the choice as it increases the myocardial O_2 consumption or demand by increasing the HR and systemic BP. Direct laryngoscopy and tracheal intubation may initiate sympathetic nervous system stimulation and subsequent myocardial ischaemia. It is aggravated more when there is previous existance of systemic hypertension. So the sympathetic pressure response produced by direct laryngoscopy and tracheal intubation can be minimised by the addition of following drugs. Lignocaine in the dose of 1 to 2 mg/kg, administered intravenously about 90 seconds before direct laryngoscopy, decreases the magnitude and the duration of the elevation of systemic BP. An alternative to lignocaine is nitroprusside. It is administered 15 seconds before laryngoscopy and intubation in the dose of 1 to 2 µg/kg/minute IV. Like lignocaine, nitroprusside also effectively attenuates the pressure response related to intubation, but not the HR. Another alternative to attenuate the sympathetic pressure response in patients with IHD is infusion of esmolol in the dose of 100 to 300 µg/kg/min before and during the laryngoscopy and intubation. It is especially useful for blunting the increase in HR, evoked by intubation. A small dose of fentanyl (1 to 2 mg/kg IV) or equivalent doses of other short acting opioids, administered before the direct laryngoscopy and intubation, may also be useful for blunting the circulatory responses, evoked by laryngoscopy and tracheal intubation. The continuous infusion of nitroglycerine in the dose of 0.25 to 1 µg/kg/min IV may also be used as prophylaxis against the development of coronary vasospasm and subsequent development of myocardial ischaemia in vulnerable patients. But, many controlled studies do not consistently confirm that this approach decreases the incidence of intraoperative myocardial ischaemia.

Maintenance of Anaesthesia

The choice of drugs used for maintenance of anaesthesia depends upon the preoperative evaluation of patient and the presumed left ventricular function. Sympathetic activation due to the surgical stimulation are not detrimental for normal left ventricular function. But in patients with IHD, the sympathetic activation by surgical stimulation is harmful due to increased O_2 demand in a already compromised heart. From this point of view, volatile anaesthetics (sevoflurane, isoflurane, desflurane) are useful by minimising this sympathetic stimulation and subsequent decreasing the myocardial O_2 requirement. The volatile anaesthetic may be administered alone or in combination with N_2O and opioids. If the use of volatile anaesthetics is associated with much reduction of systemic blood pressure, then it will decrease the coronary perfusion pressure and its flow which will be detrimental for IHD patients. So, excessive reduction of BP by voltile anaesthetic agents is never desirable in IHD patient.

In patients with severely impaired LV function, if slight myocardial depression by volatile anaesthetic agents is associated with much reduction of cardiac output, then in such circumstances short acting opioids in liberal doses are selected instead of volatile anaesthetics. For severly compromised patients high dose opioid such as fentanyl 50 to 100 mg/kg/IV or equivalent doses of other short acting opioids is used as sole anaesthetic agent. In such circumstances, benzodiazepine or N_2O or low-dose volatile anaesthetics can be used, if adequate amnesia can not be ensured with this high dose of opioid alone. In such situation, you will have to keep in mind that addition of N_2O and volatile anaesthetic agent to opioid is associated with myocardial depression which is not found when any of these drugs is administered alone.

Regional anaesthesia is a well accepted technique for patients with IHD. But, the reduction of systemic blood pressure should be maintained strictly within 20% of the pre-anaesthetic mean arterial pressure (MAP) value. In one sense the regional anaesthesia is beneficial for IHD patients, because it reduces the myocardial O_2 requirement by producing the sympathetic nervous system blockade. In another sense, the regional anaesthesia is not beneficial for IHD patients, because flow through the coronary arteries, narrowed by atherosclerosis, is pressure dependent. So, much decrease of mean arterial pressure (< 20% of pre-anaesthetic value) is associated with the severe reduction of blood

flow through coronary arteries which is greater than the reduction of O_2 requirement. So, prompt treatment of hypotension (that exceeds 20% of pre-anaesthetic value) by IV administration of ephedrine, phenylepherine or any other vasoconstrictive agent which is very well known to a working anaesthetist is often recommended. A disadvantage of using IV fluid load to treat the hypotension, induced by regional anaesthesia, is the interval which is necessary to become effective and the preloading by IV fluid to maintain BP is not so effective as vasoconstrictive agent.

Regarding muscle relaxants, vecuronium, rocuronium, atracurium and cisatracurium are the drug of choice for patients with IHD. Because they are associated with minimal to no effects on HR and systemic BP. Atracurium and mivacurium release histamine and there is transient alteration of BP. Pancuronium increases heart rate with BP and may precipitate myocardial ischaemia. However, it has been used without any apparent adverse effects in many patients with IHD for many decades. Pancuronium is especially used to offset the negative inotropic and negative chronotropic effect of other anaesthetic drugs, such as, volatile anaesthetic agents. The idea that simultaneous use of β-blocker therapy prevents pancuronium induced increase in HR, but it is not always correct as this drug most likely increases the HR by its vagolytic property, but not by sympathomimetic mechanism.

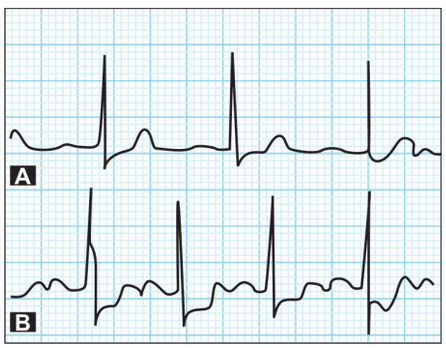
Glycopyrrolate is preferred as anticholinergic drug during reversal of nondepolarising neuromuscular blockade, if excessive increase in HR is a great concern. The combination of anticholinesterase and anticholinergic agent can be used safely for reversal of muscular paralysis in IHD patients. Myocardial ischaemia should also be anticipated during emergence and extubation due to hypertension and tachycardia. So, extubation at the deep plane of anaesthesia or the use of short acting beta-blocker during extubation should be considered. To prevent intraoperative myocardial ischaemia intraoperative blood loss needs accurate replacement and haemoglobin should be maintained by regular measurement.

Monitoring During Anaesthesia

The aim of intraoperative monitoring for patients with ischaemic heart disease is early detection of myocardial ischaemia which is influenced both by the complexity of operative and anaesthetic procedure and the severity of disease. During the routine use of expensive and complex monitors to detect intraoperative ischaemia, one should keep in mind that most of the myocardial ischaemia are not associated with any intraoperative haemodynamic abnormalities and such monitoring should not be used routinely. So, ECG is the most acceptable and cost effective methods for detecting intraoperative myocardial ischaemia. But, the sensitivity and specificity of it varies greatly.

There is good correlation between the lead of ECG used to monitor the myocardial ischaemia and the anatomical distribution of ischaemia. Usually lead II likely reflects the area of ischaemia supplied by the right coronary artery. It is also useful in identifying P waves and subsequent cardiac rhythm disturbances due to ischaemia. Whereas lead V_5 reflects the area of ischaemia supplied by anterior desending coronary artery. Lead I and aVL reflect the area supplied by the circumflex coronary artery. The diagnosis of ischaemia by ECG mainly depends on the changes of ST segment. These changes are characterised by depression or elevation of it by atleast 1 mm. The depth of changes of ST segment is parallel to the severity of myocardial ischaemia. There is also associated T-wave changes with ischaemia. But, there are numerous factors which can produce these changes without ischaemia. Except ischaemia, other factors which can produce the ST segment changes are: conduction defect, arrhythmia, electrolyte imbalance, digitalis therapy, etc. Visual detection of ST segment changes is sometimes unreliable. So, computerised analysis of ST segment changes is incorporated in some machine and offers a high modality for detection of ischaemia by a very simple and noninvasive method in high risk patient (Fig. 27.1).

Transesophageal echocardiography (TE) and measurement of pulmonary capillary wedge pressure (PCWP) is also sometimes used during complex operative procedures for detection of ischaemia. TE is gradually becoming accepted standard procedure for the intraoperative diagnosis of myocardial ischaemia. It is based on the principle that the ventricular wall motion abnormalities occur before the changes in ST-segment takes place in ECG. Whereas, other conditions responsible for ventricular wall motion changes should be excluded preoperatively. The limitation of TE for monitoring of ischaemia is its cost and the need for extensive training for its interpretation. Another limitation of it is that the TE probe can not be introduced before induction of anaesthesia. So, there is a critical period of induction during which myocardial ischaemia may develop in the absence of this monitoring. The present status of TE for monitoring of ischaemia is it provides minimal additive value over analysis of ST-segment on the ECG.



Figs 27.1 A and B: ECG of lead V5 at rest A. ECG of lead V5 after 5 minutes of exercise B. Her ST- segment is depressed horizontally 3 mm (0.3 mV), indicating a positive test for ischaemia

The value of measurement of PCWP for random or routine monitoring of ischaemia is questionable. Only the value and safety of PCWP monitoring is widely accepted in selected patients. PCWP monitoring and diagnosis of ischaemia correlates well when the left ventricular ejection fraction is more than 0.5 (or 50%) and there is no previous evidence of left ventricular dysfunction. Contrary, when the ejection fraction is less than 0.5, then there is no longer a predictable correlation between the findings and the diagnosis.

Postoperative Care

During the postoperative period, the myocardial ischaemic patients should be cared on the following aspects:

i. The relief of postoperative pain in ischaemic patient is very vital, because otherwise it activates the sympathetic nervous system leading to increased myocardial oxygen demand and ischaemia. Adequate relief of pain also facilitates deep–breathing and coughing which may decrease the likelihood of atelectasis and the development of pneumonia.
ii. In the intraoperative period patient's body temperature decreases which may predispose to shivering on awakening. This shivering leads to the abrupt increase in myocardial O_2 demand and ischaemia. So, in the postoperative period all the attempts should be made to check the shivering and O_2 administration is mandatory. It is of interest that postoperative myocardial infarction most often occurs within 48 to 72 hours after operation and this is a period that usually corresponds to the discontinuation of supplemental O_2 and less aggressive treatment of pain. So, following major surgery, all patients at risk should have supplemental O_2 for 3 to 4 days postoperatively, particularly at night.

Continuous ECG monitoring is also useful for detecting postoperative myocardial ischaemia which is often though asymptomatic.

Perioperative Acute Myocardial Infarction (MI)

Perioperative MI most frequently occurs around 3 to 4 days after surgery. Symptoms may be typical or atypical. In 20% case the symptoms may be silent. In perioperative MI, the mortality rate is very high and may rise upto 50%. The diagnostic criteria for MI may vary, but the sole reliance on CK-MB asssay for the diagnosis of MI will over estimate the incidence of it, especially in patients with ischaemic limbs or after aortic surgery. During the management of perioperative MI, the therapeutic options are reduced or limited. This is because thrombolysis is generally contraindicated during perioperative period. Other noncontraindicated possible treatment of MI are aspirin and beta-blockers. Emergency angioplasty for MI is probably atleast as effective as thrombolysis.

28 Valvular Heart Diseases and Anaesthesia

INTRODUCTION

The perioperative management of a patient with valvular heart disease is a very important aspect for an anaesthetist during his clinical practice. So, for proper management of this group of patients he must know the haemodynamic changes associated with every particular type of valvular lesion. The valvular lesion produces haemodynamic burden on left or right ventricle or both or on atrium alone. Initially, CVS tolerates this and tries to compensate the overload. But always the aim of this compensation is to maintain the adequate cardiac output. So, during examination of a patient an anaesthetist will get many findings which are due to this compensatory changes, but are not due to the actual pathology. Then, this haemodynamic burden gradually leads to cardiac muscle dysfunction and failure, when this compensatory mechanism is crossed. So, at this stage during examination of a patient an anaesthetist will get only the signs of heart failure.

More or less all the valvular lesions produce two types of haemodynamic overload such as pressure overload (MS and AS) and volume overload (MR and AR) on left or right ventricle and left or right atrium. Pressure overload produces more damage on heart and morbidity than the volume overload. Other than the knowledge regarding the haemodynamic changes, perioperative management of these group patients with valvular heart disease depends also on the knowledge, regarding the effects of different drugs used for anaesthesia purpose perioperatively on the different haemodynamic parameters such as: heart rate, rhythm, BP, SVR, PVR, etc.

MITRAL STENOSIS (MS)

Aetiology and Pathophysiology (Fig. 28.1)

Acquired mitral stenosis is almost always rheumatic in origin and particularly affects the female. However, in some elderly heavy calcification of the mitral valve apparatus can also produce an acquired form of mitral stenosis. There is also a rare form of congenital mitral stenosis. In mitral stenosis the normal left ventricular filling is restricted by the decreased area of flow from left atrium across the stenosed valve. The normal cross sectional area of the mitral valve is 4 to 6 cm^2. Symptoms appear when this area is reduced to about 2.5 cm^2 (< 50% of normal). When the valve area is measured between 2.5 to 1 cm, then mitral stenosis is recognised as moderate. But, below 1 cm^2 symptoms are severe. At this level, the left intra-atrial pressure is >25 mm of Hg and pulmonary hypertension sets up. Normally, the mitral transvalvular (between LA an LV) pressure gradient is 5 mm of Hg. When it exceeds 10 mm of Hg, then mitral stenosis is considered as severe (Table 28.1).

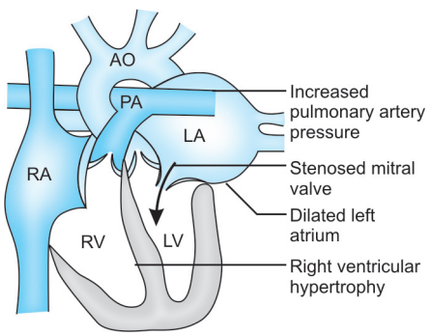


Fig. 28.1: Mitral stenosis

In the early phase of mitral stenosis, the compensation that is aimed at the LV

Table 28.1: Compensatory changes in MS

Mitral stenosis
↓
Decreased flow through mitral valve
↓ Decreased cardiac output → cold calm periphery
Increased volume and pressure of LA
↓
Increased force of contraction of LA
↓ Compensatory increase in cardiac output
Increased flow through mitral valve
↓
Hypertrophy and dilatation of LA
↓
But is limited due to the thin wall of LA chamber
↓
No valve in pulmonary vein
↓
So pressure is directly transmitted to the pulmonary vasculature
↓
Development of pulmonary congestion
↓
So dyspnoea by slight exertion (commonest symptom of MS)
↓
Pulmonary hypertension
↓
Concentric RV hypertrophy without the increase of size of it

filling and subsequently the good cardiac output is normally achieved by increasing the pressure gradient across the stenosed mitral valve. This increased pressure gradient across the stenosed mitral value increases the flow from the LA to LV and compenste this stenosis. This LV filling and cardiac output also dependent upon the increased atrial contraction or kick and the duration of ventricular diastole. So, this valvular obstruction produces increased left atrial volume and left arterial pressure (mechanism of compensation). Thus with increased volume and pressure, dilatation and hypertrophy of the left atrium occurs. The stroke volume or CO may decrease (decompensation) during stress induced trachycardia by reducing the duration of ventricular diastole and thus by reducing the time of LV diastolic filling or when an effective atrial contraction is lost by huge atrial dilatation or by the development of atrial fibrillation.

Symptomatic patients with mitral stenosis typically exhibit dyspnoea on exertion or orthopnoea or paroxysmal nocturnal dyspnoea, although left ventricular contractility is usually normal. Actually this dyspnoea in MS is due to the increased pulmonary venous pressure in response to increased left atrial pressure. This results in transudation of fluid into the pulmonary interstitial space, decreased pulmonary compliance, and increased work of breathing, leading to progressive dyspnoea on exertion, orthopnoea, or paroxysmal nocturnal dyspnoea. When the pulmonary venous pressure exceeds the oncotic pressure of plasma proteins (25 to 30 mm of Hg), then overt pulmonary oedema develops. During compensation with the increase of pulmonary venous pressure there is also concomitant increase in lymphatic drainage from the lungs. This also causes thickening of capillary basement membrane (as compensatory mechanism) which enable the patients to tolerate the increased pulmonary pressure without the development of pulmonary oedema.

Surgical correction of mitral stenosis is indicated when the symptoms increase and /or evidence of pulmonary hypertension develops. Otherwise, mild symptoms of mitral stenosis are treated by diuretics which act by decreasing the preload and subsequently the left atrial pressure. In the presence of atrial fibrillation due to LA hypertrophy and enlargement which is commonly occurs as compensatory mechanism to MS, the HR is controlled by digoxin, β-blockers or Ca^{2+} channel blockers. If pulmonary hypertension and right ventricular failure develop as a consequence to severe MS then inotropic support by dopamine or dobutamine in the dose of 1 µg/Kg/min IV and reduction of pulmonary pressure by nitroprusside in the dose of 0.1 to 0.5 µg/Kg/min IV may be useful. Catheter balloon mitral valvotomy often provides mechanical relief, if the patient is not fit for cardiac surgery. In the presence of heavy valvular calcification or when the surgery is indicated, then the treatment is open commissurotomy or valve reconstruction or mitral valve replacement.

Preoperative Abnormalities

On examination of patient with mitral stenosis the pulse may be found irregular, if atrial fibrillation develops, and this is due to the left atrial hypertrophy and dilatation. The palpation of precordium of a patient suffering from MS may also reveal a palpable first heart sound. On auscultation, there may be an opening snap that occurs during the early diastole. When the 'snap' is more closer to the second heart sound, then it is assumed that the MS is more severe. Calcification of mitral valve also may result in disappearance of the opening snap. In MS this opening snap is followed by a rumbling mid-diastolic murmur with presystolic accentuation. The loudness of the murmur is no guide to the severity of the stenosis and may be inaudible if still the stenosis is severe and cardiac output is low. Atrial fibrillation (AF) may cause decompensation of the haemodynamic changes of mitral stenosis by decreasing the left ventricular filling volume due to the ineffectful contraction of left atrium and by decreasing the left ventricular filling time. Thus, it reduces the cardiac output. This is manifested clearly by cool, cyanosed peripheries and low volume pulse (Fig 28.2).

The chest X-ray in mitral stenosis shows the left atrial enlargement with a prominent left atrial appendage and a double contour on the right border of the heart. Left atrial enlargement is also often visible on chest radiograph as straightening of the left border of the heart, widening of the carinal angle and displacement of the barium–filled oesophagus on a lateral view. The Kerley B lines may be present. The ECG may show P mitrale (large biphasic p-wave) and it is due to the left atrial enlargement. Definitive diagnosis of mitral stenosis is made by echocardiography which allows the precise measurement of mitral valve ring, left atrial dimensions and demonstration of any abnormal movement of thickened and calcified mitral valve cusps. It also permits assessment of the transvalvular pressure gradients.

In the presence of AF which is common for mitral stenosis, the systemic thromboembolism may occur. This is because of the stasis of blood in the distended left atrium (LA) which predisposes to the

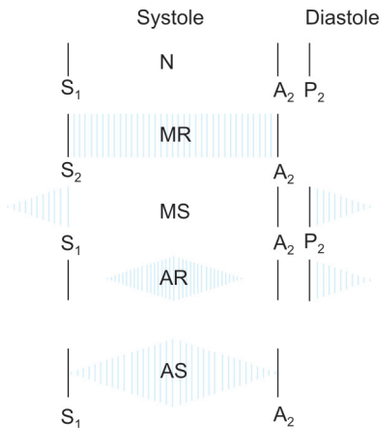

Fig. 28.2: Comparison of systolic and diastolic heart sounds in various abnormalities

formation of thrombi, especially with the onset of AF. Venous thrombosis is also encouraged by the low cardiac output and decreased physical activity, characteristic of these patients.

The patient with symptomatic mitral stemosis when comes for anaesthesia for any non cardiac surgery usually takes digoxin, diuretics, β-blockers, and anticoagulants. Digitalis is most often administered to increase the myocardial contractility and to slow the ventricular rate in responses to AF as it reduces the rate of conduction through AV node. Slowing of the ventricular rate caused by digitalis also prolongs the duration of diastole and thus improves the left ventricular filling with increased cardiac output. An adequate digitalis effect on heart is indicated by the ventricular rate, which is slower than 80 beats/min at rest. Digitalis toxicity is suggested by the prolongation of PR interval in ECG. Concomitant use of diuretics with digitalis increases the vulnerability of the development of digitalis toxicity and it is due to the total body depletion of potassium.

Symptomatic history is a good guide to the severity of disease like MS. Dyspnoea on mild exertion with episodes of paroxysmal nocturnal dyspnoea indicate the left atrial pressure (LAP) is of 15 to 20 mm Hg or greater.

Anaesthetic Problem

The anaesthetic management of a patient with mitral stenosis scheduled for non-cardiac surgery includes the avoidance of events which may further decrease the cardiac output. Tachycardia and AF reduces the LV diastolic filling time, LV filling volume and cardiac output and thus precipitate pulmonary oedema. So, they (tachycardia and AF) should be avoided at any cost. Simultaneously the large decrease in systemic vascular resistance due to any cause may result in severe hypotension, because there is limited capacity to increase the cardiac output by compensation. So, sudden decrease in systemic vascular resistance due to any cause during anaesthesia may not be tolerated well as systemic BP is maintained only by the compensatory increase in HR (which is also not tolerated in MS). Hence, if necessary, systemic BP and systemic vascular resistance should be maintained by sympathomimetic vasoconstricting drugs like ephedrine or phenylephrine. The advantage of ephedrine is its β-adrenergic effect, which increases the myocardial contractility without increasing the HR. Because any drug-induced tachycardia would be undesirable. Phenylephrine also eliminates this increase in heart rate. But increase in left ventricular afterload which follow administration of this predominantly α-agonist drug could decrease the left ventricular stroke volume.

In mitral stenosis volume overload may easily produce pulmonary oedema. Contrary, hypovolaemia accentuated by diuretics or due to any other causes may easily reduce the cardiac output. So, a fine balance should be maintained between the hyper and hypovolaemia. Myocardial depressant drugs can cause severe hypotension and should be avoided in MS. The Trendelenberg position may easily result in pulmonary oedema and hypoxia. Hypoxia and acidosis may further cause pulmonary vasoconstriction with pulmonary hypertension and thus set a vicious cycle. N_2O may be unsafe if pulmonary vascular resistance is increased. Otherwise it is not contraindicated. Bacteraemia during surgery or any instrumentation carries the increased risk of bacterial endocarditis in MS, like other valvular heart diseases.

Anaesthetic Management

Prophylaxis against infective endocarditis is the only preoperative medical therapy for mitral stenosis in asymptomatic patients. So, prophylactic antibiotics are required for any surgery performed on mitral stenotic patient which carries the increased risk of producing bacteraemia. This usually includes dental, genitourinary, intestinal surgeries, etc. If the high ventricular rate due to AF accompanies with MS preoperatively, then it should be controlled before surgery. It is acceptable to continue the anticoagulant therapy for minor surgeries if it is started preoperatively. Whereas for major surgeries which are likely to be associated with significant blood loss, then the common practice is to discontinue warfarin 3 to 5 days before surgery and it is substituted with heparin. Atropine should be avoided in mitral stenosis as tachycardia further reduces the LV filling by reducing the filling time through the already compromised stenosed mitral valve. A sedative premedication reduces the anxiety and any associated bad circulatory responses produced by tachycardia due to anxicty.

The induction of anaesthesia on patient in the presence of mitral stenosis can be achieved by any commonly available intravenous inducing agent. But ketamine should be avoided, because it has a great tendency to increase the afterload and heart rate. Tracheal intubation is usually performed by administration of muscle relaxants that are unlikely to induce undesirable cardiovascular changes due to release of histamine or affecting the conduction of cardiac impulses. The use of succinylcholine on the patient with mitral stenosis and taking digoxin is sometimes associated with ventricular dysrrhythmias, but it is not a consistent observation. So, the use of succinylcholine is not an absolute contraindication in mitral stenosis. In this regard, pancuronium is also not the choice as it causes tachycardia (Table 28.2).

During maintenance of anaesthesia an adequate depth of analgesia, amnesia and muscle relaxation is essential. This goal is most closely reached by using the combination of N_2O, opioids, and low concentration of volatile anaesthetics agents. However, N_2O can produce increased pulmonary vascular resistance by pulmonary vascular constriction. But, it seems

Table 28.2: Goals of anaesthetic management of patients with mitral stenosis (MS)

1. Avoidance of infective endocarditis.
2. Avoidance of sinus tachycardia.
3. Prevent rapid ventricular rate in response to atrial fibrillation
4. Prophylaxis of thromboembolism.
5. Avoid marked increase in IV fluid over load.
6. Avoid head down position.
7. Avoid systemic hypotension.
8. Avoid pulmonary congestion and pulmonary hypertension.
9. Avoid any such agent which depresses cardiac contractility.

unlikely that the magnitude of this change caused by N_2O would justify the avoidance of this drug in asymptomatic patients with mitral stenosis. On the other hand, when the co-existing pulmonary hypertension is severe, then N_2O may more likely to increase the pulmonary vascular resistance and should be avoided. High doses of short acting opioids such as fentanil, alfentanil, remifentanil, etc. are used for severe mitral stenotic patients. If high doses of short acting opioids are used for caessarean section with severe mitral stenosis, then the baby may suffer from severe respiratory depression, but responds well to a single dose of naloxone.

Like any other valvular diseases of heart, in mitral stenosis light general anaesthesia (which is due to not properly titrated with the level of surgical stimulation) can also produce tachycardia, systemic hypertension, and decrease cardiac output due to the increased systemic and pulmonary vascular resistance. In such circumstances, infusion of nitroprusside in the dose of 0.5 to 1µg/kg/minute may effectively decrease the systemic vascular resistance and increase the cardiac output, particularly when the severe pulmonary hypertension or mitral regurgitation coexist with mitral stenosis. There is no contraindication for the use of anticholinesterase and anticholinergic agent for the reversal of nondepolarising muscle relaxants, though the adverse effects of tachycardia deserves consideration. In this respect glycopyrrolate is better than atropine. The use of regional anaesthesia in patient suffering from mitral stenosis bears the same advantages, disadvantages and precaution as the patient suffering from ischaemic heart disease.

The degree of intraoperative monitoring of patient with mitral stenosis depends upon the severity of the lession and the magnitude of the surgery. Monitoring of asymptomatic patients does not need any special comment. On the other hand, symptomatic patients undergoing major surgery may need extensive monitoring including intra-arterial BP, trans-oesophageal echocardiography, pulmonary artery catheterisation, etc. These monitorings are helpful in confirming the adequacy of cardiac functions including cardiac output, intravascular fluid volume, ventilation, oxygenation, etc. In the absence of pulmonary hypertenssion, the changes in CVP will mirror the left atrial pressure changes. However, if it is present, then the PAWP does not correlate very well with the left atrial pressure. In the absence of pulmonary hypertension though CVP shows correctly the left atrial pressure, still it poorly reflects the left ventricular filling. This is due to the presence of stenosis in mitral valve. Intraoperative tachycardia should be treated rapidly. In such situation esmolol is very effective and easily titrable. During operation any negative inotropic effects are easily outweighed by the benefits of controlling the rate. If the tachycardia is due to new atrial fibrillation, then DC cardioversion should be considered.

MITRAL REGURGITATION (MR)

Aetiology and Pathophysiology

Acquired mitral regurgitation is mainly due to the acquired lesion of valve. This acquired lesion of valve is due to the dilatation of ring which is again due to the rheumatic disease or papillary muscle dysfunction. The haemodynamic consideration of MR from anaesthetic point of view is same as MS, but the aetiology of it may have additional consideration in anaesthesia which is not the same as MS. Rheumatic disease is the principal cause of mitral regurgitation (MR) in under developed countries like MS. So, MR is almost always associated with MS. Therefore, though MR in under developed countries is due to the dilatation of mitral valve ring caused by rheumatic pathology, but in developed countries the principal causes of this MR are: mitral valve prolapse, myocardial infarction causing damage to the papillary muscles and damage to the chordae tendinae, and dilatation of mitral valve ring due to the dilatation of heart. MR may also follow after successful surgery of MS by valvotomy or valvoplasty (Fig. 28.3).

The mitral valve prolapse is the most common cause of MR in developed countries. In developed countries MR is also caused by the congenital anomalies, myxomatous degenerative changes, bacterial endocarditis, etc. MR is sometimes a feature of connective tissue disorders such as Marfan's syndrome. The efficacy of mitral valve depends on the proper function of chordae tendinae and their papillary muscles attached to the valve cusps. So dilatation of the left ventricle due to any cause distorts the geometry of the supporting structures of the valve (i.e. chordae

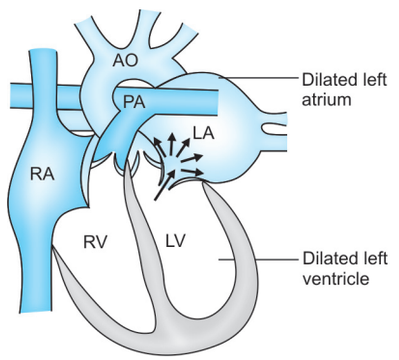

Fig. 28.3: Mitral regurgitation

tendinae and papillary muscles) and may cause mitral regurgitation. The progressive elongation of chordae tendinae due to any cause may also lead to gradual development of MR. But if MI occurs, then due to rupture of chordae tendinae mitral regurgitation suddenly becomes acute. However, this complication is rare before the 5th and 6th decade of life. In developed countries mitral regurgitation is also due to the dilated cardiomyopathy, and impaired ventricular function that results from coronary artery disease. Endocarditis may also lead to the distortion of valve leaflets and is an important cause of acute or chronic MR.

The basic haemodynamic derangement of MR is the decrease of left ventricular stroke volume in forward direction through the aortic valve. This is because a part of the left ventricular stroke volume is regurgitated back through the incompetent mitral valve into the left atrium. Patient with regurgitation fraction of more than 0.6 (> 60%) in the left atrium are considered to have severe MR. The fraction of the left ventricular stroke volume that regurgitates in the left atrium depends on: (i) the size of the mitral valve orifice. (ii) the pressure gradient across the mitral valve, and (iii) the duration of ventricular ejection, i.e. HR. On the other hand, the ventricular ejection through aorta depends on: (a) the impedence of aorta, i.e. systemic vascular resistance (SVR) and (b) the previous factors which control the amount of regurgitation. So, the pharmacological interventions that increase or decrease the SVR have an important impact on the forward ejection fraction and the backward regurgitation fraction of the left ventricular stroke volume. The pharmacological reduction of SVR increases the LV ejection fraction in the aorta and decreases the LV regurgitation fraction in the left atrium and vice-versa.

The chronic MR causes gradual dilatation of the left atrium with little increase in intra-atrial pressure and hypertrophy and, therefore, is associated with relatively few symptoms. However, rheumatic fever induced MR is associated with marked left atrial enlargement and AF. Nevertheless, the left ventricle dilates slowly in MR as the left ventricular and the left atrial pressures gradually increase as a result of chronic volume overload. Then breathlessness, pulmonary hypertension, and pulmonary oedema gradually supervene. The symptoms depend on how suddenly the regurgitation develops. Chronic MR produces a symptom complex that is similar to that of MS. But, sudden onset of isolated MR due to MI or rupture chordae tendinae usually presents with acute pulmonary oedema (Table 28.3).

Mitral regurgitation (MR) is less dependent on atrial contraction for left ventricular filling than MS. So, conversion of AF to normal sinus rhythm is of little help and produces minimal changes in cardiac output in MR. Left ventricular hypertrophy and myocardial ischaemia is unlikely in the presence of isolated MR (i.e. when not associated with MS or AS), because the left ventricular wall tension is rapidly dissipated through the incompetent mitral valve.

When MR is combined with MS, then only the increased flow rates from left atrium to left ventricle (normal amount of blood drained through pulmonary veins in left atrium plus regurgitant blood) across the stenotic valve increases the left atrial pressure and its hypertrophy. In such patient AF, pulmonary hypertension, and pulmonary oedema develop more early than those with isolated MR.

Diagnosis

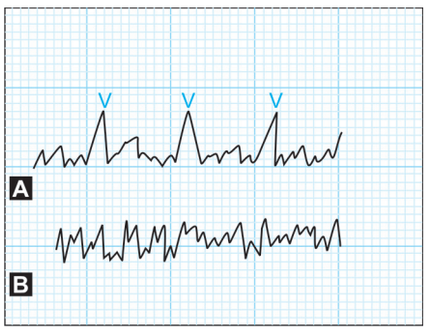
On clinical examination, the MR is recognised by the presence of apical holosystolic murmur which often radiates towards the axilla and may be accompanied by a thrill. The first heart sound is faint or silent, because mitral valve closure is abnormal. During ventricular filling

Table 28.3: Compensatory changes in MR

Mitral regurgitation
↓
Systolic leak from LV to LA
↓
No obstruction of flow through mitral valve
↓
So blood flow freely from LA to LV during diastole
↓
Mean LA pressure therefore remain normal or slight increased
↓
No increase in pulmonary venous pressure
↓
No pulmonary venous congestion
↓
Dilatation of LA and LV due to handling of large blood volume
↓
Forward flow from LV to aorta is less than regurgitation to LA due to high systemic BP
↓
So patient more complain of fatigue (due to low CD) than dyspnoea (due to pulmonary congestion)
↓
Dyspnoea occurs if MR is severe and associated with pulmonary hypertension or LV myocardial failure
↓
So presence of pulmonary hypertension in MR indicates: (i)severe MR, (ii) LVF, (iii) acute MR

increased forward flow of blood (due to normal amount of blood coming from the lungs plus the regurgitant blood) through mitral valve from left atrium to left ventricle may give rise to prominent third heart sound. The chronic MR is compensated by the development of eccentric atrial and ventricular hypertrophy and enlargement. This is detected by the apex beat which is usually displaced to the left (as a result of dilatation of LV) and feels active and rocking (due to LV hypertrophy for overload) (Figs 28.4A and B).

The radiograph and ECG in mitral regurgitation may show the features of left atrial and/or left ventricular hypertrophy. Like MS the atrial fibrillation (AF) is also common in MR as a consequence of atrial dilatation. Echocardiography provides information about the state of the mitral valve, left ventricular function and left atrial size. The severity of MR is best assessed by echocardiography. But it should be realized that the left ventricular ejection fraction as a reflection of LV performance will be overestimated in the presence of mitral regurgitation. So, doppler echocardiography is required to estimate the extent of regurgitation. During cardiac catheterisation for the tracing of pulmonary capillary wedge pressure (PCWP) the severity of MR may be indicated by the size of 'V' waves produced by the left atrium. It also can be assessed by the left ventricular angiography. The size of V wave parallels with the severity of MR.



Figs 28.4A and B: The picture shows the tracing of pulmonary artery occlusion pressure from a patient with mitral regurgitation.
A. when blood regurgitate back into the left artium through incompetent mitral valve produce large 'V' waves on tracing.
B. It shows that the magnitude of the V waves are decreased or abolished. It is due to administration of vasodilator like hydralazine. Vasodilators decrease resistance to forward ejection of the left ventricular stroke volume. As a result the stroke volume into the aorta increases and the volume of regurgitant flow into the left atrium decreases with the magnitude of the 'V' wave

Anaesthetic management

Unlike the stenotic mitral valvular lesions in MS the chronic MR causes few symptoms. So, it progresses insidiously causing LV and left atrial damage, before symptoms have developed. Thus, surgical treatment of MR is recommended when the regurgitation fraction is less than 0.6 (60%), i.e. before patient becomes symptomatic. The progressive radiological cardiac enlargement or the echocardiographic evidence of the deterioration of the left ventricular function are also the indications of surgical intervention of mitral valve. In this regard, mitral valve repair is preferred than the mitral valve replacement. This is because in mitral valve repair mortality is less and outcome is better than MS (Table 28.4).

The principles of anaesthetic management of a patient with MR for noncardiac surgery is avoidance of events that cause reduction of cardiac output. This is achieved by: (i) avoiding sudden decrease in HR, (ii) avoiding sudden increase in SVR and (iii) avoiding myocardial depression. Unlike MS, in MR the left ventricular forward stroke volume through aorta is heart rate dependent. Contrary in MS tachycardia is not desirable as it reduces the LV filling by reducing the diastolic ventricular filling time and subsequent reduces the cardiac output. But, in MR bradycardia is not desirable as it reduces the forward LV stroke volume directly due to increased back flow. So, sudden bradycardia may result in abrupt LV volume overload. Likewise, sudden increase in SVR causes reduction of LV stroke volume and causes increase in regurgitation from left ventricle to left atrium. This produces acute decompensation of LV. So, overall anaesthetic management of a MR patient is drug induced afterload reduction with nitroprusside, combined with a cardiac inotrope such as dopamine or dobutamine, and maintenance of (avoiding of bradycardia) heart rate.

Table 28.4: Goals of anaesthetic management of patients with mitral regurgitation (MR)

1.	Prophylactic antibiotic to avoid infective endocarditis.
2.	Prevent sudden decrease in heart rate.
3.	Avoid sudden increase in BP.
4.	Avoid depression of myocardial contractility.
5.	Avoid fluid overload and pulmonary congestion.
6.	Monitoring of amount of regurgitation by echo or other invasive method.

Like MS, in the patient suffering from MR prophylactic antibiotic is also started in the preoperative period to prevent the development of infective endocarditis. GA is the usual choice for MR. Induction of anaesthesia for patient in the presence of MR can be achieved with any available intravenous inducing agent, with possible exception of ketamine which should be avoided. This is because ketamine has great propensity to increase the SVR and systemic blood pressure. Thus it will reduce the forward flow from LV to aorta. Succinylcholine for intubation is not contraindicated. The anaesthetic points of view regarding the choice of nondepolarising muscle relaxants are same as MS, but pancuronium which generally produces a modest increase in HR is beneficial for MR.

Low doses of volatile anaesthetic agents can also be administered to attenuate the undesirable increase in SVR and systemic BP associated with intubation and surgical stimulation, but without depressing the myocardium. Although, any specific

volatile anaesthetic agent is not considered as superior than other, but isoflurane, sevoflurane, or desflurane (not halothane) are the choice. Because, they decrease the SVR with minimum depressant effect on myocardial contractility. In the presence of acute or severe MR when myocardial function is severely compromised, then the sole use of opioid as anaesthetic agent which minimises the likelihood of drug induced myocardial depression is the choice.

The intraoperative anaesthetic management and the maintenance of intravascular fluid volume in MR is same as the intraoperative management of MS. General anaesthesia and alterations of SVR are well tolerated unless the regurgitation through mitral valve is very severe. Other anaesthetic approaches are also well tolerated by MR. Fluid overload is a major risk factor in MR, but less than with mitral stenosis. Intraoperative monitoring of MR is also same as MS. Minor operations, performed on patients with asymptomatic MR, probably do not require any invasive monitoring. Complex invasive monitoring (such as transoesophageal echocardiography, use of pulmonary artery catheter, measurement of cardiac output by thermodilution technique, etc) are necessary for patient with severe MR undergoing a complex surgical procedure. In the tracing of pulmonary artery pressure, the presence of prominent V waves indicate appreciable regurgitation through mitral valve. Changes in V wave amplitude can also assist in estimating the magnitude of MR.

AORTIC STENOSIS (AS)

Aetiology and Pathophysiology (Fig. 28.5)

Aortic stenosis is usually idiopathic in origin, and results from the degeneration and calcification of the cusps of aortic valve. The likely aetiologies of AS vary with the age of patients. The causes of AS for infants, children and adolescents are different. The cause of AS in infants is usually congenital and it is of three types such as congenital stenosis at the aortic valve level, congenital stenosis at the subvalvular level, and congenital stenosis at the supravalvular level. The causes of AS for young adults and middle aged patients are: early calcification and fibrosis of congenitally present bicuspid aortic value and rheumatic disease. The causes of AS for elderly patients are: senile degeneration of aortic valve, calcification of bicuspid valve, and rheumatic disease (Fig. 28.5).

The aortic stenosis is more likely to occur at earlier age (below 30 to 40 years) in persons, who are born with bicuspid aortic valve than in those with normal tricuspid aortic valve. Otherwise, except the congenital forms, AS develops slowly in older age. Initially, as compensatory mechanism cardiac output in AS is maintained at the cost of steadily increasing pressure gradient across the aortic valve due to outflow obstruction. Then, the LV gradually becomes hypertrophied and maintains the cardiac output. After that when the AS becomes more severe and cardiac output gradually falls, then the coronary blood flow gradually becomes inadequate and patient develops angina, even in the absence of any coronary artery disease. It indicates increased myocardial O_2 requirement due to increased concentric myocardial hypertrophy which is again due to increased outflow obstruction. Furthermore, myocardial O_2 delivery is decreased due to the compression subendocardial coronary blood vessels by the increased left intraventricular systolic pressure. So, aortic stenosis is associated with the same risk factors as those of IHD. The fixed outflow obstruction at the aortic level limits the increase in cardiac output, which is required for increased activity. So, the effort or activity related hypotension and syncope may occur. Gradually, the LV can no longer be able to overcome the outflow tract obstruction and the left ventricular outflow failure supervenes. In contrast to MS which tends to progress very slowly, AS typically remain asymptomatic for many years. But, then it deteriorates rapidly when symptoms develop. Thus, death usually ensures within 3 to 5 years after the onset of symptoms.

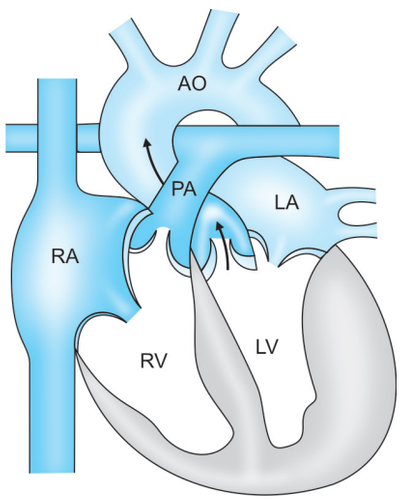


Fig. 28.5: Aortic stenosis

The severity of AS is best assessed by measuring the pressure gradient across the aortic valve by echocardiography. But, poor exercise tolerance and especially the syncope suggests severe stenosis. Critical or severe aortic stenosis, capable of causing symptoms and sudden death, is characterised by transvalvular pressure gradient higher than 50 mm of Hg and an aortic orifice area is lesser than 0.8 cm^2 (the normal aortic valve area is 2.5 to 3.5 cm^2).

The long-term prognosis of AS depends upon the degree of stenosis:
< 0.7 cm^2 – severe,
0.7 to 1.5 cm^2 – moderate,
> 1.5 cm^2 – mild.

A pressure gradient across the aortic valve of > 50 mm of Hg is considered to be severe and < 20 mm of Hg is mild. The pressure gradient between 50 to 20 mm of Hg across the aortic valve is considered as moderate. These pressure gradients are increased by tachycardia and exercise.

This pressure gradient across the aortic valve should be interpreted with the measurement of LV function, because with time the LV will fail and the measured transvalvular pressure gradient will then start to fall again. But it does not mean that AS is not severe. Aortic stenosis is almost always associated with aortic regurgitation. It is also associated with LV systolic dysfunction due to increased after load. This leads to ventricular hypertrophy and gradually progress to diastolic dysfunction due to increased LV wall thickness.

Diagnosis

The mild and moderate degree of AS is usually asymptomatic. The classical clinical symptoms of AS (which indicate severe form) are angina pectoris, exertional dyspnoea, exertional syncope, episodes of acute pulmonary oedema, etc. On clinical examination, the carotid pulse is felt as low volume and slow rising. A radial pulse is also of slow rising and of decreased amplitude. A pulse pressure of < 30 mm of Hg reflects severe AS. Contrary, if the systolic BP is > 180 mm of Hg, then the AS is not significant. Auscultation of patient with AS reveals a characteristic systolic ejection murmur over the precordium, radiating towards the neck. It is best heard on the aortic area, i.e. 2nd right parasternal intercostal space and is 'diamond' in shape. The aortic component of the 2nd heart sound is inaudible. An ejection click may be present in young patients, but not in older patients due to calcified valves. The chest X-Ray may show a prominent ascending aorta due to post-stenotic dilatation of the aortic arch. The ECG demonstrates the evidence of left ventricular hypertrophy (LVH) with the changes of ST segment. LBBB is also common in AS. In advanced cases of AS the features of LV hypertrophy are often gross and depression of ST-segment with T-wave inversion (strain pattern) may be seen in leads reflecting left ventricle.

The echocardiography examination provides a more accurate assessment of the severity of aortic stenosis. It also provides information regarding the thickening and calcification of the aortic valve, combined with decreased mobility of the valve cusps. It is also useful in determining the left ventricular ejection fraction and its extent of hypertrophy.

The doppler study permits the calculation of systolic pressure gradient across the aortic value and detects the presence or absence of aortic regurgitation. Cardiac catheterisation and coronary angiography is indicated if echocardiography studies are unsatisfactory or if it is necessary to assess the state of coronary arteries.

Anaesthetic Management

The principle of anaesthetic management of a patient with AS for noncardiac surgery is to avoid the events which causes the reduction of already jeoparadised cardiac output due to stenosis. This can be achieved by maintaining the normal sinus rhythm, avoiding tachycardia and bradycardia, avoiding sudden increase in SVR, avoiding sudden severe hypotension and optimizing the intravascular fluid volume (to maintain optimum venous return and left ventricular filling). Like anaesthetic management of other valvular disease, GA is also the choice in AS. Regional anaesthesia is not preferred, because peripheral sympathetic nervous system blockade can lead to undesirable sudden and severe decrease in venous return and and subsequently cardiac output in an already compromised patient who has limited outflow from LV. But it is not absolutely contraindicated and epidural catheter technique is often used (Table 28.5).

During anaesthetic management of a patient suffering from AS intraoperative optimum maintenance of heart rate and sinus rhythm is important, because it determines the time, available for diastolic filling of left ventricle and then subsequently the amount of ejection of blood into aorta. Sustained tachycardia can decrease the time for left ventricular diastolic filling and forward ejection, leading to reduction in CO. On the other hand, sudden severe bradycardia can also lead to acute over distension of the left ventricle. This is because the ventricle gets more time for diastolic filling. It is important to recognise that increase in SVR and BP (i.e. after load) can lead to further reduction of stroke volume and cardiac output through obstructed orifice. Contrary, sudden large decrease in SVR may be associated with large decrease in systemic BP, because cardiac output is relatively fixed. This fall in BP reduces the coronary perfusion of left ventricle which is hypertrophied and may result in ischaemia and reduced contractility. Thus, a vicious cycle sets in causing further left ventricular myocardial dysfunction, fall in BP and fall in coronary circulation.

The indications for preoperative prophylactic antibiotic and premedication for the patients with AS is like other valvular diseases. During induction of patients with AS, ketamine should not be used. All the anaesthetic drugs must be given with caution. The exact method of anaesthesia is probably less important than the care with which it is administered and the patient is monitored. The intraoperative monitoring also depends on the severity of disease and the complexity of surgery.

If the patient is symptomatic, then cardiological advice should be obtained. In symptomatic patients the aortic valve replacement or balloon valvuloplasty may be more important than the proposed

Table 28.5: Goals of anaesthetic management of patients with aortic stenosis (AS)

1. Optimization of intravascular fluid load.
2. Maintenance of preload, LV filling and cardiac output.
3. Avoidance of bradycardia and maintenance of normal sinus rhythm.
4. Prevention of sudden increase in afterload.
5. Prevention of sudden hypotension.
6. Prophylactic antibiotic.

operation. This is because mortality approaches 75% within 3 years after aortic stenosis becomes symptomatic, unless the valve is surgically replaced. Aortic valve replacement usually relieves the symptoms of aortic stenosis dramatically and the ejection fraction increases.

The dangerous feature of AS is that the signs and symptoms appear late in this disease. But once they occur, the prognosis is poor. So, an anaesthetist must be cautious during dealing of such a patient.

AORTIC REGURGITATION (AR)

Aetiology and Pathophysiology

Aortic regurgitation (AR) may be due to the disease of aortic valve cusps or dilatation of aortic root. The diseases of aortic valve cusps that causes AR are: congenital bicuspid valve, rheumatic fever, infective endocarditis, etc. The causes of aortic root dilatation leading to aortic regurgitation are: rheumatic fever, endocarditis, idiopathic root dilatation associated with systemic hypertension, ageing, dissection of aorta, aneurysm of aorta, syphilis, collagen vascular disease, Marfan's syndrome and trauma, etc. Acute aortic regurgitation is usually due to infective endocarditis. Except endocarditis other above mentioned causes are responsible for chronic MR (Fig. 28.6).

In AR there is ultimate decrease in the forward LV stroke volume due to the regurgitation of a part of ejected blood from the aorta back into the left ventricle (LV) after its ejection. Then this regurgitated blood volume in LV is added to that volume of blood which enters in LV from the left atrium and this combined volume of blood is next further ejected out into the aorta. Thus, by this compensatory mechanism the cardiac output is maintained by the increase in end diastolic LV volume during second contraction. So, gradually both the left ventricular hypertrophy and dilatation occur. The magnitude of regurgitation of blood from the aorta to the LV depends on: (i) the time available for the regurgitation to occur, i.e. HR and (ii) the pressure gradient across the aortic valve which again depends on the SVR and the diastolic ventricular pressure. Thus, the magnitude of AR can be decreased by increasing the HR upto a certain limit and by the reduction of SVR by peripheral vasodilatation.

With chronic aortic regurgitation (AR) the LV gradually dilates and hypertrophies to compensate the regurgitation. Thus, it results in large stroke volume that is entirely ejected into the aorta and a part of it is regurgitated back. So, the stroke volume of LV may eventually be doubled or tripled and the major arteries are then conspicuously become pulsatile. In some cases the stroke volume may be increased to more than 20 L/minute. As the disease progresses, then the left ventricular (LV) diastolic pressure gradually rises, at first only with exercise and then breathlessness develops. Later, the myocardium becomes stiffer, the left ventricular end diastolic pressure (LVEDP) increases, premature mitral valve closure occurs and finally the cardiac failure supervenes. A helpful indicator of the left ventricular (LV) function in the presence of aortic regurgitation is the echocardiographic determination of end-systolic LV volume and the ejection fraction. However, both of which remain normal until the LV function deteriorates. The symptoms appear late in this disease and do not correlate well with the severity of regurgitation. Severe aortic regurgitation carries a poor prognosis.

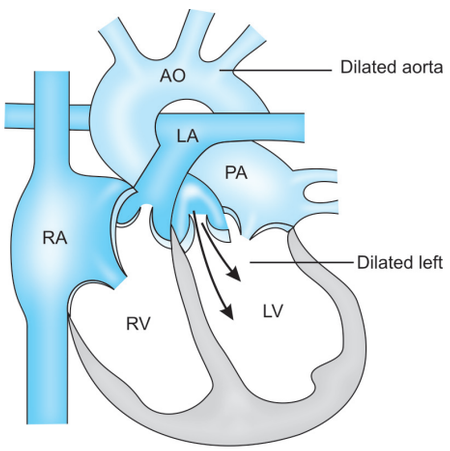

Fig 28.6: Aortic regurgitation

Diagnosis

Clinically AR is diagnosed by its characteristic diastolic blowing murmur. It is best heard along the left sternal border and is accompanied by an ejection systolic murmur due to the increased stroke volume. The peripheral signs of hyperdynamic circulation such as a widened pulse pressure, decreased diastolic BP, bounding and collapsing peripheral pulses, heaving apical impulse (volume overload), etc, are found during the clinical examination. Until the onset of breathlessness, the only symptom of AR may be an awareness of the heart beat, particularly when the patient is lying on his left side. This is only due to the hyperdynamic circulation and increased stroke volume. Clinically, dyspnoea and pulmonary oedema suggest advancement of disease. In such circumstances the diastolic BP falls in proportion to the severity of valvular lesion. In acute severe aortic regurgitation (e.g. perforation of aortic cusps due to acute endocarditis) there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of acute heart failure predominates. Like MR, the symptoms of AR may not appear, until the LV dysfunction is advanced. In contrast to AS, sudden death due to AR is rare.

The chest radiograph in AR characteristically shows the cardiac and aortic dilatation, together with the signs of left heart failure. When regurgitation is marked, then the ECG may show the left ventricular hypertrophy and changes in the ST segment. Echocardiography in AR typically shows a dilated left ventricle with vigorous contraction until heart failure ensues. The amount of regurgitation is readily detected by Doppler

echocardiography. Cardiac catheterisation and aortography can be helpful in assessing the severity of regurgitation and the dilatation of aorta.

Anaesthetic Management

The preanaesthetic management of AR includes the treatment of underlying conditions such as endocarditis or syphilis and prophylactic antibiotic. Aortic valve replacement is indicated if the patient is symptomatic. However, surgery is also advised for asymptomatic patients, if there is progressive radiological evidance of cardiomegaly and echocardiographic evidence of deteriorating LV function. ACE-inhibitors (as vasodilator) have been shown to prevent progressive LV dilatation and are recommended for asymptomatic patients (Table 28.6).

Table 28.6: Goals of anaesthetic management of patients with aortic regurgitation (AR)

1. Prophylactic antibiotic.
2. Avoidance of sudden increase in after load.
3. Prevent decrease in HR and maintain at higher side.
4. Use vasopressor carefully.

The anaesthesia induced fall in SVR is better tolerated by AR than with AS. The fall in SVR decreases the regurgitant flow. Contrary, an increase in SVR increases regurgitant flow and precipitate heart failure. A certain degree of tachycardia shortens the diastole and therefore, reduces the regurgitation. As the ventricle is less hypertrophied in AR, it is less at risk from tachycardia induced ischaemia. So, the goal of anaesthetic management for noncardiac surgery in patients with AR is to maintain adequate forward LV stroke volume by avoiding sudden decrease in HR, avoiding sudden increase in SVR and minimising the drug induced myocardial depression. During the whole intraoperative period, HR should be maintained above 80 beat/minute. Because, bradycardia can lead to acute left ventricular increasing the volume overload by increasing the duration of ventricular diastole and thus increasing the volume of regurgitation. Sudden increase in SVR may also precipitate left ventricular failure (LVF), requiring treatment with peripheral vasodilators, such as nitroprusside. Like other valvular diseases, GA is the choice for patients with aortic regurgitation (AR). Although, reduction of SVR due to regional anaesthesia is theoretically beneficial, but the uncontrolled nature of this response detracts an anaesthetist from the use of it in such patient. Then still if RA is decided, then epidural is safer than spinal as it can be slowly induced allowing appropriate measures to take if the BP falls. Vasopressors should be used carefully to avoid excessive increases in SVR.

Induction, intubation, maintenance and perioperative monitoring of anaesthesia in AR is like other cardiac valvular diseased patient.

29 Congenital Heart Diseases and Anaesthesia

INTRODUCTION

Congenital heart disease (CHD) is usually manifested in neonate, infant, or childhood. But, sometimes it may pass unrecognised and is not diagnosed until the adult life. Some congenital defects of heart (e.g. ASD) may cause no symptoms throughout the whole life and may first be detected incidentally during the routine preoperative examination by an anaesthetist. Very few years back, some CHD which were refused to be operated is now undergoing cardiac surgery. This is due to the better development of surgical technology, better intraoperative myocardial protection and major advances in the paediatric cardiac anaesthesia. Such many patients who have undergone corrective cardiac surgery may remain well for many years with full correction or under correction and subsequently to be presented for anaesthesia during noncardiac surgery. But many patients will still have residual problems. A study in 1992 had reported an incidence of 47% of adverse perioperative events in CHD patients, undergoing noncardiac surgical procedures who were operated before. The paediatric cardiac surgical procedures for CHD can be divided into three groups: curative procedures, corrective procedures and palliative procedures. In curative procedures the patients are completely cured without any residual problem and have a normal life expectancy, e.g. PDA, ASD, VSD, etc. In corrective procedures the patient's haemodynamic status is markedly improved, but their there is some residual problems and life expectancy may not have returned to normal, e.g. tetralogy of Fallot. In palliative procedures, the patients may have distinct abnormal circulations and cardiac physiology, but avoid the consequences if CHD remains untreated. Their life expectancy is not normal, but many are expected to reach the mid adulthood, e.g. Fontan procedures (Table 29.1).

The total incidence of congenital heart disease (CHD) is 7 to 10 per 1000 live births. About 85% of these children reach the adult life. Among all the other congenital anomalies, the CHD is the most common. It constitutes about 30% of all the congenital diseases. Previously, acquired rheumatic heart disease was the principal cause of all the heart diseases. But with the decline of rheumatic disease, congenital heart disease has become the principal cause of total heart diseases. Among the congenital heart disease the 10 to 15% of patients have associated other congenital anomalies such as the skeletal, genitourinary or gastrointestinal system, etc.

Table 29.1: Incidence of congenital heart disease

Disease	*Incidence (%)*
VSD	40
ASD	10
Pulmonary stenosis	7
PDA	6
Coarctation of aorta	5
Fallot's tetralogy	5
Transposition of great vessels	3

CHD can be classified into:

i. *Acyanotic defects:* Ventricular septal defect (VSD), atrial septal defect (ASD), patent ductus arteriosus (PDA), pulmonary stenosis (PS), coarctation of aorta, and atrioventricular septal defect, etc.
ii. *Cyanotic defects:* tetralogy of Fallot, transposition of great vessels (TOGV), Eisenmenger complex, etc.

These above mentioned nine congenital form of heart diseases constitute about 80% of all the total congenital heart diseases. Other wide range of more unusual and complex congenital lesions of heart comprise the remainder 20% of CHD.

The understanding of the development of heart and foetal circulation helps to understand how CHDs occur. The heart develops as a single tube which folds back on itself and then divides into two separate circulation. Failure of this separation can lead to some forms of atrial and ventricular septal defects. Failure of alignment of the great vessel with the ventricles contributes to the transposition of great vessels, tetralogy of Fallot and truncus arteriosus, etc. Due to high pulmonary vascular resistance and as the foetus can not breath in the uterus, so it has little blood flow through the lungs during intrauterine life. The foetal circulation, therefore, allows the oxygenated blood from placenta to pass directly to the left side of heart through the foramen ovale without flowing through the lungs. This oxygenated blood then from LV passes to the ascending aorta. On the other hand, the deoxygenated blood

from RV passes through ductus arteriosus (DA) to the descending aorta and reaches the placenta through the umbilical arteries for oxygenation. The congenital heart diseases (CHD) may arise if the changes from foetal circulation to the extrauterine circulation are not properly completed. ASD occurs at the site of the foramen ovale, if it does not close. Ductus arteriosus may remain open as patent ductus arteriosus (PDA), if it fails to close after birth. The failure of aorta to develop at the point of aortic isthmas can lead to the narrowing or coarctation of aorta.

Among the causes of CHD, antenatal maternal infection, antenatal exposure to drugs or toxins, and genetic or chromosomal abnormalities are the most important factors. Maternal rubella is associated with PDA, pulmonary and/or aortic stenosis and ASD. Maternal alcohol abuse is associated with septal defects. Maternal SLE is reponsible for different forms of congenital heart block of foetus and newborn, causing CHD. However, advances in molecular biology have much helped to understand the genetic basis of CHD. Genetic abnormalities are responsible for 10% of all the congenital cardiovascular lesion. Among these two-third is due to the trisomy-21(Down's syndrome) and one third is due to the trisomy-13, trisomy-18, and Turner's syndrome. Maternal diabetes and use of lithium is also associted with high incidence of CHD. A widely used abbreviation such as CHTCH-22 depicts a syndrome of CHD which is due to the defects in chromosome 22. CATCH-22 syndrome consists of cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcaemia. Another common genetic disorder is Marfan's syndrome which results from the mutations of gene, responsible for the formation of fibrin and a component of extracellular matrix. Marfan's syndrome is characterised by skeletal disproportion (arm span greater than height), arachnodactyly (long, thin, spider like fingers), sternal depression, generalised hypermobility of joints, lens dislocation and a high arched palate. The mitral valve prolapse, aortic incompetence and aortic dissection are the most serious complication associated with Marfan's syndrome (Table 29.2).

The symptoms of CHD may be absent or the child may be symptomatic and breathless. He may fail to attain the normal growth and development. The diagnosis of CHD is apparent during the first week of life in about 50% of the affected neonates and before 5 years of age in virtually all the remaining patients. Some congenital defects of heart are not compatible with extrauterine life or if compatible it is only for a short period. The clinical signs and severity of symptoms of CHD may vary with the type, complexity, and the degree of complexity of anatomical lesion. Early diagnosis is important, because many types of CHD are amenable to surgical treatment. But, this opportunity may be lost, if the secondary changes such as the pulmonary vascular damage and pulmonary hypertension develops. Persistently raised pulmonary flow (e.g. with left to right shunt) leads to increased pulmonary resistance, followed by pulmonary hypertension. Then progressive changes (including obliteration of distal vessels) take place in the pulmonary vasculature and once established, the increased pulmonary resistance becomes irreversible. Hence, if the severe pulmonary hypertension develops, then a left to right shunt which is present from early may reverse, resulting in right to left shunt and marked cyanosis (Eisenmenger's syndrome). This is more common with large VSD or persistant ductus arteriosus than with ASD. The patients with Eisenmenger's syndrome are at the particular risk from abrupt changes in after load that exacerbate R to L shunting during anaesthesia. The younger the patient will be at the time of corrective cardiac surgery, the greater is the likelihood that pulmonary vascular resistance will normalise. In older patients, if pulmonary vascular resistance is greater than 1/3 of SVR during corrective cardiac surgery, then progressive pulmonary vascular changes can not be stopped. Cardiac dysrrhythmias are not usually a prominent feature of CHD. Infective endocarditis is the most common risk factor, associated with congenital heart disease (CHD). Sudden death sometimes occur in CHD patient who have undergone surgical correction. It reflects the myocardial scarring or damage to the cardiac conducting system.

Table 29.2: Congenital heart disease with intracardiac shunt

A. Left to right shunt	VSD
	PDA
	ASD
B. Right to left shunt	Fallot's tetralogy
	Ebstein's anomaly
	Eisenmenger syndrome

Echocardiography is the initial diagnostic step, if CHD is suspected. Both, transthoracic and transesophageal route for echocardiography facilitate the early and accurate diagnosis of CHD. Recently three dimensional echocardiography, Doppler and MRI have increased the understanding of complex cardiac malformation accurately. They also allow the visualization of abnormal blood flow and transposition of vascular structures. Cardiac catheterization and angiocardiography are also definitive diagnostic procedure for patients with CHD.

PREOPERATIVE ASSESSMENT

It helps to gain a clear understanding, regarding the anatomy and pathophysiology of the patient's congenital cardiac defect.

History

At first, patient should be asked about the limitations of his daily activities. It may define clinically the nature and the severity of cardiac lesion. The history may also provide some clue regarding the presence of other anomalies and syndromes associated with CHD.

Examination

To diagnose and to assess the severity of CHD, the patient should be properly inspected, palpated and auscultated. The cyanosis, peripheral oedema and hepatospleno megaly should be searched for. The peripheral pulses, heart and lungs are assessed for murmur, signs of failure and any infection. Cyanosed patients should have a brief neurological examination also (Table 29.3).

Investigation

The laboratory tests obviously depend on the type of proposed noncardiac surgery and the severity of cardiac disease. But, the most patients will require full blood count (FBC), coagulation profile, LFT and electrolytes estimation. Recent chest radiograph, ECG, echocardiography and doppler is done routinely. TEE, MRI and other investigation are done according to the need. For example, some patients may need pulmonary function tests. Baseline SpO_2 level while breathing air is also recorded. Data from cardiac catheterisation and angiocardiography should be kept in mind.

Factors Indicating High Risk

When a patient with CHD is undergoing a noncardiac surgery, they should be balanced between the potential risks and the benefits of proposed surgery. Admission of patient in ICU or HDU or he should be removed to the specialised cardiac centre will depend on the risk factors, playing in individual (Table 29.4).

Table 29.3: Signs and symptoms of CHD

- Asymptomatic
- Dyspnoea, tachypnoea
- Cyanosis
- Failure to gain weight
- Decreased exercise tolerance
- Murmur and thrill
- Thromboembolism
- Erythrocytosis
- Heart failure
- Sudden death

Specific Problems Found in Patients with CHD

The specific problems which are usually encountered during anaesthesia in patients with CHD are:

Myocardial dysfunction

Primarily some forms of myocardial dysfunction, mainly of ventricle, are usually present in all forms of CHD which may lead to the perioperative cardiac failure. Superimposed on it is the secondary cardiac dysfunction which is due to the poor intraoperative myocardial protection.

Arrhythmias

Perioperative all types of arrhythmias may be precipitated during noncardiac surgery on CHD patient. This may be due to the original disease or due to the some iatrogenic (surgery and medications) factors. Some CHD patients develop complete heart block following cardiac surgery and have pacemakers in situ.

Air embolism

All CHD patients are at potential risk from systemic air embolism particularly in ASD, PDA, and VSD with R to L shunt. So, all intravascular lines should be free of air.

Cyanosis

Perioperative cyanosis is common in CHD patients. It is generally due to the intracardiac mixing of oxygenated and deoxygenated blood (e.g. complete atrioventricular septal defect), or shunting of blood from the right side to the left side of heart (e.g. tetralogy of Fallot, Eisenmengers syndrome) or heart failure.

Table 29.4: Factors indicating high risks of patients

1. Unexplained dizziness or syncope,
2. Fever and recent CVA,
3. Recent worsening of symptoms of myocardial ischaemia,
4. Signs and symptoms of cardiac failure,
5. SpO2 < 75% while breathing air,
6. Haematocrit value > 60%, indicating severe polycythemia,
7. Recent onset of arrhythmia,
8. Severe aortic or pulmonary stenosis,
9. Uncorrected tetralogy of Fallot or Eisenmenger's syndrome.

Anticoagulation

Most CHD patients are under anticoagulants like aspirin, warfarin, etc. So, perioperative mangement of these patients undergoing noncardiac surgery is very difficult.

Endocarditis

Most CHD patients are at increased risk from endocarditis. So, preoperative antibiotic prophylaxis are very important.

Myocardial ischaemia

Development of perioperative myocardial ischaemia with CHD patient is very common. So, it should be protected and treated immediately.

Atrial Septal Defect (ASD)

ASD is the second most common (one third) form of all the congenital heart diseases and occurs twice as frequently in females than in males. The atrial septal defect (ASD) is of two types - ostium secundum (most common, 70%) and ostium primum. The ostium secundum involves the fossa ovalis which in intrauterine life remains as the foramen ovale. Whereas, the ostium primum results from the defect of endocardial cushion or from the defect of atrioventricular valves which are associated with the 'left mitral valve' and mitral regurgitation (MR). The more severe form of ASD is the atrioventricular septal defect (AVSD) which is associated with Down's syndrome and results in severe pulmonary hypertension, if not treated in infancy. On the other hand, ostium secundum is associated with mitral value prolapse. Surgical repair of these form of ASD occasionally results in complete heart block. Most ASDs occur as a result of the spontaneous genetic mutation (Fig. 29.1).

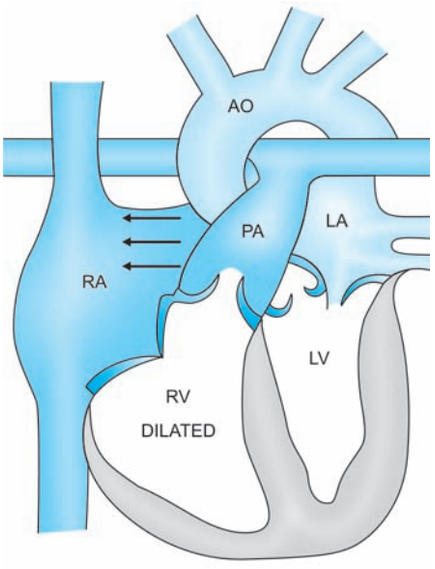

Fig. 29.1: Atrial septal defect

The right atrium and the right ventricle are much more compliant than the left side of the heart. So, a large volume of blood shunts through this defect from the left atrium to the right atrium and then through the right ventricle to the pulmonary artery. As a result, there is gradual enlargement of the right side of heart and pulmonary artery. Thus, gradually pulmonary hypertension and sometimes shunt reversal (R to L) occur in long standing cases of ASD. But it is less common and tend to occur later in life than with other types of L to R shunt such as VSD and PDA. The magnitude and the direction of blood flow through this defect are determined by the size of the defect and the relative compliance of the two atrium and the two ventricles. A small defect in the intertrial septum which is less than 0.5 cm in diameter, is associated with no haemodynamic sequelae. But, when the defect approaches ±2 cm in diameter, then clinical features appear. The ASD in which the pulmonary flow is 50% or above the systemic flow is often considered as large enough to be clinically recognisable and should be closed surgically or through trans arterial catheter technique. Severe pulmonary hypertension and shunt reversal are both taken as contraindication to corrective surgery of ASD.

The chest radiograph of ASD typically shows an enlargement of the heart and the pulmonary artery. The ECG usually shows the right axis deviation and incomplete RBBB. This is because right ventricular depolarisation is delayed as a result of its hypertrophy and dilatation. Echocardiography can directly demonstrate the defect of ASD. Sometimes atrial fibrillation and supraventricular tachycardia may accompany an ASD.

The anaesthetic management of a patient who is suffering form ASD and L to R shunt and is scheduled for noncardiac surgery, has minimal implication. The prophylactic antibiotics is needed to protect against infective endocarditis, if ASD is associated with other valvular abnormalities. During intraoperative management, the changes in SVR has an important implications on ASD. Any increase in SVR favours an increase in the magnitude of left to right shunt and right heart failure. So, it should be avoided during the perioperative period. On the other hand, any decrease in SVR tend to decrease the magnitude of left to right shunt or sometimes becomes reverse if SVR falls to a great extent. Meticulous avoidance of air entry into the intravenous line is imperative in ASD patient.

Ventricular Septal Defect (VSD)

VSD is one of the most common form of all congenital heart disease, occuring once in every 500 live birth. It occurs as a result of the incomplete septation of ventricles. Embryologically the intraventricular septum has a membranous and a muscular portion. The muscular portion is further divided into inflow, trabecular and outflow part. Most ventricular septal defects are of 'perimembranous' type, i.e. at the junction of the membranous and muscular portions (70%). Another 20% of VSD is situated in the membranous portion of the interventricular septum. Next 5% each of VSD is situated just below the aortic valve causing

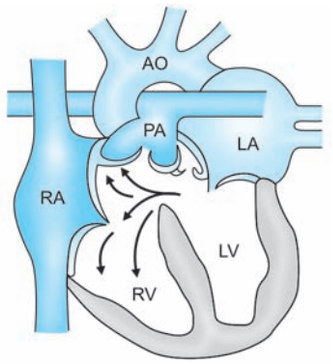

Fig. 29.2: Ventricular septal defect

aortic regurgitation and near the junction of the mitral and tricuspid valve (Fig. 29.2).

The VSD may be an isolated case or becomes a part of a complex congenital heart disease. It may be congenital or acquired. Acquired VSD may result from the rupture of interventricular septum as a complication of acute myocardial infarction or rarely from the trauma. Maximum number of small VSDs close spontaneously when a child reaches 2 years of age.

In VSD blood flows from the high pressure of left ventricle to the low pressure of right ventricle during systole, producing a holosystolic murmur. This is usually heard best at the left sternal edge, and also radiates all over the precordium. A small defect often produces a loud murmur, but contrary a large defect often produces a softer murmur, particularly if pressure in the right ventricle is elevated. This may be found immediately after birth when the pulmonary vascular resistance remains high or when the shunt is reversed—Eisenmenger's syndrome.

Symptoms, signs and pathology produced by VSD depend on the size of the defect, the difference between systemic and pulmonary vascular resistance and the rate of flow through the defect. If the defect is small, the pulmonary and systemic flow ratio is < 1.5:1 and there is no pulmonary hypertension, then there is minimal increase in pulmonary blood flow and patient is asymptomatic. On the other hand, if the defect is large enough and the

pressure in the two ventricles is equal then the flow through the pulmonary and systemic circulation depends on their relative resistance. Initially, SVR is higher than pulmonary vascular resistance and the blood flows from the left ventricle to the right ventricle (L to R shunt). These moderate sized VSD often presents with CCF, due to markedly increased pulmonary blood flow with pulmonary and systemic flow ratio 3:1 or more. These patients require early operation for closure of VSD. However, if they require anaesthesia for another noncardiac surgical procedure prior to their definitive cardiac operation, then they may present severe problems. They should must be intubated in all cases, except the very minor procedures. One should try to avoid increasing the left to right shunt (e.g. avoid hyperventilation and unnecessary high inspired oxygen levels). Care should be taken regarding the fluid administration. Inotropic support is often required. Over the time the pulmonary vascular resistance gradually increases and the pulmonary hypertension develops, causing a decline in the magnitude of L to R intracardiac shunt. Gradually, the shunt become reverse flowing right to left (R to L) with the development of cyanosis and arterial hypoxaemia. Before the development of pulmonary hypertension, these large VSD patients often require pulmonary artery banding to protect their pulmonary circulation. This band may tighten as the child grows, resulting in cyanosis. The VSDs often close spontaneously and the band may then be removed.

Like ASD, the intraoperative anaesthetic management of VSD for noncardiac surgeries includes the control of systemic and pulmonary vascular resistance on which will depend the magnitude of L to R or reverse shunt.

Patent Ductus Arteriosus (PDA)

The ductus arteriosus is a connection which arises from the arch of the aorta just distal to the left subclavion artery, and connects the arch of the aorta with the left pulmonary artery. In foetal life, the pulmonary vascular resistance is high than the systemic vascular resistance. So, the blood from the pulmonary artery, which is ejected out from the RV bypasses the deflated lungs runs through this ductus arteriosus and enters the descending aorta for oxygenation in the placenta. Normally, the ductus arteriosus closes within 24 to 48 hours after birth in a full term neonate. But, in preterm it frequently fails to close, and also sometimes in full term infant. Occassionally the persistance of this ductus arteriosus may be associated with other congenital abnormalities and is much more common in females. When the ductus arteriosus fails to close spontaneously after birth, then it results in continuous flow of blood from the aorta to the pulmonary artery, due to the reduction of pulmonary vascular resistance than systemic resistance after birth. The flow of blood through the patent ductus arteriosus after birth will depend on: the pressure gradient between the aorta and the pulmonary artery, the ratio of systemic and pulmonary vascular resistance, and the diameter and the length of the duct. As much as 50% of the left ventricular output may be recirculated through the lungs with a consequent increase in the pulmonary artery pressure which leads to progressive pulmonary vascular damage and pulmonary hypertension. If the pulmonary vascular resistance increases and the pulmonary artery pressure rises exceeding the aortic pressure, then the shunt will be reversed, flowing from the pulmonary artery to the aorta, causing central cyanosis (Eisenmenger's syndrome) (Fig. 29.3).

With small shunt there may be no symptoms for many years. This small cardiac defect is often detected accidentally during a routine preoperative physical examination. During this time a characteristic continuous systolic and diastolic murmur is heard with late systolic accentuation which is maximal in the second left

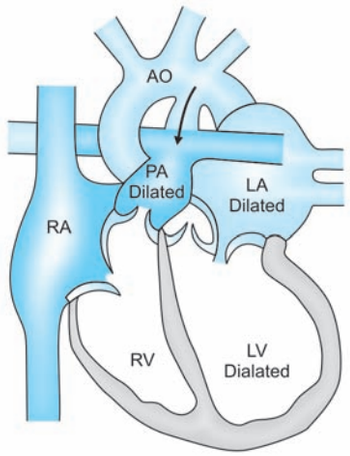

Fig. 29.3: Patent ductus arteriosus

intercostal space below the clavicle. Right ventricular hypertrophy develops, if pulmonary hypertension is apparent.

PDA can be closed surgically or through transcatheter route. Surgical correction of PDA by ligation is associated with low mortality. It is estimated that 75% of preterm infants delivered before 28 weeks of gestation require surgical closure of PDA. Alternative to surgery includes inhibition of the synthesis of prostaglandin with nonselective cyclo-oxygenase inhibitors (cox-1, cox-2). Without surgical closure, most patients with PDA remain asymptomatic, until adolescence when pulmonary hypertension and heart failure may occur. Once severe pulmonary hypertension develops, surgical correction is contraindicated. Ligation of PDA is often associated with significant systemic hypertension during the immediate postoperative period which is managed by continuous infusion of vasodilator drugs such as nitroprusside. If this systemic hypertensive persists, then long acting antihypertensive drugs will gradually substitute nitroprusside.

The first step of anaesthetic management of an uncorrected PDA patient, scheduled for noncardiac surgery, is preoperative prophylaxis by antibiotic for protection against the infective endocarditis. The principal of intraoperative anaesthetic management of PDA patient is also same like ASD and VSD, i.e. maintaining

a balance between the systemic vascular resistance and the pulmonary vascular resistance. The decrease of systemic vascular resistance improves the systemic blood flow by decreasing the magnitude of left to right shunt. But this decrease of SVR will not go below the pulmonary part when reverse shunt will flow and cyanosis will develop. Contrary, increase in SVR and decrease in pulmonary vascular resistance would increase the magnitude of L to R shunt and should be avoided. IPPV of the patient's lung is well tolerated, as increased airway pressure increases the pulmonary vascular resistance and subsequently decreases the pressure gradient between the left and right side of the heart and flow across the PDA.

Tetralogy of Fallot (TOF)

These patients have : (i) pulmonary stenosis, (ii) VSD, (iii) an overriding of aorta on the right and left ventricle and (iv) right ventricular hypertrophy. It is the most common cyanotic congenital heart disease. Right ventricular hypertrophy occurs, because the VSD permits continuous exposure of the right ventricle to the high pressure of left ventricle and pulmonary stenosis, causing right ventricular outflow obstruction. Several other anomalies may be associated with tetralogy of Fallot. These are : right aortic arch, ASD (pentalogy of Fallot), coronary arterial anomalies, etc. The cyanosis in tetralogy of fallot is due to the intracardiac right to left shunt which is again due to right ventricular hypertrophy. The magnitude of RV hypertrophy determines the severity of shunt and the severity of cyanosis. Due to pulmonary stenosis, the flow across the right ventricular outflow tract is relatively fixed. So, changes in SVR (drug induced) may affect the magnitude of the shunt. The decrease in SVR increases the R to L intracardiac shunt and increases the cyanosis with arterial hypoxaemia. Reversely, increase in SVR decreases the R to L shunt and decreases the cyanosis with increased pulmonary blood flow (Fig. 29.4).

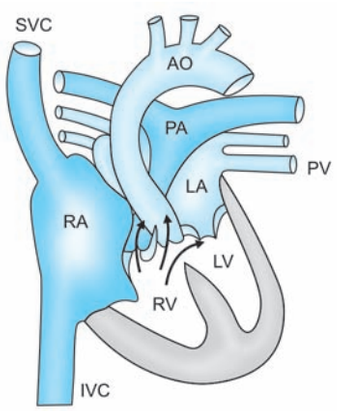

Fig. 29.4: Tetralogy of Fallot (TOF)

The diagnosis of tetralogy of Fallot is usually established by echocardiography and doppler. It assesses: (i) the presence of other associated abnormalities, (ii) the level and severity of right ventricular outflow obstruction, (iii) the magnitude of right ventricular hypertrophy, (iv) the size of the main pulmonary artery and its branches, and (v) the number, location and size of VSD. Cardiac catheterization further confirms the diagnosis by providing different anatomic and haemodynamic data. MRI of heart can also provide much of this information.

Most patients with tetralogy of Fallot present with cyanosis from birth. On examination, murmur is heard along the left sternal border due to the turbulent flow of blood across the stenotic pulmonic valve and VSD. Chest radiograph shows the evidence of decreased lung vascularity and the heart is 'boot shaped'. The right axis deviation and RV hypertrophy is the finding in ECG. Squatting position is the common picture of children with tetralogy of Fallot. Because it is speculated that squatting position increases the SVR by kinking the large arteries in inguinal area and subsequently increased SVR decreases the intracardiac R to L shunt and increases the pulmonary blood flow. The arterial O_2 tension is usually less than 50 mm of Hg. Arterial O_2 desaturation is present even when the patient is breathing with 100% O_2.

Sometimes, paroxymic cyanotic spells occur with severe arterial hypoxaemia, tachypnaea, seizures, and loss of consciousness or even death. These attacks can occur without obvious provocation. But, it is often associated with crying and exercise. The mechanism of this paroxysmal cyanotic spells is not properly known. The probable explanation is that sometimes there is sudden decrease in pulmonary blood flow due to the spasm of infundibular cardiac muscle or sudden decrease in SVR. The management of this paroxysmal cyanotic spell is administration of β-blocker such as esmolol or propranolol. It removes the dynamic infundibular obstruction by relieving the smooth muscle spasm. Cyanotic spell is also managed by intravenous administration of fluids and / or phenylephrine. It helps by increasing the SVR, decreasing intracardiac R → L shunt and increasing the pulmonary blood flow. The sympathomimetic agents with β-agonistic properties are not used. Because they may accentuate the spasm of infundibular cardiac muscle and cyanosis.

The definitive treatment of tetralogy of Fallot is complete surgical correction. Without surgery, mortality exceeds 50% by the age of 3 years. In the past, three palliative procedures were done to improve the pulmonary arterial blood flow. These palliative procedures are: (i) side to side anastomosis of the ascending aorta and the right pulmonary artery, (ii) side to side anastomosis of the descending aorta and the left pulmonary artery and (iii) end and side anastomosis of the subclavian artery to the pulmonary artery (Blalock-Taussig operation). Now, the correction of tetralogy of Fallot is done by the closure of VSD with Dacron patch and the relief of right ventricular outflow obstruction is done by placing a synthetic graft.

The aim of anaesthetic management during the noncardiac surgery of a patient with tetralogy of Fallot is to reduce the R → L intracardiac shunt and, thus, in turn to increase the pulmonary blood flow and

P_aO_2. The magnitude of R → L shunt also alter the pharmacokinetics of both the injected and inhaled drugs that by passe the lungs. The severity of R → L intracardiac shunt can be increased by: (i) decreased SVR, (ii) increased PVR and (iii) increased myocardial contractility which accentuates the infundibular obstruction to blood flow. Contrary, the R → L intracardiac shunt can be reduced by the reversed above mentioned actions. So, the pharmacological agents that decrease SVR such as volatile anaesthetics, nitroprusside, histamine releasing muscle relaxants, α-adrenergic blocking agents, etc, should be avoided. Pulmonary blood flow can be decreased by increasing the PVR that accompany many intraoperative ventilatory manoeuvers such as IPPV, PEEP etc. So, all these should be regulated and controlled. Furthermore, the loss of negative intrapleural pressure on opening the chest increases the PVR and the severity of shunt. But indeed, PaO_2 does not predictably deteriorate, either with institution of IPPV or after opening of the chest, in patients with tetralogy of Fallot and many advantages of intraoperative controlled ventilation usually offset its potential hazard.

During preoperative anaesthetic preparation of patient suffering from tetralogy of Fallot, crying should be avoided which may precipitate the hypercyanotic attack. The β-adrenergic blocker should be continued till the induction of anaesthesia to prevent the cyanotic spell. The induction of anaesthesia is usually accomplished with ketamine which improve the arterial oxygenation by increasing the SVR and thus decreasing the R→L intracardiac shunt. Ketamine also increases PVR which is undesirable in Fallot patients. But, this concern is not clinically significant. Tracheal intubation is facilitated by administration of muscle relaxants. During the use of IV drugs, it should be kept in mind that the onset and magnitude of action of drugs is more rapid in Fallot due to the R → L shunt which decreases pulmonary the dilutional effects of drugs and the metabolism of drug like fentanyl, in lungs. For this reason, it is prudent to decrease the dose of the intravenous cardiac and respiratory depressant drugs in these patients.

For intraoperative muscular paralysis, pancuronium is the agent of choice as it maintains SVR and blood pressure. Pancuronium also increases the HR which is helpful for maintaining the LV cardiac output. Use of N_2O for maintenance of anaesthesia in tetralogy of Fallot has many disadvantages. There disadvantages are: it increases PVR and decreases inspired O_2 concentration. But the advantages of N_2O are; it does not decrease SVR like volatile agents. So, balancing the advantages and disadvantages it seems prudent to limit the inspired concentration of N_2O to 50%. FiO_2 should not be reduced < 50%. Because, increased FiO_2 could decrease PVR and improve PaO_2. The use of volatile anaesthetic agents and opioids may also be considered during maintenance of anaesthesia. But the dose and the rate of administration of these agents must be adjusted to minimise the decrease of SVR.

The intraoperative ventilation for maintenance of anaesthesia should be controlled, but excessive positive pressure may adversely increase the resistance to blood flow through the lungs. The adequate intravascular fluid volume should also be maintained to avoid hypovolaemia. Otherwise, it will increase R → L shunt and cyanosis and hypoxaemia. The α-adrenergic agonist (phenylephrine) should be freely available to treat the undesirable decrease in SVR and BP. For predictable erythrocytosis due to cyanosis, it is probably not necessary to consider the blood transfusion, until about 30% of the patient's blood volume has been lost. Meticulous care should be taken to avoid infusion of air through the tubing which is used to deliver the intravenous solutions as it could lead to the systemic air embolisation.

The patients who have undergone successfully the surgical correction of tetralogy of Fallot are usually asymptomatic. But, still their life expectancy is not so hopeful. The survival rate of them is shortened due to sudden unexplained death. Cardiac dysrrhythmias, particularly ventricular are common in patients following surgical correction of tetralogy of Fallot. Pulmonary regurgitation may develop as a result of surgical repair, leading to RV hypertrophy and dysfunction.

Eisenmenger Syndrome (ES) and Anaesthesia

The persistently raised pulmonary blood flow, due to the L→R intracardiac shunt in large VSD, ASD, etc, leads to increased pulmonary resistance, followed by pulmonary hypertension. Then, progressively the changes like obliteration of distal vessels take place in pulmonary vasculature due to the presence of persistent pulmonary hypertension. Thus, once established, this increased pulmonary resistance is irreversible and pulmonary hypertension becomes permanent. Hence, when severe pulmonary hypertension develops to a level that equals or exceeds the SVR, then L → R shunt is reversed, resulting in R → L shunt and marked cyanosis which is called the Eisenmenger's syndrome. Shunt reversal occurs in about 60% of patients with an untreated VSD, 30% of patients with an untreated PDA and about 20% of patients with an untreated ASD. The murmur which was previously present associated with these cardiac defects gradually disappear when the Eisenmenger's syndrome develops. Patients with Eisenmenger's syndrome are particularly at increased risk from abrupt changes in after load that exacerbate right to left (R → L) shunting, such as vasodilatation, anaesthesia, pregnancy, etc. Central cyanosis appears and digital clubbing develops. The chest radiograph shows the enlarged central pulmonary arteries and peripheral pruning of the pulmonary vessels. The ECG shows RV hypertrophy. Palpitation is common

and is most often due to the onset of atrial fibrillation or atrial flutter. Sudden death is also not uncommon in patients with Eisenmenger's syndrome.

There are many palliative surgeries, but no treatment has proved effective in producing sustained decrease in PVR. The presence of irreversible increased PVR contraindicates the surgical correction of the original CHD that was responsible for Eisenmenger's syndrome.

The Eisenmenger's patients should be managed in a specialist centre whenever possible. The aim of anaesthetic management for patients with ES undergoing noncardiac surgery is to strictly maintain the preoperative levels of SVR and to avoid the vasodilatation by any cost. This is because the degree of shunting depends on the PVR: SVR ratio. So, reduction of SVR (epidural/spinal anaesthesia) and rise of PVR (hypoxia, hypercarbia, acidosis, cold) should be avoided. Decreasing the SVR or increasing the PVR leads to deterioration of blood oxygen saturation, rather like in patients with TOF. Desaturation episode can be treated as like TOF. To maintain the SVR, continuous IV infusions of norepinephrine can be administered during the perioperative period. The inotropic support may be required even for the shortest procedures. All the possible cares for minimisation of blood loss with the development of hypovolaemia should be taken. So, preoperative administration of antiplatelet drugs are not encouraged. Opioids can be used safely for perioperative analgesia.

Laparoscopic procedures are not recommended for ES patients. Because insufflation of peritoneal cavity with CO_2 may cause increase in P_aCO_2, resulting in acidosis and hypotension. Acidosis and hypotension increase the PVR : SVR ratio, causing more R $\rightarrow$ L shunt, cyanosis and hypoxia. Thus a vicious cycle sets up. Efforts to maintain the normocapnia may be accompanied by hyperventilation, increase in airway pressure and PVR which further increases R $\rightarrow$ L shunt. The whole thing further aggravated when IAP increases and the patients is placed in head down position. Early extubation in these patients is better to avoid the deleterious effects of IPPV.

30 Cardiomyopathies and Anaesthesia

INTRODUCTION

Cardiomyopathies are a group of diseases of unknown aetiology, affecting the cardiac muscles. It is unrelated to the usual causes of heart disease such as coronary artery disease, cardiac valvular dysfunction, essential hypertension, etc. It is common to all cardiomyopathies that they lead to a progressive life threatening congestive heart failure. Though, it is of unknown aetiology, still some probable causes for myopathies are defined. These are : idiopathic, ischaemic, infective (viral, bacterial), toxic (alcohol), systemic diseases (muscular dystrophy, collagen vascular disease, sarcoidosis, myxedema, thyrotoxicosis, pheochro mocytoma, etc), infiltrative (amyloidosis, haemochromato sis), nutritional and genetic (familial). The cardiomyopathies are classified on pathological basis into: (i) Idiopathic dilated cardiomyopathy, (ii) Hypertrophic (obstructive) cardiomyopathy and (iii) Restrictive cardiomyopathy. They can all be diagnosed by echocardiography (Table 30.1).

IDIOPATHIC DILATED CARDIOMYOPATHY (IDC)

In this type of cardiomyopathy there is gradual decrease in the contractile force of the left or right ventricle, resulting in systolic failure. It is characterised by the left ventricular (LV) or biventricular dilatation (although in early stages there may be no discernable dilatation), impaired myocardial contractility, decreased cardiac output (CO) and increased ventricular diastolic filling pressure and volume. Among these the ventricular dilatation is the most distinguishing morphological feature of IDC. Ventricular cardiac dysrrhythmias and sudden death are common in patients with idiopathic dilated cardiomyopathy. Peripartum cardiomyopathy is usually of this form and is specifically associated with late pregnancy or the first 6 months of puerperium. But, most often it is manifested in the period of first 1 to 6 weeks after delivery. The clinical course of IDC is unpredictable, although most deaths occur within 3 years of diagnosis, due to progressive congestive heart failure. There are many aetiologies of IDC such as alcohol, drugs, vitamine deficiencies, etc, but the commonest cause of IDC is IHD. The commonest problems encountered with IDC are heart failure, arrhythmias and emboli from the left side of cardiac cavities. Thus, they are treated with combinations of diuretics, ACE inhibitors, vasodilators, anticoagulants, and antiarrhythmics (Fig. 30.1).

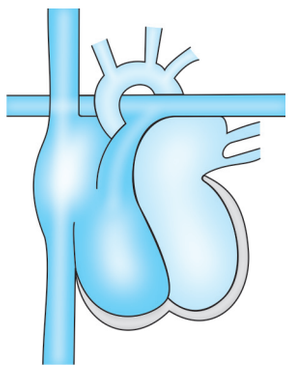

Fig. 30.1: Idiopathic dilated cardiomyopathy

In IDC there is marked reduction in the ejection fraction of the left ventricle and is most often < 0·4 (i.e 40%) when the heart failure supervenes. So, the most common initial manifestation of IDC is congestive heart failure. Though children and elders are also affected, but the most patients with IDC are first seen between 30 to 50 years of life. The haemodynamic abnormalities that predict a poor prognosis of IDC include: ejection fraction < 0.25, LVEDD (left ventricular end diastolic dilatation), hypokinetic left ventricular wall on echocardiography, PCWP > 20 mm of Hg, cardiac indess (CI) < 2.5 litre/min/m^2, systemic hypotension, pulmonary hypertension, and increased CVP.

The chest radiograph may show the evidences of cardiac enlargement, involving the all four cardiac chambers. The ECG investigation characteristically shows the evidence of LVH (left ventricular hypertrophy), ST and T wave abnormalities, and

Table 30.1: Aetiology of cardiomyopathy

- Idiopathic
- Infective – bacterial, viral
- Ischaemic
- Toxic – drugs, alcohol, poisons
- Nutritional
- Infiltrative – amyloidosis, metastasis, haemochromatosis
- Thyrotoxicosis
- Myxoedema
- Sarcoidosis
- Muscular dystrophy
- Collagen disease
- Genetic or familial

bundle brunch block. Different cardiac arrhythmias are also common in IDC. Systemic embolisation in IDC is not uncommon. It reflects the formation of mural thrombus in dilated and hypokinetic left cardiac chamber.

The preanaesthetic management of IDC includes general supportive measures which consist of adequate rest, weight control, controlled physical activity, and abstinence from tobacco-alcohol, etc. The vasodilator therapy by ACE-inhibitors, hydralazine and isosorbide dinitrate is the standard initial treatment. It helps by reducing the myocardial work for patients with symptomatic left ventricular dysfunction due to IDC. Patients with IDC are at increased risk for systemic or pulmonary embolism. As blood stasis occurs in the hypocontractile ventricle, so it leads to activation of coagulation process. Hence, long term anticoagulant therapy should be started in patient with IDC. Usually, warfarin is the drug of choice for long term anticoagulation and is often adjusted to prolong the prothrombin time to an INR (International Normalized Ratio) of 2 to 3. The risk of embolisation is greatest in patients who are suffering from : severe ventricular dysfunction, previous history of embolism, AF and present echocardiographic evidence of thrombus. Digitalis effectively controls the symptoms of congestive heart failure in patients with IDC. Other inotropes such as amrinone, milrinone, or enoxamine do not predictably improve the exercise tolerance like digitalis, when administered alone or in combination with digitalis.

During anaesthetic management of a patient with IDC, the goals are:

i. Prevention of increased ventricular afterload by controlling BP and SVR.
ii. Avoidance of drug induced myocardial depression.
iii. Maintenance of normovolaemia and preload.

During induction of anaesthesia thiopentone, propofol, etc, should be used cautiously avoiding the myocardial depression. During maintenance of anaesthesia, myocardial depression caused by the volatile anaesthetic agents must also be considered against the vasodilating properties of newer volatile anaesthetics which is desirable. Opioids are associated with benign effects on cardiac contractility. So, it can be used judiciously. However, the use of N_2O with opioids may result in unexpected depression of myocardial contractility and pulmonary vasoconstriction. So, an anaesthetist must justify himself regarding the use of N_2O in the cases of IDC according to the merit of individual patient. Skeletal muscle paralysis is provided by nondepolarizing muscle relaxants which do not release histamine and lack significant cardiovascular effects. Tachycardia should be controlled by β_1-antagonist such as esmolol, but keeping in mind the potential of these drugs to cause cardiac depression and severe bradycardia.

The perioperative monitoring of patient, suffering from IDC will depend on the extent of the surgery and the severity of the disease. For determination of cardiac filling pressure and cardiac output (CO), pulmonary artery catheterisation is necessary. It will guide the intravenous infusion of fluid and blood. It will also help in early recognition of volume overload and the need for inotropic support or administration of peripheral vasodilating drugs. On venous pressure tracings, a prominent 'A' wave reflects decreased ventricular compliance and a prominent 'V' wave indicates functional incompetance of tricuspid or mitral valve which is due to the cardiac dilatation. The intraoperative hypotension can be treated by vasopressor such as ephedrine or phenylephrine. The ephedrine provides some degree of β – stimulation, whereas phenylephrine produces α – stimulation which evoke adverse increase in LV afterload, owing to the increased systemic vascular resistance.

In selected patients the regional anaesthesia (RA) may also be an alternative to GA, but caution is indicated to avoid an abrupt onset of blockade of sympathetic nervous system and sudden severe reduction of preload and afterload. The epidural anaesthesia by a catheter produces slow changes in preload and afterload that may meet the goals of management of IDC (Fig. 30.2).

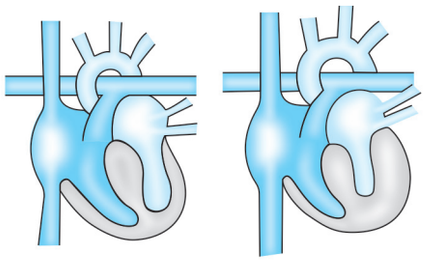

Fig. 30.2: Hypertrophic obstructive cardiomyopathy

HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY (HOCM)

HOCM is an autosomal dominant inherited condition in which there is often massive asymmetrical ventricular hypertrophy and impaired diastolic function, i.e. decreased ventricular diastolic filling causing reduction of cardiac output. It affects the patients of all ages. The excessive muscle bulk of LV wall also obstructs its outflow tract causing obstruction during systole. This HOCM is the most common form of cardiomyopathy with a prevalance of approximately 100 per 100,000 individual. In HOCM, the hypertrophy and fibroris of cardiac muscle mostly affects the septum, but may involve the whole left ventricle. Echocardiography reveals a large variation in the location and the extent of the muscular hypertrophy and fibrosis. Due to ventricular hypertrophy there is also resistance to inflow and therefore diastolic failure is the main problem. Hypertrophy of the septum may also cause dynamic left ventricular (LV) outflow tract obstruction. But, even in the presence of severe LV outflow tract obstruction, ejection fraction is usually more than 0.8 (80%), reflecting the hypercontractile condition of heart.

HOCM presents a great diversity of morphological, functional and clinical features. Some patients remain asymptomatic throughout the in life with HOCM. Some have symptoms of severe CHF and in some sudden death can occur particularly during exercise. The cause of this sudden death in HOCM is ventricular tachydysrrhythmias such as VT and VF. Symptoms and signs of HOCM is similar to those of AS. Marked left ventricular hypertrophy also makes the patient particularly vulnerable to myocardial ischaemia.

Diagnosis of HOCM is made by ECG, X-ray and echocardiography. But, suspicions always should be raised by family history, heaving or double apex, an aortic systolic murmur but without a slow rising pulse like AS. The ECG and chest radiograph are usually abnormal and may show the features of massive LV hypertrophy. ECG usually also depict wide varieties of bizarre and abnormal pattern such as pseudo-infarct, deep T-wave invertion, etc. Massive hypertrophy of intraventricular septum (IVS) presents abnormal Q-wave, mimicing myocardial infarction. The echocardiography is usually diagnostic. However, diagnosis may be difficult when the other causes of LV hypertrophy are present. When the ratio of the septal and LV free wall thickness exceed 1.3:1, then diagnosis of hypertrophic cardiomyopathy should be considered. Echocardiography is also useful for estimating the pressure gradient across the left ventricular outflow tract. Cardiac catheterisation may also demonstrate the presence of elevated LV EDP (left ventricular end diastolic pressure) as a consequence of reduced LV compliance. The reduced LV compliance also produces increased height of 'A' waves during the venous pressure tracing. It may exceed 30 mm of Hg. If severe LV outflow obstruction is present, then there is demonstrable high pressure gradient between the LV and aorta. Systemic thromboembolism is a very common complication of AF which is very commonly found in a patient presenting with HOCM.

Sudden death is an established complication of hypertrophic cardiomyopathy. The Risk factors for sudden death in HOCM are: recurrent syncope, exercise induced hypotension, marked increase in LV wall thickness, multiple episodes of non-sustained ventricular tachycardia (found in ambulatory ECG monitoring), a history of previous cardiac arrest or sustained VT and an adverse family history. Patients with above mentioned three or more risk factors are thought to be at the high risk of sudden death when they suffer from HOCM. Indeed, HOCM is the most common cause of sudden death in young athlets and ventricular arrhythmia are thought to be responsible for many of such deaths in HOCM.

Anaesthetic Management

Though pharmacological therapy to improve the diastolic filling and to decrease the myocardial ischaemia (which is due to massive muscular hypertrophy) is the primary goal of perianaesthetic management for HOCM patient, still there is no treatment that is definitely known to improve the prognosis. The β-blockers and the heart rate limiting calcium antagonists (e.g. Verapamil) have been used extensively to treat HOCM preoperatively. It can also help to relieve the angina and to increase the exercise tolerance by decreasing the heart rate (HR) with consequent prolongation of diastole and increased passive ventricular filling. But, there is no evidence that β-blockers and verapamil protect patients with HOCM from sudden death. Arrhythmias (mainly ventricular fibrillation) are common in such patients and often respond to treatment with amiodarone. Control of arrhythmias in HOCM is very important, because it causes the rapid clinical deterioration by decreasing the diastolic ventricular filling and cardiac output. Dual chamber pacing and surgery are useful in selected patients, particularly those with outflow tract obstruction due to massive muscular hypertrophy. The surgical reduction of the outflow tract obstruction is usually achieved by removing a small amount of cardiac muscle tissue from the ventricular septum. Surgery abolishes or greatly decreases the LV outflow obstruction in most patients. Digoxin and vasodilator may increase the outflow tract obstruction and should be avoided or used with caution only in failure. This is because many of these patients have diastolic dysfunction and require relatively high filling pressures to achieve adequate ventricular filling.

The intraoperative events that cause increased myocardial contractility are not desirable. Because these events may also increase the LV outflow tract obstruction. So, the use of β-stimulant to increase myocardial contractility should be restricted (only in special situation). Anaesthesia and surgery on patients suffering previously from unrecognised HOCM may manifest perioperatively as sudden unexpected hypotension. The administration of atropine in HOCM patient is questionable, as tachycardia could increase LV outflow obstruction and reduce LV filling by reducing the diastolic filling time. On the other hand, the use of scopolamine produces a desirable sedation and no increase in HR. Sedation is important, because it reduces the activation of sympathetic nervous system and LV outflow tract obstruction.

As the reduction of intravascular fluid volume causes the decrease in ventricular filling and subsequent decrease in cardiac output, so the expansion of intravascular fluid volume during the pre-operative period is useful to maintain the intraoperative stroke volume.

During induction of anaesthesia by inducing agents, the possibility of sudden decrease of SVR should be kept in mind, because it will increase the outflow tract obstruction and reduce the cardiac output. On the other hand, the ketamine is not the likely choice as it stimulates

the sympathetic system and increases the myocardial contraction (thus outflow obstruction). The activation of sympathetic system during laryngoscopy and intubation should be minimised by any cost by different procedures which are described before due to the same reasons.

The volatile anaesthetic agents which causes the reduction of myocardial contractility, but does not decrease the SVR is the ideal for HOCM patient. So, in such patient halothane is ideal. But there is no such evidence that volatile anaesthetic agents, other than halothane, is detrimental for such patients. As opioids do not produce myocardial depression, so they are likely the choice for maintenance of anaesthesia. But, the opioid and N_2O combination can not be used, because it produces the myocardial depression and increases SVR.

The nondepolarising muscle relaxants with minimum effects on cardiovascular system are the choice. In this regard, pancuronium associated with increased heart rate is not desirable. Intraoperative hypotension may be due to decreased preload or afterload or both. It should be monitered correctly by invasive method such as intra-arterial canulation, pulmonary artery catheterisation or transoesophageal echocardiography. Hypovolaemia or vasodilatation can precipitate the myocardial ischaemia and rapid decompensation. So, it should be avoided by any cost. When hypotension occurs, then drugs with predominantly α-adrenergic activity, such as phenylephrine in the dose of 50 to 100 mg IV or metaraminol are useful for normalizing the systemic BP. Drugs with predominantly β-adrenergic agonist activity such as ephedrine, dopamine or dobutamine are not recommended. Because these drugs cause increase in myocardial contractility and HR. Thus, they can increase the LV outflow tract obstruction. Intraoperative persistent increased systemic hypertension can also be treated by the gradual increase in the concentration of volatile anaesthetic agents. But, the vasodilators such as nitroprusside, nitroglycerine, etc. should not be used, as the decreased SVR produced by them can accentuate the LV outflow tract obstruction.

The factors that increase the outflow tract obstruction in HOCM are: increased myocardial contractility (β-adrenergic stimulation, digitalis, tachycardia); decreased preload (hypovolaemia, vasodilators such as nitroglycerine and nitroprus side) and decreased after load (hypotension, vasodilators, hypovolaemia).

The factors that decrease the outflow tract obstruction in HOCM are : decreased myocardial contractility (β-adrenergic blocker, volatile anaesthetics-halothane, calcium channel blockers); increased preload (hypervolaemia, bradycardia) and increased afterload (β-adrenergic stimulation, hypervolaemia).

RESTRICTIVE CARDIOMYOPATHY

It is the least common form of all the cardiomyopathies. In this rare condition, ventricular diastolic filling is impaired, because the walls of the ventricles are 'stiff'. Amyloidosis is the most common cause of stiff ventricle and the restrictive cardiomyopathy. However, the other causes of restrictive cardiomyopathy are glycogen storage disease, perimyocytic fibrosis, familial, etc. The increased stiffness of ventricular myocardium causes pressure within the ventricles to be increased precipitously with only small volume of filling. Therefore, there is impaired ventricular filling, but no apparent diastolic dysfunction. The systolic function of ventricle usually remains normal. The diagnosis of restrictive cardiomyopathy is generally considered in patients presenting with congestive heart failure, but there is no evidence of cardiomegaly or systolic dysfunction or hypertrophy.

The clinical presentation of restrictive cardiomyopathy is like constrictive pericarditis. Both the hearts (left and right) are affected equally. So, it may cause symptoms and signs of right and / or left ventricular failure. Diagnosis of restrictive cardiomyopathy is very difficult and may require investigations like complex doppler echocardiograph, CT scan, MRI, or endomyocardial biopsy. It is usually diagnosed by the method of exclusion. It also must be differentiated from the age related changes in ventricular diastolic compliance. The treatment of restrictive cardiomyopathy is symptomatic, but the prognosis is usually poor. AF is common in patient with restrictive cardiomyopathy. Angina pectoris does not occur in such patients.

The anaesthetic management of patients with restrictive cardiomyopathy includes the same principles which are described for patients with other myopathies, usually those which are associated with ventricular diastolic dysfunction. Atrial fibrillation is common in restrictive cardiomyopathy and by removing the artial contributing part to the ventricular filling, it may worsen the exiting diastolic dysfunction of LV with severe reduction of CO. So, maintenance of normal sinus rhythm is very important. It can be achieved by digitalis or amiodarone or β-blockers or cardioversion or by pace making. At the one hand, as the stroke volume tends to be fixed in the presence of restrictive cardiomyopathy, so the normal maintenance of venous return and intravascular fluid volume is essential for maintaining the normal cardiac output (CO). On the other hand, this form of myopathy is usually associated with pulmonary and systemic venous congestion which should be treated with diuretics. However this diuretics may further decrease the ventricular filling pressure and cardiac output. So, it should be used very cautiously. Anticoagulation with warfarin is likely with the aim to reduce the risk of embolic complications. The presence of anticoagulation and fixed CO may influence the decision of regional anaesthesia. The intraoperative monitoring is like other cardiomyopathies.

31 Pulmonary Diseases and Anaesthesia

INTRODUCTION

The successful anaesthetic management of patients with pulmonary or respiratory diseases depends on: (i) the accurate assessment of the nature of pulmonary diseases, (ii) the extent of functional impairment of lungs due to these diseases, and (iii) the appreciation of the effects of surgery and anaesthesia on that already impaired pulmonary function of this patient. All these factors are inter-related and among these the assessment of pulmonary function before anaesthesia and surgery is the most important. This is because on it depends the future anaesthetic plan of action. Again the proper assessment of functional impairment of lungs depends on the careful history, the careful examination of the patient the additional pulmonary functional tests, CT scan, MRI, etc.

THE EFFECTS OF ANAESTHESIA AND SURGERY ON PULMONARY FUNCTIONS

Effects of Anaesthesia

Anaesthesia affects the pulmonary functions in the following ways:

i. In normal patient general anaesthesia induces the reduction of FRC by about 450 ml (15 to 20%). The normal value of FRC in a healthy individual is 3000 ml. This reduction of FRC is due to the loss of tone of respiratory muscles, such as diaphragm, intercostal muscles, etc. In morbidly obese patient this reduction of FRC may be up to 50% of the normal value in an anaesthetised supine healthy individual. On the othe hand, ketamine does not reduce the muscle tone and consequently FRC is not reduced so much. Contrary, it is maintained at the preanaesthetic level.
ii. In normal situation anaesthesia decreases both the tidal volume and the lung compliance. This is due to the movement of diaphragm cranially and the rib-cage inwardly. Airway resistance also increases slightly after general anaesthesia due to these causes.
iii. Closing volume or capacity (CC) is the lung volume at which the closure of small airway begins. In unanaesthetized patient CC <FRC. But under general anaesthesia CC > FRC and airway closure with air trapping occurs before the lung volume reaches the FRC value. This is more common in elderly, smokers and those with underlying lung diseases.
iv. Intubation reduces the dead space to the half of the normal value by circumventing the upper airway. But the alveolar dead space rises from 50 to about 70 ml.
v. In over 80% of subjects, intubation causes atelectasis in the dependent portion of lungs. As a result 10% of the pulmonary blood flow is shunted through this areas of low V/Q ratios resulting hypoxia and hypercarbia.
vi. In anaesthesia the ventilatory response to hypoxia and $\uparrow PCO_2$ is blunted and the acute response to hypoxia and acidaemia is almost abolished by anaesthetic vapours at concentrations of as low as 0.1 MAC.
vii. Most of these adverse effects induced by anaesthesia usually improve within few hours, post-operatively. But, they are more marked and improvement is delayed in patients with lung diseases. After surgery they may last for several days.

Effects of Surgery

Surgery affects the respiratory functions in two ways—site of surgery and existing pulmonary disease.

i. The site of surgery has major implication on the respiratory functions and the incidence of complications. For example, lower abdominal surgery is associated with pulmonary complication only in 2 to 5% of cases of the general surgical population. But, this incidence of pulmonary complications in upper abdominal surgery goes up to about 20 to 40%. This incidence is more higher in thoracic surgery and it is because following thoracic and upper abdominal surgery, there is shallow respiration, inability to cough effectively and reduction of lung volumes. All these factors lead to poor basal air entry and sputum retention. Thus, this produces atelectasis and/or infection. The incidence and severity of these complications can be reduced by effective post-operative analgesia, early mobilisation and physiotherapy.
ii. Patients with already underlying pulmonary diseases are at increased risk of

developing pulmonary complications during and after surgery. Complications are minimised if the underlying conditions are identified and optimally controlled preoperatively.

HISTORY

For the assessment of pulmonary function history is very important. In history the six cardinal symptoms of respiratory diseases which are commonly asked for are: cough, sputum, haemoptysis, dyspnoea, wheeze, and chest pain. Now, among these cardinal symptoms, the detailed history regarding dyspnoea provides the best assessment for the functional impairment of lung. So, specific question is required to elicit the extent to which the activity is limited by dyspnoea. Dyspnoea at rest or during minor activities clearly indicates severe pulmonary and cardiac disease. Again for evaluating a patient with dyspnoea, one should first determine the duration over which the symptoms have become manifested. When it develops in acute form over a period of hours, the patients can have acute diseases, affecting the airways or lung parenchyma such as acute asthma, acute pulmonary oedema or acute bacterial infection – pneumonia. In other causes of acute dyspnoea, the patient can have acute diseases affecting the pleural space or the pulmonary vasculature such as pneumothorax or pulmonary embolism or the acute cardiac causes.

The subacute presentation of dyspnoea over days or weeks suggests an exacerbation of the pre-existing airway disease such as asthma or chronic bronchitis. It may also be due to the slowly progressing inflammatory process of lung parenchyma (infective or noninfective) or slowly progressing pleural diseases such as pleural effusion from varieties of possible causes or chronic cardiac disease.

The chronic presentation of dyspnoea over months or years often indicates chronic obstructive lung disease (COLD) or chronic cardiac disease. Chronic disease of airways such as COLD and asthma are characterised by periodic exacerbations and remissions of symptoms. So, patients have severe symptoms interspersed with periods in which the symptoms are minimal or absent. Ideally in such situation anaesthesia is given and surgery is performed when the patient is optimally controlled. Any respiratory symptoms suggestive of cardiac disease such as orthopnoea, paroxysmal nocturnal dyspnoea, etc, also should be noted. Dysponea can be graded using Roizen's classification. Undiagnosed dyspnoea of grade II or above should be investigated further (Table 31.1).

Among other cardinal symptoms, after dyspnoea, cough always indicates the presence of active lung disease, but does not help in differential diagnosis. The Presence of other symptoms with accompanying cough always suggests the airway diseases and may be seen in asthma, chronic bronchitis, pneumonitis, etc. A productive cough with expectoration of purulent sputum always indicates an active infection. The chronic copious sputum production may indicate bronchiectasis.

Haemoptysis can originate from the pathology of airways, lung parenchyma or pulmonary vasculatures. The disease may be inflammatory such as bronchitis, bronchiectasis, cystic fibrosis, or neoplastic such as bronchogenic carcinoma. Haemoptysis may also be due to the localised pathologies such as pneumonia, lung abscess, tuberculosis or due to diffused pathologies such as Goodpasture's syndrome, idiopathic pulmonary haemosiderosis, etc. The vascular diseases whic are potentially associated with haemoptysis, include pulmonary thromboembolic disease or pulmonary arteriovenous malformation.

Table 31.1: Roizen's classification of dyspnoea

Grade 0	No dyspnoea while walking at normal space on the ground level.
Grade I	Taking time the patient can walk as far as he likes without dyspnoea.
Grade II	Patient can move only few corners of the street without dyspnoea.
Grade III	Dyspnoea on mild exertion, i.e after walking a few steps.
Grade IV	Dyspnoea at rest.

Chest pain is another common respiratory symptom other than dyspnoea, cough and haemoptysis. It is usually due to the involvement of parietal pleura. This chest pain is often referred to as the pleuritic pain and is accentuated by respiratory movement. The common causes of this pleuritic pain are inflammatory disorders, or neoplasm. Again the inflammatory disorders may be due to the pleura itself such as pleuritis, or parenchymal disorders that extend upto the pleural surface such as pneumonia, pulmonary infarction, etc.

A history of smoking and occupational exposure to dust or fumes may suggest pulmonary pathology. The smoking history should include : the number of years and the intensity of smoking. The cigarette smoke contains highly additive nicotine and other 4700 chemical compounds. Among these 43 are known to be carcinogenic. The long-term smoking causes serious underlying problems such as COLD, IHD, vascular diseases, lung neoplasm, etc. In smokers the mucus is produced in large quantities from the respiratory tract but is cleared less efficiently due to the impaired mucociliary function. In such patients the airways remain hyperreactive and there is impairment of both the cell mediated and humoral immunity. These changes make the smokers more susceptible to respiratory complications during anaesthesia and also to post-operative atelectasis or pneumonia. The co-existing obesity with lung diseases also increases this pulmonary complications. Increased airway irritability by smoking or dust increases cough, laryngospasm and early desaturation of Hb during induction of anaesthesia by volatile anaesthetic agents, especially isoflurane. This can be avoided by using less irritant volatile anaesthetic

agents such as sevoflurane or halothane or intravenous agent such as propofol or deepening anaesthesia slowly when the volatile anaesthetic agens are used. During maintenance of anaesthesia by spontaneous respiration through ETT or LMA, it may be trouble.some due to airway irritation (Fig. 31.1).

If the patient now is not a smoker, then the duration of cessation of smoking should also be enquired. Before anaesthesia and surgery the minimum 8 weeks abstinence from smoking is required to decrease the morbidity from respiratory complications to a rate which is similar to that of nonsmokers. In very resistance cases if it is not possible, then patient can get benefit by restraining from smoking for at least 10 hours before surgery and anaesthesia. During this period the effects of nicotine, i.e activation of sympathoadrenergic system with raised coronary vascular resistance will wear off. Carboxy haemoglobin which may reach 5 to 15% in heavy smokers will also fall during this period of abstinence. Carboxy-Hb reduces the O_2 carrying capacity of blood by shifting the O_2-Hb dissociation curb towards left. Again carboxy-Hb has similar absorption spectrum to O_2-Hb. This causes the pulse oximeters to give a falsely high O_2 saturation reading. The risk of lung cancer falls progressively with increased interval following discontinuation of smoking. The loss of lung function above the expected age related decline also ceases with the discontinuation of smoking.

Fig. 31.1: Graphical representation of decline in FEV_1 annually in susceptible smokers. The blue line at the top shows the normal decline of FEV_1 within age, non smoker. The red line represents the smokers. When smoking is stopped, then the subsequent decline of FEV_1 is similar to that in healthy nonsmokers, represented by dotted red line

A detailed drug history of a patient with pulmonary diseases, going for surgery and anaesthesia, is important. The long-term steriod therapy within 3 months of the date of surgery and anaesthesia necessitates the augmented cover by steroid during the perioperative period and may cause hypokalaemia and hyperglycaemia. Bronchodilator should be continued during the perioperative period if it is used before. It should also be kept in mind that patients with corpulmonale may be receiving digoxin and diuretics which may interact with anaesthetic drugs.

The recent history of respiratory tract infection is also very important like other histories before administering any anaesthesia. There is some evidence that the incidence of laryngospasm is increased in patients with a recent history of upper respiratory tract symptoms. The patients who have active respiratory tract infections producing fever and cough, and with or without chest signs on auscultation, should not undergo elective surgery under general anaesthesia. Because it is associated with increased perioperative risk of pulmonary complications. But adult patients with simple coryza are not at the significantly increased risk of developing perioperative pulmonary problems, unless they have preexisting respiratory diseases or are having major abdominal and thoracic surgery compared with asymptomatic patients. Children with symptoms of acute or recent URTI are more likely to suffer from more incidences of laryngospasm, ronchi, creps and post-operative hypoxaemia (SPO_2 < 93%). This is more marked when intubation is performed.

EXAMINATION

For the assessment of lung condition and pulmonary function like history the physical examination is also very important. A full physical examination of patient is done with the aim of detecting the signs of airway obstruction or increased work of breathing or active infection or evidence of heart failure, because all these can be treated preoperatively. The full physical examination of a patient includes: inspection, palpation, percussion and auscultation of the respiratory system. But among these examinations, the auscultation is most important. During auscultation, both the quality and intensity of breath sounds in both the lungs should be looked for the presence of any extra or adventitious sounds. Normal breath sound is heard through the stethoscope at the periphery of the lung. These are dscribed as vesicular. In it the inspiration part is louder and longer than expiration. When the sound transmission is improved through the consolidated lung, then the resulting bronchial breath sound is of more tubular in quality and is characterised by more pronounced expiratory phase. The primary adventitious or abnormal sounds that can be heard by stethoscope during auscultation include crackles (rales), wheezes and ronchi. The crackles represent the sound which is created when the alveoli and the small airways open and close during respiration. Therefore, often they are associated with interstitial lung disease, microatelectasis or filling of alveoli by liquid.

Wheezes which are generally more prominent during expiration than inspiration reflect the oscillation of the walls of the airways that occurs when there is obstruction of airflow. Thus, it is produced by bronchospasm, airway oedema, collapse or intraluminal obstruction by neoplasm or secretions. Ronchi is the term applied to the sounds which is created when there is free liquid in the airway lumen. The interaction between the free liquid in the airway lumen and the moving air through it creates a high-pitched vibratory ronchi sound. Other adventitious sounds during auscultation of lung include pleural friction rubs and

stridor. The gritty sound which is produced by the pleural friction indicates inflamed pleural surfaces, rubbing against each other. It is heard both during inspiratory and expiratory phases of respiratory cycle. Stridor represents the flow of air through a narrowed upper airway which occurs primarily during inspiration.

After the meticulous examination of respiratory system, a careful general physical examination of the whole body is also mandatory. This is because a number of systemic diseases such as systemic lupuserythematosus, scleroderma, rheumatoid arthritis, etc. may affect the respiratory system. So, they may be associated with pulmonary complications, even though their primary clinical manifestations and physical findings are not related to lungs. Conversely, other diseases that most affect the respiratory system, such as sarcoidosis, can have findings on physical examinations with other systems which are not related to the respiratory system. So, they have findings which are not related to the lungs such as ocular findings (uveitis, conjunctival granuloma) and skin findings (erythema nodosum, cutaneous granulomas).

INVESTIGATIONS

X-ray

To evaluate the respiratory system of a patient who is presented for anaesthesia and surgery with the history of pulmonary diseases, chest radiograph is often the initial and the most important diagnostic procedure. This is because it can provide the initial evidence of pulmonary disease in patients even who are still free of respiratory symptoms at present. The example of this is the accidental finding of one or more nodules or a big mass when chest X-ray is performed due to reason other than the evaluation of the respiratory symptoms. Radiographhic findings even in the absence of respiratory symptoms often indicate localised disease affecting the local airways or a discrete disease affecting the whole pulmonary parenchyma. One or more nodules, or a large mass may suggest intrathoracic malignancy. But they can also be the manifestation of a current or previous infective process. On the other hand, the patients with diffuse parenchymal lung disease, evidenced by radiographic examination, may be free of symptoms, as is sometimes seen in the case with pulmonary sarcoidosis.

A localised opacity involving the lung parenchyma is usually characterised by having an alveolar or a nodular pattern. In contrast, the increased radiolucency can be localised as occurs with a cyst or bulla, or generalised as seen with emphysema. The chest radiograph is also particularly useful for the detection of pleural disease. An abnormal picture of the hila and / or the mediastinum structure can suggest a mass or enlargement of lymph nodes. Patients with respiratory symptoms, but a normal chest X-ray most commonly have diseases of airway. This is happened in asthma, COPD or interstitial lung disease, etc. Chest X-ray is also normal in respiratory symptoms when there is disorder of respiratory pump mechanism, i.e chest wall and neuromuscular apparatus controlling the movement of chest wall. Here, the pulmonary function test is helpful for diagonosis.

The preoperative chest X-ray is a poor indicator of the functional impairment of lungs. But, still it is important for several following reasons for the preoperative evaluation of respiratory system:

i. It helps as baseline to assess the postoperative radiographs.
ii. It helps to discover any localized disease of lungs and pleura which are not symptom producing and are not detected on clinical examination such as small neoplasm, small collapse or consolidation, not symptoms producing effusion, etc.
iii. To reveal the underlying generalised lung disease in patients presenting with acute pulmonary symptoms such as pulmonary fibrosis, emphysema, etc.

CT

For proper diagnosis of pulmonary diseases which have tremendous impact on the mode and the result of anaesthesia, preoperative CT (Computerised Tomography) offers several advantages over the routine chest X-ray. It is better for characterising the tissue densities which helps in distinguishing the subtle differences between the adjacent structures and providing accurate assessment of the size of the lesions. It is particularly valuable in assessing the hilar and mediastinal structure and its diseases, in identifying diseases adjacent to the chest wall or spine, in identifying the areas of fat bodies (pulmonary fat embolism) in lungs and calcification of pulmonary nodules. For the diagnosis, assessment and staging of malignant mediastinal diseases, CT is the most important tool among all. By the use of contrast material, CT also makes it possible to distinguish vascular from nonvascular structures. Helical CT scanning which is more informative than conventional CT allows the collection of continuous data over a large volume of lung tissue, during a single breath-holding manoeuver. With High Resolution CT (HRCT) the thickness of individual cross- sectional images is approximately 1 to 2 mm, rather than the usual 10 mm. Images in HRCT are reconstructed using high spatial resolution algorithms. The detail that can be seen in HRCT scans allows better recognition of any subtle parenchymal and airway diseases such as bronchiectasis, emphysema and diffuse parenchymal diseases.

MRI

MRI provides less described view of the airways and pulmonary parenchyma than CT. So, the role of MRI in the evaluation of pulmonary diseases is less well defined. But, MRI has certain advantages over CT in certain clinical circumstances. For example by MRI the vascular structures can be easily distinguished from the nonvascular structures without the need of

contrast media. Flowing blood does not produce signal on MRI. So, vessels appear as hollow tubular sturctures in MRI. This feature is helpful in determining whether abnormal hilar or mediastinal structures are of vascular origin or not. For diagnosis of aortic lesions such as aneurysm or aortic dissection, MRI is extremely helpful. Another advantage of MRI over CT is that it can be reconstructed in sagittal, coronal and transverse plane, whereas CT is constracted only in transverse plane.

Other radiological investigations except X-ray, CT and MRI for accurate diagnosis of pulmonary diseases are: scintigraphic imaging and pulmonary angiography. In scintigraphic imaging, the radioactive isotopes such as albumin macro aggregates lavelled with technetium 99 m or radio labeled xenon gas are administered either through intravenous or inhalational route, respectively. It is most commonly used in ventilation – perfusion lung scanning (V/Q scan), and for evaluation of pulmonary embolism. The IV isotopes demonstrate the distribution of blood flow. Whereas the inhaled isotope demonstrates the distribution of ventilation. Thus, perfusion – ventilation mismatch is constructed. One such example is pulmonary embolism where there is defect in perfusion, but no defect in ventilation. Another common use of such radioisotope scan is for the diagnosis of impaired lung function which is being considered for lung resection. The distribution of isotope also can be used to assess the regional distribution of blood flow and ventilation. The pulmonary arterial system can also be visualised by pulmonary angiography, in which radio opaque contrast media is injected into the pulmonary artery through a catheter which is previously threaded. Pulmonary angiography demonstrates the intravascular clot (pulmonary embolism) either as filling defect in the lumen of vessel (filling defect sign) or as an abrupt termination of a vessel (cut off sign). In patients with abnormal chest radiograph this test is often difficult to interpret.

The ultrasound imaging is not useful for evaluation of the pulmonary parenchymal diseases. Because the ultrasound energy is rapidly dissipated in air. USG is only helpful for detection and localisation of pleural fluid and as a guide for placement of a needle for thoracocentesis.

Measurement of Diffusing Capacity or Transfer Factor (TLCO)

The transfer factor or diffusing capacity is the measurement of lung's ability to transfer gas from alveoli to blood. This test utilizes the uptake of carbon monoxide by a single breath from a 0.3% mixture of it in the air. This gas is chosen, because it combines rapidly with Hb and provides a true estimation of diffusion or transfer across the alveolar capillary membrane. The diffusing capacity or transfer factor is reduced in patients with disease, principally affecting the alveoli such as fibrosis, alveolitis, emphysema, etc. The transfer coefficient is the measurement of diffusing capacity expressed per volume of ventilated lung during the single breath test. This is useful to confirm that a low diffusing capacity is due to alveolar disease rather than maldistribution of ventilation. The high values of diffusing capacity may be seen in alveolar haemorrhage (Table 31.2).

The measurement of H^+ ion concentration, P_aO_2, P_aCO_2 and bicarbonate concentration in arterial blood is essential in assessing the respiratory function, the degree and type of respiratory failure and for measuring the overall acid-base status. A preoperative baseline provides a guide- line for the further patient's management. It should be measured in anyone suffering from mild to severe dyspnoea on minimal exertion. CO_2 retention will be detected and the efficiency of oxygenation is assessed. A resting P_aCO_2 > 6 kPa suggests pulmonary complications and pending ventilatory failure.

Table 31.2: Patterns of abnormal ventilatory capacity in spirometry

	Asthma	*Emphysema*	*Lung fibrosis*

Pulmonary Function Test (PFT)

From anaesthetic point of view, the PFT (Pulmonary Function Test) is very helpful for determination of pulmonary functional reserve which deteriorates due to different pulmonary airways and parenchymal diseases and the effect of bronchodilators on these diseases. So, the pulmonary function test is discussed in detail in separate chapter. But few parameters of it are discussed here. These are : peak flow, spirometry and flow volume loops.

Peak flow

For evaluation of airway obstruction, the measurement of airway resistance is specific and sensitive. But the measurement of resistance is not easy and is very cumbersome. So, the airway obstruction is commonly evaluated by the measurement of maximal forced expiration or maximal midexpiratory flow rate (MMEFR). The simplest of such measurement is the peak expiratory flow rate (PEFR). This is conveniently measured by a variable orifice flow meter at bed side. The main disadvantage of this peak flow value is that it is highly dependent on personal effort and subject's cooperation. So the result vary significantly. However, as the variation of measurement in the same subject is surprisingly low, so the peak expiratory flow is fairly a reproducible test of airway function. A single result of peak expiratory flow has no value. So, serial measurement only indicates deterioation. PEF of less than 200 L/m indicates that effective coughing is difficult and pulmonary complications rate are high (Fig. 31.2).

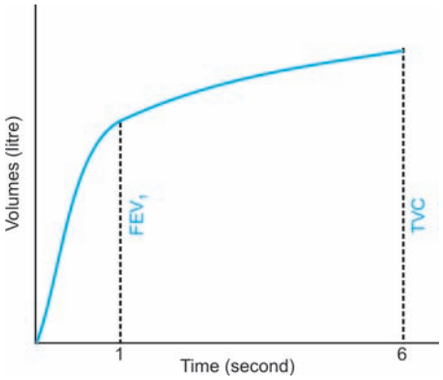

Fig. 31.2: Graph represents the peak expiratory flow, demonstrating forced expiration in first one second (FEV1) and total vital capacity (TVC) in next part of expiration

The another extensively used indirect evaluation of airway obstruction is FEV_1 (forced expiratory volume in first 1 second). It is the fraction of VC which is expired during the first second of a forced expiration. So, it is also called the timed vital capacity. The VC is the largest amount of air that can be expired after a maximal inspiratory effort. The FEV_1 is frequently measured clinically as an index of pulmonary function and gives a useful information about the strength of the respiratory muscle. FEV_1 also gives additional information, because the VC may be normal but the FEV_1 reduces in diseases such as airway obstruction (e.g. asthma) in which the airway resistance is increased by bronchial constriction (Table 31.3).

Table 31.3: Abbreviation used In pulmonary function testing in spirometer

Abbreviation	*Stands for*
TV	Tidal volume
IRV	Inspiratory reserve volume
ERV	Expiratory reserve volume
VC	Vital capacity
RV	Residual volume
IVC or IC	Inspiratory vital capacity
FEV_1	Forced expiratory volume in first 1 sec
FVC	Forced vital capacity
PEF	Peak (maximum) expiratory flow
TLC	Total lung capacity
FRC	Functional residual capacity
TLCO	Gas transfer factor for CO
KCO	Transfer coefficient for CO
TV	Volume of air inhaled or exhaled during normal breathing.
VC	Maximum volume of air that can be exhaled after a forced inspiration, i.e. VC = TV + IRV + ERV
RV	Volume of air that remains in lungs after ERV (maximum expiration).
IRV	Maximum volume of air that can be inhaled after a normal tidal inspiration.
ERV	Maximum volume of air that can be exhaled after a normal tidal expiration.
FRC	Volume of air that remains in lungs after a normal tidal expiration.
FEV_1	Volume of air exhaled in first one second during complete forced expiration.

Spirometry

Simple spirometry should be a routine procedure and carried out by all the doctors when assessing a patient who is breathless. It has been widely used to assess the functional reserve of lungs and magnitude of risks in patients with significant pulmonary diseases, scheduled for major surgery and anaesthesia. It can also be used as a bedside method using a device of bellow or in the investigating centre using sophisticated instrument. In spirometer different pulmonary volumes are studied by recording graphically the changes of volume of lungs under different condition of respiration. This graphical recording of different volume of lungs is called the spirogram or spirography which is represented in picture. The different abbreviations used in PFT by spirommeter is also shown in table. All the present results of spirometry are compared with the predicted normal values which are based on age, sex, height and ethnic group. Normally, the forced vital capacity (FVC) is measured along with forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 / FVC is measured as percentage. Normally the FEV_1 / FVC ratio is > 70%. But when it is less than 70%, it indicates airflow obstruction. In obstructive symptoms the reversibility using inhaled short-acting β_2-adrenoreceptor agonists (e.g. salbutamol or terbutaline) also can be tested. Full reversibility is diagnostic of asthma. If time permits and the patient has undertreated obstructive disease, then a course of steroids (prednisolone 20 to 40 mg daily for 7 days) should be assessed for effectiveness (Fig. 31.3).

Recently, the evidences suggest that spirometry does not always predict perioperative pulmonary complications, even in patients with severe COPD. Only specific subgroups may be benefited such as (i) those with unclear diagnosis or those with equivocal clinical and radiological findings, (ii) those where functional impairment of lungs cannot be assessed due to extreme disability.

There are no spirometric values which should be considered as prohibitive for surgery. Despite poor preoperative spirometry result, many series of patients undergoing thoracic and major non-thoracic surgery are being increasingly reported. A FEV_1 less than 1000 ml indicates that post-operative coughing and secretions clearance will be poor and increases the likelihood of a period of respiratory support following major surgery.

Flow-volume loop (F-V loop)

Sometimes, there is no clinical evidence of bronchial asthma, COPD, etc. but findings of reduced peak flow rate and FEV_1

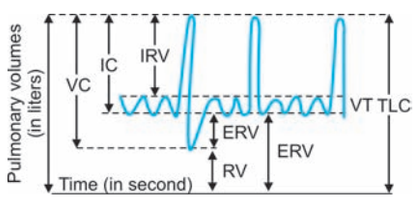

Fig. 31.3: Schematic diagram of normal spirogram showing different pulmonary volumes

is present. This indicates the presence of upper airway obstruction such as in larynx, pharynx or trachea. In such situation F-V loop is helpful in differentiating between the upper airway obstruction in pharynx, larynx or trachea (extrinsic obstruction) and diffuse airway obstruction such as asthma, COPD, etc. (intrinsic obstruction). In addition, they also provide useful data about the severity of obstruction of airway and restrictive pulmonary diseases. The F-V loop not only helps in suspecting upper airway obstruction, but may also help to localize the site and the nature of obstruction (Fig. 31.4).

In F-V loops the flow and volume are plotted on an X and Y axis respectively. Several characteristic patterns of F-V loop have been described among which few are discussed below. In fixed obstruction such as a growth in larynx, no significant change in airway diameter occurs during inspiration and expiration. As a result the inspiratory and expiratory phase shows a plateau of constant flow over the effort dependent portion of vital capacity. In variable upper airway obstruction (extrathoracic) such as in vocal cord paralysis, pharyngeal muscle weakness, chronic neuromuscular disorders, etc. the inspiratory and expiratory phases are not equal. The period of inspiration is reduced more than the expiratory period which is reflected in loop. This is because during forced inspiration the negative transmural pressure inside the airway tends to collapse the airway with increasing effort and reduce the inspiratory flow. But during expiration the positive pressure in the upper airway tries to reduce the obstruction. So, the expiratory flow is not reduced and may even be normal. In variable airway obstruction (intrathoracic) such as tumour in trachea and major bronchi, the expiration becomes longer and plateau usually occurs. This is because during expiration compressed airway lumen assumes its minimal size at the area of lesions. But the inspiratory portion of F-V loop may be quite normal. In diffuse airway obstruction the F-V loop takes a characteristic appearance which is shown in Figure 31.4.

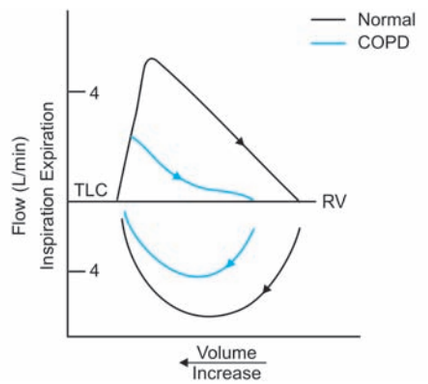

Fig. 31.4: Schematic flow-volume curve in a normal subject and in a patient with COPD

PREDICTING PERIOPERATIVE PULMONARY COMPLICATIONS

The multiple large and rigorous studies, identifying the risk factors for perioperative pulmonary complications are still lacking, though comparison of large prospective studies to identify the pulmonary risk factors are performed. This is because comparison between the studies on pulmonary function is very difficult. Still, some risk factors are identified (described below) and the incidence of perioperative complications can be reduced, if these patients are treated properly preoperatively (Table 31.4).

Formerly, spirometry was considered as an important tool for the assessment of risk factors. But, recent evidence suggests that it does not properly predict the risk of perioperative pulmonary complications.

Table 31.4: Risk factors to predict the perioperative pulmonary complications

i.	Increased age > 60 years.
ii.	Symptoms of chronic bronchitis.
iii.	Smoking within 8 weeks.
iv.	Body mass index > 30.
v.	Abnormal clinical findings in chest.
vi.	Abnormal finding in chest X-ray.
vii.	History of pulmonary malignancy.
viii.	P_aCO_2 > 6 kPa
ix.	Upper abdominal and thoracic surgery.

Therefore, it should not be used alone to determine the risks. The general scoring system such as ASA grading system, Goldman cardiac risk index and Charlson comorbidity index, etc. which assess the overall comorbidity are also the best predictors of pulmonary complications. The abnormal chest findings on clinical examination and in X-ray reflect significant lung disease and are independent predictors of pulmonary complications.

GENERAL PRINCIPLE OF POST-OPERATIVE CARE IN PULMONARY DISEASE

The post-operative care of all patients with pulmonary disease can be guided by the following principles.

Early Mobilization

Early mobilization is the corner stone of post-operative management of a patient suffering from respiratory diseases. It reduces the incidence of pulmonary thromboembolic menifestations. Lung performance, FRC and clearance of secretions are also improved when the patient is sitting or standing in comparison with the supine position.

Physiotherapy

As a part of pulmonary physiotherapy the incentive spirometry and breathing exercise helps to clear the bronchial secretions and thus reduce atelectasis and its pulmonary complications.

Oxygen Therapy

In patients with lung disease the dose dependent depression of respiratory function and the dose dependent depression of the sensitivity of central chemoreceptors to the stimulatory effect of CO_2 on ventilation can occur for up to 72 hours post-operatively. It is mostly found at night. So, supplemental O_2 should be delivered for at least this period of time. COPD patients chronically retain CO_2. Therefore, they depend on hypoxaemia

for their main ventilatory drive due to down regulation of central chemoreceptors to CO_2. Hence, O_2 therapy should be controlled and guided by adequate monitoring such as blood gas analysis. A preoperative data of P_aO_2, SaO_2 and P_aCO_2 are essential to establish a realistic target for each patient. O_2 must be humidified to help sputum clearance and physiotherapy.

Fluid Balance

Patients with lung diseases are at increased risk of fluid overload and pulmonary oedema. This is caused by dilated and hypertrophied Rt. ventricle due to commonly associated pulmonary hypertension with pulmonary disease. Thus, it may mechanically compromise the function of left ventricle leading to pulmonary oedema. So a high index of suspician regarding the fluid overload leading to pulmonary oedema should be maintained clinically. Reading of CVP as a guidence of fluid therapy are misleading in the presence of pulmonary hypertension.

Pain Management

Good analgesia is very essential for the best post-operative management of patients suffering from pulmonary diseases. This properly titrated post-operative analgeria helps by maintaing the early mobilization, increasing the compliance of physiotherapy, increasing the proper respiratory function and minimising the cardiac stress with heart diseases. Patients with respiratory diseases are best benefitted by local or regional analgesia. It helps by avoiding the sedative and respiratory depressive effect of narcotics. Risk benefit ratio of opioid based analgesia and regional analgesia should be weighted against each other. Paracetamol and other NSAIDs are not absolutely contraindicated in pulmonary airway disease. They should be used where possible.

Regular Clinical Review

Regular clinical review always allows early detection of respiratory deterioration and resolution of problem.

INDIVIDUAL PULMONARY DISEASE AND ANAESTHETIC MANAGEMENT

Bronchial Asthma

Etiology and pathology

Bronchial asthma is primarily the disease of airways which is characterised by reversible obstruction of airflow due to increased responsiveness of the tracheobronchial tree to a number of stimuli. All aspects of pulmonary functions are virtually compromised during an acute attack of it. This disease is manifested clinically by paroxysms of dyspnoea, cough and wheeze following generalised narrowing as well as inflammatory changes of air passages. As it is an episodic disease, so acute exacerbation is interspersed with symptom free periods. Usually, most of the acute attacks of bronchial asthma are mild and last for few hours. Sometimes, it becomes much more serious with severe obstruction when this condition is called the status asthmaticus. However, during symptom free phase, the patient may also experience some degree of airways obstruction daily.

Bronchial asthma is the commonest chronic obstructive pulmonary airway disease and is one of the leading causes of death in our country. High mortality from bronchial asthma is due to the ineffective or inadequate treatment, leading to gradual irreversible changes of the airways. Bronchial asthma occurs at all ages, but more common at early life. About one half of the cases develop before the age of 10 and another third develop before the age of 40. In childhood when the incidence is very high, the male-female ratio is 2:1 and it gradually equalises at the age of 30. The presence of symptoms at childhood, cough which wakes the patient at night, diurnal variation, specific trigger factors (especially allergic), abscence of smoking history and response to previous treatment, etc. may all be helpful in differentiating bronchial asthma from COPD (now called COLD).

Bronchial asthma is a heterogenous disease from the etiological point of view. It can be described under two broad headings (i.e types of asthma): allergic and idiosyncratic. In allergic type of bronchial asthma, patients should have (i) personal/or family history of allergic disease such as rhinitis, urticaria, eczema, etc. (ii) ↑level of IgE, (iii) positive skin reaction to intradermal antigen test, (iv) positive response to provocative tests involving specific antigens by inhalation, etc. On the other hand, in idiosyncratic variety no such positive history or test will be present.

In general, the bronchial asthma that has its onset in early life falls in the allergic group. Allergic asthma is dependent on an IgE response, controlled by T and B lymphocytes. It is activated by the interaction of antigen with the mast cells bound IgE molecules. Most of the allergens that provoke bronchial asthma are airborne. To induce a state of sensitivity (first reaction in the body), the allergens must be reasonably abundant for considerable period of time. Once sensitisation of body has occured, then the patient can exhibit exquisite hyper responsiveness, so that next exposure to the minute amounts of the offending agents can produce significant exacerbations of the disease. This allergic variety of asthma is most often observed in children and young adults and is usually seasonal. A nonseasonal form of bronchial asthma may result from the allergy to feathers, animal danders, dust mites, molds and other antigens that are present continuously in the environment. From the above discussion it is clear that the inhaled antigens cause an antigen-antibody reactions on the surface of bronchial mast cells to provoke an acute episode of asthma.

In idiosyncratic group of bronchial asthma, there is (i) no personal or family history, (ii) level of IgE is not elevated and (iii) negative skin test to antigen. So, this group does not depend on immunological

mechanism (antigen-antibody reaction) for its manifestation. The initial insult in idiosyncratic group is usually the common cold or upper respiratory tract illness, leading to paroxysms of wheez and dyspnoea. Bronchial asthma that develops late in life usually falls in this group. Again this idiosyncratic group cannot be confused with the group where symptoms of bronchospasm superimposed on chronic bronchitis or bronchiectasis. On the other hand, in practice there are many patients that do not fit clearly into any of the above mentioned group and they are classified as mixed group.

Though basic mechanism is still unknown, the main denomination of pathophysiology of bronchial asthma or bronchospasm is nonspecific hyperirritability of tracheo-bronchial tree and its neural control pathways. The intensity of this hyperactivity of bronchial tree is directly proportional with the intensity of symptoms and aggresiveness of therapy. Following a viral infection of the respiratory tract, the reactivity of airway rises and remains elevated for many weeks, even after recovery from infection though seemingly trivial. This is very important from the anaesthetic point of view. In this hyperactivity period, any exposure to antigen or chemical irritants (those who have no history of asthma) cause bronchospasm.

The most popular hypothesis of bronchial asthma now is that of airway inflammation with increased number of mast cells, eosinophils, lymphocytes, neutrophils and epithelial cells. This is because, even when acute episode of bronchial asthma is in remission, bronchial biopsy reveals large infiltration of mucosa by inflammatory cells and epithelial shedding. But, if this increased number of cells and inflammation is the effect or cause of antigen-antibody reaction (for allergic group) is still unknown, because increased cellularity and elevated capillary density (i.e. findings of inflammatory process) is the most ubiquitous findings even in asymptomatic group of patients. In idiosyncratic group of patient, inflammation is the effect of asthma. However, bronchospasm during anaphylactic reaction should not be confused with idiosyncratic asthma.

For pathogenesis of asthma, the above mentioned cells (mast cell, eosinophil, macrophage, lymphocyte and neutrophil) and chemical mediators (histamine, bradykinin, leukotrienes, prostglandians – E_2, $F_2\alpha$, platelet activating factors) which are released from these cells play an important role causing inflammatory reaction. This inflammatory reactions involve mucous production, bronchospasm, vascular congestion and oedema formation. These chemical mediators bring more and more eosinophils, platelets and polymorphonuclear leucocytes to the site of reaction by their chemotactic effects. Thus, these infiltrating cells, the resident macrophages and the airway epithelial cells produce additional mediators in vicious cycle and cause immediate and delayed cellular phase reaction. This local inflammatory reaction exposes the nerve endings and initiates a neurogenic inflammatory pathways, converting primary local event into a generalised reaction by reflex mechanism. This is an alternative explanation of bronchial asthma due to abnormal autonomic nervous system function. This hypothesis is supported by increased expiratory airflow obstruction in patients with bronchial asthma, being treated with a β-agonist, suggesting the presence of an imbalance between the excitatory and inhibitory neural output. It is likely that the chemical mediators released from the mast cells interact with the autonomic nervous system. Some chemical mediators can stimulate the airway's irritant receptors to trigger the reflex broncho-constriction. While the other mediators sensitize the bronchial smooth muscle to the effects of acetylcholine. In addition, stimulation of muscarinic receptors facilitates the release of mediator from the mast cells, providing another positive feedback loop for sustained inflammation and bronchoconstriction. The stimuli that interact with airway reponsiveness and incite acute episodes of bronchial asthma can be grouped into seven major categories and thats are : allergenic, pharmacologic, environmental, occupational, infective, exercise related and emotional.

The allergenic factors as the aetiology of bronchial asthma are already discussed. Among the pharmacological allergic factors, the important drugs that are commonly associated with the induction of episodes of bronchial asthma are aspirin, tartasine (colouring agent in food products), sulfiting agents (used as preservative in food preparation), beta adrenergic antagonist, etc. It is important to recognise that the drug-induced bronchial asthma is often associated with greater morbidity and sometimes with mortality. There is a great deal of cross reactivity between aspirin and other NSAID, such as ibuprofen, fenoprofen, indomethacin, phenylbutazone, etc. The exact mechanism by which aspirin and other drugs produce bronchospasm is still unknown. But the probable explanation is generation of leukotrienes which act as chemical mediator by aspirin or other drugs. This is proved by inhibition of leukotriene synthesis or receptor activity during the treatment of this type of problem. On the other hand, paracetamol (acetaminophen), sodium salicylate and propoxyphene are well tolerated by these aspirin sensitive group of patient. On exposure to even small amount of aspirin, sensitive individual develop ocular and nasal congestion and often acute severe airway obstruction. The aspirin induced hypersensitivity usually starts with perineal vasomotor rhinits that is followed by hyperplastic rhinosinusitis with nasal polyp. Progressive asthma then appears. Several sulfiting agents such as potassium metabisulfite, sodium and potassium bisulfite, etc. used in different food and pharmacological industries as preservatives, also can produce acute airways obstruction in sensitive individuals. Patients become

sensitised after first exposure. Then, after subsequent exposure, patients develop acute bronchial asthma. Exposure usually follows by ingestion of food and beverages which also contain different sulfiting agents such as shellfish, wine, salad, fruit preparations, etc. Some topical ophthalmic solutions, IV glucocorticoids preparations and bronchodilator solutions for inhalation also contain some sulfiting agents which produce bronchospasm.

The enviornmental causes of bronchial asthma are usually due to pollen (airborne antigen) and atmospheric pollutants such as ozone, nitrogen dioxide, sulphur dioxide, etc. This environmental cause of bronchial asthma can be treated by mast cells stabilising drugs. Occupation related bronchial asthma is due to exposure to large number of compound used in different types of industrial process. Respiratory infection is also an important stimuli to evoke exacerbation of bronchial asthma. Among the infections, viruses such as syncytial virus, rhino virus, influenza and parainfluenza virus, etc, are the predominant pathogens. Simple colonization of viruses do not cause bronchial asthma, but attacks of asthma occur when symptom of respiratory tract infection are present. The mechanism of virus induced exacerbation of bronchial asthma is due to the production of T-cell derived cytokines that help in the infiltration of inflammatory cells into the already susceptible airways.

Exercise also precipitates acute onset of bronchial asthma by provoking bronchospasm to some extent in asthmatic patient. When such patients are followed for sufficient periods, then it is found that they often develop recurring episodes of airway obstruction which is independent of exercise. So, onset of exercise induced bronchial asthma may be the first manifestation of the later full blown asthmatic syndrome. Exercise induced asthma is not due to the smooth muscle contraction, but due to the obstruction produced by thermal induced hyperemia and engorgement of the microvasculature structure of the bronchial wall.

Pathophysiology

The hallmarks of pathophysiology of bronchial asthma are: vascular congestion, oedema of tracheo-bronchial wall, thickening of mucous membrane, reduction of airway diameter due to contraction of smooth muscles, copious tenacious secretions and plugging of airways (mainly the small airways), hypertrophy of the bronchial smooth muscle, hyperplasia of mucosal and submucosal vessels, eosinophilic infiltration of bronchial wall and denuation of surface epithelium. All these pathological changes lead to increased airway resistance, decreased forced expiratory volume, decreased flow rates, increased work of breathing, hyperinflation of the lungs and thorax, decreased elastic recoil, altered ventilation and perfusion ratio, altered arterial blood gas concentration (Fig. 31.5).

When the forced vital capacity of an asmatic patient with acute episode goes below or becomes equal to 50% of the normal value, FEV_1 comes down to 30% or less of the predicted value and maximum midexpiratory flow rates are reduced to 20% or less of the expected, then he presents for therapy. In acutely ill patient with status asthmaticus, residual volume (RV) frequently approaches 400% of normal value and functional residual capacity (FRC) becomes double. Flow-volume loop of asthma shows characteristic downward scooping of the expiratory limb of the loop. The flow-volume loops where the inhaled and exhaled portion are flat help to distinguish the wheezing caused by upper airway obstruction such as foreign body, tracheal stenosis, mediastinal tumour, etc, from bronchial asthma. During moderate to severe attacks of bronchial asthma, the functional residual capacity may increase as much as 1 to 2 litres, whereas the total lung capacity usually remains within the normal range.

The mild bronchial asthma is usually accompanied by normal arterial O_2 and CO_2 tension. Tachypnoea and hyperventilation which is observed during a mild asthmatic attack, therefore, do not reflect the compensatory phase of arterial hypoxaemia, but, rather neural reflexes of the lungs. During moderate to severe form of attack, the abnormal blood gas analysis is the universal finding. This is associated with hypoxia, hypocapnia, and respiratory alkalosis. As the severity of obstruction to expiratory airflow increases, the associated gradual ventilation-perfusion mismatching may result in P_aO_2 less than 60 mm

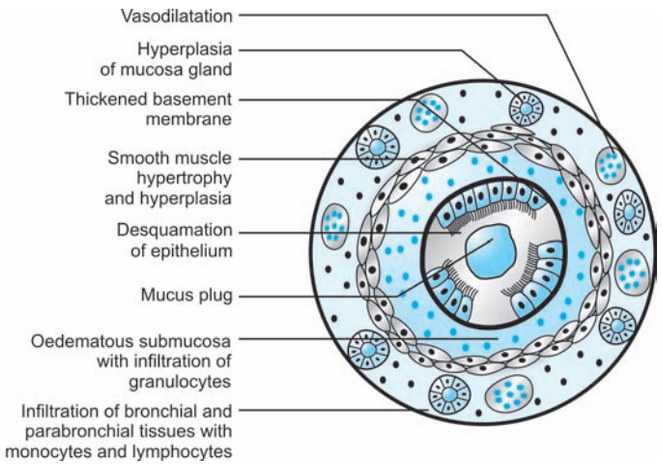

Fig. 31.5: Changes in bronchial wall during asthma

of Hg but normocapnia, while breathing room air. This is followed by compensatory hyperventilation which results in hypocapnia and normal P_aO_2. Then gradually when hypocapnia comes to normal level, it indicates severe airway obstruction. The P_aCO_2 is likely to increase when the FEV_1 is less than 25% of the predicted value and indicates impending respiratory failure. Equally, the presence of metabolic acidosis in the setting of acute bronchial asthma signifies severe hypoxia due to acute obstruction. Cyanosis is very uncommon and is late sign of bronchial asthma. Clinically hypoxia can go undetected. So, clinical indication should not be relied upon with any confidence. Therefore, in any acute condition with suspected alveolar hypoventilation, arterial blood gas tension must be measured (Fig. 31.6).

Drugs

Drugs used for treatment of bronchial asthma are classifed as:

A. Bronchodilators

1. Adrenergic stimulants –
   i. Catecholamines: Epinephrine (adrenaline), Isoproterenol (Isoprenalin), Isoetharine, Rimiterol, Hexoprenaline.
   ii. Resorcinols: Terbutaline, metaproterenol (orciprenaline), Fenoterol
   iii. Saligenin: Salbutamol (albuterol), Salmeterol

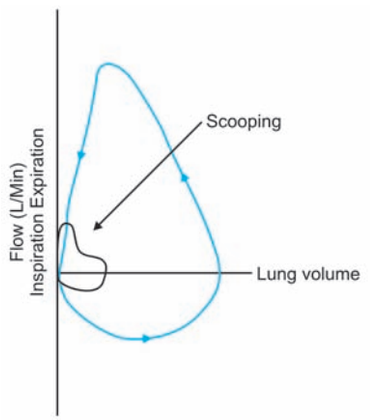

Fig. 31.6: Flow-volume curve of a normal (blue line) and an asthmatic (red line) individual

2. Methylxanthines: Theophylline, aminophylline
3. Anticholinergies: Atropine, ipratropium

B. Mast cell stabilisers

Sodium chromoglycate, ketotifen

C. Corticosteroids

1. Systemic: Hydrocortisone, prednisolone and others
2. Inhalational: Beclomethasone, budesonide, fluticasone, Triamcinolone

CATECHOLAMINES

This group of drugs causes bronchodilatation through agonistic action on β-receptor and activation of G-protein, with the resultant increased in formation of cAMP in bronchial muscle cell leading to relaxation of it. Increased cAMP in mast cells also reduces antigen: antibody reaction which inhibits the release of chemical mediators responsible for smooth muscle contraction. The catecholamines which are in wide spread clinical use for bronchial asthma are: epinephrine, isoproterenol and isoetharine. Among the catecholamines the epinephrine is the mainstay of treatment for reversible airway obstruction, but should be reserved for refractory cases and used cautiously in hypertensive patients, cardiac patients and in those receiving digitalis. They are the fastest acting bronchodilators when inhaled.

Epinephrine (adrenaline) is an α (α_1 + α_2) and β (β_1 + β_2) agonist and causes prompt but short-lasting bronchodilatation. The duration of action of epinephrine is 30 to 90 minutes and are effective only when is administered by inhalational or by parenteral routes. The α-action (weakly bronchoconstrictor) of it is masked by dominant β_2 mediated action. As epinephrine is not selective β_2 agonist, so it has considerable chronotropic and inotropic cardiac (β_1) actions also. Inhalation of adrenaline or spray of it may afford additional benefit by producing mucosal decongestion (α-action). The usual parenteral dose of epinephrine in acute bronchial asthma is 0.3 to 0.5 ml of 1:1000 solution, administered subcutaneously.

Another catecholamine such as isoproterenol is devoid of α-activity and has both β_1+β_2 activity. It is also a very potent bronchodilator and is usually administered in acute asthmatic patient as 1:200 solution by inhalation. Then in 1960, sudden deaths among the asthmatics were increased markedly when the high doses of isoprenaline was used. This is because of inhalation of several doses of isoproterenol in succession during escalation of symptom and respiratory acidosis is probably resulted in cardiac arrhythmia and asystole. Then death rate has dropped following the restriction of these inhalers and development of more selective β_2 agonists which have replaced isoprenaline. Isoetharine is the most β_2 selective compound, but is a relatively weak bronchodilator. It is employed as an aerosol and supplied as 1% solution.

RESORCINOLS AND SALIGENIN

The most commonly used resorcinols are metaproterenol, terbutaline and fenoterol. The most commonly used saligenins are salbutamol (albuterol) and salmeterol. With the exception of metaproterenol, these group of drugs are highly selective for the β_2-receptors of respiratory tract and are virtually devoid of any significant cardiac (β_1) effects, except at high doses. Their major side effect is tremor. They are active by all the routes of administration. Their peculiar chemical structure allows them to bypass the metabolic processes which degrade the catecholamines in liver when used through oral route. So, their effects are long-lasting (4 to 6 hours) than catecholamines.

The differences in potency and duration of action among these agents can be eliminated by adjusting the doses and/or administration schedules. Inhalation is the preferred route of administration of these group of drugs. Because through this

route, it further increases the bronchial selectivity of action of these drugs and allows the maximal bronchodilation with fewer systemic side effects. This is also true during the treatment of severe acute airway obstruction and making the IV therapy obsolete during emergency. The IV administration of β_2 selective agonistic agent such as terbutaline and salbutamol offers no advantages over the inhalational routes (Table 31.5).

The orciprenaline (metaproternol) also resembles to isoprenaline and is somewhat selective β_2-agonist. But as it is not a substrate for COMT like isoprenaline, so it is orally effective and longer lasting (3 to 4 hours). Now, orciprenaline (metaproterenol) is less favoured than other more selective β_2 agonists.

Both salbutamol and terbutaline are highly selective β_2-agonists. So cardiac side effects of these two agents are less prominent. Bronchial selectivity is further increased by inhaling these drugs. Muscle tremor caused by salbutamol and terbutaline is their dose related side effect. Palpitation, restlessness, nervousness, throat irritation and ankle oedema may also occur. Salbutamol and terbutaline undergo presystemic metabolism in gut wall. So, oral bioavailability of this drug is only 50%. They are longer acting and safer than isoprenaline but similar in efficacy. Inhaled salbutamol and terbutaline are currently the most popular drugs. By inhalation the peak bronchodilatation effect produced with these agents, occurs within 10 min and lasts up to 6 hours. They are convenient, effective in most mild to moderately severe cases and produce few side effects.

Table 31.5: Comparison of β_1 and β_2 activity of commonly used bronchodilators

Drugs	*Adrenergic activity*	
	β_1	β_2
Epinephrine	+ + + +	+ +
Isoproterenol	+ + +	+
Metaproterenol	+ +	+ + +
Albuterol (salbutamol)	+	+ + +
Fenoterol	+	+ + +
Isoetharine	+ +	+ + + +
Formaterol	+	+ + + +
Bitolterol	+	+ + + +
Salmeterol	+	+ + + +
Terbutalin	+	+ + + +

The regular use of inhaled β-agonists does not reduce the bronchial hyperactivity, but may even worsen it. Regular use also down regulates the bronchial β_2-receptors. This may be responsible for the gradually diminshed responsiveness seen after the long term use of these drugs. It is felt that the use of β_2-agonist inhalers should be restricted to the symptomatic relief of wheezing.

Salmeterol is the recently introduced long-acting (9 to 12 hours) congener of salbutamol and selective β_2-agonist with slow onset of action (30 minutes). As it is long-acting (12 hours), so is effective in producing sustained symptomatic relief. Therefore, it is used on a twice daily schedule for maintenance therapy and for nocturnal and exercise induced asthma, but not for acute symptoms. It should not be used as a rescue drug for breakthrough symptoms. In addtion, its long half-life means that administration of extra doses can cause cumulative side effects.

METHYLXANTHINES

The drugs used from this group of agent is theophylline and aminophylline. Theophylline and its various salts are bronchodilator of medium potency and work through an undefined mechanism. The probable explanation for their mechanism of action is direct effect on their receptors, as well as due to the release of adrenergic transmitters. The previous theory of their action that these drugs increase cyclic AMP by the inhibition of phosphodiesterase is no longer correct. Before the era of salbutamol, theophylline and its compounds have been extensively used in bronchial asthma. But, now it is not considered as first line of drugs anymore. Theophylline is one of the three naturally occuring methylated xanthine alkaloids, such as caffeine, theophylline and theobromine which are present in tea leaves, coffee seeds and coca. The therapeutic plasma concentration of theophylline traditionally have been thought to lie between 10 to 20 µg/ml. But some schools recommend a lower therapeutic plasma concentration, ranging between 5 to 15 µg/ml to avoid its toxicity.

The dose required to achieve desired therapeutic level and to reduce toxicity of methylxanthines varies widely from patient to patient. This is due to the differences in metabolism of theophylline in different patients. Theophylline clearance and thus its dosage requirement is decreased substantially in neonates, elderly, and those who are suffering with acute and chronic hepatic dysfunction, cardiac decompensation, corpulmonale and febrile illness. On the other hand, theophylline clearance increases in children. In addition, a number of important drug interaction can alter the theophylline metabolism. The clearance of methylxanthines (theophylline) also fall with the concurrent use of erythromycin, other macrolite antibiotics, quinolone antibiotics, cimetidine, etc. Clearance of theophylline also increases with the use of cigarettes, marijuana, phenobarbital, phenytoin and other drugs that induce microsomal enzymes of liver. At therapeutic concentration, the $t_{½}$ of theophylline in adults is 7 to 12 hours. Children eliminate it much faster with $t_{½}$, 3 to 5 hours, but for the elderly $t_{½}$ is more than 12 hours. In premature neonates and infants the $t_{½}$ of theophylline extends from 24 to 36 hours. Long-acting theophylline compounds are also available for maintenance of therapy and are usually given once or twice per day (Fig. 31.7).

The dose of this group of drug is adjusted on the basis of clinical response and the measurement of serum concentration. Now, the effectivenss or the role of aminophylline in the management of acute asthma is in debate. Still, in severe asthma it is used as infusion perioperatively. Both

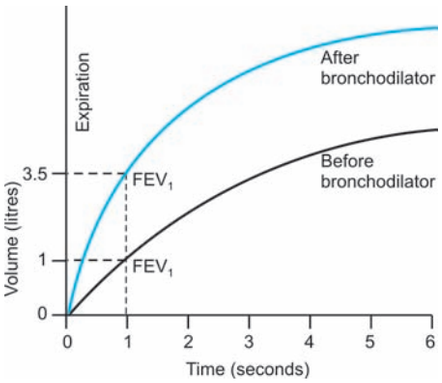

Fig. 31.7: Schematic representation of change in FEV_1 before (red line) and after (blue line) administration of bronchodilator

aminophylline and theophylline are available for IV use. The recommended intravenous dose of theophylline is 6 mg/kg as loading, followed by an infusion of 1 mg/kg/hour for the next 12 hours and then 0.8 mg/kg/hour thereafter. For older, heart failure, liver disease and corpulmonale patients the IV loading dose remains the same, but the maintenance dose is reduced to between 0.1 to 0.5 mg/kg/hour. Sometimes, for patients who are already receiving theophylline, the loading dose is frequently withheld.

The most common side effects of aminophylline and theophylline are nervousness, nausea, vomiting, anorexia and headache. At plasma levels of theophylline greater than 30 µg/ml, there is risk of seizures and cardiac arrhythmias. Very rapid IV injections of methylxanthines causes precordial pain, syncope and even sudden death and these are due to marked fall in BP, ventricular arrhythmias or asystole. Theophylline has been found to reduce the frequency and duration of episodes of apnoea that occur in some preterm infants in the first few weeks of life. So, for premature neonates, to prevent or to abolish the episode of apnoea closely monitored IV treatment by theophylline or aminophylline is employed for 1 to 3 weeks.

ANTICHOLINERGIC

The anticholinergic drugs such as atropine sulphate produces bronchodilation in patients with bronchial asthma. It acts by blocking the cholinergic constrictor tone of vagus. But its use is limited by its systemic side effects and less effectiveness than sympathomimetic agents. But after the introduction of nonabsorvable quaternary ammonium congener such as atropine methylnitrate and ipratropium bromide, the anticholinergic agent has been found to be both effective in the management of acute bronchial asthma and free of untoward side effects. The Patients of asthmatic bronchitis, COPD and psychogenic asthma respond better than pure bronchial asthma to anticholinergic agents. Because, reflex vagal activity is an important factor causing bronchoconstriction and increased secretion in chronic bronchitis and COPD, but to a lesser extent in bronchial asthma. It may also be particularly beneficial for patients with coexistent heart diseases, in whom use of methylzanthines and beta-adrenergic stimulants may be dangerous. Anticholinergic also enhances the response, achieved by sympathomimetics and produce better bronchodilatation. Ipratropium bromide given by aerosol also has been shown not to dry up the secretions (like atropine) in the respiratory tract which may lead to inspissation and plugging of bronchioles, resulting in alveolar collapse. However, the major disadvantage of inhaled anticholinergics are that they produce slower response (60 to 90 minutes may be required before peak bronchodilatation is achieved) with modest potency. So, anticholinergics are better suited for regular prophylactic use than for control of an acute attack.

GLUCOCORTICOIDS

They are not bronchodilators. But they act by (i) reducing the bronchial hyperirritability, (ii) reducing the mucosal oedema and (iii) suppressing the inflammatory response produced by AG:AB reaction or other stimuli. The indication of glucocorticoids in asthma are: (i) when severe airway obstruction is not resolving or is worsening, despite intense optimal bronchodilator therapy, (ii) in chronic disease when there has been failure of a previously optimal regimen with frequent recurrences of symptoms and increasing severity and (iii) to restore the responsiveness of sympathomimetics, once resistance to them has developed (Fact file).

FACT FILE

At the cellular level glucocorticoids act by the following mechanism:

1. Induction of synthesis of lipocortins in macrophages, endothelium and fibroblasts → ↑lipocortins inhibits phospholipase A_2 → decreases synthesis of PGs, LTs and PAF (LT - leukotriene, PAF - platelet activity factor).
2. Negative regulation of genes for cytokines in macrophages, endothelial cells and lymphocytes → decreased production of IL - 1, 2, 3, 6; TNFα, GM-CSF, γ - interferon → inhibition of fibroblast. (IL - Interleukin, TNF—Tumour Necrosis Factor, GMCSF—Granulocyte Macrophage Colony Stimulating Factor)
3. Complement function is inhibited.
4. Decreased production of ELAM (Endothelial Leucocyte Adhesion Molecule) and ICAM (Intracellular Adhesion Molecule) causing supression of adhesion and localization of leucocytes.
5. Inhibition of IgE mediated release of histamine and LT - C_4 from basophil by which AG : AB reaction is inhibited.
6. Inhibition of production of collagenase and stromelysin → prevention of tissue destruction.

The glucocorticoid molecule penetrates the cell membrane and binds to the glucocorticoid receptor (GR) which is a protein in nature and normally resides in the cytoplasm of cell. The glucocorticoid receptor is practically distributed in all the cells and made up of 800 aminoacids. The GR has a steroid binding domain near its carboxy terminus and a DNA binding domain having two 'zinc finger' at mid region. Each zinc finger is made up of a loop of aminoacids with chelated zinc ion. Normally the GR remains in cytoplasm in association with 3 proteins such as HSP_{90}, HSP_{70} and IP (HSP – Heat Shock Protein, IP – Immunophillin).

These proteins have inhibitory influence on GR and prevent its dimerization. The binding of steroid molecule to GR dissociates these three complex proteins and the dimerization region is exposed. Thus, dimerization of two GR with glucocorticoids molecule occur. Now, the diamer of two GR with steroid molecules translocate within the nucleus of cell and interacts with the sepecific DNA sequences or region called GRE (Glucocorticoid Responsive Elements). These are the regulatory region of a appropriate gene of DNA. Thus, the expressions of these genes is consequently altered resulting in promotion or supression of their transcription. The specific mRNA thus produced from genes (whose expression is altered) is directed to the ribosomes. In the ribosome the message carried by mRNA is translated for a specific pattern of protein synthesis, which in turn modifies the cell function.

Thus, in summary the corticosteroid molecules penetrate the cells and bind to high affinity cytoplasmic glucocorticoid receptor protein → a structural change occurs in the steroid receptor complex → allows its migration into the nucleus and bindings to specific sites on the DNA → transcription of specific mRNA → regulation of protein synthesis → alterations of function of cells. This process takes at least 30 to 60 minutes. So, effects of steroids are not immediate and once the appropriate proteins are synthesized, then the effects persist much longer (Fig. 31.8).

All the natural and synthetic corticosteroids, except deoxycorticosterone acetate (DOCA) are effective by the oral route. Water soluble esters of corticosteroids, e.g. hydrocortisone hemisuccinate, dexamethasone sodium phosphate, methylprednisolone, etc. can be given IV or IM. They act rapidly and achieve high concentration in tissue fluids. Insoluble esters, e.g. hydrocortisone acetate, triamcinolone acetonide, etc. cannot be injected IV. They are slowly absorbed from IM site and produce more prolonged effects (Fig. 31.9).

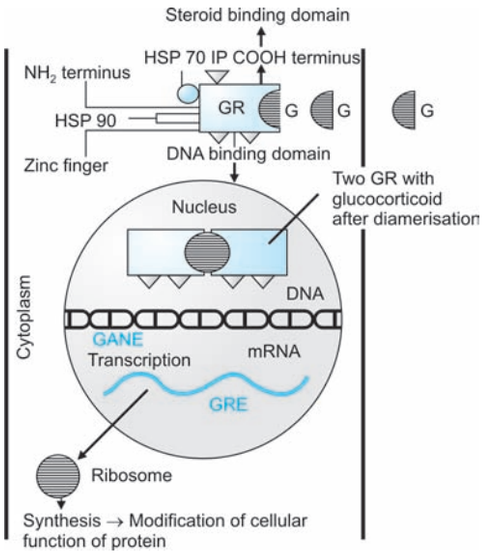

Fig. 31.8: The glucocorticosteroid molecule (G) first penetrates the cell membrane. Then it binds to the receptor GR. Normally GR resides in the cytoplasm in association with 3 another proteins - HSP 90, HSP 70 and IP. The GR has two domain, one is steroid binding domain near the carboxy terminus. Another is DNA binding domain having two zinc fingers at the middle. Binding of the G to GR dissociates the complex proteins (HSP 90, HSP 70, etc.) from GR and thus remove the inhibitory influence on it. Thus a dimerisation region is exposed. It helps dimerisation of two GR. Then the steroid molecule bound diamer of receptor translocates into the nucleus and interacts with specific DNA sequence which is called glucocorticoid responsive elements (GREs). Then expression of the genes in DNA is altered. This results in promotion or supression of their transcription and production of specific mRNA. The specific mRNA thus produced is directed to the ribosome and gives direction for specific pattern of protein synthesis which modifies cell function

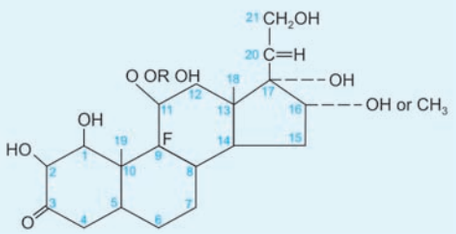

Corticosterone	DOC	+	OH at 11
Hydrocortisone	DOC	+	OH at 11 and OH at 17

Fig. 31.9: Chemical structure of corticosteroid. Black lined structure is deoxycorticosterone (DOC). Important substitutions which yield other compounds are shown by blue colour

The chemical structure of different natural and synthetic glucocorticoids are depicted in picture. Among all the glucocorticoids, hydrocortisone (naturally occuring, daily rate of synthesis 10 mg/day) undergoes high fast pass liver metabolism. So, it has low oral: parenteral activity ratio and is mainly used through IV route. Whereas oral bioavailability of other synthetic corticosteroids are high. Hydrocortisone acts rapidly, but has short duration of action ($t_{½}$ < 12 hours). In status asthmaticus the dose of it is 100 mg IV in bolus plus 100 mg 8 hourly by infusion. Prednisolone is 4 times more potent and more selective glucocorticoids than hydrocortisone, but is not used through IV route. While methyl prednisolone (solumedrol)

is available for slow IV use for its anti-inflammatory action. Triamcinolone is more potent and selective glucocorticoids than prednisolone, but IV preparation of it is not available. It is used only by oral, IM or intra-articular route. Dexamethasone is also potent and selective glucocorticoids without fluid retention and hypertensive action (mineralle corticoid actions). It is long-acting ($t_{½}$ > 36 hours) and its IV preparation is also available. As it has no fluid retention property, it is used for the management of cerebral oedema like betamethasone. Betamethasone is also available as IV preparations. Its action is like dexamethasone but is long-acting ($t_{½}$ > 36 hours). Fludrocortisone is a potent mineralocorticoids with some glucocorticoid activity. DOCA (Deoxycorticosteron Acetate) has only mineralocorticoid activity. Beclomethasone and budesonide are used by inhalation in bronchial asthma patient as spray. They have high topical potency and reduce airway reactivity. The realization that bronchial asthma is primarily an inflammatory disease which accentuates with time. So, the availability of inhaled steroids that are less hazardous in long term use have led to more extensive use of such glucocorticoids in chronic bronchial asthma (Fig. 31.10).

It should be emphasized that the effects of steroid in acute bronchial asthma are not immediate and may not be seen for 6 hours or more after the initial administration. Also the correct dose of it to use in acute situations is a matter of debate. The available data indicates that very high doses of glucocorticoids do not offer any advantage over the more conventinoal doses. So, the recommended dose of methylprednisolone is 40 to 60 mg IV every 6 hours. Since, IV and oral administration produce the same effects, prednisolone 60 mg every 6 hours orally can be used instead of IV. In UK, acute bronchial asthma is treated with dose of prednisolone 30 to 40 mg given once daily.

For bronchial asthma the corticosteroids can also be used through inhalation route and is preferred than oral administration, because it is associated with less systemic side effects than oral administration. Inhaled corticosteroids have direct anti-inflammatory action on the bronchial mucosa and thus decrease airway hyperresponsiveness. This decrease in airway hyper responsiveness is not maximum until treatment has passed several months. The corticosteroids which are used through inhalation are: beclomethasone, fluticasone, budesonide, etc. (Table 31.6).

Anaesthetic Management

The anaesthetic management of a patient with bronchial asthma requires an exhaustive understanding of the pathophysiology of this disease and pharmacology of the drugs, being used for the management of it which are already discussed. There is also evidence that the frequency of perioperative bronchospasm and laryngospasm is common in patients with the history of bronchial asthma, but where there is no symptoms before induction. Whereas symptomatic bronchial asthma patients are at increased risk for morbidity and mortality.

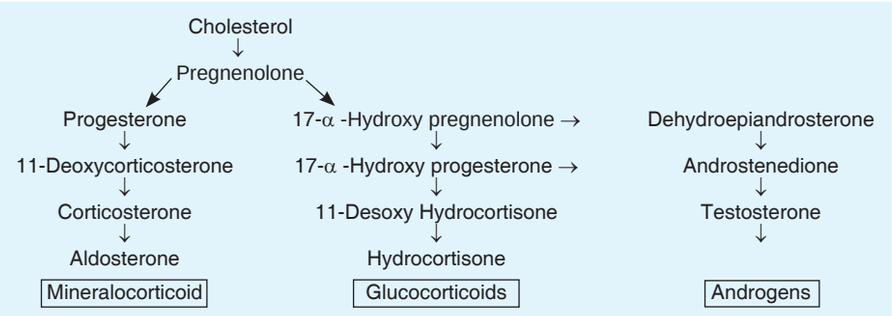

Fig. 31.10: Activity of glucocorticoids in chronic bronchial

Table 31.6: Equivalent doses of glucocorticoids

Glucocorticoids	*Dose (mg)*
Betamethasone	3
Dexamethasone	3
Methylprednisolone	16
Triamcinolone	16
Prednisolone	20
Prednisone	20
Hydrocortisone	80
Cortisone acetate	100

Perioperative assessment

The purposes of proper preoperative anaesthetic assessment of a bronchial asthma patient are: (i) to assess the degree of respiratory dysfunction, (ii) to assess the efficacy of treatment and (iii) to formulate the proper anaesthetic plan and management. Preoperative information should be obtained regarding the frequency and severity of attacks, drug history and any recent episode of respiratory tract infection. Acute recent viral respiratory tract infection increases the bronchial reactivity and increases the incidence of intraoperative bronchospasm. Physical examination of chest may be normal, though a forced expiration may provoke some end expiratory wheeze. Signs of cardiac and respiratory failure may or may not be present.

In addition to the routine tests such as complete blood count, coagulation screening, urine analysis and ECG, sometimes special attention should also be paid to the pulmonary function tests, arterial blood gases and X-ray chest. The comparison of chest X-ray with previous one is often useful to evaluate any further change in the recent disease process. In pulmonary function tests, the timed vital capacity (FEV_1) curve and flow volume loop give the most valuable information regarding : (i) the degree of airway obstruction and (ii) the degree of reversibility of obstruction with bronchodilators. Pulmonary function tests show reduction in forced vital capacity, FEV_1, FEF (25 to 75%) and PEFR. The FEF at 25 to 75% is defined as the forced expiratory flow at 25 to 75% of forced vital

capacity. FEV_1 is a relative crude indicator of small airway obstruction compared to PEFR. Normal value of PEFR is 600 to 650 L/min in adult male and 450 to 500 L/min in adult female. Comparisons with previous measurements are invaluable. FEV_1 values are normally more than 3L for men and 2L for women. FEV_1 / FVC should normally be >70%. An FEV_1, FEV_1 / FVC or PEFR less than 50% of normal is indicative of moderate to severe bronchial asthma.

A single peak flow reading can also be helpful for preoperative assessment of an bronchial asthma patient. But serial measurement is more helpful than a single result. The response to bronchodilators should also be measured. When the peak flow rate is > 80% of the predicted value with minimal symptoms, then bronchial asthma is considered as mild and patient requires little extra treatment prior to surgery. Results of peak flow rate and spirometry should always be compared with the predicted values based on age, sex and height. Anaesthesia should not be given for elective surgery, when the patient's asthma is less than optimally controlled. Viral infection are potent triggers of bronchospasm. So, postponement of elective surgery is considered with symptomatic URTI (Table 31.7).

Depending upon the spirometric pulmonary functional impairment and arterial blood gas level, the bronchial asthma has been classified into five grades (Table 31.7).

Preoperative blood gas analysis may be helpful in providing base line for further management in asthma patients. Hypoxia and hypercarbia are seen only in patients with very severe asthma. In X-ray of chest, the hyperinflation, increased lung markings and peribronchial thickening are the common radiological findings. It also helps to detect the presence of certain complications such as pneumonia, emphysema, cyst, etc.

Preoperative preparation and premedication

The proper preoperative preparation helps to reduce the perioperative morbidity and mortality in bronchial asthama patients. Preoperative chest physiotherapy, systemic hydration, appropriate antibiotics and bronchodilator therapy are some of the important points which may improve the reversible components of asthma and may reduce the intraoperative and postoperative complications. Elective surgery should not be undertaken unless and until the bronchial asthma is well controlled. The incidence of perioperative bronchospasm and laryngospasm in asthmatic patients undergoing routine surgery is less than 2%, especially if they continue their routine medication. The frequency of complications is increased in patients over 50 years and in those with active disease.

The bronchodilator drugs used to treat bronchial asthma should be continued at the time of premedication. Salbutamol and ipratropium should be changed to its nebulized form. Chromoglycate, used as mast cells stabilizer preoperatively, can be continued safely during perioperative period as it does not interact adversely with any drugs, used during anaesthesia. Leukotriene inhibitors can also be continued as preoperative medication and must restart when patient is taking oral medications post-operatively.

Exogenous corticosteroids should be continued or supplemented (if stopped before) before anaesthesia for major surgery to combat the hypothalamia – pituitary – adrenal suppression which is likely in patient taking long term oral corticosteroids and to control the hyper-reactivity of tracheo-bronchial tree to different anaesthetic drugs. It is found that hypothalamic -pituitary-adrenal suppression is unlikely as a result of long-term inhaled corticosteroids. The preoperative supplementation of steroid (if stopped before) is considered only when the previous daily dose is > 10 mg of prednisolone or inhaled beclomethasone >1.5 mg/day. Preoperatively oral prednisolone should be converted to IV hydrocortisone (1 mg prednisolone is equivalent to 5 mg hydrocortisone). When preoperative FEV_1 is less then 80%, than a preoperative course of oral corticosteroids must be used, even if patient does not get steroid before.

Opioids have a number of actions on airway. It releases histamine and other vasoactive substances from mast cells and produces bronchoconstriction. It also increases the bronchial smooth muscle reactivity and tone due to the increase in vagal nerve activity. So, the clinical use of opioids in asthmatic patients is controversial. But there is no evidence that opioids, especially the newer synthetic opioids used in doses for preanaesthetic medication or before intubation, stimulates the release of vasoactive substances from mast cells (histamine, LT, PAF) and produce bronchoconstriction. Moreover, it helps to increase the depth of anaesthesia which is mandatory for anaesthetic management of an asthmatic patients and tilts the balance in favour of use of opioids as premedicants or during induction and before intubation. On the other hand, it depresses the ventilating efforts and supresses the ventilating responses to hypoxia and hypercarbia but not in premedicant doses. So, newer opioids are safe in asthmatics in premedication doses.

The use of anticholinergic drugs in the perioperative period is also controversial and should be individualized, remembering that these drugs can increase the viscosity of secretions and make it difficult to remove, causing plugging of smaller

Table 31.7: Classification of severity of bronchial asthma

Severity of asthma	*P_aO_2 (mm of Hg)*	*P_aCO_2 (mm of Hg)*	*FEV_1 (% predicted)*
Normal patient	> 60	< 40	> 80%
Mild asthma	> 60	< 40	65 - 80%
Moderate asthma	> 60	< 45	50 - 64%
Severe asthma	< 60	> 50	35 - 49%
Status asthmaticus	< 60	> 50	< 35%

airways and alveolar collapse. On the otherhand, it decreases the airway resistance by inhibiting the postganglionic cholinergic receptors. Hence the use of anticholinergic agents such as atropine and glycopyrollate depends on the balance between their merits and demerits. The use of H_2 receptor blocker as premedicant to increase the gastric pH in bronchial asthma patient is also controversial. Histamine mediates bronchochonstriction through H_1 receptor and mediates bronchodilatation through H_2 receptor. So, H_2 receptor blocker can potentiate the H_1 receptor induced bronchospasm. But, in clinical practice it has no effect.

Anxiety may precipitate an acute attack of asthma. BDZ acts on GABA receptors present in the airway and attenuate the reflex mediated bronchoconstriction. They also relax airway smooth muscle directly. Therefore, perioperative BDZ are used to provide anxiolysis, but keeping in mind that in acutely ill patients the risk of depressing alveolar ventilation by BDZ is greater and respiratory arrest has been reported to occur shortly after their use. Admittedly, most individuals are anxious and frightened, but experience has been shown that they can be calmed equally well by the physician's presence and reassurances without using benzodiazepine. Hence, the use of benzodiazepine in preoperative preparation will depend on anaesthetist's choice. It should also be kept in mind that a large number of asthmatic patients react adversely to aspirin or any NSAID. So, NSAIDs should be used cautiously during the post-operative period for the treatment of surgical pain.

Intraoperative management

Normally, surgical and anaesthetic stimuli that do not evoke bronchoconstriction in the absence of asthma may precipitate the life-threatening bronchospasm in patients with bronchial asthma. For example, intubation (mechanical stimulus) can precipitate bronchoconstriction easily in asthmatic patient, if reflexes are not obtunded properly by deepening anaesthesia. Different drugs (chemical stimuli) used in anaesthesia can also increase the airway reactivity and precipitate bronchospasm which is not found in normal patient. So, the goal during induction and maintenance of anaesthesia in patients with bronchial asthma is to depress the airway reflexes sufficiently by increasing the depth of anaesthesia and by avoiding the drugs which can precipitate bronchoconstriction if not absolutely necessary or to balance between the prevalance of bronchoconstriction and its beneficial effect.

Regional Anaesthesia

Regional anaesthesia (RA) is an attractive alternative procedure for the patients of bronchial asthma when the operative site is superficial, lower abdominal or on the extremities. Because it avoids instrumentation of airways (intubation) and the use of multiple drugs, responsible for bronchospasm. RA such as low spinal, low epidural or caudal should be preferred for the surgeries on perineum, lower extremities, pelvis, or intra and extra peritoneal organs restricting below umbilicus. Respiratory complications are also quite common with high regional anaesthesia (T_6–T_4) like GA in bronchial asthma patient. So it is not alternative to GA. This is because high RA paralyses the normal and the accessory respiratory muscles in a already compromised patient, necessitating artificial ventilation where GA has great advantage. High RA is also not possible without sedation which further jeopardise the already compromised ventilation process. So, significant differences are not observed in asthmatic patients anaesthetized with high RA and those undergoing GA with ketamine, cisatracurium and isoflurane or sevoflurane. Nevertheless, it must be kept in mind that failed RA and the subsequent need to induce GA is always a possibility.

General Anaesthesia

During GA, induction and intubation in a bronchial asthmatic patient should be done under deeper plane of anaesthesia, because patient may develop bronchospasm in lighter plane. The cuff of an ET tube should be placed just below the cord but not touching it and without irritating the carina. Also the patient should be extubated at deeper plane of anaesthesia avoiding coughing and bucking. However, the risk of aspiration, airway obstruction and hypoventilation due to extubation at deeper plane of anaesthesia should be weighted against its benefits.

For GA, induction is most often accomplished by intravenous injection of short-acting inducing drugs like thiopentone, propofol, benzodiazepine or ketamine. But the effects of barbiturates (thiopentone) on the bronchial smooth muscle varied from relaxation to no effect to constricton. Some evidences also support that thiopentone produces a dose dependent constricton of airways by releasing histamine. Some school again thought that if thiopentone at all does not cause bronchospasm, but it fails to supress the upper airway reflexes and airway instrumentation can trigger bronchospasm. On the other hand, propofol relaxes the airway smooth muscle. But the mechanism of propofol's relative bronchodilating effect is not known. Incidence of wheezing is significantly lower in asthmatic patients induced with propofol than with barbiturates. Even, respiratory resistance following tracheal intubation in healthy patients is lower after induction of anaesthsia with propofol than after induction of anaesthesia with thiopentone. So, based on these observation it can be concluded that propofol is the agent of choice for induction of anaesthesia in patients with bronchial asthma who are haemodynamically stable. Haemodynamically unstable patient can be induced by adequate dose of benzodiazepine. Ketamine depresses the neural airway reflex pathways and directly relaxes the smooth muscle by reducing the intracellular calcium concentration. The catecholamines, released by ketamine have also bronchodilating effect. Again ketamine has also been

used successfully to decrease the airway resistance and to treat the status asthmaticus. So, alternatively ketamine can be used for induction of patients who are actively wheezing. Some generic formulation of induction agents which are available in market contain metabisulfites as preservative and the presence of these metabisulfites causes bronchospasm in patients with hyperactive airways. So, an anaesthetist should be careful of these generic formulation (Table 31.8).

After hypnosis and unconciousness, established by IV inducing agents, it is better to ventilate the patient's lungs with gas mixtures (N_2O and O_2) containing volatile anaesthetic agents. The goal is to further produce a deeper plane of anaesthesia that depresses the hyperactive airway reflexes sufficiently and permit tracheal intubation without precipitating bronchospasm. Otherwise, bronchospasm can be precipitated if tracheal intubation is done without establishing sufficient depth of anaesthesia. It is often assumed that any volatile anaesthetic agent at comparable doses is equally effective producing bronchodilation. Lesser pungency of halothane and sevoflurane (compared with isoflurane) may make coughing less likely as coughing may trigger bronchospasm. On the other hand, halothane is not ideal as it sensitizes the myocardium to catecholamines which remain at high level in asthmatic patients causing arrhythmias. Again, it is also known that the effect of sevoflurane on the airways resembles those of halothane and isoflurane. So, at conclusion, considering all aspects, it is thought that sevoflurane is the more suitable agent in patients with bronchial asthma. However, some school thought that halothane has the maximum bronchodilating effect and is more potent than sevoflurane. So, it is the best suitable agent in asthma patient producing deeper plane of anaesthesia easily and maximum bronchodilatation. The mechanism of bronchodilating effect of volatile anaesthetic agents is due to their direct effects on the airway smooth muscles. This is explained by the fact that they block the intracellular calcium influx, impair calcium release from the sarcoplasmic reticulum and disrupt the mechanism that sensitizes the myofilament contractile system to calcium. Except bronchodilatation, they also attenuate the responses of bronchial smooth muscle to broncho constricting stimuli. This action is due to the alteration of liberation of acetylcholine and the depression of ganglionic transmission in the vagal pathway.

An alternative technique to the administration of volatile anaesthetic agents which supress the airway reflexes before muscle relaxant, laryngoscopy and tracheal intubation may be the intravenous injecton of lignocaine. Lignocaine in the dose of 1 to 1.5 mg/kg through IV, administered 2 to 3 minutes before muscle relaxant, laryngoscopy and tracheal intubation is helpful for preventing reflex bronchoconstriction. Intravenous lignocaine antagonises both the reflexes and antigen induced bronchospasm in hyper reactive airway. It also relaxes the smooth muscles of airways in higher concentration. But lignocaine spray over the larynx and vocal cords before intubation has both advantages and disadvantages. The beneficial effect is surface anaesthesia produced by lignocaine block the stimuli from the laryngoscopy and intubation. But, the disadvantage is that lignocaine spray itself produces bronchospasm by placing the solution like foreign body into hyperactive airway of asthma patients which is not found in normal individuals. However, clinical evidences show that at good level of anaesthesia, lignocaine spray does not initiate bronchospasm.

The skeletal muscle relaxation for intubation and maintenance of anaesthesia is often obtained by nondipolarizing muscle relaxants. The selection of muscle relaxant for bronchial asthma patient depends mainly on the property of the release of histamine by these drugs. Drugs which release minimum amount of histamine or none is preferred for asthma patients. Non-depolarising neuromuscular blocking drugs which cause histamine release should be avoided and they are listed on the table. After tracheal intubation, it is sometimes very difficult to differentiate between in sufficient muscular paralysis from bronchospasm as a cause of decreased lung compliance. This can be helped by adding additional dose of muscle relaxant (Table 31.9).

Succinylcholine also causes the release of histamine, but to a lesser extent. Hence, there is no evidence that this drug is associated with increased airway resistance when administered in patients with bronchial asthma. Reversal of neuromuscular blockade by neostigmine and other cholinesterase inhibitor could theoretically

Table 31.8: Substances influencing bronchial smooth muscle tone

A. Bronchodilatation

1. β_2- sympathomimetics:
   Salbutamol, terbutaline, isoprenaline, adrenaline, ephedrine, etc.
2. Xanthine derivatives:
   Aminophiline, theophylline, caffine, etc.
3. Volatile anaesthetics:
   Halothane, isoflurane, sevoflurane, ether, etc.
4. Nitrites :
   Amyl nitrite, glyceryl trinitrate.
5. Prostaglandin E_1 and E_2:
   Allergic reaction, infusion, etc.
6. Muscarinic cholinergic receptor blockers :
   Atropine, glycopyrrolate, etc.

B. Bronchoconstriction

1. Muscarinic cholinomimetics
   (a) Anticholinesterases:
   Neostigmine, pyridostigmine, physostigmine, edrophonium, etc.
   (b) Choline esters and alkaloids:
   Pilocarpine, carbacol, methacol, etc.
2. β_2-adrenergic blockers:
   Atenolol, propranolol, etc.
3. Autacoids:
   Histamine, 5-HT, kinins, PG-$F_2\alpha$, etc.
   (a) Histamine releasing drugs:
   Pancuronium, atracurium, morphine, thiopentone, etc.
   (b) Allergic reactions
   (c) Carcinoid tumours
   (d) Prostaglandin administration

Table 31.9: Benzylisoquinoline and steroidal compounds

Muscle relaxants	*Doses causing release of histamine*
A. Benzylisoquinoline compound	
d - Tubocurarine	0.6 × ED_{95}
Metocurine	2 × ED_{95}
Doxacurium	4 × ED_{95}
Mivacurium	3 × ED_{95}
Atracurium	2.5 × ED_{95}
Cisatracurium	None
B. Steroidal compound	
Pancuronium	Minimum
Vecuronium	None
Pipecuronium	None
Rocuronium	None

cause bronchospasm. However, when administered with the anticholinergic drugs like atropine or glycopyrrolate, then neostigmine does not significantly change the airway resistance.

Intraoperatively the desired level of P_aO_2 and $ETCO_2$ is best maintained by mechanical ventilation. Ventilation should be controlled with warmed humidified gases whenever possible. Airflow obstruction during expiration due to bronchospasm is apparent on capnography as a delayed rise of the end-tidal CO_2 value. The severity of obstruction is generally inversely related to the rate of the rise in end-tidal CO_2 tension. For ventilation in asthma patient low inspiratory flow rate is used which provides optimal distribution of ventilation against perfusion. Severe bronchospasm is manifested by rising peak inspiratory pressures and incomplete exhalation. In the past, tidal volumes of 10 to 12 ml/kg with ventilatory rates of 8 to 10 breaths/minute were considered desirable. However, currently, minimizing the tidal volume (<10 ml/kg) with prolongation of expiratory time may allow the more uniform distribution of gas flow to both the lungs and may help to avoid air trapping during expiration. This is because during expiration sufficient time should be given to prevent air trapping in alveoli in the presence of expiratory air flow obstruction which is a characteristic of bronchial asthma. PEEP is not ideal for asthma patient as it may impair exhalation in the presence of narrowed airways (Fig. 31.11).

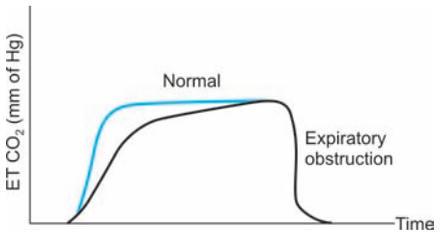

Fig. 31.11: Capnograph of a normal patient compared with expiratory airway obstruction patient (red line)

Humidification and warming of inspired gases is very vital. Nevertheless, it must be appreciated that sometimes humidification as produced by ultrasonic nebulisers and pneumatic aerosols can produce bronchospasm. Liberal use of IV fluid is mandatory during perioperative period. It helps adequate hydration and ensures the presence of less viscous secretions which can be expelled more easily. For patients with history of bronchial asthma, it is prudent to remove the endotracheal tube while anaesthesia is still in deep level. It avoids hyperreactive airway reflexes, causing bronchospasm during extubation. If there is risk of gastric aspiration, then extubation should be done when the patient is awake, but there is chance of reflex bronchospasm. However, it can be managed by continuous IV infusions of lignocaine in the dose of 1 to 3 mg/kg/hour.

Intraoperative bronchospasm

When the bronchospam occurs during intraoperative anaesthetic period, then it should be differentiated from other conditions which also reduce the pulmonary compliance and mimic bronchospasm.

For example, the conditions which mimic the intraoperative bronchospasm are:

i. mechanical obstruction of tracheal tube due to kinking, secretions, etc.
ii. endobronchial intubation,
iii. pulmonary oedema,
iv. pulmonary aspiration,
v. pulmonary embolism,
vi. pneumothorax,
vii. during spontaneous respiration, active expiratory efforts due to inadequate depth of anaesthesia.

When the diagnosis of intraoperative bronchospasm is established, then the priority should be given to increase the depth of anaesthesia by increasing the inspired concentration of volatile anaesthetic agents. Intravenous agents such as ketamine, propofol and lignocaine may also be useful to increase the depth of anaesthesia. Then, the conditions which are mimicking the acute bronchospasm should be searched for and treatment should be instituted according to the cause.

If it is confirmed that there is definite bronchospasm, then β_2-agonist should be nebulised through the endotracheal tube, keeping in mind that the requirement is more due to decreased efficiency of the drug delivery system to the lung compared to unanaesthetised ambulatory patients. In extreme circumstances, inhaled β_2-agonist are ineffective due to inadequate tidal volume. In such circumstances intravenous adrenergic agonists such as epinephrine may be necessary. Intravenous aminophylline does not provide any additional benefit over halothane. Further, it may produce dysrythmias that may accompany severe bronchospasm. Parenteral corticosteroid may be administered but it takes several hours (3 to 4 hours) to get the effect. The parameters of mechanical ventilation should be adjusted accordingly to prevent the gas trapping and barotrauma by minimising the airway pressure and prolonging the expiration.

Post-operative management

The post-operative respiration of a bronchial asthma patient must be monitored very carefully. Venturi mask with FiO_2 of 0.24 to 0.40 should be used for oxygen therapy during the immediate post-operative period. Regional nerve blocks and TENs may be used to provide post-operative analgesia without using narcotics and

depressing respiration. Following the major abdominal or thoracic surgery, good pain control is important and epidural analgesia is frequently the best choice, provided the widespread intercostal block is avoided. The narcotics for analgesia should be used very carefully for post-operative bronchial asthma patient, because respiratory depression may further compromise the airway. Morphine is contraindicated due to their histamine release property. Pethidine is safer than morphine and can be used in PCA. Fentanyl or its congeners may be the better choice. Ideally NSAIDs are to be avoided, though precipitation of bronchospasm due to the production of leukotrienes is not very common (only 5 to 10% cases). But they can be used if they have been tolerated before. If there is increasing dyspnoea and wheezing after surgery, then other conditions such as LVF, pulmonary embolism, fluid overload, etc, which may mimic bronchospasm should also be considered.

Drugs which are considered safe for bronchial asthma patients are:

Inducing agents: Propofol, ketamine, midazolam
Narcotics: Pethidine, fentanyl, sufentanil, etc.
Muscle relaxants: Succinylcholine, vecuronium, rocuronium, pancuronium, etc.
Volatile agents: Halothane, isoflurane, sevoflurane.

Prophylaxis of perioperative bronchospasm can be instituted by the following measures:

i. Continued bronchial asthma pharmaco-therapy upto the time of anaesthesia and surgery.
ii. Inhalation of β_2-agonists before induction.
iii. Corticosteroid replacement therapy.
iv. Preoperative anxiolysis.
v. Prefer regional anaesthesia, if possible.
vi. Tracheal intubation at deeper plane of anaesthesia but never at light plane.
vii. Avoid anaesthetic agents, which increase the airway reactivity.

Emergency surgery

The Bronchial asthmatic patient waiting for emergency surgery is a two-way sword. Because patients are presented usually with full stomach. So, one way of the sword is that intubation in light plane of anaesthesia or awake intubation to prevent pulmonary aspiration triggers bronchospasm. Second, if anaesthesia is deepened to prevent the reflexly initiated bronchospasm, then there is higher risk of pulmonary aspiration. So, an anaesthetist have to balance between these two and the intensity of emergency of the surgery. Furthermore, there is often insufficient time to optimize the bronchodilatation and corticoid therapy prior to surgery. So, regional anaesthesia is always preferred, if the site of surgery suits properly and permits in such situations.

CHRONIC OBSTRUCTIVE LUNG DISEASE (COLD) OR CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

The symptoms of COLD usually start after the age of about 55 years. The most common symptom of it is breathlessness. But there is often a combination of cough, wheeze and increased production of sputum with the shortness of breath in COLD. The majority of patients having COLD are tobaco smokers for a significant period of their lives. Other factors associated with COLD include: (i) occupational exposure to dusts and atmospheric pollutions, (ii) poor socioeconomic status, (iii) repeated viral infections, (iv) α-1-antitrypsin deficiency, etc. Chronic bronchitis, airway obstruction and emphysema are the three distinct components of COLD and they are most often present in different combination. Among these three pathologies, chronic bronchitis progressively lead to chronic obstructive bronchitis with extra addition of obstruction to airflow which is not fully reversible. Chronic obstructive bronchitis is also termed as chronic asthmatic bronchitis and when it is developed, then COLD consists of two components – chronic asthmatic bronchitis and emphysema (Fig. 31.12).

The chronic bronchitis is defined as a condition where there is excessive tracheobronchial mucus production for atleast 3 months of the year and for more than 2 consecutive years due to inflammation of airways, (but at this phase there is no bronchoconstriction and obstruction). The chronic bronchitis has two parts: hypersecretion of mucus and inflammatory changes. Chronic obstructive bronchitis which is the 2nd phase of COLD is also defined as the condition where there is both the excessive secretion of mucus and inflammation due to chronic bronchitis and obstruction due to bronchospasm, and experience both the severe dyspnoea and wheezing. Such patients are also said to have chronic asthmatic bronchitis as there is both the picture of chronic bronchitis (secretion and inflammation) and asthma (obstruction). It is characterised by partial reversibility of air flow obstruction with bronchodilator and abatement of inflammation. These group of patients also show the hyper responsiveness of airway to nonspecific stimuli, like bronchial asthma patients. So, confusion may persist between the chronic bronchitis with obstruction (chronic asthmatic bronchitis)

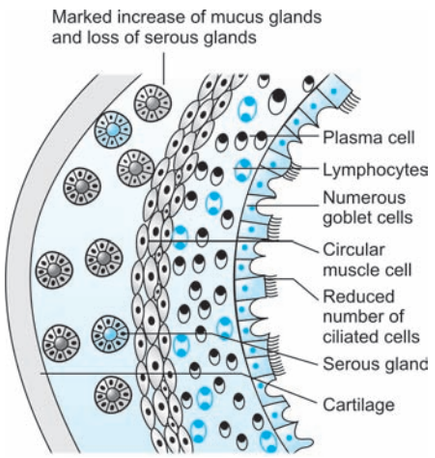

Fig. 31.12: The microscopic picture of airways of patient suffering from COLD

and those of pure bronchial asthma who also may have chronic airways obstruction with inflammation. Thus the difference between the two is that patients with chronic asthmatic bronchitis have a long history of sputum production and cough (i.e. only bronchitis part at beginning) with a later onset of wheezing (asthmatic part). Whereas the bronchial asthma patients with chronic obstruction will first give a long history of wheezing with later onset of chronic productive cough. Emphysema which is the third component of COLD is defined as the permanent, abnormal distension of air spaces distal to the terminal bronchiole with destruction of alveolar septa.

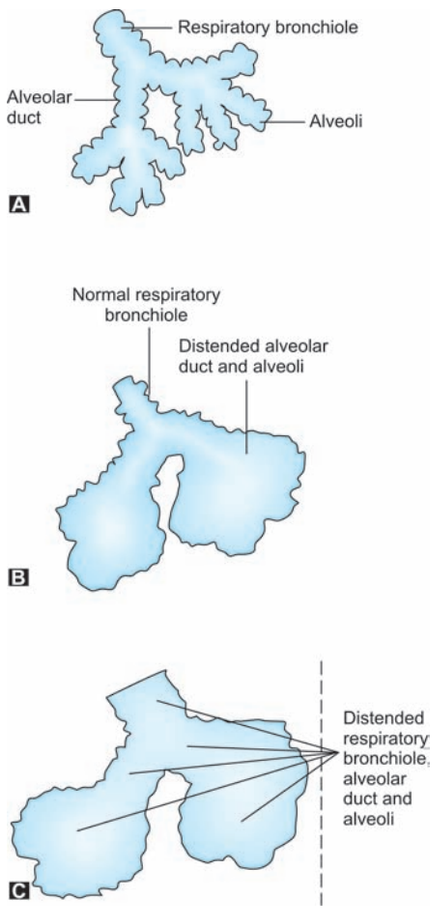
So, COLD = Chronic Obstructive bronchitis or Chronic Asthmatic Bronchitis (chronic bronchitis + asthma) + emphysema.

Patients suffering from COLD with predominant emphysema is thin, tachypnoeic and breathless at rest. They are described as 'pink puffer'. Though they are hypoxic, but CO_2 retention develops only as a late or terminal event. Whereas, patients suffering from COLD with predominant chronic bronchitis are frequently overweight with marked peripheral oedema, poor respiratory effort and CO_2 retention. They are described as 'blue bloater'. This classical two stero typed picture of 'pink puffer' and 'blue bloater' are relatively infrequent as majority of patients have a combination of features. In 'pink puffers' which is associated with emphysema P_aO_2 is usually higher than 65 mm of Hg though hypoxic and P_aCO_2 is normal to slightly decrease. Whereas, in 'blue bloaters' which is associated with bronchitis P_aO_2 is usually lower than 65 mm of Hg and P_aCO_2 is increased to more than 45 mm of Hg.

Pathology of Bronchitis and Emphysema of Cold

The hypertrophy of mucus producing glands in the submucosa layer of large cartilaginous airways, increase in number of goblet cells, reduced number of ciliated cells, increased number of neutrophil – lymphocyte-plasma cells are the usual findings of chronic bronchitis of COLD. So, it is characterized by hypersecretion of mucus, less secretion of serous fluid and inflammatory changes in bronchi. This causes daily cough and large sputum production. On the other hand, due to loss of ciliated epithelium and decrease of serous secretion, a large quantities of viscid mucus secretion becomes difficult to eliminate. Thus, there is always a tendency of retention of secretion in the airway which encourages the bacterial growth. So, a viscious cycle may be set up which leads to chronic bronchitis. This viscious cycle is like that increased and retention of secretion → bacterial growth → repeated attack of infection and inflammation → repeated attack of chronic bronchitis. Thus, with repeated acute exacerbation of inflammation and increasing retention of secretion, there is gradual spread of chronic inflammatory changes along the bronchial tree and more and more damage is encouraged. When the terminal bronchioles are affected, then more serious changes take place. These are : seepage and retention of exudate in alveoli → leading to bacterial infection → leading to patches of pneumonia during acute exacerbations. All these factors with lack of ciliary function make the airway difficult to get rid of exudate which hinders resolution. Healing takes place by organisation of fibrosis, causing obliteration of small alveoli and bronchioles and leading to obstruction during expiration. Thus, emphysema develops. Chronic bronchitis is most common in industrial areas with high rain fall. In its serious form, it usually occurs in males over the age of 40, but the onset can be dated many years earlier. The prognosis of chronic bronchitis is poor. The death often occurs within 5 years, after the first episode of acute respiratory failure (Figs 31.13A to C).

Emphysema is a condition where there is a permanent increase in the size of air spaces, distal to the terminal bronchiole. With the increase in size of air spaces, there is also destructive changes in the walls of the air spaces. Usually emphysema is of two types: alveolar or centrilobular emphysema and panacinar emphysema. In centrilobular emphysema there is no enlargement of lung. The distension and destruction are mainly limited to the respiratory bronchioles with relatively less changes in the acinus at periphery. So, there is little radiological evidence of emphysema, because the alveolar tissue is normal. These changes are extremely common in normal lungs of persons who are above the age of 50. In panacinar emphysema, where the process is extensive, distension eventually spreads to involve the respiratory bronchiole and the whole acinus. Thus the whole lungs



Figs 31.13A to C: A. Normal lung parenchyma, B. Alveolar emphysema, C. Panacinar emphysema

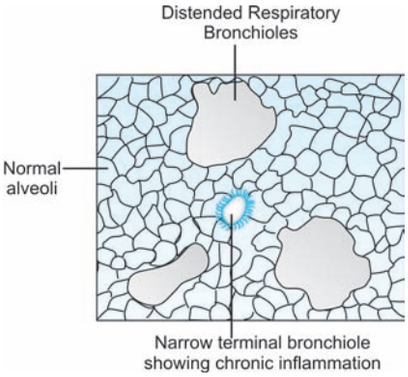


Fig. 31.14: Centrilobular emphysema. Chronic inflammation of the terminal bronchioles is an important feature. In this type of leison there is little radiological evidence of emphysema because the alveolar tissue is normal for a considerable time

become distended with definite radiological findings (Fig. 31.14).

Pathophysiology

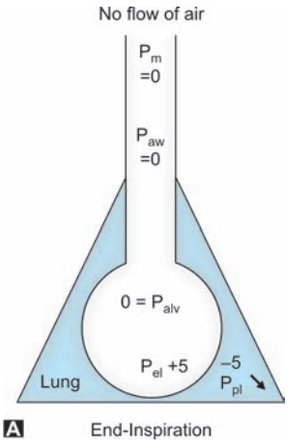
In COLD patients, initially both the chronic bronchitis and emphysema can exist without any evidence of obstruction in airways. But later by the time when a patient begins to experience dyspnoea as a result of these processes, then obstruction is always demonstrable. Thus when the two processes (bronchitis with obstruction and emphysema) are combined, then one process may dominte over the other. The therapeutic improvement of this condition depends on the extent of inflammatory airway disease, the quantitative presence of secretions and bronchospasm. Both the chronic bronchitis and emphysema result in airways narrowing. The airways narrowing in chronic bronchitis is due to inflammation, secretions, hyperactive reflexes, etc. But loss of elastic recoil of the lung in emphysema accounts for a decrease in airway caliber through the loss of radial traction on airways. In both situations (i.e. chronic bronchitis and emphysema) narrowing of airways (abstruction) is often associated with an increase in airways resistance and a diminuation of maximal expiratory flow rates.

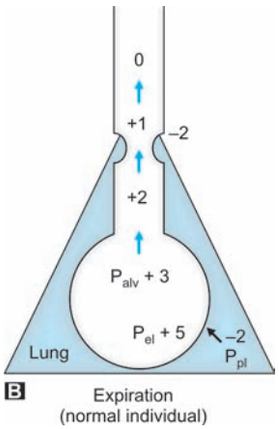
Mechanism of Diminution of Expiratory Flow Rate

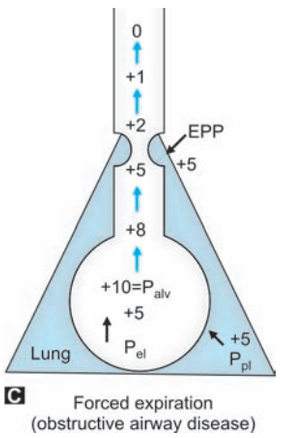
The failure to increase the flow rate by augmented expiratory effort during expiration results from the dynamic compression of airways. This can be described by a point named EPP (equal pressure point). During expiration the pressure head that helps to move the air from alveoli to mouth is provided by the P_{alv} (intra alveolar pressure). At any fixed state of the dynamic process of respiration and at any given lung volume the P_{alv} is the sum of distending P_{pl} (negative intra pleural pressure) and recoiling Pel (lung's elastic recoil pressure). At the end of inspiration, when there is no flow of air, then the P_{alv} becomes zero, i.e becomes equal to the pressure of atmosphere at the level of mouth. At that condition, P_{pl} is maximum subatmospheric (i.e −ve) but equal to and counter balances the P_{el} (which is always +ve). During expiration due to passive reduction of thoracic volume, P_{pl} (intrapleural pressure) becomes less negative and P_{alv} rises. This increased alveolar pressure head gradually decreases along the airway and finally reaches to zero at the level of mouth. When this pressure is gradually decreasing along the airway from alveoli to mouth then at some point on the airway the intraluminal pressure comes to a level that is equal to the surrounding P_{pl}. This point is called as the EPP and airways start to collapse at this level. During normal expiration the P_{pl} does not usually become equal to the intraluminal pressure at any point through out the airway from alveoli to mouth and the EPP never develops and the airway closure usually does not occur. But during forceful expiration P_{pl} rises and sometimes may become +ve. Intra-alveolar pressure (P_{alv}) also rises with forceful expiration, but it is gradually coming down along the airway towards the mouth and at mouth it becomes zero, i.e. equal to the atmospheric pressure. Along the airway when the intraluminal pressure is gradually coming down, then at point situated anywhere on the airway between the alveoli and the mouth the P_{pl} becomes greater than the intraluminal pressure and EPP develops and airways start to close at that site. If the EPP falls on the airway where cartilages are present, i.e. proximal to the eleventh generation of airways, then airways do not collapse. But, if the EPP falls on the airway where there is absence of cartilages, i.e. distal to the 11th generation of airway, then only these airways are vulnerable to collapse. However, EPP is not a fixed point on airway, but a dynamic one. It changes according to different conditions such as P_{pl}, P_{alv} force of expiration, compliance, etc. (Figs 31.15A to C).

In normal lungs airway usually does not close and if closes it occurs first at the basal portion of lungs and in the small airways of 0.5 to 0.9 mm of diameters. In normal healthy lungs airway does not collapse at the end of expiration, because P_{pl} is though high (i.e. less −ve) than begining of expiration but still subatmospheric (or negative). During forceful expiration airways closer occurs first in the basal region because the distending negative or subatmospheric P_{pl} becomes first positive in this region and volume changes during expiration is greater.

Early or premature airway closer and reduction of expiratory flow rate with air trapping in alveoli occurs with slight active expiration in patients suffering from emphysema, bronchitis, asthma, and interstitial oedema. In these four conditions, airway resistance is increased which causes a quick and larger decrease of pressure gradient from alveoli towards mouth. Therefore, it causes potential negative intraluminal and P_{pl} pressure gradient and early collapse of airways with shifting of EPP more towards the alveoli. In addition, the structural intigrity of airways is diminshed due to chronic inflammation and scarring which also causes early closure of airways with shifting of EPP towards alveoli at high lung volumes in the above mentioned diseases. Thus FRC is increased.







Figs 31.15A to C: The concept of EPP (equal pressure point). Also it tries to explain the mechanism of diminuation of expiratory flow during forced expiration.
A. End of inspiration,
B. Expiration in normal individual,
C. Forced expiration in obstructive pulmonary disease.
P_m =Pressure at mouth, P_{aw} = Airway pressure

In COLD patients RV (residual volume) and FRC are almost always higher than normal. Normal FRC is the volume at which inword elastic recoil force of lung is balanced by the outward distending force of chest wall. So the loss of inward elastic recoil property of lung in emphysema results in higher FRC. Again, prolongation of expiration due to obstruction and initiation of inspiration before the respiratory system reaches its static balance point during expiration, causes dynamic increase in FRC. With the increase of RV and FRC due to decreased elastic recoil of lung, total lung capacity (TLC) also increases (Fig. 31.16).

Both the increased airway resistance (due to mechanical obstruction – spasm) and increased lung compliance (due to loss of recoil lung eleasticity – emphysema) is responsible for prolonged expiration and long time constant (which is described later). Prolonged time for expiration signify insufficient time for expiration especially during tachpnoea, and even at normal respiratory rate. So, after every expiration lungs fail to return to their previous FRC. Thus this leads to progressive increase in lung volume which, in turn, push the tidal volume to a higher less compliant portion of the pressure-volume curve and increaes the work of breathing. Intrinsic PEEP (PEEPi) or auto PEEP is a common finding in such patient with chronic airflow obstructive disease. Additionally, hyperinflation of lungs cause flattening of the diaphragm and places it at a mechanical disadvantageous position. This disadvantageous position of diaphragm is due to the length tension relationship of diaphragmatic muscle fibres, the angle of diaphragmatic insertion with the lower ribs and Laplace's law. This is always presented as mismatched ventilation/perfusion ratio. When these mismatches are severe, then the impairment of gas exchange is reflected in the abnormalities of arterial blood gases.

There are some regions of lungs that have deficit of perfusion in relation to ventilation and it increases the wasted ventilation. Alternatively, there are some regions of lungs that have deficit of ventilation in relation to perfusion and it increases the wasted perfusion. Thus, in chronic bronchitis with obstruction and emphysema, there are increase in both the wasted ventilation and wasted perfusion. The resultant effect of this wasted ventilation and wasted perfusion is different for different patients. Some patients at the cost of extremely high effort of breathing and chronic dyspnoea maintain a strikingly increased minute volume which results both in a normal to low artrial PCO_2 and a relativley high arterial PO_2, despite high V_d / V_t and high $P_AO_2 – P_aO_2$ difference respectively. Other patients show only modest increase in minute volume and effort of breathings with less dyspnoea, which results in high

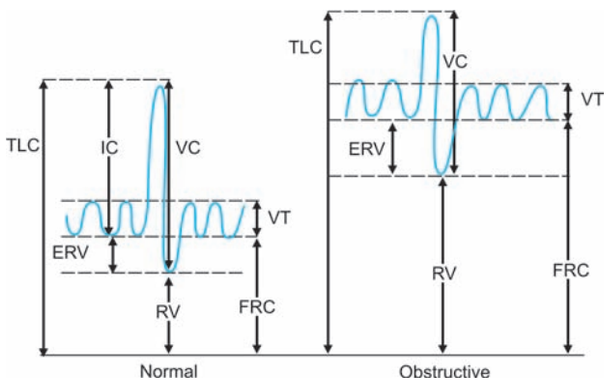


Fig. 31.16: Different lung volumes in spirogram during chronic obstructive pulmonary disease compared with normal values. In the presence of obstructive lung disease, VC is decreased, RV and FRC is increased, TLC is increased, RV / TLC ratio is increased

P_aCO_2 and severly depressed P_aO_2. The explanation behind this patient to patient difference is that the patients who maintain low arterial PCO_2 levels are of highly responsive type and have increased ventilatory drive in response to their high blood gas values. Those who chronically maintain high P_aCO_2 and low P_aO_2 levels have a diminished ventilatory drive in relation to their more severly deranged blood gas values (Table 31.10).

COLD is often associated with mild to severe pulmonary hypertension. Pulmonary hypertension is due to the reduction of total cross sectional area of pulmonary vasculature. This can be attributed to anatomical changes and constriction of vascular smooth muscle in pulmonary arteries and arteriols as well as destruction of alveolar septa with loss of capillaries. The most important is constriction of the pulmonary capillaries in response to alveolar hypoxia and this vasoconstriction is reversible which depends upon the alveolar PO_2.

According to the arterial blood gas analysis, the COLD patients are divided into 'pink puffers' where P_aO_2 is usually higher than 65 mm of Hg and P_aCO_2 is normal to slightly decreased and 'blue bloaters'where P_aO_2 is usually lower than 65 mm of Hg and P_aCO_2 is chronically increased to more than 45 mm of Hg. 'Pink puffers' individuals are typically thin build, free of signs of right heart failure and are usually found to have severe emphysema. On the other hand, 'blue bloaters' typically exhibit excessive cough and sputum production, frequent respiratory tract infections and recurrent episodes of cor pulmonale. In pink puffers, emphysema component predominates over bronchitis with obstruction component. Whereas the blue boaters individual more often meet the criteria of chronic bronchitis with obstruction than emphysema. But the common denominator in all these patients is chronic cigarette smoking. The Blue bloater patients usually develop pulmonary hypertension due to arterial hypoxaemia and respiratory acidosis which evoke pulmonary vasoconstriction. In response to chronic pulmonary hypertension, right ventricular hypertrophy and corpulmonale is developed. Later on right ventricular failure results with jugular venous congestion, peripheral oedema, systemic venous hypertension, etc. Patients with COLD who are characterised as pink puffers experience emphysematous lung destruction leading to loss of pulmonary capillaries as a result of destroyed alveolar walls. The subsequent loss of the pulmonary capillary vascular bed is manifested as decreased diffusing capacity, although the PaO_2 is typically only mildly depressed such that pulmonary vasoconstriction is minimal and cor pulmonale develops only rarely in these patients.

Table 31.10: Classification of COLD

Severity	*Spirometry*	*Symptoms*
Mild cold	FEV_1 60-80% of normal	Cough ± breathlessness on exertion
Moderate COLD	FEV_1 40-60% of normal	Cough + Breathlessness on exertion, ± Wheeze, ± sputum
Severe COLD	FEV_1 <40% of normal	Prominent cough, wheeze and breathlessness

What is time constant?

It is defined as the time taken by the alveoli to reach its final volume if the initial gas flow rate is maintained throughout the inflation. Usually the normal inspiratory time is 1 to 1.5 second. A long inspiratory time increases the mean intrathoracic pressure and reduces the venous return with reduction of cardiac output. On the otherhand, short inspiratory time causes poor distribution of the inspired gases throughout the lungs.

If the airway leading to an alveoli is narrowed and the resistance is increased, then the alveoli will still reach the same volume when inflated at same pressure. But it will take longer time to reach the final volume. Again if the wall of the alveoli is stiffened and compliance is decreased, then the alveoli will also take longer time to reach the final volume when inflated at same pressure. Thus the time constant depends on the resistance and compliance of the system and the relation is:

Resistance × compliance = Time constant

Typical values of resistance and compliance for an anaesthetized patient are 10 cm H_2O/L and 50 ml/cm H_2O (or 0.05 L/cm H_2O). So, the normal time constant is 10 × 0.05 = 0.5 second.

An increase in resistance and decrease in compliance result in longer time constant. Usually 94% of the final volume of lungs reaches within the 3 time constant due to different types of alveoli. This scattering of time constant is exaggerated in some forms of lung diseases such as asthma and emphysema. In such circumstances a short inspiratory time will result in poor ventilation of those zones of lung having a long time constant. Thus there will be a resulting increase in V/Q mismatch (Table 31.11).

Anaesthetic Management of COLD

The anaesthetic management of patients suffering from COLD and waiting for surgery include :

i. preoperative evaluation of pulmonary function – by history, clinical examination, investigation and PFTs (pulmonary function test),
ii. treatment of COLD in the preoperative period to optimise the pulmonary function,
iii. intraoperative management aimed at minimizing pulmonary complications and minimizing residual depressant effects of anaesthetic drugs on respiration post-operatively,
iv. post-operative pain control and pulmonary care to reduce the pulmonary complications.

Table 31.11: Difference between pure chronic bronchitis and emphysema (component of COLD)

Features	*Ch. bronchitis*	*Emphysema*
Airway obstruction (mechanism)	Due to mucus or inflammation	Nil
Cough	Frequent	Very less frequent
Dyspnoea	Less frequent	More frequent
Sputum	Copious	Scanty
P_aO_2	Markedly decrease (blue bloater)	Less decrease (pink puffer)
P_aCO_2	Often elevated (> 40 mm of Hg)	Usually normal or hypo (<40 mm of Hg)
FEV_1	Decrease	Decrease
TLCO	Normal	Decrease
Haematocrit	Increase	Normal
Elastic recoil	Normal	Decrease
Airway resistance	Increase	Normal to slightly elevated
Chest radiograph	Increased lung markings	Hyperinflation
Cor pulmonale	Early manifested	Late manifested
Prognosis	Poor	Good

Preoperative evaluation

Preoperative evaluation of patients with COLD is based on the recognition that perioperative pulmonary complicatoins are of predictable risks, with increased morbidity and mortality due to pneumonia, atelectasis, bronchospasm, acute respiratory failure requiring mechanical ventilation, etc. So the history, clinical examination, investigation and PFT of patients suffering from COLD provide a more accurate assessment of the likelyhood of perioperative pulmonary complications. History and clinical examinations are more important than the PFT and blood gas analysis for assessment of risks and complications. History of exercise intolerance, chronic cough, unexplained dyspnoea, etc. are very important and is directly related to the increased mortality. Decreased breath sound, wheezing and prolonged expiratory phase on clinical examination predict increased risk of perioperative pulmonary complications. However, the value of PFTs done as a routine preoperaitve evaluation of perioperative risk is in doubt. Usually, PFT is taken as a reference point during management and optimisation of pulmonary function in perioperative period, but not as a means to assess the risks. Preoperative lung function tests (PFTs) are also useful tools for assessing the lung functions and responses to the therapy. But these tests do not provide predictive information as to the likelyhood of the rate of postoperative pulmonary complications. This is because, patients defined as high risk by PFT (FEV_1 < 70% of predicted value, FEV_1 / FVC less than 65%, P_aCO_2 > 45 mm of Hg) can undergo surgery with an acceptable risk of perioperative pulmonary complications. Potential risk factors of patients with COLD for development of perioperative pulmonary complications are: smoking, operative site, anaesthetic drugs, advanced age, poor general health, etc.

Smoking increases perioperative pulmonary complications many fold in patient who is suffering from COLD. So, cessation of smoking before operation is advised strictly, although the sufficient time required for reversible changes to occur after cessation of smoking is not correctly known. Operaive site is also the most important predictor of the perioperative pulmonary complications. Upper abdominal and thoracic surgery create the greatest risks. Perioperative pulmonary complications are less likely following operations outside the thorax and the abdomen. Duration of surgery is also an important factor for the development of pulmonary complications. Duration of surgery more than 3 hours increases the risks. Anaesthetic drugs and surgical trauma disrupts the normal activity of respiratory muscles causing persistant decrease in FRC and VC with atelectasis that can last for several days after surgery, leading to increased pulmonary complications.

Preoperative preparations

The preoperative preparations of patients suffering from COLD include:

i. Stoppage of smoking,
ii. Treatment of expiratory outflow obstruction such as bronchospasm,
iii. Eradication of bacterial infection,
iv. Physiotherapy regarding lung volume expansion manoeuvres.

To stop the cigarette smoking is strongly recommended for patients before undergoing elective surgey, as the risk of post-operative pulmonary complications predictably increases many-fold with smoking. Till now the optimal period of abstinence from smoking before elective surgery is not clearly known. But, it is clear that even a brief period of abstinence from smoking improves the oxygen carrying capacity of arterial blood. Because the adverse effects of CO (carbon monoxide) on O_2 carrying capacity of Hb and adverse effects of nicotine on CVS are short-lived. Sympathomimetic effects of nicotine on CVS are transient, lasting for only 20 to 30 minutes. The elimination half-life of CO is 4 to 6 hours. So, the smoke free intervals of at least 12 hours should result in substantial decrease in carboxy haemoglobin levels. Experimentally, it is seen that 12 hours abstinence from smoking increases P_{50} value of Hb (the PO_2 at which Hb is 50% saturated) from 22 to 26 mm of Hg and the plasma levels of carboxy haemoglobin decreases from 6 to 1%. Increased levels of carboxy haemoglobin in blood can cause the pulse oximeter to falsely overestimate the SPO_2 level. Cigarette smoking also causes the hypersecretion of mucus, impairment of mucociliary transport activity and narrowing of the smaller airways. So, abstinence from smoking definitely decreases the sputum production, and improves ciliary action and smaller airway function. But these actions of

recovery occur slowly over period of weeks, after cigarette smoking is stopped. Only the effects of smoking on COHb improves faster with short-term abstinence. It is found that when abstinence from cigarette smoking in longer than 8 weeks, then the incidence of post-operative pulmonary complications decreases significantly.

Smoking also interferes the function of immune system and increases the incidence of post-operative pulmonary infections after anaesthesia and surgery. Return of normal immune function may require at least 6 weeks of abstinence from smoking. Smoking also stimulates the hepatic enzymes which increases the post-operative analgesic requirement. Like immune response, 6 to 8 weeks of abstinence from smoking makes return of the hepatic enzyme to normal level. Cessation of smoking helps to diminish the symptoms of chronic bronchitis. It also helps to eliminate the accelerated loss of lung functions observed in those who continue to smoke. For preoperative preparation of COLD patients, chronic administration of O_2 (2 L/min for few hours per day) is recommended if the P_aO_2 is less than 55 mm of Hg (the goal is to achieve P_aO_2 between 60 to 80 mm of Hg), the haematocrit is more than 55% or there is evidence of cor-pulmonale. Relief of arterial hypoxaemia by administration of O_2 is very effective than any drug in decreasing pulmonary vascular resistance and preventing excessive erythrocytosis with associates increase in blood viscoity.

Preoperative administration of broad spectrum antibiotics is indicated if there is acute episodes of worsening of clinical symptoms which is marked by increased dyspnoea, excessive purulant sputum production, wheezing, etc. Vaccinations against influenza and possibly pneumococcus may be beneficial. If exacerbations of COLD is due to the viral infections of upper respiratory tract, then preoperative antibiotic treatment will not be helpful. Drug induced diuresis may be considered for patients with cor-pulmonale and right ventricular failure (peripheral oedema). Diuretic induced chloride depletion may also result in hypochloremic metabolic alkalosis that depresses the ventilatory drive and may aggravate the chronic CO_2 retention.

Another mainstay of preoperative preparation of patients suffering from COLD is bronchodilation. Though it causes only a small increase in FEV_1 in patients with COLD, but these drugs reduce the symptoms and dyspnoea. Bronchodilators such as mainly β_2-agonist improves exercise tolerance, though there is little improvement in spirometric measurements or values. β_2-agonist also decreases the exacerbation of infections by reducing the adhesiveness of bacteria such as haemophilus influenze with epithelial cells. But anticholinergics are more effective in the treatment of COLD than β_2-agonist which is more effective in the treatment of bronchial asthma.

Another risk reduction strategy during preoperative preparation to decrease the incidence of post-operative pulmonary complications is to initiate the patient's education, regarding the lung volume expansion manoeuvres. Prophylactic lung volume expansion manoeuvres such as deep breathing exercise, incentive spirometry, chest physiotherapy, positive pressure breathing techniques, etc, are of proven benefit for preventing post-operative pulmonary complications in high-risk patients. These physiotherapy of chest reduces the risk of atelectasis, facilitates the removal of secretions from airways and increases the pulmonary functions. The institution of preoperative lung expansion manoeuvers definitely decreases the incidence of perioperative pulmonary complications than if education begins after surgery. Measurement of FRC is the most important lung volume parameter during post-operative period that provides a specific goal of therapy. Positive pressure breathing technique may be of two types—intermittent or continuous. Both are effective in reducing the incidence of perioperative pulmonary complications, but its cost has resulted in decreased usuage. Continuous positive airway pressure (CPAP) is usually reserved for very sick patients who are unable for intermittent positive pressure breathing (IPPB). Another type of positive pressure breathing such as nasal positive airway pressure – also minimises the post-operative reduction of lung volume, incidence of atelectasis and acute respiratory failure.

Intraoperative management

There is no specific drugs or anaesthetic technique for the better management of patients suffering with COLD. During management of COLD patients, always it should be kept in mind that these patients are highly susceptible to the development of acute respiratory failure during intra and post-operative period. Among the general and regional anaesthesia, regional anaesthesia is the mostly desired method. But, unfortunately it is only restricted to the surgeries of lower abdomen and extremities. Because higher RA required for upper abdominal or thoracic surgeries paralyses the more and more intercostal muscles and impairs ventilation in a patient whose respiratory system is already compromised. GA is the usual choice for upper abdominal and intrathoracic operations which are associated with high incidence of pulmonary compilations. There is some debate or controversies between the incidence of pulmonary complications and duration of anaesthesia. But the general aggreement is that operation and anaesthesia lasting longer than 3 hours are more likely to be associated with pulmonary complications. So, where there is chance of post-operative respiratory failure, tracheal intubation and mechanical ventilation should be continued post-operatively. Alternatively, post-operative epidural analgesia by narcotics or local anaestheics permit painfree breathing which allows early tracheal extubation and decreased systemic analgesic requirement with their associated depressant effects on ventilation and consciousness.

When GA is applied, then volatile anaesthetic agents, proper humidification of inspired gases and mechanical ventilation

are the cornerstones of technique. Intraoperative use of volatile anaesthetic agents is more preferable than narcotics because of the patient's ability to eliminate these drugs rapidly through the lungs and thus minimising the early post-operative residual respiratory depression and pulmonary complications. Moreover, the volatile anaesthetic agents cause bronchodilatation which has a distinct advantage over narcotics. The narcotics or opioids are less useful for COLD patients, because of their prolonged depression effects on ventilation.

COLD patients are often associated with emphysema. So, one should use N_2O carefully. Because it will diffuse in the pulmonary bullae which is commonly associated with emphysema and can lead to enlargement and rupture resulting in the development of tension pneumothorax during anaesthesia. The another disadvantage of administration of N_2O is that it limits the concentration of inspired O_2. Inhaled volatile anaesthetic agents attenuates hypoxic pulmonary vasoconstriction. This hypoxic pulmonary vasoconstriction is beneficial for maintenance of arterial oxygenation in nonanaesthetised patient by shifting the blood from hypoxic to nonhypoxic zone. But as the volatile anaesthetic agents attenutes this hypoxic pulmonary vasoconstriction, so its beneficial effect is lost and thus increase the degree of right to left intrapulmonary shunt. So, increased inspired concentration of O_2 is necessary to off-set this anaesthesia induced pulmonary changes, which can be hindered by the use of N_2O.

Intubation which bypasses nearly the entire natural airway humidification system and high flows of dry anaestheties gases greatly intensify the need for humidification of dry inspired gases to prevent drying of secretions in airways. The systemic dehydration due to inadequate fluid administration during the perioperative period also can result in excessive drying of secretions in the airways despite humidification of inhaled gases. Controlled ventilation is useful for COLD patients receiving GA. During controlled vantilation, large tidal volume (10 to 15 ml/kg) combined with slow inspiratory flow rates and low breathing rates (<10 breaths/minute) maintains the optimum ventilation-perfusion ratio.

Low breathing rates helpes by:

i. allowing complete expiration and preventing air trapping which is characteristic of COLD patients,
ii. preventing hyperventilation which causes more reduction of P_aCO_2,
iii. increasing venous return,
iv. reducing the likelihood of turbulent flow in airways.

PEEP should be avoided as a ventilatory mode in COLD patients, because it affects the expiratory flow. But large tidal volume, slow inspiratory flow and low breathing rates act as alternative to and as effective as PEEP. If any time high positive airway pressure is required to provide adequate ventilation and proper oxygenation of blood, then pulmonary barotrauma and rupture of emphysematous bullae should be kept in mind. During spontaneous ventilation of COLD patients, ventilatory depression by volatile anaesthetic agents should be observed carefully, because depression of respiration produced by narcotics and other anaesthetic agents are more sensitive than normal individual. So, whatever may be the ventilatory mode, arterial blood gases, pH, SPO_2 and $ETCO_2$ should be maintained at normal level.

The risk of pulmonary complication is often viewed as less, following surgery performed under regional anaesthesia. But, regional anaesthesia technique that produces sensory block above T_7 level are not recommended, as this high level leads to decrease in expiratory reserve volume. In turn, this decreased expiratory reserve volume causes impairment of cough which leads to reduction in clearance of secretions from airways. Also block above T_7 level produces a feeling of suffocation and uneasiness requiring sedation which further depresses the respiration. But different types of nerve blocks, field blocks, infiltration anaesthesia, etc. carry much lesser risks than epidural or spinal anaesthesia. Nevertheless, the regional anaesthesia remains a useful selections in patients with COLD only when large doses of sedative drugs are not given, because such patients are extremely sensitive to the ventilatory depressant effects of sedative agents.

Post-operative care

The aim of post-operative care of COLD patients is to reduce the incidence and the severity of post-operative pulmonary complications. This can be achieved by lung volume expansion exercise, analgesia preferably by neuraxial approach and mechanical ventilation, if needed for respiratory failure. It is stated previously that post-operative complications are greatest following upper abdominal and intrathoracic surgery. This is documented from the data that following upper abdominal surgery, the VC decreases about 40% from the preoperative value on the first post-operative day which does not return to preoperative level for next 10 to 15 days and FRC does not decrease to normal level in first 24 hours. Astonishingly, it is also found that complete analgesia does not restore VC and FRC to the preoperative levels which suggests that surgical trauma is the main determinant factor for diminution of VC and increase of FRC. Altered VC and FRC are the main responsible factors for decrease in P_aO_2 and increase in P_aCO_2 in the immediate post-operative period than the depression of ventilation by narcotics, inhalational anaesthetics, anaesthesia induced impair regional hypoxic pulmonary vasoconstriction and anaesthesia induced dimination of ventilatory responses to CO_2 and hypoxia. The incidence of post-operative pulmonary complications, however, is dramatically less after laparoscopic cholecystectomy than after open cholecystectomy.

BRONCHIECTASIS

Bronchiectasis is a chronic suppurative airway disease with focal or diffuse abnormal

permanent dilatation of bronchi and airway obstruction during expiration like COLD. It is either congenital, caused by the genetic factors, e.g. cystic fibrosis or acquired following damage to the lower respiratory tract, especially during severe early childhood infection. Most patients suffering from bronchiectasis have a chronic productive cough which may present throughout the year, despite the wide-spread availability of broad spectrum antibiotics. In bronchiectasis there is frequently a component of asthma associated with chronic inflammatory changes in the airways. It often affects the lungs at the segmental or subsegmental level. The focal bronchiectasis involves the airways supplying a limited region of pulmonary parenchyma, but diffuse bronchiectasis involves a wide spread area of lungs (Figs 31.17A and B).

The dilatation of bronchi is due to the destructive (destruction of cartilage, muscles and elastic tissue) and inflammatory changes, mainly of the walls of the medium sized airways. Thus, the dilated airways frequently contain the pools of thick and purulent material, while distal portion of it is often occluded by this secretions and is replaced by fibrous tissue. The lung parenchyma supplied by the affected airways also contains varying combinations of fibrosis, emphysema, pneumonia and atelectasis. The affected bronchial wall becomes highly inflamed and vascular with associated enlargement of bronchial arteries, causing sometimes severe haemoptysis.

Aetiology of bronchiectasis may vary from:

i. infective → by microorganisms,
ii. noninfective → due to exposure to toxic substances,
iii. obstructive → due to foreign bodies,
iv. impaired host defence mechanism → by immunoglobulin disorders causing panhypogammaglobulinemia,
v. ciliary dysfunction→ primary ciliary dyskinesia, Kartagener's syndrome and cystic fibrosis.

Whatever may be the aetiology of bronchiectasis, the infection of airways by microorganisms is the cornerstone of its pathology. Once the disease process is established, the bacterial infection can be difficult or impossible to eradicate. Pseudomonas aeruginosa is the most common pathogen that may be present for many years and be associated with intermittent exacerbations of respiratory symptoms. At the pathological site the microorganisms produce pigments, proteases and other toxins that injure the respiratory epithelium and impair mucociliary clearance. Again as a result of infection the inflammatory response of host induces epithelial injury, largely as a result of mediators, released from neutrophils. On the other hand, as protection against infection is compromised (in immunoglobin disorders patient), so the dilated airways become more and more susceptible to colonization and growth of bacteria. Thus, a reinforcing vicious cycle can result with again and again infection and inflammation, producing further damage, impaired clearance of microorganisms and further infection which then completes the cycle by inciting more inflammation.

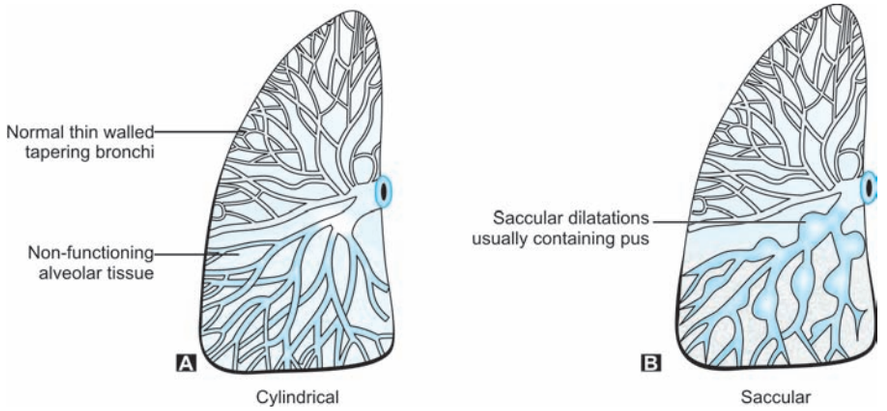
Anaesthetic management of patients with bronchiectasis invokes the same principles as outlined for patients with COLD. Prior to elective surgery, status of pulmonary function of patients should be optimized by appropriate therapy.

Preoperative therapy for bronchiectasis includes:

i. elimination of an identifiable underlying causes,
ii. improving the clearance of tracheobronchial secretions,
iii. control of infections, particularly during acute exacerbations,
iv. reversal or removable of airflow obstruction.

Appropriate treatment for bronchiectasis should be instituted when a treatable cause is found. For example:

i. If cause is the foreign body, it should be removed
ii. Acute infection should be controlled by antibiotics, guided by Gram's stain and culture of sputum
iii. Treatment of hypogammaglobulinemia by immunoglobulin
iv. Treatment of tuberculosis with antitubercular agents and allergic bronchopulmonary aspergillosis (ABPA) with glucocorticoids.



Figs 31.17A and B: Bronchiectasis means a permanent dilatation of one or more bronchi. The main bronchi upto 4th division possess large supporting cartilage rings. So, bronchiectasis only affects the bronchi beyond this point. Two main anatomical varieties of bronchiectasis are described. But, these may have similar causes and frequently both are found in the same lung.
A. This type of bronchiectasis is almost always found in the lower lobes. The bronchi are grossly dilated throughout their whole length. Intervening lung tissue is much reduced and much of it is fibrosed.
B. In this type of bronchiectasis, as the name suggests, the dilatations of bronchi tend to be more localised and exaggerated. They are roughly rounded and may be single or multiple.

In bronchiectasis due to cystic fibrosis, there is also malabsorption syndrome and it is due to pancreatic insufficiency. So appropriate advice regarding the diet and pancreatic supplements are essential. In cystic fibrosis induced bronchiectasis the secretions are typically copious and thick and contribute to the symptoms. Chest physiotherapy by chest percussion, vibrations or postural drainage frequently help the patients with copious secretions. Mucolytic agents to produce thin secretions and to allow better clearance are controversial. Antibiotics have an important role in the preoperative management of bronchiectasis. But which antibiotics should be given and the frequency and duration of administration are not well- established. When patients present with frequent exacerbation of infection, characterised by an increase in quantity and purulence of the sputum, then antibiotics are commonly used. Although, antibiotic should be choiced by culture and Gram's stain of sputum, but empiric coverage is often given initially. When *P.aeruginosa* is suspected, the appropriate treatment is oral quinolone or parenteral aminoglycosides or third generation cephalosporin. In patients with chronic purulent sputum, despite short course of appropriate antibiotic therapy, more prolonged course or intermittent but regular courses of a single or rotating simple antibiotics have been used. Bronchodilators are particularly useful in patients with airway hyperreactivity and reversible airflow obstruction. It improves the obstruction and aids the clearance of secretions. The intraoperative anaesthetic management of bronchiectasis is same as COLD. But only the especial point is that double lumen endobronchial tube may be used in severe cases and it is to prevent the spillage of purulent sputum into the normal areas of lungs.

RESTRICTIVE LUNG DISEASES (RLD)

Restrictive lung diseases are conditions where the total lung capacity (TLC) is reduced. It may be of two types, intrinsic and extrinsic. In intrinsic variety of restrictive lung disease (IRLD), there is alterations of the elastic properties of lungs, causing the lungs to be stiffed. Again IRLD may be of acute and chronic. The example of acute IRLDs are : ARDS, pulmonary oedema, aspiration pneumonitis, etc. The examples of chronic IRLDs are : sarcoidosis, silicosis, asbestosis, eosinophilic granuloma, extensive pulmonary fibrosis, etc. Initially in chronic IRLD there is an inflammatory reaction in response to different stimuli which is centered on the alveoli, impairing gas exchange. Then over a period of time which can vary from days to years, collagen fibres are formed in and around the alveoli causing more marked impairment of gas exchange and smaller, stiffer lungs. Then, pulmonary fibrosis is the final response of lung. The causes of these stimuli include those which are associated with autoimmune disorders (e.g rheumatoid arthritis, scleroderma), inhaled dusts (e.g asbestos) or ingested substances, especially drugs (e.g amiodarone, chemotherapy agents, etc.). Allergic response to inhaled substances can also cause fibrosis and chronic IRLD if exposure is prolonged.

The extrinsic variety of restrictive lung disease (ERLD) reflects the disorders of chestwall (obesity, flail chest, deformity such as severe Kyphoscoliosis, etc.); pleura (pleural effusions, pneumothorax, etc.), mediastinum (mediastinal mass), etc. Intra-abdominal pressure changes producing significant splinting of the diaphragm and small group of neuromuscular disorders where lung movement is restricted from outside are also the examples of ERLD.

The pathology of restrictive lung diseases are:

i. In RLD vital capacity is decreased (normal VC is 70 ml/kg). But, in contrast to obstructive lung disease the expiratory flow rate in RLD remains normal. So, FEV_1 remains normal and the ratio of FEV_1:FVC is preserved in restrictive lung disease. While in obstructive lung disease the ratio of FEV_1:FVC is reduced.
ii. The patients with restrictive lung disease like obstructive lung disease also complain of dyspnoea, reflecting the increased work of breathing which is necessary to expand the poorly compliant lung.
iii. Tidal volume decreases in restrictive lung disease. So, to compensate this reduced tidal volume respiratory rate increases. Despite the increase in respiratory rate, the alveolar ventilation decreases which produces proportionate increase in P_aCO_2 and decrease in P_aO_2 (Fig. 31.18).
iv. Resulting hypercarbia and associated hypoxia causes vasoconstrictive pulmonary hypertension and corpulmonale.
v. The intrinsic and extrinsic varieties of restrictive lung disease can be differentiated from each other by the measurement of elastic properties of lungs. Elastic properties of lungs can be quantitated by measuring the lung compliance which is defined as the change in volume of lung per unit change in pressure. The compliance of normal lung is 0.1 to 0.2 L/cm of H_2O, whereas in patients with intrinsic restrictive lung disease, the compliance comes down to as low as 0.02 L/cm of H_2O. The flow-volume curves are shifted downwards and to the right in patients with increased lung stiffness (Fig. 31.19).

The anaesthetic management of restrictive lung diseases includes preoperative diagnosis, assessment of the severity of impairment of lung function and treatment of the reversible components. A preoperative history of dyspnoea that limits the day-to-day activity and that can be referred to restrictive lung disease may be taken as an indication for the performance of PFTs and measurement of arterial blood gases, in additon to the routine investigation such as X-ray, CT-scan, etc. for the diagnosis

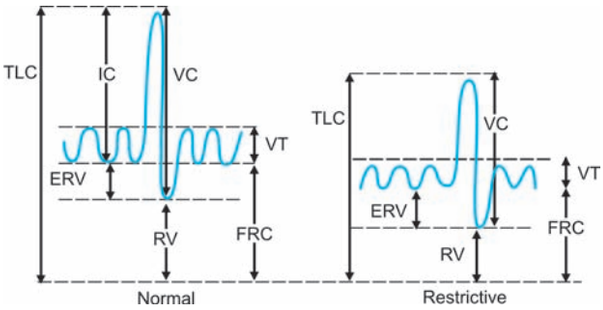


Fig. 31.18: Lung volumes in restrictive lung disease compared with normal values. In the presence of restrictive lung disease TLC, FRC, RV and VC are all decreased.

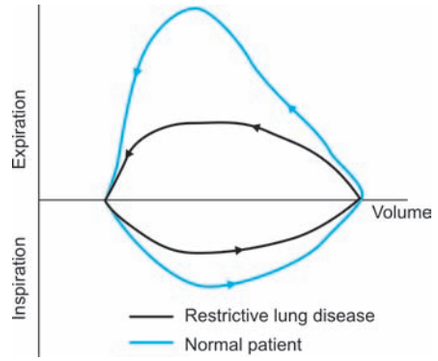

Fig. 31.19: Schematic representation of flow-volume loop in a normal patient (green line) and in the presence of a restrictive lung disease (red line)

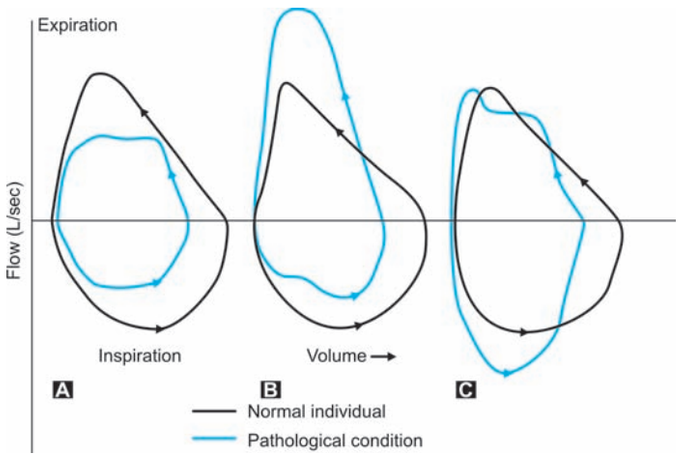
of RLD. Restrictive lung diseases should be differentiated from obstructive lung diseases by the analysis of PFTs and flow-volume loop. If VC is reduced to < 15 ml/kg (where normal value is 70 ml/kg) and resting P_aCO_2 rises than normal, then there is more chance of developing exaggerated perioperative pulmonary complications. Like COLD and bronchiectasis, the preoperative preparations of RLD also include: eradication of pulmonary infections, improved sputum clearance, treatment of cardiac dysfunction, exercise to improve the strength of breathing muscles, and other specific treatments like the drainage of pleural effusion, management of pneumothorax, etc. If there is mediastinal tumour, then the size and the degree of tracheal compression by the tumour should be assessed by CT scan or MRI. The prediction of tracheal compression by tumour mass is a useful assessment for difficult airway management. So, in such circumstances flexible fiberoptic laryngoscope/bronchoscope under topical anaesthesia is a good preoperative method for evaluating the airway obstruction. A number of asymptomatic patients have developed unexpected airway obstruction during anaesthesia without any previous warning (Figs 31.20A to C).



Figs 31.20A to C: Different flow-vloume loops in different conditions
A. Flow-volume loop in fixed obstruction
B. Variable extrathoracic obstruction
C. Variable intrathoracic obstruction

Without bronchospasm, the presence of restrictive lung disease does not influence the choice of drugs for induction and maintenance of anaesthesia. During induction and maintenance of anaesthesia, a high index of suspicion for the presence of pneumothorax and the need to avoid or continue with N_2O must be assessed. Intraoperative controlled ventilation is prudent for optimal oxygenation of patients with RLD due to their poorly compliant lungs and as sometimes high inflation pressure is needed to inflate the low compliant lungs. Regional anaesthesia is suitable for lower abdominal operations or surgeries on extremities, but sensory block should be kept below T_7 to T_{10} level, above which level regional block is associated with impairment of the respiratory muscle activity which is necesssary to maintain acceptable amount of ventilation and oxygenation. Tracheal tube must not be removed until the patients have met established criteria for extubations. Post-operative respiratory depression should be avoided by proper selection of intraoperative narcotics and sedative drugs. Post-operative pain is best managed by epidural analgesia.

Lung Cyst

These are fluid or air-filled cyst, located in the pulmonary parenchyma or adjacent to the tacheaobronchial tree. They may be asymptomatic or may be the site of recurrent pulmonary infections or may be the cause of life-threatening airways obstruction. The anaesthetic interests of the lung cyst are: the use of N_2O and the use of positive pressure ventilation. N_2O usually diffuses into the cyst and causes its expansion leading to rupture and life-threatening respiratory/cardiovascular decompensation due to pneumothorax. Institution of positive pressure ventilation may have a ball value effect causing expansion of cyst and compression of lung parenchyma or rupture leading to pneumothorax. Despite all these concerns, clinical experience confirms that N_2O, muscle relaxant induced skeletal paralysis and IPPV may all safely be utilized in patients with lung cyst.

32 Liver Diseases and Anaesthesia

INTRODUCTION

Liver is the largest gland of our body. It consists of both an exocrine or excretory and endocrine or secretory parts. The exocrine part of liver excretes bile which is conveyed by the biliary passages into the deodenum. On otherhand, the endocrine part of the liver liberates some useful chemical sustances such as glucose (from glycogen), ketone bodies, fatty acids, plasma proteins (except the immunoglobins), heparin, etc. directly into the blood stream. In addition, cholesterol which is secreted by the liver presents the cyclo-pentinoperhydro-phenanthrene nucleus for the synthesis of different steriod hormones. Liver is also involved in the various metabolic activities of all the nutritional substances of our body such as carbohydrate, proteins, lipids, vitamins and minerals, etc. These metabolic acitivities dissipate much heat and thus the liver subserves an important function for the regulation of body temperature.

The liver is a wedge-shaped organ with a broad base, directed to the right and a narrow apex, directed to the left. It occupies the whole of the right hypochondrium, upper part of the epigastrium and a part of the left hypochondrium upto the left lateral plane.

The weight of a liver in an adult person is approximately 1.4 to 1.8 Kg (average 1.5 Kg) and that in a newborn is approximately 150 gm. It is relatively larger in children than an adult. This is due to its increased haematopoietic function during fetal life and occupies about 2/5th of the abdomen. The weight of a liver represents 2% of the total body weight in adults and almost 5% of the total body weight in neonates. The liver is a highly vascular organ and so also acts as a reservoir of blood. When it is ruptured then bleeding continues, because the hepatic veins are unable to collapse as it is directly attached to the plate of liver cells. The liver cells undergo rapid mitosis and regeneration when a part of this organ is removed. Surgical removal of 2/3 of a liver may be compatible with life. But the disorganised growth of the liver cells during regeneration after degeneration or removal of a part of it or in cirrhosis is detrimental and culminates into portal hypertension. Patients with liver disease, undergoing anaesthesia and surgery, face a number of significant intraoperative and postoperative complications. This is because liver disease can alter the patient's response to anaesthesia and surgery in many ways which is discussed later. Thus, it is important to understand the applied anatomy and physiology of liver, factors altering the hepatic blood flow, details of liver functions, alter pharmacokinetics and pharmacodymnaics of anaesthetic drugs due to liver disease, etc. for proper perioperative management of these group of patients.

MACRO- AND MICROANATOMY OF LIVER

The outer surface of a liver is lined by a serous coat, which is derived from the visceral peritoneum. Beneath this serous coat there lie a thin layer of connective tissue, known as the Glissons capsule and it encloses the entire organ. It also extends into the interior of the liver as numerous branching septa and trabeculae. The radicles or branches of portal vein, hepatic artery and bile duct run together within these septa, ensheathed by the Glisson's capsule, in the form of portal triads (also called portal canals or portal tracts). On the otherhand, the hepatic veins and their tributaries, called the central vein from where the hepatic vein starts and draws the blood from liver to inferior vena cava run independently. They are not ensheathed by Glisson's capsule, but is surrounded by the laminae of hepatic cells (Fig. 32.1).

Conventionally, the liver is imagined to be composed of regular lobules. Each lobule is arranged around a central vein with portal tracts at the periphery. Thus, each hepatic lobule consists of hexagonal mass of liver cells and measures about 1 mm in width. The central vein which is a tributary of hepatic vein occupies the central axis of each hepatic lobule. Portal triads or portal canals, covered by Glisson's capsule are found in the interlobular spaces

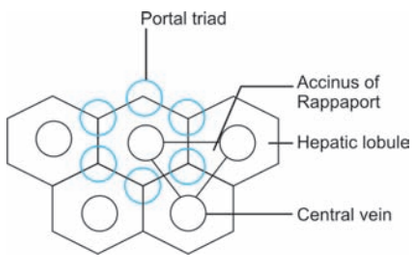


Fig. 32.1: Schematic anatomy of liver

i.e. at the meeting place of three adjacent liver lobules. Therefore, in a typical case six portal triads or portal canals are found at the periphery of a hexagonal liver lobule. The blood vessels and bile ductules of the portal canals give rise to a number of terminal branches. They arise at right angles to them and pass transversely along the sides of the two adjacent liver lobules.

The liver cells are arranged and radiate outwards as multiple sheets or plates from the central vein. These sheets or plates of hepatic cells are called the hepatic laminae. At the periphery of each lobule these multiple lamina joins together with one another and form an another plate of liver cells, called the limiting plate. The spaces between the multiple laminae or the sheets of hapatic cells are known as the hepatic lacunae which are occupied by hepatic sinusoids. These hepatic sinusoids receive a mixture of blood from both the portal vein (coming from intestine) and hepatic artery (branch of coeliac artery). The limiting plates which surround or make the periphery of each hepatic lobule presents numerous perforations. Through these perforations passes the branches of the portal vein and hepatic artery and opens into the sinusoids. After providing nutrition and O_2 to the liver cells, the blood of the sinusoids drain into the central vein. Then the central veins from the adjacent lobules join together to form the hepatic veins which finally drain into the inferior vena cava. Truely speaking, each liver lobule centered around a central vein is neither a structural nor a functional unit of liver. It is infact an independent venous unit and includes the area of liver whose venous blood drains into a particular central vein.

The sinusoidal walls (or hepatic laminae) are also fenestrated and communicates with one another by some holes, through which blood passes freely. among each other The sinusoidal walls are also lined by flattened endothelial cells. Stellate shaped Kupffer's cells, derived from the bone marrow are attached to these endothelial cells. These Kupffer's cells are actually mobile macrophages and capable of phagocytosing foreign particles, bacteria and denatured proteins. They also scavenge the breakdown products of RBCs and have an important role in the metabolism of drugs and intermediary metabolites. Along with the Kupffer's cells, there are also Pill cells which are highly mobile lymphocytes. They act as defence against virus, other infective agents and tumour cells. At the peripheral end of the sinusoids, i.e. at the periphery of hepatic lobule where the hepatic arterioles and portal venules enter, there pressure of the portal venule is about 8 to 10 mm of Hg and that of the hepatic arteriole is about 90 mm of Hg. Whereas the central veins maintain a pressure of about 5 mm of Hg or less. Inspite of this pressure differences between the portal vein and the hepatic artery, the sinusoids convey a mixture of blood from both the vessels. This is because the sinusoids act as a huge vascular reserver like sponge with intersinusoidal communication through multiple fenestretion and damp down any gradient of vascular pressure. Thus, any disease of liver, reducing the capacity of this vascular sponge, produces portal hypertension. Thereafter any small changes in hepatic venous pressure result in massive fluid transudation as the lymph and subsequent leakage of it into the outer surface of the capsule and into the peritoneal cavity. This fluid contains 80 to 90% of protein (Fig. 32.2).

The walls of the sinusoids which are made by hepatic lamina are covered by endothelial cells. Between the endothelial cells and the hepatic cells of lamina there exists a potential space known as the space of Disse. This space is filled with plasma and chylomicrons which percolate from the blood of the sinusoids into the space of disse and then enter the liver cells. Liver cells manufacture plasma proteins (except immunoglobin) and this is delivered directly into this space of Disse and from there into the sinusoidal blood. Moreover, chylomicrons are taken up by the liver cells from the space of Disse and are converted into lipoproteins. These are then again subsequently delivered into the circulating blood of the sinusoids through the space of Disse. The space of Disse also contain Ito cells. These Ito cells secrete a collagenous matrix, named proteoglycans which provides growth factor for the regeneration of the damaged liver cells and their subsequent reorganisation as hepatic laminae. It also replaces the defunct liver cells with collagen fibres (as found in cirrhosis) and store the fat-soluble vitamin A in their lipid vesicles (Fig. 32.3).

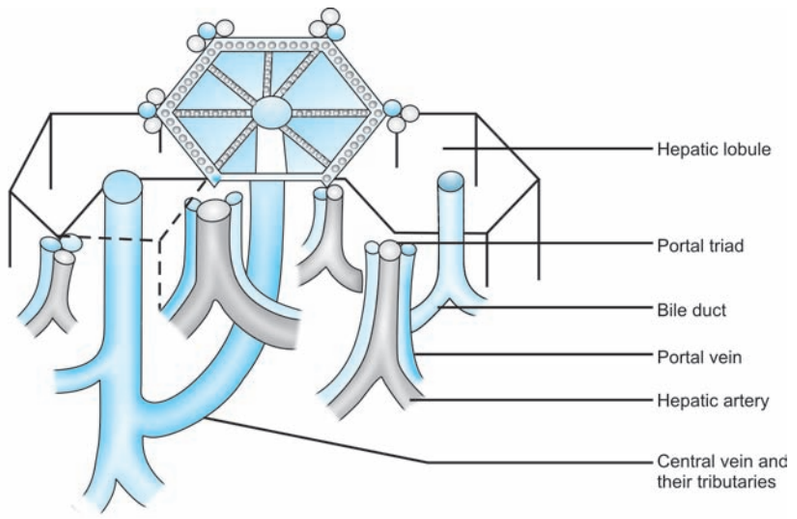

Fig. 32.2: Vascular anatomy of liver

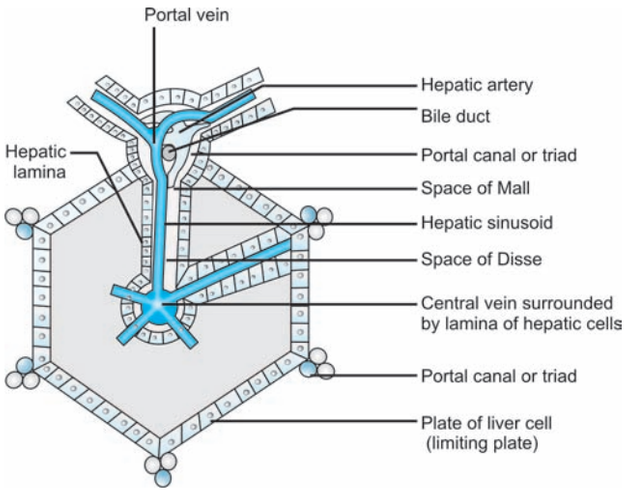

Fig. 32.3: Structures of hepatic lobules

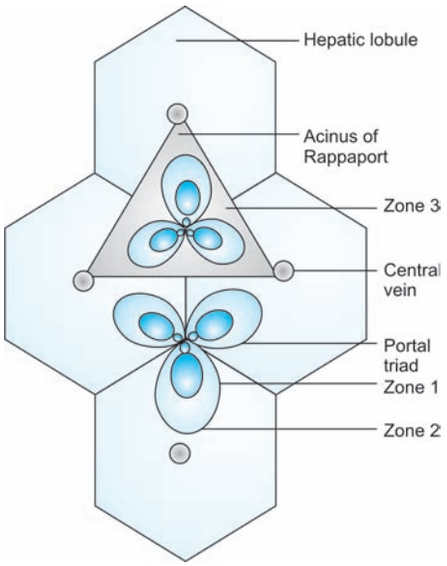

Fig. 32.4: Structural unit of liver

Between the Glisson's capsule of the portal canal and the plate of hepatic cells, around the Glisson's capsule there exist another set of potential space, called the space of Mall. At the periphery of the liver lobule the space of Disse is continuous with the space of Mall. The lymphatics of the liver begin in the space of Mall as blind radicles. During excess accumulation of plasma in the Disse's space, it is reabsorbed by the lymphatics of the space of Mall (Fig. 32.4).

The individual liver cell is roughly cuboidal in shape and presents with six surfaces. Out of these six surfaces, two surfaces are related to the blood of sinusoids and the remaining surfaces are surrounded by the polygonal network of bile canaliculi. Actually, these bile canaliculi are not the separate channels, but they are formed by the separation of plasma membranes of the adjacent liver cells. Numerous microvilli project into the walls of these bile canaliculi from the liver cells and increase the surface area of its secretion, through which the liver cells can secrete more bile. The liver cells take up the lipid soluble unconjugated serum bilirubin from the blood of sinusoids through the space of Disse and then deliver the water soluble conjugated bilirubin glucuronide into the bile with the help of an enzyme named glucuronyl transferase. The borders around the bile canaliculi are sealed by the tight junctions of cell membrane between the adjacent hepatocytes, and prevent the bile from entering the intercellular spaces of the liver, the space of Disse and the blood of sinusoids. Thus this forms the blood-bile barrier network of bile canaliculi. Bile after flowing through the canaliculi ultimately passes to the periphery of the hepatic lobules and drain into the bile ductules of the portal canal. Thus the bile canaliculi are intralaminar and centrifugal in direction, whereas the hepatic sinusoids are interlaminar and centripetal in direction (Fig. 32.4).

A new concept of functional structure of liver is now in use. According to this new concept the functional hepatic unit is called the acinus of Rappaport. It is an area of liver tissue centered around a portal triad and is drawn by joining the central veins of three adjacent liver lobules. The centre of the acinus of Rappaport is formed by the portal triad consisting of the portal vein, hepatic arteriole, biliary ductule, nerve fibre and lymphatics. This area of the acinus of Rappaport gets nutrition and O_2 from the radicles of portal vein and hepatic arterioles. Bile is collected in the bile ductule of the aforesaid portal canal. Blood flows perpendicularly from the portal triad through the sinusoids to the central vein. Each of these transverse vessels and ductules form the backbone which provides nutrition to and collect bile from an unit area of liver parenchyma which is known as the acinus of Rappaport. This acinus of Rappaport forms the structural and metabolic unit of the liver. In terms of supply of O_2 and other nutrients, an acinus of Rapport is subdivided into three zones. The most inner zone (zone-1) which is situated just around the portal triad, receive the blood with highest O_2 saturation and show maximum metabolic activity. They are thought to be involved in protein anabolism and catabolism. The intermediate zone (zone-2) being intermediate in position is moderately oxygenated. The outer zone (zone-3), which is situated close to the central vein is least oxygenated and most susceptible to anoxic injury. This site is responsible for drug biotransformation (Fig. 32.5).

BLOOD SUPPLY AND NUTRITION OF LIVER

Under normal resting conditions, the total hepatic blood flow is approximately 1500 ml/min or 1 ml/gm (of liver tissue) /min. Out of this, about 1200 ml of blood is

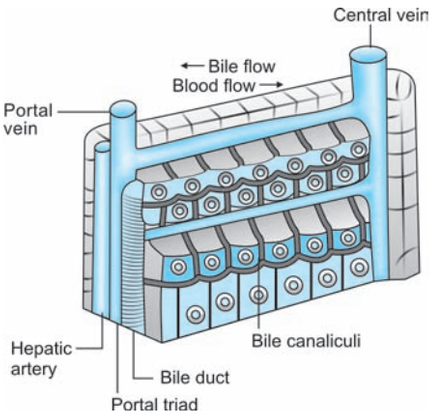

Fig. 32.5: Metabolic unit of liver

derived from the portal vein at a pressure of about 8 to 10 mm of Hg. The hepatic artery circulates blood at a pressure of about 100 mm of Hg and supplies about the remaining 300 ml of blood to liver tissues per minute. The total blood flow in a liver per minute represents about 25% of the total cardiac output. Liver receives 20% of its blood supply and 30% of its O_2 supply from the hepatic artery. On the otherhand, it receives 80% of its blood supply and 70% of its O_2 supply from the portal vein.

The hepatic arterial blood contains about 19 ml O_2 per 100 ml (95% saturated) and hepatic venous blood contains about 13.4 ml O_2 per 100 ml. So, the hepatic arteriovenous oxygen content difference is about 5.6 ml/100 ml. The portal venous blood contains about 17 ml O_2/100 ml (85% saturated) and the 'portal vein – hepatic vein' O_2 difference is 3·6 ml per 100 ml. Hence, 300 ml of hepatic arterial blood supplies 3 × 5.6 = 16.8 ml O_2 per minute of the liver's requirement. Likewise, 1200 ml of portal venous blood supplies 12 × 3.6 = 43.2 ml O_2 per minute of the liver's requirement. Thus total O_2 usuage of the liver is 43.2 + 16.8 = 60 ml per minute, of which about 70% is supplied by the hepatic portal system and 30% is supplied by the hepatic arterial system. Before entering the liver, the hepatic artery and portal vein divide into right and left branches. Within the liver they divide and redivide to form the segmental and

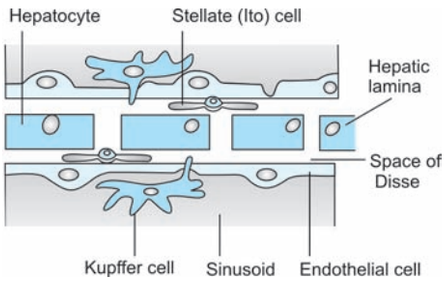

Fig. 32.6: Hepatocyte and hepatic lamina

then interlobular branches which run in the portal canals or triads. The further ramifications of these interlobular branches open into the hepatic sinusoids. The sinusoids are the hepatic capillaries bounded by the two hepatic laminae and formed by the merging of the hepatic artery and the portal vein. Thus the hepatic arterial blood mixes with the portal venous blood in the sinusoids. There are no anastomoses among the tributuries of the hepatic artery and hence each hepatic arterial branch is an end artery (Fig. 32.6).

VENOUS DRAINAGE, LYMPHATIC DRAINAGE AND NERVE SUPPLY OF LIVER

Hepatic sinusoids drain into the central veins (interlobular veins) which then subsequently join to form the sublobular veins. These sublobular veins again reunite to form the hepatic vein which ultimately drain directly into the inferior vena cava.

Liver lymph is rich in protein. Lymphatics of the liver begin blindly around the portal canals in the spaces of Mall. Probably the liver lobules are devoid of lymph capillaries and the interstitial fluid of the lobules reaches the lymphatic radicles via the spaces of Disse and spaces of Mall. In obstruction of hepatic veins the flow of the liver lymph increases. The lymphatic network of liver consists of two sets – superficial and deep. The superficial lymphatics net work run on the surface of the liver, beneath the visceral peritoneum and terminate into the caval, hepatic, paracardial and coeliac lymph nodes. The deep lymphatic net work partly end in the nodes around the end of the IVC and partly in the hepatic nodes.

The liver receives its nerve supply from the hepatic plexus. It enters the liver through the porta hepatis and contains both the sympathetic and parasympathetic fibres. The sympathetic fibres are derived from the branches of coeliac plexus and the parasympathetic fibres are derived from both the right and left vagus and right phrenic nerve.

REGULATION OF LIVER BLOOD FLOW

Liver blood flow is regulated by two mechanisms: Intrinsic and Extrinsic.

Intrinsic Mechanism of Regulation

The intrinsic mechanism for regulation of blood flow in liver does not depend on the nerves or any blood borne vasoactive compounds. It is operated mainly by three mechanisms: autoregulation, metabolic regulation and hepatic arterial buffer response.

Autoregulation

It causes local regulation of blood flow in the liver and maintain a constant pressure of hepatic artery and its branches in spite of the wide range of changes. This is also called the local pressure-flow autoregulation. It is probably performed by the hepatic arterial vasoconstriction and dilatation and is due to the myogenic response of arterial smooth muscle to stretch, imposed by increased arterial perfusion pressure. It is mainly found in the metabolically active (i.e. postprandial) liver, but not in the fasted liver. Unfortunately, as anaesthesia and surgery is performed under fasting condition, so pressure-flow autoregulation does not exist in this situation. However, this pressure-flow autoregulation is not evidenced in portal venous system. Instead there exists a linear pressure-flow relationship which means when pressure in protal vein increases, then flow in it also increases and vice versa.

Metabolic Control

Here, the metabolic factors, but not the pressure in the vessels of liver regulate the hepatic blood flow. In this mechanism both the portal venous flow and hepatic arterial flow is controlled by the changes in the composition of blood, flowing within them due to metabolism. These factors include the changes of blood PO_2, PCO_2, pH and osmolarity. The liver blood flow is increased during hypoxaemia, hypercarbia, decreased pH, postprandial hyperosmolar state, etc. and vice versa.

Hepatic arterial buffer response

Here, one flow compensates the other. Thus, when the portal blood flow decreases, then the hepatic arterial blood flow increases and maintains the total hepatic blood flow at constant level. This is called the buffer response. This reciprocal relationship between the flow of hepatic artery and portal vein tends to maintain a constant hepatic O_2 supply which is essential for the hepatocyte's function. Thus, when the portal venous flow decreases, then the hepatic arterial resistance also decreases by dilatation and hepatic arterial flow increases and vice versa. It is postulated that this is due to the locally produced adenosine

Extrinsic Mechanism of Regulation

The extrinsic mechanism for regulation of liver blood flow depends on both the neural and humoral factors.

Neural Control

The sympathetic and the parasympathetic nerves which supply the liver through the hepatic plexus terminates on the arterioles and the venules of hepatic vessels. Stimulation of this sympathetic nervous system reduces the liver blood flow and expels near about 500 ml of blood into the systemic circulation, immediately from liver. The liver in this way represents a major reservoir of whole blood, during emergency. But, the parasympathetic innervation influences the regional distribution of blood flow within the liver by exerting effects on the perisinusoidal sphincters, rather than by affecting the total liver blood flow.

Humoral Factors

The hepatic arterial bed has both the α and β adrenergic receptors, whereas the portal vasculature has only α receptors. So, epinephrine, norepinephrine and other catecholamines administered exogenously induce vasoconstriction via the α-receptors which is partially compensated by vasodilation mediated by β-receptors. Dopamine has little effect on liver vasculature due to the absence of dopamine receptors on them. Vasopressin also induces marked splanchnic vasoconstriction in the liver. Consequently, there is reduction in venous flow through the portal system and reduction in inflow resistance in the portal vasculature occuring after vasopressin administration. Thus, vasopressin becomes very effective in alleviating the portal hypertension.

EFFECTS OF ANAESTHESIA ON LIVER BLOOD FLOW

Anaesthesia alters the blood flow in liver. It is due to the effects of individual anaesthetic agents, types of anaesthesia, mode of ventilation and the type of surgery. Most of the anaesthetic agents which reduce the BP and cardiac output decreases the liver blood flow. However, among all the volatile anaesthetic agents, halothane is the most significant. Incontrast, isoflurane increases the hepatic blood flow at the inspired concentration of 1 or 2 MAC. During general anaesthesia, as the splanchnic vascular resistance increases, the liver blood flow decreases. Application of PEEP further decreases the hepatic blood flow by increasing the systemic and subsequently the hepatic venous pressure.

Regional anaesthesia definitely decreases the liver blood flow, but it depends on the extent or the height of the block. This is because higher level of regional block is associated with more hypotension and more hypotension is associated with more reduction of liver blood flow. For example, the sensory block up to T_4 level reduces the hepatic blood flow up to 20%. But, this is not significant and runs parallel to the decrease of mean arterial pressure. It is also found that up to 40% reduction of MAP, there is no significant change of blood flow in liver, as there is contribution from both the portal and hepatic vascular system. Moreover reduction of MAP by more than 40% ensues the ischaemic insult on the liver. Among the type of surgery, upper abdominal surgery causes the maximum reduction of hepatic blood flow.

Thus, in conclusion it can be said that although all the forms of anaesthesia decrease the liver blood flow, but simultaneously the O_2 requirements by the liver also decreases. So, anoxic injury does not routinely occur during anaesthesia.

FUNCTIONS OF LIVER

The liver acts as a well equipped biochemical laboratory where practically metabolism of all the nutritional substances such as carbohydrates, fats, proteins, vitamins, minerals, etc. are taken place and heat is produced. So, its functions are numerous which are briefly summarised below.

(I) In Connection with the Blood and its Circulation

1. RBC formation—in foetal life.
2. RBC destruction—in adult life.
3. Storehouse of blood and regulation of blood volume.
4. In relation with blood clotting—(i) Virtually all coagulation factors which are protein in nature are synthesised in the liver, (ii) Mast cells of liver produce heparin and prevent intravascular clotting.
5. It helps in immune mechanism through its RE system.
6. It transfers blood from portal to systemic circulation
7. It manufactures all the plasma proteins (except immunoglobulins).

8. It stores iron, copper and other haematinic factors which help in the formation of red cells and haemoglobin.

(II) Synthesis of Bile

Bile with their different constituents are synthesised and excreted continuously from the liver and is stored in the gall bladder. Cholesterol is synthesised in the liver from active acetate and is also excreted from it. Bile acids such as cholic acid, deoxycholic acid and lithocholic acid have been considered to be the derivatives of cholanic acid and are formed in the liver. These bile acids in conjugation with glycine and taurine form the compounds such as glycocholic acid and taurocholic acid respectively. Bile salts are the Na – salts of these taurocholic acid and glycocholic acid and have very important function during the process of absorption of fat. This function is performed by the emulsification of ingested fat and concurrent production of greater surface area which enables the lipase and other fat metabolising enzymes to act more efficiently (Table 32.1).

Bile pigments, named the biliverdin and bilirubin are the breakdown products of haemoglobin and are formed in the RE system in various parts of the body. Bone-marrow, liver and spleen have been considered to be the part of of this RE system and so is the site of formation of bile pigments. These bile pigments are insoluble in water. So, these are then carried to the liver and is congugated to water soluble bile pigments (bilirubin glucuronide) which are then next excreted in the bile and is responsible for the normal colour of stool.

(III) In Relation with Carbohydrate Metabolism (Fig. 32.9)

Liver is immensely related to the carbohydrate metabolism in the following way.

i. It converts non-glucose monosaccharides such as galactose, fructose, mannose, etc. to glucose and glycogen.
ii. It converts lactic acid, pyruvic acid and glycerol to glucose and glycogen.
iii. It stores carbohydrates in the form of glycogen by glycogenesis and when the blood sugar tends to be low, then it mobilises this glycogen by glycogenolysis and produce glucose.
iv. It takes an important part in regulation of blood sugar.
v. It is the seat of neoglucogenesis.
vi. It manufactures fats from carbohydrates.
vii. Glucose is metabolised here through TCA cycle and other alternative pathways such as HMP shunt.
viii. In liver glucorinic acid is formed from uridine diphosphate glucose (UDPG) and plays an important role in the conjugation of bilirubin (Fig. 32.7).
ix. Alcohol metabolism: The liver is the main site of alcohol metabolism. In it an enzyme named alcohol dehydrogenase catabolises alcohol to acetaldehyde. Then, acetaldehyde dehydrogenase an enzyme which is present in liver converts acetaldehyde to acetyl CoA. Acetyl CoA may be oxidised to CO_2 and H_2O through TCA cycle or converted to other biochemical compounds including fatty acids. When alcohol is converted to acetaldehyde and then to acetyl CoA, NAD acts as cofactor, i.e. hydrogen acceptor and forms NADH. The ATP is generated during the oxidation of this NADH by the electron transport chain (ETC) and provides energy for the synthesis of fatty acids. Thus reduced NADH ($NADH^+ + H^+ = NADH$) which is produced during the metabolism of alcohol can alter the intracellular NADH/NAD ratio appreciably. In turn, this altered ratio can affect the number of important intracellular metabolic reactions that use these 2 co-factors. High level of NADH favour the formation of lactate from pyruvate, accounting for the lactic acidosis. This diminishes the concentration of pyruvate and thus inhibits gluconeogenesis. In severe cases, when liver glycogen is depleted due to less intake of carbohydrate and is no longer available for glycogenolysis, then this will result in hypoglycemia (Fig. 32.8).

Under the influence of alcohol the hepatic microsomes help in the

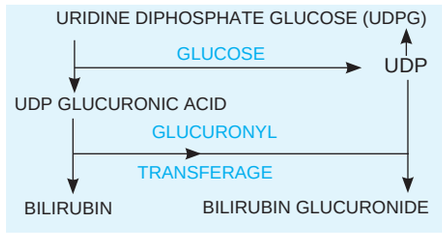

Fig. 32.7: Schematic diagram showing the conjugation of bilirubin by liver as glucuronide

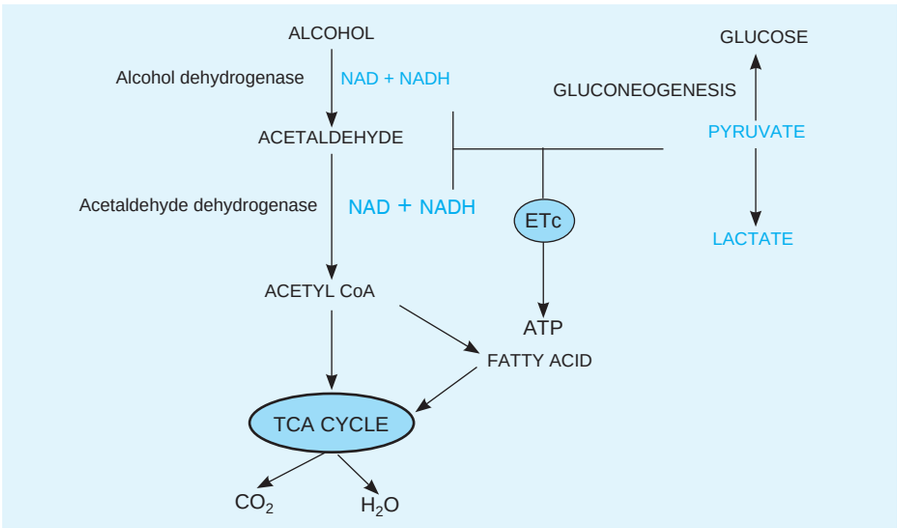

Fig. 32.8: Schematic representation of metabolism of alcohol in liver

esterification of fatty acids to triglycerides, rather than phospholipids. So the direct effect of alcohol may be alcoholic fatty liver which is due to the increased hepatic fat synthesis as well as decreased hepatic fatty acid oxidation.

(iv) In Relation with Fat Metabolism (Fig. 32.9)

Liver is related to fat metabolism in the following way.

i. It stores fats.
ii. It helps in the oxidation of fat, releasing energy in the form of ATP through TCA cycle.
iii. It is the site for synthesis of cholesterol from acetate.
iv. It is the site of synthesis of phospholipids.
v. It is the site for synthesis of fats from carbohydrates and proteins.
vi. It is the site of ketone body formation.
vii. The unused free fatty acids (FFA), which are released from the fat depot, is converted to triglycerides and other lipids in liver. These are then metabolised to meet the energy requirement when necessary (Fig. 32.10).
viii. The glycerol is oxidised in liver via the pathway of carbohyd–rate metabolism.
ix. In carbohydrate deficiency, the fat metabolism in liver is increased and fat is partially converted to glucose or glycogen.
x. Fat-soluble vitamins, e.g. A, D, E and K are stored here.

(v) in Relation with Protein Metabolism

i. Liver is the chief site for deamination of amino acid which constitute the principal step of protein metabolism.
ii. It is the main site of urea and uric acid formation.
iii. Synthesis of certain amino acids takes place in liver.

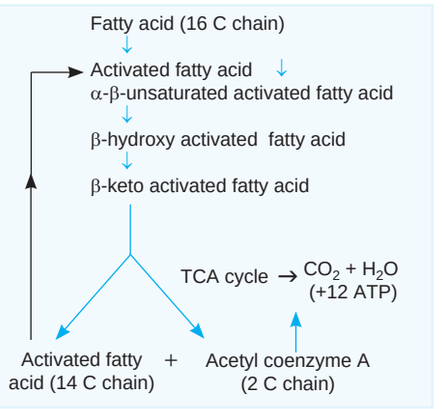

Fig. 32.10: Schematic diagram of fatty acid metabolism. During every cycle two carbon atoms are reduced and thus the fatty acid chain gradually becomes smaller and consists of less carbon atoms

iv. Plasma proteins are manufactured in liver except immunoglobulins.
v. Coagulation factors in addition to fibrinogen and prothrombin are manufactured here.

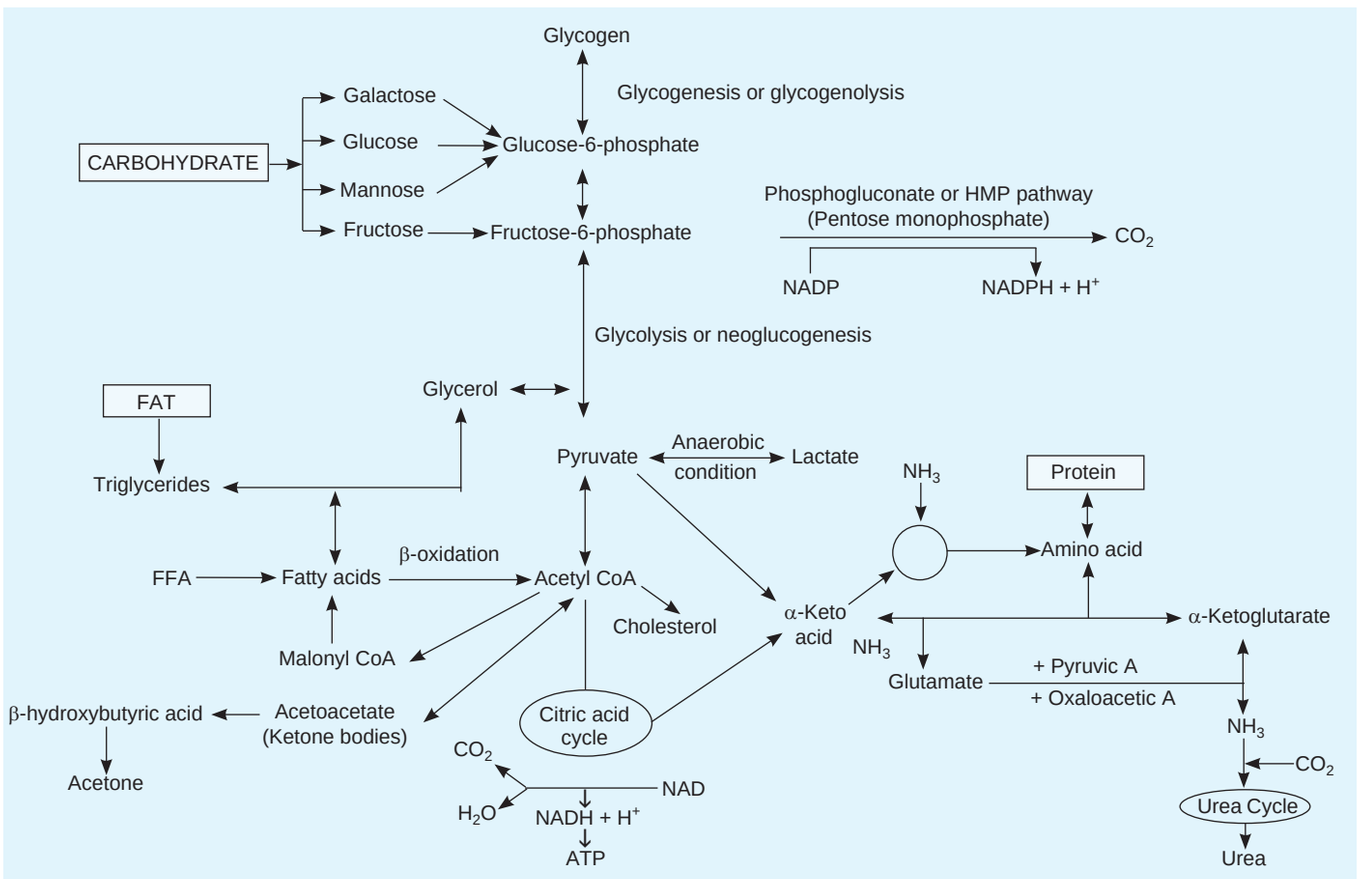

Fig. 32.9: Carbohydrate and fat metabolism in liver

Deamination is the process by which the amino radicle ($-NH_2$) is taken away from the amino acid. It is carried out chiefly in the liver with the help of an enzyme named deaminase. Deamination may also take place by the enzyme transaminase which transfers the amino group from the amino acid to a keto acid, converting the latter into an amino acid and the former into a keto acid. By this process the amino acid molecule is broken down into two parts: (i) the nitrogenous part (ammonia) and (ii) the non nitrogenous part (α-keto acid) (Fig. 32.11).

(i) The nitrogenous part of an amino acid has the following fate

a. Formation of urea: Most of the NH_3, under normal condition is converted to urea by K-H Ornithine cycle. So, about 80% of the total urinary nitrogen is found in the form of urea. Urea is mainly formed in the liver.

b. Formation of ammonium salt: A small part of ammonia combines with acids, (such as sulphuric acid, phosphoric acid, etc.) other than carbonic acid in renal tubles and appears in the urine in the form of ammonium salts, such as ammonium phosphate, sulphate, urate, etc. It is obvious, therefore, that the amount of ammonium salts which will be formed will not depend upon the amount of ammonia, but on the relative proportion of the acids or bases in the body. In acidosis more ammonia is needed to neutralize the excess acids and so there will be proportionate increase in the formation of ammonium salts. In alkalosis opposite changes will occur (Fig. 32.12).

c. Ammonia may also be used for synthesis of some simple amino acids, such as glycine, alanine, etc, and also for the amination of glutaric acid to give glutamine.

d. Ammonia may also be used for the synthesis of various nitrogenous substances such as creatine, purine, uric acid, pyrimidine, lecithine, etc.

(ii) The non-nitrogenous part of an amino acid has the following fate

a. Some will have the fate of carbohydrate. So, these amino acids increase the sugar level in blood. For this reason, in a diabetic subject about 60% of food protein is converted into sugar. These amino acids are called the antiketogenic amino acids. Because they act as carbohydrate in the body and prevents the formation of ketone bodies. They are also called the glucogenic amino acid. Glycine, alanine, serine, cysteine, arginine, lysine, valine, histidine, etc. belong to this group.

b. Some undergo the fate of fats. These amino acids are broken down in the body as fatty acids, from which the ketone bodies are formed. These amino acids are therefore known as the ketogenic amino acids. It is known that in a diabetic subject about 40% of proteins are converted into ketone bodies. Phenylalanine, tyrosine, isoleucine, etc. fall in this group (Table 32.1).

c. The sulphur and phosphorous, derived from the non-nitrogenous part of the amino acids are converted into various sulphur and phosphorous compounds and are excreted through urine.

(VI) Excretory Function

i. The cholesterol and bile pigments are excreted from liver through the bile.

ii. Various toxins, bacteria and drugs are also excreted by liver through the bile.

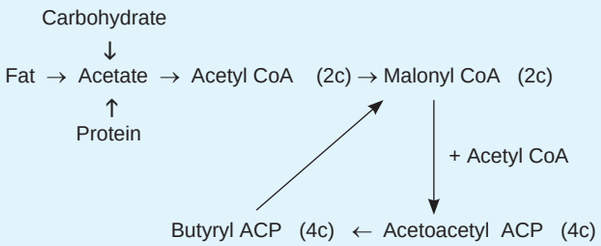
(VII) In Relation with Vitamin

i. Liver manufactures prothrombin with the help of vitamin K.

ii. It forms vitamin A from carotene and stores both the vitamin A and D.

iii. The liver is the principal storage organ of vitamin B_{12}. Therefore, in any hepatocellular disease, the uptake and storage of vitamin B_{12} by the liver tissue is decreased.

A. Synthesis of fatty acid



The two carbon (2C) acetate is thus elongated to four carbon (4C) butyryl ACP. This four carbon butyryl ACP is further elongated by 2C in each cycle by adding malonyl CoA. Finally, fatty acids with 16C are formed. For unknown reasons elongation of fatty acid stops when the chain is 16C atom long.

B. Synthesis of glycerol

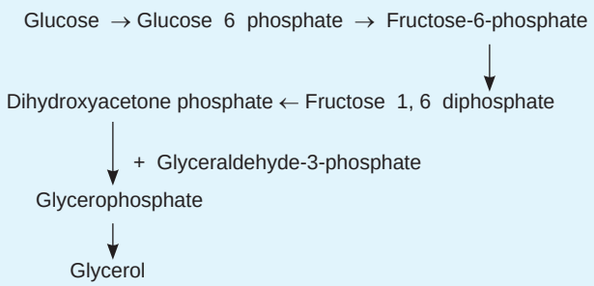


Fig. 32.11: Synthesis of fat (Triglycerides = Fatty acid + glycerol)

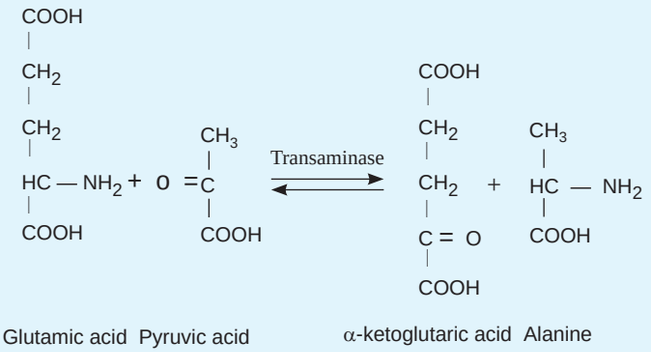
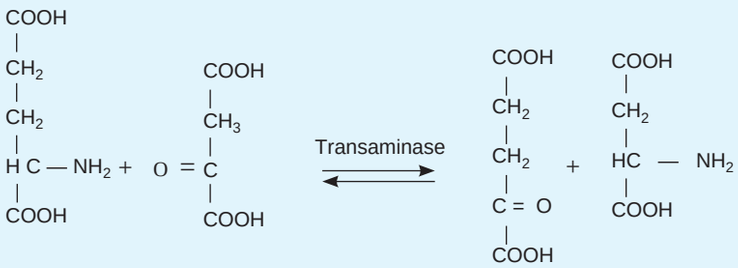
A. The example of glutamic-pyruvic transminase



Glutamic acid Pyruvic acid α-ketoglutaric acid Alanine

B. The example of glutamic-oxaloacetic transminase



Glutamic acid Oxaloacetic acid α-ketoglutaric acid Aspartic acid

Transaminase is recently referred to as aminotransferase. Transamination is reversible and combined process which is made up of deamination and amination. In most cases, there is transfer of amino group from amino acid to keto acid which is derived from either amino acid, carbohydrate and fat.

Fig. 32.12: Transamination or deamination

iv. Chronic liver disease is always associated with folic acid deficiency. It is known that the liver converts folate to its active form – tetrahydrofolate. Tetrahydrofolate is the storage form of folic acid. In liver disease this enzymatic transformation of tetrahydrofolate becomes impossible and thus folic acid is excreted through the urine.

(VIII) Detoxicating and Protective Functions

Liver is the principle site for the biotransformation of different toxic substances. They are either produced in the body during metabolism or taken along with the food. Again the liver converts some nonpolar compounds (lipid soluble) to polar compounds (water soluble), so that they are not reabsorbed by the renal tubules after filtration through the glomerulus and are thus excreted through the urine. But, many water soluble drugs such as streptomycin, neostigmine, etc. are not bio transformed by liver and are excreted unchanged through the urine. Though, the primary site of drug metabolism is the liver, still other sites are also available for drug biotransformation. These are kidney, intestine, lungs and plasma, etc. Biotransformation reaction of drug can be classified into nonsynthetic or phase I reaction and synthetic or phase II reaction.

Nonsynthetic or Phase I reaction

This is also called the functionalisation reaction. In this phase, metabolites becomes either active (mostly) or inactive. Activation is caused by the introduction of carbonyl, epoxide or hydroxyl groups into the parent compound. Phase-I reaction involves oxidation, reduction, hydrolysis, cyclization and/or decyclisation. Oxidation is the most common form of reaction in this phase, accounting for more than 90% of all the reactions. It is catalysed by the cytochrome P-450 system of liver cell and to a lesser extent by the mixed function of other oxidases present in the hepatocytes. Many of the reduction pathways in the liver are also catalysed by cytochrome P-450 system of hepatocytes.

Oxidation reaction involves addition of oxygen (negatively charged radical) or removal of hydrogen (positively charged radical) from the compound. Barbiturates, phenothiazines, paracetamol, steroids, phenotoin, benzodiazepines, theophylline and many other drugs are oxidised in this way in liver. Some other drugs, e.g. adrenaline, alcohol, mercaptopurine, etc. are also oxidized by the mitochondrial and cytoplasmic enzymes of hepatocytes. Reduction is the reverse of oxidation and also involves P-450 chytochrome enzymes. But, it works in the opposite direction. Drugs primarily reduced

Table 32.1: Synthesis of ketone bodies

Fatty acid oxidation
↓
Acetyl CoA
↓ Acetyl CoA
Aceto actyl CoA
↓ Liver
Aceto acetic acid
↓Reduced
β -hydroxybutyric acid
↓ Decarboxylation
Acetone

It has been observed that acetyl CoA produced during fatty acid oxidation, condenses with oxaloacetic acid for oxidation through TCA (or citric acid) cycle. But the formation of oxalo acetic acid is depressed when glucose supply is restricted (starvation) or glucose metabolism is impaired (diabetes). In this condition acetyl CoA cannot be properly metabolised through citric acid cycle. Thus acetyl CoA condenses to form acetoactyl CoA which next in the liver produces acetoacetic acid. Then this aceto acetic acid in form β-hydroxybutyric acid which after decarboxylation forms acetone. This aceto acetic acid, acetone and β -hydroxybutyric acid are called ketone bodies

are chloralhydrate, chloramphenicol, halothane etc.

Hydrolysis is the process of cleavage of a drug molecule by water, e.g.

Ester + $H_2O \rightarrow$ Acid + Alcohol

Amides and peptides are also hydrolysed by amidases and peptidases. Hydrolysis also occurs in liver, intestine, plasma and other tissues. Examples of hydrolysis are choline esters, procaine, lidocaine, procainamide, pethidine, oxytocin, etc. Decyclisation is opening up of ring structure of the cyclic drug molecule, e.g. barbiturates, phenytoin, etc. This is generally a minor pathway. Cyclisation is the formation of ring structure from a straight chain compound, e.g. proguanil.

Synthetic or Phase II reaction

This phase of metabolism involves conjugation of drugs or substrates, derived from phase I metabolism to form a polar, highly ionised organic acid which is easily excreted through the urine or bile. Conjugation reactions require high energy. This phase II reactions include glucoronide conjugation, acetylation, methylation, sulfate conjugation, glycine conjugation and glutathione conjugation.

Glucoronide conjugation is the most common form of all the phase II reactions. Compounds are easily conjugated with glucuronic acid which is derived from glucose. Examples are chloramphenicol, aspirin, phenacetin, morphine, metronidazole, etc. Not only the drugs, but also many endogenous substrates like bilirubin, steroidal hormones and thyroxine, etc. also undergoes transformation through this pathway. After conjugation these glucoronide compounds are excreted through the bile and can also be hydrolised by bacteria in the gut. Then the liberated drug is reabsorbed and undergoes enterohepatic circulation and its action is then prolonged, e.g. phenolphthalein, oral contraceptives etc. Some compounds are also conjugated with the help of acetyl coenzyme-A. This is called acetylation. The examples of this acetylation are sulfonamides, isoniazid, PAS, hydralazine, etc. Multiple genes control acetyl transferase an enzyme which is needed for this reaction and the rate of this acetylation shows genetic polymorphism. Amines and phenols are conjugated by methyl group which is donated by methionine and cysteine. This is called methylation. The examples are adrenaline, histamine, nicotinic acid. Chloramphenicol, adrenal and sex steroids undergo sulfate conjugation.

(IX) In Relation to Body Temperature

Liver produces a large amount of heat from metabolism of carbohydrate, protein and fat and thus takes part in controlling the body temperature.

(X) Hormone Metabolism

Liver metabolises the circulating hormones of adrenal gland (cortical and all sex hormones) by reduction and conjugation reaction. Steroid hormones like oestrogen, cortisol, testosterone, etc. are insoluble. Their solubility is increased and made excretable after being conjugated with glucorinic acid and sulphuric acid in the liver. The liver normally extracts about 97% of delivered aldosterone and inactivates it. Inactivation of insulin, glucagon, ADH and other hormones also occur here. In liver disease levels of all these hormones are increased.

CLASSIFICATION OF LIVER DISEASES

No single classification for all the types of liver diseases is entirely satisfactory. Because in many instances the aetiology and the pathogenic mechanism of liver diseases are obscure. As a consequence, one finds an abundance of nomenclatures and labels, applied to the same hepatic disorders. For example, some individuals use the term 'hepatitis' to imply the viral infection. Whereas, others use it simply to mean the evidence of hepatic inflammation. Similarly, the oftenly used words such as acute, subacute and chronic are also ambiguous. Chronicity is referred to the continuation or recurrence of the disease. Whereas the active is referred to evidence of the full presence or perpetuation of disease. This is most easily identified by the elevation of serum transaminase and by the degree of hepatocellular necrosis on biopsy. As there are many difficulties involved in defining the aetiology of many types of liver diseases, so, in most instances the disease process is best defined and described by an examination of the morphologic character of the lesion. Therefore, a morphologic classification of liver diseases is outlined in the table, which appears at present the more practical than one based on aetiology (Table 32.2).

LIVER FUNCTION TESTS

The liver has enormous capability to regenerate. So, it has a large functional reserve. Therefore, the liver disease in man does not become clinically apparent till well advanced. In addition, liver function tests (LFTs) which reflect the intracellular contents in circulation may be abnormal in the presence of relatively normal functions of liver. Many disease processes of liver may lead to the severe impairment of certain liver functions, while others remain entirely unaffected. Since, as no battery of tests is universally applicable, so those most appropriate to a given clinical problem must be selected. Also their potential value and risk should be considered and the results are interpreted in relation to the clinical findings. Thus, LFTs are only crude indicators of the real hepatic state and should always be correlated with the clinical picture. One isolated biochemical abnormality is insignificant. Tests should be done serially in order to evaluate the course of the disease process. Abnormal LFTs may also be due to the effect of some systemic diseases of liver

Table 32.2: Classification of liver diseases

Parenchymal

1. Hepatitis (viral, drug induced, toxic, ischaemic)
   a. Acute
   b. Chronic (persistent or active)
2. Cirrhosis
   a. Alcoholic (portal, nutritional)
   b. Postnecrotic
   c. Biliary
   d. Haemochromatosis
   e. Rare type (Wilson's disese, galactosemia, cystic fibrosis of pancreas, α-antitrypsin deficiency)
3. Infiltration
   a. Glycogen
   b. Fat
   c. Amyloid
   d. Lymphoma
   e. Leukemia
   f. Granuloma
4. Space-occupying lesion
   a. Hepatocellular carcinoma
   b. Metastatic tumour
   c. abscess
   d. Cyst
   e. Gummas
5. Functional disorder associated with jaundice (hereditary or acquired)
   a. Gilbert's syndrome
   b. Crigler-Najjar syndrome
   c. Dubin-Johnson and Rotor syndromes
   d. Cholestasis of pregnancy
   e. Benign recurrent cholestasis

Hepatobiliary

1. Extrahepatic biliary obstruction (by stone, stricture)
2. Cholangitis (septic, primary biliary cirrhosis, drug, toxic)

Vascular

1. Chronic passive congestion and cardiac cirrhosis
2. Hepatic vein thrombosis (Budd-Chiari syndrome)
3. Portal vein thrombosis
4. Pylophlebitis
5. Arteriovenous malformations
6. Veno-occlusive disease

(e.g. chronic heart failure, malignancy, etc.) and this also must be taken into consideration, while deciding on the anaesthetic plan.

Usually, the liver function tests are carried out for both the screening and identification of the type of liver disease with the aim of (i) detecting intrinsic hepatocellular damage, (ii) detecting cholestasis, (iii) detecting and differentiating between the types and causes of jaundice, (iv) assessing the synthetic functions of liver, and also (v) diagnosing of primary carcinoma (Fig. 32.13).

Bilirubin

Bilirubin is the degradation product of the heme part of haemoglobin (Hb) which is derived after the breakdown of aging erythrocytes by the mononuclear phagocytic system (MPS) or the reticuloendothelial system (RES). Bilirubin is the yellow pigment which is oxidised again into the green pigment biliverdin. According to some, biliverdin is formed first from heme and later by reduction forms bilurubin This unconjugated bilirubin (or indirect bilirubin) is bound to serum albumin because it is insoluble in the aqueous solution at the physiological pH. So, it is not excreted by glomerular filtration through the urine. On reaching the liver cells via the blood of sinusoids, the albumin is dissociated from bilirubin and free bilirubin enters the liver cells, where it is bound to the cytoplasmic protein, named ligandin. This cytoplasmic liver cell protein, ligandin, then assists in the transfer of bilirubin to the endoplasmic reticulum (ER) of liver cell for conjugation. In ER of liver cell, bilirubin is conjugated with glucoronic acid which is catalysed by the enzyme glucoronyl transferase. Then, this conjugated bilirubin glucoronide (or direct bilirubin) which is water soluble, is actively transported to the bile canaliculi. A small amount of conjugated bilirubin (bilirubin glucuronide) escapes in the blood of sinusoids. Therefore, the total plasma bilirubin normally includes free unconjugated bilirubin which is bound to

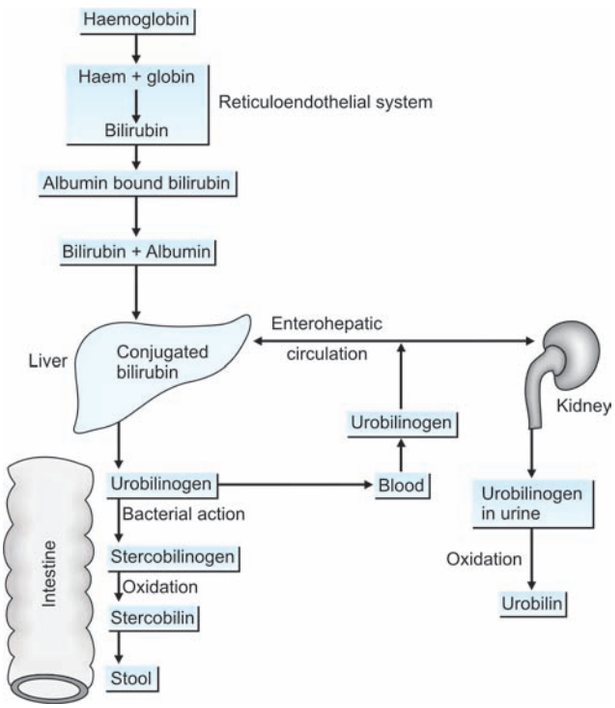


Fig. 32.13: Pathway of bilirubin formation and excretion

albumin and a small amount of conjugated bilirubin which are circulating in blood. The normal value of total plasma bilirubin is 0.2 to 0.8 mg/dl. Out of which the level of conjugated is 0.00 to 0.2 mg/dl and the level of unconjugated is 0.2 to 0.6 mg/dl.

The conjugated Bilirubin imparts the brilliant yellow colour to the bile. Most of the conjugated bilirubin passes via the bile duct into the intestine. In the intestinal mucosa, then most of the conjugated bilirubin glucoronides are again deconjugated by the intestinal bacteria and form the colourless urobilinogen. The urobilinogen and the residues of some intact pigment are then largely excreted through the faeces as stereobilinogen and stercobilin which are responsible for the brown colour of the stool. Some of the urobilinogens are reabsorbed from intestine and excreted through the urine as it is conjugated and water soluble. Some are also returned to the liver. Complete bile duct obstruction blocks the excretion of conjugated bilirubin from liver into the gut and results in disappearance of urobilinogen and stercobilinogen from the urine and stool. Thus, the assessment of urobilinogen in a freshly collected 2-hour urine specimen may distinguish the biliary tract obstruction from the parenchymal dysfunction of liver. But this test has been largely superseded by other methods. In complete bile duct obstruction as the pressure in the bile canaliculi is increased, so the conjugated bilirubin from the bile canaliculi flows back from the liver cells into the blood of sinusoids and enters the systemic circulation. So, the level of conjugated bilirubin in blood becomes very high.

The disorders of bilirubin metabolism can be divided into four major categories: (i) increased pigment production in RE system, (ii) reduced hepatic uptake of unconjugated bilirubin, (iii) impaired hepatic conjugation in the liver cell, (iv) decreased excretion of the conjugated pigment from the liver into the bile. However, the last three points can be clubbed under the heading of impaired excretion of bilirubin. The first three disorders are associated predominantly with the unconjugated hyperbilirubinaemia and no bilirubinuria. The fourth group is associated predominantly with the conjugated hyper bilirubinaemia and bilirubinuria. Now, the increased plasma concentration of unconjugated bilirubin may be due to the increased production, e.g haemolysis (factor 1) or reduced liver uptake, e.g Gilbert's syndrome and Crigler-Najer's syndrome (factor 2 and 3) or those in whom both the mechanisms operate. In haemolytic anaemia, jaundice due to unconjugated bilirubin appears only when the rate of bilirubin production exceeds the amount that can be conjugated and removed by a normal liver which has an enormous reserve. In most cases of uncomplicated haemolytic states, the mean serum bilirubin (unconjugated or indirect) level will be in the range of 3 to 4 mg/dl. Rarely, higher levels may be seen, if the haemolysis is associated with fever, sepsis, hypoxaemia, etc., or if the ability of the liver to handle the pigment load is compromised (i.e. when haemolytic disease is associated with liver disease).

Jaundice due to increased pigment production may also be seen as a consequence of large tissue infarction (e.g. pulmonary infarcts) or large collection of blood in the tissues. If hypotension or hypoxaemia supervene, then the jaundice is usually more pronounced and the resulting impairment of liver function may lead to a significant increase in the serum unconjugated bilirubin level. Except in early infancy, the elevation of serum unconjugated bilirubin levels is not harmful. Rather the prognosis depends on the haemolytic process itself than the level of the unconjugated bilirubin. However, in the neonatal state and infancy, the unconjugated bilirubin levels above 20 mg/dl may lead to kernicterus. This is due to the deposition of this water insoluble (fat soluble) bilirubin in the lipid rich basal ganglia of brain as blood brain barrier is not well developed in neonates like adults.

Currently, there are three syndromes such as Gilbert's, Crigler-Najjar II and Crigler-Najjar I which fall in the category of hereditary glucoronyl transferase enzyme deficiency disorders. In these disorders there is impairment of conjugation of bilirubin by the liver parenchymal cells. These three syndromes reflect progressive decrease in the activity of glucuronyl transferase enzyme and thus may be the part of a spectrum of a single disease, i.e. from minimal deficiency to complete absence of glucoronyl transferase enzyme (Gilbert's is the mild, Crigler-Najjar II is the moderate and Crigler-Najjar I is the severe form). These three syndromes are characterised by unconjugated hyperbilirubinaemia, normal liver function tests and no overt or clinically recognisable haemolysis. The liver cells during liver biopsy usually appear normal by light microscope.

Normally, between the 2nd and 5th days of life, almost every neonate shows some transient unconjugated hyperbilirubinaemia. During intrauterine period, the placenta serves to clear the unconjugated bilirubin from the fetus. But after birth, neonates detoxify the pigments themselves by their liver. However, at this stage the hepatic enzyme, named glucuronyl transferase, remains immature. As a result, the unconjugated hyperbilirubinaemia develops (usually not exceeding 5 mg/dl). Within several days to weeks after birth, the activity of glucouronyl transferase enzyme increases and concomitantly the serum unconjugated bilirubin level returns to normal. In infants with erythroblastosis (a superimposed haemolytic process), the excessive pigment load leads to more pronounced jaundice and unconjugated bilirubin level may go upto 20 mg/dl or above. Neonatal jaundice is not present at the time of delivery. If jaundice is present at birth, then other causes must be considered. During

neonatal period if unconjugated bilirubin level exceeds 20mg/dl, the patient usually develops Kernicterus (bilirubin encephalopathy) and eventually dies. This condition results from the deposition of unconjugated bilirubin in the lipid rich basal ganglia (as unconjugated bilirubin is fat soluble and not water soluble). The current therapeutic approach of this unconjugated hyperbilirubinaemia is phototherapy, in which the strong white or blue light leads to the photoisomerisation of nonwater soluble bilirubin to its water soluble isomers that are rapidly excreted in the bile without prior need for conjugation. Another novel approach involves decreasing the bilirubin production from heme by inhibitors of heme oxygenase. Synthetic protoporphyrins such as tin protoporphyrin also have been administered successfully to the patients with neonatal unconjugated hyperbilirubinemia, causing marked reduction in the serum bilirubin level with no major side effects (Table 32.3).

In jaundice, due to primary or parenchymal liver disease, the plasma usually exhibits the elevated levels of both the conjugated and unconjugated bilirubin, but urine contains the only water soluble conjugated bilirubin. The relative proportion of these two pigments are highly variable. Such serum bilirubin pigment pattern is also seen with extrahepatic biliary obstruction. One cannot differentiate the intrahepatic and extrahepatic causes of jaundice only by the levels of unconjugated and conjugated bilirubin in serum, but from the prehepatic causes of jaundice. Thus, the main purpose of the initial fractionation of the serum bilirubin is to distinguish hepatic parenchymal and biliary obstructive diseases from the prehepatic disorders which are associated with predominantly unconjugated hyperbilirubinaemia. In many familial hepatic abnormalities such as Dubin-Johnson syndrome (autosomal inheritance), the jaundice is largely due to the increase in conjugated bilirubin. Functionally, in Dubin-Johnson syndrome there exists a defect in excretion of bilirubin into the biliary canalienli from the liver cells after conjugation (at cellular levels). But, there is no defect in the conjugation process of unconjugated bilirubin. So, bilirubin after conjugation flows back from the liver cells into the blood due to the defect in excretion into biliary canaliculi. Other familial defects in hepatic excretory function where conjugated hyperbilirubinaemia occur are Rotor syndrome (actually this syndrome is due to impairment of storage capacity), benign recurrent intrahepatic cholestasis, recurrent jaundice during pregnancy, etc. Acquired defects of hepatic excretory function at cellular level where conjugated hyperbilirubinaemia occur are drug induced cholestasis (e.g. use of oral contraceptives), hepatitis and cirrhosis. Hepatitis and cirrhosis are the most common disorders associated with jaundice. When the liver cells are damaged as in viral hepatitis, then there is often impairment in all the three major hepatic phases of bilirubin metabolism, namely uptake, conjugation and excretion. This is due to the impairment of function of liver cells. There is also little increase in the level of serum unconjugated bilirubin. The acquired defects of biliary excretory function at extrahepatic level may be due to stones, tumours or strictures in biliary tree. The clinical pictures of this obstructive jaundice are quite similar to that of intrahepatic cholestasis, with pronounced elevation of serum conjugated bilirubin.

	• Stone in CBD
	• Stricture of CBD
	• Cirrhosis
	• Pregnanct

Serum Enzyme Assays

A number of serum enzymes have been used to distinguish and assess the hepatocellular functions. But, none can truly distinguish or assess these processes definitely and especially all have inherent limitations in sensitivity and specificity. On the otherhand, the elevation of these enzyme acitvities may also be seen in association with nonhepatic disorders. Nevertheless, with proper and careful interpretations, a number of serum enzymes provide important clinical tools regarding the assessment of liver functions. These enzymes are:

Aminotransferase (Transamines)

As an indicator of hepatocellular function, assays of many serum enzymes have been proposed. But among these, AST (aspartate aminotransferase, previously called SGOT) and ALT (alanine aminotransferase, previously called SGPT) enzyme activities have been proven to be the most useful. In contrast to ALT which is found primarily in the liver, AST is also present in many tissues, including heart, skeletal muscle, kidney and brain. Thus, AST is somewhat less specific as an indicator of liver function than ALT.

In a hepatocyte, ALT is found exclusively in the cytosol, while different isoenzymes of AST exist in mitochondria and the cytosol. The normal level of AST and ALT in serum is 35 U/L. The source of normal serum AST and ALT level is still unclear. Although the elevated serum levels of AST or ALT may also be observed in a variety of non-hepatic disease, notably in myocardial infarction and skeletal muscle disorders, but these disorders can usually be distinguished clinically from liver disease. In contrast, uremia may also lead to a falsely low aminotransferase value.

The absolute levels of aminotransferase correlates poorly with the severity of liver disease or its prognosis. Only serial determination of value is usually most useful. Very high level of these enzymes suggests the development of cholangitis with resultant hepatic cell necrosis. Modest elevation of transaminases occur in alcoholic hepatitis. Minimal elevation of AST and ALT is found in association with the biliary tract obstruction. In general, serum AST and ALT levels are parallel with each other, with some exceptions (e.g. in alcoholic hepatitis AST/ALT > 2) (Table 32.4).

Alkaline Phosphatase

Alkaline phosphatase is a plasma membrane derived enzyme of uncertain physiological function that hydrolyses synthetic phosphate esters at pH 9. Human serum contains several forms of it and different techniques of assesment of alkaline phosphatase have been developed that utilize different substrates. Alkaline phosphatase usually arises from the bone, intestine, liver and placenta. In the absence of bone disease or pregnancy, the elevated levels of alkaline phosphatase reflect impaired biliary tract function. In liver diseases the increased level of alkaline phosphatase is due to the increaed synthesis of this enzyme by hepatocytes and biliary tract epithelium, or due to the regurgitation of this enzyme by biliary obstruction. The probable explanation of it is that bile acids play a role both in inducing the synthesis and promoting the solubilisation of this membrane's associated enzyme activity.

Slight to moderate rise of alkaline phosphatase level occurs in parenchymal liver disorders such as hepatitis and cirrhosis. But very high level of it is found in infiltrative disorders, e.g. myobacterial infection of liver. However, consistently and striking increase in alkaline phosphatase level which is 10 times greater than normal value (normal value is 30 to 120 U/L) occurs with the extrahepatic biliary tract (mechanical) obstruction or with intrahepatic (functional) cholestasis, (as in drug induced cholestasis or primary biliary cirrhosis). Conversely, it is unusual for the serum alkaline phosphatase to remain normal when there is obstructive jaundice. On the otherhand, a normal alkaline phosphatase enzyme level argues strongly against the presence of cholestasis or obstruction.

In metastatic or infiltrative liver diseases such as leukaemia, lymphoma and sarcoidosis, etc. the alkaline phosphatase level is usually mildly elevated. Sometimes alkaline phosphatase level is also elevated in nonhepatic disorders, most commonly in some bone disorder such as Paget's disease, osteomalacia, bone metastasis, etc. and sometimes with malignancy. Several methods can distinguish different isoenzymes of alkaline phosphatase of different origins. For example, in contrast to that of alkaline phosphatase which is derived from bone, the hepatic isoenzyme of alkaline phosphatase is stable on treatment with heat (56°C for 15 minutes). These isoensymes can also be distinguished by electrophoresis. But, this is not practical for the diagnosis of specific diseases. Because the parallel determination of serum 5′-neucleotidase helps in diagnosis. An increase of both 5′-neucleotidase and alkaine phosphatase diagnose hepatobiliary disease.

Table 32.4: Abnormalities shown by tests of liver function

Test	*Type of liver disease*	
	Obstructive	*Parenchymal*
AST and ALT(SGOT and SGPT)	↑	↑ to ↑↑↑
Alkaline phosphatase	↑↑↑	↑
Albumin	N	↓ to ↓↓↓
Prothrombin time	N to ↑	↑ to ↑↑↑
Bilirubin	N to ↑↑↑	N to ↑↑↑
γ-glutamyl transpeptidase (GGT)	↑↑↑	N to ↑↑↑
5' - nucleotidase	↑ to ↑↑↑	N to ↑

Correctable with parenteral vitamin K if elevated. N = Normal , ↑ = Elevated , ↓ = decreased

5-Nucleotidase

It is an enzyme which catalyzes the hydrolysis of phosphate at the position 5 of a pentose component of a nucleotide. The enzyme 5 nucleotidase is widely distributed in all the tissues, but the hepatobiliary disease is associated with higher elevation of this enzyme. The normal value of this nucleotidase enzyme is 1 to 18 U/L. The principle importance of 5-nucleotidase measurement is to confirm the hepatic origin of an elevated alkaline phosphatase level in children or pregnant women or in those settings where coincident bone disease may be present. In the contrary, lack of elevation of 5 nucleotidase always does not exclude an hepatic source of elevated serum alkaline phosphatase level.

Gamma (γ)-Glutamyl Transpeptidase (GGT)

The GGT plays a major role in amino acid transport and catalyses the transfer of γ-glutamyl group from peptides such as glutathione to other amino acids. It is distributed in various tissues, as well as in the hepatobiliary system. In liver disease, the plasma level of GGT correlates well with that of the alkaline phosphatase levels and is the most sensitive indicator of biliary tract disease. GGT levels are also elevated in pancreatic, cardiac, renal and pulmonary disorders, as well as in diabetes and alcoholism. So, overall lack of specificity of GGT has constrained its usefulness.

Serum Proteins

Extensive liver cell damage or injury leads to decreased blood levels of albumin, prothrombin, fibrinogen and other serum proteins which are exclusively synthesised by the hepatocytes. So, in contrast to the measurement of serum enzymes which reflect directly the liver cell injury, estimation of serum proteins also reflect the synthetic dysfunctions of liver cells.

During interpretation of serum protein levels in hepatic diseases, there are three important principles:

i. Liver proteins are neither early, nor sensitive indicators of liver disease. This is because of the huge hepatic reserve and the prolonged half-live of serum proteins.
ii. Decrease in serum protein levels is not specific for liver disease, because there are many other factors which cause the decreased level of serum proteins such as nutritional deficiency, malabsorption, etc.
iii. Liver proteins are of little value in the differential diagnosis of liver diseases.

Albumin and Globulin

The normal serum value of albumin ranges from 35 to 55 g/L and it is the most important protein, synthesised by the liver. The half-life of albumin is 14 to 20 days and daily turn over is < 5%. Moreover, there is a substantial power of reserve for synthesis of albumin by hepatocytes. Thus, adequate synthesis of albumin may continue, though there is extensive hepatocellular injury. So, albumin estimation is not a good indicator for acute and mild hepatocellular injury. On the other hand, serum levels of albumin are also influenced by a variety of non-hepatic factors such as nutritional status, hormonal factors, kidney diseases (nephrotic syndrome), protein losing enteropathy, etc. which are not associated with the dysfunction synthesis of albumin by liver. Still, reduction of serum albumin levels provide an excellent indicator of chronic liver disease (provided other systems remain free of diseases).

Serum globulins are a heterogenous group of proteins (α, β, γ, etc) which are synthesised in a variety of tissues. The normal serum globulin level is 20 to 35 g/L. It is often elevated in association with chronic liver disease, e.g. cirrhosis hepatitis, fatty liver, etc. This reflects the increased stimulation of synthesis of immunoglobin by the peripheral RE system, due to the shunting of the antigens which bypass the liver and are not cleared by the hepatic Kupffer cells. There are many other nonhepatic conditions where globulin levels are also elevated. The albumin/globulin ratio has no physiological significance.

Clotting factors

Virtually all the coagulation factors, which are protein in nature are synthesised in the liver and requires the presence of vitamin K as cofactor (factor V, XII, XIII do not need vitamin K for synthesis). Like serum protein, these coagulation factors are also normally present in plasma in excess concentration. So, impaired coagulation is usually seen only in severe liver disease. Impaired coagulation can be most efficiently determined by the one-stage prothrombin time (PT). PT measures the rate of conversion of prothrombin to thrombin in the presence of thromboplastin and calcium and requires the integrity of other vitamin K dependent clotting factors (Table 32.5).

Thus, prothrombin time (PT) depends on sufficient intestinal uptake of Vit-K and normal synthesis of clotting factors by liver. Absorption of vitamin K requires adequate dietary intake, normal function of intestinal mucosa and normal biliary secretions (as vitamin K is a fat soluble vitamin). As coagulation factors are of shorter half-life than that of serum proteins, so the prothrombin time may be an early indicator than serum albumin level in hepatic injury. In both acute and chronic hepatocellular injury, an increase in the prothrombin time serves as an ominous prognostic sign. As vitamin K is a fat soluble vitamin, so the prolongation of prothrombin time can also result from vitamin K malabsorption which may occur with cholestasis due to biliary tract disease or due to malabsorption of any cause (e.g. pancreatic insufficiency, steatorrhoea, etc.). Poor dietary intake, antibiotic therapy and use of warfarin type of anticoagulants are additional causes of prolonged prothrombin time, owing to the deficiencies of active vitamin K. These process can be distinguished from the failure of hepatic synthesis by demonstrating the normalisation of prothrombin time (within 24 to 48 hours) after parenteral injection of vitamin K. The partial thromboplastin time (activated PTT) which reflects the activity of fibrinogen, prothrombin and clotting factors such as V, VIII, IX, X, XI, XII may also be prolonged in severe liver disease. Before any surgical procedure on patient with liver disease including liver biopsy, clotting functions should always be assessed in all of them (Fig. 32.14).

Table 32.5: Numerical system for International Nomenclature of blood coagulation factors

Clotting Factor	*Synonym*
I	Fibrinogen (100)
II	Prothrombin (80)
III	Tissue thromboplastin
IV	Calcium
V	Labile factor (18)
VI	Accelerin (6)
VII	Stable factor (6)
VIII	Antihaemophilic factor (AHF) (10)
IX	Christmas factor (24)
X	Stuart factor (50)
XI	Plasma thromboplastin antecedent (PTA) (25)
XII	Hageman factor or Surface factor (60)
XIII	Laki-Lorand factor (LLF) (90)

Blood Ammonia

Liver is the major site of amino acid or protein metabolism and their interconversions. It synthesises proteins from amino

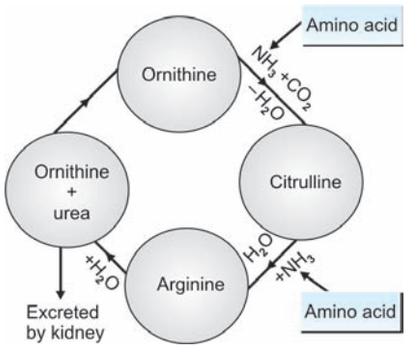

Fig. 32.14: Krebs-Henuseleit ornithine cycle. Formation of urea → Krebs- Henuseleit cycle. In this cycle one acid (carbonic acid) and two molecules of NH_3 are neutralised

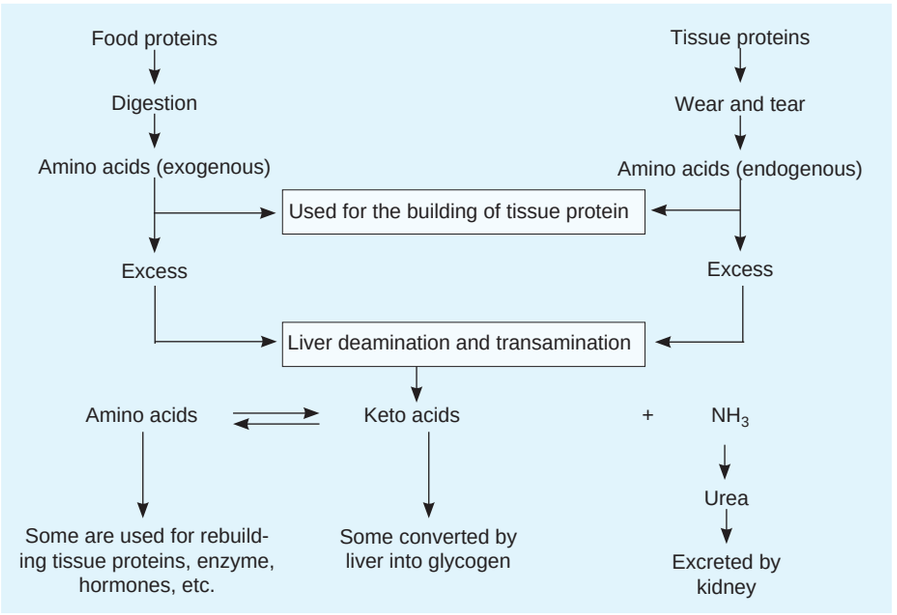

Fig. 32.15: Synthesis of proteins and amino acids in liver

acids supplied from dietary source or from metabolic turnover of endogenous protein (primarily from muscle). Protein is also directly synthesised in the liver. The dietary amino acids enter the liver through portal vein and are also catabolised to urea. In liver diseases, disruption of this normal amino acid metabolism pathway leads to elevated plasma amino acid concentrations.

Liver handles the amino acids by two major reactions: transamination and oxidative deamination. In transamination amino acid enters the citric acid cycle. But in oxidative deamination amino acids are converted to keto acids and ammonia. This ammonia is the toxic product of nitrogen metabolism. So it is converted to urea by Krebs-Henuseleit or ornithine cycle and is of very clinical importance in a patient with severe liver disease. In advanced liver disease, urea synthesis is often depressed, leading to an accumulation of NH_3 in blood. This is sometimes associated with a significant reduction of blood urea nitrogen (BUN) which is an ominous sign of liver failure. Urea is mostly excreted by the kidney. 25% of the formed urea is also diffused into the lumen of intestine from blood where it is again converted to NH_3 by bacteria named urease. The intestinal production of ammonia also occurs from the bacterial deamination of unabsorbed amino acids and also from the protein which are derived from the diet, from the exfoliated cells of intertine or from the blood in the GI tract. NH_3 from the GI tract is reabsorbed and transported to liver by portal system and again converted to urea. Kidney also produces the varying amounts of amonia. The contribution of gut and kidney in ammonia synthesis has important implications in the management of hyper-ammonaemic state, frequently seen in patients with advanced liver disease. Hyper-ammonaemia usually leads to hepatic encephalopathy (Fig. 32.15).

EFFECTS OF LIVER DYSFUNCTION ON PHARMACOKINETICS AND PHARMACODYNAMICS OF ANAESTHETIC DRUGS

Liver plays a critical role in nutrition, drug metabolism, synthesis of plasma proteins, detoxification and elimination of many endogenous and exogenous toxic substances, etc. which are described before. So, acute and chronic liver dysfunctions usually alter the pharmacokinetics and pharmacodynamics of anaesthetic drugs. It is due to the result of portal hypertension, reduced level of serum albumin and other proteins causing altered drug binding, altered volume of distribution of drugs due to the increased total body water, reduced metabolism of drugs secondary to abnormal function of hepatocyte, etc. Enzyme induction due to chronic alcohol ingestion, changes of hepatic blood flow and the severity of the underlying hepatic diseases also influence the effects of drugs. In addition, the influence of liver disease differs for elimination of enteral and parenteral group of drugs. Portal hypertension causes reduction in the portal venous blood flow to the liver and hence the drugs given by the oral route will have prolonged half-life.

The clearance of drugs by liver is dependent on its availability to the liver cells, which in turn is dependent on the liver blood flow. So, the metabolism of drugs like lignocaine and pethidine which have high clearance ratio are affected more than the drugs like benzodiazepines (BDZ) which have low clearance ratio. On the other hand, these drugs are more affected by altered protein binding, intrinsic hepatic clearance and metabolism.

Premedicants

The advent of day care anaesthesia has virtually reduced the number of patients who are routinely subjected to premedication. The trend is now either no premedications or oral administration of short acting benzodiazepines in very small doses. The recovery time and elimination kinetics of a sedative dose of benzodiazepines is prolonged in patients with liver dysfunction. It is due to reduced protein binding and reduced metabolism of BDZ in liver disease. Therefore, these drugs should be used with caution when repeated injections or infusions are required. However, their effects may be reversed by flumazenil.

IV Inducing Agents

Most intravenous inducing agents undergo extensive hepatic metabolism. However, studies suggest that after a single bolus dose, pharmacokinetics of these agents is not much altered. But, there are no studies showing that the duration of action of weight adjusted dose of thiopentone is altered in patients with liver dysfunction. Propofol has a very large volume of distribution and is extensively protein bound. So, there is little difference in pharmacokinetics of propofol between the normal and liver dysfunction patients. Though the kinetics of thiopentone and propofol is not affected after a single bolus dose, but prolonged mean clinical recovery time has been reported mainly after propofol infusion in liver dysfunction.

Opioids

Opioids are extensively metabolised by the liver. Therefore, their duration of action is significantly prolonged in liver disease. Decreased plasma protein binding capacity in liver disease also leads to potentially exaggerated sedative and respiratory depressant effects of opioids. Doubling of half-life has also been observed in morphine and pethidine in hepatic dysfunction and, therefore, it is recommended to increase the administration interval by 1.5 to 2 folds for these group of drugs. In addition, decreased clearance of norpethidine in patients with advanced liver disease may precipitate neurotoxicity more commonly. Fentanyl and sufentanil are highly lipid soluble synthetic opioids and are extensively metabolised in the liver. However, their single dose pharmacokinetics is not much altered in liver diseases. But, continuous infusion or repeated dosing may prolong their effect. Unlike these drugs, the half-life of alfentanil is almost doubled in patients with cirrhosis of liver which can lead to prolonged duration of action and enhanced effects. The remifentanil is rapidly hydrolysed in plasma by tissue esterases, leading to rapid recovery which is independent of dose and duration of infusion. So, the available data indicates that its elimination is unaltered in patients with severe liver disease or in those undergoing liver transplantation.

Muscle Relaxants

Suxamethonium and mivacurium are the substrates for hydrolysis by plasma cholinesterase enzyme. Plasma cholinesterase is synthesised in liver. So, low plasma cholinesterase concentration in liver dysfunction may prolong the half-life of succinylcholine and mivacurium. However, the reduction of plasma cholinesterase level is such that, even in fulminant hepatic failure, the action of succinylcholine is unlikely to be prolonged significantly. But, care should be taken if mivacurium or succinylcholine is administered by infusion.

The non-depolarising muscle relaxants are highly water soluble (e.g. d-tubacurarine, galamine and pancuronium atracurium, vecuronium, rocuronium, etc.) and are therefore easily excreted through the urine. However, increased volume of distribution in patients with liver disease leads to an apparent resistance to these agents with prolonged elimination. The modern steroid based drugs such as vecuronium and rocuronium show little alteration in their pharmacokinetics in a jaundiced patient. The atracurium and cisatracurium undergo organ independent elimination by ester hydrolysis and spontaneous Hoffman degradation in the plasma. So, they have no change in elimination half-life or clinical duration of action, even in patients with both hepatic and renal failure. But, many of the newer non-depolarizing drugs are given by infusion and their effect may be unpredictable in patients with hepatic disease. So, careful monitoring of neuromuscular function should be carried out with a nerve stimulator during anaesthesia when muscle relaxants are used, especially by infusion in liver dysfunction patients.

PREOPERATIVE EVALUATION AND RISK ASSESSMENT OF PATIENT WITH LIVER DYSFUNCTION

Liver diseases can alter the responses of patients to anaesthesia and surgery in many ways. So, it is important to understand the applied anatomy and physiology of liver, the factors altering hepatic blood flow, the liver functions and the pharmacokinetics and pharmacodynamics of anaesthetic drugs for proper perioperative management of these patients. But, the complex functions of liver, the effects of perioperative stress and strain on the liver function and the unpredictable effect of drugs in patients with liver disease has made the preanaesthetic evaluation and the risk assesment is challenging. The perioperative risk assessment should take into account the type of liver disease, the degree of hepatic impairment and the intrinsic surgical risk associated with the procedure. Patients with liver disease undergoing nonhepatic surgery and anaesthesia face significant postoperative complications also.

For the assessment of risk, liver disease can be graded (according to Child's classification which is modified by Pugh) on the basis of the impairment of the synthesis functions of liver, mainly plasma

albumin levels and prothrombin time. Mild hepatic disease consists of positive clinical history and evidence of liver pathology coupled with normal plasma albumin and prothrombin times. Other tests of hepatic function such as aminotransferase may be elevated. Moderate liver disease consists of plasma albumin level of at least 3 g/dl and prothrombin time is not greater than 2.5s. Severe liver disease is defined as when albumin level falls below 3 g/dl and prothrombin time is above 2.5s. The perioperative risk assessment of patient according to the type of liver disease is described below under the heading of asymptomatic and symptomatic patients and under the heading of individual disease (Table 32.6).

Asymptomatic Patients

Asymptomatic patients with abnormalities of standard liver enzyme tests including asperate aminotransferase (AST), alamine aminotransferase (ALT) and alkaline phosphatase occur in 0.1 to 4% of the general population. The incidence is as high as 36% in patients with history of alcohol and drug abuse. Minor elevations of these enzymes less than twice of the normal value in asymptomatic patients, who have normal serum bilirubin and INR do not warrant additional testing before anaesthesia and surgery. On the other hand, larger elevations of transaminases during routine preoperative investigations signify a subclinical acute process such as viral hepatitis or a chronic disorder such as chronic hepatitis. So, they require additional analysis starting from the careful history and physical examination of patient to the history of previous surgeries, jaundice, blood transfusion, use of alcohol and other recreational drugs, sexual history, etc. Careful attention should also be paid to the systemic effects of liver disease including pruritus, excessive bleeding after minor trauma, abdominal distention and weight gain. Physical examination should also focus on the signs of liver disease such as icterus, pallor, hepatomegaly, splenomegaly, testicular atrophy, palmar errhythema, spider nevi and gynecomastia. Further investigations should also be carried out to assess the hepatic functions such as coagulation profile, electrolytes and liver enzymes. AST/ALT ratio may also be helpful in distinguishing between the viral and alcohol related hepatitis. Alcohol tends to preferentially damage the mitochondria of hepatocyte, therefore causing much elevation in AST which is usually greater than twice of the ALT values. In contrast, a decrease in this ratio is more consistent with a diagnosis of viral hepatitis. Elevated alkaline phosphatase with abnormal bilirubin and GGT indicate hepatobiliary disease. Asymptomatic patients with significant abnormal liver function should have elective surgery postponed and is further investigated to reassess the perioperative risks.

Symptomatic Patients with Acute and Chronic Hepatic Diseases

Patients with acute liver disease or failure rarely represents for anaesthesia and surgery. This is because mortality rate is very high and is near about 10 to 100%. Acute hepatic failure during postanaesthetic period is due to the decompensation of previously apparent well patients with chronic liver disease. Paradoxically, hyperacute hepatic failure (encephalopathy within 7 days) has the best prognosis.

Table 32.6: Spectrum of liver disease

	Early stage	*Late stage*
1.	Inflammatory response in liver usually predominates	Fibrotic response in liver usually predominates
2.	Drug resistance is often observed	Drug sensitivity is often observed
3.	No portal hypertension is observed	Portal hypertension is the dominant feature
4.	Major laboratory abnormalities are elevated enzymes such as aminotransferase	Major laboratory abnormalities are disorders of hepatic synthetic functions such as abumin, prothrombin time, etc.

Bilirubin level in plasma is elevated in both the stages

Some causes of acute liver disease or failure presenting for surgery and anaesthesia are:

i. Viral hepatitis: Type A to G , cytomegalo virus, herpex simplexvirus, Epstein – Barr virus, etc.
ii. Drugs: Halothane, paracetamol excess, idiosyncratic reactions, etc.
iii. Toxins: Carbon tetrachloride, mushrooms poison etc.
iv. Others: Acute fatty infiltration of pregnancy, HELLP syndrome, Wilson's diseaese, REYE's syndrome, etc.

Some causes of chronic hepatic diseases presenting for surgery and anaesthesia are:

i. The commonest cause of chronic liver disease is cirrhosis. Cirrhosis can be acquired such as due to alcohol, viral hepatitis, drugs, secondary biliary disease etc. Or cirrhosis can be inherited such as due to primary biliary cirrhosis, haemochromatosis, Wilson's disease, galactocaemia, sickle cell disease, etc.
ii. Chronic hepatitis is also wide spread. It is defined as any hepatitis lasting longer than 6 months. The causes of chronic hepatitis are: viruses, alcohol, autoimmune, metabolic and drugs (isoniazid, methyldopa). Chronic hepatits B develops in 3% of those infected. It is widespread in the Far East, Africa and infects 300 million people world wide. Other high risk groups include — homosexuals, IV drug abusers, haemophiliacs, haemodialysis patients. Chronic hepatitis B may progress to cirrhosis or hepato – cellular carcinoma. Chronic hepatitis C develops in 75% of those infected. Risk groups are

similar to hepatitis B and cirrhosis or hepatocellular carcinoma can develop.

Hepatitis

A hepatitis patient should always be taken seriously for anaesthesia. So, an accurate diagnosis of the cause of hepatitis is exceedingly important during preanaesthetic investigations. There are two points of serious concern in a patient suffering from acute viral hepatitis and who may require surgery and anaesthesia. These two points are:

i. The combination of surgery, anaesthesia and acute viral hepatitis is associated with high mortality rate. Available data indicates that perioperative mortality rate ranges from 10 to 100%, if a patient with acute viral hepatitis requires surgery and anaesthesia. Thus, a disease of low to moderate mortality is converted by the surgery and anaesthesia to one of high mortality.
ii. Hepatitis B and C can be highly contagious via parenteral inoculation to the operating theatre personnel.

However, the exact time of surgery and anaesthesia which is safe after an acute attack of viral hepatitis is still unknown. It is usually said that surgery is permissible some 30 days after the liver function studies have returned to normal. It is prudent to postpone the elective surgery in the acute phase of hepatitis and wait for the level of transaminases to return to the normal ranges. In case of hepatitis B and C, there should be sufficient time to ensure that the patient does not enter into the phase of chronic persistent or chronic active hepatitis. A jaundiced patient waiting for anaesthesia and surgery should be differentiated between acute viral hepatitis and posthepatic biliary obstruction as a cause of jaundice where in one condition early surgery is necessary and in one condition where early surgery and anaesthesia is associated with high mortality rate.

There are three principal hepatitis viruses: A, B and C (older nomenclature of C is non-A / non-B). Hepatitis A is the classic oral-faecal, food-borne hepatitis with low mortality rate and does not progress to chronic hepatitis. Hepatitis B and C have higher mortality rate and can progress to chronicity. The chronic phase of these viral hepatitis may be either chronic persistent hepatitis or chronic active hepatitis. Chronic persistent hepatitis is a mild non progressive disease. In most cases it is due to either hepatitis B or C viruses. This chronic persistent viral hepatitis may be due to some unknown reasons and is slow to resolve, at times taking as long as 18 months. Then, these patients eventualy do resolve and the prognosis is generally favourable. Since these patients are eventually cleared of liver disease, usually with in a year, so it is prudent to defer the elective surgery until their liver function studies become normal, for at least 1 month. If emergency surgery is required, then the risk in these patients is probably not increased (but there is no data to confirm this point).

Chronic active hepatitis has also been termed as chronic aggressive hepatitis. It is produced by hepatitis B and C viruses and progress in most patients to cirrhosis and hepatic failure. Patients with chronic active hepatitis will eventually die of liver failure within 2 to 10 years, unless other causes of death supervene. The bilirubin level increases and aminotransferase levels fluctuate between 200 to 800 U/L. There will be elevated prothrombin time and hypoalbuminaemia. Purely elective surgery is not wise in chronic active hepatitis and they fall within the domain of severe hepatic impairment (Table 32.7).

Table 32.7: Causes of hepatitis

A. Viral infections	
• Hepatitis A virus	• Hepatitis E
• Hepatitis B virus	• Herpes simplex virus
• Hepatitis C virus	• Cytomegalovirus (CMV)
• Hepatitis D virus	• Epstein-Barr virus (EBV)
B. Toxins	
• Alcohol	• Drugs, e.g. methyldopa, isoniazid, halothane, amiodarone, herbal drugs
C. Miscellaneous	
• Wilson's disease	• Haemochromatosis
• Autoimmune hepatitis	• α_1-antitrypsin deficiency

Alcoholic Liver Disease (Alcoholic Hepatitis)

Patients with alcoholic liver disease or alcoholic hepatitis tend to have increased postoperative complications such as poor wound healing, infections, delirium and bleeding. Alcoholic hepatitis similar to other forms of liver disease or hepatitis runs as continuum and the severity of complications depends upon the severity of the liver pathology. The end result of alcoholic hepatitis is cirrhosis. Patients with alcoholic fatty liver tolerate surgery well. While those with cirrhosis have increased postoperative morbidity and mortality. Asymptomatic alcoholic hepatitis produces some hepatomegaly with minimal alterations of liver functions tests. Mild alcoholic hepatitis adds mild jaundice with liver tenderness. Some acute alcoholic hepatitis adds increasing jaundice, fever, leucocytosis and elevated prothrombin time. If patient is considered to have mild alcoholic hepatitis, evidenced by slightly elevated aminotransferase, lactate dehydrogenase, alkaline phosphatase and mildly elevated bilirubin with little or no change in prothrombin time, then the patient should be advised to abstain from alcohol to improve liver functions and then surgery and anaesthesia can be proceeded with.

Cirrhosis

The table illustrates the polarisation of the spectrum of liver disease. A chronic inflammatory process of liver initiated either by virus infections or by toxins (alcohol) or due to any other causes shown in table produces an inflammatory response in hepatocytes. After a variable

period of time this chronic inflammation is replaced by scar tissue (fibrosis) leading to cirrhosis. Cirrhosis is then the end stage of chronic liver inflammatory disease which is characterised by severe fibrosis and irregular nodular regenerations of the remaining liver parenchyma. The bundles of scar tissue infringes on the hepatic sinusoidal space, increasing their pressure. This increased sinusoidal pressure is transmitted to the low pressure, high flow portal venous system and in turn increase its pressure (portal hypertension). As a result, this increased pressure forces portal blood out of the liver. The blood is then diverted through the other vessels, such as gastric and oesophageal veins where there is communication between the portal and systemic circulation producing oesophageal varices. Therefore, increased portal venous pressure causes portal hypertension and other stigmata of it. Patients with cirrhosis have altered and reduced hepatic blood flow, that further worsens the liver functions and decreases the metabolism of commonly administered drugs. Associated with cirrhosis they have also nutritional disorders, ascites, coagulopathy, renal dysfunctions and high risk of developing encephalopathy (Table 32.8). There is no question that patients with advanced liver disease are at severe risk if they require major surgery and anaesthesia. The risks of surgery in these patients correlate well with the Child's classification of risk assessment. This classification is not only applied in cirrhotic patient, but also in other liver dysfunction. In this classification, there are five factors affecting mortality and infuencing the gradings. These are ascites, albumin, bilirubin, encephalopathy and nutritional status. However, this Child's classification is modified by Pugh who added prothrombin time as another risk factor. Prolongation of prothrombin time greater than 2.5s from control, implies increased anaesthetic risk and if greater than 4.0s implies severe risk. AST and ALT levels are not included in this list of risk factors, because elevation of these plasma enzymes do not imply acute injury. For each factor, score of 1 to 3 is alloted and usually three classes – A, B and C are described. Mortality rate in group A, B and C are respectively < 10%, 30% and > 40%. The causes of mortality in the perioperative period in patients with eirrhosis of liver or liver dysfunction are: sepsis, renal failure, bleeding, hepatic failure and hepatic encephalopathy. However, this score is simple, but lacks linearity. Because it does not take into account any specific underlying disease process. Although three of these factors such as ascites, encephalopathy and nutritional status are purely subjective, but this score still remains a useful tool for preanaesthetic assessment of patients with cirrhosis (Table 32.9).

Table 32.8: Causes of cirrhosis

- Any cause of chronic hepatitis
- Primary biliary cirrhosis
- Secondary biliary cirrhosis (stones, strictures)
- Alcohol
- Wilson's disease
- Haemochromatosis
- Cystic fibrosis
- α_1-antitrypsin deficiency

ANAESTHETIC MANAGEMENT OF PATIENT WITH LIVER DISEASE AND JAUNDICE

The most common liver disease encountered during anaesthesia is inflammatory hepatitis (alcohol or virus) leading to cirrhosis. If these patients require anaesthesia during an acute attack of hepatitis, mortality can be extremely high. Among them some patients with chronic hepatitis may remain in some stages of progression to cirrhosis and portal hypertension which require anaesthesia for nonhepatic surgical events. Sometimes patients present for surgery with acute biliary tract obstruction and jaundice (e.g. stone in CBD, etc.) without any hepatitis. The pathognomonic features of advanced jaundice due to hepatitis or posthepatic obstruction or due to other causes which frequently anaesthetists have to encountered and manage are hyperdynamic circulation, hypoxaemia, metabolic alkalosis, clotting abnormalities, altered hepatic blood flow, cirrhosis, ascites, renal impairment, hepatic encephalopathy and altered drug handling.

Table 32.9: Child's classification (modified by Pugh) of risk for cirrhotic patients undergoing major surgery

	Group A	*Group B*	*Group C*
Serum bilirubin (mg/dl)	< 2	2 - 3	> 3
Serum albumin (g/dl)	> 4	3 - 4	< 3
Ascites	None	Controlled	Poorly controlled
Neurological disorder	None	Minimal	Advanced
Nutritional status	Excellent	Good	Poor
Prothrombin time (seconds)	< 2.5	2 - 4	> 4
Surgical risk	Good	Moderate	Poor
Mortality risk	< 10%	30%	> 40%

Group A → 1point each,
Group B → 2 point each,
Group C → 3 point each.

Grading

Grade 5 – 6 : Good risk (30% mortality)
Grade 7 – 9 : Moderate risk (40% mortality)
Grade 10 – 15 : Poor risk (90% mortality)

Hyperdynamic Circulation

The striking features of a patient with advanced liver disease with or without jaundice is decreased systemic vascular resistance and increased cardiac output, resulting in a bounding pulse. The increase in cardiac output is proportional to the decrease in SVR, which is again proportional to the severity of liver disease. But, if tense ascites is present, then cardiac output (CO) will decrease due to the reduction of preload due to pressure on IVC and it will not improve, until paracentesis is done. The decreased vascular resistance is due to the arteriolar vasodilatation in hepatic diseased patient. Blood pressure tends to be normal or may even be a bit lower. So, hypertension is very unusual in a jaundiced patient. The atherosclerotic changes in the vascular system are generally minimum in liver dysfunction. Deficiency of cholesterol and abnormal lipid metabolism are responsible for this. The tragedy is despite having the increased cardiac output in jaundiced patient, many patients have overt signs of an underlying cardiomyopathy. So, the low peripheral resistance of a liver-dysfunction patient exerts a protective effect on left ventricular function. Thus, an abrupt return of vascular resistance to normal values due to any cause can unmask the acute left ventricular decompensation. Cardiac glycosides are not of any benefit to cardiomyopathy in liver dysfunction patient. Plasma levels of catecholamines are increased, indicating hightened sympathetic tone (compensatory mechanism) to compensate the blunted baroreceptor reflexes, which occurs in jaundice. These appears to be due to the decreased numbers of adrenergic receptors by down regulation. So, there is a rightward shift of the dose response curve, in contrast to normal patient causing increased dose requirement of pressure raising drugs. Thus, for the planning of anaesthetic management several considerations regarding the cardiovascular system in liver dysfunction or jaundiced patients should be kept in mind.

Table 32.10: Effects of liver dysfunction on respiratory system

- Decreased alveolar ventilation
- Hypoxaemia: Hepatopulmonary syndrome (intrapulmonary shunting)
- Pulmonary hypertension: PPS, hypercapnoea, acidosis
- Pulmonary aspiration: Gastro-oesophageal reflux
- Require postoperative ventilatory support

Table 32.11: Effects of liver dysfunction on haematology

- Blood loss: Varicose vein, peptic ulcer
- Anaemia: Chronic illness, haemolysis
- Platelets: Dysfunction, ↓ number
- Coagulation abnormality
- Fibronolysis
- Blood and blood products should be ready for management

Drugs such as isoflurane and sevoflurane which depress the myocardial contractility are not absolutely contraindicated in liver dysfunction patient, but should be used with great care. Since the decreased peripheral resistance seems to be somewhat of compensatory safe guard, so correction or normalization of this variable may not be in the patient's interest. If catecholamines or pressure raising agents are used, then the dose should be more than of normal patients. This is because of the down-regulation and decreased number of receptors. Liver disease causes various types of shunt such as from cutaneous spider angioma to portal systemic arteriovenous shunts. These shunts, in combination with reduced SVR and increased extracellular fluid due to activated renin angiotensin system, increases the cardiac output often by 50%. In contrast, some alcoholics may have decreased cardiac output secondary to cardiomyopathy (Table 32.10).

Hypoxaemia

In a jaundiced or liver diseased patient arterial hypoxaemia is common. This hypoxaemia is primarily due to the diffusion and perfusion mismatch in lungs. Thus, arterial oxygen partial pressure usually remains < 70 mm of Hg. This diffusion – perfusion mismatch is due to the increased intrapulmonary shunting, and this is because of the dilatation of the pulmonary precapillary or capillary bed. This hypoxaemia is further exacerbated in upright position, because gravity further increases the blood flow in the bses of lung where perfusion is greater than ventilation, causing more diffusion – perfusion mismatch. This peculiar hypoxaemia can also be due to the true pulmonary shunt. Incidence of pleural effusion is more common in jaundice or may develop frequently in the post-operative period, especially if the abdominal right upper quadrant surgery has been performed. Lung infections are also common in a liver disease patient.

From the anaesthetic point of view, hypoxaemia is never allowed in liver compromised patients for any reason. So, always a high inspired O_2 concentration (FiO_2) should be employed during anaesthesia. Sometimes splinting of diaphragm by ascites, causing a decrease in P_aO_2 cannot be improved by increasing the FiO_2. However, this should be managed by diuretics or paracentesis. Pulmonary problems should be resolved in the preoperative phase by (i) stopping smoking, (ii) giving appropriate antibiotics for lung infections, (iii) paracentesis, (iv) physiotherapy, etc. For moderate to major surgeries, the anaesthetist should also consider the placement of an indwelling arterial catheter for perioperative blood–gas analysis (Table 32.11).

Metabolic Alkalosis

Patients with liver dysfunction and jaundice often have metabolic alkalosis (compensatory). The explanation of this metabolic alkalosis is like that in liver dysfunction aldosterone levels remain high. This hormone causes excessive renal absorption of Na^+ in exchange of urinary

potassium with H^+ loss and renal retention of ammonia causing azotemia. This K^+ loss is of particular importance, if the patient is under diuretic therapy preoperatively specially. So, an anaesthetist must be careful about potassium replacement in hepatic failure patient. Failure to replace potassium perioperatively can lead to cardiac arrhythmias, increased plasma ammonia and difficulty in reversing the neuromuscular block.

Clotting and Bleeding Abnormalities

As liver is the site of synthesis of vit-K dependent clotting factors such as II, V, VII and X ; so their levels are reduced in hepatic disease or in jaundiced patient. Thus, the prothrombin time which measures the activities of these factors and the extrinsic pathway is increased. Activated partial prothrombin time (aPTT) which measures the activities of II, V, VIII, IX, X, XI, XII clotting factors and intrinsic pathway is also increased. Thus, they provide an excellent assessment of the risk of surgery. So, Vit-K should be given parenterally for atleast 72 hours before surgery when prothrombin time (PT) increases. When PT is greater than 2.5 s, in a patient facing a major surgery, then the fresh frozen plasma (FFP) is probably indicated. Still, if there is persistent hepatic dysfunction, then repeated doses of FFP may be required. The rational approach in bleeding disorder is to administer 2 to 6 U of FFP at 6-12 hour interval in an attempt to bring the PT to 2 to 3 s of control. If surgery progresses with enough bleeding, then FFP requirement certainly increases. If correction of PT is not obtained, even after what would seem to be adequate by recommended FFP therapy, then there may probably exist fibrinogen degradation product in the circulation. As factor VII has a half-life of only 4 to 8 hours, so the response to FFP measured by PT may not be long lasting.

Disorders of bleeding also develop in patients with liver diseases due to absolute deficiency in number and quality of platelets. Redistribution of platelet to the spleen is also considered to be the most important factor leading to absolute thrombocytopenia in liver compromised patient. The platelet infusions may be indicated when platelet count is less than 40,000 to 50,000/cu mm. Platelet function is best assessed by bleeding time. There would appear to be no problem in insertion of an epidural catheter, if the PT has been corrected to 2 to 3 s of control value and the platelet count is > 40000/cumm, with normal bleeding time.

Hepatic Blood Flow

The total hepatic blood flow is the result of hepatic arterial flow plus portal venous flow. Among these, the portal venous flow is responsible for 70% of the total O_2 supply to the liver. Buffer response autoregulates the total hepatic blood flow, i.e. when BP drops due to any reason (e.g. haemorrhage), then blood flow in the portal venous system drops first due to low pressure system. Then, due to dilation of the hepatic artery, blood flow through it again increases, so as to keep the total hepatic blood flow within normal limits. Again the liver cells have unique property to increase the oxygen extraction from blood when blood flow drops.

General and regional anaesthesia cause the reduction of liver blood flow and it is generally parallel with the drop of systemic blood pressure and cardiac output. So it seems that BP is the major determinant factor of blood flow in liver. So, during anaesthesia on a liver dysfunction patient blood pressure should be maintained strictly whithin its normal range. During inhalational anaesthesia at equi-anaesthetic concentrations, halothane compromises the hepatic blood flow to maximum extent than other inhalational agents. This is due to the absence or attenuation of buffer response during inhalational anaesthesia as hepatic artery does not dilate in reponse to decreased portal venous blood flow and hypotension by volatile agents. Isoflurane and sevoflurane produce lesser reduction of hepatic blood flow than halothane. Hepatic blood flow is best preserved during anaesthesia, if there is proper maintenance of CO and BP. Intravenous anaesthesia by newer synthetic opioids and propofol is considered to be the best technique in this regard. But, patients with compromised liver functions respond poorly to opioids due to decreased clearance and increased CNS susceptibility. Thus, a high-dose of fentanil or sufentanil is rarely an option for anaesthesia in patients with poor liver function.

Except anaesthetic agents, other factors that alter the hepatic blood flow are controlled ventilation, hypocapnia and surgical intervention. Controlled ventilation, particularly PEEP can cause upto 30% reduction in hepatic blood flow. Hypocapnia is also associated with a significant reduction in hepatic blood flow. This is due to the increase in hepatic arterial vasoconstriction and simultaneously the increase in resistance. So, $ETCO_2$ tension should be kept as near normal as possible. Surgical manoeuvers, especially in upper abdomen decrease the splanchnic and total hepatic blood flow to a greater extent and even more than the general anaesthetic agents. So, during surgical manoeuvers care should be taken to avoid undue pressure and strain on the supplying vessels of the liver by manual traction, packs, retractors, etc.

Ascites

The presence of ascites with liver disease indicates advanced pathology and carries a bad prognosis. So, preoperative amelioration of ascites considerably improves the surgical prognosis. Thus, forced sodium and water excretion by diuretics is the corner stone of preoperative therapy for ascites. Spironolactone is a weak diuretic and acts by inhibiting the action of aldosterone at distal tubule. It inhibits Na^+ reabsorption at distal tubule, but spares

K^+ (potassium sparing diuretic). Thus, conservation of K^+ is helpful in a jaundiced patient who has hypokalemia due to increased aldosterone level. The dose of spironolactone required to induce diuresis is proportional to the plasma aldosterone concentration. Like spironolactone, other K^+ sparing and distal tubular acting diuretics such as triamterene or amiloride are also the drugs of choice. Frusemide is not well tolerated in patients with ascites, cirrhosis or other liver dysfunctions. Because, it prevents reabsorption of both Na^+ and K^+ at proximal tubule. So, though natriuresis, induced by frusemide is helpful, but hypokalemia is not helpful for liver dysfunction or jaundiced patient. Hypokalaemia produces a dangerous situation in liver disease. So, K^+ level should be monitored and maintained strictly within normal level. Following aggressive diuretic therapy an anaesthetist will often find low serum Na^+ level in patients scheduled for surgery. This is probably without hazard, if the sodium is not less than 130 m.mol/L.

In some patients, diuresis can not be initiated, despite the maximal dose of diuretic agents (e.g. 400 mg of spironolactone) which act on distal tubule. This is because of the avid proximal tubular sodium reabsorption. Then, more potent, proximally acting diuretics (frusemide, thiazide, etc.) can be added cautiously to this regimen. In such situation, spironolactone plus frusemide (20 to 80 mg per day) is usually sufficient to initiate a diuresis in most patients. However, such aggresive therapy must be used with great caution to avoid plasma volume depletion, azotaemia and hypokalaemia which may lead to encephalopathy.

Except diuresis, paracentesis may also be employed successfully to reduce ascites. Paracentesis is considered as complimentary to diuretic therapy and makes the patient definitely comfortable. Ascites can also be controlled by peritoneovenous shunts which moves the ascitic fluid into the vascular compartments, causing over expansion of vascular volume, ↑CO, ↑renal blood flow, ↑excretion of Na^+ and water. More recently, transjugular intrahepatic portosystemic shunting (TIPS) has been used effectively to control the refractory ascites and may improve the postoperative outcome in these patients.

Renal Impairment

There are varieties of changes in renal function, induced by advanced liver disease. Among these the hepatorenal syndrome and acute tubular necrosis are common. These are due to the increased renin-angiotensin activation, which produces excessive sodium and water retention. The hepatorenal syndrome is a unique pathological condition of kidney which is seen only in advanced liver disease. It is a functional renal failure, occurs spontaneously and is more commonly due to the fluid shifts, particularly in patients with obstructive jaundice. However, the kidney is normal histologically and functions normally following a liver transplantation or if this kidney is transplanted into a healthy recepient. All the pathological changes seen in ascites (renal sodium and water retention and plasma volume expansion) are present in an extreme form in the hepatorenal syndrome. So, maintenance of an adequate urine output by fluids and diuretics is the mainstay of prevention of this syndrome. It is a serious complication in patients associated with cirrhosis and ascites. It is characterised by worsening azotemia with avid Na^+ and water retention and oliguria in the absence of identifiable specific causes of renal dysfunction. Once renal failure occurs due to any cause in the presence of cirrhosis, then mortality is usually 100% (Table 32.12).

Table 32.12: Renal effect of liver dysfunction

- Water overload
- Hypernatraemia
- Hyperkalaemia
- Circulatory decompensation
- Oedema and ascites
- Hepatorenal syndrome

The exact cause of this syndrome is not fully known, but altered renal haemodynamic appear to be the probable explanation. The kidneys are structurally intact and renal biopsy is also normal. The risk is great, if the serum bilirubin levels are high and there is endotoxemia from infected bile. The hallmark of this hepatorenal syndrome is intense sodium retention, oliguria, hypotension and intense azotemia. The patient hardly excretes any Na^+. The onset of this syndrome is very rapid. Urine analysis reveals little sodium (< 10 m.mol/L). Sometimes, in severe liver dysfunction patients can also develop acute oliguric renal failure due to haemorrhage, hypotension, etc. This oliguric renal failure can be differentiated from the hepatorenal syndrome as urinary sodium is > 30 m.mol/L in oliguric renal failure. Diagnostic criteria of hepatorenal syndrome are: (i) urinary sodium < 10 m.mol/Litre, (ii) urine : plasma osmolarity and creatinine ratios > 1, (iii) presence of chronic liver disease and ascites.

The anaesthetic management of this problem includes adequate preoperative evaluation of fluid, electrolyte and renal status. Urinary output is measured by bladder catheterisation. Central venous pressure measurement is strongly advised during extensive operative procedure to guide the fluid therapy. The most important factor predisposing to renal failure in the presence of hyperbilirubinaemia is hypovolaemia. Therefore, patients should not be allowed to be dehydrated. IV fluid (0.9% normal saline) should be used liberally to ensure moderate to high CVP and urine output of 1 ml/Kg/hour or 50 ml/hour (in adult). If despite hydration, the urine output is low, then 20% mannitol administered intravenously is the treatment of choice. The dose of mannitol is 0.5 g/Kg over 30 minutes.

A suitable antibiotic should be given preoperatively along with premedication, if there is endotoxaemia. As there is activation

of aldosterone – renin – angiotension system, these patients are avid Na^+ retainers. Thus, Na^+ containing IV fluid should be administered cautiously during perioperative period. The use of nephrotoxic drugs such as NSAIDs and gentamicin in repeated doses should be avoided. Worsening of hepatorenal failure may result in death, despite haemofiltration or dialysis and can only be corrected by liver transplantation.

Hepatic Encephalopathy

Sometimes hepatic encephalopathy is seen in individuals with severe liver disease. It is characterised by decrease in consciousness, fluctuating neurological signs, flapping tremor and distinctive EEG changes. This occurs in hyperacute (within 7 days), acute (7 to 28 days) and subacute (28 days to 6 months) hepatic failure. This classification does not include fulminant hepatic failure, where encephalopathy developed within 8 weeks of precipitatory illness. In severe cases of hepatic encephalopathy irreversible coma and death may occur. Generally, this is a lethal syndrome with more than 90% mortality.

In hepatic encephalopathy, there are two issues of interest to the anaesthetist. First is the high level of ammonia which is most often incriminated in the pathogenesis of hepatic encephalopathy. Second is the excessive concentration of GABA which is an inhibitory neurotransmitter of CNS and is responsible for the reduced level of consciousness. In severe liver dysfunction, due to intrahepatic and extrahepatic shunting of portal venous blood into the systemic circulation, liver is largely bypassed. As a result of this process various toxic substances, mainly NH_3, absorbed from the intestine are not detoxified by the liver and lead to elevated blood ammonia level, causing metabolic abnormalities in CNS. The salient point for an anaesthetist regarding hepatic encephalopathy is hyperventilation, producing respiratory alkalosis which strongly helps in conversion of ammonium ion (NH_4^+) to ammonia (NH_3). Ammonia (NH_3 not the ammonium ion NH_4^+) is the form that can cross the blood-brain barrier and cause or exacerbate encephalopathy (Table 32.13).

Increased GABA level in CNS reflects the failure of liver to extract precursor amino acid which synthesise GABA in brain or to remove GABA which is produced in the intestine. It has been also recognised that benzodiasepine receptors (BDZ) are closely associated with GABA receptor and also facilitate GABA transmission. Thus, BDZ sometimes can precipitate hepatic encephalopathy or coma. This finding can be substantiated by the fact that injection of flumazenil ameliorate the symptoms of clinical coma and EEG signs in a high percentage of cases. Thus the clinical information to the anaesthetist is that CNS depressant drugs such as sedatives (BDZ), narcotics, barbiturates, etc, which are related to GABA receptors may precipitate hepatic encephalopathy and coma. The mechanism behind the increased CNS susceptibility of these drugs which may be amplified by other altered drug handling phenomenans are ↓biotransformation, ↓albumin binding, etc., in liver diseases. So, large doses of these drugs should be avoided in late stages of liver dysfunction. Thus, a typical high dose of narcotic technique used for cardiac anaesthesia has no role in liver disease and may be detremental. In such situations, inhalational anaesthetics have no limitation and are favoured.

Other factors which can precipitate hepatic encephalopathy are GI bleeding, azotemia, hypokalaemia (directly stimulating ammonia production by kidney), hyponatremia, hypoxia, infection, surgery, etc. In severe encephalopathy, the decreased level of consciousness may compromise the airway and intubation may be required if cerebral oedema develops.

Table 32.13: Grades of hepatic encephalopathy

Grade 0	Alert and oriented
Grade I	Drowsy and oriented
Grade II	Drowsy and disoriented
Grade III	Stupour and restlessness
Grade IV	Coma-Nonresponsive to deep pain

Cirrhosis

Before surgery and anaesthesia cirrhotic patients may be benefited from increased aggresive preoperative treatment of coagulopathy are done which are usually associated with cirrhosis, ascites and encephalopathy are done which are usually associated with cirrhosis. Patients with cirrhosis develop coagulopathy as a result of decreased synthesis and shortened half-life of Vit-K dependent coagulation factors and abnormalities (both qualitative and quantitive) of platelets. Vit-K administration normally corrects the prolongation of prothrombin time. However, it is not effective when the decreased synthesis of coagulation factors is due to the nutritional deficiency. In these cases FFP infusion usually brings the prothrombin time to normal. If this also fails, then cryoprecipitate is helpful to reduce the prothrombin time within 3 seconds to normal.

The cirrhosis is the most common cause of portal hypertension. In cirrhosis the vascular bed of liver is distorted and blood flow is mechanically obstructed. So, the normal portal venous pressure which is about 7 mm of Hg is raised upto 50 mm of Hg. As the portal venous system lacks valves, so the resistance at any level between the right side of the heart and the splanchnic vessels in intestine results in retrograde transmission of this elevated pressure. This facilitates retrograde blood flow from the present high pressure portal venous system to the lower pressure systemic venous system or circulation. The major sites of this collateral flow of blood between the portal and the systemic venous system involve the veins around the rectum (haemorrhoids), cardio-oesophageal junction (oesophagogastric varices), retroperitoneal space and falciform ligament. The major clinical manifestations of portal

hypertension include: haemorrhage from the gastroesophageal varices, splenomegaly with hypersplenism, ascites and hepatic encephalopathy.

Cirrhosis is thought to be a major risk factor for patients undergoing non-hepatic surgery. Elective surgery is contraindicated in Child-Pugh class C patients. Surgery should also be avoided in patients with severe hypoalbuminaemia, evidence of infection and encephalopathy. Alternatives to surgery should be considered, as it is associated with high mortality rate.

PREOPERATIVE LABORATORY INVESTIGATION

The following preoperative laboratory investigations should be done before anaesthesia and surgery for a liver dysfunction patients. These are:

i. Full blood count and studies of clotting profile: among these the prothrombin time is the best marker of liver dysfunctions.
ii. Electrolytes, urea and creatinine: the urea level in blood is falsely low due to decreased hepatic production.
iii. Blood glucose level: Hepatic stores of glucose and glycogen are often affected. Patients frequently suffer from hypoglycaemia.
iv. Liver function tests (LFTs): LFTs must always be interpreted against the careful history and examination of that particular patient. The liver has large reserve of its functional capacity and can often withstand considerable damage before LFTs become deranged. On the other hand, serum liver functions tests are rarely specific. So, the serial measurements are useful and indicate trends. Among the liver function tests, prothrombin time, albumin level and bilirubin level are the most sensitive markers. It is important not to give the fresh forzen plasma, unless there is active bleeding before the LFTs are performed. Because, it will alter the prothrombin time which is an excellent guide to overall liver functions. AST and ALT (liver transaminases) are sensitive markers and can even indicate mild liver damage. But, they have no role in mortality prediction. Although, the levels of transaminases increase in liver diseases, but it may also decrease in severe liver disease. Alkaline phosphatase is increased with biliary obstruction. Antinuclear antibody is present in 75% of patients with chronic active hepatitis. Smooth muscle antibody is present in nearly all the cases of primary biliary cirrhosis. α-fetoprotein is a marker of hepatoma.
v. Imaging techniques: Ultrasound is the main initial investigation of obstructive jaundice. Other useful investigations include ERCP, CT, MRI and CT or MRI guided – cholangiograms.
vi. Arterial blood gases.
vii. Urine analysis.
viii. Hepatitis screening (Table 32.14).

SOME PERIOPERATIVE CONSIDERATIONS

During anaesthsia of patients suffering from liver diseases there are some principles or guide lines. These guide lines are given below. H_2 antagonists or proton pump inhibitors should be routinely used preoperatively in liver dysfunction patients. Rapid sequence induction of anaesthesia will reduce the risks of gastric aspiration. Hepatic blood flow is often altered during anaesthesia and surgery. This is due to the effect of anaesthetic drugs, positive pressure ventilation, PEEP and surgical technique. In most cases anaesthesia reduces liver blood flow, particularly if halothane is used. However, isoflurane actually seems to improve the hepatic blood flow. Sevoflurane is also a preferred volatile agent for liver disease. Regional techniques can be used as long as coagulation is not much deranged and it should be remembered that all the local anaesthetics are metabolised by liver.

POSTOPERATIVE JAUNDICE

The occurrence of postoperative jaundice is a problem of increasing incidence. It is perhaps seen more frequently now than in earlier years. This is because many patients are now undergoing more major surgical procedures and survive too. The incidence of postoperative jaundice varies from 1%

Table 32.14: Preoperative preparation of liver dysfunction patient

- Restore and maintain euvolaemia.
- Correct electrolyte imbalance, if any.
- Maintain normal glucose level.
- Correct coagulopathy with FFP and platelets.
- Use Vit-K, according to the laboratory test.
- Use DDAVP and aminocaproic acid as necessary.
- Optimize the patient's nutritional and medical status.
- Ascites if massive - abdominal paracentesis is preferred. Otherwise, treated with Na^+ and water restriction and diuretics. Rate of reduction of ascitic fluid should be 0.5 kg of body weight per day.
- Administration of thiamine to patients experiencing acute withdrawal of alcohol and prophylaxis for delirium and tremors.
- Prevent hepatorenal syndrome by avoiding dehydration, avoiding nephrotoxic drugs like aminoglycosides and NSAID, using dopamine infusions, using powerful diuretics, avoiding renal contrast, paracentesis of tense ascites, etc.
- Iotrogenic factors, precipitating encephalopathy should be used cautiously like injudicious use of sedatives like BDZ, opioids, etc.
- Lactulose and neomycin should be used to limit bacterial toxins.

of all the patients undergoing abdominal surgery to 17% of all the patients undergoing major surgery. Although postoperative jaundice is relatively common, but significant postoperative liver dysfunction is relatively rare. This rare postoperative liver dysfunction has varied aetiology and often resolves without treatment. It should be remembered that hepatitis due to volatile anaesthetic agents is extremely rare and is largely diagnosis of exclusion.

There are three major pathological mechanisms for postoperative jaundice. These are: postoperative increased pigment load, postoperative impaired hepatocellular function and postoperative intrahepatic/posthepatic obstruction of bile flow. Most of the etiologies for postoperative jaundice become apparent within three weeks of surgery and can be classified as mild or severe if the serum bilirubin is less than 4 mg/dl or greater.

Increased pigment load occurs as a result of haemolysis following blood transfusions, drugs (which sometimes induce haemolysis) and also from reabsorption of blood from the extravascular space. Approximately 10% of stored whole blood undergoes haemolysis within 24 hours of transfusion. Each 0.5 L of stored blood yields 7.5 g of haemoglobin, which is then converted to 250 mg of bilirubin. Multiple blood transfusions may, therefore, limit the ability of liver to conjugate and excrete this bilirubin load i.e. reserve of the liver function (Table 32.15).

Hepatocellular damage and impaired hepatocellular functions postcoperatively are caused by nonanaesthetic drugs used during anaesthesia, anaesthetic agents (mainly halothane), ischaemia due to hypotension, sepsis and viral hepatitis, etc. With lesser degree of hypotension and hypoxaemia, morphological changes may be slight, but significant impairment of function may occur in severe hypotension and hypoxemia. Prior shock or hypotension plus pigment overload may produce significant liver dysfunction and jaundice. Extensive sepsis also can produce jaundice of cholestatic type. Concurrent renal impairment due to hypotension and hypoxaemia may also enhance the degree of liver dysfunction and jaundice, and this is because of decreased renal excretion of conjugated bilirubin. Drug induced hepatotoxicity is primarily due to idiosyncratic reactions or alterations in bile flow by drug, resulting in cholestasis.

Table 32.15: Causes of postoperative liver dysfunction or jaundice

1. Bilirubin overload (haemolysis)
   - i. Blood transfusion
   - ii. Haematoma reabsorption
   - iii. Haemolytic anaemia :

     Sickle cell, G-6-P deficiency, mismatched transfusion etc.
2. Hepatocellular injury
   - i. Exaccerbation of pre-existing liver disease
   - ii. Hepatic ischaemia due to hypovolaemia, hypotension and cardiac failure
   - iii. Septicaemia
   - iv. Hypoxia
   - v. Viral hepatitis
   - vi. Drug induced (halothane, antibiotics)
3. Cholestasis (Obstruction)
   - i. Intrahepatic:

     Benign, infective, drug induced, pregnancy, etc.
   - ii. Extrahepatic: Retained stone in bile duct, postoperative cholecystitis, bileduct injury, pancreatitis, etc.

The extrahepatic obstruction flow of bile due to surgical damage of biliary passage or stones within if causing postoperative jaundice need to be considered and may be excluded by sonography. Benign postoperative intrahepatic cholestasis mimics biliary obstruction and usually occurs after major surgery associated with hypotension, hypoxaemia or multiple transfusions.

GUIDELINE FOR ANAESTHESIA IN PATIENTS WITH DECOMPENSATED LIVER FUNCTION

An anaesthetist should always show a considerable degree of latitude when making a mind to administer anaesthesia in patients with advanced liver disease. The choice of drugs and monitoring of patient during anaesthesia of patient suffering from liver dysfunction mainly depends upon the severity of the disease, the type of surgery and the experience of anaesthetist. The surgical procedures can be divided into two groups: surgery on diseased liver to correct dysfunction of it and extrahepatic surgery with liver dysfunction. The surgery on liver may extend from a simple biopsy to liver transplantation. Whereas the extrahepatic surgery with liver dysfunction include different general surgeries with jaundice or asymptomatic carrier state of hepatitis and various surgeries to correct the complication which is developed due to liver dysfunction e.g. making portacaval shunts, trans-oesophageal ligation of varices, etc.

The type of anaesthesia in liver dysfunction can be divided into regional and general. The regional anaesthesia plays a significant role in patients with liver disease. The main limitation of regional anaesthesia in liver dysfunction is clotting and bleeding abnormalities causing haematoma in epidural or subarachnoid space. Otherwise, it is very safe, if it fits well with the type of surgery, i.e. lower extremities, obstetric and gynaecological operations (lower abdomen), or some upper abdominal surgeries such as cholecystectomy, etc. Now, mastectomy and other cardiac and thoracic surgeries also can be done by cervical or thoracic epidural anaesthesia. Different types of nerves and plexus blocks such as brachial or cervical plexus block are also very safe for liver dysfunction patients. Clotting and bleeding abnormalities of patients with liver disease should be corrected before administering anaesthesia, especially regional anaesthesia. Otherwise, it is sheer madness to operate upon them. If regional anaesthesia is selected as the ultimate choice, then the guidelines for detection of clotting and bleeding abnormalities are: prothrombin

time must be less than 2.5s of control value, platelet count should be > 40,000 / Cu.mm, bleeding time which measure the both platelet quantity (number) and quality should not be greater than 12 minutes. If bleeding and clotting parameters are within these guidelines; then spinal, epidural and other regional blocks with epidural catheter for postoperative pain control can be employed safely after major surgeries.

During administration of GA care should be taken by the anaesthetist when he uses CNS depressant drugs like sedatives, narcotics, etc for induction. Large doses of them always should be avoided. Titrating dose is mandatory. Regarding premedications, none to small amount is suggested, according to the severity of liver dysfunction and physical status of the patient. If premedications are needed at all, drugs handled by phase II biotransformatione such as morphin, lorazepam or oxazepam, etc. are recommended. Glycopyrrolate is preferred to atropine as it does not cross the blood brain-barrier. Regarding induction, the preferred inducing agent is propofol. Thiopentone also can be used safely. Regarding the neuromuscular block, many anaesthetists still use succinylcholine during elective surgery for intubation. This is because there is only theoretical speculation that the action of succinylcholine can be prolonged due to deficiency of plasma cholinesterase in patients with liver disease. It is true, but seems clinically insignificant, because the action of succinylcholine rarely becomes prolonged and cause any problem of overwhelming magnitude. Vecuronium, cis-atracuronium and atracurium are ideal muscle relaxants for patients with liver dysfunction. Vecuronium is used for longer surgical procedures and atracurium is used for shorter ones. Isoflurane and sevoflurane are the backbones of anaesthetic regimens for patients with liver disease, but doses should always be adjusted so as not to depress much the cardiovascular system. N_2O does not produce any injury to the hepatocytes and can be used safely even in severe liver dysfunction patients, if there is no contraindication, e.g. bowel distension, middle ear surgery, etc. Small doses of opioids play an important role in the anaesthetic regimen by reducing the need of inhalational anaesthetics, particularly if there is hypovolaemia and central pump failure. But, larger doses of opioids should always be avoided. There is no contraindication for use of neostigmine for reversal of neuromuscular block and it responds well in normal fashion in patients with liver dysfunction.

The monitoring of liver dysfunction patients during perianaesthetic period include all the standard monitoring, depending on the gravity of the surgical procedures and the physical status of the patient. PT, aPTT, platelet count and haematocrit values are required periodically. Standard monitors include pulse oximeter, ECG, $ETCO_2$, HR, BP, etc. Urine output should always be monitored with a catheter. Invasive monitors such as intra-arterial catheter, CVP, Swan-Ganz catheter, TEE, etc, are also indicated depending on the clinical circumstances. Coronary vasoconstriction caused by vasopressin which is used to control the variceal haemorrhage can be reversed by conventional doses of nitroglycerin. Somatostatin can be used instead of vasopressin and causes less coronary vasoconstriction. Where there is concern about renal perfusion, then dopamine drip in the dose of 1 to 2 µg/Kg/min may be of immense value.

HALOTHANE AND HEPATIC TOXICITY

The liver dysfunction produced by halothane is called the halothane associated hepatitis (HAH). This HAH is defined (though the definition is unsatisfactory) as the appearance of liver damage within 28 days of halothane exposure in a person in whom other known causes of liver disease have been excluded. Two syndromes are recognised in HAH or halothane induced liver dysfunction: (i) The first is associated with the transient rise of the values of liver function tests and has low morbidity. This occurs often after the initial exposure to halothane. (ii) The second is associated with repeated exposure and high rise of values of liver function tests. It has an 'immune' mechanism with the development of fulminant hepatic failure (FHF) and is associated with high mortality rate. FHF is rare with an incidence of 1 in 35,000 after halothane anaesthesia.

Halothane induced liver dysfunction may be due to (i) the direct effect of drug on the hepatocytes itself or (ii) the effect of metabolites of drug on the hepatocytes or (iii) an immune reaction following repeated exposure to halothane. Indirect cause for liver dysfunction after halothane exposure is due to hypotension, diminished liver blood flow and subsequent reduced hepatic O_2 availability. These also appear to be of genetic susceptibility for halothane induced hepatotoxicity as shown by *in vitro* test.

Metabolic cause for liver dysfunction is also due to the metabolites, produced by metabolism of halothane in the hepatocytes. Up to 20 to 40% of halothane is metabolised in human liver. Whereas enflurane 2 to 8%, isoflurane 1%, sevoflurane 0.2% is metabolised in liver. The metabolism of halothane in liver takes two pathways: One is the oxidative pathway and another is the reductive pathway. The the metabolites of reductive pathways do not produce any injury to hepatocytes. But metabolites of oxidative pathway bind to liver microsomes which contain the cytochrome P-450 system and induce hepatotoxicity. The chance of metabolic reaction causing hepatotoxicity by volatile agents is thought to be related to the amount it is metabolised. As for example enflurane only 2 to 8% is metabolised, it should therefore cause 10 times fewer reactions than halothane. Isoflurane is only 1% metabolised. There is, therefore, a theoretical risk for reaction to isoflurane and indeed there have been only a few case

reports of isoflurane induced hepatotoxicity. So isoflurane is considered safe for use in patients at risk of hepatic failure. Sevoflurane and desflurane also appear to be safe in liver failure.

The immunological mechanism of hepatitis, particularly fulminant hepatic failure (FHF) is evidenced or proved by the presence of antibodies to halothane in the sera of patients suffering from FHF after exposure to halothane and are present in 70% of such patient. Antibodies have not been found in patients with liver disease of other etiologies. It is also not found in patients exposed to halothane but without developing FHF. The antibody is not directed against the reductive metabolites of halothane, but only against an oxidative metabolite compound such as trifluroacetyl halide (TFH). These are IgG type of antibodies and react with the cell surface of hepatocytes, making them susceptible to antibody dependent cell mediated toxicity. Halothane is a small molecule and itself is unlikely to be immunoreactive. It is postulated that binding of oxidative metabolite of halothane to the liver cytochrome which act as a hapten induce a hypersensitivity reaction. FHF which carries a high mortality rate is particularly due to immune reaction following repeated exposure. Any time interval between two exposures are not considered safe, as the mechanism is immunological and any exposure after the first could trigger an immunological response.

HAH is usually present in two forms. One is characterized by moderate elevation of liver transaminase and transient mild jaundice with low morbidity and no mortality. Another is characterised by development of FHF with high mortality and is associated with repeated exposure to halothane (or isoflurane, enflurane, sevoflurane due to cross sensitivity).

33 Thyroid Diseases and Anaesthesia

INTRODUCTION

The hypothalamus, pituitary and thyroid gland, making an axis are involved in the regulation of various cellular activity in the body. In this axis as the target organ, the thyroid gland is very important. The different forms of thyroid diseases are very common and it affects 5 to 10% of total general population, of which females are more affected than male. The thyroid gland is not so essential for life. But its absence causes impairment of cellular activity or metabolism and as a consequence produce several defects such as slowing of both physical and mental growth, reduction of cardiac contractility, poor resistance to cold, etc. In children mental retardation and dwarfism is manifested in the absence of thyroid hormone. In the contrary, excess thyroid secretions lead to nervousness, body wasting, tremor, tachycardia, excess heat production, etc.

The thyroid hormones are synthesised in the body from iodine and an essential amino acid, named tyrosine. After absorption from GI tract, the dietary iodine is converted to iodide and actively transported to thyroid gland. The thyroid gland has also the special capacity of abstracting iodide from the circulating blood. In the thyroid gland this iodide is again oxidized to iodine by peroxidase enzyme and combines with tyrosine to form monoiodotyrosine (MIT) and di-iodotyrosine (DIT). In the gland these two compounds are again coupled to form tri-iodotyrosine (T_3) and tetraiodotyrosine or thyroxine (T_4). The last two compounds are released from the thyroid gland and are called the thyroid hormones. But, the T_4 is formed in far excess in amount than T_3. After their formation, the T_4 and T_3 are immediately attached or conjugated to thyroglobulin which is also a specific protein, secreted by the thyroid cell. This conjugated material is popularly known as the colloid substance and it is in this form that the T_4 and T_3 is stored in the acini of thyroid gland. When required by the body, this conjugation breaks and large amount of T_4 with little amount of T_3 is liberated into the circulation (Fig. 33.1).

Physiology

The thyroid gland predominantly secretes two hormones, named tetraiodothyronine or thyroxine (T_4) and a small amount of tri-iodothyronine (T_3). But 85% of this small amount of circulating T_3 is also produced from T_4 by the process of monodeiodination in other peripheral tissues such as muscle, liver, kidney, etc. *In vivo* T_3 is more potent than T_4 and metabolically is more active. While T_4 is probably metabolically inactive and may be regarded as prohormone of T_3. The 99% of circulating T_4 and T_3 are bound to a special transport protein in plasma, called the thyroxine binding globulin (TBG). The remaining small fraction of circulating thyroid hormones remains as unbound or free form and diffuses into tissues to exert their metabolic function.

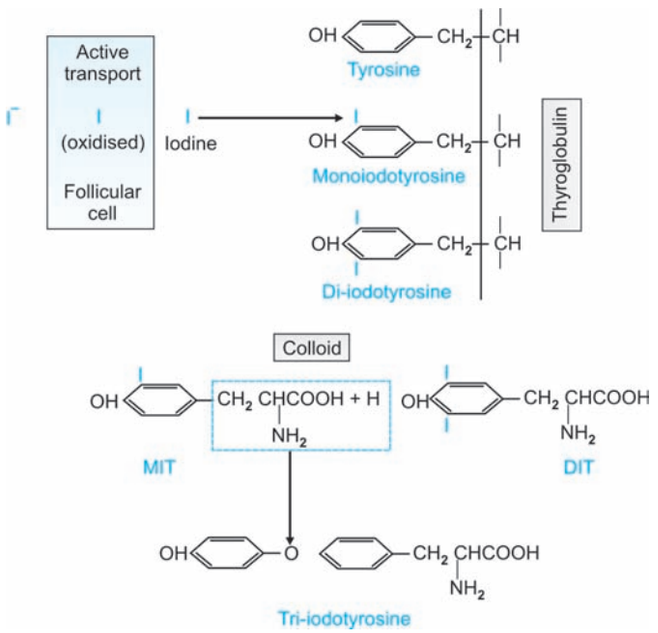

Fig. 33.1: Synthesis of thyroid hormones

It is possible to measure the total, bound (with TBG) and unbound (free) fraction of thyroid hormones, i.e. T_4 and T_3 in plasma. But, the advantage of measurement of free hormone is that they are not influenced by the changes in the concentration of TBG or plasma protein. For example, during pregnancy the TBG level is increased and with it the total T_4 and T_3 level may be increased. But, the free thyroid hormone level may remain normal.

The production of thyroid hormones from the thyroid gland is stimulated by another hormone named TSH (thyroid stimulating hormone). This TSH is released from the anterior pituitary gland in response to another thyrotrophin releasing hormone (TRH), secreted from hypothalamus. A circardian rhythm for the secretion of TSH is found with the peak at 0100 hour and 1100 hour of the day. But, this circardian variation is small and does not influence the timing of blood sampling for the assessment of thyroid function. There is some negative feedback response of thyroid hormones on the secretion of TSH from the anterior pituitary. So, when the plasma concentration of T_4 and T_3 are raised in primary hyperthyroidism, then the TSH level is reduced. Similarly, when the plasma concentration of T_4 and T_3 are decreased in primary hypothyroidism, then the TSH level is raised. In subclinical hyper- and hypothyroidism the T_4 and T_3 level remain normal, but the TSH level suppressed or raised. This is because the anterior pituitary gland is very sensitive to minor changes in thyroid hormone level, though it remains still within its normal range.

The three major forms of thyroid diseases that are frequently encountered in clinical practice by an anaesthetist are hyperthyroidism, hypothyroidism and goitre. Although no age group is exempted from thyroid disease, but the patient most likely to be affected are middle aged and female. In addition, the increasing tendency to screen the population and ready access to accurate tests of thyroid functions have led to the identification of many patients with abnormal result who are either asymptomatic or with nonspecific complaints such as tiredness, more sleep, weight gain, etc. (Table 33.1, Fact file-I).

HYPERTHYROIDISM

In over 90% of patients the principal cause of hyperthyroidism is Graves disease. The other causes of hyperthyroidism are multinodular goitre, thyroiditis, some drugs, etc, which are displayed in Table 33.2. The most common symptoms of hyperthyroidism are: loss of weight, heat intolerance, palpitation, tremor, etc, which are also displayed in table. Although the diagnosis of this disease, i.e. hyperthyroidism can usually be made clinically, but still it is important to confirm this disease by laboratory tests such as by measuring the levels of circulating thyroid hormones and TSH. The serum T_4 and T_3 level are elevated and TSH level is reduced in majority of patients. But, T_4 is in the upper part of the normal range and T_3 is only raised in 5% of hyperthyroidism patient. This special condition is called the T_3 thyrotoxicosis and is found particularly in those who are suffering from recurrent hyperthyroidism, or following thyroid surgery or after a course of antithyroid drugs. Other tests which are also performed to establish the aetiology of hyperthyroiroidism include the estimation of TRAB (TSH – receptor antibody) which is elevated in Graves disease, isotope scanning, etc. Diagnosis of hyperthyroidism during pregnancy is very

Table 33.1: Patterns of thyroid function tests in different thyroid diseases

Thyroid disease	*T_3*	*T_4*	*TSH*
1. Hyperthyroidism (Graves disease)	H	H	L
2. T_3 hyperthyroidism	H	N	L
3. Subclinical hyperthyroidism	N	N	L
4. Primary hypothyroidism	L	L	H
5. Subclinical hypothyroidism	N	N	H
6. Secondary hypothyroidism	L	L	L
7. Secondary hyperthyroidism	H	H	H

FACT FILE - I

The thyroid gland secretes three hormones -thyroxine (T_4), Triidothyronine (T_3) and calcitonin. The first two are secreted by the follicular cells of thyroid gland and have the same biological activity. So, they are termed as thyroid hormones. While the last one is secreted by the interfollicular cells and its biological activity is entirely different from thyroid hormone. It takes part in Ca^{2+} metabolism.

Both T_4 and T_3 are the iodine containing derivative of a chemical compound, named thyronine which is produced by the condensation of two molecules of amino acid, called tyrosine. The total body content of iodine (I_2) obtained from food product is 40 to 50 mg. Out of this, 1/4th is present in the thyroid gland. Concentration of iodine in blood is low (0·2 to 0·4 μg/dl). But the thyroid follicular cells have an active transport process and concentrate it in the gland. This trapping of I_2 in the gland is stimulated by TSH and exceed the gradient of more than 100 fold between plasma and gland. The total iodine content of thyroid gland also regulates the uptake of it by the gland. Little store of iodine stimulate and the large store inhibits the uptake of iodine by the gland. This iodine concentrating ability is also found in other organs such as salivary gland, skin, intestine, gastric mucosa, placenta, breast, etc. But their uptake of iodine is not regulated by TSH.

Dietary iodine is first absorbed by the GI tract. Then it is converted to iodine ion (I^-) and actively transported to the thyroid gland. After trapping of iodide (I^-) by the follicular cells of thyroid gland, it is further oxidised to iodine (I). Then it combines avidly with the tyrosine residue of thyroglobulin, and form MIT and DIT. Then the pairs of iodinated tyrosyl residues couple together to form T_4 and T_3. Normally, much more T_4 is formed than T_3. But during the iodine deficiency, relatively more T_3 (active form) is formed.

The thyroid hormones are synthesised and also stored as colloid in the cavity of the thyroid follicle, (but not in the cells of the follicle) as a part of thyroglobulin molecule. Thyroglobulin is glycoprotein in nature and is also synthesised by the thyroid follicular cells. Then, the thyroglobulin is transported from the cells to the cavity of the follicle, where MIT, DIT and by further coupling T_3 and T_4 are formed. During the release of thyroid hormones, colloid is taken back into the follicular cells from the cavity by endocytosis and broken down into T_4, T_3, DIT and MIT. T_4 and T_3 so released from thyroglobulin is secreted into the circulation, while MIT and DIT residues are deiodinated and the released iodine is reutilised. The uptake of colloid and breaking down of it is stimulated by TSH. The resting thyroid gland has follicles distended with colloid and the cells are flat or cubical. While the TSH stimulated gland has columnar cells and colloid virtually disappears.

difficult. This is because in pregnancy oestrogen induced increase in TBG results in increased total protein bound T_4 and T_3 level (Table 33.2).

The symptoms and signs of hyperthyroidism reflect the excessive effect of T_4 and T_3 hormone on the cellular activity, particularly its metabolism which are also listed in the table. It mainly increases the carbohydrate and fat metabolism. Thus, the thyroid hormone determines mainly the growth and the metabolic rate of the body. But from the anaesthetic point of view the important thoughts are that the increase in metabolic rate is associated with an increase in O_2 consumption and CO_2 production which indirectly increases the minute ventilation. The cardiac contractility and HR are also increased. This is due to the alteration in physiology of adrenergic receptor and other internal proteins or receptors by increased circulating level of thyroid hormones, as opposed to the increases level of plasma catecholamines (Table 33.3).

The patients suffering from hyperthyroidism are usually treated by antithyroid drugs, inorganic iodine, β-adrenergic antagonist, radioactive iodine and / or surgical removal of thyroid gland. During the period of treatment of hyperthyroidism, patients are continuously monitored by the measurement of plasma TSH level which indicates if hypothyroidism is developing or not and the plasma T_4 level which indicates if hyperthyroidism is developing or not.

Table 33.2: Causes of hyperthyroidism

A.	*Thyroid overactivity*
	Graves disease
	Toxic multinodular goiter
	Solitary toxic adenoma
	Hashimoto's thyroiditis
	Thyroid cancer
	TSH - secreting pituitary tumour
B.	*Extrathyroidal*
	Administration of thyroid hormones (iatrogenic)
	Ectropic thyroid tissue
	Choriocarcinoma and hydatidiform mole

Table 33.3: Clinical features of hyperthyroidism

Goiter - diffuse or nodular
Weightloss, diarrhoea, nausea and vomitting.
Tachycardia, atrial fibrillation, angina, heart failure.
Tremor, nervousness, anxiety, hyperreflexia, myopathy.
Heat intolerance, fatigue.
Exophthalmos, and other eye signs.

The commonly used drugs for the medical management of hyperthyroidism are: (i) the antithyroid drugs such as carbimazole, methimazole, propylthiouracil, etc. (ii) iodine containing compounds such as potassium iodide, Lugol's solution of iodine, etc (iii) lithium, and (iv) glucocorticoids. The other modes of treatment of hyperthyroidism are: use of radioactive iodine and surgery (Table 33.4).

As antithyroid agent, the thiourea derivatives are first discovered in 1940. Subsequently, the methyl and propyl thiouracil derivatives and thiomidazole derivatives such as methimazole and carbimazole were discovered and found to be safe and effective for the treatment of hyperthyroidism. All these antithyroid drugs bind to thyroid peroxidase enzyme and inhibit the iodination of tyrosyl residue of thyroglobulin. Thus, they inhibit the production of MIT and DIT. They also stop the coupling of iodotyrosine residue of MIT and DIT to form T_3 and T_4. Thus, the thyroid colloid is gradually depleted of thyroid hormones i.e. T_4 and T_3 overtime and blood levels of T_3 and T_4 are reduced. However, they do not interfere with the trapping of iodine by thyroid gland from plasma and do not modify the action of T_3 and T_4 on peripheral tissues or on pituitary gland. The antithyroid drugs also do not affect the release of T_3 and T_4 from thyroid gland which are already synthesised in the cell. Hence, their effects are not apparent, till the thyroid gland is depleted of its hormone content. Propylthiouracil also inhibits the peripheral conversion of T_4 to T_3. In India only carbimazole is available and routinely used. But, it acts largely by getting converted into methimazole by the peripheral tissues.

Table 33.4: Mechanism of action of antithyroid drugs

	Drugs	*Mechanism of action*
A.	Antithyroid drugs Propylthiouracil Carbimazole Methimazole	Inhibit the thyroid hormone synthesis
B.	β-adrenergic agonist Esmolol Propranolol	Impair the peripheral action of T_4 and T_3
C.	Iodine compounds Potassium iodide Lugol's solution	Inhibit the release of T_4 and T_3
D.	Lithium	Inhibits the release of T_4 and T_3
E.	Glucocorticoids	Immunosuppressive action Impair the peripheral action of T_4 and T_3

Though iodine is a constituent of the thyroid hormones, but still it is the fastest acting thyroid inhibitor. All the facets of thyroid function seem to be affected by iodine. But the most important function of it is inhibition of the release of thyroid hormone from the follicular cells which has been already synthesized. The endocytosis of colloid and proteolysis process of thyroglobulin with the attached MIT, DIT, T_3 and T_4 which help in the release of thyroid hormones comes to a halt. Thus, the enlarged gland slowly shrinks, and then, it becomes firm and less vascular (Table 33.5).

With daily administration of iodine the thyroid status starts to return to normal slowly and peak effects are seen within 10 to 15 days after starting of iodine. After that the 'thyroid escape' may occur spontaneously and thyrotoxicosis may return with greater severity. So, this group of drugs i.e. iodine is only used temporarily for the preoperative preparation of patient before thyroiectomy. It is generally given for 10 days just before surgery with the aim

Table 33.5: Differences between propylthiouracil and carbimazole

	Carbimazole	*Propylthiouracil*
1.	More potent (3 times).	Less potent
2.	Plasma half-life 6 to 10 hours.	Plasma half-life 1 to 2 hours.
3.	Less plasma protein bound.	High plasma protein bound.
4.	Large amount crosses the placenta.	Little amount crosses the placenta.
5.	Duration of action 12 to 24 hours.	Duration of action 4 to 8 hours.
6.	So single daily dose is used.	Multiple daily dose is used.
7.	Produces active metabolic - methimazole.	No active metabolite.
8.	Does not inhibit the peripheral conversions of T_4 and T_3.	Can inhibit the peripheral conversion of T_4 to T_3

to make the gland firm, less vascular and easier to operate on. Though iodine itself lowers the thyroid status, but it cannot be solely relied upon to attain euthyroidism which is done by the concomitant use of carbimazole before starting iodine. Propranolol may be given additionally for the control of symptoms of hyperthyroidism, especially tachycardia before anaesthesia and surgery if needed (Fact file-II).

The commonly used radioactive isotope of iodine for the treatment of hyperthyroidism is I^{131} (other isotopes are I^{127}, I^{125}, etc). Its half-life is 8 days and emits both the γ-rays and as well as β-particles. The former are useful in tracer studies as they traverse the tissues and can be monitored by a counter. While the later are utilized for their destructive effect on the thyroid cells. After administration the radioactive I^{131} is actively concentrated by the thyroid gland, incorporated in their colloid and then emits radiation from within the follicles. The β-particles penetrate only the 0·5 to 2 mm of tissues. Thus, the thyroid follicular cells are affected from within the gland and undergo pyknosis and necrosis. Then the necrosed tissues undergo fibrosis when a sufficiently large dose of I^{131} has been administered, without damage to the neighbouring tissues. Hence, with the careful selected doses of radioactive iodine it is possible to achieve the partial ablation of thyroid gland without surgery. It is used as sodium salt of I^{131} which is dissolved in water and taken orally. The response of radioactive iodine is slow. Its action starts after 2 weeks of administration and gradually increases to reach a peak effect at 3 months. The common indications for the use of I^{131} are: (i) patient above 45 years of age, (ii) recurrence of hyperthyroidism after surgery, (iii) hypersensitive or refractory to antithyroid drugs, (iv) patient unfit for surgery (Fact file -III).

For surgical management of hyperthyroidism, two types of surgeries are advocated. These are subtotal thyroidectomy and excision of only toxic nodule. Surgical treatment for hyperthyroidism is only indicated when there is large goitre, causing tracheal compression and cosmetic concerns and medical or radioiodine therapy have failed. Any patient with hyperthyroidism scheduled for surgery should be rendered first euthyroid by drugs before anaesthesia. This is because toxic patients cannot be dealt as such for the fear of development of thyroid crisis during surgery and anaesthesia. Therefore, the principles of preparation of a hyperthyroid patient before surgery and anaesthesia are as follows:

i. Patients suffering from mild hyperthyroidism :
   They are usually treated by only iodine preparation 14 days before operation. For this purpose Lugol's iodine (10%) is used in the dose of 5 drops 3 times per day.
ii. Patient suffering from severe hyperthyroidism :
   They are usually treated by carbamizole. But it takes long time, usually 8 to 12 weeks to make the patient euthyroid. However, with this treatment the size and vascularity of the gland increase and make the operation very difficult. Some surgeons, therefore, stop or reduce the dose of the antithyroid drug 14 days prior to the surgery and for these 14

FACT FILE - II

Advantages and disadvantages of antithyroid drugs over surgery and I^{131}.

A. Advantages

i. Can be used in young adults and children.
ii. No surgical risk such as injury of nerve, parathyroid gland, haematoma and airway obstruction.
iii. No anaesthetic risk.
iv. Used in pregnancy.

B. Disadvantages

i. Prolonged treatment is needed.
ii. Release rate is high.
iii. Not applicable in psychiatric patient.
iv. Drug toxicity can occur.

Thyroidectomy and I^{131} are contraindicated during pregnancy. Propylthiouracil is preferred than carbimazole during pregnancy. This is because its greater protein binding capacity allows less transfer to the foetus and less chance of foetal hypothyroidism and goiter caused by antithyroid drugs. Due to the same reason it is also preferred in the nursing mother after delivery.

FACT FILE - III

Advantages and disadvantages of radioactive I^{131}.

A Advantages

i. Treatment is simple, inexpensive and outpatient procedure.
ii. No surgical and anaesthetic risk.
iii. Cure is permanent.

B Disadvantages

i. Delayed response.
ii. Contraindicated during pregnancy.
iii. Not suitable for young patients.
iv. More likely to develop hypothyroidism and needs life long T_4 treatment.

I^{131} is the treatment of choice after 35 to 40 years of age and if chronic heart failure, angina or any other contraindication to surgery is present. In some centre the cut off age for the treatment of hyperthyroidism by radioactive iodine has been lowered to 25 years.

days they administer only iodine with the idea that iodine will cause diminution of the size and vascularity of thyroid gland. While this is true, but others do not favour the use of iodine, since it causes an increased friability of the gland which proves troublesome during operation.

iii. During an emergency, patients also can be prepared for surgery in less than 1 hour by IV administration of esmolol or propranolol.

The common complications of thyroid surgery which may concern an anaesthetist are: damage to the recurrent laryngeal nerve, airway obstruction, postoperative bleeding, thyroid crisis and postoperative hypoparathyroidism. The most common nerve liable to damage during thyroid surgery is the adductor fibres of recurrent laryngeal nerve. When this type of nerve damage is unilateral, then it is characterised by the paralysis of vocal cord of one side which assumes an intermediate position and produce hoarsness of voice. Whereas the bilateral injury of this nerve causes paralysed vocal cord of both side which can then collapse together, producing apnoea and total airway obstruction during inspiration.

Airway obstruction is also a common complication following thyroid surgery. It may be due to (i) adducting malfunction of vocal cords caused by recurrent laryngeal nerve injury of both side described above or (ii) collapse of trachea for tracheomalacia, reflecting weakness of tracheal ring due to chronic pressure from goitre or (iii) haematoma formation at surgical site causing tracheal compression. This emergency condition caused by haematoma at operative site is promptly treated by the removal of surgical stitches and evacuation of blood clot or reintubation.

Another complication followed by thyroid surgery and is important from the anaesthetic point of view is thyroid crisis. It is a medical emergency situation and is characterised by tachycardia, hyperthermia, dehydration, tremor, congestive heart failure, shock, etc. It can occur intraoperatively or 6 to 10 hours postoperatively. When the thyroid crisis occurs intraoperatively then it mimicks the malignant hyperpyrexia. But unlike malignant hyperthermia, thyroid crisis is not associated with muscle rigidity, raised creatinine kinase, metabolic (lactic) acidosis, and respiratory acidosis. It generally occurs when the patient is not properly made euthyroid prior to the surgery. This condition usually results from the sudden entry of huge quantity of thyroid hormones into the circulation due to: (i) pumping out of thyroid hormone from the gland by manipulation during surgery, and (ii) absorption of thyroxine from the raw cut surface of the thyroid gland (Fig. 33.2).

The immediate treatment of thyroid crisis is very important and life saving. It includes:

i. sedation by morphine, or pethidine, or benzodiazepine,

ii. control of hyperpyrexia by infusion of IV – cooled crystalloid solution, continuous ice sponging, air conditioning of room, etc,

iii. control of severe tachycardia by propanolol or continuous infusion of esmolol, until the HR is < 100 per minute,

iv. control of cardiac failure by digitalis,

v. control of hypotension by IV fluid and glucocorticoids (100 to 200 mg every 8 hours) from coexisting adrenal gland suppression,

vi. control of increased plasma T_4 and T_3 level by potassium iodide (1 gm IV over 12 hours) which block the release of T_4 and T_3 from thyroid gland and propylthiouracil (200 to 600 mg every 6 hours orally or by nasogastric tube) which inhibit the extrathyroidal convertion of T_4 to T_3.

Hypoparathyroidism causing tetany due to hypocalcaemia may also occur following thyroidal surgery. It results from either removal of the parathyroid glands with the thyroid tissue or impairment of blood supply to the parathyroid glands during thyroid surgery. If two of the four parathyroid glands remain intact, then tetany does not develop. If damage to all the parathyroid

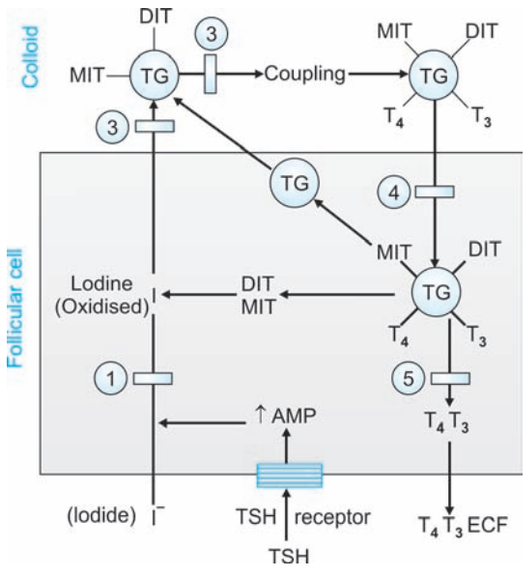

Fig. 33.2: The pathways of synthesis and secretion of thyroid hormones and the different sites of action of antithyroid drugs, such as: 1 = Potassium perchlorate, 2 and 3 = Carbimazole, propylthiouracil, 4 = Lithium, 5 = Iodide. (TG = Thyroglobulin, MIT = Monoiodotyrosine, DIT = Diiodotyrosine)

glands occur during thyroid surgery then symptoms of hypoparathyroidism typically develop 24 to 72 hours after operation. But, it may manifest as early as 1 to 4 hours postoperatively. Laryngeal muscles are most sensitive to hypocalcaemia. So, inspiratory stridor which gradually leads to laryngospasm may be the first manifestation of the surgically induced hypoparathyroidism. Treatment of this emergency condition consists of prompt administration of calcium through intravenous route, until laryngeal spasm or laryngeal stridor ceases.

Anaesthetic Management

When surgery is indicated due to any reason (on thyroid or any other organ than thyroid) on a patient suffering from hyperthyroidism, then it should be deferred until an euthyroid state is achieved. This can be performed by some preoperative preparation which are discussed before. Usually it is the dictum that all the drugs used to maintain the euthyroid state should be continued throughout the perioperative period. During emergency, when the surgery cannot be deferred and there is a state of hyperthyroidism, then the hyperdynamic cardiovascular system has been controlled by continued IV infusion of esmolol in the dose of 100 to 300 µg/kg/minute. The poor control of hyperthyroidism and surgery may precipitate life-threatening condition of thyroid crisis.

Preoperative medication and preparation

Proper evaluation of a hyperthyroid patient prior to surgery is the corner stone of anaesthetic management of it. Among these the full thyroid function tests, the assessment of cardiovascular system and the assessment of airway are most vital. For evaluation of airway, otherthan clinical examination, CT scan or MRI is very helpful. Benzodiazepine is the choice of agent for sedation as preoperative medication and should be used judiciously. It will reduce both the anxietly and HR. The use of anticholinergic agent as premedicant is not always the choice, because it contributes to the increased HR. But it is also not always absolutely contraindicated and where possible glycopyrolate is preferred than atropine.

Induction and maintenance of anaesthesia

Among all the inducing agent for hyperthyroid patient, thiopentone is the most choiced agent. Because its thiourea structure provides some antithyroid activity. However, it is also unlikely that a significant antithyroid effect can be produced by an induction dose of thiopentone. Propofol also can be used for induction of anaesthesia in hyperthyroid patient. But, ketamine is never used, except in some special situation like hypotension, shock, etc, where it is only indicated. This is because it can stimulate the sympathetic nervous system and increase the HR, SVR, BP, etc. Other drugs that also stimulate the sympathetic nervous system should also be avoided because of the possibility of exaggerated elevation in HR and BP. Before the use of any muscle relaxant, depolarizing or non-depolarizing, for tracheal intubation the possible obstruction of airway by a huge goitre and failed intubation should be kept in mind. Otherwise, their use is not contraindicated in hyperthyroid state, provided they do not affect the cardiovascular system.

Throughout the whole perioperative period, the hyperthyroid patient should be monitored for its full cardiovascular function and body temperature. The patient should be positioned with 15° to 20° head raised. It will help by increasing the venous drainage and reducing the blood loss from operative site. But it may increase the chance of venous air embolism. Patient's eyes should be well covered, because exophthalamos in Graves' disease may increase the chance of corneal injury. Adequate depth of anaesthesia during intraoperative period must be achieved to prevent the exaggerated sympathetic response due to laryngoscopy, intubation and surgical stimulation which is already present in hyperthyroid patient. Among the volatile anaesthetic agents isoflurane, sevoflurane, and desflurane are the attractive choice for the maintenance of anaesthesia with adequate depth. This offsets the increased response of sympathetic nervous system due to surgical stimulation and also not sensitise the heart to catecholamines. An alternative choice to volatile anaesthetic agents, where it is contraindicated, is short acting narcotics combined with N_2O. There is clinical impression that the MAC value of volatile anaesthetic agent is increased in hyperthyroid patient. This is due to the increased alveolar circulation caused by increased cardiac output. But practically there is no change in MAC value or anaesthetic requirements of volatile anaesthetic agents.

Thyrotoxicosis is often associated with an increased incidence of myasthenia gravis and myopathies. Therefore, any muscle relaxants should be used cautiously and monitored closely by peripheral nerve stimulator. Pancuronium is not the choice as muscle relaxant for hyperthyroid patient in view of the ability of this drug to stimulate the sympathetic nervous system and to increase the HR with BP. Hence, administration of muscle relaxant with minimal effect on cardiovascular system is always preferred for hyperthyroid patient. Antagonism of neuromuscular blockade by anticholinesterase combined with anticholinergic agent in hyperthyroid patient introduces a great concern regarding the drug induced tachycardia. So, it should be controlled by using glycopyrrolate which has less chronotropic effect than atropine and by β-blocker.

The management of hypotension due to any cause during surgery should be treated by cautious use of sympathomimetic agents with the possibility of exaggerated responses in a hyperthyroid patient. For

these reasons the use of decreased dose of phenylephrine is more logical than ephedrine. This is because the former is direct acting and does not act in part by releasing the endogenous catecholamine like the later. During the immediate and delayed postoperative period the patient should be closely monitored for any thyroid crisis, recurrent laryngeal nerve injury causing respiratory difficulty, airway obstruction by formation of haematoma at the surgical site, hypoparathyroidism, etc, which are specific to thyroid surgery. The management of this complications are discussed before.

HYPOTHYROIDISM

It is a condition where the body tissues are exposed to decreased circulating concentration of thyroid hormones such as T_4 and T_3. It may be the end result of number of diseases of the thyroid gland (primary hypothyroidism), or it may be secondary to pituitary failure (secondary pituitary hypothyroidism) or hypothalamic failure (secondary hypothalamic hypothyrodism). The syndrome of adult hypothyroidism is also known as myxoedema. But sometimes this is used mainly to refer specifically to the skin changes in hypothyroidism. However, when hypothyroidism is present since birth or before it during intrauterine life, then this hypothyroidism is called the cretinism.

The prevalance of hypothyroidism in general population is 1:100. But, if the subclinical hypothyroidism (characterised by normal T_4 and raised TSH) are included, then the prevalance rate may rise to 1:500. Females are more affected from hypothyroidism than male and the male female ratio is 1:6. There are many causes of hypothyroidism and these are displayed in the table. Among these the spontaneous atrophic hypothyroidism, thyroid failure following the use of I^{131} or surgical removal of thyroid gland for hyperthyroidism and the hypothyroidism due to Hashimoto's thyroiditis account for about 90% of cases in those parts of the country which are not significantly iodine deficient (Table 33.6).

The clinical features of hypothyroidism depends on the duration and the severity of it, because the complete thyroid failure may develop over months and even years insidiously. The main consequence of hypothyroidism is the infiltration of body tissues by many substances such as mucopolysaccharide, hyaluronic acid and chondroitin sulphate, etc, causing thickening of it. Thus, there is development of low pitched voice, poor hearing, slurred speech, large tongue and compression of median nerve at wrist, etc. The infiltration of dermis by the previously described substances give rise to non-pitting oedema or myxoedema which is most marked on the skin of the hands, feet and eyelids. There is also periorbital puffiness which is often striking of hypothyroidism. When this is combined with facial pallor due to vasoconstriction or anaemia and parchment paper like lip, then the clinical diagnosis of hypothyroidism is simple. But, most of the cases of hypothyroidism are not so obvious. However, sometimes the diagnosis of hypothyroidism is possibly entertained in the middle aged woman by the complain of tiredness, weight gain, depression, carpal tunnel syndrome, etc, which provide an opportunity for early treatment, otherwise missed.

In the most common form of hypothyroidism such as primary hypothyroidism, there is low serum T_4 and high serum TSH level. The serum T_3 level is not important for hypothyroidism, so is not measured. Other nonspecific biochemical abnormalities of hypothyroidism include the elevation of enzyme lactate dehydrogenase (LDH), elevation of creatine kinase, raised cholesterol level, raised triglyceride concentration, low Na^+ concentration, etc. In severe prolonged hypothyroidism the ECG shows sinus bradycardia, low voltage complexes, and ST and T wave abnormalities. In rare secondary hypothyroidism there is both low T_4 and TSH level. The treatment of hypothyroidism consists of oral administration of thyroid hormone T_4. The optimal therapy of hypothyroidism is characterised by the disappearance of all the symptoms, and normal T_4 and TSH level.

Table 33.6: Causes of hypothyroidism

A.	**Primary**
	• Spontaneous atrophic
	• Hashimoto's thyroiditis congenital
	• Excess iodine (inhibits release)
	• Dietary iodine deficiency
	• Previous subtotal thyroidectomy
	• Previous radioiodine therapy
B.	**Secondary**
	• Hypothalamic dysfunction
	• Ant pituitary dysfunction

Anaesthetic Management

In our day-to-day practice, the likely presence of undiagnosed subclinical hypothyroidism in many patients who undergoes uneventlful anaesthesia and the lack of increased morbidity and mortality during anaesthesia of diagnosed mild hypothyroid patient indicates that there is no reason for delaying elective surgery in these patients. It also indicates that the patients suffering from mild to moderate hypothyroidism are not extra sensitive to inhaled anaesthetic agent and opioids and have no prolonged recovery time or do not experience increased cardiovascular complications. So, elective anaesthesia and surgery should not preferably be deferred in patient suffering from mild to moderate hypothyroidism. However, this is not applicable for severe hypothyroidism patient with some present complication due to it such as pericardial effusion, severe bradycardia, hypotension, etc, provided the surgery is not emergency.

Most patients suffering from hypothyroidism usually receive thyroid hormone replacement therapy and are in euthyroid state during elective surgery and

anaesthesia. So, they must continue it preoperatively and at the morning on the day of anaesthesia. The serum T_4 is a long acting agent and its half-life is 7 to 8 days. So, its scheduled morning dose on the day of surgery is optional. Whereas, T_3 is a short acting drug and its half-life is 1 to 2 days. Therefore, a patient must not omit its usual morning dose of T_3 on the day of surgery and anaesthesia. Hypothyroid patients are more prone to respiratory depression in response to sedatives and narcotics. They also fail to response to hypoxia by increasing the rate and depth of respiration, i.e. minute ventilation. So, they usually do not require much sedation as preoperative medication. Regarding the anticholinergic agent, they are helpful to counter the usually present sinus bradycardia and for this purpose atropine is preferred than glycopyrrolate. Hypothyroid patients usually suffered from increased gastric emptying times (i.e. delayed process of gastric emplying). So, premedications of hypothyroid patients by H_2 histamine antagonist and prokinetic agent such as metoclopramide is very essential. Theoretically, myocardial ischaemia may be worsened by the thyroid hormone replacement therapy. Because it increases the myocardial O_2 demand due to its inotropic and chronotropic effects on myocardium. But the recent available data shows that the symptoms of angina pectoris actually decrease with the thyroid hormone replacement therapy. So, a controversy may condense regarding the use of thyroid hormone from outside as a preoperative medication in such patient.

The induction of anaesthesia of a hypothyroid patient can be performed by the usual inducing agents such as thiopentone, propofol, ketamine, benzodiazepine, etc. But it depends on the severity of the disease and the presence of associated complications. This is because hypothyroid patients are more susceptible to hypotensive effect of inducing agents as there is blunted baroreceptor reflex, diminished intravascular volume, and reduced cardiac output. Therefore, ketamine is frequently recommended as the choiced inducing agent for severe hypothyroid patient and in myxoedema coma. Benzodiazepine is also a good choice as inducing agent in severly ill patient. Sometimes, the possibility of coexistant congestive heart failure and adrenal insufficiency should be taken into account in cases of refractory hypotension in a hypothyroid patient. Theoretically, decreased cardiac output may speed up the induction of anaesthesia by inhalation anaesthetic agents and decrease the MAC valve. But, practically the MAC value of inhalation anaesthetic agents does not truly decrease in hypothyroid patient. In such patient tracheal intubation can be facilitated by muscle relaxation produced by succinylcholine or any nondepolarising agent. But, it will have to keep in mind that the coexisting skeletal muscle weakness may be present in association with hypothyroidism and may potentiate the action of muscle relaxant. Other potential problems which should be kept in mind during induction and intubation of a hypothyroid patient include: large tongue, compression of trachea by large goitre, anaemia, hypoglycaemia, hypothermia due to low BMR, hyponatraemia, etc.

The maintenance of anaesthesia of a hypothyroid patient is usually achieved by using the mixture of N_2O and O_2 which is supplemented by short acting narcotics or volatile anaesthetic agent. However, the excessive volatile anaesthetic agent is not recommended because it may cause the excessive cardiac depression and peripheral vasodilatation, causing abrupt decrease in systemic blood pressure. Therefore, adequate muscle relaxation by the judicious use of neuromuscular blocker (NMB) and minimum use of IV and inhalation anaesthetic agent is the appropriate goal for the management of severe hypothyroid patient. Among the NMB agents, pancuronium is preferred for hypothyroid patients due to its cardiovascular stimulating effect. On the otherhand, the short and intermediate acting NMB agents are also preferred. This is becasue they are less likely to produce prolonged neuromuscular blockade as the reduced skeletal muscular activity is associated with hypothyroidism. Controlled ventilation is preferred than spontaneous ventilation in hypothyroid patient, because they are more prone to hypoventilation and hypoxia in response to anaesthetic drugs. On the other hand, hypothyroid patients are more vulnerable to less production of CO_2 due to decreased BMR. This when again is associated with mechanical ventilation, then it causes decreased P_aCO_2 and subsequently low $ETCO_2$ value.

The aim of perioperative monitoring of a hypothyroid patient is directed to the prompt recognition of any exaggerated depression of cardiovascular system and early detection of onset of any hypothermia. So, continuous monitoring of BP (noninvasive or invasive according to the gravity of necessity), HR, ECG, temperature, $ETCO_2$ etc. is mandatory. In addition, the glucose solution used as IV fluid should contain Na^+ to decrease the incidence of hyponatraemia, because the hypothyroidism is usually associated with the later. In the face of hypothermia which is common in hypothyroidism the body temperature is maintained by increasing the temperature of OT, by using a warming device placed under the patient, by warning the inhaled anaesthetic gases and IV fluid by warmer, etc.

` The perioperative hypotension of a hypothyroid patient is treated mainly by IV fluid, sympathomimetic agents and glucocorticoids. Regarding the sympathomimetic agents, the α-adrenergic agonist such as phenylephrine could adversely increase the systemic vascular resistance in the presence of a heart that cannot reliably increase its contractility. On the other hand, β-adrenergic agonist may precipitate the cardiac arrhythmia. Therefore, a useful approach for the management of

hypotension in a hypothyroid patient is small dose of IV ephedrine (2.5 to 5 mg) while continuously monitoring the CVS. The possibility of acute adrenal insufficiency is thought when there is persistent hypotension despite adequate treatment with IV fluid and sympathomimetic agents. Then, glucocorticoids should be used.

Antagonism of nondepolarising neuromuscular blockade by anticholinesterase combined with anticholinergic agent usually does not pose any extra hazard to hypothyroid patients. But, recovery from general anaesthesia and extubation may be delayed in such patient. This is due to hypothermia, respiratory depression or slow drug biotransformation in hypothyroid patients. Patients should remain intubated until they respond appropriately and the body temperature is near 37°C. Hypothyroid patients often require prolonged ventilation, because they are at increased vulnerability to respiratory depression. Despite all these facts, comparing patients who have mild to moderate hypothyroidism with euthyroid patients fails to demonstrate any significant difference in respect to the incidence of cardiac dysrhythmias, the time to tracheal extubation, the need for vasopressor, hypothermia, and the need for the postoperative ventilatory support.

Myxoedema coma

This is a rare and acute presentation of hypothyroidism in which there is loss of deep tendon reflexes, hypoventilation, hypothermia, cardiovascular collapse, coma and death. Body temperature may be as low as 25°C and convulsions are not uncommon. Myxoedema coma is a medical emergency condition. Sepsis and exposure to cold may be an initiating factor of it. However, treatment must begin before the biochemical confirmation of this medical emergency condition is established. For this situation T_4 is not usually available for parenteral use. T_3 is given as an intravenous bolus stat in the dose of 20 µg. It exerts its physiological effect within 6 hours and is repeated 8 hourly, until there is definite clinical improvement. Administration of T_3 is accompanied with administration of cortisol, if adrenal insufficiency is suspected. In responders, there is gradual rise of body temperature within 24 hours. After 48 to 72 hours it is possible to start substitution by oral thyroxine. Other measures of management in myxoedema coma include slow rewarming, IV fluid, high flow of O_2, broad spectrum antibiotics, etc. During fluid replacement it is important to remember that these patients may be vulnerable to water intoxication and hyponatraemia. Occasionally, assisted ventilation may be necessary (Fact file- IV).

Hashimoto's thyroiditis

It is an autoimmune disease. Hence, it is also known as autoimmune thyroiditis. In 90% of patients with this disease antibody against thyroid peroxidase are present in the serum. This condition is also not infrequently associated with other autoimmune diseases such as autoimmune gastritis, pernicious anaemia, mysthenia gravis, etc. This is the most common cause of goitrous hypothyroidism. It typically affects in the age between 20 to 60 years of old women who present with small or moderately sized diffuse goitre. At this stage it may be impossible to differentiate Hashimoto thyroiditis from simple goitre by palpation alone. Usually this disease runs in two stages. At first, there is moderate and uniform enlargement of gland with soft to firm feel. Then, usually it turns hard and nodular which depends on the relative degree of lymphocytic infiltration, fibrosis and follicular cell hyperplasia of the gland. The thyroid function is usually low. But, in some patients the serum T_4 is normal and TSH is normal or raised. This patients are at increased risk of developing hypothyroidism in future.

Hypothyroid state which is common for this disease is treated by thyroxine therapy. It also helps to shrink the goitre. The dose of thyroxine should be sufficient to suppress the serum TSH to undetectable levelw ithouti nducinghype rthyroidism.

FACT FILE - IV

Graves disease

It accounts for 70 to 80% of the cases of hyperthyroidism. It is distinguished from other forms of hyperthyroidism by the presence of diffuse thyroid enlargement, ophthalmopathy, and pretibial myxoedema (rare). It most commonly affects the 30 to 50 years age group of people. However, it may occur at any age but unusual before puberty. It mostly affects the women, but the cause of this predilection is still unknown. In Graves disease the hyperthyroidism results from the increased production of IgG antibodies directed against the TSH receptor on the thyroid follicles which stimulate the receptor. This produces marked T_4 and T_3 secretion and enlargement of thyroid gland (goitre). However, due to feedback effects of T_4 and T_3, the plasma TSH level is low.

Another hallmark of this disease is exophthalmus. It occurs in 50% of patients suffering from Graves disease and often precedes the development of hyperthyroidism. The cause of this ophthalmic manifestation is still properly not known. But the probable explanation is that there is cytokine-mediated proliferation of fibroblasts which secrete hydrophilic glycosaminoglycans. This results in increased interstitial fluid content which combined with chronic inflammatory cell infiltration causes marked swelling of the orbital tissues and increased retrobulbar pressure. The other antithyroid antibodies which are present in Graves disease also include antibodies to thyroglobulin and thyroid peroxidase. In Hashimoto's thyroiditis the autoimmune antibodies ultimately destroy the thyroid gland. But during the early stage of inflammation of gland it causes excess thyroid hormone secretion and thyrotoxicosis.

34 Psychiatric Diseases—Pharmacology and Anaesthesia

INTRODUCTION

The term 'psyche' means mental process. So, the 'psychiatric disorders' mean the mental disorders. The term 'mental disorders' encompasses a broad range of conditions which are characterised by abnormal patterns of behaviour with psychological signs and symptoms that result in mental dysfunction. Mental disorders are highly prevalent in medical practice, although they are frequently ignored or untreated and may present either as a primary disorder or as a comorbid condition. Approximately 20% of people in UK suffer from psychiatric ill health and apparently 1% of them will have a major disorder.

The important considerations during anaesthetic management of a patient with psychiatric diseases are :

i. The psychotropic drugs that the patients are taking may have potential serious interactions with the anaesthetic agents.
ii. As the patients are frequently depressed, so they have little understanding or appreciation of the course of anaesthesia.
iii. Patients suffering from psychiatric diseases may have associated co-pathology as the consequence of frequent alcohol or drug abuse by them.
iv. Patients who require ECT may require repeated anaesthesia.
v. History taking from a psychiatric patient may be difficult. So, the relatives or care givers of this patient may need to be present during preoperative assessment. The consent for surgery or anaesthesia can only be given by a competent relative, though the majority of patients with psychiatric disorders can give consent themselves normally.
vi. Psychiatric patients are often surprisingly healthy strong muscular and may become suddenly aggresive by unfamiliar faces or surroundings.
vii. Adequate sedative premedication should always be considered and adequate personnel should always be present during induction and emergence from anaesthesia of such patient.
viii. Many patients are on the long term medication and this should be continued throughout the perioperative period, whenever possible and have definite effect on anaesthesia.

During the last 50 years, psychiatric treatment has witnessed many major changes due to the advent of many specific drugs for specific illness. It has also changed the trend from custodial care of patient towards the restoring of individual patient in his own place in the community. Before 1952, the aim of psychiatric treatment was to quieten and sedate the agitated and violent patients. But, the introduction of chlorpromazine in that year had changed the situation and most schizophrenics could now be rehabilated to their productive life. Next in the year of 1957 – 1958 came the tricyclic antidepressants and MAO inhibitors which successfully covered the another group of psychiatric patients. Then, after 1980 many novel antipsychotics and antidepressants have been introduced. After that development of meprobamate and chlordiazepoxide has proved that anxiety could easily be tackled without producing any marked sedation. Now, the goal of treatment of psychiatric patient has been more realised by the development of benzodiazepine (BDZ) in 1960. Buspirone is a recent significant addition.

CLASSIFICATION OF PSYCHIATRIC DISEASES

Like any growing branch of medicine, the psychiatric illnesses have also seen the rapid changes in its classification. This is only to keep up with the growing research data and to deal with the changing epidemiology, symptomatology, prognostic factors, treatment methods and new theories for causation of psychiatric disorders. Now, all the principal types of psychiatric disorders are classified as psychosis, affective disorder and neuroses.

Psychosis

These are severe mental illnesses, characterised by the serious distortion of thought, behaviour, incapacity to recognise the reality and perception (delusions and hallucination), and misconception. This psychotic patient is unable to meet the ordinary demands of life.

Psychoses can be classified again into two disorders: cognitive disorder and functional disorder.

Cognitive disorder (Acute and chronic organic brain syndrome)

The prominent features of this cognitive disorder are confusion, disorientation, defective memory and disorganised behaviour. Examples of this disroder are delirium and dementia. Some toxic or pathological basis can often be found for this disorder, otherwise no definite aetiology can be detected.

Functional disorder

No underlying cause or pathology can often be found for this disorder. Memory and orientation are mostly retained, but emotions, thought and behaviour are seriously altered. This disorder is again classified into schizophrenia and paranoid states.

Schizophrenia (split mind)

It is characterised by inability to think coherently. There is also splitting of perception and interpretation from reality (hallucination).

Its prevalence rate normally varies between 2 to 4 per 1000 normal population. Schizophrenia is characterised by the presence of any one of the Schneider's first rank symptoms in the absence of any physical disease. Schneder's first rank symptoms include auditory hallucination, thought withdrawl, insertion or broadcasting, delusional perception, somatic passivity and feelings, etc. Chronic schizophrenia is characterised by the presence of 'negative symptoms' such as withdrawal, catatonic disturbances and lack of emotion. It commonly begins in late adolescence of either sex and is found in any social group. In the acute phase, patients may be highly delusional and / or aggresive and may not be able to give informed consent. Controlled schizophrenics may be completely lucid and rational, but care must be taken to ensure that their medication is continued where and when possible. Some chronic schizophrenics have predominantly negative symptoms and it is difficult to communicate with them.

Paranoid states

It is characterised by the loss of insight into the abnormality and false believes.

This is also called the delusion disorder. This disorder is characterised by:

i. persistent delusions of persecution (being persecuted against), grandeur (inflated self-esteem), jealousy,
ii. absence of hallucination
iii. personality disturbances,
iv. no underlying organic causes,
v. absence of schizophrenia and mood disorder.

Affective Disorder

The primary symptom of affective disorder is the change in mood. It may be manifested as mania and depression.

Mania

It is characterised by the elation, hyperactivity, uncontrollable thought and uncontrolled speech. It may be associated with violent behaviour.

Depression

It is characterised by the sadness, guilty, physical slowing, mental slowing, melancholia, self destructive idea, etc. Affective disorder may be bipolar (manic and depressive) with cyclically alternating manic and depressive phases. It may also be polar (manic or depression) with a waxing and waning of any single disorder.

Neuroses

This disorder represents the most largest proportion of all the psychiatric illness, attending psychiatric out patients department (75%). These are less serious condition. Here, ability to comprehend reality is not lost, though sometimes patient may undergo extreme suffering. In these disorders catecholamine levels may be very high or the patient may suffer from hyperventilation. These patients require only a great deal of reassurance, but no drug. Premedication is often required to smooth the induction for these patients. Depending on the predominant feature, it may be classified as: anxiety, phobic states, obsessive - compulsive and hysterical.

Anxiety

It is an unpleasant emotional state or thought for the future.

Phobic states

It is characterised by fear for unknown or some known specific objects, person or situation.

Obsessive, compulsive

It is defined as abnormality of thought or behaviour where the patient has limited ability to overcome, even on voluntary effort.

Hysterical

It is a drama like symptom, resembling serious physical illness. But, it is situational and always in the presence of others. The patient does not pretend and actually undergoes the symptoms against his or her will, though the basis is only psychic and not physical.

MULTIAXIAL CLASSIFICATION OF PSYCHIATRIC DISORDERS

Labelling a patient with a diagnosis of psychiatric disorder is not enough. This degrades the patient just as a diseased individual in hospital, but does not give any direct attention to the whole individual in a society. So, a recent classification is adopted by APA (American Psychiatric Association) in DSM-IV (Diagnostic and statistical Manual – IV). This method of classification helps in more holistic assessment of a patient as a whole human. In this system an individual patient is diagnosed on 5 axes.

Axis–I: Presence or absence of any major mental disorders (clinical psychiatric diagnosis).

Axis – II: Presence or abscence of any underlying developmental and personality disorders.

Axis – III: Presence or abscence of general medical disorders.

Axis – IV: Presence or abscence of psychological and enviornmental or social problems (psychosocial disorder).
Axis – V: Overall rating of general psychological functions.

PSYCHO-PHARMACOLOGY AND ANAESTHETIC DRUGS INTERACTION

Till recent years the exact pathophysiology of many psychiatric illnesses are not clear. But some ideas have been formed. As for example, dopaminergic overactivity in the limbic system may be involved in schizophrenia and mania. On the otherhand, the monoaminergic (NE,5-HT) deficit may underlie the depression disorder. So, treatment of psychiatric diseases are emperical, symptom oriented and not disease specific. However, this emperical and symptom oriented management is highly effective in many situations. The drugs which are used for psychiatric diseases and have a significant effect on higher mental functions are also called as psycoactive or psychotropic drugs (Fact file I).

The psychotropic drugs can be classified as follows :

Antipsychotic Drugs

They are useful in all types of psychosis, especially schizophrenia. They are also called neuroleptics, major tranquillizers or antischizophrenic drugs.

Antianxiety Drugs

These are also called anxiolytic, sedative or minor tranquillizer. They are useful for anxiety and phobic states.

Affective Disorder Drugs

i. Antidepressant drugs.
ii. Antimanic or mood stabilizing drugs.

Psychotomimetics or Hallucinogens

Now they are seldom used therapeutically to produce psychosis like states. But, majority are the drugs of abuse.

FACT FILE - I

Tranquilizer is an old term. It means 'a drug which reduces the mental tension and produces the calmness without inducing sleep or depressing mental facilities'. This term is confusing and should not be used any more. Its division into major and minor tranquilizers is also not justfied. Because the 'minor tranquilizers' are not less important drugs. They are more frequently prescribed and carry higher abuse liability than the 'major tranquilizers'. Instead of tranquilizer, the newer terms such as sedative and hypnotic are more commonly used. Sedative is a drug that subdues the excitement and produces the calmness without inducing sleep, though drowsiness may be produced. Sedation also refers to the decreased responsiveness of CNS to any level of stimulation. It is associated with some decrease in motor activity and reduction of formation of idea, but does not induce sleep. Whereas hypnotic is a drug that induces and / or maintain sleep (similar to normal arousable sleep). This should not be confused with 'hypnosis' which means a translike state where the subject becomes passive and highly suggestible. Both sedatives and hypnotics are more or less general CNS depressants with different time action and dose action relationship. Those with quicker onset, shorter duration and steeper dose response curve are referred to as the hypnotics. Whereas, more slowly acting drugs with flatter dose response curve are referred to as the sedatives. However, there is considerable overlap. A hypnotics at lower dose may act as sedative and sedative in higher dose may act as hypnotic.

ANTIPSYCHOTIC DRUGS

The antipsychotic drugs are those agents which are used for the treatment of psychoses or psychotic symptoms. These are also known as the major tranquilizers, neuroleptics or antischizophrenic drugs. But, the term antipsychotic is the most appropriate. These drugs have salutary effect on psychosis.

Classification

i. Phenothiazines
- a Chlorpromazine (CPZ), and triflupromazine (aliphatic side chain)
- b Thioridazine (piperidine side chain)
- c Fluphenazine and trifluoperazine (piperazine side chain)

ii. Butyrophenones
Trifluperidol, Haloperidol, Penfluridol, Droperidol.

iii. Thioxanthenes
Flupenthixol, chlorprothixene, Thiothixene.

iv. Miscellaneous
Pimozide, Molindone, Loxapine

v. Atypical
Risperidone, Clozapine

The pharmacological and mechanism of action of all these drugs in this group is more or less same, like chlorpramazine (CPZ). So, the pharmacology of chlorpromazine is described here as the prototype of all the antipsychotic drugs. However only they differ from each other in varying degree of actions (Fig. 34.1).

Mechanism of action

The exact mechanism of action of all these antipsychotic drugs is still unknown. But most probably, one of the major mechanism of action of these agents is the antidopaminergic activity. The dopaminergic projections to the temporal and prefrontal areas, constitute the limbic system of brain and is responsible for the psychological state. Also the dopaminergic projection to the mesocortical areas are probably responsible for emotional reactions. Over activity of this dopaminergic

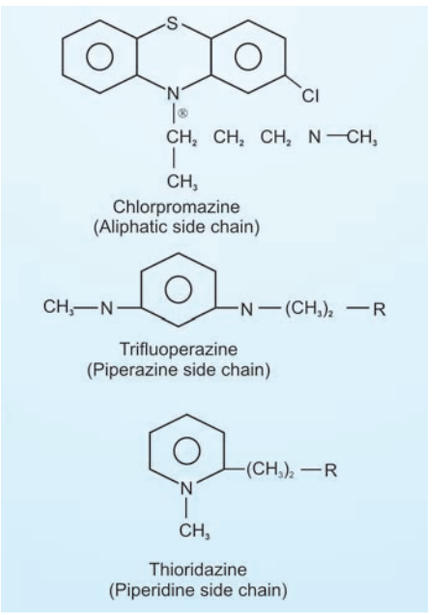

Fig. 34.1: Structure of various phenothiazines

pathway is responsible for this psychiatric illness. All the antipsychotic drugs have potent dopamine D_2 receptor blocking action and act at these areas. So the antipsychotic potency of these agents has shown good correlation with their affinity and blocking property to this dopamine D_2 receptor. Phenothiazines and thioxanthenes also block D_1, D_3 and D_4 receptors. Clozapine has weak D_2 blocking action, but is selective for D_4 receptors and also has significant $5HT_2$ and α_1 blocking action. The extrapyramidal symptoms (EPS), caused by this group of drugs is due to the blockade of D_2 receptors, situated in the extra pyramidal system (basal ganglia). Antiemtic action of these group of drugs is also due to the D_2 receptor blockade action in CTZ area. Sedation produced by these agents is caused by adrenergic blockade action which is maximum for chlorpromazine and thioridazine.

Pharmacological action

These antipsychotic group of drugs reduce the irrational behaviour, the agitation and the aggressiveness of patient. They control the psychotic symptomatology. Disturbed thinking of patient is corrected. Disturbed behaviours are gradually normalised. Difficulties in attention and concentration are slowly corrected. Anxiety is relieved. Hyperactivity, hallucination and delusions are suppressed.

All phenothiazines, thioxanthenes and butyrophenones have the same antipsychotic effects. But potency among them differs in term of equieffective doses. The aliphatic and piperidine side chained phenothiazines (CPZ, triflupromazine, thioridazine) have low antipsychotic potency than piperazine side chained phenothiazines (trifluoperazine), but produce more sedation and cause greater potentiation of hypnotics and opioids. The sedative effect of these antipsychotic drugs is produced immediately, while the antipsychotic effect takes weeks to develop.

In normal individuals, the antipsychotic drugs also produce indifference to the surroundings, paucity of thought, psychomotor slowing, emotional quietening, reduction in intiative and tendency to go off to sleep from which the subject is easily arousable. Spontaneous movements are minimised but slurring of speech, ataxia or motor incordination does not occur. This has been referred to as the 'neuroleptic syndrome' and is quite different from the sedative actions of barbiturates, benzodiazepine and other similar drugs. These effects are appreciated as 'neutral', but 'unpleasant' by most of the normal individuals (Table 34.1).

Performance and intelligence of the patient are relatively unaffected by this group of drugs, but vigilence is impaired. They lower the seizure threshold and can precipitate fits in untreated epileptics. Like sedatives and hypnotics the medullary respiratory and other vital centres are not affected by these agents except at very high doses. They have potent antiemetic action which is exerted through the centre of CTZ, but are ineffective in motion sickness.

All the neuroleptics also have the varying degree of α-adrenergic blocking activity. This may be graded as CPZ > triflupromazine > thioridazine > fluphenazine > haloperidol > trifluoperazine > clozapine > pimozide. Thus it is concluded that more potent compounds have lower propensity for α-adrenergic blocking activity. All the neuroleptics also have anticholinergic property in varying degree. The gradation of anticholinergic property is like that : thioridazine > chlorpromazine > triflupromazine > trifluoperazine = haloperidol. The phenothiazines also have weak H_1 antihistaminic and anti-5HT actions as well (Fact file II).

The neuroleptics produce hypotension by central, as well as by peripheral blocking action of sympathetic tone. The hypotensive action is more marked after parenteral administration of this agent. It is roughly parallel to the α-adrenergic blocking property of this group of drugs. This is accentuated by hypovolaemia. Reflex tachycardia accompanies hypotension (Table 34.2).

The release of ACTH in response to stress is diminished by the use of these drugs. So, Corticosteroid levels fail to increase under circumstances of stress. High doses of CPZ directly depress the

Table 34.1: Comparative properties of antipsychotic drugs

Drugs and doses (in mg)	*Sedation*	*Extrapyramidal*	*Hypotension*	*Antiemetic*
Chlorpromazine(100-800)	S	M	S	M
Thioridazine (100-400)	S	L	S	N

FACT FILE - II

The antipsychotic drugs most likely exert their effects by inhibiting the binding of dopamine at their post synaptic receptors. So, they have an array of effect of overdose such as neuroendocrine, autonomic, cardiac, ophthalmic etc. But still their therapeutic index is high and the overdose effects are rarely irreversible and serious. The most troublesome (but not serious) side effects of antipsychotic drugs are : parkinsonism and dystonia. 50 to 70% of patients receiving antipsychotic drugs manifest some form of extrapiramidal system. It gradually diminishes after 2 to 3 months of initiation of treatment. Acute dystonia manifested by contraction of skeletal muscles of mouth, neck, tongue, etc, is treated by diphenhydramine, 25 to 50 mg IV.

Table 34.2: Side effects of antipsychotic drugs

Cardiovascular system	Hypotension Tachycardia ↑ PR interval ↑ QT interval
CNS	Sedation Extrapyramidal symptoms (dystonia, parkinsonism) Cognitive impairment Seizure
ANS	Blurred vision Urinary retention
GI	↓ Bowel motility Cholestatic jaundice
Ophthalmic	Opacities of lens and cornea ↑ IOP
Haematology	Agranulocytosis Leukopenia
Endocrine	Weight gain Amenorrhoea Galactorrhoea

heart and produces some ECG changes. These changes are : increased PR interval, QT prolongation, widening of QRS complex and T wave suppression. CPZ also exerts some antiarrhythmic action and probably it is due to some membrane stabilization property of it. However, arrhythmia may still occur in overdose of these agents especially with thioridazine.

Most of the antipsychotic agents have a narrow therapeutic window. If the blood level is below than the lower limit of window, then the drug is ineffective and if the blood level is higher than the upper limit of the window, then there is toxicity. All the antipsychotic agents are highly lipophilic and highly protein bound in nature. So, half-life of all the antipsychotics are long and theoretically a single dose administration per day is enough to produce sustained therapeutic blood levels. Once the drug is withdrawn, it may remain in the body for many days to many months.

Drug Interactions (Anaesthetic Implications)

As all the neuroleptic agents have central sedative properties, so they potentiate the actions of all the CNS depressing agents, like hypnotics, anxiolytics (sedative), alcohol, opioids, antihistaminics and analgesics. Therefore, overdose of symptoms may easily occur and the requirements of the anaesthetic drugs should be decreased. As all the antipsychotic agents have the potent dopamine receptor blocking action, so they block the actions of levodopa and other DA agonists which are used in Parkinsonism. So the doses of drugs used in parkinsonism should be increased. The central anticholinergic effects of all the antipsychotic agents are additive with those of atropine and hyoscine. So, the glycopyrrolate is the preferred antisialogogue where antipsychotic drugs are used. The α-adrenoreceptor blockade action of antipsychotic agents also aggravates the hypotensive effect of an anaesthetic agent. This may be an important consideration during the management of anaesthesia. This is particularly true with acute blood loss or institution of IPPV or regional anaesthesia, as the compensatory sympathetic nervous system mediated vasoconstriction is attenuated by the antipsychotic drug induced α-adrenergic blockade. Seizures may occur often with clozapine than with other antipsychotic agents. When considering GA, especially administering succinylcholine, then the patients with the history of neuroleptic malignant syndrome are more vulnerable to develop malignant hyperthermia, due to the common pathology. The neuroleptic malignant syndrome consists of marked mascular rigidity, immobility, fever, fluctuating BP and HR, myoglobin in blood etc. It is presumed due to drug induced interference with the dopamine's role in central thermoregulations.

ANTIANXIETY DRUGS

Anxiety is an emotional state which is associated with uneasiness, discomfort and fear about some defined or undefined objects. The antianxiety drugs are also called minor tranquillizers or anxiolytics. They are all illdefined mild CNS depressants, without interferring the normal mental or physical functions. This group of drugs differ markedly from the antipsychotic group of drugs and more closely resembles to sedative or hypnotics. Anxiety is very unpleasant in nature and some degree of it is always part and parcel of life. Treatment of anxiety is always not necessary. But it is needed when anxiety is disproportionate to the situation or excessive.

Characteristic of Antianxiety Drugs

i. They cannot control thought disorder of schizophrenia.
ii. They do not produce extrapyramidal side effects.
iii. They have anticonvulsant property and produce skeletal muscle relaxation.
iv. They produce physical dependence.
v. They carry abuse liability.

Classification of Antianxiety Drugs

i. **Benzodiazepines**
Chlordiazepoxide, diazepam, oxazepam, alprazolam, lorazepam, temazepam, midazolam, etc.
ii. **Azapirones**
Buspirone, gepirone.
iii. **Other sedatives**
Meprobamate, hydroxyzine.
iv. **β-blocker**
Propranolol (Fig. 34.2).

Benzodiazepine (BDZ)

All the BDZs have the selective taming effect and supress the induced aggresion. They have slow and prolonged action and relieve anxiety at low doses without producing global CNS depression. In contrast to barbiturates, BDZ are more selective for limbic system. They have also been proved to be clinically better in both quality and quantity for improvement of anxiety and stress related symptoms. However, they have very little effect on other body systems. Withdrawal syndrome is milder and delayed due to their long half-life. They reduce nightmare and have been found to be relatively save even in gross overdoses. They have least cardiovascular and respiratory depression effect at antianxiety doses.

The benzodiazepines act through BDZ receptors which is a part of the $GABA_A$ (which is discussed in Chapter 14) receptors and so facilitates the release and action of major inhibitory neurotransmitter such as GABA. Thus, it produces antianxiety, muscular relaxation and anticonvulsant action. Among all the BDZs the most commonly used agents in anaesthesia practice are midazolam, alprazolam, lorazepam, diazepam and temazepam.

Azapirones (Buspirone)

It is a new class of non BZD, antianxiety agents and buspirone is the first of all the azapirone group of drugs. The characteristics of buspirone is that it does not produce sedation or functional impairment and does not act through BZD or GABA receptors. It has no muscle relaxant or anticonvulsant property and does not produce physical dependence.

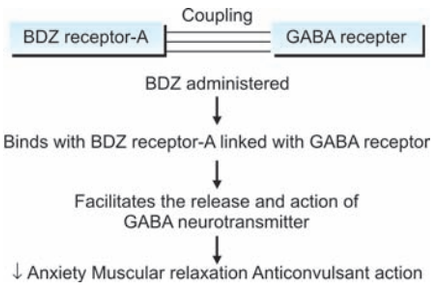

Fig. 34.2: Probable mechanism of action of benzodiazepine (BDZ)

The mechanism of action of buspirone is not exactly known. But the probable explanation is that it acts by selective partial agonistic action on $5HT_{1A}$ receptors. It has no antipsychotic or extrapyramidal effects. Buspirone relieves only mild to moderate anxiety, but is ineffective in severe cases. The therapeutic effects of buspirone develops slowly over 2 weeks. Occasionally a mild mood elevating action of buspirone has also been noted and it is due to the facilitation of central noradrenergic system.

Buspirone is rapidly absorbed through oral route and undergoes extensive hepatic first pass metabolism. Hence, the oral bioavailability of it is only less than 5%. It may cause rise in BP in patients on MAO inhibitors. But, it does not potentiate the action of CNS depressants, like benzodiazepine and barbiturates.

DRUGS FOR AFFECTIVE DISORDER

Affective disorders are also called the mood disorders and the two extremes of this pathological states are depression and mania. So, the classification of the drugs used in this disorder are similarly divided into antidepressants (mood elevators) and antimanias (mood stabiliser). Antidepressant agents again are of two types, i.e. tricyclic antidepressants (TCA) and MAO inhibitors (MAOI). The main antimanic agents is lithium.

Antidepressant

Antidepressants are those psychiatric drugs which are used for the treatment of depressive illness. They are also called mood elevators. The first antidepressant to be discovered was imipramine in 1958. It is different from phenothiazines only by a replacement of a sulphur atom with an ethylene linkage. Due to this small structural difference, imipramine was no longer effective as an antipsychotic agent, instead was quite beneficial in depressed patients. Since 1958, the number of antidepressants discovered has been gradually increasing.

The mechanism of action of imipramine (tricyclic compound) is to inhibit the NA and 5HT (seretonin) reuptake by the presynaptic neurons at nerve terminal, thus increasing the NA and / or 5HT concentration at the receptor site on the past synaptic membrane. So, tricyclic compounds are also called Mono Amine Reuptake Inhibitors (MARI). As the large number of congeners of imipramine or tricyclic compound were soon added, so they are collectively called Tricyclic Antidepressants (TCA). But it includes very few tricyclic compounds in structure as well. Some of these compounds have relatively greater inhibition on NA reuptake than 5HT or greater inhibition on 5HT reuptake than NA. Most significant development in this subject in the past 15 years is the introduction of highly Selective Serotonin Reuptake Inhibitor (SSRI) and also some atypical antidepressants. Most of the TCA compounds do not inhibit DA reuptake, except maprotiline and buproprion. Moreover, amphetamine and cocaine (which are not antidepressants, but CNS stimulants) are strong inhibitors of DA uptake. So, at the end, it can be summarised that inhibition of DA reuptake correlates with the stimulant action of CNS and is not involved in antidepressant action. Whereas inhibition of NA and 5HT reuptake is associated with antidepressant action, but not correlates with CNS stimulant action. Inhibition of 5HT reuptake is also responsible for sedation.

On the otherhand, MAOI act on the monoamino oxidase (MAO), which is a mitochondrial enzyme and is responsible for the degradation of NA, DA and 5HT after their reuptake at the nerve terminal. Thus, MAOI allow NA, DA and 5HT to accumulate in their respective neurons in

the brain and periphery. Two isoenzyme forms of monoamino oxidase (MAO) have been identified. These are MAO-A and MAO-B. The MAO-A preferentially deaminates 5HT, adrenaline and NA, whereas the MAO-B preferentially deaminates all the nonpolar aromatic amines such as phenyl ethylamine, etc. The tyramine and dopamine are deaminated by both. Their distribution also differs. Both these enzymes are present in neural and non neural tissue with a preponderance of MAO-A enzyme in the brain and MAO-B enzyme in the liver and lungs. MAOI inhibit both these MAO enzyme and thus the resultant increased amine level (NA, DA, 5HT) in brain is probably responsible for the antidepressant action. Older MAOIs are non selective (inhibiting both MAO-A and MAO-B isoenzyme) and irreversible. However, newer types of MAOIs are selective for the MAO-A isoenzyme and cause reversible inhibition (reversible inhibitor of monoamine oxidase A or RIMA) (Fig. 34.3).

Classification of Antidepressant Agents

Tricyclic antidepressants and related compounds

i. **Both noradrenaline (NA) and serotonin (5HT) reuptake inhibitors**
Imipramine, trimipramine, amitriptyline, clomipramine, doxepin etc.

ii. **Selective noradrenaline reuptake inhibitors (NA>5HT)**
Nortriptyline, protriptyline, desipramine, amoxapine.

iii. **Selective serotonin (5HT) reuptake inhibitors (SSRI)**
Fluoxetine, fluvoxamine, paroxetine.

iv. **Atypical**
Trazodone, mianserin, bupropion, tianeptine.

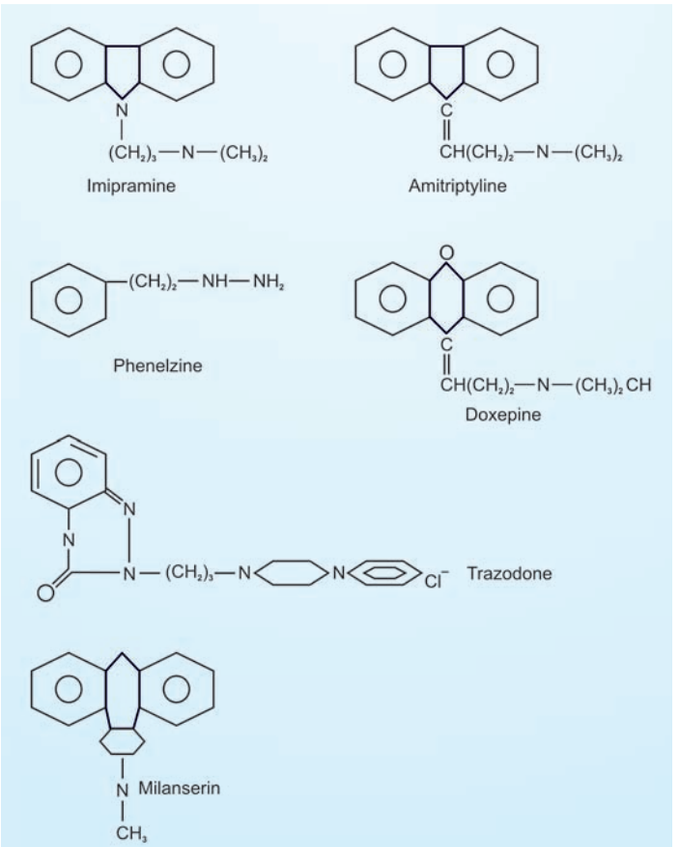

Fig. 34.3: Structural formula of some commonly used antidepressant

MAO inhibitors (MAOI)

i. **Nonselective inhibitors**
Phenelzine, isocarboxazid, tranylcypromine.

ii. **Selective inhibitors**
a. Selegiline (deprenyl) – Selective MAO-B inhibitors.
b. Moclobemide and clorgiline – Selective MAO-A inhibitors.

Pharmacological action of TCA

The older TCAs inhibit the reuptake of both the monoamines (NA,5HT) and also interact to block the variety of other receptors such as muscarinic, α-adrenergic, histamine (H_1), $5HT_2$ and occasionally dopamine (D_2). So, they have properties which include α-antagonist, anticholinergic, antidopaminergic and antihistaminic. However, relative potencies to block these receptors differ among different compounds. The newer selective serotonin reuptake inhibitors (SSRI) and atypical tricyclic antidepressants interact with fewer receptors and have more limited spectrum of action. So, they produce fewer side effects. The action of imipramine is described as prototype of all the TCAs and their related compounds (Fig. 34.4).

In depressed patients the TCA gradually elevates the mood. Patients become more communicative and start to take interest about their surroundings. Thus, TCAs are only antidepressants, but not euphoriants. They produce sedation, but this sedative property varies among different compounds. Most TCAs are potent anticholinergic and

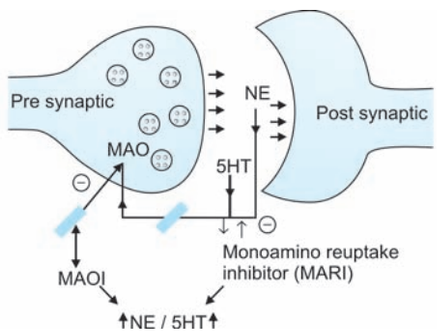

Fig. 34.4: Mechanism of action of antidepressant

cause dry mouth, blurring of vision, constipation, and urinary hesitancy. The tolerance to anticholinergic effects develop gradually, but antidepressant action is maintained. They also potentiate the action of exogenous catecholamines. All the TCAs cause tachycardia and it is due to anticholinergic and NA potentiating actions. Postural hypotension caused by TCAs is due to the inhibition of cardiovascular reflexes and α-blocking effect. The effects of TCA on CVS are common and prominent. It occurs at therapeutic concentration and may be dangerous in overdose. ECG changes due to TCAs are: T wave suppression or inversion (most consistant changes), prolongation of PR interval and widening of QRS complex. Arrhythmias may occur in overdose of TCAs. It is due to the interference to intraventricular conduction and NA potentiating action, combined with Ach blocking actions. The SSRI and atypical antidepressants are safer in this regard, but tolerance to these atypical antidepressants are higher and develops quickly. Increased appetite and weight gain is noted with most TCAs and trazodone, but not with SSRI and bupropion. Seizure threshold is lowered and fits may precipitate by TCAs. Cardiac arrhythmias induced by TCAs (especially in patients with ischaemic heart disease) may be responsible for sudden death in these patients (Fact file III).

Anaesthetic implications and drug interaction between anaesthetic agents and TCA

The interactions of TCAs with anaesthetic drugs are common and generally predictable. The increased catecholamine concentration at the central sites by TCA may lead to increased anaesthetic requirements and exaggerated response to endogenous or exogenous catecholamines. Similarly, the increased concentration of NA at post-synaptic sites in the peripheral sympathetic nervous system is responsible for the increased systemic blood pressure. This potential for hypertensive crisis is maximum between the first 14 to 21 days, during acute treatment with TCA for acute depression. Whereas, the subsequent chronic management by TCA is associated with down regulation of receptors and decreased risk of hypertensive crisis, even after administration of sympathomimetic agents. The threshold for ventricular dysrhythmias may also be lowered during chronic management by TCA. Still where possible, administration of catecholamine or drugs causing release of cathcholamines (e.g. ephedrine, mephentermine) should be avoided. Therefore, if augmentation of blood pressure is necessary, then direct acting agents such as methoxamine or phenylephrine may be used but with caution. If hypertensive episode occurs, then alpha blockers such as phentolamine may be used. However peripheral vasodilating agent such as sodium nitroprusside is better alternative.

Although, it has been recommended that TCAs should be discontinued 2 weeks before anaesthesia, but this may not be possible in many psychiatric patients as illness will be aggravated. They abolish the antihypertensive action of clonidine by preventing their transport into the adrenergic neurons. They potentiate the effect of other CNS depressants, including alcohol and antihistamines. By their anticholinergic property, they delay gastric emptying. Centrally acting anticholinergic drugs (atropine, hyoscine, not glycopyrolate) should be avoided as premedication for patients taking TCA, because their additive effect may precipitate confusion postoperatively, especially in the elderly. Dangerous hypertensive crisis with excitement and hallucination may occur, if MAOIs are used with TCAs.

FACT FILE- III

Tricyclic antidepressants and cardiovascular system

In addition to producing anticholinergic effect and sedation, TCA may cause CVS abnormalities. It includes arrhythmias and orthostatic hypotension. TCA compounds try to slow the both ventricular and atrial depolarization. This is manifested as increased PR interval, QT interval and wide QRS complex. These changes are benign and gradually disappear with continued therapy, in the absence of excessive plasma concentration. So, the previous thought that TCA increases the risk of cardiac arrhythmias is not now correct in the absence of overdose. In the presence of co-existing cardiac dysfunction such as heart block, prolonged QT interval, etc, there may be increased risk. So, sometimes when the TCA therapy is contraindicated due to patient's bad cardiac status, then ECT may be advised.

SSRI (Selective serotonine reuptake inhibitors)

This group of drugs was first introduced in 1987 and is now the most commonly prescribed antidepressant agents. They are highly selective for the inhibition of serotonin (5HT) reuptake at the presynaptic nerve terminal and are considerably less toxic than TCAs. The CVS side effects of it are very rare. Bradycardia has occasionally been reported. In patients with coronary artery disease, SSRI may precipitate coronary artery vasoconstriction. Nausea, vomiting and diarrhoea are common side effects of SSRI due to the inhibition of serotonin reuptake in the GI tract. Platelet aggregation may occasionally be inspired. 'Serotonine syndrome' may sometimes be precipitated by the addition of drugs such as MAOIs, TCAs, pethidine or pentazocine, etc, with SSRI. It is due to increased concentration of serotonin at synaptic levels in the brainstem and spinal cord. This syndrome consists of confusion, agitation, rigidity, autonomic instability, arrhythmias and sometimes coma. The treatment of these symptoms is supportive. Acute withdrawal of SSRI after use of many years may precipitate a syndrome of anxiety, agitation and increased sweating. Unlike TCA, the SSRI lacks anticholinergic effects. They also do not cause postural hypotension or delayed conduction of cardiac impulses. SSRI does not reduce the seizure threshold level.

Among the SSRI, fluxetine is the potent inhibitor of certain cytochrome P_{450} enzymes. Hence, it may increase the plasma concentration of drug that depends on hepatic clearance. So, the addition of

fluoxetine to TCA may result in 3 to 5 fold increase in plasma concentration of TCA. This mechanism may also be responsible for 'serotonine syndrome'.

Pharmacological actions of MAOI

MAOI are the toxic psychopharmacological agents. So the nonselective MAOI are rarely used nowadays. However the selective MAO-A inhibitors possess antidepressant property and is still used now in some countries. They are indicated in patients suffering from major depression, not responding to TCA and in whom ECT is contraindicated or refused. In contrast to TCA, the MAOI has negligible anticholinergic effects and do not sensitize the heart to cardiac dysrhythmogenic effects of epinephrine. Orthostatic hypotension is the most common side effect, observed in patients being treated with MAOI. The mechanism for this hypotension is unknown, but it may reflect the accumulation of some false neurotransmitters such as octopamine which are less potent than norepinephrine.

Anaesthetic implication and drug interaction of MAOI

Certain varieties of cheese, beer, wines, pickled meat and fish, etc. contain large quantities of tyramine and dopa. They are the precursors of norepinephrine (NE or NA). In MAO inhibited patients, these indirectly acting sympathomimetic amines escape their degradation in the intestinal wall and liver during absorption. Then reaching into the systemic circulation, they displace the large amount of NA from transmitter loaded adrenergic nerve endings, causing hypertensive crisis. This is called 'cheese reaction'. It can be treated by IV injection of rapidly acting α-blocker, e.g. phentolamine, prazosin or chlorpromazine or directly acting vasodilators. Certain cold and cough preparations also contain some indirectly acting sympathomimetic amines (which act by stimulating the release of NE), e.g. ephedrine which causes in hypertension. So, any indirectly acting sympathomimetic agent such as ephedrine and metaraminol which may potentiate the hypertension leading to crisis should be avoided. Excitement and hypertension also occur due to the increase in biological t½ of DA and NA that are produced from levodopa. Action of barbiturates, alcohol, opioids and antihistamines are also intensified and prolonged.

The interaction between MAOI and pethidine is also important, though uncommon. In this reaction high fever, sweating, excitation, restlessness, rigidity, hypertension, delirium, convulsion and severe respiratory depression with coma may occur. So, morphine appears to be the safe in this purpose. Other opiates which can safely be used with MAOI include fentanyl, alfentanil and remifentanil. The most accepted explanation of the reaction between MAOI and pethidine is MAOI retard hydrolysis of pethidine, but not its demethylation. Thus, excess of norpethidine (normally a minor metabolite but increase when hydrolysis is inhibited) is produced by demethylation of pethidine which has excitatory actions. Other possible explanation of this reaction is mass discharge form sympathetic nervous system, caused by the excess opioid and increased CNS concentration of serotonine (secondary to blockade of 5HT uptake). These hypertensive responses may be eliminated by withdrawal of MAOIs, 2 weeks before anaesthesia or by avoiding administration of pethidine. But like TCA, this also may not always be practical in the psychiatric patients, because withdrawal of these agents so long before surgery and anaesthesia will produce recurrence of depression in more severe form. So, it is no longer recommended that these drugs (MAOI) should be stopped 2 weeks preoperatively. But, care should be taken to avoid interaction with the anaesthetic drugs (Fig. 34.5).

Benzodiazepines are acceptable for preoperative treatment of anxiety in these group of patients. Induction of anaesthesia in these patients can safely be performed with drugs like thiopentone and propofol. But, it will have to be kept in mind that CNS depression effects and depression of ventilation may be exaggerated. Ketamine is exception to this as it stimulates the sympathetic system. N_2O combined with volatile anaesthetic agent is acceptable for maintenance of anaesthesia. But, halothane is not preferred as it may cause cardiac arrhythmia. Anaesthetic requirement in these patients is usually increased due to the increased level of catecholamines in the CNS. The spinal and epidural anaesthesia is acceptable in this group of patients. But, hypotension and subsequent administration of vasopressors may put direction in favour of GA. If vasopressor is needed, then direct acting agent such as phenylephrine is the choice, though ephedrine can be used with no apparent adverse effects. But, the dose should be reduced to minimise the likelihood of an exaggerated hypertensive response. The choice of nor depolarising muscle relaxant is not influenced by MAOI with the possible exception of pancuronium.

Pancuronium should be avoided in patients taking MAOIs, as it releases the stored adrenaline. Tranylcypromine is the most hazardous among all the MAOIs due to its stimulant action. Phenelzine has been shown to decrease the pseudocholiner esterase concentration and so there have been isolated reports of prolonged action of suxamethonium. This appears to be unique to phenelzine.

The new generation of selective MAO-A inhibitors such as RIMA (reversible inhibition of monoamine oxidase type A) are now being increasingly used. They are of short half-life, well tolerated, have

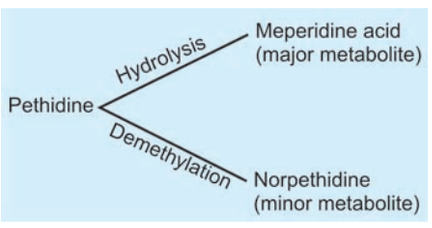

Fig. 34.5: Metabolism of pethidine

anticholinergic effects and do not cause postural hypotension. They have no central excitatory side effects, no interactions with tricyclic antidepressants and a clinically insignificant response to ingesting tyramine. RIMA may still cause an excitatory response to pethidine. So, pethidine should be avoided in patients taking RIMA. Indirectly acting sympathomimetics (e.g. ephedrine, metaraminol) should also not be used with RIMA. Selegiline is a selective MAO-B inhibitor, used in the treatment of Parkinson's disease. Interactions of it with anaesthetic agents are fewer than with the MAO-A inhibitors. Still, pethidine is best avoided and vasopressor should be used with care with MAO-B inhibitors.

Postoperative pain management is influenced by the interaction between MAOI and opioids. If they are needed, then morphine and fentanyl is the drug of choice. But, the dose should be titrated according to necessity to achieve desired analgesia. On the otherhand, alternative to opioids is the NSAID (nonopioid analgesics), peripheral nerve block or transcutaneous electrical nerve stimulation (TENS). In such circumstances, the use of opioids through spinal or epidural route is not well studied.

Antimanic Agents

Mania is an autosomal dominant disease with variable penetrance among the offsprings. It is manifested by inflated self esteem, flight of ideas, short attention, decreased sleep, increased verbalization, etc. Lithium is the mainstay of antimanic treatment. Alternative treatment is the carbamasepine or sodium valporate.

Lithium

It is a small monovalent cation (Li^+) and is the drug of choice for the management of bipolar manic depressive illness (MDI). It is extensively used at centres where its serum levels can be measured accurately. Practically, it has no effect on normal individuals and is neither sedative, nor euphoriant. On prolonged administration, it acts as a mood stabilizer in patients suffering from MDI. However, the mechanism of action of lithium is still not exactly known. Therefore, the probable explanation of action of lithium are :

i. As the lithium resembles sodium ion, so it penetrates the voltage sensitive Na^+ channel and accumulates inside the cell, causing partial depolarisation. Hence, Li^+ replaces body Na^+ and is equally distributed inside and outside of the cell. Thus, it affects the ionic movement across the cell membrane (mainly the brain cells) and modify the transmission of impulses imparing the action potential of nerve cells.
ii. It decreases the release of NA and DA in brain, without affecting the release of 5HT. Thus, it may correct the imbalance in the turnover of brain monoamine.
iii. Li^+ inhibits the hydrolysis of inositol-1-phosphate. Thus, it results in reduction of supply of free inositol for regeneration of membrane phosphatidyl-inositides which are the source of IP (Inositol triphosphate) and DAG (Diacyl glycerol). Thus, hyperactivity of neurons which is responsible for manic states is reduced as supply of the inositol from extracellular sources is meagre.

However, the hypothesis (i) and (ii) can not explain why Li^+ has no effect on normal people, not suffering from MDI. Only hypothesis (iii) can explain this.

Li^+ is efficiently absorbed from stomach after oral administration. It has a very low therapeutic window. So, as the margin of safety is narow, therefore, the monitoring of serum Li^+ concentration is essential for optimal therapy. Hence, the use of it without monitoring the serum levels is associated with unaccepted toxicity of lithium or no therapeutic effect. The therapeutic serum concentration of Li^+ for acute mania varies between 1 to 12 mEq/L. But, for prophylaxis this level may fall to 0.6 to 0.8 mEq/L. Monitoring of serum lithium concentration by flame photometry, usually 12 hours after the last oral dose, is recommended. Because it decreases the likelihood of toxicity.

Toxicity of Li^+ occurs when the serum concentration of it exceeds than 2 mEq/L. Toxicities are manifested as skeletal muscle weakness, ataxia, sedation, widening of QRS complexes, AV block, hypotension and seizures. Lithium treatment can also cause hypothyroidism and vasporessin resistant diabetes insipidus like syndrome (polyuria, polydipsia). Toxicity of lithium is also made worse by sodium depletion and dehydration.

Li^+ is handled in the body by kidney in much the same way as Na^+. So, most of the filtered Li^+ is reabsorbed from the proximal convoluted tubule and inversely related to the concentration of Na^+ in the glomerular filtrate and its reabsorption. Therefore, the loop diuretics and thiazides increases the serum lithium concentration by enhancing the renal Na^+ excretion and increasing the reabsorption of Li^+. Hence lithium toxicity may ensure in hyponatraemic states, when there is intense attempt of renal conservation of sodium and consequently in the absence of Na+ intense absorption lithium. When Na^+ is restricted then a large fraction of the filtered Li^+ is also reabsorbed and vice versa. So, IV administration of sodium containing solution or osmotic diuretics favours renal excretion of lithium in patients who show evidence of lithium toxicity.

Anaesthetic implications

During preoperative evaluation of manic patients, specially those who are under lithium treatment, the search for evidence of lithium toxicty is an important consideration and recently measured serum lithium concentration should be reviewed. In the perioperative period, Na^+ containing solution should be administered intravenously and judiciously to reduce the serum Li^+ level. Loop and thiazide diuretics should not be used or used very cautiously in patients receiving lithium. Monitoring of these patients by ECG for evidence of lithium induced changes is useful to recognise the toxicity. Li^+ potentiates sedative effect

of intravenous and inhaled anaesthetic agents and, therefore, their dose should be reduced. As lithium tends to act as an imperfect Na^+ ion, so potentiation of both depolarizing and non depolarizing muscle relaxants occurs in patients receiving lithium and hence close monitoring of neuromuscular function in necesary. Lithium is contraindicated in sick sinus syndrome.

Anaesthesia and Electroconvulsive Therapy (ECT)

For the first time in the year of 1934, Von Mednna used 25% camphor (prepared in oil) intramuscularly to produce convulsions for therapeutic purpose of depression. Later, he used metrazol for the same purposes. Then, in the year of 1938, Cerletti and Bini used a safer form of convulsive therapy for the management of severe depression by using electric current and they called it as electroshock therapy (EST) which now came to be known as the electroconvulsive therapy (ECT). Thereafter, this year 1970s saw a widespread criticism of ECT, restricting the use of it and making some modifications. Following this modifications, now the ECT technique has become the much more safer mode of treatment for severe psychiatric diseases which are unresponsive to drugs or when the patient becomes acutely suicidal.

Some physiological effects of ECT are:

i. Cardiovascular effect:
   Immediate cardiovascular effects of ECT are bradycardia and hypotension. It is due to the immediate parasympathetic stimulation following ECT. After 1 minute of parasympathetic stimulation, there is sympathetic stimulation which is characterised by tachycardia, hypertension, dysrhythmias, increased myocardial O_2 consumption, etc.
ii. Cerebral effect:
   The cerebral effect of ECT are: increased cerebral blood flow, increased ICP, increased cerebral O_2 consumption, etc.
iii. Others:
   Increased intragastric pressure, increased IOP, etc.

The contraindications of ECT are:

i. Absolute :
   Recent myocardial infarction, recent CVA, ↑ICP due to intracranial mass lesion.
ii. Relative:
   Uncontrolled angina, congestive cardiac failure, severe pulmonary diseases, pheochromocytoma, severe hypertension, severe osteoporosis, major bone fractures, glaucoma, retinal detachment, etc.

The pretreatment or preanaesthetic assessment of patient waiting for ECT consists of (i) informed consent, (ii) detailed medical and psychiatric history, (iii) general and systemic physical examination, (iv) routine laboratory investigation on the light of history and examination, (v) ECG and plasma pseudocholinesterase level, (vi) examination of funds oculi (to rule out papilledema), etc.

So, some important points regarding the preoperative assessment before ECT are:

i. ECT is usually carried out in elderly patients who have a variety of coexisting diseases. So, an anaesthetist must be very careful.
ii. The majority of patients are taking psychiatric drugs which have the potential to interact with anaesthetic agents, used during GA for ECT.
iii. Patients are mostly non cooperative. So, histories are not reliable, even regarding preoperative fasting.
iv. Sedative premedication is not always indicated as it prolongs the recovery.
v. ECT is a repeated procedure. So, previous anaesthetic note should be studied carefully to see the effect of anaesthesia on previous ECT (Table 34.3).

The exact mechanism of action of ECT is still unclear. But one hypothesis states that ECT possibly affects the catecholamine pathways between the diencephalon (site of seizure generation) and limbic system (responsible for mood disorder), involving hypothalamus which is responsible for severe psychiatric illness. The previous concept of the therapeutic benefit of ECT on psychiatric illness depend on the production of generalised tonic clonic seizures, but that is not correct. Because, now it is established that therapeutic efficacy of ECT is related to the amount of electric current passing through the brain, but not on the production of tonic clonic seizures. The electrical stimulus given during ECT produces grand mal seizure which consists of brief tonic phase followed by long clonic phase. The EEG changes during ECT is similar to that of spontaneous grand mal seizure and typically 8 to 10 ECT is necessary which show 80% favourable response.

The techniques used for administration of ECT are of two types: direct ECT and modified ECT. In direct technique, ECT is given in the absence of muscular relaxation and general anaesthesia. This is infrequently used now. In the later technique, ECT is modified to reduce or avoid generalised tonic clonic seizure by drug induced muscular relaxation and general anaesthesia.

General anaesthesia is usually administered to ensure the patient's safety and comfort during ECT. Patients are fasted as in GA. Sedative premedications are usually not used, because it prolongs the period of recovery following ECT. Anticholinergic (atropione or glycopyrolate) is given before induction of anaesthesia or delivery of electric current. This is to

Table 34.3: Side effects of ECT

↑ Cerebral O_2 consumption
↑ Intragastric pressure
↑ Intraocular pressure

decrease the oral secretions and to prevent the vagal stimulation during ECT which can cause severe bradycardia or even cardiac arrest. Bradyarrhythmias are also particularly common during stimulus titration where subconvulsive stimuli are used to determine the seizure threshold. Centrally acting anticholinergic drugs such as atropine may have synergistic effects with central and peripheral anticholinergic effects of TCA (Tricyclic antidepressant) which the patients are already taking and manifests as delirium and confusion during postanaesthetic period. For this reason, glycopyrrolate is preferred to atropine when ECT is administered to patients being treated with TCA. Sympathetic stimulation during ECT in patients with cardiovascular disease may be undesirable. So, high rise of blood pressure and tachycardia during intubation and electric current therapy can be controlled by esmolol (50 to 200 µg/kg/min) or nitroglycerin or nitroprusside. Monitoring of ECG is useful for recognising ECT induced cardiac dysrhythmias.

For induction during ECT, the commonly used agents are thiopentone, propofol or methohexital. Among these, methohexital is the inducing agent of choice and is used most commonly in the dose of 0.5 to 1 mg/kg through IV. Thiopentone has no advantage over methohexital and may be associated with longer recovery time, but it can be used. Prior treatment of patients with TCAs or MAOIs could enhance the sedative effects of thiopentone. Propofol in the dose of 1 to 2 mg/kg is now also the agent of choice, giving rapid onset and recovery. Like thiopentone, ketamine and etomidate have also been successfully used for induction of GA in ECT.

The use of muscle relaxants in ECT has virtually eliminated the potentially dangerous skeletal muscle contractions and the fracture of bone that can be produced by seizure activity. Succinylcholine in a dose of 0.3 to 0.5 mg/kg through IV route is the most commonly used muscle relaxant for ECT. This lower dose of succinylcholine is particularly selected, because it helps in sufficient visual confirmation of seizure activity during ECT. When it is not possible to visualise the seizure activity due to higher doses of muscle relaxants, then the most reliable method to confirm electrically induced seizure activity is the EEG. Alternatively, one limb can be isolated from the effect of muscle relaxant by applying tourniquet before its administration to see the seizure activity. Low dose of mivacurium (0.08 mg/kg) has also been tried. But although the recovery in case of mivacurium was found to be good, still seizure modification was inadequate. Therefore, if mivacurium is used, the dose should be at least 0.15 mg/Kg and reversal will probably be necessary. Longer acting muscle relaxing agents are not generally suitable for ECT.

Provided there are no risk for aspiration, then the airway and arterial oxygenation can normally be maintained with an oral airway and mask, unless muscle relaxants are used. Ventilatory support and delivery of supplemental O_2 by mask and IPPV is recommended both before production of seizure and until the effects of succinylcholine or mivacurium have been dissipated. After induction of anaesthesia (but before application of ECT stimulation) hyperventilation of the patient's lungs by bag and mask lowers the seizure threshold and prolongs the duration of seizure. Thus, it increases the effectiveness of ECT. When the limbs are flaccid by muscle relaxant, then a rubber 'bite block' is inserted into the mouth between the teeth before electrical stimulation is applied. This will prevent damage to the lips, tongue and teeth during convulsion by electrical stimulation which is given after induction and muscular paralysis by muscle relaxant. During seizure, artificial ventilation with O_2 is continued to avoid arterial desaturation, until adequate spontaneous ventilation has returned. Denitrogenation of the patient's lung by 100% O_2 before production of convulsion by ECT decreases the likelihood of arterial hypoxaemia if it becomes difficult or impossible to support the ventilation in the presence of seizure induced skeletal muscle contractions. Patient should be recovered in the lateral position by trained nursing staff with equipment available immediately for treatment of any emergency. Furthermore, it is important to keep in mind that apnoea may last for 2 to 3 minutes following ECT, requiring ventilation even in the absence of succinylcholine. Monitoring of arterial O_2 saturation by pulse oximetry is mandatory to guide the need for supplemental O_2 and mechanical ventilation for patients undergoing ECT. It is confirmed that ECT does not increase the succinylcholine induced release of potassium. But, monitoring of the neuromuscular blockade by succinylcholine by peripheral nerve stimulator is also sometimes necessary, because repeated anaesthesia is given by it for ECT. The use of peripheral nerve stimulator may help to identify the degree of blockade by succinylcholine with previously unrecognised atypical cholinesterase enzyme. It is also possible to establish the dose of the anaesthetic inducing drug and succinylcholine that will produce the most predictable and desirable effects in each patient.

Special attention should be given to the patients with permanent pacemaker, waiting for ECT. But, fortunately most pacemakers have inbuilt safety measures such as a shield which are not affected by the electrical currents necessary to produce seizures. During ECT of a patient with pacemaker, an external magnate should be kept ready for converting pacemaker to synchronous non demand modes if malfunction occurs in response to the externally delivered electrical current. The continuous monitoring of cardiac activity by ECG and peripheral arterial pulses by palpation is very impotant for uninterrupted function of artificial cardiac pacemaker.

35 Obstetrics Analgesia and Anaesthesia

INTRODUCTION

The obstetric anaesthetic care usually accounts for approximately 10 to 15% of total anaesthetic procedures. It always should be kept in mind that the patients who enter the obstetric wing of an hospital may potentially require the anaesthetic care either for labour analgesia or for CS which may be an emergency or may be a planned one. Hence, anaesthesiologist should be cautious about the relevant history of all the parturient patients. This history will include the present and past medical, surgical and obstetrics history, parity, age, duration of pregnancy etc. The patient should also be examined previously with the potential idea of future planned or emergency surgery. These preanaesthetic examinations include general survey with special attention to BP, airway assessment, examination of spinal cord for regional anaesthesia (RA), etc. Regardless of the time of last oral intake, all obstetric patients should be considered to have a full stomach. So, they are all at the increased risk of pulmonary aspiration, if surgery is at all needed. Therefore, those patients who are specially at high possibility of operative delivery should take nothing permouth during the progress of labour. On the other hand, if the labour is uncomplicated then small amount of clear fluid can be provided during the prolonged labour. However, if there is any doubt, then prophylactic oral administration of 0.3 M sodium citrate at every 2 to 3 hours interval will help to maintain the gastric pH above 2.5 and decrease the chance of aspiration pneumonitis. This prophylaxis also can be taken by oral or parenteral use of H_2 blocker and metoclopramide in high risk patients who are expected to receive GA. H_2 blockers reduce the volume of gastric secretion and pH after its administration. But it has no effect on the gastric contents which is already present. On the other hand, metoclopramide reduces the gastric volume which is already present by accelerating the gastric emptying. But it can not increase the gastric pH. Contrary it increases the lower oesophageal sphincter tone and reduces the incidence of gastric regurgitation. All parturient patients should be placed in 15° left lateral position by an wedge, placed under the right hip to avoid inferior vena caval compression by gravid uterus and reduction of preload.

The majority of obstetric patients are in child bearing age and therefore are healthy. So, they are considered to be at very less anaesthetic risk. But, certain changes in body due to pregnancy such as PIH (pregnancy induced hypertension), PET (pre-eclamptic toxaemia), excessive weight gain, oedema, etc; and certain other medical diseases which are aggravated by pregnancy increases the obstetric anaesthetic risk. The obstetric meternal mortality rate is calculated as the number of maternal death divided by the number of live birth. Recently, this rate has decreased tremendously and now approximately this number has touched to 6 to 12 per 100,000 live birth. The principal causes of maternal death associated with live birth are: pulmonary embolism (20%), PIH (20%), sepsis (15%), cardiomyopathy (10%), haemorrhage (5%), cerebrovascular accident (4%), anaesthesia (3%) and other medical condition (20%). On the other hand, the common among these causes of maternal morbidity which are encountered during obstetric practice is severe haemorrhage and severe pre-eclampsia. Anaesthesia accounts for approximately 2 to 4% of total obstetric maternal death. The anaesthetic risk factors for this maternal death include: age over 35 years, multiple pregnancy, black patients, PIH, previous PPH, emergency LUCS, etc. Among the anaesthetic causes the most maternal deaths occur during or after LUCS. Recently this figure has been reduced due to frequent use of RA than GA.

PHYSIOLOGICAL CHANGES DURING PREGNANCY

Before any discussion regarding the anaesthesia in obstetrics, every clinician should have a profound knowledge about the changes which occur during the whole period of pregnancy and delivery. Because pregnancy affects virtually all the organs of body and brings about multiple changes which alter the usual responses to anaesthesia. These changes occur due to mechanical and hormonal influences and are appeared to be useful to meet the demands of placenta, uterus, foetus and to tolerate the increased stress during pregnancy, labour and delivery. For example, during the whole period of pregnancy

(280 days calculated from the first day of last menstrual period) the uterus itself increases in weight from 30 gm to 1000 gm which has profound implication on anaesthesia that is discussed later.

Changes in Cardiovascular System (CVS)

The changes in CVS that occur during pregnancy serve two functions. These are: (i) to maintain increased uteroplacental circulation which are necessary to continue pregnancy, and (ii) to maintain the increased exchange of O_2, CO_2, nutrients, and other waste products between the mother and foetus.

The maternal blood volume increases by about 40% during the whole period of pregnancy. But the plasma volume increases in excess than that of the red cell volume. Therefore, it apparently reduces the Hb concentration and produces the dilutional anaemia in pregnancy which is physiological in nature. This dilution of blood reduces its viscosity and causes better perfusion in tissues, which thus offsets the side effects of anaemia by increasing the delivery of O_2 to tissues. This drawback of anaemia is further offset by the increase in cardiac output and the shifting of O_2-Hb dissociation curve towards right. The blood volume increases by about 1000 to 1500 ml at term and this will allow a woman to tolerate the blood loss during delivery which is near about 400 to 500 ml in vaginal delivery and 800 to 1000 ml in CS (Table 35.1).

During pregnancy cardiac output also increases by about 40%. This increase in cardiac output is due to both the increase in heart rate (10%) and stroke volume (30%). The increased stroke volume is again due to myocardial hypertrophy and enlargement of cardiac chambers. Most of this changes in cardiac output is observed during 1st trimester and to a lesser extent during 2nd trimester of pregnancy. In 3rd trimester, cardiac output does not appreciably increases except during the process of labour and delivery. After 28 weeks of pregnancy the cardiac output decreases in supine position. This is due to the compression of inferior vena cava by gravid uterus and impairment of venous return to the heart. This is called the supine hypotension syndrome and is found in 20% of patient. This syndrome is characterised by dizziness, restlessness, hypotension, pallor, sweating, nausea and vomitting, etc. when the patient lie directly on his back. Turning the patient on her side typically improves these symptoms. So, a pregnant patient with more than 28 weeks gestation should never be placed supine without left uterine displacement. This can be performed by placing a wedge (> 15°) under the right hip. The trendelenburg position of patient due to any cause increases the compression on inferior vena cava and the risk of supine hypotension syndrome. The abdominal aorta is also compressed by a gravid uterus when the woman lies in supine position. This results in decreased circulation in femoral artery and more importantly the uteroplacental flow. This reduction in uteroplacental blood flow produced by aortocaval compression causes decreased cardiac output (due to reduction of preload), decreased uterine arterial perfusion (due to compression of aorta), increased uterine venous pressure (due to vena caval compression) and increased sympathetic tone. All these factors result in foetal hypoxia and acidosis. During the process of labour, contraction of uterus relieves this compression on inferior vena cava, but increases the compression on aorta. These problems of aortacaval compression will be grossly aggravated following sympathetic blockade during subarachnoid or epidural anaesthesia. Therefore, strict avoidance of supine position and adequate IV fluid to increase preload are the very essential part of any technique of RA.

Table 35.1: Cardiovascular changes during pregnancy

Parameters	*Changes*
Heart rate	+ 10 to 15%
Stroke volume	+ 25 to 30%
Cardiac output	+ 35 to 40%
Systolic pressure	– 5 to 10 mm of Hg
Diastolic pressure	– 15 to 20 mm of Hg
Systemic vascular Resistance (SVR)	– – 15 to 20%

Due to elevation of diaphragm by the enlarged gravid uterus, heart is also displaced upwards, laterally, and forwards. This results in the appearance of a normal heart to an enlarged heart on a plain chest X-ray and also left axis deviation in an ECG. Thus, the usual changes in ECG during pregnancy show the flattened T-waves or Q-waves in lead III and as well as innocent depression of ST segment. Sinus tachycardia, premature ventricular contractions, or bouts of paroxymal atrial tachycardia are also more common in pregnancy. In pregnancy, SVR is reduced. It decreases both the diastolic and systolic blood pressure, but reduction of diastolic BP is more than systolic BP. During pregnancy, the central venous pressure, pulmonary artery pressure and pulmonary capillary wedge pressure are all usually remain unchanged.

The physical examination of a pregnant patient often reveals splitting of 1st heart sound, audible 3rd heart sound, and a soft systolic ejection flow murmur (grade I and II).

Respiratory System

With the progressive enlargement of uterus, diaphragm is gradually elevated towards thorax which is about 4 to 5 cm in height. This reduces the volume of lungs. But, usually, it is compensated by an increase in both the anteroposterior and transverse diameter of thoracic cavity due to hormone induced relaxation of the costal ligaments. This explains why thoracic breathing is favoured over abdominal breathing in pregnancy. In pregnancy, O_2 consumption is increased by 20%. Therefore, to meet this increased need of O_2 the minute and alveolar ventilation is also increased by 50% and 70%, respectively. This is again due to the increase in both

tidal volume and respiratory rate. In pregnancy, the vital capacity (VC) and closing capacity (CC) remain unaltered, but FRC is reduced by 20%. This is prinicpally due to the reduction in expiratory reserve volume as a result of a larger than normal tidal volume. Therefore, CC exceeds FRC in 50% of pregnant women and early airway closure occur during normal respiration with normal tidal volume. This is again more usual when the patient lies in supine position and so atelectasis with hypoxaemia occurs more readily in this position. This phenomenon along with the increased O_2 consumption explains the cause of rapid O_2 desaturation during the periods of apnoea, and explain why preoxygenation with 100% O_2 prior to induction of GA is mandatory to avoid hypoxia in pregnant woman. However, FRC returns to normal within 48 hours of delivery.

Due to increase in ventilation P_aCO_2 decreases up to 25 to 30 mm of Hg, causing respiratory alkalosis. This is compensated by decrease in the plasma HCO_3^- level. Pregnancy induced respiratory alkalosis reduces the unloading of O_2 in tissue level. But this is compensated by increase in P_aO_2 due to hyperventilation, increase in 2,3-DPG level which decreases the O_2 affinity to Hb and increase in cardiac output which enhances the delivery of O_2 to tissues.

Pregnancy is associated with decreased airway resistance and pulmonary compliance. Dead space usually remains unaltered in pregnancy, but intrapulmonary shunt increases towards term. The flow-volume loops of lungs are unaffected by pregnancy. A chest X-ray during pregnancy often reveals prominent vascular markings due to increased pulmonary blood volume increased pulmonary circulation and raised diaphragm.

During pregnancy capillary dilatation and oedema of mucous membrane occurs throughout the respiratory tract. This easily predisposes the upper airway to trauma, bleeding, and obstruction. Hence, small ET-tube than the calculated one and gentle laryngoscopy is essential during administration of GA in pregnancy (Table 35.2).

Table 35.2: Respiratory changes during pregnancy

Parameters	*Changes*
Respiratory rate	+ 15%
Tidal volume	+ 40%
Alveolar ventilation	+ 70%
Minute ventilation	+ 50%
Airway resistance	– 35%
Total compliance	– 30%
Residual volume	– 20%
Closing capacity	Unchanged
Vital capacity	Unchanged

Central Nervous System

The pregnancy has also profound effects on CNS, the actual mechanism of which is still not known. But probably it is due to the high concentration of progesterone associated with pregnancy. It decreases the dose of inhaled anaesthetic agents. The MAC value of all the volatile anaesthetic agents decreases upto 40% in pregnancy which again returns to normal on the 3rd day after delivery. Like volatile anaesthetic agents, LA agents also show higher sensitivity to neurons during pregnancy. Therefore, less amount of LA agents (30% reduction) is required during RA (spinal or epidural) to produce the same level of analgesia and anaesthesia. This event can be explained by two mechanism – hormonal and mechanical. The hormonal effect is mediated by progesterone which make the nervous tissue more sensitive to LA agents. The mechanical effect causing reduced dose of LA agent during spinal or epidural anaesthesia is due to the obstruction of inferior vena cava by gravid uterus. This causes distention of epidural venous plexus. Therefore, the volume of the potential epidural space and CSF are reduced. This enhances the more cephalad spread of same volume of LA agents during both the spinal and epidural anaesthesia in pregnant than non-pregnant state and needs the reduced doses of drug.

GI Effects

Pregnancy places the parturient women at higher risk for regurgitation and pulmonary aspiration. This is again due to the hormonal and mechanical effects. The hormonal effect is due to the higher level of progesterone and gastrin, secreted from placenta. This high level of progesterone decreases the tone of lower gastroesophageal sphincter and increases the chance of regurgitation. On the other hand, gastrin increases the secretion of HCl in stomach. The enlarged gravid uterus displaces the stomach upwards and anteriorly. This again promotes the incompetence of lower gastroesophageal sphincter. Thus, the above mentioned three factors (progesterone, gastrin, and upward displacement) increases the risk of severe aspiration pneumonitis during GA in pregnancy. Nearly all pregnant patients have gastric pH < 2.5 and the residual volume of gastric secretion is > 25 ml. Thus, it has also a profound effect on causing pulmonary complication.

The effect of pregnancy on gastric emptying time is in controversy. It is particularly delayed following administration of opiates for labour analgesia and onset of labour. Otherwise, gastric emptying takes place at widely variable rates during pregnancy. Anticholinergic agents delay the gastric emptying and reduce the tone of lower gastroesophageal sphincter. Contrary, prokinetic agent like metoclopramide usually speed up the gastric emptying, but is unable to reverse the effects of opiate and anticholinergic agent. However, the spinal and epidural anaesthesia do not affect the gastric emptying time. It is the loss of tone of lower gastroesophageal sphincter and not the rise of intra-abdominal or intragastric pressure which is the common cause of high incidence of gastroesophageal reflex (heart burn) and oesophagitis occuring during prganancy. Intragastric pressure remains unchanged throughout the pregnancy.

Haematological Changes

The maternal blood volume increases markedly during pregnancy. This increase

in blood volume results from both the increase in plasma and erythrocyte volume. The usual pattern is that there is initial increase in plasma volume and this is followed by an increase in the volume of circulating erythrocytes due to increased erythropoiesis. But the increase in plasma volume is much more than the increase in volume of erythrocytes. So, the concentration of Hb apparently (falsely) decreases during pregnancy due to the dilutional effect. The average Hb concentration at term is 12 gm/dl, as compared with a level of 13 gm/dl for nonpregnant women. The Hb concentration below 11 gm/dl, especially in late pregnancy, is suggestive of an abnormal process. The blood leucocyte count varies considerably during normal pregnancy. Usually, it ranges from 5000 to 12000 per cumm of blood. But during labour and the early puerperium it may become markedly elevated, attaining the levels of 25000 per cumm.

The plasma levels of several coagulation factors are increased during pregnancy. The concentration of plasma fibrinogen (factor I) increases by about 50%. The normal value of it ranges between 200 to 400 mg/dl (average 300 mg/dl). In pregnancy, it increases to an average value of 450 mg/dl (ranges between 300 to 600 mg/dl). The other clotting factors, and activation of which are increased appreciably during pregnancy are: factor VII, factor VIII, factor IX, factor X and factor XII. But the level of factor II (prothrombin) does not increase or increases only slightly during pregnancy. Whereas those of factors XI and XIII are decreased during pregnancy. Prothrombin time and partial thromboplastin time (PTT) are both shortened slightly as pregnancy progresses (Table 35.3).

Although some investigators have described a moderate decrease (10%) in the number of platelets, but still there is some controversy regarding this fact. This is because clotting time does not differ significantly between the normal pregnant and non-pregnant women. Pregnancy is associated with lower level of antithrombin III and increased level of plasminogen (profibrinolysin).

Table 35.3: Haematological changes during pregnancy

Parameters	*Changes*
Plasma volume	+ 40%
Red cell volume	+ 20%
Total blood volume	+ 45%
Haematocrit	– 15%
Plasma albumin	– 15 %
Plasma globulin	↑
Plasma fibrinogen	+ 50%
Plasma cholinesterase	– 30%

Renal Changes

Apparently the kidney increases in size slightly during pregnancy. Glomerular filtration rate (GFR) and renal blood flow (RBF) increase upto 50% during early pregnancy. The elevated GFR has been found to persist upto term, whereas the RBF decreases towards the non-pregnant value during the 3rd trimester of pregnancy. Pregnancy is associated with increased renin and aldosterone secretion which subsequently promotes the increased Na^+ and water retention. This causes the increased circulating volume of blood during pregnancy. During pregnancy, the concentration of creatinine and urea in plasma decreases upto the level of 0.5 to 0.6 mg/dl and 8 to 9 mg/dl, respectively as a consequence of increased GFR. Some times, the urea concentration during pregnancy may be as low as to suggest impaired hepatic synthesis, which often occurs with severe liver disease. So creatinine clearance is the most useful test for renal function during pregnancy.

The glycosuria which often found during pregnancy is not necessarily always taken as abnormal finding. The appreciable increase in glomerular filtration rate, together with the impaired renal tubular reabsorption capacity this huge amount of filtered glucose is responsible in most cases for glycosuria in pregnancy. Even though glucosuria is common during pregnancy, still the possibility of diabetes mellitus which has separate inplication on pregnancy can not be ignored. Proteinuria does not occur normally during pregnancy, except occasionally a mild one (< 300 mg/dl) during or soon after vigorous labour. If not the result of contamination during collection, blood cells in the urine during pregnancy indicates the disease somewhere in the urinary tract.

Hepatic Changes

During pregnancy there is no distinct change in size and morphology of liver. The overall hepatic function remains unchanged throughout the whole period of pregnancy, except minor increase in the serum transaminases and lactic dehydrogenase level in plasma during 3rd trimester. The total alkaline phosphatase activity in serum approximately becomes double during normal pregnancy and commonly reaches the levels that would be considered abnormal in the nonpregnant woman. Much of this increase in serum alkaline phosphatase level is due to the secretion of it from placenta. Pregnancy is associated with decrease in plasma albumin level, showing it to average 3 gm/dl, compared with 4 to 6 gm/dl in nonpregnant woman. This probably is due to the expanded plasma volume. But, globulin level in plasma increases in pregnancy and results in a decrease in the albumin to globulin ratio, similar to that found in certain hepatic diseases. There is also 30% reduction in serum (pseudo) cholinesterase activity in pregnancy. But, rarely it is associated with prolonged action of succinylcholine. This decreased activity of pseudocholinesterase persists upto 6 weeks after delivery. But, the breakdown of mivacurium by pseudocholinesterase does not appreciably alter during pregnancy.

Metabolic Changes

In response to the rapidly growing foetus and placenta and their increasing metabolic demands, the pregnant woman undergoes some metabolic changes that are numerous

and intense. This is because the altered carbohydrate, fat and protein metabolism favours the foetal growth and development. The first and foremost metabolic changes that occur in pregnancy is weight gain of mother. The large increament in maternal body weight during pregnancy is the result of metabolic alterations, especially retention of water, and deposition of fat and protein. The average total gain of body weight in a pregnant woman during the whole period of pregnancy is about 11 Kg and the minimum amount of extra water that an average pregnant woman could be expected to retain is about 6.5 L. The total accumulation of protein throughout the whole pregnancy is 1 gm, out of which 500 mg is needed for the development of foetus and placenta and another 500 mg is required for the development of rest such as in the form of uterus (as contractile protein) plasma protein, Hb, etc.

The pregnancy is potentially a diabetogenic process. So, a already present diabetes mellitus is aggravated by pregnancy or a clinical asymptomatic individual becomes an overt one. The diabetogenic effect of pregnancy is principally due to the lactogen secreted from placenta which is called placental lactogen. It opposes the action of insulin and produces or aggravates the diabetes mellitus. Thus, the ability of placental lactogen to oppose the action of insulin leads to increased maternal secretion of insulin. Therefore, hyperplasia of the beta cells of pancreus occurs in response to an increased demand for insulin secretions. The placental lactogen also promotes lipolysis which brings about an increase in the level of plasma free fatty acid. These plasma free fatty acids provide alternative source of energy other than glucose in mother. Hence, in pregnancy starvation induces much more intense ketonaemia and ketonuria.

The plasma lipid level increases appreciably during the later half of pregnancy. This increase involves the total lipids, esterified and nonesterified cholesterol, phospholipids, neutral fat and lipoproteins, etc.

UTEROPLACENTAL CIRCULATION

The delivery of most of the substances essential for the growth and metabolism of foetus and placenta, and as well as the removal of most of the metabolic wastes from them depends upon the adequate perfusion of these. This is called the uteroplacental circulation and in turn it depends upon the blood flow through the uterus by uterine and ovarian arteries and through the placenta by umbilical arteries and veins. There is progressive increase in uteroplacental blood flow throughout the pregnancy. It represents about 10% of total cardiac output or 500 ml/min in late pregnancy. Among these 80% of the flow goes to the placental circulation and the rest goes to the growing myometrium of uterus.

During pregnancy due to the maximum dilatation of uterine vasculature, its autoregulation is lost. Then, the blood flow through uteroplacental circulation is directly proportional to the difference between the uterine arterial and venous pressure, and inversely proportional to the uterine vascular resistance. During autoregulation uterine arteries are under the neural control which are mediated by mainly α-adrenergic receptors and to a lesser extent by β-adrenergic receptors. Therefore, α-adrenergic agonistic agents cause uterine vasoconstriction and decrease the uteroplacental blood flow. The example of some α-adrenergic agonists are adrenaline, noradrenaline, phenylphrine, mephentermine, etc. As β-receptors are sparse on uterine vasculature, therefore predominant β-adrenergic agonists such as ephedrine does not decrease much the uteroplacental blood flow. Hence, it is the vasopressure of choice to treat hypotension during obstetric regional analgesia and anaesthesia. However, practically many clinical studies suggest that predominat α-adrenergic agonists though constricts the uteroplacental vasculature, still are associated with less foetal acidosis than ephedrine. This is becasue they maintain the adequate uterine blood flow by maintaining systemic blood pressure and a pressure head to flow, provided excessive vasoconstriction is avoided.

The three major factors which decrease the uteroplacental blood flow during pregnancy are: (i) systemic hypotension by decreasing the difference between uterine arterial and venous pressure, (ii) uterine vasoconstriction by increasing the uterine vascular resistance, and (iii) uterine contraction by decreasing the difference between uterine arterial and venous presure by elevating the uterine venous presure. The intense uterine contraction decreases the uteroplacental blood flow by compressing the uterine arterial vessels as they traverse through the myometrium. Hypertonic uterine contractions by oxytocin infusion or due to other causes can critically reduce the uteroplacental blood flow and compromise the foetus.

Effects of Anaesthetic Agents on Uteroplacental Blood Flow (UPBF)

More or less all the anaesthetic agents affect the UPBF by acting directly or indirectly. Among the intravenous anaesthetic agents thiopentone, benzodiazepines and propofol reduce the UPBF. This is due to indirect effect of systemic hypotension, produced by these agents in high doses. But the clinical inducing dose of these group of drugs does not produce any alteration in UPBF, if the BP is maintained with in normal level. However, a small inadequate dose of these inducing agents may reduce the UPBF and it is due to the stimulation of sympathetic system during laryngoscopy. Injection ketamine causes the activation of sympathoadrenal axis and may reduce the UPBF by vasoconstriction. But the increase in BP by ketamine counter acts the effect of vasoconstriction and ultimately the UPBF remains the same. This explanation is applicable when the dose of ketamine is kept below 1 to 1.5 mg/Kg of body weight. But, when

the dose of ketamine is increased to >2 to 3 mg/Kg, then it causes the hypertonic contraction of uterus and drastically reduces the UPBF.

The effects of volatile anaesthetic agents on UPBF also depend upon the interactions between the effect of these agents on systemic BP and direct uteroplacental vasodilatation with uterine myometrial relaxation produced by them. In clinical doses (around the value of 1 MAC) they produce the maximum vasodilatation effect and uterine relaxation than the sytemic reduction of BP. Therefore, in these doses the UPBF does not decrease, rather increases till systemic BP falls to a greater extent. N_2O has negligible effect on UPBF. Regional anaesthesia (central neuroaxial block) does not directly affect the UPBF, provided the systemic BP is maintained. In severe hypotension, the UPBF is proportional to the fall of BP. In pre-eclampsia, the RA has very beneficial effect on UPBF and this is due to reduction of the uterine vasoconstriction by cutting down the sympathetic supply to it. But again this beneficial effect on UPBF is maintained upto a certain level of hypotension, below which the uterine and placental circulation is severly compromised. The use of recommended dose of epinephrine with LA agent during CNB is not contraindicated for obstetric analgesia and anaesthesia. Becasue the intravascular uptake of epinephrine from epidural space is so small that it only produces the β-adrenergic effects and dilate the uterine vessels, instead of vasoconstriction.

Transfer of Anaesthetic Agents Through Placenta

Most of the drugs used during anaesthesia can cross the placental barrier except the muscle relaxants. Because they are highly ionised and placental transfer of them is impaired causing minimum or no effect on foetus. The transfer of any anaesthetic agent through placenta depends on multiple factors such as the route of administration, the total dose, the method of administration (single shot large, multiple small boluses, continuous infusion, etc), and the timing of administration. But the effect of anaesthetic agent on foetus depends on the above mentioned factors (placental transfer) plus the maturity of foetal organs (liver and brain). For example, giving a drug many hours before delivery is least likely to produce any foetal effect after delivery. Similarly, a single IV bolus dose of any anaesthetic agent during uterine contraction and just prior to delivery also produce minimum concentration of it in foetus. Foetal effects of any anaesthetic agent is evaluated by observing the foetal heart rate variability, intrapartum acid-base status and by Apgar score and neurobehavioral examination during postpartum period.

All the opiates cross the placenta barrier, but the newborns are most sensitive to morphine regarding the respiratory depression effect of it than any other opiates. The maximum respiratory depressions effect of meperidine which occurs 1 to 4 hours after administration is higher than other opiates, but still less than morphine. Fentanyl readily crosses the placental barrier, but produce minimal respiratory depression effects if the dose of it is kept below 1µg/Kg. Remifentanil also crosses the placental barrier readily like fentanyl, but foetal blood concentration is generally half than that of the mother. Butrophanol and nalbuphine produce less respiratory depression than morphine and pethidine (meperidine), but have significant depressed neurobehavioral effect on focus.

The commonly used inducing agents in GA such as thiopentone, propofol, ketamine and benzodiazepines, etc, readily cross the placental barrier. But, except benzodiazepines, other agents in the usual induction dose do not cause any significant effect on foetus due to their characteristic distribution, metabolism, and placental uptake. Only benzodiazepines in the induction dose have profound effect on foetus regarding the respiratory depression and neurobehavioral effect. All the inhalational agents freely cross the placenta. But, they produce minimal foetal depression, if the dose is kept below the value of 1 MAC and is used for less than 10 minutes before delivery.

LA agents also freely cross the placenta barrier, but it depends on three factors such as: pK value of this agent, maternal and foetal pH, and the degree of protein binding of LA agents. Bupivacaine and ropivacaine are more protein bound than lignocaine. So, these LA agents diffuse poorly across the placenta and causes lower foetal blood level than lignocaine. Foetal acidosis causes higher concentration of LA agent in the foetal blood. This is because H^+ binds with the nonionized form of LA agents and causes trapping of it on the foetal side of placenta. Other drugs which are used during anaesthesia such as ranitidine, metoclopramide, atropine, antihistamine, phenothiazines, β-blocker, vasodilator, etc; can cross the placenta. But, glycopyrrolate can not, because it is an ionised quaternary ammonium structure.

EFFECTS OF ANAESTHETIC AGENTS ON UTERINE ACTIVITY

Intravenous anaesthetic agents such as thiopentone, propofol, benzodiazepines have no effect on uterine contraction. Opiates minimally decrease the uterine muscular activity. Ketamine in the dose of > 2 mg/Kg through IV increases the uterine contraction. Below this dose, it has also little effect on uterine contraction. All the volatile anaesthetic agents such as halothane, isoflurane, sevoflurane, desflurane, etc. decreases the uterine muscular activity equally at equipment doses, and causes dose dependent myometrial relaxation. Thus, they produce uterine atony and increases the postpartum blood loss. But, at concentration < 0.7 MAC (low doses) they do not interfere the action of oxytocin on myometrium. N_2O has no effect

on uterine activity. Uterine myometrium also contains both the α and β receptors which respectively produces the muscular contraction and relaxation. Therefore, the α-adrenergic agonistic agents such as phenylephrine, mephentermine, ephedrine, etc. augments the uterine contraction. But this effect is found only in high doses. Whereas, the β-adrenergic agonistic agents such as salbutamol, retordrine, etc; produce the uterine relaxation and is used to treat the premature labour.

Regional anaesthesia (RA) has little effect on uterine contraction. Therefore, it does not affect the course of labour. Regional analgesia using the combination of low dose of local anaesthetic agents such as bupivacaine 0.125% and low dose of opiates such as fentanyl 5 µg/ml does not prolong the labour and does not increase the chances of instrumental delivery or CS. But when the higher concentration of LA agents are used, it prolongs the labour by only affecting the second stage. This is indirect effect and is due to the loss of Ferguson reflex which produce motor weakness and impair the expulsive or bear down effort. This is not the direct effect of RA on the course of labour. Epinephrine has both the α and β action. But in low concentration, β action predominates over α action. Therefore, epinephrine containing LA agent used for obstetric RA may produce prolongation of labour as it is used in very low concentration producing only β effect. But clinically prolongation of labour is generally not observed as it is used in very very low concentration, e.g. 1:200,000 to 1:400,000 dilution.

CONSEQUENCES OF PAIN IN LABOUR

Pain is a noxious and unpleasant stimulus. It produces great fear and anxiety. Which again aggravate the pain. Thus, a vicious cycle sets up. Pain during labour causes reduction of uterine blood flow, ↓FHR, ↓foetal oxygenation, foetal acidosis, etc. All these are mediated by the activation of sympatho-adrenal axis of mother. So, painful labour is associated with increased maternal plasma cortisol and catecholamine levels which are responsible for the reduction in uteroplacental blood flow. Thus, effective pain relief during labour reduces the plasma cortisol and catecholamine concentration with their bad effects. Pain relief also prevents the metabolic acidosis of mother by reducing the rate of rise of plasma lactate, pyruvate, and decreasing the maternal consumption of O_2 up to 15%.

Pain during labour also produces hyperventilation and hypocapnia of mother. This causes the reduction in uteroplacental blood flow and even tetany in some parturient patients. This respiratory alkalosis further impairs the fetomaternal gas exchange by shifting the oxy-Hb dissociation curve to the left. Thus, foetal PaO_2 may fall producing foetal acidosis (Fig. 35.1).

PAIN PATHWAYS IN LABOUR

Pain during the First Stage of Labour

Pain during the first stage of labour is due to the stretching, distortion, tearing, and possibly the ischaemia of uterine tissues. It is also due to the simultaneous dilatation of cervix with stretching of lower uterine segment. The intensity of pain during the first stage of labour increases progressively with the rising of the strength of contraction and stretching of the uterus and cervix. These painful stimuli are transmitted through A-delta and C affarent fibres accompanying the sympathetic pathway. It passes gradually through the pelvic and the inferior, middle, and superior hypogastric plexus → lumbar sympathetic chain → the white rami of T_{10} to L_1 spinal nerves → posterior root of these spinal nerves → T_{10} to L_1 segment of spinal cord. During the early part of the first stage of labour, only the nerve roots of

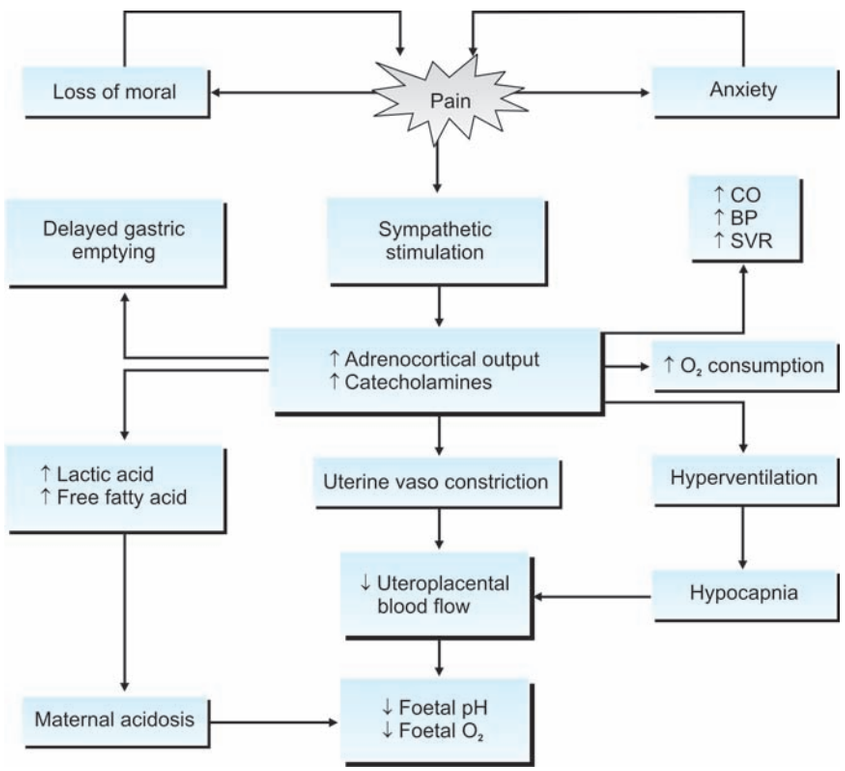

Fig. 35.1: Effect of pain on mother and foetus

T_{11} and T_{12} spinal segment are involved. But as the intensity of uterine contraction increases, then gradually the T_{10} and L_1 nerve roots with their corresponding spinal segments are recruited.

Backache is a frequent complain during the progress of labour. It may be caused by one or other of these two mechanisms which is explained below. Pain originating from the uterus or cervix may be referred to the cutaneous branches of the posterior divisions of T_{10} to L_1 spinal nerves which migrate caudally for an appreciable distance before they innervate the skin overlying the vertebral column. For example, the posterior cutaneous branches of T_{11} spinal nerve supply the skin overlying the L_3 and L_4 vertebrae. Pain due to pressure on the periuterine tissues by foetal head which is found in association with the foetal malpresentation or unusual shape of sacrum is referred to the L_5 and S_1 segment of spinal cord which is felt as very low back pain.

Pain During the Second Stage of Labour

In the second stage of labour, pain is mainly caused by the distension and stretching of the pelvic structure and perineum which is due to the descent of foetal presenting part. This is also added to the pain of uterine contraction of the first stage of labour. Once the cervical dilatation is complete, the pain induced by uterine contraction may become less intense. The pain initiated by uterine contraction is continued to be referred to the T_{10} to L_1 dermatones. But the pain produced by stretching and pressure exerted on the intrapelvic structure including the pelvic floor (levator ani), bladder, urethra, rectum is referred to the sacral segment. With the above manifestation, the direct pressure on the root of the lumbosacral plexus by the foetal presenting part is also manifested as a pain which is felt low on the back or on the inner side of thighs. The pain produced by the stretching of perineum is transmitted through the pudendal nerve ($S_{2,3,4}$), posterior cutaneous nerve of thigh ($S_{2,3}$), genitofemoral nerve ($L_{1,2}$), and the illioinguinal nerve (L_1).

During the first stage of labour, an epidural block in which the level of anaesthesia is limited only to the $T_{11,12}$ segment of spinal cord (in very early stage) and later is extended to the T_{10} and L_1 spinal segment is sufficient to provide excellent pain relief. While the neural blockade of sacral segment is not necessary for the relief of pain in the first stage of labour. Premature blockade of sacral segment in the early stage of labour can result in the loss of stimulating effect of Ferguson's reflex which initiates more contraction and helps in the rotation of foetal presenting part. Thus, premature blockade of sacral segment cause more incidence of instrumental delivery and CS.

ANALGESIA FOR VAGINAL DELIVERY

Pain during vaginal delivery can be alleviated by different processes. These are:

i. Psychological and non pharmacological technique,
ii. Pharmacological technique,
iii. Nerve block technique – central or peripheral (Table 35.4).

Psychological and Non-pharmacological Technique

In this technique, exhaustive counselling of mother is done from 6 weeks before delivery, regarding the normal anatomy of reproductive system, physiology of pregnancy, physiology of normal delivery and postpartum advice, etc. By this psychological counselling, pain during the process of labour and vaginal delivery can be reduced by recognising or preconditioning the cerebral cortical activity or thought of patients. Usually fear of unknown or previous unpleasant experience aggravates the labour pain. Thus removal of this fear by proper counselling helps to reduce the pain. The patient concentrates her mind away from the delivery process and tries to relax herself. This distraction of mind from the process of normal delivery inhibits the incoming painful stimulus from uterus and thus subsequently reduces the pain sensation, associated with uterine contraction.

Some common psychological techniques used to reduce the labour pain are: Lamaze, Duola, Dick Read, Le Boyer and Bradley etc. Among these, Lamaze technique for relief of labour pain is the most popular. In this technique, patient is trained to take deep breath at the begining of each uterine contraction. This is followed by

Table 35.4: Pain pathway in labour

Site of origin	*Pathway*	*Site of pain*
Uterus and cervix	Affarent fibres which accompany the sympathetic pathway to T_{10} - L_1 spinal segments	Whole abdomen and groin
	Dorsal rami of T_{10}-L_1 spinal nerves. This is referred to cutaneous branches of posterior divisions	Mid back
Pressure by presenting part of foetus on periuterine tissue	Lumbosacral plexus	Low back, thigh
Bladder, urethra, rectum	Pudendal nerve ($S_{2,3,4}$)	Referred to perineum and sacrum
Vagina	Pudendal nerve ($S_{2,3,4}$)	Perineum
Perineum	Pudendal nerve ($S_{2,3,4}$) Genitofemoral nerve ($L_{1,2}$) Ileoinguinal nerve (L_1) Post cutaneous nerve of thigh ($S_{2,3}$)	Perineum

gentle exhalation in a shallow pattern until the uterine contraction ends. Other psychological techniques used to reduce the labour pain are: hypnosis, mesmerism, acupuncture, TENS (transcutaneous electrical nerve stimulation) etc. But, success of all these techniques varies from patient to patient and frequently needs combination of some of these techniques or addition of some newforms of pain relieving method.

Pharmacological Technique

Nearly all opioids and non opioid analgesics and sedation can be used to alleviate the labour pain. But, all these agents relieve the labour pain to different extent and have their own advantages and disadvantages. They all cross the placenta and affect foetus.

Opioids

Opioids are the most commonly used agents for the relief of labour pain. But, foetal depression limits the use of these agents at the early stage of labour. They are also used where RA techniques are not possible and not used. Among the opioids the most commonly used agents are: meperidine, morphine, fentanyl, butorphanol and nalbuphine etc. and they produce more or less comparable pain relief. But the choice of drugs for clinical use depends on their potential side effects, desired onset of action, duration of action and the familiarity of these agents by the anaesthetist. The main drawbacks of the use of opioids for the relief of labour pain are: foetal respiratory depression, foetal respiratory acidosis, abnormal neurobehavioural pattern of foetus, loss of beat to beat variability of foetal HR, decreased foetal movement, ↓Apgar score, ↓SPO_2 of foetus, maternal respiratory depression, maternal nausea and vomiting, maternal delayed gastric empting, etc. The loss of beat to beat variability of foetal heart rate and decreased foetal movement by opioids make the intrauterine monitoring of foetal well being difficult.

Though, morphine is the gold standard of all the opioid analgesics, still it is not commonly used in the practice of obstetric analgesia. This is because it appears to cause more respiratory depression of the foetus than any other opioids in equipotent analgesic doses. The other drawbacks of morphine are delayed onset of action and prolonged duration of action. The peak effect of it occurs 20 to 30 minutes after IV administration and 1 to 2 hour after IM injection. The duration of action of morphine is 4 to 6 hour. The most commonly used opioids in the practice of obstetric analgesia is meperidine. The peak effect of it occurs 5 to 10 minutes after IV and 30 to 60 minutes after IM administration. The usual IV doses of meperidine for obstetric analgesia is 25 to 50 mg and IM dose is 50 to 100 mg. The duration of action of meperidine of this dose is 2 to 4 hour. Therefore, the meperidine is given during early stage of labour when delivery is not expected at least within 4 hours after its administration. The fentanyl is also used to relief labour pain through IV or IM route and the usual dose is 25 to 50 µg and 50 to 100 µg respectively. After IV administration the peak effect of fentanyl occurs within 2 to 4 minutes after its administration and duration of action lasts for 40 to 60 minutes. It is found that the above mentioned doses of fentanyl does not cause: neonatal respiratory depression, ↓Apgar score, adverse effects on neonatal neurobehavioural score and adverse effect on umbilical cord blood gas analysis. So, it is concluded that the fentanyl may be used as analgesics to reduce the labour pain, as an alternative to either RA or GA. Another two commonly used opioids for obstetric analgesia are butorphanol and nalbuphine. They are synthetic agonist and antagonist opioids in nature. The analgesic dose of butorphanol is 2 mg and nalbuphine is 10 mg which is equivalent to 10 mg of morphine, 100 mg meperidine and 100 µg fentanyl in respect to the respiratory depression. But the advantage of these two drugs is that increasing the doses of them does not produce more respiratory depression with cumulative action (ceiling effect). On the other hand, large doses of these two compounds may produce excessive sedation, dizziness, somnolence, etc.

Benzodiazepines

Benzodiazepines are also used in the practice of obstetric analgesia. The indications are: to reduce anxiety, as anticonvulsant in eclampsia, as adjunct to opioids and as premedicant for CS. Among all the BDZs, the commonly used agents in obstetric analgesia and anaesthesia are: diazepam, lorazepam, midazolam etc. and they all cross the placental barrier readily. Within 1 minute after IV administration, the maternal and foetal plasma concentration of all these BDZ approximately becomes equal. The use of BDZs in obstetric practice has also many advantages and disadvantages like opioids. The advantages of the use of benzodiazepines are the reduction of maternal anxiety and subsequently its consequences such as ↑catecholamines, ↓uteroplacental circulation due to constriction of uterine artery, foetal acidosis, etc. It also reduces the requirements of opioids (it is used to alleviate the labour pain) and cuts down its complication. But the disadvantages of the use of BDZ are mainly on foetus. These are foetal respiratory depression, hypotonia, lethergy, hypothermia, depressed feeding, ↓SPO_2, etc. These adverse effects are found when the unusual large nonobstetric doses of BDZs are used for obstetrics analgesia and anaesthesia. But, small doses of BDZs have minimal effects on foetus and neonats, though beat to beat variability is markedly decreased even in small doses.

Lorazepam does not offer any extra advantages over diazepam in obstetric analgesia and anaesthesia practice except that only less than 1% of it is transformed to other pharmacologically active metabolites. If the total maternal dose of diazepam during labour exceeds than 20 to 25 mg

then the drug itself and its pharmacologically active metabolites persist above the therapeutic level for about atleast 1 week. The usual nonobstetric doses of lorazepam (1 to 2 mg) is associated with adverse effects on neonates. The advantage of midazolam over the other BDZ is that it is water soluble and rapid onset and short duration of action.

Another usual drawback of the use of BDZ in obstetric practice is the anterograde amnesia of mother produced by it. But all the mothers desire to recall the birth of their baby and it is highly pleasure to them. So, amnesia produced by BDZ is an unwanted effect in obstetric practice, though it is highly desirable in other surgical patients.

Ketamine

Ketamine is also used in obstetric practice to reduce the labour pain, because it has strong analgesic effect, even though in very low doses (0.1 to 0.25 mg/Kg). But in higher doses (1 mg/Kg), it causes induction of anaesthesia. In very low doses it produces only analgesia without any effect of sedation or unconciousness. In both the above mentioned doses, ketamine does not affect the uterine blood flow, foetal Apgar score and uterine muscle tone. But in higher doses than 2 mg/Kg, ketamine can produce hypertonic uterine contraction. The main drawback of use of ketamine in obstetric practice is its unpleasant effect of hallucination which some obstetricians do not like. But this hallucination is usually not found in very low doses which is used in obstetric analgesia, but not in anaesthesia.

Phenothiazine derivatives and hydroxyzine

Among the phenothiazine derivatives, promethazine is the most commonly used agent in the practise of obstetric analgesia and anaesthesia. Other phenothiazine derivatives which are also used in obstetric analgesia and anaesthesia practice are: promazine, chlorpromazine, prochlorperazine etc. But, they are not popular because they possess high α-adrenergic blocking activity and frequently cause hypotension. Hydroxyzine is not a phenothiazine derivative. But it has similar property of ataraxia (a state of detached serenity without depression of mental faculties or impairment of consciousness) like promethazine. So, it is frequently used in combination with promethazine and meperidine. However, both these drugs reduce the requirement of opioids, anxiety, nausea, and vomiting of mother. Also they do not appreciably produce neonatal depression. These are the advantages of promethazine and hydroxyzine. The principal disadvantage of hydroxyzine is that IV preparation of it is not available. So it is only administered through IM route causing delayed onset and prolonged action. The usual dose of promethazine and hydroxyzine used for obstetric analgesia and anaesthesia are 25 to 50 mg and 50 to 100 mg IM respectively.

Barbiturates

The short and medium acting barbiturates such as pentobarbital (nembutal), secobarbital (seconal), amobarbital (amytal), etc, are not used now a days in obstetric practice to reduce anxiety and labour pain, because they have prolonged effect of depression on neonates, even with smaller doses that does not cause clinical maternal depression. NSAID such as ketorolac is not recommended to relief the labour pain, because it suppresses the uterine contractions and promotes the premature closure of ductus arteriosus.

Inhaled analgesic

The inhalation of different volatile anaesthetic agents is also a popular method for alleviation of labour pain. Through this inhalation route different inhaled anaesthetic agents are administered alone in subanaesthetic concentration, only to reduce labour pain but without any loss of consciousness or as supplementation to regional or local anaesthesia. This form of relief of labour pain should not be confused with inhalational anaesthesia where patient losses his consciousness with the loss of protective laryngeal reflexes. With this technique patient remains conscious and co-operative with the presence of full laryngeal reflexes, while she enjoys the analgesic effect of inhalational agent. Usually the volatile pharmacological agent is administered either by patient herself or by anaesthetist via a face mask in intermittent or continuous way. However, the main disadvantage of this method is that as the inhalational anaesthetic agents are used in subanaesthetic concentration, so this method does not always provide adequate amount of pain relief. Hence, it is usually used as an adjunct to other methods of pain relief.

The commonly used inhaled anaesthetic agents are: N_2O and O_2 mixture (50:50 N_2O-O_2 mixture called entonox), desflurane (0.2%) isoflurane (0.25%), enflurane (0.2%), etc. Entonox has been used for many years to relief the labour pain as a sole analgesic agent or as an adjunct to other systemic or regional analgesic technique. But, truly speaking, and is unfortunate to say that the analgesia provided by 50% N_2O alone is not reliable. The maximum analgesic effect of N_2O occurs within 30 to 60 seconds after the starting of its inhalation. It is, therefore, advised that patients should start to inhale the gas at the early onset of uterine contraction and discontinue it after the peak of contraction, if intermittent method is applied. During the use of entonox the lack of proper use of scavenging system put the labour room staff at the unnecessary risk of exposure to the excessive level of N_2O over a prolonged period.

The subanaesthetic concentration of other volatile anaesthetic agents such as desflurane, isoflurane, enflurane etc. has also successfully been used to provide labour analgesia, and their effectiveness also appears to be comparable to that of

N_2O. The above mentioned dose of these volatile anaesthetic agents are not fixed. It depends on the response of patient. If the patient becomes drowsy, non-cooperative, confused and gradually progresses to unconsciousness then the inspired concentration of volatile anaesthetic agents should be lowered quickly. The major risk of this method of obstetric analgesia and anaesthesia is accidental anaesthetic overdose producing unconsciousness. So, a trained person must remain in continuous verbal contact with the patient and monitor the consciousness.

Nerve Block

Two types of nerve block are used to relief the labour pain for vaginal delivery. These are: peripheral nerve block and central neuraxial block.

Peripheral nerve block

Among the peripheral nerve block for obstetric analgesia and anaesthesia the pudendal nerve block is most commonly used. This is often combined with local infiltration of subcutaneous tissue of perineum by local anaesthetic agents, if other forms of anaesthesia are not applied or is inadequate. Thus, it provides complete perineal anaesthesia only for the 2nd stage of labour. The pudendal nerve is derived from $S_{2\text{-}4}$ nerve roots and provides sensory innervation to the valva, lower part of the vagina and perineum. It also provides motor innervation to the perineal muscles. The pudendal nerve can easily be blocked through transvaginal route by depositing LA agents behind the sacrospinous ligament. This nerve block provides adequate local anaesthesia only for the 2nd stage of vaginal delivery, outlet forceps manipulation, episiotomy and its repair etc. But it does not provide adequate analgesia for mid forceps manipulation, repair of upper vaginal laceration, exploration of uterine cavity etc. The pudendal nerve block is associated with low complication, but high incidence of failure rate.

Another technique of peripheral nerve block for obstetric analgesia and anaesthesia is the paracervical block. In this technique, the paracervical ganglion (or FranKenhausen's ganglion) which transmits all the visceral sensory nerve fibres from uterus, cervix and upper vagina is blocked. So, this technique provides pain relief for the later part of the first stage of labour and the first part of the 2nd stage of labour. The paracervical ganglion is situated lateral and posterior to the junction of the cervix and the body of the uterus. Hence, for this technique LA agent is deposited through the vaginal route into the fornix of vagina, lateral to the cervix. However this block does not affect the somatosensory fibres from lower vagina, perineum and valva. Therefore, it does not afford any pain relief during the second stage of labour. On the other hand, it does not adversely affect the dilatation of cervix and the progress of labour.

Recently, this paracervical plexus block is not used for obstetric analgesia and anaesthesia. This is because it is associated with high rate of foetal bradycardia, foetal acidosis, decreased foetal oxygen saturation and increased likelihood of foetal depression. However, the probable explanation of these complications in paracervical block is the close proximity of injection site to the uterine artery which result in uterine arterial vasoconstriction, uteroplacental insufficiency and high levels of LA agent in the foetal circulation. The foetal bradycardia usually develops within 5 to 10 minutes after the injection and it lasts for 10 to 30 minutes.

Central neuraxial block (CNB)

Recently, the CNB is the most commonly used technique for obstetric analgesia and anaesthesia. Compared to the pharmacological method and GA, this technique of obstetric analgesia and anaesthesia is less likely to produce drug induced depression of foetus and aspiration pneumonitis of mother. It also provides relief in labour pain, while allow the patient to remain awake and to participate actively in labour and delivery. CNB is associated with lower level of catecholamines in maternal circulation which is beneficial to the foetus. The most common forms of CNB for obstetric analgesia and anaesthesia are lumbar epidural, caudal epidural, subarachnoid, and different combination of these techniques, such as combined spinal and epidural by LA agents and/or opioids with their different concentration. Though, LA agents and opioids alone can provide adequate labour analgesia, still the combination of these two agents at different concentration is most popular. This is because the synergistic effect due to the combination of these two types of agents decrease the individual dose requirement with few or nil maternal and foetal side effects if these agents are used alone.

Lumbar Epidural Anaesthesia — Analgesia for Vaginal Delivery

This is the most commonly used regional anaesthesia-analgesia technique to relief pain in all the stages of labour. It can be provided by a single shot or by continuous technique using catheter. Continuous epidural anaesthesia-analgesia by catheter provides the greater flexibility than the single shot technique. For obstetric analgesia and anaesthesia epidural catheter is placed at lumbar region and analgesia is achieved when the patient wants it during any stage of labour. But, it is often advantages if the catheter is placed in early stage of labour when the patient is comfortable and can be positioned easily. Moreover, if emergency LUCS is needed at any time during the progress of labour, then it can be converted into epidural anaesthesia and again this can be exended for postoperative analgesia. A more conservative approach for the commencement of epidural labour analgesia (recommended by some obstetrician) is to wait till the labour is well established, which is characterised by: regular uterine contraction at 3 to 4 minutes interval and lasting for 1 minute,

minimum cervical dilatation of 3 to 4 cm, no foetal distress and engagement of foetal presenting parts.

For lumbar obstetric epidural anaesthesia-analgesia, the optimal interspinous space is L_{2-3} or L_{3-4} which is used by maximum anaesthetist. This is because this space helps to achieve the level of analgesia with minimum amount of drug extending between T_{10} to S_5 dermatomes. Any position of patient, i.e. lying or sitting can be used. But sitting position is more helpful for identifying the midline in obese patient. Sitting position also helps for better sacral spread of analgesia, if lumbar epidural is given at second stage of labour. One disadvantage of sitting position for epidural block is that as in this position there is more CSF pressure, so there is increased incidence of unintentional dural puncture. Most anaesthetists prefer midline approach, while some favour the paramedian approach for epidural placement of catheter. The incidence of wet tap during lumbar epidural procedure varies between 0.2% to 10%, depending on the skill of anaesthetist. If unintentional wet taps occur, then the clinician has two choices: (i) he can try again at the another higher or lower interspinal space, or (ii) he can put the epidural catheter in the subarachnoid space and convert the continuous epidural to continuous spinal anaesthesia-analgesia. For detection of epidural space by the loss of resistance technique, usually air or normal saline is used. But the amount of air injected in the epidural space should be as little as possible, probably less than 3 to 5 ml. This is because injection of large amount of air in the epidural space is associated with headache, and unilateral or patchy anaesthesia-analgesia.

In obstetric epidural anaesthesia-analgesia, the commonly used drugs to relief the labour pain are local anaesthetic agents in different concentration with or without combination of opioids. These two agents such as LA agents and opioids have synergistic effect on each other and have separate sites of action. Opioids act on the opiate receptors situated at the dorsal horn cells of the spinal cord, while LA agents act directly on the neuronal axons of the nerve roots. This synergistic effect helps to reduce the concentration or doses of these two agents. Therefore, the incidence of side effects of both the LA agents and opioids are reduced. For example, hypotension due to chemical sympathectomy and motor block due to the block of conduction of motor nerve fibres which are common adverse effects of LA agents in higher concentration in epidural space are absent in lower concentration of there agents. Therefore, the patient can help from herself in 2nd stage of labour by bearing down and accelerating the normal vaginal delivery. In some low concentration of bupivacaine such as 0.062 to 0.125%, patients even can walk during the first stage of labour because in this lower concentration bupivacaine only block the sensory fibres, sparing the motor. So, this is called the 'walking or mobile epidural'.

Similarly the nausea, vomiting and respiratory depression which are the common side effects of opioids are also absent in low doses of opioid in epidural space. When opioid is omitted then the higher concentration of LA agent such as bupivacaine in 0.25 to 0.5% or ropivacaine in 0.2% is needed. This high concentration of LA agent reduces the normal pelvic muscle tone by blocking the motor nerve which normally help in rotation and engagement of foetal presenting parts and thus impair normal vaginal delivery. This high concentration of LA agent abdominal muscles and will impair the mother's ability to bear down as the labour progress.

Among the LA agents, bupivaciane, levobupivaciane and ropivacaine are the drug of choice for obstetrc analgesia by most of the anaesthetist. Bupivaciane is choiced for obstetric analgesia and anaesthesia because it produces optimal clinical effect in very low concentration, long duration of action, apparent lack of tachyphylaxis and high protein bound causing less placental transfer. But, the main disadvantage of bupivacaine is its cardiotoxicity. Bupivacaine is also effective for only sensory block but without any motor block in concentration as low as 0.125% or 0.0625% when it is combined with opioids for early labour. But some higher concentration of bupivacaine such as 0.125% with opioid or 0.25% alone without opioid are needed in later stages of labour. The concentration of 0.5% bupivacaine is only reserved for use during CS which causes both the sensory and motor block producing obstetric anaesthesia. Ropivacaine is a newer amide local anaesthetic agent with near similar in structure and pharmacodynamics to bupivacaine. It is the first levo isomer (levo isomer of bupivacaine is levobupivacaine) LA agent to be marketed. It is less soluble than bupivacaine. Therefore is less potent. Cardiotoxicity of ropivacaine appears to be intermediate in position between those of lignocaine and bupivacaine. Unlike bupivacaine, progesterone does not appear to enhance the cardiotoxicity of ropivacaine. Clinically only for obstetric analgesia to alleviate labour pain it is used in the concentration of 0.2%. It is now thought that the reduced toxicity and reduced motor block produced by ropivacaine is due to its low potency.

Levobupivacaine is now used to provide the epidural labour analgesia. It is the levo isomer of bupivacaine. The normally marketed bupivacaine contains the mixture of R-enantiomer (racemic bupivacaine) and S-enantiomer (levobupivacaine). It is confirmed that levobupivacaine is long acting and possess more safety profile than the recemic mixture of bupivacaine. The lethal dose of levobupivacaine is 1.5 to 2 times higher than that of its racemic mixture i.e. bupivacaine. The usual concentration of levobupivcaine used in clinical practice is 0.25 to 0.5%.

The addition of epinephrine to the LA agent during epidural anaesthesia-analgesia to relief labour pain is a controversial topic. It is known to all that epinephrine reduces

the systemic absorption of LA agent and subsequently its toxicity. Therefore, it can increase the total dose of LA agent without increasing without toxicity, provides longer duration of action and intensify the sensory and motor block. But, all these advantages of epinephrine by adding to LA agent is unnecessary during epidural analgesia by catheter for vaginal delivery. This is because small amount of LA drug in the form of low concentration is used for epidural analgesia to relief labour pain in vaginal delivery as motor block is not needed and prolonged or indefinite period of action of LA agent is obtained by catheter without adding epinephrine. Only the advantages of adding epinephrine to the LA agent for epidural anaesthesia-analgesia to relief labour pain is acts as a marker in test dose during testing of inadvertment placement of catheter into blood vessel. The other disadvantage of epinephrine is its β-mimetic action which decreases the uterine contraction and unnecessarily prolongs the duration of labour. On the contrary, many anaesthetists prefer epinephrine in the concentration of 1:200,000 to 1:400,000 with LA agents for epidural anaesthesia-analgesia during CS where large amount of drug in the form of higher concentration are used to obtain profound both motor and sensory block.

Like LA agents, opioids are also not used alone clinically for epidural labour analgesia, because opioids alone frequently does not provide satisfactory and complete result. On the other hand, high doses of opioids are also needed when used alone for obstetric analgesia and this high doses have many adverse effects such as maternal and foetal respiratory depression, nausea and vomiting of mother, loss of beat to beat foetal heart rate variability, etc. So, the combination of LA agent in low concentration and opioids in low dose has now become very popular for obstetric analgesia and anaesthesia. Among the opioids the most commonly used agents are fentanyl and sufentanil in the doses of 25 to 50 µg and 10 to 20 µg respectively. The most significant advantage of this combination of LA agent and opioid in low doses is the striking lack of motor blockade which allow a mother to experience a pain free, unparalysed, pleasant vaginal delivery. Till now the maximal total dose of fentanyl and sufentanil when used continuously by catheter through epidural route is not clear. But some believe that the maximum dose of sufentanil in continuous epidural should not exceed beyond 30 to 50 µg. For fentanyl this maximum dose may go upto 200 to 300 µg.

After successful placement of epidural catheter a preliminary test dose is mandatory. This test dose helps to diagnose, if there is any unintentional subarachnoid or intravascular placement of needle or catheter. For the test dose, 2 to 3 ml of local anaesthetic agent with 1:200,000 epinephrine as marker is used. This test dose should be given at the interval between two uterine contractions. This will help to reduce the false +ve sign of an intravascular injection of marker, (i.e. epinephrine) manifested by tachycardia which can also occur due to the painful uterine contraction if it is given during the period of contraction. This test dose will also help to diagnose the unintentional subarachnoid placement of needle or catheter by extensive block like spinal anaesthesia with this small amount of drug used in this test dose.

After 5 to 10 minutes of test dose, the principal mixture of LA agent and opioid can be administered by three methods. The first choice is administration of bolus 10 ml mixture of local anaesthetic agent and opioid which is given in two incremental doses (5 ml each) with an interval of 1 to 2 minutes between two injections. This initial mixture usually contains 0.0625 to 0.125% bupivacaine or 0.1 to 0.2% ropivacaine with 10 to 20 µg sufentanil or 50 to 100 µg fentanyl. This will achieve sensory block extending upwards upto T_{10} level of dermatomes if the catheter is placed through L_2-L_3 interspinous space in horizontal lying down position. After the first bolus dose patient should be monitored continuously by BP, heart rate, SPO_2 level, etc, for the first 30 to 40 minutes or until the patient becomes stable. This bolus dose can be repeated several times according to the need, till the total process of vaginal delivery is completed. Epinephrine in concentration of 1:400,000 to 1:800,000 can also be added with the LA solution to prolong analgesia with fewer additional doses.

The second choice is instead of repeated bolus injection continuous infusion of local anaesthetic agent and opioid mixture is employed at the rate of 10 to 15 ml/hour which may contain bupivacaine (0.0625 to 0.125%) or ropivacaine (0.1 to 0.2%) with fentanyl (1 to 2 µg/ml) or sufentanil (0.2 to 0.4 µg/ml). Later this dose is adjusted according to the patient's response and progress of labour.

The third choice is patient's control epidural analgesia (PCEA). In this method, the patient itself administered the mixture of drug (i.e. LA agent and opioid) through epidural catheter. There are different PCEA settings which can be changed by the patient himself according to the response. But a typical setting is 5 ml/hour as basal infusion rate and 5 ml as bolus at 10 to 20 minute lockout interval. Thus, within an hour 20 to 30 ml of 125% bupivacaine and 50 kg of fentanyl may be administered. The great advantage of PCEA is that the total drug requirement is less and patient's satisfaction is greater in this method. For the relief of pain during second stage of labour, the sensory block should be extended below upto $S_{2\text{-}4}$ level of dermatomes. For this, the drug should be administered in semirecumbent or sitting position of patient through epidural catheter which will reduce the total dose of LA agent.

Caudal Epidural Anaesthesia and Analgesia for Vaginal Delivery

Caudal epidural block is also administered to relief the pain during any stage of labour. But it is usually accomplished only when the labour is well established and is in

second stage. To relief the pain during first stage of labour, i.e. to extend the sensory block upto T_{10} level through caudal epidural route, large volume of LA agent is required. So, this epidural route is usually not used to relief the labour pain during first stage. It is performed on patient, positioned either prone or on their sides. For caudal epidural block coccyx is always used as landmark and then for next successful result the sacral cornu and the sacro-coccygeal ligament, covering the sacral hiatus is palpated. After successful placement of an epidural needle in sacral canal through sacral hiatus, rectal and vaginal examination is mandatory. This is because it will exclude the possibilities of accidental puncture of foetal presenting part by the needle and its subsequent sequelae. Through this epidural needle epidural catheter can also be passed into the sacral canal for continuous caudal block. A test dose of LA agent mixed with epinephrine is also mandatory to use through needle or catheter, since it is possbile to enter the needle or catheter in an epidural vessel or dural sac which ends at S_1 or S_2 vertebral level producing spinal anaesthesia. The volume of LA agent and opioid mixture to provide labour analgesia (not anaesthesia) through sacral route during the first stage of labour should extend upto the T_{10} level of dermatome. Therefore, the volume of drug is very high through sacral route which varies from 10 to 20 ml in first bolus dose. The subsequent doses of drug to maintain labour analgesia is also very high which is 15 ml for every sitting. Hence, to achieve the T_{10} level of block through sacral route with smaller volume of drugs, placing the patient in head down position is necessary.

The lumbar epidural route to relief labour pain is preferred to caudal route because:

i. The level of analgesia extending between T_{10} to L_1 dermatomes which is necessary during first stage of labour can be achieved easily through lumbar route and spare the block of sacral dermatomes which is not desired for the first stage of labour.
ii. Less amount of drug is required through lumbar route than caudal anaesthesia-analgesia during the whole delivery process through vagina.
iii. In lumbar epidural obstetric analgesia pelvic muscles retain their tones. This help in the rotation of foetal presenting part and normal vaginal delivery.
iv. Placement of lumbar epidural needle is technically more easier than caudal procedure, though in the previous technique there is more chance of dural puncture. On the contrary, the advantage of caudal epidural analgesia placed just before the vaginal delivery if it is not placed before over lumbar epidural block is that the onset of perineal analgesia and muscle relaxation is more quick in the previous one.

Subarachnoid Anaesthesia-Analgesia for Vaginal Delivery

The subarachnoid block is not so popular to relief the labour pain for vaginal delivery. But, it has some definite indications, advantages and disadvantages. It is particularly indicated in a very distress (from pain) parturient patient where placement of epidural catheter is very difficult or impossible. In such circumstances, single shot subarachnoid anaesthesia-analgesia produced by LA agent or opioids or their mixture is very useful for emergency instrumental vaginal delivery in patient who does not have epidural catheter before. But, the disadvantages of this technique is that it does not provide flexibility of an epidural catheter. The other problem of subarachnoid anaesthesia-analgesia to relief the labour pain is that it is very difficult to titrate the dose and concentration of LA agent or opioid by which we can get only the sensory block where motor block is not at all desirable for 1st and 2nd stage of labour or both motor and sensory block in 2nd and 3rd stage of labour where operative intervention is needed. The another advantage of single shot subarachnoid injection of LA agent or opioid or their mixture is that unlike epidural it provides effective and rapid onset of labour analgesia or anaesthesia. If only opioid is given in subarachnoid space to relief labour pain then it needs very small dose than the only opioid given in epidural space (though this dose is greater than when used with LA agent). This is because it directly acts on the dorsal horn cells of the spinal cord, without usual systemic effects of narcotics. Thus, the only intrathecal opioids have the potential advantage (unlike only narcotic through epidural space which needs larger doses and may have systemic effect) of providing effective and safe labour analgesia with no motor and sympathetic block. Hence, there is no hypotension, no adverse effects on uterine contraction and no maternal and foetal respiratory depression (due to small doses). So, this technique of using opioids alone in subarachnoid space to relief the labour pain is especially indicated in patients with cardiac disease who require adequate analgesia without motor block and hypotension. Thus it will prevent the potentially dangerous increase in HR and myocardial O_2 consumption associated with painful labour.

The continuous subarachnoid anaesthesia-analgesia to relief labour pain by using conventional epidural catheter in subarachnoid space (but not the microcatheter which is specially designed for continuous spinal anaesthesia) is also considered in cases of accidental (during attempt of continuous epidural) or deliberate dural puncture for high risk patients. But, surprisingly due to unknown reason the incidence of PDPH is very low in this continuous spinal labour analgesia and anaesthesia using conventional epidural needle and catheter, during accidental or deliberate dural puncture. In 1980, spinal micorcatheter was first introduced for continuous spinal anaesthesia. Then it quickly gained popularity because of the fast onset of block, convenience and low incidence of PDPH. But, it causes high incidence of cauda equina syndrome because of improper mixing of

local anaesthetic agent of relatively higher concentration with CSF than that of used for epidural space. This is again also due to less turbulance of flow produced during injection of drug within the intrathecal space through the microcatheter. Hence, there is controversy regarding the use of micro-catheter for continuous subarachnoid analgesia-anaesthesia.

To relief labour pain through subarachnoid route for vaginal delivery, the commonly used LA agents are hyperboric lignocaine (25 to 50 mg or 0.5 to 1 ml of 5% hyperboric lignocaine), bupivacaine (5 to 10 mg or 1 to 2 ml of 0.5% hyperboric bupivacaine) and tetracaine (4 to 5 mg). This dose provides analgesia or anaesthetia extending from T_{10} to S_5 dermatomes. But small doses of hyperboric LA agents such as lignocaine (15 to 20 mg), or bupivacaine (2 to 5 mg) or tetracaine (3 mg), administered in subarachnoid space in sitting position, provides only sacral anaesthesia and analgesia (saddle block) which is sometimes helpful only during 2nd stage of labour.

For the subarachnoid labour analgesia the commonly used opioids and their dose when used alone or with LA agents are morphine (0.25 mg), meperidine (10 to 20 mg), fentanyl (25 µg) and sufentanil (5 to 10 µg). When morphine is used alone without LA agent, the onset of analgesia is slow, taking 40 to 60 minutes and lasting for 24 hours. The side effects of intrathecal morphine are frequents and these include: dizziness, pruritus, nausea, vomiting, drowsiness, retention of urine, respiratory depression, etc. Pruritus produced by intralhecal morphine can be lessened by the use of IV naloxone in the dose of 0.4 to 0.8 mg, followed by infusion of it in the dose of 0.4 mg/hour. But this naloxone does not effect the analgesia caused by narcotics. Increasing the subarachnoid dose of morphine from 0.25 mg to 1 mg does not prolong the analgesia, instead increase the complications. Intrathecal 25 µg fentanyl alone also provides labour analgesia within 5 minutes and lasts for 1 to 2 hour. When it is used with LA agent the dose of fentanyl should not be reduced. Intrathecal 10 µg sufentanil alone also provides analgesia within 5 minutes and this action lasts for 3 hours. The onset of action of intrathecal 10 mg meperidine is 10 minutes and it lasts for approximately 2 to 4 hours. However, intrathecal opioids only do not provide adequate analgesia for episiotomy or for the use of forceps. Therefore, it needs supplemental anaesthesia by mixing opioids with LA agents. Addition of 0.2 mg epinephrine to intrathecal opioid does not prolong the duration of pain relief. But it decreases the severity and incidence of pruritus, while increases the incidence of nausea and vomiting.

Combined Spinal Epidural (CSE) Analgesia to Relief Labour Pain

This technique is also widely used now to provide the optimum and prolonged analgesia to relief labour pain and if necessary anaesthesia in obstetric practice. By this method we obtain the benefits and remove the disadvantages of each technique such as spinal and epidural. It offers rapid onset, and effective analgesia, minimum risk of toxicity of LA agent and opioids, and minimally impaired or no motor block. The rapid onset of action performed by the spinal part of CSE overcome the disadvantage of delayed onset of action by epidural part of it. This delayed onset of action by epidural part of CSE may sometimes be thought as incomplete or patchy analgesia, causing unnecessary increase in the dose of LA agent and subsequent motor blockade. Furthermore, this method make possible to prolong the duration of analgesia as necessary by the use of epidural catheter which can not be obtained from the spinal part of it. Patients found greater satisfaction with CSE than the only continuous epidural analgesia. This is perhaps because of rapid onset and greater feeling of self control by patient. In addition, if an operative delivery is necessary, then the same epidural catheter may be used to provide operative obstetric anaesthesia. The onset of action of analgesia in CES is almost immediate due to its spinal component. The duration of this spinal analgesia lasts for 2 to 3 hours, but depends on which opioid (alone) or which mixture of opioid and LA agent is used. The addition of isobaric bupivacaine to the opioids in the subarachnoid space during CSE produces a greater density of sensory blockade and minimum or nil motor blockade. Conventionally in subarachnoid space 25 µg fentanyl or 10 µg of sufentanil is used only for spinal analgesia. But 15 µg fentanyl or 5 µg sufentanil produces same effect when either of these agents is mixed with isobaric bupivacaine and is injected in the subarachnoid space. Another potential advantage of CSE technique for obstetric analgesia is that it may be associated with the significantly reduced duration of first stage of labour. On the other hand, the use of continuous epidural infusion by dilute LA agent such as 0.0625 to 0.125% bupivacaine plus opioid such as fentanyl 15 µg provides only sensory analgesia without any motor block which may permit many obstetric patients to ambulate during labour. Then it is termed as ‘walking epidural’. This is becaue any form of central neuraxial block or analgesia where there is no motor block is termed as like that. But, before ambulation every patient should be assessed carefully for the maternal and foetal well being and also the adequate motor function of mother.

GENERAL ANAESTHESIA FOR VAGINAL DELIVERY

To relief pain during labour GA is usually avoided for normal vaginal delivery. This is because of the increased risk of gastric aspiration in lungs in an unprepared patient and complete absence of mother’s co-operation which is a part and parcel of normal vaginal delivery. But, sometimes it is necessary in the following emergency situation such as acute foetal distress

requiring immediate expulsion of baby, instrumental vaginal delivery, manual removal of retained placenta, tetanic uterine contraction, replacement of inverted uterus, psychiatric patients who become sudden uncontrollable, etc; and where epidural catheter is not in place before. If epidural catheter is in place before for labour analgesia then obstetric regional anaesthesia is rapidly instituted through this catheter instead of analgesia.

If sudden decision of GA for vaginal delivery is taken, then previous important medical history of patient is quickly taken and a naso or orogastric tube is put into the stomach to aspirate the gastric contents, provided the patient is not properly prepared. After that the tube is removed. This is followed by quick preoxygenation of patient by 100% O_2 for 3 to 5 minutes or 4 full breaths, while monitors are applied by assistant. Once all possible monitors are applied and obstetrician is ready, then rapid sequence induction is instituted, applying cricoid pressure when patient becomes unconscious and reflexes are lost. For rapid induction the commonly used drugs are thiopentone (4 to 5 mg/Kg), propofol (1 to 2 mg/Kg) or ketamine (1 mg/Kg, used only if there is hypovolaemia or hypotension) which is followed by succinylcholine (1 to 1.5 mg/Kg). The fasiculation produced by succinylcholine is usually not prevented by the use of small dose of nondepolarising agent. Because most pregnant patient usually do not fasciculate and moreover this fasciculation does not appear to promote regurgitation as increased intragastric pressure caused by fasciculation is matched by similar increase in the tone of gastro-oesophageal sphincter by succinylcholine.

After a successful intubation with a 7 or 7.5 ET-tube, patient is ventilated by 100 O_2 and 1 to 2 MAC of any potent volatile anaesthetic agent. After the action of the succinylcholine is over if skeletal muscle relaxation is needed, then any short to intermediate acting nondepolarising muscle relaxing agent is used. Once foetus and placenta is delivered then N_2O and opioids are added or propofol infusion is started to avoid recall. Simultaneously, concentration of volatile anaesthetic agent is reduced to 0.5 MAC or discontiued and oxytocin infusion is started at the rate of 10 to 20 U/L in IV fluid. At the end of surgical procedure, the action of nondepolarising muscle relaxant is reversed by anticholinesterase and the patient is extubated, while reflexes are fully returned.

ANAESTHESIA FOR CAESAREAN SECTION (CS)

There are lots of medical and obstetric indications for CS which are done under RA or GA. But, the choice between these two type of anaesthesia is determined by multiple factors which include: indication for CS, the severity of urgency, skill of anaesthetist, patients preference, surgeon's preference, etc. However, now, RA is most frequently preferred than GA for ELUCS, because the later is mostly associated with increased maternal mortality and morbidity. But recently many studies has showed that morbidity and mortality in these two types of anaesthesia is equal. Death or severe maternal morbidity in RA is mainly due to severe hypotension, or epidural haematoma or sepsis of spinal cord. Death associated with GA is mainly due to airway problem, failed intubation, failed ventilation, aspiration pneumonitis, pulmonary oedema, etc. The advantages of GA over RA for caesarean section are: very reliable, rapid onset, better control of airway, better control of ventilation, less incidence of severe hypotension and better management of patient in the face of severe bleeding such as in placenta praevia, accidental haemorrhage, etc. Whereas the advantage of RA over GA are: minimal risk to pulmonary aspiration, less neonatal depression due to minimal or no exposure of foetus to potentially depressant general anaesthetic drugs, provide better option for postoperative analgesia, pleasant experience by mother during birth of her child.

After taking decision for RA in CS next question arises whether spinal or epidural. Except for few special indications for each technique, usually the decision between the spinal or epidural anaesthesia depends on the physician preference. Continuous epidural anaesthesia allows slow, better and prolonged control of sympathetic, sensory and motor block which is very helpful for severly ill patient, prolonged surgery and postoperative analgesia. Contrary, the spinal anaesthesia has more rapid onset, is easier to perform, produce more intense motor, sensory and sympathetic block and because of small dose of LA agent it does not have the potential for serious drug toxicity.

Now at the end of discussion, we can say that whatever may be the type of RA, patient should always be prepared for GA, because at any time during the process of applying RA it may be needed. Though, the principle disadvantage of GA is drug induced foetal depression, but the present technique of it limit the dose of IV inducing agent and reduces the foetal depression. Clinically, it is not significant in GA if delivery of foetus occurs within 10 minutes of induction of it. On the contrary, whatever may be the type of anaesthesia such as regional or general, if the baby is delivered within 3 minute of uterine incision then there is better Apgar score.

Regional Anaesthesia

The CS performed by RA (spinal or epidural) requires sensory block upto the level of T_7 dermatomes. Therefore, it blocks more than half of the sympathetic outflow (this is because sympathetic block is always two dermatomes above the sensory block) and causes high incidence of severe hypotension. So, patients waiting for RA during CS must receive 500 to 1000 ml of crystalloid IV fluid (usually Ringer's lactate) prior to central neural blockade. But, small volume of IV administration of colloid is more effective than

huge volume of crystalloid. Whatever may be, the prophylactic IV administration of fluid (crystalloid or colloid) does not consistently prevent hypotension induced by sympathectomy in RA. So, if hypotension still persists in spite of adequate preload, then 10 mg IV ephedrine should be used to maintain the systolic BP above 100 mm of Hg or MAP should not be reduced < 20% of previous one. Instead of epihedrine, 25 to 100 µg of IV phenylephrine can also be used safely. Some anaesthesiologist use the ephedrine or phenylephrine prophylactically to avoid the immediate precipitous fall of BP after regional block which sometimes can cause cardiac arrest. This prophylactic measure is more applicable in spinal anaesthesia than epidural. But, it may produce severe hypertension if the severity of proposed hypotension is not properly titrated with the doses of pressure rising agent and given at proper time which is matched with the peak level of hypotension. Therefore many anaesthetists do not like it. Slight 10 to 15° head down position of patient reduces the chances of hypotension by encouraging the venous drainage and increasing preload. But it does not increase the extension of sensory and sympathetic block by allowing more cranial flow of LA agent. During continuous epidural by using catheter for CS, if there is unintentional dural puncture, then it can be converted to continuous spinal anaesthesia by advancing the epidural catheter through this needle in subarachnoid space. It during first attempt of epidural anaesthesia there is unintentional dural puncture then another attempt through the spaces above or below the previous one is again tried.

The commonly used drug for spinal anaesthesia in CS are lignocaine (50 to 100 mg), bupivacaine (10 to 15 mg) or tetracaine (5 to 10 mg). But 0.1 mg epinephrine can also be used with this LA agent for spinal anaesthesia which enhances the quality of block and prolongs the duration of action of it. The addition of 25 µg fentanyl or 10 µg sufentanil or 0.2 mg morphine with the LA agent enhances the intensity of block and prolongs the duration of action without adversely affecting the neonatal outcome.

The commonly used drug for epidural anaesthesia in CS are: 15 to 20 ml of 2% lignocaine or 0.5% bupivacaine, or 3% chloroprocaine. Similar to spinal block addition of 50 to 100 µg of fentanyl or 10 to 20 µg of sufentanyl or 5 mg of morphine, etc, with the LA agents greatly enhances the intensity of block and prolongs the duration of action of it without adversely affecting the neonatal outcome. For epidural anaesthesia the 15 to 20 ml of the recommended initial volume of drug is not injected quickly as bolus. It is injected slowly in 5 ml incremental doses at 1 to 2 minute intervals. If due to any reasons sensory levels recede and pain develops, then LA agent is further added through catheter in 5 ml incremental doses to maintain a sensory block upto T_7 level. Patchy epidural blocks due to some unknown reasons is usually treated by small doses of IV ketamine, prior to deliver of baby. But after delivery of baby, it is managed by adequate doses of opioids, propofol; etc. However, if pain remains intolerable, inspite of these above mentioned measures, then it necessities GA with ET-intubation (Fig. 35.2).

General Anaesthesia

In recent decades the use of GA for CS has declined dramatically. But still it is used in some circumstances where RA is contraindicated such as when patient refuses to give consent, coagulopathy, local sepsis, systemic infection, etc; or anaesthesiologist has failed to provide RA due to some technical difficulties or there is no time to institute RA, for example, during life threatening severe maternal haemorrhage, life threatening foetal compromise etc. Several recent studies also have found that the maternal death rate associated with properly managed RA has dramatically declined, but not in GA. Therefore, the difference in rate of maternal mortality between RA and GA has increased to 16 times. There are no absolute contraindications for GA in CS like RA. But, there are certain conditions such as malignant hyperthermia, very difficult airway, etc; where modified general anaesthetic technique is required. The two principal problems associated with GA for CS are failed intubations and pulmonary aspiration of gastric contents.

Failed intubations

The most common causes of maternal death related to GA during CS are failed intubations with concomitant, failure to ventilate by mask or failure to recognise oesophageal intubation. On the otherhand, the common causes of failed intubation in obstetric patient compared with nonobstetric surgical patients are: weight gain, oedema of the airway, large breasts obstructing the manipulation of handle of laryngoscope, short neck (due to oedema); etc. Therefore, anticipation of difficult airway and subsequent difficult intubation may help to reduce the incidence of maternal hypoxaemia and death during GA. Hence, careful assessment of airway before CS under GA is very crucial and anticipation of difficult intubation may help to reduce this catastrophy. Among all the methods of evaluation of airway Mallampatti classification is the most useful predictors. It has been found that airway of Mallampatti class IV, protruding maxillary incisions, short neck, mandibular recession, etc; are associated with greatest risk for failed intubation. Hence, simple examination of oropharynx, neck, mandible, dentition, etc; often helps to predict which patient will produce problem or not. The patient which has normal airway before pregnancy, becomes problematic during this pregnancy. Again it has been demonstrated that labour is associated with changes in the maternal airway. So, all the patients must have a repeat airway assessment before induction of anaesthesia for CS, though the patient is examined initially. Last, it may be said that the experience of anaesthetist is the key factor for general anaesthesia related maternal mortality.

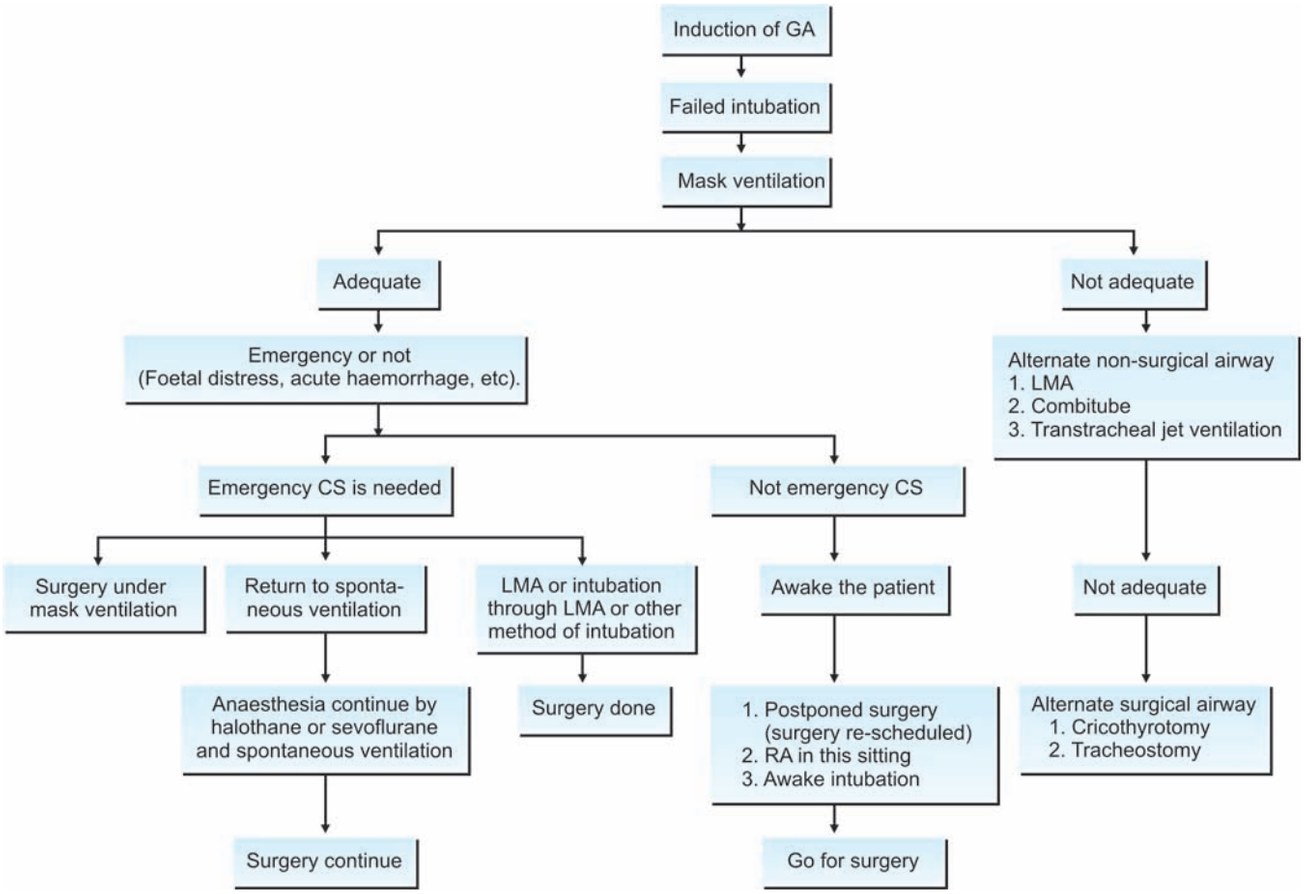

Fig. 35.2: Algorithm for difficult intubation in obstetric practice

Because, in one vast study in a big teaching hospital it is found that the most cases of failed intubation is occured when patients are cared by less experienced anaesthetist.

Anticipating difficult intubation, varieties of laryngoscope blades, different sizes of ET tube, stylettes, bougies, classic LMA, intubating LMA (fastrach), fibreoptic laryngoscope, combitube, kit for cricothyrotomy and tracheostomy etc. should be made ready. Proper positioning of the head and neck may facilitate tracheal intubation in difficult cases. These manipulations are: flexion of cervical spine, elevation of shoulder and extension of atlanto-occipital joint etc. When difficult intubation is anticipated, then anaesthesiologist must have a clear plan and obviously mother's life will get priority over foetus. After failed intubation if mask ventilation is possible, then different methods of intubation should be tried. Or in the absence of foetal distress patient can be awakened and later an awake intubation by infiltration of LA agents can be tried. If mask ventilation is not possible, then other methods of ventilation by using LMA, combitube, etc; are tried. But still if ventilation is not adequate then cricothyroitomy or tracheostomy or awakening the patient can be tried to save the mother's life.

Pulmonary aspiration of gastric contents

Another important cause of maternal death related to GA during CS is pulmonary aspiration of gastric contents. Therefore, increase of gastric pH and decrease of its volume in a labour patient is prime important for an anaesthetist. However both of these effects can be accomplished by the following methods. Generally, gastric pH can be raised by routine use of antacids prior to induction of anaesthesia. But use of antacids does not reduce the risk of pulmonary aspiration. Because though antacids increase gastric pH, but as most antacids contain suspension of particulate matter so they may produce severe pulmonary reaction if they are aspirated. So, instead of nonclear antacid, clear antacid such as 0.3 M sodium citrate is used. The advantage of both these type of antacids is that they act immediately. But disadvantage is that they immediately increase the volume of gastric content after their use.

Except antacids, gastric acidity is decreased (or pH is increased) and volume of gastric content also can be decreased by using H_2 receptor blocker (ranitidine) or proton pump inhibitor (omeprazole, pentaprazole etc). But both of these drugs do not act immediately like antacids. Therefore, atleast 1 to 2 hours of interval after oral administration or 45 to 60 minutes of interval after

IV or IM administration of these drugs is required. It should also be kept in mind that both these drugs can not change the pH and volume of gastric contents which is already secreted into the stomach.

Metoclopramide is an another prokinetic agent that increases the emptying of stomach and raises the lower gastro-oesophageal sphincter tone. Thus, it reduces the gastric volume (not the gastric pH) and decreases the subsequent chances of aspiration of gastric contents by regurgitation or vomiting. On the other hand, it does not raise the gastirc pH and has no adverse effects on foetus or neonates. To prevent pulmonary aspiration of gastric content the use of IPPV before intubation should also be avoided. Because it can inflate the stomach by air and thus can make the patient more vulnerable to regurgitation and pulmonary aspiration of gastric contents. Another mechanical way to reduce the risk of pulmonary aspiration of gastric contents is Sellick's manoeuver (cricoid pressure) which occludes the oesophagus. Finally, the risk of pulmonary aspiration of gastric contents can also be minimised by intubating the trachea with an ET-tube and extubating the patient only after she is fully awake with good return of laryngeal reflexes (Table 35.5).

Table 35.5: Some strategies to reduce maternal mortality in obstetric anaesthesia

1. Less experienced anaesthetist should not take sole responsibility for obstetric anaesthesia.
2. The anaesthetist must have a skilled help irrespective of his or her experience.
3. Antacid does not give full protection aganist Mendelson syndrome. Therefore H_2 blocker and prokinetic agent are mandatory.
4. Cricoid pressure must be applied.
5. Failed intubation drill should be exercised by all obstetric anaesthetist.
6. No matter how urgent the obstetric anaesthesia, history and monitoring must not be neglected.
7. Epidural labour analgesia should be supervised by a skilled person and an anaesthetist should be available immediately in emergency.

Steps of general anaesthesia in CS

- Taking of history and airway assessment meticulously.
- Proper preparation of patient by oral antacid or H_2 blocker or proton pump inhibitor and metoclopramide.
- The patient is placed supine with 15° left uterine displacement by putting a wedge under the right buttock.
- Starting of IV infusion by large bore cannula.
- Preoxygenation by 100% O_2 with high flow rate (> 6 lit/min) for 3 to 5 minutes. 4 full vital capacity breaths of 100% O_2 is also adequate for denitrogenation.
- Monitors are applied.
- The patient is prepared by antiseptic dressing over abdomen and is draped.
- The surgeon is ready to begin surgery and an assistant of anaesthesist should apply cricoid pressure.
- Rapid sequence induction and muscular paralysis is performed, by using thiopentone (4 to 5 mg/Kg) or propofol (1 to 2 mg/Kg) or ketamine (1 mg/Kg, in hypovolumic or asthmatic patient) and succinylcholine (1 to 1.5 mg/Kg). Defasciculation is not necessary in CS.
- Trachea is intubated by a proper sized ET-tube and cuff is inflated. Cricoid pressure is maintained till trachea is sealed off. Proper placement of ET-tube is confirmed by capnography.
- Maternal P_aCO_2 below 25 mm of Hg by hyperventilation is avoided. Because it can reduce the uterine blood flow by vasoconstriction and subsequently foetal acidosis. Hyperventilation also causes a leftward shift of the maternal O_2-Hb dissociation curve and decreases O_2 availability to the foetus.
- Respiration is maintained by IPPV using 50:50 N_2O:O_2 mixture with any potent volatile anaesthetic agent in low concentration (0.5% halothane or 0.75% isoflurane or 1% sevoflurane or 3% desflurane). This low concentration of volatile anaesthetic agent helps to produce amnesia and does not cause excessive uterine relaxation or impair uterine contraction by oxytocin.
- Non-depolarising muscle relaxant of intermediate duration of action such as rocuronium, atracurium, cisatracurium or mivacurium are used when necessary.
- The 20 to 30 unit of oxytocin per litre of IV fluid is infused after the neonate is delivered. Then, the umbilical cord is clamped and placenta is removed.
- Anaesthesia is deepened by increasing the percentage of N_2O in inspired gas mixture by upto 70% and by further adding narcotics, benzodiazepines or propofol.
- If there is hypotonicity of uterine muscle, then halogenated volatile anaesthetic agent should be discontinued.
- If there is still relaxation of uterine musculature, then 0.2 mg of methylergonovine or 0.25 mg of 15 methyl prostagland in $F_2\alpha$ IM may also be given.
- At the end of surgery, the effect of muscle relaxant is reversed by anticholinesterase with glycopyrolate and extubated when there is full return of laryngeal reflexes.

Acid Aspiration or Mendelson's Syndrome

It was first described by Mendelson in 1946 in which gastric contents had been regurgitated and aspired in the lungs and initiated a series of characteristic pulmonary signs and symptoms constituting a syndrome. So, now it bears his name. The morbidity and mortality of this syndrome is very high and it depends upon the volume, nature, acidity and the nature of distribution of aspirated material in lungs. If the inhalation of gastric contents is of sufficient quantity or solid, then it will cause asphyxia due to obstruction. Otherwise, if the gastric content is of very low pH (< 2.5), though is of small amount (as small as 25 ml) causes serious pulmonary reaction and death without producing asphyxia. It has been found that 60% of the obstetric patients at term have more

than 40 ml of gastric juice and pH is less than 2.5 in empty stomach.

The pathophysiological consequences and the clinical picture of this syndrome following aspiration of gastric acids fit with the acute respiratory distress syndrome (ARDS). But this ARDS may also develop due to other causes. These other causes are pulmonary injury by other substances except acid which enter through airway or by indirect blood borne insult to lungs. Some severe form of this syndrome may develop immediately and patient collapse. But sometimes the symptoms following aspiration of little to moderate amount of liquid gastric contents with low pH may become apparent slowly over 6 to 8 hours after the incident (Table 35.6).

After aspiration of gastric acid content in lungs there is severe inflammation of pulmonary tissue and simultaneously there is also release of large number of mediators which include cytokines (such as tumour necrosis factor, interleukins 1 and 6, platelet activation factor), prostaglandins, leukotrienes, lysosomal enzyme, etc. These mediators trigger a complex interactions between the endothelial cells, platelets, coagulation pathways, and WBC which become activated and damage the vascular endothelium. Then fluid and cells pass across the damaged endothelium from the blood vessels into the interstitial space, causing pulmonary oedema and further tissue inflammation. Thus, a vicious cycle of endothelial injury, intravascular coagulation, microvascular occlusion, tissue damage and further release of inflammatory mediators ensues. Patient often suffers from cough, tachypnoea, weeze, ronchi, hypoxia and all the other features of pulmonary oedema. The criteria defining ARDS are: (i) hypoxaemia which is defined as P_aO_2 < 200 mm of Hg, (ii) chest radiograph showing diffuse bilateral infiltrates, (iii) absence of raised left atrial pressure: PAWP < 15 mm of Hg, (iv) impaired lung compliance.

Table 35.6: Conditions predisposing to ARDS

Direct through airway
• Aspiration of gastric contents
• Toxic gases
• Near drowning
Indirect by bloodborne
• Severe sepsis
• Multiple trauma
• Anaphylaxis
• Pancreatitis
• Drugs
• Ammiotic fluid and fat embolism

The term ARDS is often limited to the patients requiring ventilatory support. But the less severe form of ARDS is conventionally referred to as the acute lung injury (ALI). Suction through an endotracheal tube which reveals bile stained fluid is often diagnostic. While over the longer term, serial chest X-ray and serial arterial blood gas estimation will reveal progressive changes.

Management of this Mendelson's syndrome is very difficult. It includes: proper arterial oxygenation by ventilation through ET tube, suction through ET tube, correction of blood volume and acid base balance, steroid, antibiotics, etc and adequate monitoring in ICU.

As prevention is better than cure, so an anaesthetist will always try to take measure which will prevent to develop it. This is described in table.

PRE-ECLAMPSIA, ECLAMPSIA AND ANAESTHESIA

Pre-eclampsia is also termed as pregnancy induced hypertension (PIH). Hypertension in pregnancy may be due to PIH or chronic essential hypertension existing before pregnancy or recent development of essential hypertension during this pregnancy or chronic hypertension with superimposed pre-eclampsia. Pre-eclampsia complicates upto 8 to 10% of all pregnancies and is the most common difficult condition encountered by an anaesthetist during his practice of obstetric anaesthesia where otherwise a previously healthy patient suddenly becomes severely ill. The classic triad of pre-eclampsia are: hypertension, proteinuria (> 500 mg/day) and oedema (hand and face). Hypertension in pre-eclampsia is usually defined as systolic and diastolic BP above than 140 mm of Hg and 90 mm of Hg respectively, or persistent increase in systolic and diastolic BP by 30 mm of Hg and 15 mm of Hg respectively above the normal baseline value. The other characteristic features of pre-eclampsia are: (i) hypertension occuring after 20 weeks of gestation and resolving within 48 hours after delivery or develops in the early postpartum period and returning to normal within 3 months of delivery, (ii) oliguria, (iii) serum and urine creatinine concentration ratio > 0.09 mm/L, (iv) headache with visual disturbances, (v) increased level of liver enzymes, (vi) ↑lactate dehydrogenase, ↑thrombocytopenia, ↑haemolysis, and DIC. When convulsions occur in pre-eclampsia then this condition is called eclampsia where prognosis of both the mother and foetus worsens. But it is less common. Severe PIH contributes about 30 to 40% of maternal death and 15 to 20% of perinatal death. The principal causes of maternal death in pre-eclampsia are: stroke, pulmonary oedema and hepatic failure. There are some predisposing factors for pre-eclampsia. These are: a family history of pre-eclampsia, chronic renal disease, chronic hypertension, multiple gestation, age > 40 years, diabetes, etc. (Table 35.7).

HELLP syndrome found in pre-eclampsia is a pathological condition which is characterised by haemolysis (H), elevated liver enzymes (EL) and low platelet count (LP). This represents a severe form of pre-eclampsia with above mentioned signs. It occurs in 20% of pregnant patients who develop severe pre-eclampsia with many of the manifestations occuring in the post partum period. Its severity ranges from a mild self limiting condition to a fulminant process leading to multiorgan failure. No signs and symptoms of this syndrome are diagnostic, because all these signs and symptoms are found in patients with

Table 35.7: Measures to avoid acid aspiration

Decreasing the acidity of gastric fluid
- Use of antacid to neutralise the existing acid.
- Use of H_2 blocker to stop secretion of acid and elevate pH.

Decreasing the volume of gastric fluid
- By restricting intake.
- By increasing emptying of stomach by metoclopramide.
- By decreasing the gastric secretion.
- By physical mean - suction through large bore tube.

Preventing the regurgitation of gastric secretion
- Increase in intragastric pressure should be avoided.
- Increase in tone of lower gastro-oesophageal sphincter.
- Induction in upright position.

Preventing the inhalation of regurgitant material
- By applying cricoid pressure.
- By suction.
- By induction in Trendelenberg position.

Avoiding GA
- RA avoid gastric aspiration.

Avoiding difficult intubation
- By proper assessment of airway.
- By appointing skilled anaesthetist.

severe pre-eclampsia-eclampsia, but without HELLP syndrome.

Pre-eclampsia may be classified as mild or severe according to the severity of symptoms and signs which are demonstrated in table. Assuming no presence of any coagulopathy, haemostasis is not usually a problem unless the platelet count is decreased below 40,000/cumm in pre-eclampsia. In such circumstances, RA is contraindicated. This abnormal platelet count usually returns to normal within 72 hours of delivery. But this thrombocytopenia may persist for longer periods (Table 35.8).

Pre-eclampsia is the disease of theories, as the precise cause of it is still unknown in spite of excessive resreach. It is mainly associated with abnormal activities of trophoblastic cells and abnormal placentation. Thus, it leads to maladaptation of maternal spiral arteries and is particularly found in

Table 35.8: Classification of pre-eclampsia

	Mild	*Severe*
Systolic pressure	< 160 mm of Hg	> 160 mm of Hg
Diastolic pressure	< 110 mm of Hg	> 110 mm of Hg
Urine output	> 500 ml/24 hour	< 500 ml/24 hour
Urinary protine	< 5 gm/24 hour	> 5 gm/24 hour
Platelet count	> 100,000/cu mm	< 100,000/cu mm
Pulmonary oedema	Absent	Present
Headache	Absent	Present
Epigastric pain	Absent	Present
Visual disturbance	Absent	Present
HELLP syndrome	Absent	Present

women with vascular disorders. The secondary pathology in pre-eclampsia is also linked to immunological basis and endothelial dysfunction (vascular hyper- reactivity), causing excessive activation of coagulation. This is due to abnormal metabolism of prostaglandin. This pre-eclamptic patient has increased production of TXA_2 (thromboxane A_2) which is a potent vasoconstrictor and help in platelet aggregation and decreased production of PGI (prostacyclin) which is a potent vasodilator and reduce platelet aggregation. Another mechanism of action of endothelial dysfunction is decreased production of nitric oxide (NO) which is a potent vasodilator and increased production of endothelin 1 which is a potent vasoconstrictor. Thus, marked endothelial immunological injury due to its hyperreactivity leads to wide spread systemic manifestation as well as reduced placental perfusion (Table 35.9).

The systemic manifestation of pre-eclampsia include: generalised oedema with special importance to airway, ↑SVR, ↓intravascular volume, hyperdynamic circulation, decreased GFR, ↑uric acid, liver dysfunction, pulmonary oedema etc. The pulmonary oedema in pre-eclampsia is due to: (i) high left atrial and pulmonary capillary wedge pressure, (ii) low plasma colloid and osmotic pressure, and (iii) increased pulmonary capillary permeability. Increased level of uric acid in pre-eclampsia results from decreased renal excretion, tissue ischaemia and oxidative stress. Acute renal failure is rare in pre-eclampsia, but is mostly associated with

Table 35.9: Complications of pre-eclampsia

CVS	Hypertension, ↓ intravascular volume, ↑ vascular resistance, ↓ cardiac output, heart failure, stroke.
RS	Airway oedema, pulmonary oedema.
Kidney	↓ GFR, Oliguria, proteinuria, renal failure.
NS	Hyperexcitability, convulsions, headache, visual disturbance, intracranial haemorrhage, cerebral oedema.
Liver	Elevated liver enzymes, impaired functions, haematoma, rupture of blood vessels.
Haematology	Thrombocytopenia, coagulopathy.

HELLP syndrome. Liver dysfunction is also mostly associated with HELLP syndrome. Cardiac output in pre-eclampsia may be high, normal or low depending on the severity of increase of SVR, severity of diminution of intravascular volume and hyperdynamicity of cardiac function (contractility).

Immediate delivery of foetus and placenta is the definitive and principal way of treatment for pre-eclampsia and eclampsia during life threatening condition of mother at any stage of gestation. Otherwise (i.e. when there is no life threadning condition to mother), the aim of treatment of pre-eclampsia is control of hypertension and prevention of convulsions. The drugs used to treat hypertension in pre-eclampsia are: hydralazine, labetalol and methyldopa (250 to 500 mg orally). The other agents

Table 35.10: Pharmacology of labetalol and hydralazine

	Labetalol	*Hydralazine*
Mode of action	Slight α blocker mainly β blocker	Direct vasodilatation
Dose	10 to 20 mg IV	5 to 10 mg IV
Maintenance	20 to 160 mg/hour	2 to 20 mg/hour
Speed of onset	Quick	Gradual
Tachycardia	Absent	Present

used during emergency are: nitroglycerine, Na-nitroprusside, esmolol. Nitroprusside is helpful only for short-term basis, because prolonged infusion of it is associated with increased risk of cyanide toxicity. Ca^{2+} channel blocker are usually not used because they are contraindicated in pregnancy (Table 35.10).

$MgSO_4$ is the agent of choice to control convulsions and for prevention of recurrent eclamptic fits. It is effective in more than 50% of patients, without serious maternal morbidity. Another beneficial effect of $MgSO_4$ is that it causes vasodilatation and decrease SVR, causing increased cardiac output. The initial bolus dose of $MgSO_4$ is 4 gm and is administered IV slowly over 10 minutes. This is followed by infusion at the rate of 1 to 3 g/h. $MgSO_4$ has low therapeutic index with serum Mg^{2+} level between 4 to 6 mEq/L, being safe and effective. It is excreted through kidney. Therefore, in the presence of renal failure the dose of $MgSO_4$ should be reduced and guided by serum magnesium level. During the use of $MgSO_4$, the level of plasma Mg should be monitored carefully in conjunction with the clinical signs which include respiratory depression and decreased tendon reflex, indicating toxicity. If toxicity of $MgSO_4$ occurs, then 10 ml of 10% calcium gluconate is given IV slowly which counteract the side effect of Mg.

Anaesthetic Consideration

The first step during anaesthetic management of a pre-eclamptic – eclamptic patient includes: detailed history taking regarding the severity of condition, degree of systemic involvement, fluid status, airway assessment, cardiovascular status, renal condition, coagulation status, etc. It also includes: complete blood count, liver function tests, renal function tests, platelet count, coagulation profile, etc. But routine coagulation screening is not recommended by all clinicians, except the presence or suspected of coagulopathy clinically. Central neuraxial block (CNB) is contraindicated in the presence of coagulopathy or low platelet count (< 100,000/cu mm). But, some anaesthetists take this lower count of platelet as 70,000/cu mm for contraindication of CNB.

Pre-eclampsia – eclampsia is associated with exaggerated Na^+ and water retention. But still it is characterised by decreased intravascular volume (hypovolaemia). This is due to the shift of fluid and protein in the interstitial space from intravascular compartment. Thus, the intravascular fluid volume is inversely proportional to the severity of hypertension in pre-eclampsia and eclampsia. So, measurement of CVP in the presence of severe pre-eclampsia – eclampsia will be a false guide. Therefore, before any mode of anaesthesia patient should be hydrated properly by IV infusion. This will improve maternal tissue perfusion, increase cardiac index, decrease SVR, and increase GFR, etc.

Regarding the mode of anaesthesia in pre-eclampsia-eclampsia, it is found that any form of anaesthesia (RA or GA) is equally safe, if they are properly conducted with extra caution. But, there should be some choice as both these modes of anaesthesia have their own advantages and disadvantages. But in the absence of coagulopathy the first choice of anaesthesia for most patients with pre-eclampsia-eclampsia during the process of labour, vaginal delivery and CS is continuous epidural analgesia and anaesthesia. It offers the advantage of gradual onset of sympathetic blockade, gradual hypotension, cardiovascular stability due to gradual compensation with passing of time and no neonatal depression that cab be caused by general anaesthetic drugs. Reduction of hypertension and diminution of vasospasm (due to sympathetic block) caused by RA will improve uteroplacental blood flow, provided severe hypotension is avoided. The RA also reduces the risk of upward exaggerated haemodynamic alterations associated with intubation and extubation and airways complications. On the other hand, if CNB is badly managed, then it frequently associated with extensive sympatholysis and profound hypotension (if not controlled) which may lead to decreased cardiac output, decreased uteroplacental blood flow and in extreme condition even foetal and maternal cardiac arrest. This is more likely with single shot spinal anaesthesia if severe hypotension is not corrected immediately. Hence, even though the single shot spinal block is considered acceptable by many anaesthetist, but is still taken by others to be relatively contraindicated for women with severe pre-eclampsia–eclampsia. However, multiple recent studies have suggested that the magnitude of decline of maternal BP after spinal and epidural block appears to be similar. Hence, spinal block is not contraindicated and can easily be instituted on a severe pre-eclampsia patient undergoing CS. Hypotension induced can easily be avoided by meticulous attention, use of IV colloid infusion and / or use of vasopressor (ephedrine 5 mg) in a titrable fashion, because pre-eclamptic patients tend to be very sensitive to these agents. It is also true that hypotension associated with CNB can easily be controlled than the exaggerated surge of hypertension in GA during laryngoscopy, intubation and extubation which can only be controlled by appropriate treatment with labetalol, nitroglycerine, nitroprusside, hydralazine, trimethaphan, etc. In GA, the risk of failed intubation also should be weighed against the risk of hypotension when deciding between GA and RA for CS of patient who is suffering from

severe pre-eclampsia-eclampsia. If GA is instituted on a pre-eclamptic-eclamptic patient receiving $MgSO_4$, then anaesthetist should be careful regarding the use of muscle relaxant – depolarising and non depolarising. This is because the action of both will be potentiated by $MgSO_4$. Hence, the use of muscle relaxant in a patient receiving $MgSO_4$ should be guided by the peripheral nerve stimulator. $MgSO_4$ also blocks the release of catecholamines after sympathetic stimulations and blunts the response of vasoconstrictor. Therefore, there is also more chance of severe hypotension after CNB in a patient receiving $MgSO_4$. All the pre-eclamptic and eclamptic patients associated with severe hypertension, pulmonary oedema, refractory oliguria, receiving IV vasodilators, etc, should must be monitored by intra-arterial BP, CVP, PCWP, etc.

OBSTETRIC HAEMORRHAGE AND ANAESTHESIA

Obstetric haemorrhage is one of the leading cause of maternal morbidity and mortality, necessitating immediate anaesthesia and surgical intervention. The common causes of this obstetric haemorrhage are placenta praevia, abruptio placentae, uterine inversion, uterine rupture, and uterine atony. Placenta praevia and abruptio placentae account for about 0.5 and 1 to 2% of total pregnancies, respectively.

In placenta praevia, the placenta is situated on the lower uterine segment, covering the internal os which may be complete or partial. The complete placenta praevia is more dangerous than the partial one, regarding the severity of bleeding. Placenta praevia presents usually as painless vaginal bleeding and stops spontaneously in mild cases usually in partial one. But severe bleeding can occur at any time usually in complete placenta praevia. During severe bleeding there is two problems : on the one hand the life of mother and on the another hand the life of the foetus. If the duration of pregnancy is less than 37 weeks and bleeding is mild to moderate, then conservative management may be allowed by bed rest and close observation. Whereas the definitive management of obstetric haemorrhage for any cause after 37 weeks of gestation is CS.

In abruptio placentae there is premature separation of placenta causing painful bleeding which may be revealed through vagina or concealed. Occasionally, the blood may extend into the myometrium which is called the couvelaire uterus. Any vaginal bleeding of a pregnant woman is assumed to have placenta praevia, until proved otherwise. The actual diagnosis is performed by ultrasound. Uterine rupture is another cause of obstetric haemorrhage causing emergency. It is relatively uncommon and can occur as a result of dehiscence of a previous scar on uterus or due to any intrauterine manipulation or due to very prolonged labour. It can present as acute foetal distress, frank haemorrhage, loss of uterine tone, or severe hypotension with occult bleeding into the abdomen.

In all the acute obstetric haemorrhage the mother should be assessed first about its haemodynamic status. If the bleeding is mild to moderate, resuscitation by fluid is adequate and the condition of patient is stable when decision for surgery is taken, then RA may be considered. Otherwise, acute bleeding or a patient with unstable haemodynamic status may require surgical intervention under GA. All these patients should be tackled with atleast two largebore (16 or 18 G) intravenous catheter. Intravascular volume deficit must be replaced vigorously. A central venous line is especially useful for monitoring of preload and rapid transfusion. Two units of whole blood should be immediately available.

The choice between the regional and general anaesthesia during surgery to tackle obstetric haemorrhage depends upon the urgency for delivery and maternal haemodynamic stability. In such situation close communication is very necessary with the concerned surgical team regarding about the mother, foetus, or both who are in immediate danger requiring GA or there is time to safely administer RA. If epidural catheter is already in place for painless labour (labour analgesia), then severe hypotension due to massive bleeding and delay in establishing adequate anaesthesia by further adding anaesthetic dose of LA agent through this epidural route may prohibit its use.

In acute emergency if GA is decided, then adequate pre-oxygenation is quickly achieved by four full breaths of 100% O_2, while possible necessary monitors are being applied during this period of preoxygenation. For induction instead of thiopentone and propofol, ketamine in the dose of 1 mg/Kg is used for hypotension. Other steps for emergency CS are also taken which will help in prevention to develop aspiration pneumonitis (Mendelson's syndrome) and will also help to develop proper ventilation with adequate oxygenation if failed intubation occur. Continuous precise foetal monitoring is very essential, becasue it may help by avoiding the unnecessary GA as emergency for acute foetal distress, diagnosed by imprecise monitoring. Otherwise extra time may be allowed to institute RA. For example, in most of the cases the foetal distress is diagnosed by foetal heart rate variability. But, it has high false positive result and may land in GA showing acute distress, giving no time for RA. Hence, careful interpretation of other parameters such as foetal pulse oxymeter or foetal scalp pH is necessary which may change the mode of anaesthesia.

In abruptio placentae, RA is contraindicated if there is coagulopathy, particularly following foetal demise. This coagulopathy is due to activation of circulating fibrinolysin (plasminogen) and the release of tissue thromboplastin. This may precipitate DIC which is characterised by low fibrinogen level, low platelet count, and high fibrinogen degradation product. Fibrinogen level is mildly reduced with level between 150 to 250 mg/dl in moderate abruptio placentae. But in severe one the fibrinogen level may go below 150 mg/dl.

36 Anaesthesia in Laparoscopic Surgery

INTRODUCTION

Due to the development of better surgical equipments and anaesthetic facilities and also due to the increased knowledge and understanding of the anatomy and pathophysiology of different diseases, the different surgical procedures gradually also have improved. Thus, it reduces the trauma to the patient with the reduction of morbidity, mortality, hospital stay and consequently the reductions in health care costs by the concept of 'minimally invasive or endoscopic surgery'. Endoscopic procedures had first started in the early 1970's for various gynaecological operations (for diagnosis and treatment). Then it soon becomes very popular among the gynaecologists only. But, during this period it was not very popular among the general surgeons, until 1987, when, laparoscopic cholecystectomy was first described in late 1980's by Phillipe Mouret in France. After that gradually it became a well established technique for cholecystectomy in this country (France). Then, very soon this technique was accepted by surgeons all over the world and now more than 80% of all the cholecystectomies are done by laparoscopic procedure with less postoperative pain, reduced hospital stay, reduced cost and earlier return to the work. During that period acute cholecystitis, obesity and previous intra-abdominal surgeries were considered as the contraindications for cholecystectomy by laparoscopic procedure. But these are now no longer considered as contraindications like before for laparoscopic cholecystectomy and the procedure has become quite safe in the hands of experienced surgeons. Subsequently, many other new intra- and extra-abdominal laparoscopic or endoscopic surgical techniques have been developed such as gastrointestinal surgeries (oesophagectomy, vagotomy, appendi sectomy, fundoplication, colonic, gastric, splenic, hepatic), gynaecological surgeries (hysterectomy), urological (nephrectomy), hernia repair, testicular surgeries, etc.

So, these new minimum invasive endoscopic surgical techniques have created the new interests to anaesthetist with separate anaesthetic considerations for the management of such patients. Gradually, the list of the surgical procedures which are now commonly performed endoscopically has grown rapidly. The laparoscopic surgical techniques which are included in this list are now extending from intraperitoneal to transabdominal preperitoneal to totally extra-peritoneal procedures. For example, a laparoscopic fundoplication procedure which is performed as antireflux surgery proves a very cost effective technique for patients suffering from gastroesophageal reflux and on long-term medical management. Pathophysiological changes due to pneumoperitoneum, different patient's position (required during laparoscopic surgeries), long duration of some laparoscopic surgeries, risk of some unsuspected visceral injury, the difficulty in evaluating the amount of blood loss during surgery and some other factors make the anaesthesia for laparoscopic surgery a potentially high-risk procedure. Young healthy women are the largest group of patients who are undergoing the different gynaecological and different surgical (mainly cholenystectomy) laparoscopic surgery. Usually they are associated with minor to moderate cardiorespiratory changes which are of little concern to an anaesthetist. But, older patients with known or latent co-existing systemic diseases waiting for endoscopic surgery are prone to more risk, necessitating intensive care and thorough knowledge of pathophysiological changes associated with laparoscopic surgery.

Compared with the open laparotomy the major advantages of laparoscopic surgery are: Reduced tissue trauma (as less surgical exposure), reduced wound size, reduced postoperative pain due to small wound, reduced incidence of postoperative ileus, earlier mobilisation of patients, shorter hospital stay, improved postoperative respiratory function, etc. For example, following open cholecystectomy forced vital capacity (FVC) is reduced by approximately 50% and changes are still evident up to 72 hours postoperatively. Contrary following laparoscopic cholecystectomy FVC is reduced by approximately only 30% and becomes normal within 24 hours postoperatively.

On the other hand, technically the laparoscopic surgery differs from the open laparotomy by the following points:

i. Laparoscopic surgery needs gravitational displacement of abdominal viscera from the operative site by Trendelenburg or anti-Trendelenburg position.

ii. It needs pneumoperitoneum which separates the abdominal wall from viscera. For pneumoperitoneum the upper limit of IAP (intra-abdominal pressure) is 15 to 20 mm Hg. Modern pneumoperitoneum producing equipment has the ability to maintain continuously this upper limit of IAP automatically. Older laparoscopic equipment which may not have this automatic adjustment for upper limit can deliver uncontrolled gas flows, producing a very high intra-abdominal pressure (sometimes greater than 40 mm Hg).
iii. It needs decompression of abdominal viscera, especially the stomach by nasogastric tube and the bladder by catheter to prevent the injury during insertion of trocar.

PATHOPHYSIOLOGICAL CHANGES OF RESPIRATORY AND CVS DURING LAPAROSCOPY

Two systems of our body are mainly affected during laparoscopic surgery. These are: respiratory system (RS) and cardiovascular system (CVS).

Changes in Respiratory System During Laparoscopy

The insufflation of CO_2 (current routine practice) in to the peritoneal cavity to create pneumoperitonium for laparoscopic surgery results in ventilatory and respiratory changes in patients. Dure to pneumoperitoneum the resulting increase in intra-abdominal pressure (IAP) displaces the diaphragm upwards and causes decrease in compliance of both the chest wall and the lungs, increase in airway resistance, and an increase in peak inspiratory pressure. There is also increase in the risk of gastric regurgitation during pneumoperitoneum.

The compliance of lung is reduced to 30 to 50%, but the shape of the pressure – volume loop of it does not change. Once the pneumoperitoneum is created upto the surgeon's desired level and IAP is kept constant, then further lung compliance is not affected or reduced after reaching its upper limit either by the subsequent patient tilting or by the increase of minute ventilation which may be required to avoid intraoperative hypercapnia. That means compliance decreases and becomes fixed at a given increased IAP. Then, further decrease or deterioration of compliance cannot be detected by increasing IAP. After that point if there is any deterioration of lung's compliance occurs, then it will be only due to the lungs pathology. Therefore, continuous compliance and pressure volume loop monitoring are helpful in diagnosing any second complication resulting from the increased airway pressure due to bronchospasm, changes in muscle relaxation, endobronchial intubation, or pneumothorax, etc. Which are responsible for decrease in compliance of lungs (Fact file-I).

The elevation of diaphragm and subsequently the increased intrathoracic pressure also causes diminished FRC, increased ventilation-perfusion mismatch (preferential ventilation of nondependent areas of lungs can be associated with intrapulmonary shunting and hypoxaemia), increased physiological dead space and increased intrapulmonary shunt contributing to decrease in arterial oxygenation. Such changes would favour the development of atelectasis of lungs. But these changes are generally not found or minimal in normal healthy individuals. On the contrary, in obese patients, in respiratory disabled patients or in patients with cardiovascular problems, these changes may be more significant.

FACT FILE - I

Pneumoperitoneum → ↑IAP → ↑Diaphragm → ↓Compliance of lung → ↑ Airway resistance and ↑airway peak pressure → ↓ FRC → ↑ V/Q mismatch, ↑shunt, ↑dead space, and ↑atelectasis → ↑ hypoxia and ↑$PaCO_2$.

Pneumoperitoneum →↑ IAP and ↑diaphragm → compression of venous capacitance vessel, ↑intrathoracic pressure, compression of arterial resistance vessel (↑SVR) → ↓venous return → ↓ CO → ↑ sympathetic neurohormonal response → ↑ SVR → ↓ CO → vicious cycle.

Due to increased systemic absorption of highly soluble CO_2 by the vasculature of peritoneum, arterial CO_2 tension ($PaCO_2$) increases. It reaches a plateau value at 15 to 30 min after the beginning of CO_2 insufflation of peritoneum under general anaesthesia and this is found only in anaesthetised patient with spontaneous ventilation and in head down (Trandelenburg) or head up tilt position. But, during laparoscopy under local anaesthesia where the patient is not under GA, $PaCO_2$ remains unchanged or remains normal. It is due to the compensatory increase in minute ventilation (hyperventilation) by the stimulation of the respiratory centre by hypercapnia. In such condition, hyperventilation in unanaesthetised patient is achieved by increasing the respiratory rate, rather than by increasing the tidal volume. Usually, the mechanical factor (decreased tidal volume) is compensated by the increase in respiratory rate (in unanaesthetised under local anaesthesia patient), or by controlled ventilation (in anaesthetised paralysed patient) except in anaesthetised spontaneously ventilated patient where both the increase in respiratory rate and tidal volume is jeopardised. This is because if laparoscopy is performed under general anaesthesia with spontaneous ventilation, the compensatory hyperventilation is not achieved. This is again due to anaesthesia induced depression of respiratory centre causing reduction of both respiratory rate and tidal volume. As it takes 15 to 30 minutes for $PaCO_2$ to reach a plateau value after the starting of pneumoperitoneum by CO_2, so GA with spontaneous respiration can be considered only for short laparoscopic procedures with low intra-abdominal pressures.

Like local anaesthesia, during laparoscopy under regional anaesthesia, $PaCO_2$ remains also unaltered due to the absence of ventilatory depressant effects provided the level of block is not much high up. For monitoring of $PaCO_2$ and oxygen saturation, capnography and oximetry are two

reliable devices for a healthy patient. But in sick patients (ASA III – IV) $ETCO_2$ tension is not always reliable, because $PaCO_2$ and ET CO_2 tension gradient increases due to the inadequate capacity of excretion of CO_2 through alveoli. So, for higher risk patients preoperative pulmonary function tests and intraoperative arterial blood gas sampling is recommended as preoperative assessment and as a guide line for intraoperative monitoring of patient respectively (Table 36.1).

The increase in $PaCO_2$ during pneumoperitonium by CO_2 gas is due to: (i) increased absorption of CO_2 from the peritoneal cavity because of its high diffusibility and large absorption area (the absorption of any gas from peritoneal cavity depends on its diffusibility, the absorption area and the perfusions of the walls). (ii) Impairment of pulmonary ventilation and perfusion by mechanical factors such as abdominal distension, patients's position, depression of ventilation by premedicant and anaesthetic drugs. (iii) Accidental events such as CO_2 emphysema, capnothorax (pneumothorax by CO_2), CO_2 embolism, etc. The $PaCO_2$ does not increase if other gases like N_2O, helium, O_2, etc. are used for pneumoperitoneum instead of CO_2 which indicates that the absorption of gases through the peritoneal cavity plays a vital role for increase in $PaCO_2$ rather than the impaired mechanical ventilatory factors due to ↑IAP, in healthy patients. This is because in healthy patient the mechanical factors responsible for ↑$PaCO_2$ is compensated by hyperventilation in unanaesthetised patient or controlled ventilation by IPPV in anaesthetised patient except in anaesthetised patients with spontaneous respiration. Whereas in cardiorespiratory compromised patient both absorption of CO_2 and compromised mechanical factors play vital role (mechanical factor cannot be compensated) for ↑$PaCO_2$.

Table 36.1: Causes of ↑$PaCO_2$ during laparoscopy surgery

i.	Increased physiological dead space and V/Q mismatch • Steep head down position • Abdominal distension • Reduced cardiac output • Reduced ventilation
ii.	Absorption of CO_2 through peritoneal cavity
iii.	Depression of respiration by anaesthetic drug in a spontaneous ventilated patient
iv.	Increased metabolism for stress due to inadequate anaesthesia
v.	Accidental events such as: • Capnothorax • CO_2 emphysema • CO_2 embolism • Change of position of ET tube

Haemodynamic Changes During Laparoscopy

The haemodynamic changes observed during laparoscopic surgery result from the combined effects of anaesthesia, ↑$PaCO_2$ due to CO_2 absorption from peritoneal cavity, ↑IAP due to pneumoperitoneum, patient's position, intravascular volume status and the preexisting cardiorespiratory status of the patient. Peritoneal insufflation raising IAP higher than 10 to 12 mm Hg (the 12 mm of Hg of abdominal pressure is the threshold pressure and up to that level it has minimal effects on haemodynamic function) causes major haemodynamic alterations. These are characterised by ↓ cardiac output, increased systemic vascular resistance (↑SVR), increased pulmonary vascular resistance (↑PVR), increased mean arterial pressure and pulmonary hypertension. Cardiac output is reduced by 10 to 30% whether the patient was placed in the head down or head up position and this is well tolerated by a healthy patient. The causes of this reduction of cardiac output are: (i) pooling of blood in the legs due to increased IAP, (ii) reduced venous return due to compression on inferior vena cava, and compression on both the venous capacitance system and the arterial resistance vessels (this compressive mechanical effect on the venous system will involve in the reduction of venous return to the heart and on arterial resistance vessels will involve in increase in systemic vascular resistance) and (iii) decreased venous return due to increased intrathoracic pressure.

All these above mentioned factors lead to reduced venous return to heart and this reduced venous return to heart causes reduction in left ventricular end diastolic volume (preload) and reduced cardiac output. But, paradoxically, CVP (central venous pressure) and PCWP (pulmonary capillary wedge pressure) rises due to increased intrathoracic pressure inspite of reduction of preload. So, in pneumoperitoneum the measurement of right atrial pressure and pulmonary artery pressure which is generally taken as the cardiac (left ventricle) filling pressure cannot be a proper guide for the left ventricular end diastolic pressure and cardiac output. Following pneumoperitoneum, due to this mechanical factors both the right and the left sided filling pressure of heart (but not the filling volume) will substantially increase. Decreased cardiac output associated with pneumoperitoneum and ↑IAP is also associated with decreased stroke index, since heart rate is not significantly affected. Normally, cardiac index is reduced to 30% from the baseline when the patient is kept in anti-Trendelenburg position and is further reduced to 50% by starting of pneumoperitoneum in this position provided the laparoscopy surgery is done in head up tilt position. Then, the cardiac index gradually comes to normal within 10 minutes after insufflation. The magnitude of reduction of CI is directly proportional to the increased IAP, caused by insufflation (Fig. 36.1).

The pneumoperitonium and ↑IAP is associated with ↑SVR (afterload). Increase in mean arterial pressure (MAP) reflects the increased afterload with an associated deterioration in CI. The magnitude of reduction of CI is directly proportional to the insufflation pressure. The threshold of intraperitoneal pressure that had minimum effect on haemodynamic function is 12 mm Hg. The causes of ↑SVR due to pneumoperitoneum are: (i) compression of intra-abdominal aorta and arterioles by raised IAP

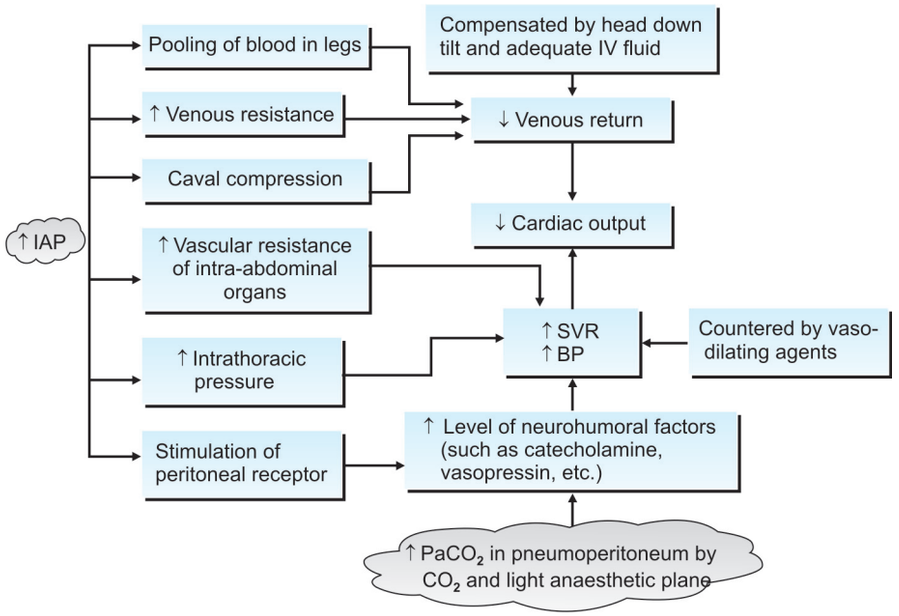

Fig. 36.1: Increased IAP due to pneumoperitoneum patients's position

(mechanical factors) and (ii) release of neurohumoral factors such as catecholamines, prostaglandins, renin-angiotensin and vasopressin, etc. due to mechanical stimulation of peritoneal receptor caused by stretching due to pneumoperitoneum. Within physiological limits, a normal heart tolerate this increase in afterload and ↓CO. But, patients with cardiac disease cannot tolerate this ↑afterload and ↓CO. The ↑SVR in pneumoperitoneum is also due to the reflexly increased sympathetic activity in response to the reduced cardiac output. This is proved by the fact that SVR decreases in Trendelenburg position which tries to increase the venous return and CO and increases in head up position, which tries to decrease the venous return and CO. The increased SVR or afterload can be corrected by vasodilating agents like isoflurane, nitroglycerine, nitroprusside, nicardipine and α_2 agonist (clonidine or dexmedetomidine), etc.

The magnitude of the cardiovascular response due to pneumoperitoneum is directly proportional to the insufflation pressure. So to avoid any cardiovascular response, IAP should be kept below 12 mm Hg. On the otherhand, most of the anaesthetic agents depress the myocardium and further reduce the cardiac output. Head up tilt further detoriates these parameters (↑SVR ,↓CO).

Increased intra-abdominal pressure (IAP) also results in venous stasis in lower limbs which predisposes to the development of thromboembolic complications. Increased IAP decreases renal plasma flow, GFR and urine output. ↑IAP also leads to decreased blood flow to the intra-abdominal organs except adrenal gland. Mesenteric, intestinal mucosa and splenic blood flow is also decreased. Thus, the intestinal mucosal ischaemia results in decreased intestinal mucosal pH and may delay the return of normal bowel function.

Haemodynamic changes due to pneumoperitoneum are well tolerated in healthy patients as suggested by the normal arterial O_2 saturation and normal plasma lactate level, observed during laparoscopic procedures. But this tolerance might be different in patients with impaired cardiac function, anaemia or hypovolaemia. Therefore, IV nitroglycerine, IV nicardipine or IV dobutamine is used to manage the haemodynamic changes (↑SVR, ↑MAP, ↓CO), induced by ↑IAP in selected patients with heart disease. In these patients preoperative preload is also augmented by the judicious use of IV fluid that offsets the haemodynamic effect of pneumoperitonium, i.e. reduction of preload and subsequent reduction of cardiac output.

Steps to prevent haemodynamic changes

Several steps can be taken during laparoscopic surgery to prevent the haemodynamic changes caused mainly by pneumoperitoneum and head down or head up position of patient. These are as follows.

i. Premedication with α_2 adrenergic agonist such as clonidine or dexmedetomidine (more selective α_2 agonist).
ii. Use of anaesthetic agents having least haemodynamic effects, such as fentanyl / alfentanil / sufentanil, isoflurane / sevoflurane, vecuronium, etc.
iii. Maintenance of proper plane of anaesthesia.
iv. Increasing the circulating blood volume by infusing 7 to 8 ml/kg of crystalloid solution before inducing the pneumoperitoneum.
v. Considering the gasless laparoscopy.
vi. Slow insufflation of CO_2 for pneumoperitonium (rate 1 lit/min) which will allow adequate time for compensation.
vii. Maintaining low intra-abdominal pressure (10 mm Hg).
viii. Head up tilt after insufflation.
ix. Considering the vasodilating drugs like nitroglycerine, nicardipine nintroprusside, etc. for prevention of haemodynamic changes associated with pneumoperitonium, i.e. ↑SVR.

PROBLEMS DURING LAPAROSCOPY

Problems Due to Hypercarbia

Mild hypercarbia (P_aCO_2 is between 45 to 50 mm Hg) have little impact on the haemodynamic system. Increasing $PaCO_2$ from 55 to70 mm Hg has a direct myocardial depressant and vasodilating effect. At cellular level, it has a depressant effect

on myocardial contractility and a stimulant effect on myocardial irritability and arrhythmicity. Hypercarbia also decreases the responsiveness of blood vessels to catecholamines. It also causes vasodilatation especially on the venous side leading to peripheral pooling of blood, decreased venous return and decreased cardiac output. Exception exists in the pulmonary vessels which undergo vasoconstriction in response to ↑$PaCO_2$. However, the effect of ↑$PaCO_2$ on pulmonary vessels is due to indirect acidosis rather than direct hypercarbia. But the local effect of $PaCO_2$ on pulmonary vessels is over shadowed by its systemic effects or the effects of ↑$PaCO_2$ on the central nervous system. Hence, the net effect of CVS in response to ↑$PaCO_2$ usually are (after an initial increase) the decrease in cardiac output, ↓stroke volume, ↓heart rate, ↓force of myocardial contraction and increase in blood pressure, ↑central venous pressure, vasoconstriction of pulmonary vessels and increase in peripheral vascular resistance and cardiac arrhythmias. Respiratory acidosis also increases sympathetic outflow resulting cardiac arrhythmia, especially in the presence of halogenated anaesthetic agents such as halothane, isoflurane and sevoflurane. Among these halothane is the most notoreius. Bradycardia and other cardiac arrhythmias may also occur from increased vagal reflexes and it is due to the peritoneal stretching during insufflation of peritoneal cavity.

In summary gas insufflation into the peritoneal cavity which is followed by stretching of the peritoneum which is followed by raised intra-abdominal pressure and altered patient's position all together can cause a range of clinical responses. These are:

i. *Sympathetic response:* Hypertension, tachycardia, ↑SVR. These are treated by increasing the dose of volatiles, short acting opioids (fentanyl, sufentanil, remifentanil), vasodilators and/or betablocker.
ii. CVS response: CVS depression with fall in cardiac output leadint to hypotension, tachycardia or bradycardia. This is treated by fluids, vasodilators, and/or inotrops.
iii. *Vagal response:* Asystole, sinus bradycardia, nodal rhythm, hypotension etc. This can be treated by vagolytics.

Problems Related to Patient's Position

For laparoscopic surgeries patient is positioned with a head down (for pelvic or infra-mesocolic surgery) or head up (for supramesocolic surgery) tilt and it may be added with lithotomy position. These altered positions of patients working synergistically with the ↑IAP are responsible for the development of different pathophysiological changes during laparoscopy. The changes are also influenced by: (i) extent of the tilt, (ii) intravascular volume status, (iii) the patient's age, (iv) anaesthetic drugs administered, (v) associated cardiac disease and (vi) type of ventilation techniques. The changes in respiratory system and CVS due to head down position is same as that due to ↑IAP, but only in exaggerated form. On the other-hand, the changes in respiratory and cardiovascular system due to head up position is opposite to the changes due to ↑IAP and favours improved pulmonary dynamics.

In head down position the FRC, total lung volume, FVC and the compliance of lung decreases which facilitate the development of atelectasis, intrapulmonary shunt, hypoxia and hypercarbia. In head down tilt, there is also increase in central blood volume and decrease in vital capacity and all of these are due to the diminution of diaphragmatic excursion. Thus, the changes due to head down position is unfavourable for respiratory system. In healthy patient these changes in respiratory system are minimally seen, but are more marked in obese and elderly patient. In the contrary, changes due to head up position is favourable for the respiratory system.

When head down tilt does not increase more than 15°, then shift in blood volume is too small to induce any clinically significant haemodynamic changes. In normal healthy subject, isolated increased hydrostatic pressure associated with head down position results in increased venous return, ↑CVP and ↑CO (whereas isolated ↑IAP due to pneumoperitoneum causes ↑CVP ↓CO). So, during laparoscopic surgery, Trendelenburg position and pneumoperitonium producing (↑IAP) together causes ↑↑CVP, ↑↑PCWP and ↓↑CO. These changes are tolerated well by healthy patient, but not by patients with low cardiopulmonary reserve. Isolated reverse Trendelenburg position decreases the preload, CVP, MAP and CO, i.e. ↓preload, ↓CVP, ↓MAP, ↓CO (↑IAP also causes ↓preload though CVP paradoxically increases, ↑MAP, ↓CO). So during laparoscopic surgery anti Trendelenburg position with pneumoperitoneum together causes : ↓↓preload, ↓↑CVP, ↓↑MAP, ↓↓CO. The steeper will be the tilt, the greater will be the fall in CO.

If there is intraoperative hypoxia during laparoscopic surgery, the causes may be:

i. Hypoventilations due to pneumoperitoneum, head down position, inadequate ventilation during IPPV, etc.
ii. Ventilation – perfusion mismatch due to reduced FRC, atelectasis, endobronchial intubation, extraperitoneal gas insufflation, bowel distension, pulmonary aspiration and rarely pneumothorax.
iii. Reduced cardiac output due to IVC compression, arrhythmias, haemorrhage, myocardial depression, venous gas embolism, extraperitoneal gas.

So, the patient should be tilted very slowly and progressively, avoiding sudden respiratory and haemodynamic changes. The position of ET tube should be checked after every change in position of patient. Mask ventilation may inflate the stomach. So, it should be aspirated by a ryle's tube before introduction of trocar and cannula to prevent gastric perforation.

CONTRAINDICATION OF LAPAROSCOPIC SURGERY

There is no absolute contraindication for laparoscopic surgery. Therefore, all the contraindications to laparoscopic surgery are relative. For example, when the physiological effects arising from the CO_2 insufflation into the abdominal cavity under pressure is combined with the effects arising from the variations in positioning of patients, then it has a major impact on cardiopulmonary function, particularly in ASA grade III and IV and is contraindicated. But, the recent report of 'gas less laparoscopy' using an abdominal wall lifting device may obviate the requirement of pneumoperitoneum and allow safe laparoscopy for these ASA grade III and IV patients. Successful laparoscopic procedures also have been now carried out on patients who are anticoagulated, morbidly obese or pregnant which are previously contraindicated. Even the different literatures now confirms that LC (laparoscopy cholecystectomy) can be safely be performed in all the trimesters of pregnancy with no increase in fetal and maternal morbidity. The available datas suggest that the efficacy and safety during LC in pregnancy can be increased by using the open Hasson technique for instrumentation. This safety also can be increased by:

i. Limiting the IAP during pneumoperitoneum in pregnancy.
ii. Ensuring adequate maternal oxygenation and normocapnia by proper ventilation.
iii. Using appropriate maternal and foetal monitoring.
iv. Using active antithromboembolism measures.
v. Preventing aortocaval compression by tilting the patient on left side.

Acute cholecystitis, despite concerns about the technical difficulties due to associated oedema, inflammation and necrosis, etc. is no longer considered as contraindication to the laparoscopy which was taken as contraindication previously. Any previous intra-abdominal surgery was initially taken as contraindication for laparoscopic surgery, but they are now considered safe in experienced hand. There is considerable controversy regarding the appropriateness of laparoscopic surgery for the treatment of known malignant disease. For example, laparoscopic cholecystectomy in known gallbladder malignancy is controversial. Fit and young patients tolerates the physiological changes well and definitely are not contraindicated. But the elderly patients of ASA III and IV status with cardiac and pulmonary disease have more marked and deleterious responses to laparoscopy but still they are not contraindicated. Contrary, they should be thoroughly reviewed and their medical condition is optimised preoperatively and should have a surgeon well experienced in this procedure.

COMPLICATIONS OF LAPAROSCOPIC SURGERIES

Surgical Complications

Unusual and unexpected vascular trauma and haemorrhagic shock is responsible for 30% of major complications of endoscopic on laparoscopic surgery. Blood vessels of the anterior abdominal wall, or peritoneal cavity or retroperitoneal space may be punctured by the Verres needle or trocar and canula. Near the level of umbilicus, both the medial vessels (superficial and inferior epigastric) and lateral vessels (superficial and deep circumflex iliac) are at the increased risk of injury. But, we will have to keep in mind that blood loss in the anterior abdominal wall and retroperitoneal space may be considerable in amount before detection than the blood loss into the peritoneal cavity before detection. Retroperitoneal haematoma can develop insidiously and result in significant amount of blood loss without major intraperitoneal effusion, leading to delayed diagnosis. Other than injury of blood vessels, another important complications of endoscopic surgery is trauma to the abdominal visceral which may lead to peritonitis, subdiaphragmatic abscess formation and septic shock. Accidental fulguration by electrocautery has also been associated with bowel burns and bowel gas explosions (Fact file- II).

Examples of other complications resulting from endoscopic surgeries are: hepatic and splenic rupture, avulsions of of band arising from previous adhesions, omental disruption, or herniation at trocar insertion site, etc. To avoid the above mentioned injuries caused by blind Verres needle or trocar insertions, 'Hasson' minilaparotomy technique has also been advocated for creation of pneumoperitoneum. In this technique a minilaparotomy incision is primarily made, through which a trocar is inserted under direct visual guidance to create pneumoperitoneum.

FACT FILE- II

i. Laparoscopic surgery provides lots of benefits which include : Less trauma, less pain, quick recovery, less pulmonary complications, less hospital stay, less cost, etc.
ii. Pneumoperitoneum causes cardiorespiratory changes. $PaCO_2$ increases due to absorption of CO_2 through peritoneal cavity when CO_2 is used for pneumoperitoneum.
iii. In sick patients (ASA III and IV) these cardiorespiratory changes due to IAP and head down tilt is further accentuated by $\uparrow PaCO_2$.
iv. Hence, better knowledge of pathophysiology of these haemodynamic changes allow successful anaesthetic management of sick patients by optimising preload and use of vasodilating agents.
v. Gasless laparoscopy is theoretically helpful, but technically is very difficult.
vi. Alternative to CO_2, other inert gases such as argon, helium, N_2O do not seem to reduce the haemodynamic changes.
vii. The death rate in laparoscopic surgery is 0·1 to 1 per 1000 cases. The incidence of both visceral injury and haemorrhagic complications is 2 to 5 per 1000 cases. This is favourable when compared with open surgery.
viii. No anaesthetic technique is superior to other. But GA with controlled ventilation is safest for operative laparoscopy.

It is very important to mention that all the above mentioned complications of endoscopic procedure are surgery related. But anaesthesiologist must be aware of all these surgical complications and also the timing of their occurrence. Because they should be prepared to respond promptly to these adverse situations.

Respiratory Complications

The use of pressurised gas during pneumoperitoneum introduces the possibility of extravasation of used gas along the tissue planes, resulting in subcutaneous or retroperitoneal emphysema. This may prolong the surgery or cause its abandonment. Subcutaneous emphysema occurs when the tip of the Veress needle does not enter the peritoneal cavity before the insufflation of gas. This produces the insufflating gas to accumulate in between the fascias sheath and the peritoneum or in the subcutaneous tissue plane of anterior abdominal wall. The incidence of this complication is near about 0.4% to 2% and is the most common. If the insufflating gas is CO_2 then the extraperitoneal accumulation of this gas may cause quick absorption of it than the intraperitoneal insufflation and may be the cause of sudden rise in $PaCO_2$ and $ETCO_2$ tension.

If the pressure used to inflate the peritoneal cavity by gas is too high, then this gas may be forced out through the occasionally present congenital foramina (patent pleuroperitoneal canal) in the diaphragm causing pneumothorax, pneumopericardium or pneumomediastinum. These complications occur primarily on the right side and usually also is reduced within 30 to 60 minutes of desufflation. The insufflated gas from peritoneal cavity also may track around the aortic and oesophageal hiatuses of the diaphragm into the mediastinum and then may rupture into the pleural space. Commonly, these weak points or defects in the diaphragm occur at the pleuroperitoneal hiatus or foramen of Bochdalek. Sometimes, these complications remain undiagnosed and pneumomediastinum or pneumothorax may become life threatening. The subcutaneous emphysema over the chest wall, neck and face should also alert the anaesthetist regarding the possibility of these dreadend complications. The intraoperative diagnosis of these complications can be confirmed by the presence of increased airway pressure, haemodynamic instability and O_2 desaturation. If the patient is haemodynamically unstable and there is clinical evidence of pneumothorax, then abdominal insufflation should be stopped immediately. The diagnosis of pneumothorax should be confirmed by chest radiograph and immediate decompression of thorax should be done by putting a tube in the pleural cavity. Once the chest decompression is in a satisfactory position, then the abdomen can be insufflated again by gas and the procedure can be continued, if the patient remains stable.

Gas embolism is the most feared complication of endoscopic surgery which may lead to hypoxemia, pulmonary hypertension, pulmonary oedema and cardiovascular collapse. The causes of gas embolism are : (i) the Veeres needle or trocar cannula may directly be into a vessel, or (ii) the gas may be forced into the vessels through open sinuses of the surgical site by high intra-abdominal pressure. Unlike air embolism, in CO_2 embolism there is no bronchoconstriction, but only the end tidal CO_2 tension may increase transiently.

Sometimes inadvertently endotracheal intubation may be converted to endobronchial intubation by the cephalad shift of the diaphragm along with the intrathoracic organ due to ↑IAP due to intraperitoneal insufflation and head down position of the patient. So, the ET tracheal tube should be firmly taped and its cuff should lie well above the carnia. Therefore, it should be rechecked after pneumoperitonium and after any further change in the patient's position. Increased intra-abdominal pressure decreases the risk of regurgitation (by increasing the lower oesopahgeal sphincteric tone) and head down position further reduces the risk of aspiration of these regurgitated material into lungs. Still preoperative administration of H_2 receptor blockers is recommended, since the risk of regurgitation and aspiration persists in high-risk patients.

Cardiovascular Complications

There is high incidence of cardiac arrhythmias during the laparoscopic surgeries. Hypercapnia is the major cause of it. Other precipitating factors of cardiac arrhythmia are hypoxia, haemodynamic changes and vagal reflexes (resulting from the sudden stretching of peritoneum due to pneumoperitoneum). In light plane of anaesthesia this intense vagal stimulation may cause severe bradycardia, cardiac arrhythmias and even asystole. 27% incidence of vagal stimulation have been reported in spontaneously breathing patients under halothane. This incidence may be reduced to 5% in mechanically ventilated patients and when peritoneal insufflation done with N_2O rather than CO_2. Therefore, mechanical ventilation and adequate depth of anaesthesia by the use of isoflurane/sevoflurane etc. is recommended to reduce the incidence of cardiac arrhythmia during laprascopic surgery. Arrhythmias may be the first sign of gas embolism. The cardiac arrhythmias occurring during the early part of CO_2 insufflation (when $PaCO_2$ is at normal level) is mainly due to the vagal stimulation, caused by the rapid haemodynamic changes and rapid rise of IAP. So, these arrhythmias are quickly treated by stoppage of insufflation, injection of atropine (for bradycardia) and deepening of anaesthesia only after recovery of heart rate from bradycardia.

Nerve Injury

Sometimes nerve injury is a potential complication during laparoscopic surgery in head down and lithotomy position. The commonly inflicted nerves are brachial plexus and common peroneal. The nerves of

brachial plexus are commonly injured due to the over extension of arm. So, prevention of over extension of arm and cautious use of shoulder braces can reduces the incidence of brachial plexus injury. Common peroneal nerve is highly vulnerable during prolonged lithotomy position and so care should be taken during the positioning of patient in lithotomy position. Lower extremity compartment syndrome is also reported after prolonged lithotomy position.

ALTERNATIVES TO CO_2 PNEUMOPERITONEUM

Besides CO_2, pneumoperitoneum can also be produced by using air, O_2, N_2O and N_2. But, CO_2 is generally preferred and at present it is the most commonly used gas for laparoscopy This is because of its greater solubility in blood (so the risk of gas embolism is reduced), rapid elimination by the lungs, ready availability, low cost and noninflammability during electrocautery which is part and parcel of laparoscopic surgery. N_2O also can be used for insufflation of peritoneal cavity during laparoscopy surgery to produce pneumoperitoneum, but it is inflammable during electrocautery. Another advantage of N_2O to produce pneumoperitoneum is that it does not increase the size of CO_2 bubbles in blood. Other alternative approach for pneumoperitoneum in laparoscopy is the use of inert gases or even gasless laparoscopy.

Inert Gases

Among the inert gases, only argon and helium have been used to cause pneumoperitoneum, instead of CO_2 during laparoscopy. The only advantage of inert gases is that it avoids the increase in $PaCO_2$, secondary to CO_2 absorption through peritoneum. But the inert gases cannot avoid the pulmonary and haemodynamic changes due to ↑IAP. On the contrary, the main disadvantage of the use of inert gases is their low blood solubility and decreased safety in the event of gas embolism.

Gasless Laparoscopy

Peritoneal cavity can also be expanded by elevating the abdominal wall by using a fan retractor instead of using any gas. Thus, it avoids the haemodynamic and respiratory changes due to the increased IAP and the use of CO_2, specially in patients with cardiorespiratory compromised. But, gasless laparoscopy compromises surgical exposure and increases the technical difficulty. Therefore, combining the abdominal wall lifting with fan retractor and low pressure CO_2 pneumoperitoneum (5 mm Hg) might improve the surgical exposure and will reduce the bad effecct of high pressure CO_2 pneumoperitoneum on RS and CVS. The other advantages of gasless laparoscopy is that it is associated with the less incidence of PONV and less incidence of metastasis of malignancy at the site of laparoscopic part.

LAPAROSCOPY DURING PREGNANCY AND CHILDREN

The most common surgeries that are performed by laparoscopy during pregnancy are appendisectomy and cholecystectomy. During laparoscopic surgery in pregnancy the important points that should be kept in mind are the following:

i. Any abdominal surgery during (endoscopic or not) pregnancy increases the risk of miscarriage and premature labour and this is maximum before 12th week of pregnancy and after 24th week of pregnancy. So, the laparoscopy performed between 12 and 23 weeks of pregnancy has the minimum risk for miscarriage and preterm labour and provides adequate intra-abdominal working space for endoscopy.
ii. Laparoscopy has the special risk of directly hitting and damaging the gravid uterus. This can be avoided by the alternative sites of entry for the verres needles and trocar cannula.
iii. Open laparoscopy can be used to avoid damaging the uterus.
iv. Pneumoperitoneum produced by CO_2 can induce significant foetal acidosis. So, maternal $PaCO_2$ should always be monitored closely and maintained at normal levels. Hence, the mechanical ventilation should be adjusted correctly to maintain a physiological maternal alkalosis.
v. Tocolytics should be used routinely during laparoscopy to arrest preterm labour.
vi. Foetal monitoring is must during laparoscopy by transvaginal USG.
vii. IAP during pneumoperitoneum in the state of pregnancy should be limited between 8 and 10 mm Hg. Gasless laparoscopy is an alternative to avoid the potential side effects of CO_2 pneumoperitonium and elevated IAP during pregnancy. Operation in a left lateral position is a safeguard against the supine hypotension which is often found during pregnancy.
viii. Laparoscopy during pregnancy under epidural anaesthesia reduces the hazards of anaesthetic drugs on foetus and the course of pregnancy.

The diagnosis of acute appendicitis continues to be a great problem for clinicians, despite the significant advances in surgery over the past century. In 20% of patients with appendicitis, the diagnosis is missed clinically. On the other hand, the appendix is normal in 15 to 40% of cases when they are undergoing emergency surgery for suspected appendicitis. Now, more and more laparoscopy guided surgery is performed in children and the most common indications of these is appendisectomy. But, datas concerning the haemodynamic changes and ventilatory tolerance produced by pneumoperitonium in children is inadequate. Due to the increased ratio of peritoneal surface area to body weight, the absorption of CO_2 in CO_2 – pneumoperitoneum is intense and faster in children. But, during brief laparoscopy, $ETCO_2$ tension rises slightly and no increase in ventilation is required.

In a recent randomised study, it is seen that the laparoscopic appendisectomy does not improve the postoperative recovery and analgesia in children. The laparoscopic appendisectomy technique is associated with longer duration of surgery, but shorter hospital stay and no difference in terms of time to return to normal activity compared with conventional open surgery.

ANAESTHETIC PROCEDURE

Any standard anaesthetic technique such as LA, RA or GA adapted for laparoscopic surgery does not play any major role in patient's outcome. But, GA with endotracheal intubation and controlled ventilation is considered as the safest technique for long laparoscopic surgical procedures. During pneumoperitoneum CO_2 which is absorbed through the peritoneum increases $PaCO_2$ and thus makes the tracheal intubation and artificial ventilation necessary. General anaesthesia and artificial ventilation is also chosen, because under LA or RA patients feel great discomfort which is due to the creation of pneumoperitoneum and the extent of the changes of the position of patient necessary for the procedures.

In general, the local or regional anaesthetic technique is not recommended for upper abdominal and long laparoscopic surgeries. The choice of agents for induction and maintenance of GA are not important, except that the cardio-depressant agents should be avoided. There is higher incidence of PONV after laparoscopic, surgery especially following gynaecological procedures. So, an antiemetic agent should be given prophylactically in all the cases of laparoscopic surgeries. As the pneumoperitoneum needs increment of minute ventilation by 15 to 25%, so it can be achieved by increasing the respiratory rate rather than the tidal volume which avoids much alveolar inflation and reduces the risk of pneumothorax (by rupturing the emphysematous bullae). This principle is more applicable for COPD and emphysematous patients. Whatever may be the technique of ventilation, $ETCO_2$ tension should be maintained at approximately 35 mm Hg. The N_2O used for maintenance of anaesthesia is not contraindicated for any laparoscopic surgery, but it is better to avoid in laparoscopic intestinal and colonic surgery. IAP should be monitored closely and is not allowed to exceed maximally above 15 mm Hg in any condition. Theoretical profound muscle relaxation is not necessary for laparoscopic surgery, but inadequate muscle relaxation may intensely increase IAP without adequate pneumoperitoneum and reduces working space. Reversely, adequate muscle relaxation provides adequate working space without much increase of IAP.

The use of LMA as an alternative to ET tube in laparoscopic surgeries has both the advantages and disadvantages. The advantages of LMA are: less laryngeal irritation, less postoperative cough, easy to insert, etc. which are discussed in appropriate chapters. The disadvantages of LMA in laparoscopic surgery are: (i) It cannot protect the airway from aspiration of gastric contents and (ii) controlled ventilation is sometimes difficult when the airway pressure exceeds 20 cm of H_2O due to decreased thoracopulmonary compliance due to pneumoperitoneum. So, the use of LMA for laparoscopic surgery is limited only to the healthy and thin patients for spontaneous or controlled ventilation. GA with spontaneous respiration without LMA or intubation should be used only for short procedures with low IAP and slight degrees of tilt.

Laparoscopic surgeries performed under local anaesthesia requires very short, precise and gentle surgical procedure such as tubal ligation, some diagnostic procedures, some investigation during infertility management, etc. Laparoscopic surgery done under LA provides several advantages. These are: fewer haemodynamic changes, early diagnosis of complication, early recovery, reduced PONV and avoidance of complications of GA. But the success of endoscopy under LA depends on the relaxed and co-operative patient, trained OT staff, skilled surgeon, and as low as possible increased IAP. During laparoscopy under local anaesthesia patients usually suffer from discomfort due to pneumoperitoneum and so necessitiate IV sedation. But, sedation and pneumoperitoneum both usually produce O_2 desaturation and so care should be taken. Regional anaesthesia (spinal and epidural) for laparoscopic surgeries share the same advantages and disadvantages like LA, but it may be applied for surgical procedures which are longer than that can be done under LA but shorter than that which need GA. Whereas very long surgical cases should be done under GA, rather than RA. The RA provides better muscle relaxation and so less sedation is needed (than LA), without major impairment of ventilation. The surgical stress related to metabolic responses are also reduced in RA which is a great advantage of it than GA. The haemodynamic effects of pneumoperitoneum under RA is still being studied. So, the patient's co-operation, experienced surgeons, less increase in IAP and moderate head up or head down tilt are the key factors for the success of laparoscopic surgeries under regional anaesthesia (RA).

37 Laser Surgery and Anaesthesia

INTRODUCTION AND PHYSICS

The full form of the word laser is Light Amplification by Stimulated Emission of Radiation. In simple form, it can be said that laser provides a huge quantity of energy in the form of light or photon particles which can be transferred very rapidly to a remote and a very specific location to destroy the tissue by heat and vaporization. Actually, visual light is an electromagnetic wave with combined electrical and magnetic properties. It propagates at a speed of 299792458 meter/second. Thus ordinary light is a form of radiant energy that spans in the mid-range of whole spectrum of electromagnetic wave. It is released as photons and travels as a wave. This was the explanation of Maxwell about light in 1864. The wavelength of visible light ranges between 385 to 760 nanometer. The light below this wavelength is called the ultraviolet rays and the light above this wavelength is called the infrared rays. Subsequently Max Plank had said that if a light only of blue in colour and of certain wavelength falls on a specific metal, then it emits some electrons from the metal at a rate which is proportional to the brightness of the light. After that in 1905, Einstein, by his quantum mechanics explained that electromagnetic radiation or wave of normal light which consists of photons have properties of both the particle (mass) and the energy (wave). Einstein also said that emission of electron from a specific metal as a result of this fall of blue light is independent of the number of photons, present in the falling light. Energy is the key factor for emission of electron from metal i.e. only photons of high energy with high frequency wave can provide this energy which is necessary to stimulate this electron emission from metal. Lower energy photons, even arriving in large numbers at a given time can not emit electrons from this specific metal. These findings results in the development of laser.

The electrons usually encircle the nucleus of an atom in many orbits and each orbit has a specific energy level with fixed number of electrons. If an electron moves from one orbit to another, i.e. from higher to lower or lower to higher orbit, then it absorbs or emits an amount of energy which is exactly equal to the difference in energy between the two adjacent orbits. When an energy or a photon falls from outside on an atom, then the electron of lower energy orbit, absorbs it and jumps to the outer next higher energy orbit. This phenomenon is called the stimulated absorption and the new state of this atom is called the stimulated state. Similarly, when an electron from higher energy orbit enters into the next inner lower energy orbit, then it emits some energy or photon. This phenomenon is called the spontaneous emission and the new state of this atom is called the emission state. A third situation, predicted by Einstein in 1917 is the stimulated emission which is a combination of previously mentioned both the states of a atom. Here, if a photon or energy of a particular wavelength colloids with an atom which is ready from previously for a spontaneous emission (i.e. having an electron already in the higher energy orbit and ready to enter in lower energy orbit with emission of energy or photon) then two photons or energy waves will come out of this atom (one that is falling on the atom and the other by the mechanism of spontaneous emission). Thus, the emitted two photons will have the identical wavelength, phase and directions. This phenomenon is called the stimulated emission.

The energy differences among the different orbits are specific to different atoms. Thus, the emission and absorption spectra of energy of an atom is very specific, like fingerprint for this atom and hence is used for atom's chemical identification. Normally, in the thermodynamic equilibrium state, the electrons of an atom usually lie in the orbit of lowest available energy. So, the key for formation of laser is to pump up the electrons to the higher energy orbit (stimulated state) where they will wait for an external photon to collide and start a chain reaction (or amplification) of stimulated emission, i.e. when one photon will collide with an stimulated atom, then two photons will come out, which again falls on another atom lying in already stimulated state. Thus 4 photons will come out which again fall on another stimulated atom and this type of chain reaction will go on repeatedly. The technology for previous pumping up of electron from lower energy orbit to higher energy orbit in an atom of a material (which is known as the laser medium) and to achieve stimulated state of an atom was introduced in 1958. Then later, a method was also developed by placing the laser

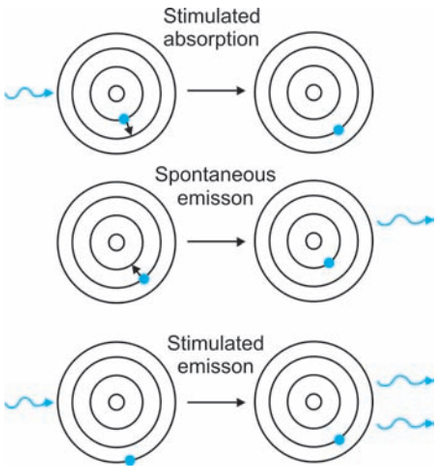

Fig. 37.1: Interaction of photon with electron
Stimulated absorption: Here a photon strikes an electron and transfers its energy to this electron. This transferred energy pushes the electron into a higher oribt.
Spontaneous emission: Here an electron is pushed from higher energy orbit to lower energy orbit. Thus it losses some energy which is emitted as photon.
Stimulated emission: Here, an incoming photon interact with an electron that is already pushed in a high energy orbit before by some energy, with the result that two photons or energy particles leave the electron and it is pushed back in the lower orbit.

medium between two parallel reflecting mirrors, so that stimulated emitting photons could traverse the medium by repeatedly striking the more and more atom of this laser medium which are already in the stimulated state and emitting more and more photon and thus maximising the number of stimulated emission (Fig. 37.1).

Now, this amplified photons or light energy that is radiated by the mechanism of stimulated emission (laser light) differs from the ordinary light in that the laser light consists of photons that have very well defined and narrowband of wavelength. Whereas, the ordinary light consists of photons of wide wavelength and less defined. Laser light has no dispersion. It is confined and propagated as a very narrow beam. Whereas, the ordinary light spread out in all directions from the point of its source. All the waves of photons (or energy) of Laser light always remain in the same phase, whereas the waves of ordinary light remain in different phases. This property of Laser is called the coherent, i.e. all the peaks of the wave of the energy or photon move synchronously at the same direction and same amplitude. Another property of laser is that it is monochromatic, i.e. all the waves of same wavelength. Thus these three characteristics allow the Laser: (i) To generate intense light beam, (ii) To send such light beam efficiently and accurately at distance places through lenses and (iii) to deliver intense energy on a small target site.

So, to produce Laser, we need three things: (i) The Laser medium containing the atoms whose electrons could be capable of creating the Laser light, (ii) An energy source to pump and excite—(stimulate) the electrons of the atom of Laser medium from lower energy orbit to higher energy orbit and (iii) Two resonating mirrors to amplify the amount of liberated photons and to create the chain reaction. In a laser tube, the application of an energy source on a lasing medium back and fourth between the carefully aligned mirrors and are focussed into a high intensity beam. Three types of laser medium are used practically. These are : (i) Gaseous laser medium, for example CO_2, argon, krypton, helium, neon, etc, (ii) Liquid laser medium such as some dyes and semiconductors, and (iii) Solid laser medium such as chromium, neodymium, holmium and synthetic crystals known as YAG (Yttrium Aluminium Garnet). According to the mode of delivery of light beam laser also can be classified into intermittent, short, long or continuous. Gas laser produces either a continuous or intermittent pulsed beam. But, solid laser always produces intermittent pulsed beam. The continuous wave of CO_2 laser produces radiation, having a wavelength of 10 µm. It is strongly absorbed by water and damages tissue surfaces up to the depth of 200 µm. For this reason the CO_2 laser is suitable for removing any superficial lesions, for example removal of a small growth from the vocal cords or larynx. For energy source, which is used to pump and excite the electrons from lower energy orbit to higher energy orbit in the atoms of a laser medium, usually the xenon flash lamp (for solid laser medium) or high electrical power (for gaseous laser medium) is used. As lasers mediums are not very efficient in converting electrical energy into light energy, so they require a large power supply (e.g. a laser with 10 W output requires in excess of 1000 w of current) (Table 37.1).

Table 37.1: Different types of laser and their wavelength and colour

Laser type	*Colour*	*Wavelength (nm)*
Argon	Blue / green	488-515
CO_2	Far-infrared	10,600
Helium-neon	Red	633
Dye	Blue to red	360-670
Ruby	Red	694
Nd-YAG	Near infrared	1064

After emission of Laser, usually a light guide is used which directs the laser beam to the surgical site. But, now the development of fiber-optic bundles provide a convenient, flexible way to deliver the laser light to a distant surgical site. At the end of this light guide or the fibre-optic bundle, there is a lens which focuses the laser light to a minimum size (sometimes the spot size is 30 µm or 0.03 mm), creating a very high density of power or energy over a small area. In operating microscpe, the laser light is focussed on the tissue by the lenses of microscope.

CLINICAL APPLICATION AND BIOLOGICAL EFFECTS OF LASER

So long, we have learnt that laser is nothing but a intensly amplified number of photon particles or energy, directed at a very small pinpoint area. Actually, it does not increase the energy of a particular photon, but simply places or concentrated the more photons or energy at a given place and time than the ordinary light sources. This high density of power or energy, delivered at the

very small target site, produces enormous heat at the rate of many thousand calories per second (approximately 2500 cal/sec). This causes rapid vaporization of any tissue or material, except metals. So, to remove tissues (by heat and vaporization) laser is used as a scalpel, allowing highly precised microsurgery, to perform in a confined or difficult to reach sites. Laser also causes electrocoagulation. So, laser surgery is relatively dry, providing a near instantaneously sealed small blood vessels and lymphatics, even in the presence of clotting abnormalities. In summary, the advantages of using laser include: Less bleeding, ability to coagulate small blood vessels, maintenance of sterile operating conditions, less tissue handling and reaction, increased precision of dissection and preservation of surrounding normal tissues (Fig. 37.2).

Normally water is the main constituent of tissues, and a living tissue is a complex aqueous solution, containing varieties of molecules. Absorption of laser energy in this water of living tissue (mechanism of action of laser on tissues) depends on the wavelength of this laser light. The larger will be the wavelength, the more will be the absorption of laser light in the water and more will be the production of heat for vapourisation of the tissues. CO_2 laser (10600 nm wavelength) is completely absorbed by water. So, after falling of CO_2 laser on tissues it can not penetrate or pass,

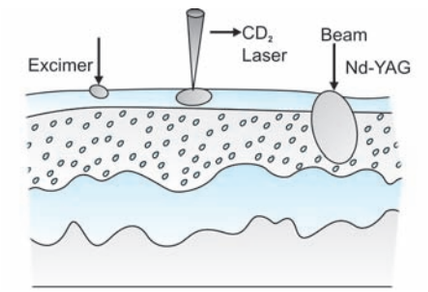

Fig. 37.2: Laser beam of different wavelength causes different patterns of tissue destruction. The actual tissue destruction by laser light depends on both the laser parameters and tissue factors. The laser parameters are: power density, duration, and wavelength. The tissue factors are: Absorption, scatter, thermal conductivity and local circulation

except for a few superficial cell layers of the tissue. Thus, only these surface tissues or cell layers are heated and vapourised with surprisingly little damage to the underlying cells or tissues. Excimer laser is of greater wavelength than CO_2 laser and so has an extremely precise effect on the very superficial cells than CO_2. The Nd-YAG laser is of short pulsed, high powered glass laser which can be transmitted by fibreoptic bundle. The wavelength of YAG laser is 1064 nm and is so less absorbed by water. It is absorbed preferentially by the haemoglobin and pigmented tissues and has deep penetrating effect. So, it can pass through the cornea and is useful in treating the detached retinas. The Nd-YAG laser beam diffuses several millimeters through a tissue which is 100 to 1000 times greater than CO_2 laser. As Nd-YAG laser disseminates widely, so it does not cause heat and vaporisation of tissues, but produces thermal coagulation. Some lasers such as ruby laser has wavelength of 694 nm (very small). So it is also poorly absorbed by tissues except by the cells containing dark pigments. The argon (wavelength 514,488 nm) and krupton (wavelength 476,521,568 nm) gas lasers is transmitted through water though they have large wavelength (so pass through cornea), but intensly absorbed by Hb. It provides the ability to penetrate the skin or occular structures and selectively coagulate the vascular or pigmented regions (also useful in treating detached retinas) (Fact file-I).

FACT FILE - I

Laser light striking the tissue surface may be :

i. Reflected

Reflection of laser rays from the shiny surfaces may damage the eyes of any person in the vicinity.

ii. Transmitted

Laser light which is transmitted through superficial tissues to the deeper layers of variable depth is partially determined by the wavelength.

iii. Scattered

After striking the tissue surface, some laser light scatters. Shorter wavelength induces greater scattering.

iv. Absorbed

After falling most of the laser rays are absorbed by the tissues. This produces the clinical effect by converting the absorbed light into heat. Organic tissues contain various substances capable of absorbing light. Each substances has a particular absorption spectrum which is determined by its chemical structure. Laser light which has the frequencies close to the absorption spectrum of the tissue will be most effective for that tissue.

HAZARDS OR RISKS OF LASER

There are four main risks or hazards of laser surgery. These are:

i. Atmospheric pollution,
ii. Perforation of great vessels or structures,
iii. Gas embolism,
iv. Energy transfer at wrong location,
v. Fire.

Atmospheric Pollution

An important problem during laser surgery is the pollution of enviornment of OT. This is due to the excessive smoke produced during vapourisation of tissues. The plumes of smoke and fine particles, produced during the vapourisation of tissues by laser energy may be transported and deposited in the distant tissues, especially during laryngeal surgery. Here, the smoke and fine particles can be deposited in the alveoli, causing bronchitis, increased tracheo-bronchial secretion, interstitial pneumonia, inflammation and reduced mucociliary clearance, etc. CO_2 laser produces smoke maximally, whereas Nd-YAG laser (contact probe) produces much less. However, the effective method of preventing this dissemination of smoke is immediate sucking of it from the surgical site. Many OT personals may find the odour of this smoke very objectionable and complain of headache, nausea vomiting and irritation due to inhalation of this smoke (Fig. 37.3).

Perforation of Great Vessels or Structures

Sometimes the desired depth of tissue penetration by laser beam cannot be controlled. Thus, it may cause perforation of

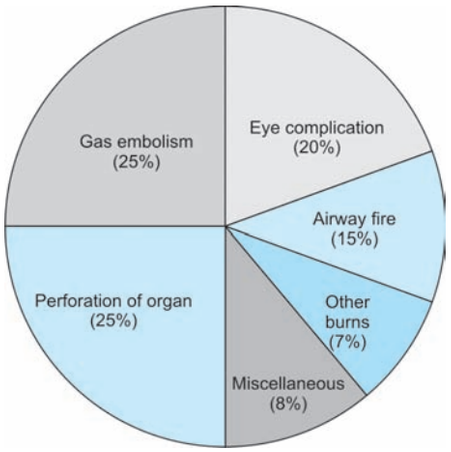

Fig. 37.3: Type and percentage of laser injury

the structure (if it is hollow) or may cause damage to the other tissues and great vessels underneath the said tissue. Vessels greater than 5 mm are not coagulable by laser energy and may cause profuse bleeding. With Nd-YAG laser, it is impossible immediately to assess the depth of injury, until the necrosis of tissues becomes maximal, several days after the laser surgery.

Gas Embolism

The tip of the contact probe of Nd-YAG laser contains a gas as coolant. During hysteroscopic surgery by Nd-YAG laser, if this coolant gas of the probe accidentally leaks and inflates the uterine cavity, then fatal gas embolism may occur. So, the liquid coolant in the laser probe is strongly recommended during the hysteroscopic surgery. If a coolant gas has to be used, then CO_2 is preferred because it produces less damage following embolisation than either N_2 or air. Venous gas embolism has also been reported during section of tumour by Nd-YAG laser in the trachea and during various types of laparoscopic and endoscopic procedures by it.

Energy Transfer at Wrong Location

The misdirected laser energy may perforate the hollow viscous or the large blood vessels, situated by the side of the operative site. For example, laser-induced pneumothorax has been reported following a laryngeal procedure. Similarly pressing the laser control trigger at the wrong time and at wrong site also can precipitate tragic scenarioes including ignition of surgical drapes or burning of a ET tube during airway surgery.

Fire

Laser light can ignite plastic, rubber or any other inflammable materials except metal. So, during the laser therapy of any lesion within airway or at any other site of body a careful consideration should to be given to the fire. This is discussed in more details below.

LASER SURGERY OF LARYNX AND FIRE OF ET TUBE

An important complication during airway surgery by laser is ET tube fire or the anaesthetic gas mixture is catching fire by itself. Laser induced ignition of ET tube or its cuff is responsible for most of the perioperative complications (40%) of laryngeal laser surgery. This is followed by postoperative laryngeal web (20%) and laser related facial burns (10%). Fire during laryngeal laser surgery is due to (i) the proximity of ET tube to surgical sites around the larynx where laser is used, (ii) the use of high energy, delivered by laser light during laryngeal laser surgery and also (iii) the presence of other hydrocarbon materials including plastic, rubber, other PVC material and even tissue except ET tube which can catch fire and burn easily, especially in an O_2 enriched atmosphere.

The CO_2 laser beam can penetrate an endotracheal tube and ignite fire, which would then be supported by O_2 and N_2O gas mixture present within the tube. Usually most fires are located on the outer surface of ET tube causing local thermal tissue destruction. But some times fire can catch the inner-side of tube, without recognition from outside, and produces a blow torch like flame. This is due to the flow of O_2 enriched gas mixture through the tube. In such situation ventilation further blows the hot smoke and toxic products of combustion in the fashion of blow torch like flame down to the pulmonary parenchyma, causing serious lung damage. Again the perforation of ET tube or the puncture of cuff by laser beam causes O_2 enriched gas to flood the operative site and increases the chance of a devastating fire.

So, the fire due to laser can be the result from the following :

i. Direct ignition of ET tube by laser
ii. Indirect ignition of ET tube from reflected laser light
iii. Incandescent particles of tissue, blown from the surgical site.
iv. Ignition of cottonoids or gauze pieces by laser.

So, to reduce the incidence of fire of ET tube, two things can be done.

i. Reduction of inflammability of ET tube by different methods.
ii. Removal of inflammable ET tube from the airway by using Venturijet ventilation by a metallic canula or apneoic anaesthesia technique with intermittent ventilation.

Reduction of the Inflammability of ET tube

The inflammability of ET tube can be reduced by changing the material by which it is made or by adopting some procedures which will prevent the catching of fire of conventional inflammable tube made of PVC, red rubber or silicon. The ideal properties of a laser safe ET tube which will not catch fire should be the following:

i. Noninflammable
ii. Malleable
iii. Thin walled
iv. Disposable
v. Soft, pliable, low pressure cuff
vi. Inexpensive
vii. Electrically nonconductive
viii. Impervious to multiple wavelength of laser beam (Fact file-II)

FACT FILE- II

Thin plastic endotracheal tube cuff is extremely susceptible to laser energy. Simple puncture of the cuff by misdirected laser beam is more common than combustion. Then this unrecognized cuff puncture may lead to enrichment of the area, surrounding surgical site and ET tube, with O_2. This increases the likelihood of catastrophic airway fire. Practically, the laser resistant ET tube cuff which maintain its mechanical properties necessary to minimise the tracheal trauma is not available. Sometimes, it is recommended to fill the cuff with coloured saline which clearly identify the puncture and also helps off the fire. The cuff should be placed as far distal as possible in the trachea from the laser surgical site. Surgeon should completely cover the visible part of the cuff with moist cotton plugs during the laser surgery. The cotton tails attached to the plugs should be replaced by uninsulated wire.

Only metal ET tube is 100% resistant to fire caused by laser energy. But the ET tubes which are made up of only metal have many disadvantages because it can not maintain the mechanical property of conventionally used PVC and red rubber tube. So, ET-tube made up of materials other than metal and conventionally used materials is tried which are less inflammable. But like PVC and red rubber ET-tube they also provide fuel for potential airway fire during microlaryngeal laser surgery though with less incidence and less severity. So, the different types of endotracheal tubes made up of different materials are used and different methods are also employed to prevent fire during administration of anaesthesia in laser surgery. These are:

i. Red rubber endotracheal tube, protected usually by adhesive aluminium or copper foil—most widely used.
ii. Polyvinyl chloride (PVC) endotracheal tube—most susceptible to fire. It can also be protected like above.
iii. Silicon endotracheal tube—less inflammable with laser beam. It also can be protected like above.
iv. Norton (metal) endotracheal tube.
v. Oswal – Hunton (metal) endotracheal tube – enormous cost. So it is rarely used.
vi. Xomed laser shield endotracheal tube
vii. Mallinckrodt laser – Flex endotracheal tube

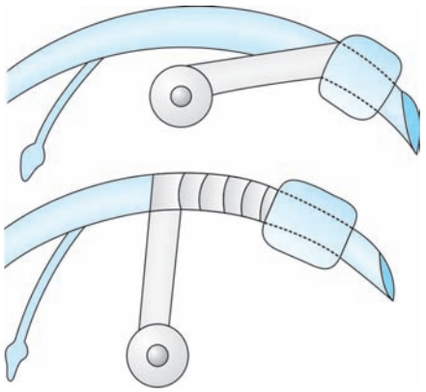

Fig. 37.4: The method of wrapping of ET tube by metal foil

viii. Bivona 'Foam Cuff' laser endotracheal tube.

Red rubber and PVC endotracheal tube

Red rubber and PVC endotracheal tubes are highly inflammable to laser energy. But this high inflammability can be reduced by adapting different methods. Among these the most popular approach is by wrapping the red rubber or PVC endotracheal tube with metallized foil or tape. Three types of foil or tape have been used : aluminium foil, copper foil and plastic tape thinly coated with metal on one side. All these foils and tapes have adhesive coating on one side. These tape and foil are widely available from retail electronics, arts and crafts, or building supplying shops. Lead foil is similar in appearance with adhesive coating on one side, but is very toxic and should never be used in the airway (Fig. 37.4).

These tapes though give protection to the shaft of the tube from laser energy but does not provide any protection to the cuff from fire as the cuff is not included within the wrapping. If the wrapping of endotracheal tube is the chosen method for laser protection, then the technique for wrapping is also important in ensuring the protection from both the ignition of fire and foil or tape induced mucosal abrasions. It is often helpful to first sparingly paint the tube with a medical adhesive such as benzoin. Then, one end of the tape should be cut and wrapping is begun by aliging the cut end

FACT FILE - III

Laser resistant ET tubes are usually bulkier and more rigid than conventional tubes. So, they are more liable to produce mucosal abrasions and requires particular care. Surgeons must be particular that laser energy should not reflect from the smooth metal surfaces of any surgical instrument or metal ET tube and is directed at other sensitive structures.

of the tape with the junction of the tube and the proximal end of the cuff. After that wrapping is done in a spiral fashion with 30 to 50% overlapping between the layers. The wrapping of ET tube with metal foil or metal coating tape should also include the inflation pilot tube and should be continued until just short of the pilot balloon, with care taken not to wrinkle the tape at any point which may cause abrasions of the tracheal mucosa (Fact file-III).

Norton Tube

It is a spirally winded stainless steel endotracheal tube without any cuff. Sometimes separate cuff may be placed at the distal end of this tube. The exterior of the tube has a matte or sand blasted finish. This decreases the reflection of laser beam and hence the incidence of fire is caused by reflected laser beam. The tube has a rough exterior and is of thick walled. The roughness of the exterior of the tube can cause damage to the mucosal surface of airway. The wall thickness is also considered as a disadvantage, since a smaller calibre tube (with further reduction of inner diameter) is usually selected in laryngeal laser surgery. This is because it will allow the surgeon a better exposure. The ET-tube large external diameter (thick) and its stiffness or rigidity (as made of metal especially which are not spirally winded) make the surgical exposure and the positioning of an operating laryngoscope difficult. The norton tube also may not be airtight into the trachea and it is due to the absence of cuff. This could cause contamination of the surgical field with back flowed anaesthetic gases which have a high concentration of O_2 and thus increases the chances of combustion

of tissues by laser energy. During the use of this type of metal ET tube ventilation of patient may also be impaired by the leak at the site of larynx and it is due to the absence of cuff of the tube. Norton tube is more or less similar to Oswal-Hunton ET tube, so the later is not discussed further.

Laser-Flex endotracheal tube

It is made up of flexible stainless steel with a plastic adapter at the proximal end. It has two PVC cuffs on the distal end. The two cuffs can be inflated via two separate pilot tubes. The proximal cuff, when filled with saline, shields the distal cuff from the unintentinal laser beam contact. Therefore, the proximal water filled cuff allows for a tracheal seal and also protects the distal cuff.

Xomed Laser Shield Endotracheal Tube

It is a fabricated ET tube made up of a non-reflective silicone elastomer with an outer layer coated by finely divided aluminium powder. This aluminized powder layer also extends over the inflatable cuff. It is designed to offer protection from CO_2 laser at a power settings below 25 W and at focal diameters of less than 0.8 mm in the pulsed mode only. The tube can, however, be penetrated and perforated by CO_2 laser, if sufficient energy is used. The cuff of this ET-tube is very thin and is easily punctured by CO_2 laser. Penetration and ignition of the xomed tube by laser required higher energy than either red rubber or the PVC tubes. However, the prohibitive cost and the possibility of silica ash (if set on fire) which causes extensive damage to the lungs than the PVC or red rubber ET-tube (if they caught fire) are points against the use of xomed tube (Fact file-IV).

FACT FILE - IV

It has been found that during laser resection of tumour, carbon monoxide is evolved in the smoke. Patients undergoing laser resection of an airway tumour by venturi jet ventilation can absorb this carbon monoxide through lungs. This CO may result in false overestimation of arterial O_2 saturation in pulse oximetry. Jet ventilation without ET tube usually provides adequate ventilation without introducing large obstacles or inflammable material at the surgical field. This is a great advantage. But the potential disadvantages of it include : barotrauma, pneumothorax, gastric distension, only dependence on IV anaesthetic agents, applicable only for compliant lungs.

Bivona 'foam cuff' laser endotracheal tube

This ET tube features a metal aluminium spiral tube in core which is covered with silicone from outside and a cuff made of foam. The 'foam cuff' consists of polymethane sponge with a silicone envelope. The tube is inserted initially after aspirating all the air out of the foam cuff and it is squeezed. Then once the tube is inserted, the pilot tube is simply left open to the air. The cuff inflates automatically without air having to be injected. Inflation of the foam cuff with saline solution is however recommended for CO_2 laser surgery. The pilot tube runs along the outside of the wall of the main tube and is marked in black, so that it can be positioned away from the laser beam. A distinct advantages of this ET tube is that the foam cuff will still remain inflated even when it gets struck by the laser beam. This feature allows continued IPPV and also causes separation of anaesthetic gases enriched with O_2 from the surgical site which catch fire.

Type of Ventilation when ET-tube is not used for Reduction of Incidence of Fire

A. Venturi jet ventilation by metallic cannula

This is a very simplest form of ventilation avoiding reducing the use of ET tube and thus subsequently reducing the risk of fire altogether. This procedure involves the use of a high pressure jet of O_2 and subsequently the entertainment of it by atmospheric air. The metallic injector or canula for O_2 jet is placed into the lumen of a rigid laryngoscope or bronchoscope, which are placed in larynx and are open at both ends and permits entrainment of O_2 with air during inspiration and escape of CO_2 during expiration while the patient is in muscle relaxant. This system is safe and reduces the chance of barotrauma producing pneumothorax. Intravenous anaesthesia is usually emplyed to ensure an adequate depth of anaesthesia during venturi jet ventilation as only the O_2 and air without any gaseous anaesthetic mixture is used for ventilation. In such situation the depth of anaesthesia is very important, because it prevents the patient from moving and coughing during the surgical procedures using laser. So, a suitable muscle relaxant should be used and the depth of neuromuscular transmission is monitored with a nerve stimulator.

B. Apnoeic anaesthesia technique with intermittent ventilation

The need for an alternative technique of ventilation for laryngeal laser surgery was felt because of the shortcomings (mentioned later) of the conventional technique of ventilation by ET tube and the venturi jet ventilation by metallic cannula. Thus, the apnoeic anaesthetic technique with intermittent ventilation provides a good alternative as it allows the intermittent withdrawl and insertion of ET tube and permits unhindered surgery by laser in the interval. In this procedure the muscle relaxant must be used to maintain the adequate depth of anaesthesia. The withdrawal of endotracheal tube connotes the apnoeic phase. Laser surgery is done in the apnoea period in between two ventilatory spells through ET tube by reinserting it. Such an approach totally eliminates the risks of airway fire, barotrauma and other complications associated with endotracheal tube and eliminates the disadvantages of jet ventilation by metallic cannula (as enriched O_2 enviornment around the surgical site causes fire), besides providing a clear and unobstructed view of the laser site to the surgeon. But hypoxia, hypercarbia during apnoeic phase and their associated complications are the inherent dangers of this technique. However the risks are largely held in check by the alertness of concerned anaesthetist, judicial use of monitors and their interpretations, along with in depth understanding of the physiology of respiration.

In this type of anaesthesia, the ET tube is removed intermittently and surgery is done after removal of the tube. Then, again ET tube is reinserted and ventilation is resumed when SPO_2 falls. This insertion and removal of ET tube is done in cyclical manner. Before removing the tube N_2O is switched off and the patient is ventilated with 100% O_2 with isoflurane mixture in order to achieve a high PaO_2, although an SPO_2 is of 100%. Sevoflurane is not generally used in this procedure, because it is very short acting and the adequate depth of anaesthesia cannot be maintained for the desired period. Halothane is also not used as it is phasing out due to its propensity causing arrhythmia. Supplemental doses of thiopentone and muscle relaxant are given when required. After induction, intubation, and placement of operating bronchoscope or microlaryngoscope as a first step of this apnoeic anaesthetic technique, the endotracheal tube is gently withdrawn without disturbing the position of microlaryngoscope. This marks the begining of the 1st apnoea phase. The surgeon now starts excising the lesion with laser which is now clearly visible and accessible to him, because of no hinderance by the ET tube or metallic cannula for O_2 jet. Also there is no risk of fire, since there is no combustible material and O_2 rich anaesthetic mixture at the surgical site. The endotracheal tube is reintroduced after the apnoeic phase through the suspension of laryngoscope and ventilation is resumed when there is:

i. Sliding down of SPO_2 to 93% (allowing for an after drop to 90%)
ii. Apnoeic period beyond 7 minutes.
iii. Any severe arrhythmias or obvious ST segment changes
iv. Extremes of HR and BP
v. Compulsory stoppage of surgery at intervals to allow the laserised area to cool and also to allow the suction and evacuation for clearing off the excessive smoke and charred tissue that accumulates.
vi. Completion of the laser excision.

At the end of first and subsequent apnoeic phase, ET tube is further reintroduced. Thus resumption of ventilation is done with 100% O_2 and hyperventilation is performed for first few seconds in order to correct the arterial desaturation and to wash off the accumulated CO_2. This is followed by ventilation of patient with O_2 and isoflurane mixture till SPO_2 reaches 100% and ET CO_2 comes down to 30 mm of Hg. The ET tube is then again withdrawn and the next episode of apnoea and surgery begins. Thus these cycles of ventilation – apnoea – ventilation continues till the surgeon achieves a satisfactory clearance of the disease. Towards the end of surgery isoflurane is switched off. Satisfactory SPO_2 and ET CO_2 level is achieved with ventilation. Patient should receive steroid as prophylaxis against postoperative laryngeal oedema. The microlaryngoscope is removed and the patient is intubated with normal size conventional oral cuffed endotracheal tube. Then neuromuscular block is reversed by neostigmine with atropine sulphate and the patient is extubated (Fact file- V).

No ET tube is safe for laser except metal. ET tubes of all materials except metal are infact quite vulnerable to fire and the vulnerability of different types of tubes (red rubber, PVC, silicone) depends on the type of laser. For CO_2 laser PVC tube is most vulnerable and then red rubber and silicone tube. But red rubber tube produces more toxic combustion products than PVC tubes. Silicone tube is most resistant to ignition than the other two varities but produces copious white silica ash if it catch fire, suggesting the potential for late development of silicosis. For Nd-YAG laser PVC tube is resistant (*in vitro*) as it is transparent. But during practical use any coating of mucuous and blood on PVC tube will absorb laser energy and does not make it safe, catching fire.

AIRWAY FIRE PROTOCOL

The incedence of ET tube fire during the laser assisted airway surgery is estimated to be in the range of 0.14 to 1.5%. During laser surgeries surgeons also should take the responsibility to prevent fire. They should set the laser power as low as possible (10 to 15w) and use the noncontinuous mode. They must always use wet gauzes to protect the nontarget tissue in the surgical field and the cuff of ET tube. Between the repeated pulses of laser, sufficient time should be allowed to disperse the heat. Nitrous oxide and oxygen mixture is known to support the combustion. So, the FiO_2 should be kept as low as possible as the patient's O_2 saturation of haemoglobin permits (usually between 0.25 to 0.3). Some anaesthetists avoid the use of

FACT FILE - V

As ET tubes of any material such as PVC or red rubber or silicone (except metal) are not resistant to laser so protection of tube from fire by laser should be given at first. Initially, the protection of tube by wrapping it with moistened muslin or dental acrylic was tried. But problem is that when the muslin is dried, it becomes highly inflammable by the laser. On the other hand, the dental acrylic makes the tube hard and rough (outer surface) and may cause trauma to the mucuous surface of larynx. So, the best approach to the problem of fire by laser is by wrapping the nonmetallic tube (PVC, red rubber and silicone) with metallised foil tape. The metallised foil tapes, which are in use are of aluminium and copper with adhesive on one side. But these metallised foil tapes do not provide protection to the cuff of the tube and is not 100% resistant to all types of laser. So, now Mercel laser guard tape (approved by FDA) consisting of an adhesive metal foil laminated on a synthetic sponge surface is used and provides protection against most of the lasers. But it can not protect the cuff. There is another ET tube (FDA approved) which uses integral laser resistant metal coating during the manufacture of the tube.

Laser resistant cuff that will maintain the mechanical properties and also will minimise the tracheal trauma are not yet available. The air filled ET tube cuff is highly susceptible to misdirected laser. Simple puncture is more common than fire of the cuff. Unrecognised cuff puncture causes leaking and enrichment of the ventilating O_2 around the surgical site and hence more likelihood of airway fire. So, to prevent the cuff injury, it should be placed in the trachea as distal as possible from the surgical site and the visible portion should be moistened by cotton pledgets continuously by surgeon. Many authors recommend filling of the cuff with saline, coloured with methylene blue which will help to detect the rupture of cuff.

N_2O and use air / O_2 mixture. Altenatively, helium / O_2 mixture can be used.

Whatever the type of ET tube is used, the cuff should be inflated with sterile saline to which methylene blue may be added. This is because the methylene blue will help to detect the cuff rupture easily by a misdirected laser beam. Also the cuff should be placed as far distally as possible, so that it is out of the line of target of laser. Though sudden airway fire and explosion usually incapacitate all the operating room staff temporarily, still surgeon and anasthetist must act quickly, decisively and in a very coordinated fashion. Usually surgeon detects the fire first. So he should stop the laser as soon as he will detect the fire and inform the anaesthetist immediately. Anaesthetist immediately stops ventilation, disconnects the circuit from the anaesthetic machine and extubates. Before extubation pharynx should be flushed with water. So, as a source of water a 50 ml syringe, filled with cold saline, should always be immediately available. These manoeuvres will remove the flame and stop the flow of O_2 enriched gas to the burning site. After extubation the flaming tube should be diped into a bucket of water which should always be available in OT during laser surgery. Then, ventilation should be done with 100% O_2 by mask. After that direct laryngoscopy and rigid bronchoscopy should be performed to assess the damage and to remove all the debris. If the fire is of interior blow torch type, then fibre-optic assessment of distal bronchial damage (if available) and gentle bronchial lavage is necessary. If the airway damage is severe and artificial ventilation is needed for proper management of complication then patient should be reintubated for ventilator management or tracheostomy should be done.

Pulmonary damage due to heat or smoke inhalation also necessitates prolonged intubation and mechanical ventilation. Pulmonary damage from heat and/or smoke inhalation should be assessed by taking repeated arterial blood gas samples and repeated chest radiographs. Late complications from airway fire include the formation of granulation tissue or stenosis in the larynx and/or trachea. So a brief course of high dose of steroids may be helpful. Fortunately, in most of the cases small fire involves exterior of the tube and does not cause appreciable damage of the local tissue. In case of difficult airway, leading to difficult intubation during induction of anaesthesia the tube should not be removed immediately. Because there is further fear of difficult reintubation or failed intubation and hypoxia. Here, all the above mentioned steps should be taken immediately to stop the fire and the patient is not extubated. Instead, the tube and trachea should be flushed with water. After flushing and extinguishing the fire, a tube exchanger is inserted through the lumen of the previous tube and the burn tube is removed. Then another ET tube is inserted over the tube exchanger.

LASER SAFETY PROTOCOL

In every hospital where laser is used for different surgical procedure should have a laser safety protocol. This protocol is described below:

i. A designated trained laser safety officer must be present continuously in OT when a laser machine is in use. An indicator light must be displayed outside the operation theatre when the laser is in play.
ii. Laser light is usually reflected off from the mirror like shiny exterior smooth surfaces metal instruments and metal ET tube. So, all the surgical metal instrument and tube used during laser surgery should have matt exterior surfaces, rather than shiny.
iii. The eye is the most susceptible part of body for injury by laser. So, all the operating room personnel must use safety glasses. These should have side shields. It will protect the lateral aspect of eye. If an anaesthetised patient is scheduled to recive laser therapy close to the eyes, then a protective metallic eye cover with matt finish should be applied. Otherwise, the eye should be taped closed and covered with moist swabs.
iv. Damage to the skin by laser beam can also occur. But it depends on the type of laser in use. The OT personnels do not normally need to protect against skin damage. Because they will be able to move away from the path of an misdirected laser beam. But the anaesthetised patients must have all the exposed skin covered with drapes, except the surgical site because they cannot move. The drapes should be made of absorbable material and not plastic which is potentially highly combustible. Plastic drape is much more combustible than canvas type drapes. So, it should be avoided. Tissues adjacent to the surgical site should be protected with moistened gauzes or swabs.
v. Some fluids used for skin preparation during surgery also are in flammable. So, these should not be used during laser surgery.
vi. Efficient smoke evacuation system must be maintained close to the surgical site.
vii. During the laryngeal laser surgery conventional ET tube made of PVC or red rubber should be avoided if possible in fear of fire and ventilation is maintained by venturi principle. If in any circumstances the use of an ET tube can not be avoided then specially prepared non-flammable laser tubes are used or tracheal tube protector such as metal foil or metalised tape can be wrapped around the conventional tubes which are discussed before.
viii. All the airway fire protocols should be maintained.

38 Anaesthesia for ENT Surgery

INTRODUCTION

The patients who have undergone ear, nose and throat (ENT) surgery are usually young and healthy adult. But the patients approached for laryngeal operation or throat surgeries are usually older. Previously most of the operatins in ENT department were done as indoor cases. But, now-a-days many ENT operations are performed as day cases under LA or under fast track GA. Thereby, the need for in-patient admission for ENT surgery is reduced and also the workload on the ENT anaesthetic department has been lowered.

Children and young adults are apprehensive. So, if they are chosen for ENT surgeries under LA, they require extensive reassurance and exhaustive counselling or they need GA. Some of them may have an atopic history which influences the anaesthetic technique, if GA is required. Older patients for laryngeal operations usually have hypertension, IHD (ischaemic heart disease) and other co-existing diseases. So, they require proper perioperative care as most laryngeal operations are done under GA.

During ENT operations under GA, two things should be taken in mind by an anaesthetist. These are smooth anaesthesia and clear airway. Because most of the ENT operations are now done under microscope. So, a very smooth and deep anaesthesia is needed which will help to avoid coughing, straining, bucking, etc. that occurs under light anaesthesia and causes venous congestion and increases bleeding and spoils the goal of microsurgery under a high powerful microscope. Operations on nose and throat but not ears involve the airway, and both the surgeon and the anaesthetist work on this airway, fighting with each other and causing complete or partial obstruction of airway. Complete airway obstruction is a life threatening condition. Partial obstruction of the airway may lead to hypoxaemia and hypercapnia. So, maintenance of clear airway by an anaesthetist is very crucial for ENT surgeries. Patient's eye should be protected from corneal abrasions in all ENT procedures.

GENERAL PRINCIPLE

An anaesthetist, during preparation of the patients for ENT operations under GA will be concerned with the following particular problems.

1. The provision for satisfactory pulmonary ventilation while permitting adequate surgical access for the nose and throat surgeries, because the airway is shared by both the surgeon and the anaesthetist in such surgeries.
2. The prevention of aspiration of blood, pus or other materials into the lungs during nose and throat surgeries.
3. The provision of good operating conditions for microsurgery of the ear and larynx.
4. Care of patients undergoing major surgery of the head and neck.
5. Maintenance of the airway in upper respiratory tract obstruction – partial or complete.

Sharing of Airway

Problems arise when the airway is shared by both the anaesthetist and the surgeon. But, these are usually solved by the following ways. For nasal operations, the problem is solved by the passage of an oral endotracheal tube. Surgeon usually approaches the nose from the patient's right hand side. So, it will be helpful to shift the endotracheal (ET) tube to the left side of the patient's mouth.

For oral operations, e.g. tonsillectomy, where the surgeon uses mouthgag and tongue blade, the airway problem is solved by an anaesthetist by the use of nasotracheal tube which will give a clear oral surgical field to the surgeon without compromising the airway. But sometimes, nasal intubation is difficult, due to the presence of some nasal obstruction or is undesirable in small children or if postnasal space is required during surgery, then in that situation, adequate surgical exposure and an unobstructed airway can also be provided by an anaesthetist by the presence of an oral endotracheal tube with the use of Doughty's modifications of Boyle-Davis gag. In this modification, the ET tube lies comfortably within the slot of the tongue plate of Boyle-Davis gag and does not obstruct the surgeon's view. However, sometimes the ET-tube is also compressed by the tongue plate of Boyle-Davis gag which is detected during IPPV by the decrease in compliance of lungs and the increase in inflation pressure or in spontaneously breathing patients by decreased movement of the reservoir bag.

This difficulty can be corrected by using a long metallic special connector with larger portion of it inside the tube. This will prevent the compression and subsequently the obstruction of the tube.

Prevention of Aspiration

In oral, laryngeal and nasal surgery, not only the restoration of airway, but also the protection of airway from aspiration during anaesthesia (if intubated or non-intubated) and the quick restoration of the postoperative protective laryngeal reflexes after extubation should be in the forefront of an anaesthetist's mind.

Although, a cuffed ET-tube provides a larger protection from aspiration, still it is possible for blood to collect in a pool above the cuff and may enter the lungs when the cuff is deflated, either deliberately at the end of the operation for extubation or accidentaly anytime. Therefore, it is an usual practise to insert a well lubricated gauze pack into the pharynx or around the laryngeal inlet above the cuff of ET-tube before the nasal or oral operations is started.

For quick restoration of the postoperative protective laryngeal reflexes, the following measures are usually taken. It is generally agreed that preoperative medications with long acting opiate drugs has a depressant effect on laryngeal protective reflexes. So, better it should not be used where a quick return of reflexes are desired. But the use of narcotics is not absolutely contraindicated. It depends on an anaesthetist's judgement. For example, the newer short acting opioids like fentanyl and its congeners, especially remifentanil can be used safely. Again local anaesthetic agents applied topically either in the form of spray or gel may reduce the integrity of the laryngeal protective reflexes and should be avoided. However, this is also not absolutely contraindicated. On the whole, the conduct of GA should obviously be designed in such a fashion that it will ensure rapid return of the swallowing and cough reflexes (i.e. protective laryngeal reflexes) at the end of the each ENT surgical procedure. There is little objective evidence of the superiority of any particular anaesthetic technique in this respect. So, an anaesthetist must apply his or her own judgement and assessment of the preferable method, but ensure that the depth of anaesthesia will not be very light intraoperatively causing cough, ↑BP ↑HR, increased bleeding at operative site, etc; which is very troublesome specially during microsurgery.

Postoperatively, the likelihood of aspiration is also reduced if the patient is placed in the lateral position with head tilted slightly down. At the end of every ENT surgery the pharynx should be sucked out completely under direct vision and there should be evidence that the reflex activity of larynx has returned before the ET-tube is removed. The partial incompetence of the laryngeal closure reflex may persist for two hours after extubation, even after the relatively short duration of anaesthesia. So, the practice of maintaining the lateral position and avoiding the fluid intake for 2 hours postoperatively is important. It should also be borne in mind that a progressive impairment of protective laryngeal reflexes occur with advancement of age.

PREOPERATIVE EVALUATION AND AIRWAY ASSESSMENT

Since, anaesthesia in ENT surgeries is very challenging, so the proper preoperative evaluation and the proper airway assessment of every patient by proper history, clinical examination and investigation is very vital.

History

1. Many preparations of antihistamines and certain other medications which are used rampantly in patients suffering from common cold may contain aspirin. So, a special attention should be given to the platelet function tests and coagulation profiles preoperatively in these patients.
2. Polyps and other causes of nasal obstructions, for which the patients come for surgery, may make the ventilation by mask very difficult. Hence, clinical examination for the above causes and airway assessment for obstruction in these patients is mandatory.
3. Stridor is a common ENT problem. So, it requires direct laryngoscopy or bronchoscopy for preoperative airway evaluation of patient. Age of onset, cause, and positions of patients that make the stridor better or worse should be evaluated well. Along with the stridor some other symptoms such as wheeze, cyanosis, chest retraction, nasal flare, etc; which indicate some form of airway obstruction should also be carefully noted preoperatively.
4. Patients with longstanding history of stridor, haemoptysis or hoarseness of voice are usually booked for diagnosis by endoscopy or are booked for major surgery (when diagnosis is confirmed beforehand and it is usually malignancy). These patients are usually elderly with significant comorbidity. For example, COPD, CVS disorders, anaemia, alcoholism, smoking, etc, are commonly associated problems with these patients. So, the assessment of all the risks in these group of patients, preoperatively, is very important for better perioperative management.
5. Endocarditis from recurrent streptococcal bacteraemia due to infected tonsil or due to other infected focus in body such as in ear, throat or nose is not uncommon in patient especially children scheduled for ENT surgeries with cardiac vulvular disease. So, during anaesthesia of ENT surgery anaesthetist should be careful about it.
6. Prolonged preoperative airway obstruction, presented for ENT surgery, specially in children, causes chronic hypoxaemia, hypercarbia which may lead to corpulmonale. So, all these should be taken into consideration before anaesthesia. Along with corpulmonale right ventricular hypertrophy, cardiomegaly,

pulmonary artery hypertension, ventricular dysfunction, and cardiac arrhythmia are some possible complications of these patients who are suffering from chronic airway obstruction. So, proper evaluation of these patients by an anaesthetist before being put up for ENT surgery is vital.

7. Enlarged tongue or tonsil and/or adenoid make a patient more prone to the obstructed sleep apnoea syndrome (OSA). These syndrome consists of periods of absent nasal and oral airflow during sleep, despite continuing respiratory effort. This is at least partly due to the backward movement of tongue and pharyngeal wall collapse (glossoptosis) secondary to the interference of the normal coordinated contraction of pharyngeal and hypopharyngeal muscles. These OSA patient are at increased risk of airway obstruction specially duing induction and recovery phase of anaesthesia. So, vigorous clinical monitoring, use of different airway devices (nasopharyngeal or Guedel) or carrying out induction and recovery in sitting or lateral position etc. may minimise the risk of OSA syndrome and can reduce the complications due to airway obstruction.
8. Most patients who are sheduled for ENT surgeries such as tonsillectomy, adenoidectomy, or maringotomy with tube insertion, etc, are usually present with chronic URTI, especially children. But, here postponement of surgery due to chronic URTI is not recommended, since removal of the infected focus is important to resolve this chronic URTI.

Airway Assessment

Before bringing the patient to OT, an anaesthetist must try to ensure whether problems will precipitate or not from the airway. Preoperative airway assessment should start from the history of airway diseases – such as abscess, tumour, infection, trauma, the presence of postirradiation or postsurgical scarring, or any postoperative difficulty of airway from record of previous anaesthesia, etc. After history, proper assessment of airway is next done by physical examination of patient. The physical examination include: (i) general appearance of the patient-gross deformities of head and neck, obesity, etc, (ii) observation of type of patient breathing – stridor, mouth breathing, wheezing, etc. (iii) inspection of mouth and chin – extent of opening of mouth, loose teeth, size of tonsil, size and mobility of tongue, micrognathia, Mallampati score, etc. (iv) inspection of nose – nasal obstruction, mucosal congestion, deviated nasal septum, etc. (v) inspection of neck and larynx – short neck, position of trachea, mobility of cervical spine, mobility of atlanto occipital joint, thyromental distance, goitar, etc. Indirect laryngoscopy can be carried out before surgery for extra information of the airway. If it is needed, the help of CT scan and MRI may be taken for the proper assessment of airway. If there is any substantial doubt about the airway, one has to consider special technique for intubation such as awake intubation, intubation for accessory devices fibre optic intubation or performing a tracheostomy under local anaesthesia before induction of anaesthesia.

PREOPERATIVE MEDICATION

Narcotics or Opioids

The disadvantages of opioids as premedicant in ENT surgeries have already been mentioned in previous discussion. These disadvantages of opioid are also compounded by the fact that operation on the middle and inner ear may themselves be associated with nausea and vomiting which may be exaggerated by these narcotics or opioids used during premedication. Keeping all these in mind, it is still justified to use narcotic analgesics where it is necessary such as to relieve severe pain preoperatively, to maintain an intraoperative stable haemodynamic condition and for preparation of a major ENT surgery such as for malignancy.

Sedatives and Tranquillisers

Among the sedatives and tranquillisers benzodiazepines are the most widely used drugs which are very effective in relieving anxiety when given by mouth, preoperatively. They produce both the sedative and amnestic effect. The commonly used benzodiazepines are diazepam, lorazepam, alprazolam and midazolam. In children, trimeprazine and promethazine are also very popular drugs as premedicants. It provides sedative, antiemetic, antisialogogue and amnestic effects.

It is always worthy by re-emphasizing that frequent pre-anaesthetic visits to an anthetist's clinic by patient and his relatives and are associated with a reduced incidence of nervousness and apprehension. Thus, it also reduces the dose of preoperative sedatives.

Anticholinergic

Although, there are some objections to the routine use of atropine before anaesthesia, but ENT surgeons find it very helpful to have a dry mucous membrane when they are operating on the nose and throat. This may only be achieved by the use of atropine or glycopyrrolate preoperatively by IV route. But before induction and institution of an IV route in case of children IM route is the only option. If atropine is contraindicated or tachycardia is not desired, then glycopyrrolate is the best alternative or perhaps is the first choice. It should be given IM at least 30 minutes preoperatively. IV administration of atropine or glycopyrrolate at the time of induction is not seen to be so effective.

Antiemetic

Although, there may be an increased incidence of nausea and vomiting after aural operations, still it is questionable whether routine use of antiemetic drugs is justifiable or not. This is because many

patients may be subjected to unnecessary antiemetic therapy. Therefore, it may be thought reasonable to prescribe them only when a patient complains spontaneously of previous postoperative vomiting, although there is no drug that can gurantee success. Drugs which are successful in the treatment of motion sickness are likely to be successful antiemetic after operation on ear such as cyclizine and prochlorperazine (stemetil).

ANAESTHETIC AGENTS

Inducing Agents

Any of the inducing agents that are used for induction of anaesthesia in other discipline of surgery can be used for ENT surgeries. So, it does not need any special discussions.

Muscle Relaxants

ET-intubation is needed for most of the ENT surgeries where GA is applied. But this should be performed with the background in mind of obstructed airway and possibilities of difficult intubation. So, obviously suxamethonium is the choice to facilitate intubation where possible difficulty of it is anticipated. But the choice of relaxants for the next part of the operation after intubation and reversal from suxamethonium is influenced by the expected duration of that part of operation. For shorter procedures, supplementary doses of suxamethonium may be given by intermittent bolus doses or by infusion. If operation is longer than 30 minutes duration, then a non-deporizating relaxant is preferable. On the other hand, muscular relaxation is not an absolute prerequisite for ENT surgeries. So, anaesthesia can be maintained by volatile anaesthetics and spontaneous ventilation after intubation.

Nitrous Oxide

Like other surgeries, N_2O also plays an integral part in the anaesthetic gas mixture used for the majority of ENT operations. But, in middle ear surgery its use has definite disadvantages. Since, N_2O is 34 times more soluble than nitrogen in blood, so during N_2O anaesthesia, N_2 molecules leaving from air cavities in the body are replaced by greater number of molecules of N_2O. Therefore, if the cavity is not distensible (e.g. middle ear), then there will be a constant rise in pressure in it; which may reach maximum after 30 to 40 minutes of the onset of inhalation of N_2O. When N_2O is withdrawn, it takes also a similar time for the pressure to return to normal. Hence, during certain types of tympanoplasty, variation of pressures of this magnitude may cause the instability of graft (dislodgement of graft). So if N_2O is used , it should be turned off some 30 to 40 minutes before the expected completion of surgery.

Alternatively, N_2O should be omitted altogether and anaesthesia should be maintained with volatile agents, O_2 and air (which should be used in place of O_2/N_2O gas mixtures). However, recently, surgical techniques have been improved and modified over the years, so that an increase in middle air pressure has no longer any importance and does not influence the result of surgical procedure. It is, therefore, no longer necessary to turn off the N_2O before the end of surgical and anaesthetic procedure.

Halothane and Other Volatile Anaesthetic Agents in ENT Surgeries

Like other surgeries halothane is also the most commonly used volatile anaesthetic agent in ENT surgeries, both during controlled and spontaneous ventilation. Whereas most ENT surgeons wish to use adrenaline as topical or locals injectable forms for vasoconstriction which makes the field dry. But it is well-established that adrenaline in the presence of halothane may induce different cardiac arrhythmias, even ventricular fibrillation. So, to balance between the use and the non-use of adrenaline, the present dictum is that adrenaline can be used safely with halothane, provided there are limits to its concentration and dose used in a given period, and hypoxia and hypercarbia are avoided, or the two drugs should never be used simultaneously i.e. when adrenaline is used halothane should be turned off. Alternatively the surgeon should be aware of the properties of other vasoconstrictors such as octapressin, ornithine-8-vasopressin (POR-8), etc, which are more compatible with halothane. Otherwise, other volatile anaesthetic agents such as sevoflurane, isoflurane, etc. are better choice than halothane in the presence of adrenaline as they maintain a good haemodynamic stability and there is less chance of arrhythmia.

Anaesthetic Circuits

The anaesthetist must keep himself out of the surgeon's way during the ENT surgeries. So, it could be inconvenient to use equipment with an expiratory valve close to the patient which may need frequent adjustment. Hence, this would preclude the use of Mapleson-A circuit, Ruben valve or a miniature ventilator. So, it indicates the use of circle system in adult or T-piece arrangement in children. However, the Bain anaesthetic circuit which is a co-axial system with the expiratory valve on the bag mount, is particularly useful in these conditions.

Induced Hypotension

Most of the ENT surgeries are performed with the help of microscope. So, it is argued that even a small amount of blood would be magnified under the operating microscope and this will make the microsurgery difficult and does not allow the surgeon to take the necessary decision for a successful outcome. Hence, in order to minimise the bleeding (especially during microscopic surgery) it has long been advocated that one should induce deliberate hypotension, aiming at mean arterial blood pressure around 50 to 55 mm of Hg. This can be

achieved by using drugs such as sodium nitropruside, nitroglycerine, hydralazine, betablockers etc. On the otherhand, induced hypotension has a potentially harmful effect on the cochlear blood flow during otological surgery. Autoregulation is also lost during controlled hypotension.

Experienced practitioners have used hypotensive techniques for many years with impressive safety. But, even when adequate precautions are taken, still controlled hypotension is not free of complications. These complications, however uncommon, may become major problems involving the heart and CNS. So, the goal of induced hypotension should be diminished bleeding, rather than an absolutely bloodless field. Again newer reports say that there is no correlation between the blood pressure and quality (i.e. dryness) of the operative field. So, individual anaesthetics and surgeons vary in their views and their desirabilities.

An anaesthetist should not practise unnecessarily the hypotensive technique on his patients and also the surgical colleagues should not force to practise it against the anaesthetists will. For those anaesthetists who are unwilling or insufficiently experienced to use the hypotensive method, a modified hypotensive technique can be achieved. This is based on the clear airway, controlled ventilation with halothane, absence of straining, use of topical vasoconstrictors and moderate degree (15°) of head-up tilt. Another best way to reduce the surgical bleeding during microscopic surgery is (usually) to combine the use of opioids with isoflurane or sevoflurane in a N_2O/O_2 or air/O_2 gas mixture. This is titrated to maintain a systolic blood pressure at around 90 mm of Hg. The total intravenous anaesthesia with propofol as the main agent can also be used. The advantages of using propofol for ear operations are its lower incidence of postoperative nausea and vomiting, the reduction of blood pressure without a compensatory increase in heart rate, the preservation of autoregulation of inner ear blood flow during controlled hypotension and its excellent recovery profile.

Blood Loss

Blood loss in most ENT operations is small, with obvious exception for major head and neck surgeries especially for malignancy. For example, in majority of adenotonsillectomy operation in children the blood loss is less than 10% of the estimated total blood volume of the body. Sometimes, up to 20% of the estimated total blood volume of the body may be lost during operation. So, in such circumstances if postoperative haemorrhage (if occur) is added to this loss, then blood transfusion should be given to this patient. An experienced anaesthetist usually can estimate the amount of intraoperative blood loss by visual impression. But, if there is any doubt, then it is a simple matter to get some estimation of blood loss by weighing swab and measuring of the contents of suction bottle.

Laryngeal Mask Airway (LMA)

Now, instead of ET-tube, the LMA has been used for many types of ENT surgeries. But to justify its use, the anaesthetist must be able to explain that it has some advantages over the traditional use of an endotracheal tube for that particular case. After the introduction of a flexible reinforced version, LMA is now gradually becoming very popular in ENT surgery. This fexible reinforced version has many advantages in comparison to standard classic LMA. These advantages which make the flexible reinforced LMA more useful in ENT surgeries are: (i) it is more resistant to kinking and obstruction caused by oropharyngeal instruments (e.g. mouth gag), (ii) it is less likely to be displaced during movement of head and neck, (iii) it can be connected to a breathing system at any angle.

Gradually, LMA itself is becoming an important anaesthetic tool in ENT surgery because it can be inserted blindly without the need of muscle relaxant in a spontaneously ventilating patient where there is any chance of difficulty or failed intubation. Another advantage of LMA over ET-tube during ENT surgery is that coughing which increases the risk of rebleedding or displacement of grafts after ear surgery can be avoided. This is because LMA is better tolerated and associated with less coughing in comparison to ET-tube. Another advantage of LMA over ET-tube is that in case of an expected prolonged recovery, following a major surgery of head and neck, the trachea can be extubated in deep plane of anaesthesia and then a LMA can be inserted further to maintain the patient's airway during the prolonged recovery period. This technique will also help to reduce the incidence of postoperative coughing and subsequently bleeding.

INDIVIDUAL SURGERY

Tonsillectomy

The age of most of the patients scheduled for tonsillectomy operation are less than 15 years and most of these children attend hospital on the day of surgery. During routine preoperative anaesthetic evaluation of these patients, special emphasis is given on checking for loose tooth, recent ingestion of aspirin and determination of coagulation profile. As discussed before, the use of premedication is also debatable in tonsillectomy operation, because some anaesthetists like them and some do not. If premedication is given, it is administered most conveniently to the younger child as syrup of trimeprazine (1.5 mg/Kg) or promethazine (1 mg/Kg) or diazepam (0.2 mg/Kg) and atropine (0.02 mg/Kg) orally.

The aims of different techniques of anaesthesia for elective tonsillectomy are:

1. To provide deep anaesthesia that prevents reflex tachycardia arising from surgical stimuli in light plane of anaesthesia and cardiac arrhythmias. This is because one of the important intraoperative complication in tonsillectomy

is arrhythmias which is caused by the increased levels of endogenous epinephrine from light general anaesthesia and sensitization of myocardium to this catecholamine.

2. To provide adequate muscle relaxation which will allow easy placement of mouth gag.
3. To prevent bucking, coughing or straining.
4. Rapid recovery to consciousness and also rapid return of protective airway reflexes.

Most of the children who are presented for tonsillectomy surgery are younger enough and allow an IV induction of anaesthesia. But in some children with poor venous access, inhalation induction may be preferred followed by IV access. Oral or nasal intubation is facilitated by succinylcholine or performed under deep inhalational anesthesia.

Anaesthesia for tonsillectomy is usually maintained by using N_2O, non-depolarising muscle relaxants and narcotics with or without volatile anaesthetic agents. A topical spray of 4% lignocaine on tonsillar operative area or infiltration of 2% lignocaine at surgical site will help to decrease the general anaesthetic requirements, the incidence of arrhythmias, and postoperative stridor and laryngospasm. Blood loss should be replaced, if it exceeds 10% of the circulating blood volume.

Tracheal extubation is performed with the patient's head slightly down in a lateral position, and after complete suction which ensures that the pharynx and larynx is free from blood secretions and tissue debris. Extubation may be done either under deep anaesthesia or when the patient is fully awake. When 'extubation is done under deep anaesthesia' to prevent cough, vomiting, laryngospasm, etc. then the anaesthetist must continue to take the responsibility of protecting the airway after extubation too. Commonly trachea is extubated in the operating room when the patient is awake and protective airway reflexes have come back. It results in some cough and laryngospasm which usually do not interfere with the surgical closure of tonsillar bed. Sometimes IV lignocaine (1 mg/Kg) may be used to decrease this laryngospasm after extubation.

After extubation, patient should be observed for any bleeding and for any airway obstruction in recovery room for at least 90 minutes in tonsillar position (i.e. on one side, with the head slightly down). This is because it will allow the blood or secretions to drain out rather than to flow back into the larynx through vocal cords. Then the pharynx should be rechecked directly for bleeding before discharge from the recovery room.

The incidence of nausea and vomiting can be as high as 70% during the first 24 hours after tonsillectomy. Although, post-operative bleeding is the most serious complication, but persistant vomiting and poor oral intake are the most common cause for readmission after discharge. To reduce the incidence of post tonsillectomy (postoperative) vomiting, it is important to modify some anaesthetic techniques and also to develop some recovery protocol, such as avoidance of narcotics as postoperative analgesic, emptying of stomach from blood by suction, administration of antiemetic regimen, proper hydration and never force early oral food or fluid intake, etc.

Use of LMA in tonsillectomy is very difficult because Boyle-Davis gag cannot be placed in position if LMA is used and obstruction to the airway occurs more frequently. Also LMA cannot protect the larynx from regurgitation and aspiration of stomach content during operation. It also cannot protect from aspiration of blood coming from operating site.

Adenoidectomy

The adenoidectomy surgery is usually combined with tonsillectomy or examination under anaesthesia (EUA) of ear (for paediatric group of patient). In the absence of tonsillectomy operation the adenoidectomy surgery is usually performed as a day case procedure. For this surgery oral tracheal intubation is must and is performed under deep inhalation anaesthesia or is facilitated by the use of succinylcholine. Nasal intubation is not done for adenoidectomy as it obliterates the surgical space. After intubation, Boyle-Davis gag is inserted into the oral cavity and adenoid is curetted. Then nasopharynx or post-nasal space is tightly packed by gauzes to achieve haemostasis for 3 minutes. After removal of the pack when proper haemostasis is achieved (if haemostasis is not achieved, nasopharynx should be packed again), then only the patient is extubated and is turned to tonsillar position.

Peritonsillar Abscess

It is usually drained and/or decompressed by giving incision or doing needle aspiration under local anaesthesia. General anaesthesia with intubation is only applied in paediatric age group of patients or uncooperative patients. In peritonsillar abscess the risks of GA includes difficult intubation, because the respiratory tract is already partially obstructed due to inflammation, oedema and abscess itself. Intubation may cause further obstruction because difficult intubation produces further oedema, traumatic rupture of the abscess and subsequent spilling of pus into an unprotected airway before intubation. On the other hand, difficult intubation in peritonsillar abscess may be due to distorted anatomy, oedema and trismus. If difficult intubation is anticipated, then the following three methods can be adopted: (i) Awake intubation under local block, (ii) Intubation with inhalational anaesthesia with spontaneous respiration, (iii) Elective tracheostomy. Sometimes, planning of intubation and GA for drainage of a peritonsillar abscess may include the preoperative partial decompression of abscess by needle aspiration. It will help to minimize the risk of rupture of abscess and aspiration of pus during subsequent intubation.

Bleeding Tonsil after Tonsillectomy

The management of bleeding tonsil after tonsillectomy is a great challenge to an anaesthetist. The incidence of this post operative bleeding that actually requires re-surgery is near about 0.3% and usually occurs within 6 hours of primary surgery. The problems which an anaesthetist faces during handling of such patients are unsuspected hypovolaemia, full stomach (due to blood or food) and airway obstruction by blood. So, before sending the patient to the OT, the following things should be done: (i) blood loss should be assessed which is usually underestimated, (ii) no premedication should be given, (iii) coagulation profile should be checked, (iv) blood should be grouped, cross matched and kept ready for transfusion, (v) patient should be properly hydrated by IV fluids.

By nasogastric tube blood should be sucked from stomach before reinduction of anaesthesia. Rapid sequence induction with cricoid pressure and head slightly down in lateral tilted position is followed to prevent the aspiration of blood which is continuously oozing out. During induction and intubation of GA, an assistant must be available who will continuously suck blood from the pharynx. Like elective tonsillectomy, extubation should also be done when the patient is fully awake and the protective airway reflexes have returned.

ANAESTHESIA FOR MINOR SURGERY SUCH AS ENDOSCOPY AND MICROSURGERY OF LARYNX

Endoscopy of upper airway includes: laryngoscopy for any diagnostic or operative purposes, on larynx, microlaryngoscopy which means laryngoscopy aided by an operating microscope, oesophagoscopy, bronchoscopy, etc. Any laryngeal endoscopic procedure may or may not be accompanied by laser surgery. Patients presenting for laryngeal endoscope surgery are often evaluated preoperatively for stridor, hoarseness of voice, haemoptysis, etc with which the patients are usually presented. The possible causes of these symptoms are foreign body aspiration, papillomatosis, trauma, tracheal stenosis, vocal cord dysfunctions, etc. which have tremendous implication on subsequent intubation and GA.

The operating microscope has revolutionized the treatment of operative laryngeal disorder. At the same time, a wide variety of anaesthetic techniques have also come up for microlaryngeal and endoscopic surgery. But the common aims of all these anaesthetic techniques are: (i) to provide the surgeon a clear, immobile view, (ii) to provide the adequate space for work to surgeon, (iii) to provide good ventilation and oxygenation for patient, (iv) to protect the trachea from aspiration and, (v) rapid awakening with quick return of the protective airway reflexes.

Patients coming for microlaryngoscopy (endoscopy) or microsurgery of larynx have varieties of upper airway pathology which extends from a minimum to severe one, for examples, a small lesion on vocal cord (carcinoma *in situ*, polyp, etc.), or a large potentially obstructive lesion above the glottis (such as papillomatosis) or a large friable subglottic tumour that will completely obstruct the glottic opening. So, according to the pathology, preoperative decision about tracheal intubation or different modes of ventilation and anaesthetic management is taken on.

Only light premedication by benzodiazepines is desirable or advisable for rapid reawakening from the brief endoscopic or microsurgical procedures. Antisialagogue is must to facilitate the drying up of oral secretions. Small dose of narcotics may also be helpful. If there is any doubt about the airway (regarding intubation or ventilation) preoperatively, then direct laryngoscopic examination should be performed (after topical laryngeal block) in the awake patient to assess the difficulty of any mask ventilation or intubation.

As previously said, although varieties of anaesthetic techniques have been developed to satisfy the requirements of adequate pulmonary ventilation and oxygenation and unimpeded surgical view for microlaryngeal surgery, but a few among them are used practically. The most popular anaesthetic technique among them is the use of Coplan's microlaryngoscopy tube (a type of ET-tube). It is a narrow (5 mm ID), long tube (31 cm) and constructed of soft plastic with a 10 ml cuff volume (high volume low pressure cuff). The Coplan's tube can be passed either orally or nasally. The small diameter of this tube does not impede the surgeon's view and allows good access to the larynx.

Of all the pathological conditions of larynx asking for microsurgery, in 95% of cases the pathlogy is situated on the anterior 2/3rd of vocal cord or the anterior commissure. Only in 5% cases the pathology involves the posterior 2/3 of vocal cord or the posterior commissure. Hence, this small tube does not obscure the anterior commissure. Posterior commissure can be inspected by moving the tube aside. Adequate ventilation and oxygenation can be maintained in adults by controlled ventilation through this small endotracheal tube, and the cuff of the tube also protects the trachea from contamination by blood or tissue debris. This narrow ET-tube also allows a variety of general anaesthesia regimens even for an indefinite period of surgery. At the end of surgical procedure the pharynx and larynx is cleared by suction under direct vision, muscle relaxants are antagonised and tracheal extubation is performed in lateral position. Oxygen is administered to minimise the risk of hypoxaemia if laryngeal stridor occurs (Fact file-I).

Another method of anaesthesia for microlaryngeal surgery is jet ventilation by metal canulla using venturi entrainment effect of air.This method provides both anaesthesia and ventilation without the use of an endotracheal tube. This venturi injector technique to achieve artificial ventilation was first used in bronchoscopy and was then subsequently adopted for

FACT FILE - I

The anaesthetic goal for endoscopy include: (i) adequate ventilation and oxygenation during surgical manipulation of airway, (ii) profound muscle paralysis to provide good relaxation of masseter muscle for introduction of suspension laryngoscope, (iii) an immobile surgical field, and (iv) a good cardiovascular stability during the period of rapidly varying surgical stimulation. Several methods have been successfully used during endoscopy to provide adequate vantilation and oxygenation. But, most commonly the patients are intubated by a small diameter ET-tube such as 4 to 6 mm of ID. However, unfortunately the ET-tubes of these sizes are designed for paediatric group of patients. Therefore, they tend to be too short for adult trachea. Hence, a special type of ET-tube called microlaryngeal tracheal tube (MLT) is commonly used whose size varies from 4 to 6 mm ID. The other characteristics of this tube are : the same length as an adult tube, has high volume low pressure cuff, and more stiffer (less prone to compression) than a regular tracheal tube. The advantages of intubation for endoscopy or microlaryngosurgery are: better ventilation and oxygenation, protection from pulmonary aspiration, ability to administer inhalational anaesthetics, provide unlimited time for surgery, continuous monitoring of $ETCO_2$.

Insome cases, the intubation may interfere the surgeon's performance such as when the lesion involves the posterior commissure of vocal cord. In such circumstances, a simple alternative is insufflation of high flows of O_2 through a small catheter placed in the trachea. These patients are usually not paralysed by neuromuscular blocker. This is because, though oxygenation is maintained for brief periods in patients with good lung function, but it is inadequate for longer periods unless the patient is allowed to breathe spontaneously.

Another possibility for ventilation and oxygenation for endoscopy and microlaryngeal surgery is the intermitted—apnoea technique in which alternate apnoea and ventilation with 100% O_2 by face mask or tracheal tube is performed. In this technique full muscle relaxant is used and the surgeon acts during the apnoeic period.

An another sophisticated technique for endoscopy or microlaryngosurgery involves jet ventilator by connecting a jet ventilator to the side effect of the laryngoscope. During inspiration O_2 under high pressure is directed through the glottic opening and entrains room into the lungs by venturi effect. Expiration is passive and patients are kept under spontaneous respiration. Therefore, it is crucial to monitor the movement of patient's chest wall (as there is no breathing bag) and to allow the sufficient time for expiration to avoid air trapping and barotrauma.

A variation of this above mentioned technique is high frequency jet ventilation where muscle relaxont is used. It utilises a small cannula or tube in the trachea, through which gas is injected 100 to 300 times per minute. In this technique, capnography will tend to greatly underestimate the $PaCO_2$. This is due to constant dilution of alveolar gases by O_2. In all the above mentioned technique such as insufflation by high flow of O_2, intermittent apnoea, jet ventilation, and high frequency jet ventilation (except standard anaesthetic technique using Coplan's microlaryngoscopy tube (MLT) or stand and (ET-tube) need continuous intravenous anaesthetic.

laryngeal (diagnostic and short therapeutic) procedures. In this procedure a thin 16 G cannula is introduced into the trachea either by the oral, nasal or transtracheal route through the cricothyroid membrane, just below the cricoid cartilage. Intermittent jet of O_2 down the cannula will entrain sufficient amount of air through the glottis to provide adequate pulmonary ventilation. With lungs of average compliance, this is true even if the glottis tends to close reflexly or becomes partially obstructed during inspiration. If the glottis is open (by muscle relaxant), additional air will be entrained and a given tidal volume will be achieved more quickly. In this method, it is not easy to measure the tidal volume directly, but rough clinical assessment of tidal volume by observation of chest movement can be made. If there is some degree of glottic obstruction then a longer expiratory phase will be observed. The failure to allow adequate deflation of lungs increases the risk of pneumothorax. This method is also applicable in children. But for paediatric group of patient it is essential to use smaller bore cannula and lower inflating pressure.

Similar anaesthetic technique using ventilating laryngoscope also have been described. Here, the cannula is incorporated into the blade of laryngoscope. So, the surgeon has an unobstructed view of the larynx. As the jet of O_2 is applied above the vocal cords, so it is difficult to control the direction of gas flow. Hence, alignment of the laryngoscope blade with the tracheal axis is essential. Also the vocal cords need to be relaxed fully and any pathological condition in the airway must not be so large as to obstruct the airflow into the trachea. It has also been observed that blood and biopsy material may be blown into the lungs by this jet ventilation technique.

Another method of ventilation for microlaryngeal surgery is the apnoeic oxygenation technique when a period of ventilation is followed by a period of apnoea when the ET-tube is taken out and it is again followed by intubation and ventilation, thus repeatating this cycle again and again. It is found that ventilation of lungs by 100% O_2 (not jet) by ET-tube can provide adequate oxygenation in apnoeic patient (i.e. when ventilation is not done) for certain period of time after the elimination of body N_2. But the limiting time factor for apnoea from clinical point of view is the rate of rise of arterial PCO_2. This may be reduced slightly by using higher flow rates of gas, such as 10 lit/min. In practise it is not advisable to prolong the procedure for more than 10 minutes. So, it is a suitable method for brief therapeutic and diagnostic microlaryngeal surgical procedure (It is further discussed in LASER Chapter).

Good muscle relaxation is an essential part of anaesthetic management for the microsurgery of larynx. So, succinylcholine infusion is useful for short cases. If the procedure is expected to exceed at least 30 minutes, then non-depolarising neuromuscular blocking drugs such as vecuronium, mivacurium or atracurium are also used.

Technique of Anaesthesia

Use of the injector technique (jet ventilation) or a small endotracheal tube allows a surgeon more time for leisurely examination of the larynx and microsurgery which is not possible by apnoeic oxygenation technique. In addition, many things such as teaching and photography may be done without being pressed for time

by the above two techniques. Anaesthesia is provided by an intravenous inducing agent. This is followed by suxamethonium and the chosen technique and equipment which is then put in place. A few minutes of preoxygenation before induction of anaesthesia helps to provide a favourable alveolar-arterial O_2 tension gradient. Further suxamethonium is given when it is required to maintain apnoea. During jet ventilation, if jets of O_2 only are used for ventilation, then it is important to give supplementary doses of IV induction agent (e.g. propofol). Otherwise, the patient may awake during the procedure and experiences the terror of being paralysed but awake (feeling of drowning) and may also hear remarks of OT personnels.

In children, microlaryngoscopy is performed by using spontaneous respiration via an oral tracheal tube which is one size smaller than that is used normally. The larynx should be sprayed with measured quantity of lignocaine in an attempt to prevent postoperative laryngospasm.

Major Surgery of Larynx

Major surgeries of larynx in ENT department includes laryngectomy, hemimandibulectomy, laryngoesophagectomy, etc. and these are done for malignancy of larynx. Airway obstruction by tumour is the major anesthetic problems in this group of surgery. Alcohol, smoking and old age are the aetiological factors of laryngeal malignancy which may also influence the course of anaesthesia. So, anaesthetist has to frequently face the patients who are elderly, having bronchitis, emphysema and chronic cardiovascular diseases, etc. If the tumour interferes with proper eating, then weight loss, malnutrition, anaemia, dehydration and electrolyte imbalance can also be significant and a anaesthetist has to face all rhese problems. So, these patients are properly evaluated and treated as representing difficult ET-intubation and with potential problems in airway management preoperatively. Respiratory functions should be assessed preoperatively by pulmonary function test. But this is difficult to measure accurately if there is any airway obstruction. Chest physiotherapy should always be prescribed as it aids the clearance of secretions pre and post operatively. These operations are often prolonged and associated with considerable blood loss, necessitating generous pre-operative provisions of compatible blood.

If the patients are scheduled for tracheostomy, then respiratory obstruction is suspected. So, narcotic and sedative premedications should be avoided. All the patients should have preoperative assessment of airway by flexible nasal or oral endoscope to know the magnitude of obstruction of larynx which have a great implication during induction and intubation. If there is a possibility of complete mechanical obstruction and failed intubation after muscular paralysis, then an inhalational technique should be used for intubation. If the inhalational technique results in possibility of severe obstruction, then an awake intubation should also be tried. Laryngoscopy and intubation sometimes become difficult if preoperative radiotherapy has done, because it reduces the mobility of the floor of the mouth due to fibrosis.

If respiratory obstruction is suspected, IV inducing agent should be given very slowly till consciousness is lost. Then patient's lung should be inflated using face mask and bag. If it is possible, it will indicate that patient will not go to the "not to ventilate and not to intubate condition", then only succinylcholine is given to facilitate intubation. If not, anaesthesia is deepened slowly with halothane, isoflurane or sevoflurane and intubation is tried preserving spontaneous respiration. All these volatile anaesthetic agents dilate the bronchi, depress the airway reflexes and permit the use of higher concentration of O_2.

Induced hypotension is often used to reduce the blood loss during surgical dissection of neck tissue. But, it is not without risk in debilitated patients and it may be unnecessary and dangerous too in these group of patients. Therefore, alternatively deep halothane anaesthesia and 10° to 15° tilt (head up) is sufficient to produce moderate hypotension and diminish the intraoperative blood loss, instead of restoring deliberate induced hypotension.

Intraoperative surgical manipulation of the carotid sinus during the dissection of the tissue of neck may elicit a vagal reflex that causes bradycardia, hypotension, arrhythmia or even cardiac arrest. If this is persistent, then the infiltration of this carotid sinus with local anaesthetic agent or IV atropine may be an effective treatment. Trauma to the right stellate ganglion and cervical autonomic nervous system during laryngeal surgery can prolong the QT interval and lower the threshold for ventricular fibrilation. But its incidence is low. Like neurosurgery, opened neck veins may also create the possibility of air emboli during major laryngeal surgery.

When the larynx and trachea has been dissected free to divide the trachea, then it is important to check whether a second sterile cuffed tracheostomy tube, catheter mount and a compatible connector which will attach the tracheostomy tube with anaesthetic machine are included in the surgical instruments trolly or not. Before division of trachea, patient is ventilated with 100% O_2 for two minutes. Then, the previous ET-tube is withdrawn from the larynx, trachea is divided and a second tracheal tube is rapidly placed through the opened end of trachea. After this the second tracheal tube is connected to the anaesthetic circuit and secured firmly. This tube should be positioned carefully within the shortened trachea to prevent inadvertent one-lung anaesthesia. The previous oral ET tube, having been withdrawn above the incision, is left in place until the new airway is secured. In cases of difficulty, it can be remanipulated into the trachea, so that the cuff lies distal to the incision.

At the end of surgery, patient should be reversed from the neuromuscular

block completely and the tracheal tube is changed for tracheostomy tube. When a patient with previous tracheostomy presents for anaesthesia, a cuffed tube should be inserted before induction of anaesthesia and anaesthesia is maintained through this tracheostomy route.

ANAESTHESIA FOR NASAL SURGERIES

All the Operations on nose have one common feature, i.e they involve surgery on a very vascular structure. In 1942, Moffatt had first described the method of topical anaesthesia for nasal surgeries using cocaine. Cocaine is a first discovered local anaesthetic agent with intense vesoconstrictive properties. There are three advantages of this local anaesthetic method for nasal surgeries by cocaine with vasoconstrictive property. These are: (i) minimal patient's discomfort from pain during operation, (ii) shrinkage of blood vessels of mucuous membrane, and (iii) blood less surgical field. Cocaine is known to have sympathomimetic side effects and sensitizes the organs to epinephrine by blocking its reuptake at the synaptic level. Major cardiovascular complications (VT, VF, MI, etc.) are reported even after the use of topical cocaine, especially when it is combined with the use topical epinephrine or with the use of halothane. So, this lead to the question whether cocaine still has a role in nasal surgery or not. Because sudies have shown that lignocaine with epinephrine and/or oxymetazoline are good effective alternatives to cocaine.

Still, if one wants to use cocaine, the dose will be 4% solution or less (without the addition of epinephrine) with a maximum dose of 1.5 mg/Kg or a total dose of 160 mg. Now, most of the nasal operations are done under local anaesthesia using various local anaesthetics (lignocaine or bupivacaine) mixed with some vasoconstrictor (adrenaline). When epinephrine is used, the maximum concentration of it should not exceed 1:1,00,000 or 10 µg/ml. Lower concentration is also acceptable, because no difference were found in the degree of vasoconstriction with the use of epinephrine at concentration as low as 1:4,00,000 (2.5 µg/ml). Concentration and total dose of epinephrine should be kept as low as possible, because it is known that the combined use of volatile anaesthetic agents during GA (especially halothane) and epinephrine can induce cardiac arrhythmias.

By blocking the sphenopalatine ganglion, most of the sensory supply to the nose, (including the anterior ethmoidal nerve) can be blocked. But only the columella is not affected by this method and requires a separate injection. Indications and contraindication of LA and/or GA for nasal and ear surgeries are like ophthalmic anaesthesia and are discussed in details in 'opthalmic anaesthesia' Chapter (Fact file -II).

Nasal surgical procedures such as septoplasty, removal of polyp, reduction of fractured nasal bones, etc, are often carried out safely under local anaesthesia by using infiltration of tissue by local anaesthetic agents combined with or without sedations. However, potentially serious complications may arise, if the patient moves during endoscopic sinus surgery. These serious complications may include: entering the intracranial space, blindness due to entry into the orbital cavity, damage to the internal carotid artery, etc. So, paralysis of patients is advised when the risk of complications from movement is high. Thus, GA is recommended for these type of endoscopic surgeries, where chances of movement is high such as in paediatric and psychiatric group of patients. GA for these endoscopic nasal surgery has been revolutionised by the introduction of LMA. In the presence of nasal packing, difficulty in maintaining airway is almost completely eliminated by leaving LMA in place postoperatively, until the patient himself rejects it spontaneously in the recovery room.

General anaesthesia for nasal surgeries may be maintained by using either spontaneous or controlled ventilation. During GA and surgery whatever tube is used (ET or LMA), pharynx should be packed with gauze, so that blood, pus or debris does not contaminate the larynx and at the time of extubation may not lead to coughing and/or laryngospasm. After surgery, the packs are removed, the pharynx is cleared and the patient is turned in lateral tonsilar position. It is more safe to extubate the patient while completely awake. Sometimes, after nasal surgery but before extubation, blood may collect at the back of the softpalate. Therefore, in the immediate postoperative period following extubation, these clots may dislodge from its site and fall into the glottis leading to complete airway obstruction. This clot is called the 'coroner's clot'. So, thorough suctioning before extubation, and reduction of bleeding by using topically applied vasoconstrictive drugs and head up position by 15 to 20° which provide a mild degree of hypotension will help to reduce the incidence of this problem.

FACT FILE - II

Most nasal surgeries can be performed satisfactorily under local anaesthesia with or without sedation. The nasal septum and the lateral wall of the nose get their sensory innervation by anterior ethmoidal and sphenopalatine nerves. Both these nerves can be blocked by topical application of LA agent by packing the nose with gauze or cotton soaked with local anaesthetic agent. This topical anaesthetic agent should be allowed to remain in place for atleast 10 minutes before surgery. Somtimes, in addition to this topical application, local infiltration of LA agent in the submucosal level is often required. This is mainly found, particularly if scar tissue is present from prior surgery. The use of epinephrine containing LA solution or cocaine solution (usually a 4% or 10% solution) will shrink the nasal mucosa and reduce the intraoperative blood loss. The disadvantasge of cocaine is that it is very rapidly absorbed and may cause detrimental cardiovascular effects. GA is needed for nasal surgeries when the topical or local infiltration block is inaqdequate producing discomfort, or paediatric and psychiatric patients are met.

ANAESTHESIA FOR EAR SURGERIES

The ear gets its sensory supply by four nerves: These are: (i) the auriculotemporal nerve, (ii) the great auricular nerve, (iii) the auricular branch of the vagus nerve, and (iv) the tympanic nerve (Fig. 38.1). The auriculotemporal nerve is the branch of the mandibular division of trigeminal nerve. It supplies the external auditory meatus. It can be blocked by giving 3 ml of local anaesthetic agent into the anterior wall of the external auditory meatus. The greater auricular nerve is the branch of the cervical plexus. It supplies the middle and lower aspect of auricle and a part of the external auditory meatus. The auricular branch of the vagus nerve supply the concha and the external auditory meatus. These two nerves, i.e. the great auricular and the auricular branch of the vagus can be blocked by giving 3 ml of local anaesthetic agent posterior to the external auditory meatus. The tympanic nerve is the branch of the glossopharyngeal nerve and supplies the tympanic cavity. It can be blocked by instillation of 4% lignocaine into the middle ear.

Ear surgeries can be performed both under local anaesthesia and GA. Operations such as premeatal operations, stapedectomy and uncomplicated middle ear surgeries (of less than 2 hours duration etc,) are all usaully performed under LA. GA is needed only when the patient is non cooperative or for paediatric age group. When surgery is performed under local anaesthesia, then usually the surgeon injects the local anaesthetic agent. But both the surgeon and the anaesthetist must keep track on the total amount of the local anaesthetic agent used in order to prevent toxic blood concentration of it. If the patient is very anxious, then a benzodiazepine premedication is often given. A small dose of IV fentanyl (0.5 to 1 µg/Kg) or a small dose of IV propofol (0.3 to 0.5 mg/Kg) can be given just before the injection of local anaesthetic agent. For many anxious patients, carefully titrated sedation (by propofol 0.5 to 0.7 mg/Kg IV, followed by an propofol infusion with or without midazolam at the dose of 0.02 to

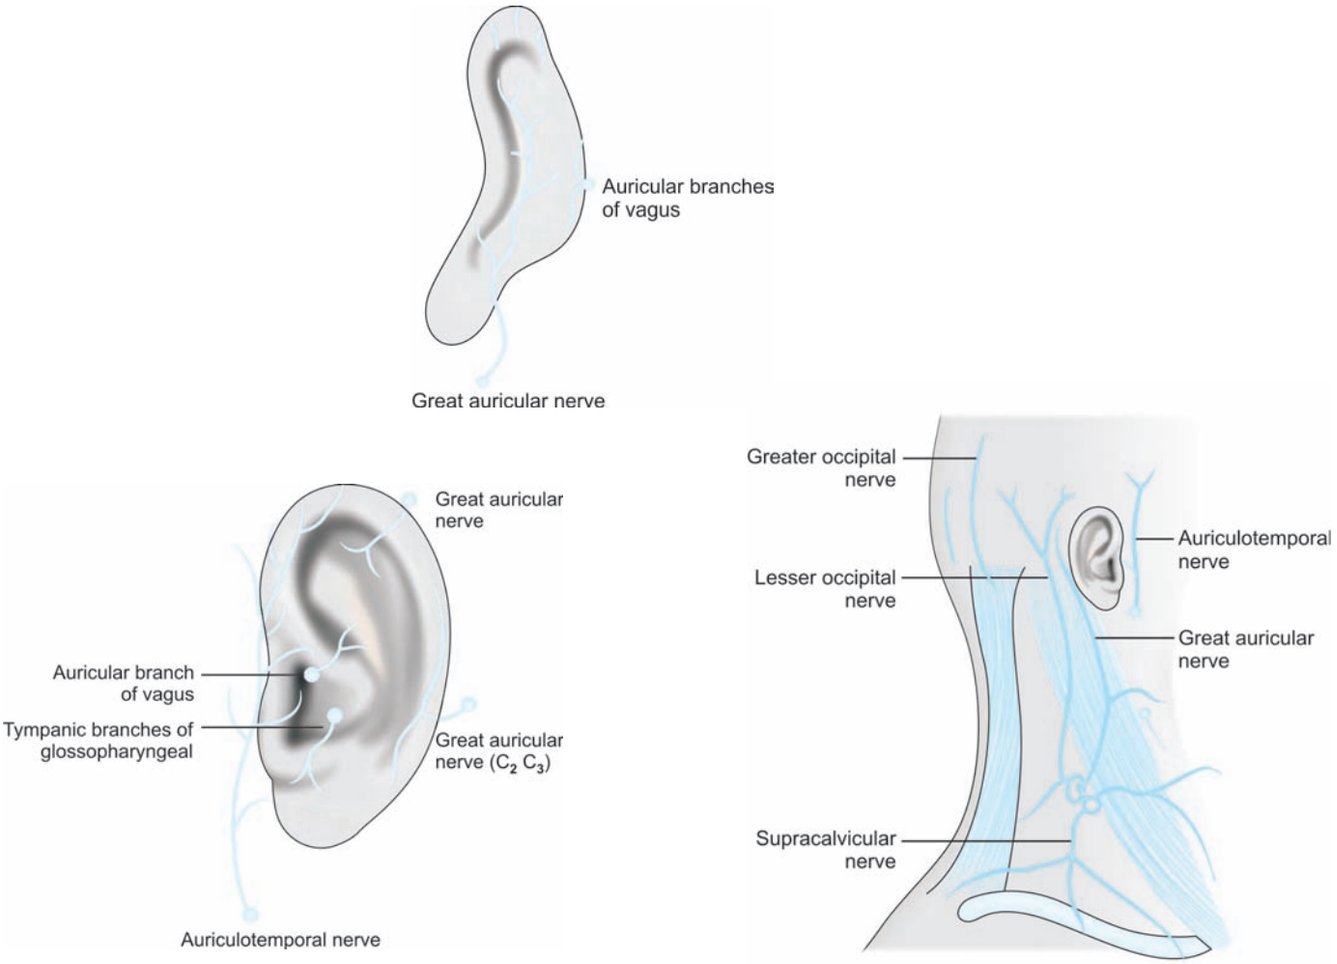

Fig. 38.1: Sensory supply of nerves: (i) Auriculotemporal nerve, (ii) Auricular nerve, (iii) Auricular branch of the vagus nerve (iv) Tympanic nerve

0.04 mg/Kg/min) have also been helpful. By this carefully titrated awake sedation, patients become calm, cooperative, and can gossip with the surgeon during operation under local anaesthesia. Full sedation should be avoided, because it will cause the patient to be uncooperative and may cause airway problems. Though the cases are selected for LA, but still the preoperative workup of patient by anaesthesiologist should be the same as for the GA. Due to high incidence of PONV, antiemetics should be used routinely during ear surgeries. Addition of epinephrine to the local anesthetic agent increases the duration of it and causes vasoconstriction and thereby decreases the bleeding. Safe dose of epinephrine is 0.05 to 0.1 mg and can be repeated after 20 minutes.

Ear surgeries under GA are done only for the paediatric, uncoopearative and anxious group of patients and for procedures such as tympanoplasty and mastoidectomy in adult. The things that should be kept in mind during ear surgery under GA are: (i) the possibility of facial nerve injury, (ii) the effect of N_2O in middle ear surgery, (iii) the extremes of head position, (iv) the possibility of air emboli, (v) blood loss and control of bleeding during microsurgery of ear.

During surgery under GA with muscle relaxant, monitoring of evoked facial EMG activity may assist in the preservation of the function of facial nerve. Facial nerve also can be monitored by using a nerve stimulator during GA. Its function also can easily be monitored, if deep muscle relaxation is avoided or at least 30% of the muscle response (as measured by a twitch monitor by TOF) is preserved. However, many studies revealed that despite significant neuromuscular block, as measured by no response state on the stimulation of ulnar nerve, facial nerve activity could still be detected on elctrical stimulation.

Middle ear, like other cavities (e.g. sinuses) of the body is a closed air containing space which is connected to the environment by eustachian tube (whereas sinuses are connected with environment through ostium). During N_2O anaesthesia, N_2O enters the cavity 34 times rapidly than N_2 exits the cavity (as N_2O is 34 times more soluble in blood than N_2, blood gas coefficient of N_2 being 0·013 and N_2O 0.46). This results in the increase in volume and pressure of air in the middle ear. As a result, there is bulging of ear drum and lifting of the tympanic membrane which causes disruption of the graft in tympanoplasty surgery. Normally, when the middle ear pressure rises between 200 to 300 mm of H_2O, automatic venting of air occurs through the eustachian tube. But, when the eustachian tube remains blocked due to inflamation or oedema, then venting of air can not occur and the middle ear pressure rises, causing problems. In eustachian tube block, the middle ear pressure can rise upto 375 mm of H_2O within 30 minutes of the starting of N_2O inhalation. In addition, after discontinuation of N_2O, the gas is rapidly absorbed in blood than N_2 which enters in the cavity, causing marked reduction of the volume and negative pressure in the middle ear. Sometimes, this negative pressure in the middle ear becomes so great that it causes serious otitis, disarticulation of stapes and impaired hearing, etc.

Finally, it can be concluded that fluctuation of middle ear pressure during N_2O anaesthesia causes problems (is also a cause for PONV) only in susceptible persons i.e those with the previous eustachian tube block due to otologic surgery, acute or chronic otitis media, sinusitis, URTI, adenoids etc. There is also no evidence of interference in graft placement or outcome of surgical procedure in type 1 tympanoplasty if N_2O is used in less than 50% concentration. But it is better to avoid possibilities of complications. So anaesthetist should limit the concentration of N_2O to 50% and discontinue N_2O 15 to 20 minutes before the closure of the middle ear. The subsequent decrease of middle ear cavity pressure to the subatmospheric level can be avoided by flushing the middle ear cavity with air prior to closure of the tympanic membrane. During ear surgery under GA, an anaesthetist should be careful about the extreme positions of neck, such as extreme extension or rotation which may cause injury to the cervical spine, brachial plexus, etc. Patients with limited carotid artery supply to the brain are especially vulnerable to further decrease in flow from exaggerated neck position. Also, in patients with Down syndrome or with rheumatoid arthrosis extreme rotation of the neck should be avoided because of the risk of $C_1 - C_2$ sublaxation.

Control of bleeding during microsurgery of ear under GA can be done by maintaining 10 to 15 degree head up tilt position which will increase the venous drainage and will decrease the venous bleeding. Thus they will create a relatively dry operative field and help in microsurgery of ear. Infiltration of operative area by local anaesthetic agent mixed with adrenaline is also helpful for controlling the bleeding and helps in post-operative analgesia. But, the total dose of adrenaline should be limited to 0.1 mg (20 ml of 1:200000 solution in which 1 ml contain 5 µg adrenaline) which can be repeated after 20 minutes. This is also a safe practice in a well ventilated patient who is given halothane anaesthesia. Isoflurane and sevoflurane does not sensitize the myocardium to catecholamines to the same extent as does the halothane and hence are more safe. Topical application of epinephrine in the ear is also helpful to reduce bleeding from operating site and to make a dry operative field. But higher concentrations of adrenaline like 1:50,000 need not provide any additional vasoconstrictive effects.

LMA is used in major ear surgery but the anaesthetist must be aware that if the airway is lost during the procedure, as a result of movement of the head, then the operation may have to be abandoned.

39 Anaesthesia for Geriatric Patients

INTRODUCTION

There is no precise definition of the term, named elderly, geriatric or aged. There is also no specific clinical marker for geriatric group of population (in the society) from which we can stamp that the patient is elderly. This is because ageing is a continuous process. So the determination of age at which people are considered elderly also remains arbitrary. But, still it is generally agreed for administrative and epidemiological purposes that patients aged more than 65 years are considered as geriatric or elderly. However, some specific classifications of geriatric population are : persons between 65 to 74 years of age are called as 'elderly', persons between 75 to 84 years of age are called 'aged' and those above 85 years of age are called 'very old'.

Age itself is an independent factor for increased morbidity and mortality in a society. It is also an important independent factor for a number of diseases, injuries, hospitalisation and adverse drug reactions which occur predominantly in this age group of patients. It itself has also been shown to be an independent predictor for perioperative outcome. As all over the world, the geriatric population is now on the rise, so India is also not lagging behind of the fact that more and more number of geriatric patients are coming for surgey in this country also. So, the anaesthesiologists are now going to encounter more and more number of elderly patients in OT. Therefore, it is mandatory to understand precisely the pathophysiological changes which occur with age and to evaluate its affect on anaesthetic risk. Thus, equipped with proper knowledge an anaesthesiologist will be in a better position to take a good perioperative care of the geriatric group of patients.

The speciality of geriatric cases such as geriatric medicine have, therefore, become increasingly important and is gradually now developing in recent years in all the countries. Geriatric medicine is not concerned merely with prolonging the lives of elderly. But it is much more concerned with the keeping old people young. Similarly, surgery on the elderly should comprise not only the possibilities of treating an illness by operation, but also include an assessment of the patient's ability to withstand the surgery and benefit from it. The modern development in anaesthesia has made surgical proecedures which was previously deemed unfit due to age, now feasible. But this must not obscure the dangers of postoperative period that will throw an additional strain on the cardiovascular and respiratory systems which the aged patient may not be able to sustain. On the other hand, the general view is that all the surgeries in the very old are 'unwarranted interference' and cannot be justified, especially if it does not improve the quality of life and bring comfort for the remaining months or years of the patient's life.

Ageing is defined as the a progressive physiological process that produces measurable changes in the structure and function of tissues and organs. Till now mechanism of ageing is not yet clearly understood. But it is postulated that decreased cellular energy production due to the deterioration of mitochondrial function (mainly in cardiac and neural tissues) plays a fundamental role in the age-related decline of tissue or organ functions. Ageing is a natural, inevitable and biological phenomenon of every cellular structure. However, the onset and the rate of progress of age varies with every individual, depending on few known and many unknown variables. The biological age (decrease of production of cellular energy with passing of time) of a person is not indentical with the chronological age.

Ageing appears to be a universal phenomenon which is characterized by degenerative changes, involving both the structure and functions of tissues. It is not a linear progress as it was earlier thought of. The decrements of function of tissues due to ageing in most organs are now believed to be relatively subtle upto the middle past of adult life and then the progress is faster after seventies. The elderly persons who maintain a greater average functional capacity than others is referred to as physiologically youngs and when the function declines early they are often referred to as physiologically old. In healthy geriatric patients the maximum organ function is higher than the basal level at all ages. The difference between these two (maximum level of organ function and basal level of organ function) is the functional reserve of the organ system. The functional reserve of organs is able to meet the additional demands of cardiac output, CO_2 elimination or protein synthesis imposed by trauma, surgery or disease.

PHYSIOLOGICAL AND PATHOLOGICAL CHANGES ASSOCIATED WITH AGEING

Perhaps chronological ageing only wrinkles the skin. But worry, doubt, fear, anxiety and self distrust, etc, wrinkle the soul (biological aging) as chronological age progresses. With the current continuation of the decline in fertility and increase in life expectancy, the current population of the world will be aged much faster in the next half century than the previous one. For example, the total population of the elderly persons of the world is supposed to grow 3.5 times in 75 years, from 2.5 billion in 1950 to 8.46 billion in 2025 (projected). The world population of 60 years old and above will increase 6-fold from 201 million (in 1950) to 1·2 billion in 2025 (projected). In this period the fastest growing age group will be 80 years and above. Most astonishingly this population will increase from 13 million (in 1950) to 137 million in 2025. We are concerned with the fact that in many developed countries 2/3 of the hospital beds are occupied by the aged of which 50% need surgery. As the age advances, the physiological functions of the body get compromised. Degenerative changes in all the tissues are more common, but history is always not reliable. So, hospital notes sometimes become formidable. With this, the body's mechanism of drug handling gets altered, leading to ever increasing problems to anaesthesiologist during the administration of anaesthesia. So, it will be worthwhile to recapitulate the physiological changes and the altered mechanism of drug handling in this elderly age group of patients (Fig. 39.1).

Cardiovascular Function

The geriatric surgical group of patients have the higher incidences (50 to 60%) of overt and /or subclinical cardiovascular diseases. The coronary disease has been found even in completely symptom-free octogenarian. More than half of all the mortality in this geriatric population is due to this cardiovascular disorders. With the increased age the ventricular compliance gradually decreases and it is due to the gradual increase in ventricular wall thickness, myocardial fibrosis and valvular calcification. Thus, due to increased stiffness of cardiac chambers (reduction of compliance) haemodynamic function of an elderly heart runs within a narrow range of end-diastolic pressure and subsequent end-diastolic volume. Hence, they become volume dependent (preload) and easily become volume intolerant.

With increased age the elastic fibres of blood vessels show thickening and fragmentation. This along with the progressive arteriosclerotic changes in the arterial wall make the arterial tree narrow and less distensible. So, this causes the rise in systolic BP (due to non distensibility), pulse pressure and impaired vascular compensation for blood loss (as vessels fails to contract properly). With increased age the narrowing and the stiffness of the wall of the blood vessels also causes ↑SVR and ↑diastolic pressure. This increase in SVR and diastolic pressure causes increased impedence to the ejection of stroke volume and elevated systolic pressure associated with that given stroke volume. Thus, this increase in afterload further increases the ventricular work load which again increases the wall thickness and stiffness of ventricle with further decrease in diastolic ventricular filling and cardiac output (a viscious cycle). Due to the impedence of ejection, cardiac index (CI) also progressively decreases with age (linear relationship). Age imposes a ceiling on the increase of cardiac output as a person grows from childhood. It becomes maximum at the middle of the life, then it decreases approximately 1% per year starting from the middle of adulthood.

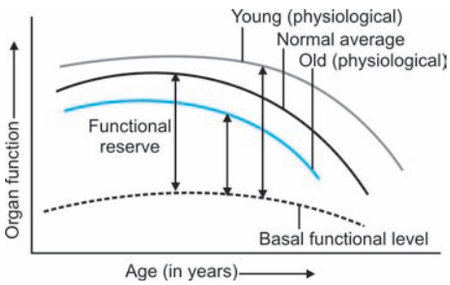

Fig. 39.1: When there is lesser rate of decline of functional reserve, then this geriatric person is called 'physiological young'. Contrary, when there is greater rate of decline of functional reserve, then this geriatric person is called 'physiological old'. They have significant different functional reserve. Functional reserve is the difference between the maximum (unbroken lines red for average, blue for young and green for old) and the basal level of function (broken red line)

As age advances, so due to the decrease in ventricular end-diastolic volume (due to stiffness and hypertrophy of wall) the ventricular diastolic filling and subsequent CO now depends on atrial contraction. Hence, the loss of sinus rhythm or the atrial 'kick' (e.g. atrial flutter and fibrillation) produces severly compromised CO in elderly patients. In the elderly persons the haemodynamic insufficiency due to diastolic ventricular dysfunction is more common than the young adults. In children and young adults the CO increases by tachycardia and β-adrenergic agonistic action. But, in the elderly or aged persons during demand, the CO can only be increased by increasing the left ventricular end-diastolic volume in response to augmented preload (by IV fluid or by prolonged filling time by reduction of heart rate) which compensate for slow heart rate (as the HR decreases with age). This increase in cardiac output is associated with little enhancement of ejection fraction. Here the mechanical compensatory mechanism predominates over heart rate caused by adrenoceptor activation or baroreflex activity. So due to limited reflex mediated ability to increase the heart rate, hypotension can be frequent and severe during both intraoperative and postoperative period in the older surgical patients. Thus, Frank-Sterling principle with increased O_2 demand works in elderly heart.

Only loss of arterial elasticity (not narrowing due to atherosclerosis) causes

reduction of diastolic BP and increase in systolic BP and widens the pulse pressure, while narrowing of the arterial wall with loss of elasticity causes both ↑systolic, ↑diastolic pressure. Reduction of diastolic BP decreases coronary artery perfusion and narrowing of coronary artery due to atherosclerosis in aging process further decreases the coronary flow. So, hypotension is usually badly tolerated by the aged persons. Due to same reasons, blood flow to the kidneys and brain is also reduced with age with impaired autoregulation. The physiological response to cardiovascular disturbance may be also blunted with advanced age, due to reduced baroreceptor sensitivity and impaired autonomic function. Atrial fibrillation is common in older people.

Pulmonary Function

With advancing age, there are also changes both in the chest wall and the lung parenchyma. In the lung parenchyma, the quality of elastin deteriorates with age (but quantity of elastic tissue does not decrease). This results in progressive loss of lung recoiling effect and decrease in tethering property of it which are normally helpful for the patency of small airways and homogeneous distribution of inspired gases. Thus, the lungs become more compliant (due to loss of recoiling or elastic property) and the patency of airways is impaired. But, due to increased rigidity of chest wall the compliance of it (i.e. chest wall) is reduced and, therefore, the total pulmonary compliance decreases.

The breakdown of alveolar septa (due to reduction of tethering property) with increasing age also causes the merging of small alveoli into a large alveoli and reduces the total alveolar gas exchanging surface area. So, the lung becomes emphysematous and dead space (anatomic and alveolar) increases. As the lungs become emphysematous and the recoiling property is lost, so the residual volume of lung increases at the expense of expiratory reserve volume. At the same time FRC increases at the expense of vital capacity (↓VC) also. Closing volume and closing capacity both increase gradually overlapping FRC. So, airway closure occurs at increasing lung volumes with increasing age. Even small airways close during tidal volume. This critical relationship between CV and FRC is more marked in the supine and lithotomy with head down position and gradually increases the mismatch of ventilation/perfusion ratios. The alveolar – arterial O_2 gradient widens with age which indicates inadequate oxygenation.

The anatomical dead space also increases as the diameter of larynx and trachea increases with age. So, a large ET-tube is needed for older patients. Calcification, fibrosis and osteoarthritic changes of the chest wall also reduces the movement and compliance of it. This results in decreased FEV_1 and tidal volume. Thus V_D/V_T ratio increases with age, causing VQ mismatch, arterial hypoxaemia and reduction of CO_2 elimination. Ronchi are fairly common in the elderly patients without underlying pulmonary disease, but crepitations are usually a sign of incipient pneumonia or CHF (Fig. 39.2).

It is advisable whenever possible to have a preoperative chest X-ray in all the elderly patients. Atelectasis, pulmonary embolism and chest infection are all more common in the elderly patients. The later in part is due to the ineffective mucociliary activity for advanced age. P_AO_2 and P_aO_2 decrease with age (P_AO_2 = 100 − age / 4 mm of Hg). The geriatric persons also have the markedly decreased ventilatory response to hypercapnia and hypoxia. The elderly has further increased incidence of sleep apnoea which make them more susceptible to hypoxaemia in recovery room.

Renal Function

Like all other organs, kidney also becomes aged with time. So, among all the geriatric patients who undergo surgery, 30% have kidney dysfunction. Also acute renal failure is responsible for 1/5th of the total perioperative death in geriatric population. The prevalence of renal disease among the geriatric group of patient not only increases the perioperative risk of acute renal insufficiency or failure in them, but also affects the duration of action (pharmacokinetic) of many anaesthetic and adjuvant drugs. With ageing the renal tissue mass is atrophied, the total number of nephrons decrease, fatty tissue accumulates and interstitial renal fibrosis occurs. About 20% of renal tissue mass is lost by the eighth decade and more than one third of glomeruli with their tubule disappear.

The renal plasma flow (RPF) decreases (10% per decade) along with the decrease of GFR. This decrease of renal blood flow is about one-half of that of the young adults. The rate of decrease of GFR is 7 to 8 ml/min/1.7 m^2/day. This decrease of GFR and RPF is more sharp than decrease of renal tissue mass. This is because renal vasculature is compromised preferentially with age. The active tubular secretion and reabsorption of drugs and other solutes is also reduced with age. Thus, the elimination

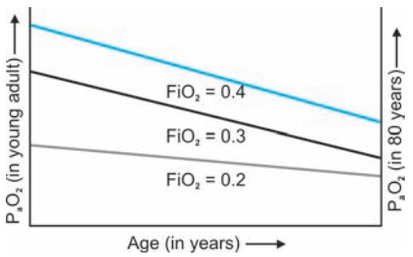

Fig. 39.2: The decrease of arterial O_2 tension with age at different inspired O_2 concentration (FiO_2)

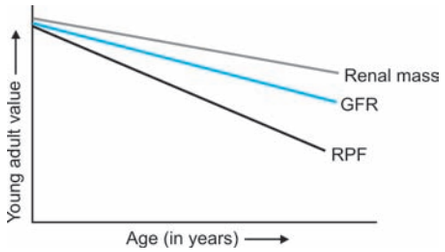

Fig. 39.3: The effect of age on renal function such as RPF (renal plasma flow), GFR and renal mass in man

half-life of virtually every anaesthetic drug is prolonged in elderly patients, especially in those with pre-existing renal dysfunction (Fig. 39.3).

Excretion of free water load is also markedly delayed in elderly people. Creatinine clearance also declines, but the serum creatinine level does not rise as creatinine load on the kidney also decreases due to the reduction of skeletal muscle mass with increasing age. So, a modest rise in serum creatinine level in elderly persons may represent a significant renal impairment. Tubular functions is also impaired with reduced renal concentrating ability and reduced free water clearance. Fluid balance in elderly patient is more critical, as responses to both the fluid loading and dehydration are impaired. Although renal function detoriates with advancing age, still the residual function is sufficient to avoid gross uraemia if demands are basal. The other changes in renal function in geriatric patients are: ↓responsiveness to ADH, ↓absorption of filtered glucose, ↓ability to conserve Na^+ and to concentrate urine and functional hypoaldosteronism. In older age the reduction of lean body mass decreases the total body stores of K^+ and thus predisposes to hypokalaemia. Therefore, due to the limited renal functional reserve, geriatric patients require meticulous calculation and monitoring of fluid and electrolyte balance during the perioperative period. But no fluid replacement protocol is appropriate for this group of patient. Acute renal failure is usually responsible for at least approximately one-fifth of the perioperative mortality in elderly surgical patients. This age related changes in renal function has important pharmacokinetic consequences causing prolonged elimination half-life of anaesthetic drugs and its metabolites which require renal route for their clearance.

Hepatic Function

With advancement of age the size of hepatic tissue, hepatic blood flow and hepatic function decreases. This loss of hepatic function is quantitative and not qualitative (i.e. the quality of hepatocellular enzymatic function does not decline). This is because normally as much as 40 to 50% of the total hepatic tissue may involute by the age of 80 years. Thus, there is progressive redistribution of perfusion away from the hepatic splanchnic vascular bed to the other organs due to atrophy of it. Hence, this quantitative loss of hepatic tissue plays a major role in the age related decline of anaesthetic drug clearance. The duration of clinical effect of anaesthetic agents may be further prolonged if their primary or secondary metaboites take the renal route for elimination instead of the drug itself. On the other hand, as the quality of hepatocellular function does not decline, so the microsomal and non-microsomal enzyme activity of hepatic cells appear to be well preserved. But, the hepatic synthesis of plasma cholinesterase is deficient in many elderly men. The hepatic capacity for protein synthesis significantly reduced by the eighth decade of life. But still this reduction of protein synthesis can meet the requirements for normal coagulation due to previous huge reserve. Due to the present limited hepatic functional reserve the elderly persons produce many postoperative complications and so require supportive therapy and intensive care.

Nervous System (Central, Peripheral, Autonomic)

With increased age, the brain also has undergone definite structural and functional changes. Age reduces the brain size and weight. The average weight of brain of an 80-year-old person is approximately 20% less than that of an 30 year old person. The very rapid decrease of brain tissue occurs after the 6th decade of life. At the same time, there is also a compensatory increase in CSF volume. So, aging produces a low pressure hydrocephalus. Normally, the supportive glial cells constitute about almost ½ of the total brain mass and reduction of brain size reflects not the atrophy of glial cells, but the reduction of the number of neurons. The average rate of neuronal loss in brain tissue is 55,000 per day. However, among the neurons those responsible for the synthesis of neurotransmitters undergo the greatest degree of age related attrition. With increased age, the intelligence does not decline. The storage, integration and consequently the processing of information which is responsible for language skills, aesthetic skill and personality remains also intact. However, on the other hand the short-term memory, visual reaction time and auditory reaction time, etc, that require rapid retrieval of information and immediate processing gradually decreases. With ageing the cerebrovascular diseases are common and confusion is more likely during both the pre and postoperative period. In elderly, the autoregulation of cerebral blood flow (perfusion) in response to change in arterial blood pressure is still maintained. Therefore, ageing is not associated with inadequate cerebral perfusion with the change of BP. If there is any decrease in cerebral blood flow, then it is the consequence of cerebral atrophy. But this reduced cerebral blood flow is not the cause of cerebral atrophy. The cerebral vasoconstriction response to hyperventilation remains intact in elderly persons like young brain tissue (Table 39.1).

The intrinsic mechanism that couple cerebral electrical activity, cerebral metabolism and cerebral blood flow remain similarly intact with increased age. In aging brain, there is generalised depletion of neurotransmitters such as dopamine, norepinephrine (NE), epinephrine (E), tyrosine, serotonine, etc, and simultaneous increase in activity of enzymes such as MAO and COMT which are responsible for breakdown of these neurotransmitters. One of the example of this deficiency of neurotransmitter is Alzheimer's disease, where there is deficiency of acetylcholine in cerebral cortex. The affinity of these neurotransmitters to their receptors is also

Table 39.1: Summary of anatomic and functional changes due to ageing

System	*Anatomic changes*	*Functional changes*
1. Body composition	↓Skeletal muscle mass	↑Drug effect
	↓Lean tissue	↓Metabolism and heat production
	↓Relative	↓Resting cardiac output
2. CVS	↓β-adrenergic responsiveness	↓Cardiac and arterial compliance
	↓Vascular elasticity	↓Maximal heart rate and CO
	↓Ventricular hypertrophy	↓Pulse pressure
3. Nervous system	↓Neuronal tissue mass	↓Neural plasticity
	↓Central neurotransmitter acitivity Deafferenation	↓Anaesthetic requirement
		Impaired (↓↑) autonomic homeostasis
4. Pulmonary system	↑Thoracic stiffness	↓Vital capacity, ↑RV
	↓Lung recoil	↑Work of breathing
	↓Alveolar surface area	↓Efficiency of gas exchange
5. Blood and immune system	Thymic involution	↓Immune competence
	Reabsorption of bone marrow	↓Hematopoietic reserve
6. Renal/hepatic system	↓Tissue mass	↓Drug clearance
	↓Vascularity and perfusion	↓Ability to withstand salt and water loads
		↓GFR, ↓Plasma flow

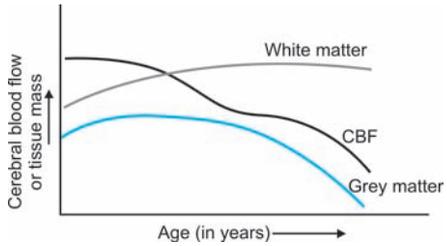

Fig. 39.4: The relation between the increased age and brain tissue mass and CBF (cerebral blood flow)

diminished and it is due to the reduction of number of receptors. In ageing brain, the upregulation (increase in number of receptor sites in response to reduction in neurotransmitter activity) is less vigorous than in the young population. The CNS 'plasticity' (the ability to reroute the neural pathways) to compensate the neural injuries is less marked and less complete in aged person than young. Therefore, recovery from neural injury (e.g. stroke, accident, etc) in geriatric patient is slow and incomplete.

In the elderly persons at peripheral nervous system there is also reduction of both the velocity and the amplitude of the electrical transmission of impulses through both the afferent (sensory) and efferent (motor) pathways. In old age the degenerative changes in sensory receptors also occur and the threshold for perception of snsory stimulus such as touch, pain, temperature, smell, vision, hearing etc. increases. Hence, impairment of cortical transmission thus delays the onset of voluntary motor activity. But skeletal muscles do not undergo any change with age except man, as enzymatic machinary within it remains intact. With increased age, the number and density of motor end plate also decreases. To compensate this, there is both the thickening and the spread of the existing post-junctional membrane beyond the usual areas of motor end plate, and increase in the number of cholinergic receptors at the end plates and surrounding areas. However, the sensitivity to non-depolarising relaxants does not decrease significantly with age. Alternatively the sensitivity to succinylcholine is increased in some elderly. It is due to the reduced plasma cholinesterase enzyme concentrations and not due to the changes at neuromuscular junction itself with age.

With increased age the plasma levels of NE increases gradually, though there is attrition of neurons in the sympathoadrenal pathways. But, clinically the increased effect of NE is not always found due to the reduction of the autonomic end-organ responsiveness with age. There is significant impairment of the ability of β-adrenergic agonist to stimulate β-receptors, causing less positive inotropic and chronotropic actions. The probable mechanism of reduction in action of β-adrenergic agonists are attrition of receptors, reduced affinity of neurotransmitter towards the receptors and impairment of adenylcyclase activation due to decreased cell membrane fluidity. The autonomic reflexes maintaining the cardiovascular homeostasis also decreases progressively with age. So, BP is less well maintained in a steady state level in adverse situations (i.e. in hypotension or hypertension) in elders than the young. Hence, the anaesthetic agents (such as β-blockers, etc.) and the techniques (spinal or epidural) that block the sympathetic system causes more hypotension in an elder than a young (Fig. 39.4).

Haemopoietic Function

Age has little effect on RBC, WBC and platelet count. The hypercoagulability of blood and thrombosis in vessels is not directly related to ageing. The age actually indirectly enhances the platelet mediated haemostasis. The common observation of ecchymotic lesions on the skin of the extremities of many elderly individuals is the result of age related increase in the fragility of cutaneous blood vessels. The volume of bone marrow and also the mass and volume of spleen, responsible for haemopoiesis, reduces in size with age. So, anaemia cannot be corrected easily in elderly patients, though clinically significant anaemia is not the physiological process of aging. Although, the volume of bone marrow, spleen and other haemopoietic reserved tissues are reduced with age, but the effect of aging is rarely enough to alter the day to day haemostasis or the acute

haematologic responses to accidental injury or mild stress. With age anatomical involution of thymus occurs (that begins at young adulthood) and causes a decrease in the immune responsiveness in elderly. With the quantitative age related change in thymic mass, there is also progressive change of thymic composition. Thus, both these quantitative and qualitative changes of thymus play a central role in reduction of the adaptive immune system, primarily the T-lymphocyte mediated responses. So, elderly are particularly predisposed to streptococcal pneumonia, meningitis and septicaemia. Infection or sepsis is notoriously occult in geriatric surgical patients. It is the second only cause after cardiac failure of perioperative morbidity and mortality. Erythropoietin levels are generally normal, but may be depressed easily by infection.

Body Composition, Drug Distribution and Metabolism

After 60 years of age, the body weight decreases rapidly and the body composition also changes. Throughout the whole path extending from young adulthood through middle age to the old age, a person generally gain 12 Kg of adipose tissue, but lose about 8 Kg of skeletal muscle mass. When this loss of muscle mass and atrophy of central organs is combined with the loss of subcutaneous fat, then it produces a significant fall in total body weight in aged men. The age-related changes in body composition are universal, progressive and irreversible. This change is due to the steady increase in the ratio of lipid to aquous tissues (i.e. lipid fraction increases and water fraction decreases), and results in the increase in lipid fraction of total body mass which acts as reservoir for anaesthetic and other lipid soluble drugs. This total body fat increment is more profound in woman than man. Thus, the significant reduction of intracellular and interstitial water reflects the attrition of metabolically active tissues. Diminished thirst, poor diet and the use of diuretics to treat the age related hypertension also make the intracellular and interstitial dehydration a more common finding during the preoperative examination of elderly patients.

Glucose intolerance is almost universal among the elderly patients. The cause of glucose intolerence at this age is due to the insulin antagonism and impairment of insulin function, but is not due to the decreased insulin secretion. The reduction of lean body mass that provides the storage for carbohydrate is also an explanation for the carbohydrate intolerence. So, the loss of skeletal muscle mass is also associated with the progressive impairment of ability to handle an intravenous glucose challenge.

In elderly the basal resting metabolism is reduced by 10 to 15% and it is in parallel with the reduction of lean tissue mass. So, the rate of production of body heat gradually declines. Simultaneously, there is also age-related impairment of thermosensitivity and also the impairment of autonomic thermoregulation which in combination increase the risk of inadvertant hypothermia, especially in cold enviornment in OT. The Intraoperative decrease in core body temperature is almost 1°C per hour which is about twice that observed in young adults under similar circumstances. So, core body temperature of geriatric patients frequently fall during intra-and postoperative period (Table 39.2).

In a similar manner to the reduction of intracellular and interstitial water volume, the plasma volume which is a major determinant of β-phase (molecular aspect of drug distribution from plasma to other compartment) of pharmacokinetics of drugs is also reduced. So, the doses of

Table 39.2: Effects of aging on pharmacology of anaesthesia related drugs

	Drugs		*Pharmacology*
1.	Inducing agents		
	Propofol		↑drug effect
	Thiopentone		↓dose requirement
	Cause	(i) CNS changes	
		(ii) decreased volume of distribution	
2.	Benzodiazepines		
	Diazepam		↓dose requirement
	Midazolam		↑drug effect
	Cause	(i) CNS changes	
		(ii) ↓liver and renal mass	
		(iii) ↓blood flow of liver and kidney	
3.	Opiates		↑drug effect
	Morphine		↓dose requirement
	Fentanyl		
	Cause	↓volume of distribution	
		↓hepatic and renal blood flow CNS changes	
4.	Volatile anaesthetics		
	Halothane		↑drug effect
	Sevoflurane		↓dose requirement
	Isoflurane		
	Cause	CNS changes	
5.	Muscle relaxants		↓dose requirement

	Nondepolarizing agent		↓dose requirement ↑drug effect
	Cause	Neurogenic atrophy decreased renal and hepatic function	

drugs based on body weight shows higher concentration than expected in blood in older one and explain increased sensitivity to drugs in elders.

Most of the drugs which are used in anaesthesia are metabolised in liver (small amount is metabolised in extra hepatic tissue) before elimination and very small amount is eliminated in intact form through bile or urine. Therefore, with age as the hepatic blood flow and hepatic mass is reduced, so the clearance of drugs also declines. Thus, there is a growing interest in replacing the pharmacokinetic parameters which are derived from the multicompartmental models by a more complex but realistic analysis such as context-sensitive pharmacokinetics. This context sensitive pharmacokinetics of anaesthetic drug definitely show the difference between the elderly and younger populations. MAC is the minimum alveolar concentration (in volumes percent) of an volatile anaesthetic agent at 1 atmospheric pressure that prevents the movement of 50% of population to a standard given stimulus. For inhalational agents, the anaesthetic requirement is typically quantified by MAC. Whereas for intravenous agents, anaesthetic requirement is typically quantified by ED_{50} which is required to abolish reponse to a given standard stimulus in 50% of subjects. With increasing age, MAC or ED_{50} requirement decreases progressively with increased sensitivity to many anaesthetic agents, especially the CNS depressant drugs. MAC decreases steadily with age (4 to 5% per decade after 40 years for example, the MAC of isoflurane is approximately 0.92 at 80 years of age).

Diazepam have elimination half-life of 20 hours at 20 years of age and 85 hours in 80 years of age. The plasma concentration of midazolam required to prevent response to verbal command in an 80 years old person is only 25% of that required in a 40 year old, proving increased sensitivity of brain to benzodiazepine. MAC decreases with age, proving increased sensitivity of inhalatinal agent in elderly. MAC values of halothane are 0.84, 0.76 and 0.64 at 25, 42 and 81 years of age respectively. While MAC values of isoflurane are 1.28, 1.15 and 1.05 at 26, 44 and 64 years of age respectively. Therefore, the incidence of awareness during anaesthesia is a rare occurrence in the elderly. Plasma proteins are often reduced, resulting in reduced protein binding of drugs and its metabolites. Thereby there is every chance of increasing the free anaesthetic drug levels and its possible toxic effects. About 15 to 20% decrease in plasma albumin concentration leads to decreased binding and increased bioavailability of intravenous induction agents. Study has shown that there is 44% decrease in thiopentone requirement in elderly persons compared to a young adult as up to 80% of this drug is albumin bound. On the other hand, the brain sensitivity to thiopentone does not reduce with age. This also explains the increased response of thiopentone in geriatric patients. Though, propofol has a decreased (15 to 30%) dose requirement in elderly patient, still the rapid clear headed recovery is not observed in them. Inspite of the increased incidence of hypotension and apnoea the propofol is not contraindicated in elderly patients, if not judiciously administered. The cardiovascular stimulatory effects of ketamine are retained in the elderly age group of patients. Thus, this effect makes this agent very useful in high risk patients, but with cautious use in ischaemic heart disease. Ketamine's hallucinogenic effects are not more marked in the elderly.

Regional anaesthesia provides a desirable alternative to GA as maintenance of intraoperative consciousness in former permits prompt recognition of angina pectoris and acute changes in cerebral function, during intraoperative period. RA is associated with less postoperative confusion compared to patients rceiving GA. Apart from decreased operative blood loss, lowered incidence of postoperative deep vein thrombosis in RA following hip surgery has been observed in elderly patients and it is a great advantage. Another advantage of RA over general anaesthesia in elderly patients is less respiratory problems in postoperative period. Limb and plexus nerve blocks are also ideal for surgery performed on extremity in elderly. Still in patients with severe cardiovascular disease, GA is a better alternative. One review had concluded that RA may reduce mortality in one month but RA and GA appear to produce comparable results for long-term mortality. Like most other drugs, the dose requirements for RA are significantly less in elderly. The level of subarachnoid analgesia is usually two segments higher in elderly patients which may even be unpredictable due to higher specific gravity of CSF in this age group. There is also decreased segmental dose requirement of local anaesthetic agent during epidural analgesia in elderly. This may reflect the decreased volume of epidural space in elderly patients due to arterio sclerotic changes of vertebral column. Though hypotension is more frequent, postspinal headache is less in geriatric group of patients.

ANAESTHETIC MANAGEMENT AND PERIOPERATIVE RISK OF GERIATRIC PATIENTS

For anaesthetic management of elderly patients, there is no specific technique or specific anaesthetic agent which can reduce the perioperative risk or mortality in this group of patients. There is no difference in outcome between the GA and RA when they are applied correctly on elderly for the same surgery. Though regional anaesthesia has many advantages over general anaesthesia, but hypotension is more commonly seen in elderly patients undergoing spinal/epidural anaesthesia. This is due to the impaired autonomic function and reduced compliance of arterial tree in geriatric group of patients. Conversely, the rates of intravenous fluid administration that would be modest for young adults

may precipitate congestive heart failure and pulmonary oedema in elderly patients. GA may be the best for those who require precise control of blood pressure and heart rate. RA for hip fracture may reduce mortality at 1 month, but regional and general anaesthesia appear to produce comparable results for long term mortality. The overall perioperative morbidity and mortality rate is same between healthy, fit, octogenarians and young adults, undergoing similar surgical procedures. Only very debilitated and sickly older patients are particularly prone to perioperative complications.

The three major risk factors that appear to determine the mortality rates for geriatric patients are: (i) the operative site, (ii) the need to perform surgery on an emergency basis, and (iii) the physical status of patient at the time of surgery. When elderly patients are undergone emergency surgery, then mortality rate rises many fold. It is due to (i) the inadequate preoperative evaluation and preparation of elderly patient and (ii) the nature of surgical lesion and its acute consequences, such as haemorrhage, dehydration, ischaemia, acidosis, etc. on already critically reduced organ's reserve. Infection and sepsis are two major important causes of death in elderly patients, despite vigorous IV antibiotic therapy. This is due to age related reduction of immune response. Operative site is also an important determining factor of mortality rate for elderly patients. Superficial surgery as for example cataract surgery, skin biopsy, superficial excision, etc, under local anaesthesia has much lesser risk than a surgical entry into any major body cavity. Mortality risk for herniorrhaphy, transurethral prostetectomy, etc, is in between the above mentioned two categories of surgery. The preoperative physical status of elderly patients clearly correlates well with the perioperative mortality.

Age was previously misunderstood as a factor of increased mortality. But, now it has been properly evaluated that age related disease, causing poor physical status is the most important determinant of mortality rate and not the age itself. For example, one half of the elderly surgical patients have hypertension which have widespread effects on multiple organs, causing decreased reserve and thus increase the risk of anaesthesia, despite continuing therapy. The significant portions of geriatric patients also have coronary artery, metabolic (most common is diabetes mellitus), pulmonary, renal and hepatic diseases with ill effects on multiple organs and reduce the reserve in every systems. Preoperative malnutrition or hypoalbuminemia or the development of negative protein balance may also have predictive value on the rate of surgical and anaesthetic mortality for elderly patients. The metabolic response of elderly patients to tissues injury is sluggish. The ability to ambulate properly after surgery are also the fundamental determinants of uncomplicated surgical recovery. But, these can not be achieved in older adults simply by giving injection of growth hormone or increasing the parenteral protein replacement.

Though, there is no specific or best anaesthetic agent or technique for the elderly patients, still a satisfactory and uncomplicated anaesthetic course can be carried out by: (i) a proper and good preoperative evaluation and preparation of patient, (ii) a proper anaesthetic plan, and (iii) vigilant monitoring to suit the physical status of the patient with the type and site of surgery. In old age, the arm – brain circulation time is increased and dose requiements for induction agents are drastically reduced. So, during induction of anaesthetic drugs should be titrated very slowly against the effect. Due to the loss of functional reserve of all the organs, anaestheitc agents which have cardio deperssant effects and reduces cardiac output (e.g. volatile anaesthetic and others) should be used very cautiously. Regional anaesthesia (causing pharmalogical sympathectomy) is also less well tolerated in elderly patients who have already reduced circulating blood volume due to age related physiological changes. From the begining of young adulthood the MAC (for inhalational agents) and ED_{50} value (equivalent to MAC for non-inhalational agents) decline linearly with increasing age. Typically, an 80-year-old patient requires only 2/3 to 3/4 of the anaesthetic dose which is needed to produce similar effects in a young adult. This reduction in MAC and ED_{50} with age probably reflects the fundamental neurophysiological changes in the brain (reduced neuron density and reduced concentration of brain neurotransmitter) due to aging. The amount of anaesthetic requirement may be a quantifiable measure of the functional reserve of the central nervous system. The reduction of requirement of IV anaesthetic agents (due to $\downarrow ED_{50}$) is similar to that observed for inhalational agents (due to $\downarrow$MAC). This is simply due to the result of higher than expected initial plasma concentration of these drugs, during the early phases of their redistribution from plasma to body tissues. This may be again due to the exaggerated age related early or alpha phase of pharmacokinetic changes rather than pharmacodynamic changes. The classic two or three compartment models used for pharmacokinetic analysis of IV anaesthetic agents is also less predictable for elder subjects. Dosage of opioids and benzodiazepines should be reduced due to age related changes in pharmacokinetics and pharmacodynamics of these drugs, for example, increased sensitivity of cerebral cortex (pharmacokinetic) and reduced elimination (pharmacodynamic) of fentanil etc. As remifentanyl, atracurium and cisatracurium do not depend on organ based elimination, so their clinical effects in elderly patients are prompt and predictable.

The dose of nondepolarizing muscle relaxants is same or slightly increased in elders than youngers. But their duration of actions is prolonged due to the decreased rate of clearance. These pharmacodynamic change reflects the quality and quantity of

cholinoreceptor dynamics at the neuromuscular junction, but not the skeletal muscle mass itself. The cholinoreceptor upregulation appears to offset the declining prejunctional acetylcholine mobilization.

Though the dose of anticholinesterase to reverse the effect of muscle relaxant is same in elderly and younger patients, but the incidence of arrhythmias produced by these drugs is higher in elderly, especially who have cardiovascular disease. For any given level of pre-existing neuromuscular blockade, the choice of reversal agent is determined by the speed and the completeness of recovery of neuromuscular transmission, but not by the patient's age. In elderly the action of all the drugs become prolonged if they require hepatic or renal biotransformation for their elimination. Elderly patients due to the loss of muscle mass and impaired thermoregulations are more prone to perioperative hypothermia. So, body heat should be conserved aggressively by fluid warmer or body warming devices, whenever possible, to avoid the cardiovascular and metabolic stress due to shivering with already diminished reserve.

Though the function of central nervous system return quickly and completely after general anaesthesia, still neurological examination shows abnormality upto 60 minutes after recovery. The residual central nervous system dysfunction in subtle form after general anaesthesia is unique for the geriatric population. In 25% cases there is memory deficit and impaired spatial and verbal cognition even upto 7 days postoperatively. All these are due to the increased volume of distribution, reduced drug clearance, delayed transfer of drugs among compartments and the combination of these factors. For the older patients postoperative delirium, disorientation and acute brain syndrome are common and it is due to the disorder of metabolic states such as the hyper and hypoglycaemia, hypoxia, hypercarbia, fluid and electrolyte imbalance, prolonged anaesthetic effects, etc. It also may be the expression of subclinical age related neurological disease.

Intraoperative gross central nervous system injury can happen from cerebral embolism, haemorrhage or ischaemia. Such injuries are distinguishable from residual central nervous system dysfunction or residual anaesthetic effect by their severity, focal nature and the absence of conspicuous improvement in the first few hours after anaesthesia. Reduced responsiveness of protective airway reflexes in elderly patients need routine protection against regurgitation and aspiration of gastric contents. All the elderly patients should be administered O_2 postoperatively to compensate for the inevitable decrease in oxygenation due to loss of body reserve.

40 Obesity and Anaesthesia

INTRODUCTION

The obesity is defined as an abnormal growth of adipose tissue. It may be due to enlargement of fat cells in size (hypertrophic obesity) or due to increase in fat cells in number (hyperplastic obesity) or even a combination of both. It is the consequence of an interaction between the environmental forces and the individual genetic substrate. The genes which are responsible for fat metabolism enhance the storage of fat without causing obesity where food is limited and cause an increased risk of obesity when food is abundant and energy expenditure is less or reduced.

The term 'obesity' is derived from the Latin word 'obesus' which means 'fattened by eating'. This is due to the excessive net energy intake in excess of net energy expenditure. The excess energy intake is laid down on various parts of the body as fat, resulting in obesity. Modern life-styles and better standards of living have been in the way of contributing increased prevalence of obesity. So, obesity is a chronic disease that is gradually becoming widespread and is posing a serious risk in the development of non-insulin dependent diabetes mellitus, hypertension, ischaemic heart diseases, peripheral vascular disease, gallstones, osteoarthritis, etc. which cause increased risk for anaesthesia and mortality. Hence, undernutrition and malnutrition are the problems of developing countries, while obesity is the bane of developed countries.

The total body fat and its distribution in a person are affected by his or her gender, age, degree of physical activity and number of drugs used. In both men and women, body fat increases with age. In lean young healthy men, the body fat is usually less than 20% of his body weight and may rise with age to more than 25%. In young women, body fat stores may be below 30% and increases gradually to more than 35% in older women. At all ages after puberty women accumulate more fat than men. Sometimes, the term obesity is frequently used synonymously with overweight from the aspect of risk factors. But, the term 'overweight' means an excess average weight for a given sex, height and age. Overweight is usually due to obesity, but can arise from other causes also such as abnormal muscle development or fluid retention (Fact file- I).

The regional fat maldistribution also has a profound influence on health risks. For example, only increased deposits of visceral or abdominal fat correlate well with the risks for heart disease, diabetes and hypertension. For estimating or measuring the total or regional body fat, there are several techniques which are listed in the table. Among these, the dual energy X-ray absorptiometry provides the best method for assessment of total body fat, but not the regional body fat. The regional body fat can only be measured accurately by MRI or CT-scan. But for practical purposes, waist circumference or sagittal diameter of it is the most useful parameter for estimation of regional fat in body. The ratio of waist circumference to hip circumference is also widely used to measure or estimate the regional fat distribution, but is not so accurate. For estimation of total body fat X-ray absorptiometry, CT-scan, MRI, etc. are highly accurate, but such measurements may not be clinically feasible. (Table 40.1) Body weight, though, is not an accurate measurement of excess body fat, still it is a widely used index of obesity. In epidemiological studies, it is conventional to accept deviation of +2 SD (Standard Deviation) from the median weight for that height as the cutoff point for obesity. So, overweight or obesity can be defined from the tables of height and weight. On the other hand, the ideal body weight (Broca index) can also be estimated from the height (cm) by deduction of 100 from it. For example, if a person's height is 160 cm, then his ideal body weight should be 160 – 100 = 60 Kg. A person is said to be obese when his or her actual body weight exceeds this ideal body weight by more than 20%. However, the most widely used formula for relating height and weight in a person is the body mass index (BMI) which is calculated by Weight (Kg)/Height^2 (meter) [i.e. BMI = Mass (Kg)/[Height (m)]^2. A BMI between 20-25 Kg/m^2 is considered usually as a good weight for most individual. A BMI of 25 to 30 Kg/m^2 is considered as overweight, but with low risk for associated serious medical complications. Those with BMI of >30 Kg/m^2, > 35 Kg/m^2 and >55 Kg/m^2 are respectively considered as obese, morbidly obese and supermorbidly obese. Weight gain confers increased health risk even if the BMI does not excees 25 Kg/m^2.

FACT FILE- I

There are four processes which are involved in the regulation of food intake. These are : (i) olfactory and gastatory factors which can stimulate or inhibit the intake of food according to its appetizing property, (ii) release of gastrointestinal hormones such as cholecystokinin and gastrin releasing peptide, (iii) gastrointestinal distension, and (iv) activation of thermogenic component of effarent sympathetic nervous system. All these factors work together to induce safety after ingestion of food and also do not produce new arousal for seeking food till the next blood glucose level dips.

Excessive nutrient is stored in the body as fat. To maintain the normal body fat, dietary nutrients should be oxidized in the proportion by which they are taken through diet. Among the ingested carbohydrate, fat and protein, the intake of carbohydrate approximates the body stores of it. While intake of fat and protein constitutes a small fraction of the stored quantities of these nutrients. Therefore, as the daily intake of carbohydrate nearly equals the body store of it, so carbohydrate store is more vulnerable to the changes in the dietary carbohydrate than fat or protein. The respiratory quotent (RQ) of fat (0.7) is less than that of carbohydrate (1). Hence, if the percentage of dietary fat increases, the RQ should be declined to maintain the body weight stable. But if RQ does not decline (which normally occurs in obese patient) the body continues to oxidize the carbohydrate store and must replace these by eating more food to obtain carbohydrate or synthesise endogenous glucose from protein stores. This adjustment strongly depends on the genetic determinants.

If the carbohydrate oxidation is reduced or not available, the oxidation of fat increases to provide for nutrient needs and lower the RQ. If the body is unable to reduce the carbohydrate oxidation, the compensatory mechanism is increased foods intake to provide needed carbohydrate with increasing fat storage and obesity.

Estimated total energy need = BMR × Activity factor

(For low or sedentary activity the activity factor is 1.3, for intermediate activity such as regular exercise the activity factor is 1.5, and for high activity the activity factor is 1.7.)

Estimation of basal metabolic rate (BMR):

For women:

15 to 30 years = (LBW × 0.0621 + 2.0357) × 240 kcal/day
30 to 60 years = (LBW × 0.0342 + 3.5377) × 240 kcal/day

For men:

15 to 30 years = (LBW × 0.063 + 2.8957) × 240 kcal/day
30 to 60 years = (LBW × 0.0484 + 3.6534) × 240 kcal/day
LBW = Lean body weight
Daily energy requirement (calculated)
At rest : 2000 kcal (8.4 MJ)
Light work : 2700 kcal (11.3 MJ)
Heavy work : 3500 kcal (14.6 MJ)

Table 40.1: Methods of estimating body fat and its distribution

Method	*Accuracy*	*Ease of use*	*Estimation of regional fat*
Weight and height	High	Easy	No
Circumferences	Moderate	Easy	Yes
Skinfold	Low	Easy	Yes
Density			
Immersion	High	Moderate	No
Plethysmograph	High	Difficult	No
Ultrasound	Moderate	Moderate	Yes
Potassium isotope	High	Difficult	No
Heavy water	High	Moderate	No
Bioelectric impedance	High	Easy	No
Total body electrical conductivity	High	Moderate	No
Computed tomography	High	Difficult	Yes
MRI	Difficult	High	Yes
Neutron activation	Difficult	High	No

In a woman, a weight gain of more than 5 Kg is associated with an increased risks of diabetes and heart disease. In men any weight gain after age of 25 years appears to carry increased health risks (Table 40.2).

The another method of assessing the total body fat is measurement of skin fold thickness. It is a rapid and noninvasive method and several varieties of callipers are available for this purpose. The measurement is taken at the four sites of body such as at midtriceps, biceps, subscapular and suprailiac regions and the sum of the measurements should be less than 40 mm in boys and 50 mm in girls. Unfortunately, any standards of the subcutaneous fat for determination of obesity do not exist for comparison. Further, in extreme obesity, measurements of subcutaneous fat may be impossible. The another main drawback of skinfold measurements for assessing total body fat is their poor repeatability (Fig. 40.1).

It is now also recognised that in addition to the amount of excess fat present in an obese individual, the anatomical distribution of this fat has an important bearing

Table 40.2: Body mass index according to weight

Weight	*BMI [Wt (Kg) / Height^2 (m^2)]*
Underweight	< 18.5
Normal	18.5-24.9
Overweight	25-29.9
Obese	30-39.9
Extremely obese	> 40

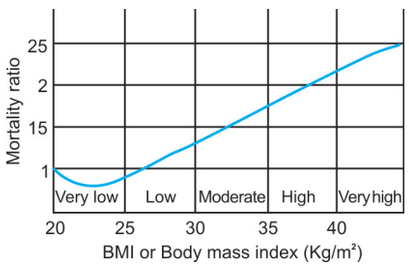

Fig. 40.1: The relationship between the BMI and overall mortality rate. At BMI greater than 20 Kg/m^2 but less than 25 Kg/m^2 there is decrease in mortality

on the health risk. Central or android type of distribution of fat, which is more common in men, manifests as abdominal obesity. In contrast, peripheral or gynecoid type of distribution of fat, which is more common in females, manifests as deposition of fat mainly around the hips, buttocks and thighs. The central adipose tissue is more metabolically active than the fat deposited in the periphery. Here the obese individuals who have a more central distribution of body fat tend to suffer more from metabolic complication such as dyslipidaemias, glucose intolerance, diabetes mellitus, ischaemic heart disease, heart failure and stroke, etc. As abdominal fat is more easily mobilised, men also tend to lose weight more readily than women.

When triglycerides are deposited in fat cells, then the cells initially increase in size, until a maximum limit is reached, at which point the cells divide. Moderate degrees of obesity (BMI < 40 Kg/m^2) are likely to result from an increase in the size of fat cells, whereas extreme obesity (BMI > 40 Kg/m^2) is likely to result from the proliferation of fat cells from the adipocytes (Fact File- II).

Fat Cells and Obesity

The fat cells not only store the fat, but also secrete some enzymes named lipoprotein lipase which hydrolyses the triglycerides of VLDL and chylomicrons. They also produce some complements like D_2, C3b, cytokines, etc (such as angiotensinogen, leptin, lactate) and metabolise glucose to provide glycerol-3-phosphate for synthesis of triglyceride. Fat cells also synthesise long chain fatty acids when there is abundancy of diet (Table 40.3).

FACT FILE - II

There are three known predictors which control the future weight gain. These are: (i) Low metabolic rate, (ii) High RQ indicating high carbohydrate oxidation and the need to eat more to replace this carbohydrate, and (iii) Insulin resistance. The regulation of food intake is controlled by feedback system with afferent and efferent signals. Factors that increase hunger include decrease in blood glucose level, an increase in gastric contractions or abdominal uneasiness. These peripheral signals are integrated by neurotransmitters in the brain to regulate food intake. Several neurotransmitters increase or decrease the food intake. In addition, some neurotransmitters are specific modulators for the intake of specific food such as fat, carbohydrate and protein. Thus decrease or increase of intake of carbohydrate, fat and protein occur as a major response to specific neurotransmitter which are controlled by the genetic code of this individual.

PHYSIOLOGICAL CHANGES ASSOCIATED WITH OBESITY

Obesity is associated with certain physiological changes that have important anaesthetic implications. This is because obese individuals handle drugs differently than their normal counterparts as the pharmacokinetic and pharmacodynamic of drugs are changed in obese patients. So, understanding of these physiological and pharmacological changes is necessary for the proper management of anaesthesia on obese patients presenting for surgery either to reduce the obesity (gastric bypass, vertical banded gastroplasty, uvulopalatopharyngoplasty, liposuction) or presenting for surgery for other diseases.

Cardiovascular System

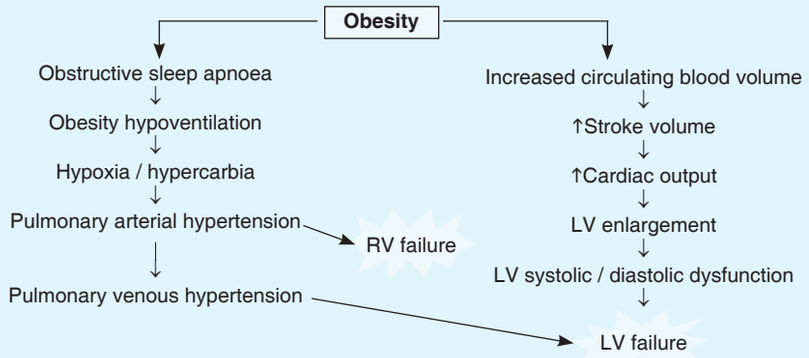
Obesity is associated with increased work load on the heart. This is due to the developement of hypertension and/or hypervolaemia. Obesity is also associated with increase in absolute blood volume, although this is lower than normal value in relation to body mass (occasionally 45 ml/Kg). Increased extracellular fluid volume resulting in hypervolaemia and increased cardiac output is estimated to increase by 0.1 L/min for each Kg of weight gain. Each Kg of fat contains extra 3000 metres of blood vessels. Mild to moderate degree of systemic hypertension is seen in 50 to 60%, of obese patients while severe hypertension is present in 5 to 10% of obese patients (mechanism being unclear). The probable hypotheses are: (i) obesity is associated with hyperinsulinaemia and increased insulin resistance which enhance Na^+ reabsorption from the renal tubules, (ii) obesity causes increased sympathetic outflow, promoting arterial vasoconstriction and (iii) enhancement of pressure activity (or sensitivity) of nonepinephrine and angiotensin II in obesity. Obesity is also associated with an increased risk of sudden death, and this is probably due to sudden cardiac arrhythmia. It is also associated with an increased risk of artherosclerosis probably due to abnormal lipid profile. The abnormal lipid profile in obesity includes decreased level of HDL cholesterol, and increased level of LDL cholesterol. Obesity is also associated with pulmonary hypertension which is probably due to chronic arterial hypoxaemia and increased pulmonary blood volume. Therefore all these factors such as hypertension, ↑cardiac workload, atherosclerosis, hyperinsulinaemia, diabetes, etc. which are common in obese individuals, compound the likely development of ischaemic heart disease. (IHD) (Table 40.4).

Table 40.3: Some specific causes of weight gain

A.	Genetic
	Pradder-Willi syndrome, Laurence-Biedl syndrome, etc.
B.	Endocrine factors
	Hypothyroidism, insulinoma, Cushing's syndrome.
C.	Drugs used
	Phenothiazines, tricyclic antidepressants, sulphonyl urea, oral contraceptive, glucocorticoids, antiepileptic (valproate).

With obesity, there is increase in the volume of epicardial fat but no myocardial fatty infiltration. So, obesity is not directly responsible for the myocardial weakness and heart failure but indirectly responsible for all these ailments. Hence, obesity-induced cardiomyopathy is mainly due to hypertension, IHD, hypervolaemia, ventricular dysfunction and these are responsible for heart failure. LV

Table 40.4: Obesity induced cardiomyopathy and association of obesity with congestive heart failure



hypertrophy and its dysfunction demonstrated, by echocardiography, is characteristic of obesity. Obesity induced changes in cardiovascular system reduce its reserve and limits its exercise tolerance. Morbidly obese patients tolerate exercise poorly. This is because increase in cardiac output necessary for exercise is achieved only by increasing the heart rate without an increase in stroke volume or ejection fraction, i.e. increased myocardial contractility in oberity due to cardiomyopathy. On changing position from sitting to supine, obesity is also associated with higher increase in PCWP and mean pulmonary artery pressure.

Respiratory System

Moderate obesity in the absence of underlying pulmonary disease has little effect on respiratory function. Whereas in severely obese individuals, obstructive sleep apnoea (OSA) syndrome is a potentially serious problem. This is because increased BMI is associated with an exponential decrease in respiratory compliance. In extreme cases the compliance can fall up to 30% of the predicted value. The reason for this decrease in respiratory compliance is due to twofold accumulation of fat in and around the chest wall leading to reduction of chest wall compliance and due to increased pulmonary blood volume resulting in decrease in lung compliance and splinting of diaphragm. The reduction of this total respiratory compliance (chest wall and lungs) is in turn associated with a decrease in FRC and encroachment on closing volume which causes impairment of gas exchange. Therefore, the increase in intrapulmonary shunt and increase in alveolar-to-arterial oxygen tension difference which are evident as arterial hypoxaemia is more worsened during induction of anaesthesia of an obese person. So always a high inspired O_2 concentration is required during the induction of anaesthesia and whole perioperative period to combat this arterial hypoxaemia. Reduced FRC can be increased by administering PEEP or large sustained manual inflation. But, the use of PEEP does improve this arterial O_2 tension (P_aO_2) at the expense of cardiac output and oxygen delivery to tissues (Fact file -III).

FACT FILE- III

Obesity also imposes a restrictive ventilation defect. This is due to the extra weight, added to the thoracic cage and the abdominal wall impeding motion of the diaphragm, especially in supine position. This results in decrease of functional residual capacity (FRC), expiratory reserve volume (ERV) and total lung capacity. FRC declines exponentially with increasing BMI. FRC may be decreased to such a point that small airway closure occurs within the tidal volume resulting in a ventilation-perfusion mismatch (shunt and arterial hypoxaemia). Further, induction of anaesthesia in an obese individual results in 50% decrease in FRC as compared to 20% decrease in a non-obese individual.

Sleep Apnoea

Sleep apnoea is defined as an intermittent cessation of airflow to lungs through the nose and mouth during sleep. By convention an apnoea of at least 10 second duration is considered important. But, in most patients these sleep apnoeas are of 20 to 30 seconds duration and also may be as long as 2 to 3 minutes.

The sleep apnoea which is a type of respiratory dysfunction is a serious consequence of obesity. The cessation of breathing during apnoea may be either due to occlusion of airway (obstructive sleep apnoea or OSA) or absence of respiratory effort (central sleep apnoea), or a combination of these two factors (mixed sleep apnoea). Approximately, 5% of morbidly obese patients present with features of OSA (obstructive sleep apnoea) characterised by episodes of apnoea or hypopnoea during sleep. Failure to recognise and appropriately treat these conditions may lead to sometimes serious cardiovascular complications and increased mortality rate.

Hypopnoea is defined as 50% reduction in airflow which is sufficient to cause a decrease in arterial O_2 saturation. More than 10 to 15 apnoeas per hour or more than 30 apnoeas per night is significant in OSA. It is also important to say that clinical sequelae of OSA such as hypoxaemia, hypercarbia, systemic and pulmonary hypertension, cardiac arrhythmias, right ventricular failure and polycythaemia are more important than the frequency and duration of apnoea. All such patients usually always show some evidences of sustained daytime hypoxaemia in addition to the nocturnal ventilatory disturbance, usually as a result of reduced ventilatory drive and/or diffuse airway obstruction. Most of these patients are obese and sleepy and are, therfore, said to have the Pickwickian syndrome.

Apnoea occurs when the pharyngeal airway collapses (obstructive) due to relaxation of muscles during sleep and / or there is no central drive (central) for respiration. Both these mechanisms are also responsible

for apnoea during anaesthesia in obese patients. In an obese individual local fat accumulation in the tracheopharyngeal area or compression of pharynx by the superficial fat masses of neck also predisposes to airway collapse. (In nonobese patient with OSA the adenotonsillar hypertrophy, craniofacial skeletal abnormalities such as retrognathia and macroglossia, etc. are taken as responsible for airway closure during sleep). Normally, the patency of pharyngeal airway is maintained by the action of dilator pharyngeal muscles. During sleep the tone of there muscles is reduced and airway becomes narrowed causing turbulent flow and snoring (a high frequency vibration of the palatal and pharyngeal soft tissues) and obstruction. The resulting hypoxia and hypercarbia from this airway obstruction causes arousal of the individual which in turn again restores the upper airway tone. The individual then falls asleep again and the cycle is repeated. The predisposing factors for sleep apnoea during anaesthesia of an obese patient are degree of obesity (BMI > 30), middle age, male and anaesthetic drugs depressing the respiratory centre and muscle tone (Fig. 40.2).

Disturbed sleep at night in OSA patients leads to day time somnolence and inability to concentrate the mind. Obese individuals with OSA gradually develop features of chronic hypoxia and hypercarbia in the form of polycythaemia, pulmonary hypertension right heart failure and respiratory acidosis. An extreme form of OSA is the obesity hypoventilation syndrome (OHS) which initially results in the desensitisation of respiratory centres to hypercarbia (limited to sleep) manifesting as central apnoeic events (apnoea without respiratory efforts). Eventually, patients with OHS present with type II respiratory failure with increasing dependence on hypoxic drive for maintaining ventilation.

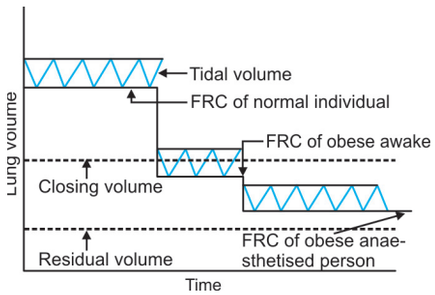


Fig. 40.2: The effect of severe obesity on FRC during awake and anaesthetised condition which result in small airway closure, ventilation perfusion mismatch and impaired arterial oxygenation

Anaesthetic management of a patient with the history of obstructive sleep apnoea poses significant risks. These patients are highly sensitive to all the anaesthetic drugs, causing upper airway obstruction or apnoea, even in minimum doses. So, sedatives (benzodiazepine) or opioids should be used very cautiously in the perioperative period. Upper airway abnormalities due to decreased anatomical space (due to accumulation of fat), accomodating the large tongue and displacing it anteriorly, causes great difficulty in exposure of glottic opening during direct laryngoscopy. When awake, these patients compensate for the compromising airway anatomy by increasing their craniocervical anagulation which increases the space between the mandible and the cervical spine and elongates the tongue and soft tissues of neck. This postural compensation is lost when these patients are rendered unconscious or paralysed. So, all the anaesthetic drugs should be titrated to get their just desired effect and preferably short acting agents such as sevoflurane, propofol, remifentanil should be used. N_2O should be avoided in the presence of coexisting pulmonary hypertension. Neuromuscular blocking drugs characterised by rapid spontaneous recovery should be selected. Tracheal extubation is not considered, until patients are fully conscious with intact airway reflexes. Oxygen consumption is increased by the metabolically active adipose tissue and the workload of in obese subjects supporting muscle. So, oxygen desaturation occurs rapidly in the obese apnoeic patients.

Others

Very frequently obesity is associated with glucose intolerance and diabetes. This is due to increased resistance of insulin by the presence of increased adipose tissue. So, hyperinsulinaemia is a uniform feature and its level is directly related to the degree of obesity. Thus, NIDDM commonly coexists in obese individuals. Reversely, NIDDM is almost non existant in an individual with a BMI below 22 Kg/m^2. Still, in obese patients with NIDDM the catabolic response to surgery may necessitate the use of exogenous insulin during the perioperative period.

Obese patients are also more prone to gall bladder and biliary tract diseases due to the increased excretion of cholesterol through hepatobiliary system. The amount of cholesterol synthesised in the body per day is increased by about 20 mg for each Kg increment of adipose tissue. So that a 10 Kg increase in adipose tissue mass increases the daily cholesterol production and excretion by an amount comparable to the cholesterol present in one egg. On the other hand, obesity is usually associated with abnormal liver function tests and fatty liver infiltration. So, volatile anaesthetic agents should be used cautiously.

The incidence of deep vein thrombosis is almost double in obese patients than in an nonobaese. This is due to the effects of polycythemia, increased abdominal presure and prolonged immobilisation.

Obesity also increases the gastric volumes, raises the intra-abdominal pressure and increases the incidence of hiatus hernia which pose a significant risk of aspiration.

INFLUENCE OF OBESITY ON DRUG PHARMACOKINETIC

The pharmacokinetic of drugs used in the anaesthesia practice is changed due to the pathophysiological changes associated with obesity. The volume of distribution of drugs in obese individual is influenced by the increase in blood volume and cardiac

output, decrease in total body water content (fat contains less water) and the lipid solubility of drug. Despite the occasional presence of liver dysfunction, hepatic clearance of drugs is not usually altered in obese individuals. Renal clearance of drugs is increased due to the increased renal blood flow and GFR in obese. For a desired concentration of drugs in plasma, two factors operate. One is the increased plasma volume in obesity which decreases the drug concentration in plasma and the other is the less blood flow in adipose tissue which increases the plasma drug concentration. So, the actual plasma concentration for a given bolus inducing dose of a drug is difficult to predict. It would, therefore, be wise to calculate the initial loading dose of a drug on the basis of 'ideal body weight' (lean body mass) than the present actual body weight. Subsequently, the further doses should be adjusted according to the pharmacological response of patient to the initial dose. Repeated injection or infusion of drugs, particularly the lipophilic group, could result in a cumulative effect and hence a prolonged response. It is due to the gradual storage of drugs (mainly lipophilic) into depot fat and later its subsequent release from it into systemic circulation as the plasma concentration of drug declines. It should be kept in mind that just as the increased fat depot in obesity increases the storage of drugs, but poor total blood supply to adipose tissues also limits the delivery of drugs to it. So, multiple factors playing on the pharmacokinetics of a drug make the calculations of its plasma concentration composite and difficult.

ANAESTHETIC MANAGEMENT OF OBESE PATIENT

Regional Anaesthesia vs General Anaesthesia

Bony landmarks are likely to be obscured in obese patients. So, spinal and epidural anaesthesia is technically very difficult in such group of patients. As compared to a nonobese individual, in obese the requirement of local anaesthetic agents for spinal and epidural anaesthesia is 20% lower. This is due to the reduced volume of epidural space because of fatty infiltration and vascular engorgement of it. But the advantages of regional technique over general anaesthesia in obese individual include the avoidance of difficulties related to securing the airway, perioperative hypoxaemia, ventilation and pulmonary complications. Regional anaesthetic techniques also provide good postoperative pain relief and hence use of drugs such as opioids that may depress respiration can be avoided.

Preoperative Assessment

A detailed preoperative assessment of an obese patient is routinely performed before induction of anaesthesia which includes mainly the air passage, respiratory system and cardiovascular system. Difficulties in mask ventilation and tracheal intubation should always be anticipated in obese patients and this is because of the unique anatomical features in them such as big-fat face and cheeks, short neck, large tongue, restricted mouth opening, little airway space due to excessive palatal and pharyngeal soft tissue, high and anterior larynx, limitations of movement of cervical spine, and restriction of atlanto-occipital flexion and extension due to accumulation of fat in neck etc. A BMI of 45 is associated with 13% risk of difficult intubation. Though inspection of previous anaesthetic records might provide some evidence of previous difficulties, but one should bear in mind that an uneventful previous anaesthesia may not be relevant any longer in this present case and it is due to the further accumulation of fat and weight gain during this interval. Preoperatively, airway is assessed clinically by different measurements and scoring systems, and by investigation such as X-ray, MRI of soft tissues, CT-scan, etc. and also by referral to an otolaryngologist for direct and indirect laryngoscopy which helps in a more complete evaluation of airway. It is also useful to assess the airway in both erect and supine positions (Table 40.5).

With airway assessment, the venous access and the risk of aspiration also should be assessed. If any difficult intubation is anticipated in any clinical scoring system or in radiological investigations then the possibilities of awake intubation, fiberoptic aided intubation, cricothyroid puncture with jet ventilation, tracheostomy and provision of postoperative ventilation should always be kept in mind and make ready. In addition to the airway assessment, preoperative assessment of patient should also include the full blood count, chest X-ray, supine and upright blood gases, lung function tests and overnight oximetry according to the merits and demerits of each case. Patients with symptoms, suggestive of OSA should also be evaluated by polysomnography and their condition is optimised with preoperative noninvasive ventilation such as CPAP and BIPAP. The possibility of other endocrine disorders associated with obesity (such as thyroid) or mistaken for obesity (such as Cushing's disease where diureal variations in plasma

Table 40.5: Medical and surgical complications associated with obesity

	Hypothyroidism
	Cushing's syndrome

cortisol and the concentration of urinary free cortisol is abnormal) should also be considered and is evaluated if necessary.

Like respiratory system, cardiovascular system also should be evaluated properly before anaesthesia of an obese patient. The severity of impairment of CVS may be underestimated by clinical evaluation only. So, echocardiogram may be frequently asked for to get information about the left ventricular function and other associated abnormalities (e.g. ventricular hypertrophy, cardiomegaly, cardiomyopathy etc). But echocardiography may be technically difficult in an obese patient and it is due to inability to obtain a proper acoustic window because of fat. Rapid weight gain, preoperatively, due to oedema may indicate worsening cardiac failure and it can be mistaken for obesity. In such circumstances cardiac performance may deteriorate quickly following induction and tracheal intubation or due to many other reasons during anaesthesia. So, an anaesthesiologist must always be prepared with a selection of inotropes, vasodilators and other drugs. Preoperative ECG is mandatory for obese patients. Overlying excessive adipose tissue may result in low voltage complexes in ECG, masking any ventricular hypertrophy that might be present.

Premedication

In obese patients the opiates and sedative drugs as premedication should be used very cautiously and in a titrating doses. This is because with the same degree of sedation there is more chance of airway obstruction in obese than nonobese patients. But, the degree of central repiratory depression is same for the same doses of drug in both the obese and nonobese patients. Premedication in obese patients should be given orally or IV. The intramuscular route for delivery of drugs in obese patients is associated with unpredictable pharmacokinetics and frequently the drug is deposited mainly into subcutaneous fat. So, this route should be avoided especially in obese patients. Antisialogogue should be used routinely in obese patients as there is more chance of difficult intubation and increased secretions make it more difficult. The obese patients are traditionally presumed to be at the increased risk for pulmonary aspiration (probably due to increased intra-abdominal pressure, delayed gastric emptying and increased incidence of hiatus hernia) during the induction of anaesthesia and intubation. But there is no supporting evidence for this notion. So, perhaps a group of anaesthetists thought that the greater risk of pulmonary aspiration is potentially related to the technical difficulty during tracheal intubation. So, as prophylaxis a combination of H_2 receptor blocker (ranitidine 150 mg) or proton pump inhibitor (omeprazol) and a prokinetic agent (metoclopramide 10 mg) should be administered orally 12 hours and 2 hours before surgery to reduce the risk of aspiration. In addition, some anaesthesiologists also advocate administering 30 ml of 0.3 M sodium citrate orally just before induction of anaesthesia. The advantages and disadvantages of administration of sodium citrate just before induction and intubation is discussed earlier.

The morbidly obese patients are more likely to develop deep vein thrombosis. Because they are likely to be less ambulent in the postoperative period. So, a low dose of subcutaneous heparin should be given as prophylaxis in the preoperative period and continued into the post operative period, until the patient is fully mobile. Other measures like pneumatic leggings, a graded compression stockings are also useful in reducing the incidence of deep vein thrombosis in obese patients.

Induction of Anaesthesia

Induction of anaesthesia is very tricky in an obese patient. Always an experienced assistant or a second anaesthetist should be available during induction, apprehending difficult intubation, ventilation and other airway related problems. On the other hand, tracheal intubation and IPPV is very essential for oxygenation in the morbidly obese patients as spontaneous respiration is very difficult and sometimes becomes impossible too. Intubation may be warranted for all, except the briefest procedures due to the risk of aspiration. IPPV is often necessary, because there is increased work of breathing and tendency to hypoventilation in spontaneous respiration. The choices among the awake intubation, intubation under inhalational anaesthesia or intubation after muscle paralysis depends on the experience of anaesthesiologist and his preoperative evaluation regarding the anticipated difficulties of intubation. Some authors recommend awake intubation when the actual body weight is >175% of average body weight. Presence of features suggesting significant OSA may also indicate the possible difficulties with bag and mask ventilation.

Another approach for intubation in obese patient is by direct laryngoscopy under topical and infiltration anaesthesia. If laryngeal structures can not be visualized, then fibreoptic intubation is probably a safe option. Blind nasal intubation with spontaneous ventilation can also be tried, but practically it is very difficult (not practised frequently) and trouble-some as nasal bleeding might cause further deterioration of an already difficult airway.

Apart from different techniques of intubation, rapid sequence induction and intubation using succinylcholine following an adequate period of preoxygenation and deep sedation is essential. The low FRC associated with obesity means that there is rapid decrease in arterial oxygen tension during direct laryngoscopy and tracheal intubation. The risk of quick arterial oxygen desaturation emphasizes the importance of maximising the oxygen content in the lungs before initiating direct laryngoscopy and also emphasizes the importance of monitoring of the arterial oxygen saturation continuously by pulse oximetry.

The anaesthetist should be well prepared with a full range of aids for tracheal intubation such as short-handled laryngoscope, polio blade, McCoy laryngoscope, gum elastic boogies, LMA, etc, anticipating difficult intubation. Equipment for emergency cricothyrotomy should also be kept ready and capnograph must be available to confirm the correct placement of ET tube. The obese patient will require ventilation with high inspired O_2 fraction and the addition of PEEP to maintain adequate arterial oxygen tension.

Maintenance of Anaesthesia

There is nothing special for maintenance of anaesthesia in obese patients. Use of sevoflurane and propofol during intraoperative period helps in rapid recovery from anaesthesia in such group of patients. Though, it is often stated that obese individuals awake slowly from GA than nonobese individuals, but the same does not happen in actual practice if short acting agents are used in very titrating doses. N_2O is frequently used for maintenance of anaesthesia in obese patients, because of its rapid elimination and quick recovery. But the frequent need for increased oxygen concentration in the inspired anaesthetic gas mixture may sometimes limit the usefulness of N_2O. Controlled ventilation using a large tidal volume is often used in an attempt to improve the oxygenation in obese individual, but the adverse effects of it on cardiac output and subsequently less tissue oxygen delivery must be borne in mind.

For noninvasive blood pressure monitoring, the width of sphygmomanometer cuff should be 20% greater than the diameter of arm. Invasive blood pressure monitoring may be required, if necessary. An arterial line allows accurate monitoring of arterial blood pressure and frequent blood gas analysis. Central venous pressure monitoring is desirable, as it helps in better assessment of cardiac functions in obese patients. Obese patients with cardiac failure may benefit from the use of a pulmonary artery catheter. The fluid balance may be difficult to assess clinically and increased blood loss is common in obese patients due to difficult surgical conditions.

Postoperative Care

The incidence of postoperative mortality of obese patients is twice than that of the nonobese patients. Pulmonary atelectasis is common and lung capacities remain in decreased state for at least 5 days after abdominal surgery in obese patients. So, to optimise the FRC and closing capacity ratio, ideally the obese patients are recovered in a head up or semisitting position (since this position is best for respiratory mechanics) and extubation is done when the reflexes are recovered fully. Postoperative ventilation is sometimes required in obese patients who are suffering from co-existing cardiorespiratory diseases and especially in those who have undergone prolonged surgery. It is mandatory that obese patients should be monitored intensively for hypoxaemia, especially with the history of OSA syndrome and humidified oxygen should be given regularly during postoperative period. Obese patients with the history of OSA syndrome may also benefit from nocturnal nasal CPAP. The episodes of OSA are most frequent during rapid eye movement (REM) sleep. But the incidence of it is relatively low in the initial postoperative period, and is common between the third to fifth postoperative nights. The hazards of OSA may, therefore, be worst a few days after surgery. This has great implications for the duration of postoperative monitoring by oximetry and oxygen therapy. The maximum decrease in P_aO_2 occurs typically at second and third days postoperatively. Regular physiotherapy should be administered postoperatively for obese patients.

41 Ophthalmic Anaesthesia

ANATOMY

Osteology

Our eyeballs lie in two bony cavities, called orbits. It is situated in the sagittal plane of skull and on either side of the root of the nose. Each orbit is pyramid in shaped, with base lying anteriorly and apex posteriorly at the optic canal. The shape of each of the orbit is also like a truncated pear and is made up of seven bones. Optic canal forms the stalk of this pear. The orbit develops around the eyeball. So, nearly one millimeter behind the anterior margin of the orbit lies the widest diameter of the cavity that corresponds with the equator of the eye ball. The seven bones that take part in the formation of bony orbit are: frontal, maxilla, zygomatic, lacrimal, ethmoid, palatine and sphenoid. Each orbital cavity has a roof, a floor, a medial wall and a lateral wall of the orbit. All the walls are directed forwards, laterally and slightly downwards, diverging anteriorly. The roof, floor and lateral wall are more or less triangular, but the medial wall is oblong.

The medial wall of each orbit lies in the sagittal plane of the head, and is parallel with the medial wall of the contralateral orbit. The lateral wall of each orbit forms a 90^{o} angle with the lateral wall of the contralateral orbit. The medial and lateral walls of each orbit make a 45° angle posteriorly with each other. The apex of the orbit, including the optic foramen lies in the same sagittal plane as the medial wall of the orbit. The anterior end of the medial wall lies about 20 mm in front of the lateral wall. The globe occupies the frontal half of each orbit, and projects anteriorly beyond the anterior margin of it. When the eye is in primary gaze, then the visual axis lies in the sagittal plane. The anatomical axis of each orbit diverges from the visual axis by 23 degrees.

The orbit lies beneath the anterior cranial fossa and above the maxillary sinus. The medial wall of the orbit separates it from the ethmoidal sinuses and the middle meatus of the nose. The lateral wall separates the orbit from the middle cranial fossa posteriorly and from the muscular temporal fossa anteriorly. The anterior margin of each orbit is known as the orbital rim. It forms a protective buttress for all the vital structures held within the orbit and comprises of three robust bones such as zygomatic, frontal and maxillary. The orbital rim forms the rounded rectangular base of the pear shaped orbital pyramid which tapers posteriorly to form a tight apex and made up of the greater and lesser wings of the sphenoid bones. The greatest diameter of the orbit is the part which is situated immediately inside the rim. The volume of an adult orbit is about 30 ml, while that of an average sized globe is 6.5 ml. The typical dimensions of an orbit at the rim are 35 mm vertically and 40 mm horizontally. The depth of an orbit measured from the inferior orbital rim to the optic foramen ranges from 42 to 54 mm. The lateral orbital rim lies 12 to 18 mm behind the cornea, allowing exposure of the globe at its equater. Medially, the orbital margin breaks its continuity at the lacrimal fossa.

The orbital rim or the anterior orbital margin of the orbit consists of superior, lateral, inferior and medial parts. The superior orbital margin is formed entirely by the orbital arch of the frontal bone. It is sharp at its lateral two-third and rounded at its medial one-third. At the junction of these two parts of superior orbital margin lies a notch, called the supraorbital notch through which passes the supraorbital nerves and vessels. Sometimes, this notch is converted into a foramen, or into a canal by a periosteal ligament which ossifies in about 20% of cases. Another small foramen, named supraciliary canal is also found near the supraorbital notch. It transmits a nutrient artery and a branch of supraorbital nerve to the frontal sinus. About 6 mm medial to the supraorbital notch, there is another notch called the Notch of Arnold which transmits the medial branches of the supraorbital nerve and vessels. Just medial to it (i.e. 10 mm medial to the supraorbital notch,) lies the supratrochlear notch which transmits the supratrochlear nerves and vessel. The lateral orbital margin is formed by the zygomatic process of the frontal bone above and the frontal process of the zygomatic bone below. It is the strongest portion of the orbital outlet. There is a tubercle, called the zygomatic or the molar tubercle which is situated just outside the orbital margin, below the fronto-zygomatic suture. The inferior orbital margin is formed by the zygomatic bone laterally and the maxillary bone medially, usually in equal parts. The suture between the two is frequently

marked by a tubercle which can be felt on palpation. The infraorbital foramen lies about 4 mm below this tubercle and transmits the intraorbital nerves and vessels. The medial orbital margin is formed by the frontal bone above and the frontal process of the maxilla below. The medial margin of the orbit is indistinct in its lower part. In this indistinct part it presents a double countour, forming lacrimal fossa for the lacrimal sac. The anterior margin of the lacrimal fossa or the anterior lacrimal crest lies on the frontal process of the maxilla and the posterior margin of the lacrimal fossa or the posterior lacrimal crest lies on the lacrimal bone. At the junction of the medial and superior margins, a tubercle is present which is called the lacrimal tubercle. The orbital septum is attached to the entire medial orbital margin (Fig. 41.1).

The roof of the orbit is formed anteriorly by the orbital plate of frontal bone and posteriorly by the thick lesser wing of sphenoid bone. The fossa for the lacrimal gland is located on the roof, anteriorly and laterally. The trochlear fossa is a small dimple which is located on the roof, 5 mm behind the rim on the medial side and lodges the cartilaginous trochlear pully, through which passes the tendon of superior oblique muscle. The roof of the orbit is separated from the lateral wall, anteriorly by the zygomatico frontal suture and posteriorly by the supraorbital fissure. The roof of the orbit is separated from the medial wall by the sutures which are situated between the orbital plate of the frontal bone above and ethmoid, lacrimal and maxilla below (from posterior to anterior). In the fronto-ethmoidal sutures there are foramina through which passes the anterior and posterior ethmoidal vessels and nerves. Superior to the roof of the orbit and in the anterior cranial fossa lies the frontal lobe of the brain. Inferior to the roof of the orbit lies the frontal nerve, levator palpebrae superioris muscle, superior rectus muscle, superior oblique muscle, supra-orbital artery, trochlear nerve and lacrimal gland. Optic foramen lies at the apex of the roof. A prominent tubercle on the sphenoidal part of the roof gives origin to the extrinsic muscles of the eye ball (Fig. 41.2).

The floor of the orbit is formed by three bones: zygomatic bone laterally, maxillary bone medially and a small portion of palatine bone posteriorly. The infraorbital fissure (posteriorly) and its canal (anteriorly) extend forwards from the apex to the floor. This canal which transmits infraorbital vessels and nerves finally exits at the infraorbital foramen. It is situated 1 cm inferior to the midpopint of the inferior orbital rim. The nasolacrimal canal which is 12 mm in length lies in the maxillary bone. It commences anteromedially from the orbital floor and passes vertically and slightly lateral to the nasal cavity. It passes the nasolacrimal duct and drains tears from conjunctival sac to the inferior meatus of the nose. In the extreme anteromedial angle of the floor and just behind the inferior orbital margin and lateral to the nasolacrimal canal, there lies a fossa which gives origin to the inferior oblique muscle. Superiorly, the floor is related to the inferior rectus muscle, inferior oblique muscle and the nerve to inferior oblique. Inferiorly the floor is related to the maxillary antrum and the palatine air cells. Anteriorly the floor and the

lateral wall are continuous with each other while posteriorly the floor is separated from the lateral wall by the inferior orbital fissure (Fig. 41.3).

The medial wall of the orbit is more or less quadrangular in shape and comprises of four bones: most anteriorly the frontal process of the maxilla, followed by the lacrimal, ethmoid and the lesser wing of sphenoid (from anterior to posterior). The lacrimal fossa which measures about 15 mm × 5 mm and houses the lacrimal sac is situated on the medial wall of the orbit and is bounded by the anterior and the posterior lacrimal crests. The anterior lacrimal crest is formed by the frontal process of the maxilla and the posterior lacrimal crest is formed by the lacrimal bone. Besides the lacrimal sac, the fossa also lodges the lacrimal fascia, the areolar tissue containing the plexus of veins and some fibres of the orbicularis oculi muscle which is known as the Horner's muscle. The lacrimal fossa which contains the nasolacrimal sac continues below with the nasolacrimal canal and contains the nasolacrimal duct. The anterior lacrimal crest extends inferiorly to join with the lower orbital margin and forms an elevation called the lacrimal tubercle. The posterior lacrimal crest extends superiorly to join with the superior rim. In the medial wall, the anterior and posterior ethmoidal foramina traverse the suture line between the ethmoidal bone and the orbital plate of the frontal bone. The ethmoidal bone is the thinnest and the weakest part of the orbit and is called the lamina papyracea. The two medial walls of the orbit are almost parallel. The medial wall of the orbit is related medially to the anterior, middle and posterior ethmoidal sinuses, middle meatus of the nose and the sphenoidal air sinuses. The superior oblique muscle, the medial rectus muscle, the nasociliary nerve and the terminal part of the ophthalmic artery run over the lateral surface of the medial wall (Fig. 41.4).

The lateral wall of the orbit is made up of the zygomatic bone (anterior 1/3) and the greater wing of the sphenoid bone (posterior 2/3). The superior and inferior orbital fissures separate the posterior portion of the lateral wall of the orbit from the roof and the floor of it, respectively. It is triangular in shape with the base lying anteriorly. The greater wing of the sphenoid separates the superior and inferior orbital fissures. A prominence, called the lateral orbital tubercle of Whitnall is situated 4 mm behind the midpoint of the lateral orbital margin and 10 mm below the zygomaticofrontal suture. This tubercle of Whitenall gives attachment to the (i) lateral palpebral raphe, (ii) lateral horn of the tendon of levator palpebrae superioris, (iii) lateral end of the suspensory ligament of Lockwood and (iv) lateral check ligament of the lateral rectus muscle (Fig. 41.5).

Fig. 41.4: Medial wall of the orbit

The zygomatic bone of the lateral wall has two minute foramina for the zygomaticofacial and zygomaticotemporal nerves on their way to innervate the fascial skin. There is a small bony projection on the inferior margin of the superior orbital fissure which is called the spinal recti lateralis. It provides origin to a part of the lateral rectus muscle and the common tendinous ring of Zinn. The lateral wall is related laterally to the temporal fossa anteriorly and middle cramial fossa posteriorly. Medially the lateral wall is related to the lateral rectus muscle, lacrimal nerve and vessels, zygomatic nerve and a communication between the zygomatic and the lacrimal nerves (Fig. 41.6A).

The superior orbital fissure is a gap which is situated between the greater and the lesser wings of the sphenoid bone. It lies between the roof and the lateral wall of the orbit. The frontal bone forms the lateral boundary of the fissure. It is comma or retort-shaped because it is wider at the medial end and narrower at the lateral end. At the junction of these two parts of superior orbital fissure lies the spine which gives origin to the lateral rectus muscle. Its medial end is separated from the optic foramen by the posterior root of the lesser wing of the sphenoid bone. The anterolateral part of this fissure is closed by duramater, so that no structure can pass through it. However, its posteromedial part communicates with the middle cranial fossa, allowing the passage of the nerves and vessels for the eyeball. The annulus tendineus communis, spans over the superior orbital fissure and divides the fissure into three parts : (i) the upper or lateral part transmit the trochlear, frontal and lacrimal nerves and the superior ophthalmic vein, (ii) the middle part transmits the superior divisions of the oculomotor nerve, the nasociliary nerve, the sympathetic root of the ciliary ganglion, the inferior division of the oculomotor nerve and the abducent nerve. It is also called the oculomotor foramen, (iii) the inferior part transmits only the ophthalmic vein (Fig. 41.6B).

The inferior orbital fissure lies between the lateral wall and the floor of the orbit. It connects the orbital cavity with the inferotemporal fossa in front and the pterygopalatine fossa behind. It is bounded anteriorly by the maxilla, and posteriorly by the greater wing of the sphenoid bone. It is separated from the posterior end of the superior orbital fissure by a bridge of bone extending from the greater wing of the sphenoid. Both the fissures are covered by a periorbital membrane and the Muller's muscle. The inferior orbital fissure transmits the infraorbital nerve, the zygomatic nerve, the branches from the pterygo palatine ganglion and a communication between the inferior ophthalmic vein and the pterygoid venous plexus (Fig. 41.7).

The optic foramen is actually a canal which is formed by the union of the two roots of the lesser wing of sphenoid with its body. The optic canal starting from the optic foramen is a communication between the apex of the orbit and the middle cranial fossa. The canal is about 10 mm in length and about 5 mm in breadth. The optic canal transmits the optic nerve and along with it the meninges, the ophthalmic artery and few twigs of the sympathetic plexus along the artery. At this optic canal the duramater splits into two layers − the inner layer forms the sheath of the optic nerve, while the outer layer continues with the periosteum. The common tendinous ring is also attached to the infraoptic tubercle which is an elevation present inferolateral to the optic foramen. The posterior ethmoidal air sinuses are situated just medial to the optic canal.

The anterior and posterior ethmoidal foramen and its canals are situated at the junction of the roof and the medial wall of the orbit and form a communication between the orbit and the anterior cranial fossa. The anterior ethmoidal canal transmits the anterior ethmoidal nerve

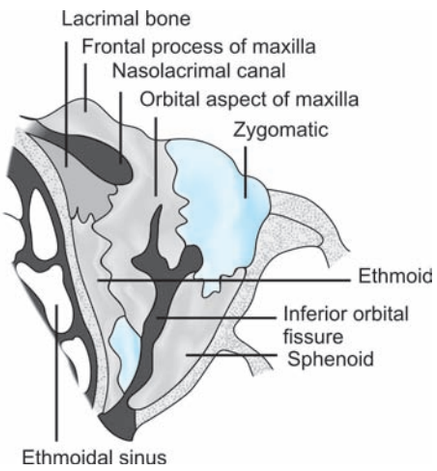

Fig. 41.6A: The floor of the right orbit

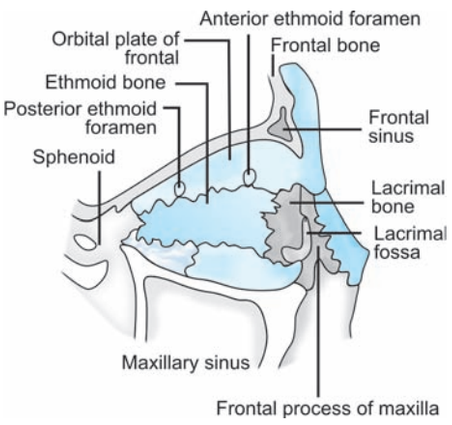

Fig. 41.6B: The medial wall of the right orbit

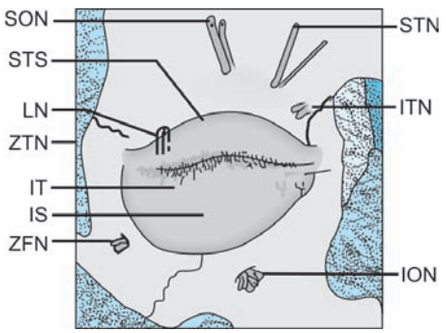

Fig. 41.7: The apex of orbit, fissures, vessels and nerves

and vessels, while the posterior ethmoidal canal transmits the posterior ethmoidal vessels and nerve.

ORBITAL CONNECTIVE TISSUE

Orbital Periosteum

The periosteum of the orbit is known as the periorbita and it lines the bones of the orbit loosely. It can easily be stripped off from the underlying orbital bones. It is thickened along the anterior orbital margin and is called the arcus marginalis. Along the anterior orbital margin it blends with the periosteum of the facial bone and with the orbital septum circumferentially. Posteriorly at the orbital apex, the periorbita is continuous through the optic canal with the pericranium and also with the dural sheath of the optic nerve (Fig. 41.8).

Here, it provides origin to the four rectus muscles from a common tendon. Anteriorly, it encloses the lacrimal sac in its fossa and passes down with the nasolacrimal duct to become continuous with the periosteum of the inferior meatus of nasal cavity. It forms a dense membrane covering the superior orbital fissure. The fine lamelle of the periorbita divide the orbital fat into many lobules and form a coverings for the nerves and vessels. The orbital septum is a weak membranous sheet which is attached to the anterior margin of the orbit and is continuous with the facial periosteum and the periorbita of the orbit. It defines the antomical anterior border of the orbit. On the nasal side it is attached with both the anterior and the posterior lacrimal crests. Its central attachments are in the upper and lower eyelids and lie deep to the orbicularis oculi muscle (Fig. 41.9).

Tenon's Capsule

Tenon's capsule or the bulbar fascia is a thin fibrous membranous structure which envelops the eyeball from the limbus to the optic nerve. It extends from the corneal limbus anteriorly to the optic nerve posteriorly where it blends with the meninges of the optic nerve. Posteriorly it is in contact with the orbital fat and is pierced by the ciliary nerves with their accompanying arteries. Anteriorly it merges with the sub-conjunctival connective tissue and is pierced by the tendons of six extra-ocular muscles (the four rectus muscles pierce the tenon's capsule behind the equator, while the two oblique muscles pierce it anterior to the equator) prior to their insertion on the sclera. At the site of the insertion of the tendons of extraocular muscles, the Tenon's capsule sends tubular reflection around these tendors so as to clothe them like a glove and allows unrestricted control of the movement of muscles within this capsule. The globe rotates around its centre point within the smooth inner lining of this Tenon's capsule. However, this movement is possible due to the great mobility of the anterior part of the optic nerve. The tubular reflections of the medial and lateral rectus muscles from Tenon's capsule send expansions to the neighbouring structures. The lateral expansion from the reflection of lateral rectus is attached to the Whitnall's tubercle and is called the lateral check ligament, while that of the medial rectus to the lacrimal crest is called the medial check ligament. These expansions are quite strong and limit the action of the respective muscles. Therefore, they are known as the check ligaments. The expansion from the reflection sheath of the superior rectus is attached to the levator palpebrae superioris through a band and that of the inferior rectus is inserted between the tarsal plate and the orbicularis of the lower lid. The expansions from the reflection sheaths of the superior oblique and inferior oblique muscles are attached to the trochlea and the lateral part of the floor of the orbit, respectively. The expansions of the fascial sheaths of the inferior rectus and the inferior oblique muscles also extend posteriorly and are joined by the expansions from the lateral and medial rectus muscles to form a sling on which the eyeball rests. It provides an effective support to the eyeball and is so known as the suspensory ligament of Lockwood. All these fibrous expansions from the reflection covering of the muscles are attached to the conjunctiva, thereby preventing its folding during their action. The intermuscular septa between the adjacent margins of the four rectus muscles which divide the orbital space into intraconal and extraconal area are well-developed in the anterior part of the orbit. They merge with the Tenon's capsule in this area.

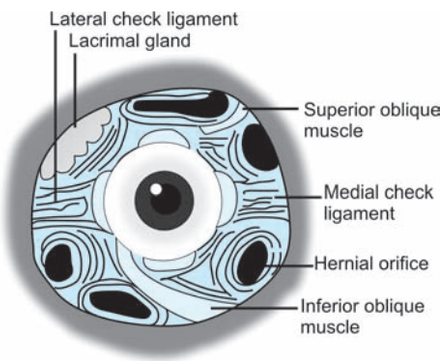

Fig. 41.8: The connective tissue diaphragm of orbit with the hernial orifices. It is situated just anterior to the globe of equator. The eyelids and orbital septum are removed

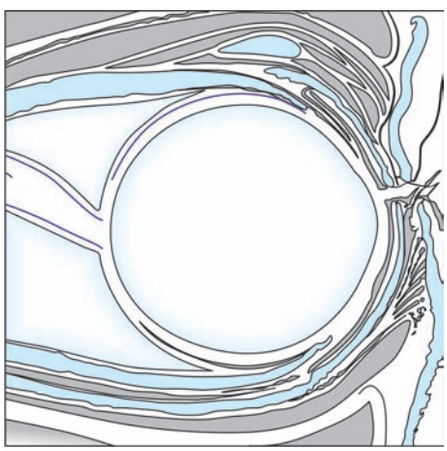

Fig. 41.9: The display of connective tissue (white lines) around the structures in the orbit

Diffuse Connective Tissue System

The diffuse connective tissue system of the orbit is divided into two parts: (i) The

clearly defined supporting connective tissue system of anterior orbit and (ii) the diffuse ill defined connective tissue system of the posterior orbit.

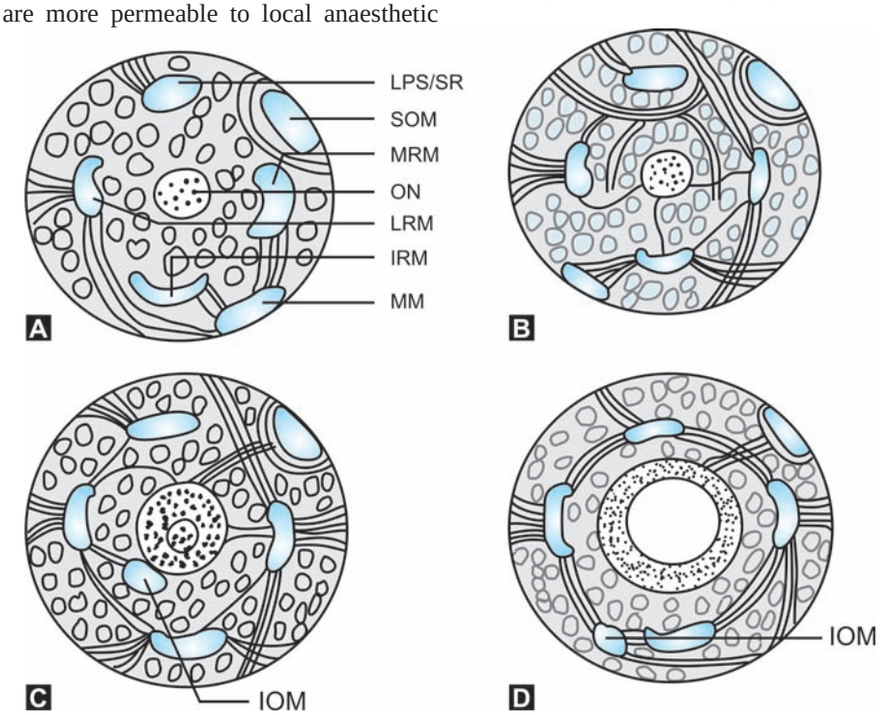
The clearly defined supporting connective tissue system in anterior orbit consists of a diaphragm which extends out from the Tenon's capsule and the globe to the periorbita just behind the orbital margin. Condensation of these tissues above and below the globe form the suspensory ligaments which are known as the Ligaments of Whitnall and Lockwood, respectively. They support the globe and limit its displacement. Several sheets of connective tissue also fan out from the respective muscle sheaths which is formed by the reflection of Tenon's capsule to attach to the periorbita at the sides of the orbit. In case of the medial and lateral rectus muscle, these are called the medial and lateral check ligaments which are considered to act as a servo-mechanism of the eyeball. The intermuscular septa, between the adjacent margins of the four rectus muscles are well-developed in the anterior part of the orbit. They merge anteriorly with the Tenon's capsule in this area.

The diffuse ill-defined connective tissue system of the posterior orbit is derived from the fascial sheath of the extraocular muscles. It radiates out from the fascial sheath of rectus muscles to the periorbita and encloses all the structures, including the nerves and vessles of the orbit. Adipose tissue lies between these radiations. Unlike the anterior orbit, posteriorly the intermuscular septa are less well-developed, particularly in the inferotemporal quadrant of the orbit where almost none exists. Of the rectus muscles, only the medial rectus is significantly separated from the adjacent bony orbital wall by a fat compartment. The connective tissue around the medial rectus muscle exhibits connections or extensions to the orbital floor and roof. At the level of the equator, a condensation of connective tissue of the medial rectus extends nasally to the medial orbital wall. This is called the medial check ligament. The medial compartment opens anteriorly above and below the medial check ligament as two hernial orifices in the connective tissue diaphragm that surrounds the globe. Thus local anaesthetic agent, deposited in the medial orbital compartment by injection will spread through these orificies to the orbital spetum into the upper and lower eyelids. This spread of local anaesthetic agent in the upper and lower eyelids is in this tissue plane which is deep to the orbicularis oculi muscle and where lies the fine terminal motor branches of the 7th cranial nerve. So they are readily blocked (Figs 41.10A to D).

The quality of these connective tissues among the different individuals varies. The quality deteriorates with increasing age and thus the weaker connective tissues are more permeable to local anaesthetic agents injected into the mid-orbit. So, the critical concentrations of drug to block the oculomotor nerve near the apex are more easily attained in the elderly as compared to young adults. Similarly, orbital haemorrhage in the elderly which drains in the anterior orbit, causing black eye, may be of less important than a similar bleeding in younger patients, in whom more firm tissues may trap blood and result in a dramatic loss of vision from the unrelieved building up of pressure (Fig. 41.11).

SPACES IN THE ORBIT

Surgically, there are four spaces in the orbit which are of immense importance to the anaesthetist. These spaces are: (i) subperiosteal, (ii) peripheral, (iii)



LPS – Levator palpebrae superioris, SR – Superior rectus, SOM – Superior oblique muscles, MRM – Medial rectus muscle, ON – Optic nerve, LRM – Lateral rectus muscle, IRM – Inferior rectus muscle, MM – Muller's muscle.

Figs 41.10A to D: Schematic diagram shows extraocular muscles and the connective tissue system, in different coronal sections of the orbit.
A. Coronal section at the apex of the orbit,
B. Coronal section of the orbit at the posterior pole of the globe,
C. Coronal section of the orbit, midway between the posterior pole and the equator of the globe,
D. Coronal section at the equator of the globe.

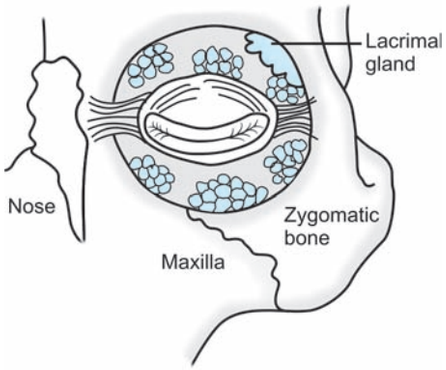


Fig. 41.11: The pads of orbital fat, coming out of different apertures of the connective tissue system of the left orbit

central and (iv) sub-Tenon's space. Each space is self-contained and an inflammatory process may remain confined in it for a considerable period.

Subperiosteal Space

This space lies between the bones of the orbit and the periorbita (periosteum). It is an uneven potential space, which is obliterated at sutures. Periosteum is detachable in most parts, except its firm attachment at the sutures margins, roof and fissures.

Peripheral Orbital Space

It is the space between the periorbita and the extraocular muscles with their fascial expansions among them, forming more or less a continuous circular septum. This space is limited anteriorly by the check ligaments and posteriorly by the approximation of the common tendinous ring and the periosteum, at the optic foramen. This peripheral space contains lacrimal gland, branches of the trigeminal (frontal, lacrimal, infraorbital and nasociliary) and trochlear nerves, lacrimal and infraorbital vessels and the ophthalmic vein. Collection of fluid in this space may extend through the orbital septum and lead to oedema of the eyelids.

Central Space

It is a cone-shaped area enclosed by the four rectus muscles, and their fascial expansions in between them. Anteriorly the space is limited by the posterior aspect of the eyeball, laterally by the muscles and their fascial sheaths and posteriorly by the common tendinous origin of the extraocular muscles at the apex of the orbit. It contains the optic nerve and its meningeal coverings, superior and inferior divisions of the oculomotor nerve, abducent nerve, ophthalmic artery, superior ophthalmic vein and nasociliary nerve. The last three passes to the peripheral surgical space, after piercing the medial aspect of the space. The presence of any tumour or fluid in this space usually results in proptosis (Fig. 41.12).

Sub-Tenon's Space

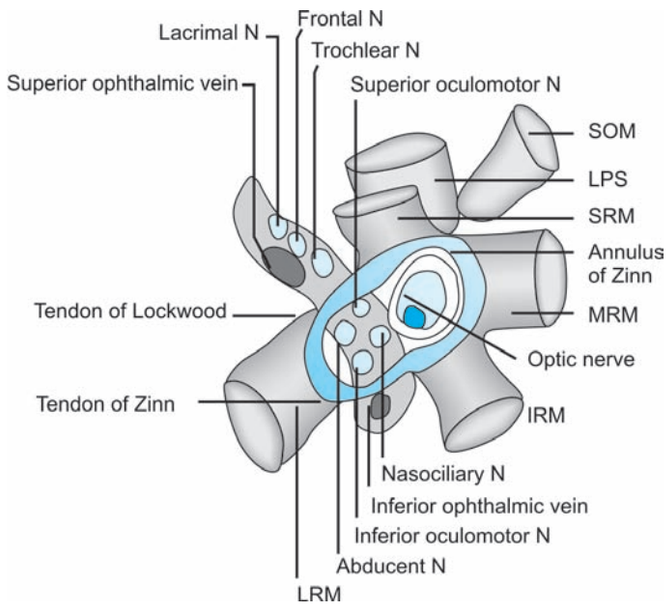
It lies between the Tenon's capsule and the sclera and forms a potential space around the globe. It contains insertions of the tendons of the extraocular muscles, some nerves and vessels piercing the eyeball and some loose reticular tissues.

SKELETAL MUSCLES OF THE PERIORBIT AND ORBIT

Orbicularis Oculi Muscle

The orbicularis oculi muscle is situated around the anterior margin of the orbit and intimately attached to the deep surface of the skin. It is responsible for the closure of the eyelid, including the automatic and reflex blinking action. It is innervated by the facial nerve (VII cranial nerve), entering from the deep surface of the muscle. It is divided into three parts : orbital part, preseptal part and pretarsal part. The last two parts together are called the palpebral part.

The orbital part of this muscle originates from the medial third of the upper and lower orbital margins, medial palpebral ligaments, maxillary process of the frontal bones and the frontal process of the maxilla. These fibres of muscle are arranged in a concentric manner around the anterior orbital margin and cover



SOM – Superior oblique muscle, LPS – Levator palpebrae superioris,
SRM and IRM – Superior and inferior rectus muscle,
MRM and LRM – Medial and lateral rectus muscle.

Fig. 41.12: The apex of orbit with the annulus of Zinn

the lids. It intermixes with the brow muscle and the frontalis. This orbital part of the orbicularis oculi muscle helps in the firm closure of the eyelid.

The palpebral part (preseptal and pretarsal) originates from the medial palpebral ligament and the adjacent bone and forms the lateral palpebral raphe by merging with the septum orbitale to get attached to the Whitnall's tubercle. The pretarsal part contributes to form more or less the entire thickness of the eyelid margin. The follicles of the eyelashes, glands of Moll and meibomian ducts traverse the pretarsal part of this muscle. The palpebral part of the orbicularis oculi muscle helps in smooth and gentle closure of the eyelids during blinking.

The third part of the orbicularis oculi muscle which is known as pars lacrimalis is attached to the posterior lacrimal crest and the lacrimal fascia. It helps in dilatation of the lacrimal sac and thus facilitates the drainage of tear by tear-pump mechanism.

Extraocular Muscles

These extraocular muscles are involved in the movement of eyeball and its adnexa. They may be divided into three broad groups:

i. Extrinsic muscles of the eyeball,
ii. Muscles of the lid,
iii. Non-striated muscles of the lid.

Extrinsic muscles of the eyeball

These muscles are comprised of four recti and the superior and inferior obliques. These four recti with their average 40 to 42 mm of length have a common origin from a tendinous ring (annulus of Zinn) which is attached to the sphenoid bone at the apex of the orbit. The ring encircles the optic foramen and the medial end of the superior orbital fissure. This annulus ring forms the apex of the interconal space whose base is Tenon's capsule covering the posterior surface of the globe. The interconal space is now no longer considered as a closed compartment which was originally thought. But, because of its intimate relationship with the optic, oculomotor, sensory and autonomic nerves, this intraconal space is important for understanding and mastering the orbital regional anaesthesia. The four rectus muscles of orbit run forwards after their origin from the tendinous ring close to the optic foramen and are then inserted into the sclera, anterior to the equator of the globe. Their muscle belly is replaced before their insertion by a tendon near the globe. The superior and inferior oblique muscles are inserted obliquely in the postero-superior and postero-inferior quadrant of globe, respectively and is almost lateral to the mid vertical plane.

The superior rectus muscle

It takes origin from the upper part of the annulus of Zinn, from the lateral side of the optic foramen and the optic nerve sheath. It is inserted into the sclera, 7.7 mm behind the limbus by a tendon. At the origin this muscle is related inferiorly to the dural sheath and the optic nerve, superiorly to the levator muscle and the frontal nerve, medially to the medial rectus and laterally to the lateral rectus, lacrimal artery and nerve. The levator palpebrae superioris remains above the superior rectus muscle throughout its course. Between the superior rectus and the optic nerve lie the orbital fat, the ophthalmic artery and the nasociliary nerve. In the later part of the course, the tendon of the superior oblique muscle runs between the superior rectus and the globe. The superior rectus muscle is supplied by the superior division of the oculomotor nerve which enters the muscle from its undersurface at the junction of its middle and posterior-third (Fig. 41.13).

The inferior rectus muscle

It arises from the lower part of the annulus of Zinn. It is shortest of all the rectus muscles of orbit. It passes forwards along the floor of the orbit and is inserted into the sclera, approximately 6.5 mm away from the limbus. The optic nerve, orbital fat, the inferior divisions of the oculomotor nerve and the eyeball lie above the inferior rectus muscle. The floor of the orbit, maxillary sinus and the infra orbital vessels and nerves lie below it. The nerve to the inferior oblique and the lateral rectus form the lateral relations of this muscle. The inferior oblique muscle crosses the orbit below the inferior rectus and fibrous the sheaths of these two muscles blend at the crossing. The inferior rectus is also attached to the lower lid by a fascial expansion of its sheath. It is supplied by a branch from the inferior division of the oculomotor nerve which enters the muscle from bulbar surface.

The medial rectus muscle

It takes origin from the medial part of the annulus of Zinn and the sheath of the optic nerve. It is the strongest and the thickest of all the extrinsic muscles of the eyeball. It runs forwards and medially along the medial orbital wall and is inserted into the sclera, 5.5 mm behind the limbus. The superior oblique muscle lies above the medial rectus. The ophthalmic artery and its branches, the ethmoidal nerve and the infratrochlear nerve are present between these two muscles. The floor of the orbit lies below the medial rectus muscle. The orbital plate of the ethmoid bone and the ethmoidal air cells are placed medial to this muscle, while central orbital fat lies laterally. The medial rectus muscle is supplied by a branch from the inferior division of the oculomotor nerve from its lateral surface.

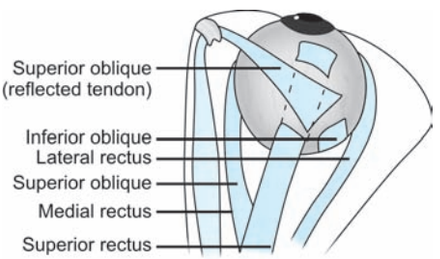


Fig. 41.13: Extraocular muscles of the eyeball

The lateral rectus muscle

It arises from the lateral part of the annulus of Zinn. Then the muscle runs forwards and laterally between the eyeball and the lateral orbital wall. It is inserted into the sclera, 6.5 mm behind the limbus. The lacrimal gland, the lacrimal nerve and the lacrimal artery lie above this lateral rectus muscle. The floor of the orbit and the tendon of the inferior oblique form the lower relations of this muscle. Laterally, it lies directly on the periosteum. It is supplied by the 6th cranial nerve which enters the muscle from its medial aspect.

The superior oblique muscle

It takes origin from the periosteum of the body of sphenoid bone, just above and medial to the optic foramen. It is the longest and thinnest of all the extrinsic muscles of the eyeball. After origin, it runs forwards between the roof and the medial wall of the orbit, and between the superior and medial rectus. Then behind the anterior orbital margin it becomes a rounded tendon which passes through a pulley called the trochlea After that the superior oblique muscle runs downwards, backwards and laterally at an angle of about 55°, underneath the superior rectus muscle and fans out before its insertion on the posterior superior quadrant of the sclera. The superior oblique muscle has two distinct parts. A direct muscular part which is 40 mm in length and extends from its orign to the trochlea, and a tendinous reflected part which is 20 mm in length and runs from the trochlea to its insertion. It is supplied by the trochlear nerve.

The inferior oblique muscle

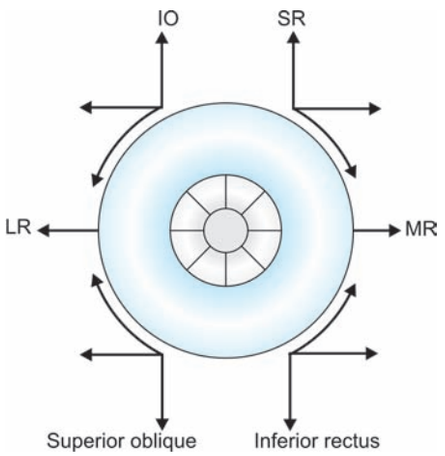
It is the only extrinsic muscle of the eyeball which does not take origin from the annulus of Zinn. It arises from a rough area (small depression) on the orbital plate of maxilla, just lateral to the lacrimal fossa. Then, it runs backwards and laterally, passing between the inferior rectus and the floor of the orbit and curves around the eyeball to lie underneath the lower border of the lateral rectus. It is inserted on the posterolateral quadrant of sclera, underneath the lateral rectus muscle. The muscle is innervated by inferior division of oculomotor nerve (Fig. 41.14).

Muscles of the lids

The levator palpebrae superioris and the superior palpebral muscles elevate the upper eyelid. The tendinous palpebral expansion of the inferior rectus and the inferior palpebral muscle retract the lower eyelid. The orbicularis oculi helps in the closure of eyelids.

The levator palpebrae superioris (LPS)

It takes origin from the under surface of the lesser wing of the sphenoid bone, just superior and slightly medial to the superior rectus muscle. The thin, flat belly of this muscle runs forward under the roof of the orbit and lies on the superior rectus muscle. These two muscles have a common fascial sheath. In the region of the superior fornix, it forms an expanded aponeurosis with an anterior and a posterior lamella which fans out and occupies the whole breadth of the upper part of the orbit. It is here, where its direction is changed from horizontal to nearly vertical, moulding itself on the eyeball and the upper eyelid. The anterior lamella has multiple diffuse terminal attachments which is described below. While the posterior lamella which is known as the sympathetic muscle of Muller is inserted on the superior border of the tarsal plate.



MR = Medial rectus, LR = Lateral rectus
SR = Superior rectus, IR = Inferior rectus
IO = Inferior oblique, SO = Superior oblique

Fig. 41.14: Actions of extraocular muscles of right eye

The insertion of the anterior lamella has been divided into the following parts:

i. The bulk of the fibres passes through the muscle fibres of the orbicularis oculi and get inserted into the skin of the upper eyelid, at and below the upper palpebral sulcus.
ii. Some fibres are attached to the front and lower parts of the tarsal plate.
iii. The fascial sheath of the muscle is also attached to the conjunction of the superior fornix.
iv. The two horns of the levator aponeurosis get attached to the orbital bones, at the midpoint of the lateral and medial orbital margin. The lateral horn is stronger than the medial horn. The lateral horn divides the lacrimal gland into orbital and palpebral portions, and supports the gland against the orbital roof. The medial horn is attached to the frontolacrimal suture medial to the palpebral ligament.

The roof of the orbit, the trochlear and the frontal nerves and the supraorbital vessels lie above this levator palpebrae superioris muscle. The trochlear nerve crosses the levator near its origin from lateral to medial side. Similarly, the frontal nerve crosses it obliquely from lateral to medial. The superior rectus muscle and the eyeball lies below this muscle. The muscle is supplied by the superior division of the oculomotor nerve. The sympathetic fibres carrying through the oculomotor nerve supply the nonstriated superior and inferior palpebral muscles along the respective divisions of the oculomotor nerve.

Non-striated muscles of the orbit

A group of the nonstriated muscles of the orbit almost completely envelop the eyeball. It has superior, inferior and medial palpebral parts. The superior palpebral part

of this muscle is also known as the superior palpebral muscle of Muller. This muscle arises from the inferior aspect of LPS at the level of superior fornix in the form of a wide band and runs a near vertical course to be inserted on the upper edge of the superior tarsal plate. The inferior palpebral part is also known as the inferior palpebral muscle of Muller and passes from the bulbar surface of the inferior rectus muscle to the lower margin of the lower tarsal plate. The fibres of these muscles spread out mostly as a fascia, lying between the inferior rectus and the inferior oblique muscle. These muscles are innervated by the sympathetic nerve. The superior palpebral muscle elevates the upper lid and the inferior palpebral muscle retracts the lower lid. So, the irritation of sympathetic nerve results in the retraction of both the eyelids.

NERVES OF THE EYE, ORBIT AND PERIORBIT

The cranial nerve II (optic), III (oculomotor), IV (trochlear), V (trigeminal), VI (abducent), and VII (facial) are responsible for the sight, motor function, sensation and autonomic control of the ocular region of the face. So they are called the nerves of the eye, orbit and periorbit.

Optic Nerve

Strictly speaking, the optic nerve is not a cranial nerve, rather it is an extension of the brain. Because, unlike of the other cranial nerves, it carries meningeal coverings over it from the cranial cavity. The outer meningeal covering of the optic nerve is nothing but the extension of dura, and blends anteriorly with the sclera (Fig. 41.15).

The middle and inner coverings of the optic nerve are also continuation of the arachnoid and the pia matar. Like the meninges, the subdural and the subarachnoid space also separate the three sheaths of the optic nerve from each other. From the optic chiasma to retina the total length

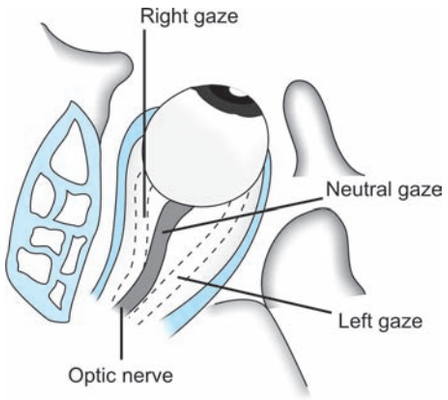


Fig. 41.15: Schematic diagram of the transverse section of the orbit, showing different positions of the optic nerve, during neutral, right and left gaze

of an optic nerve is approximately 5 cm. Anatomically, the optic nerve is divided into four parts: intracranial, intracanalicular, intraorbital and intraocular. The intracranial portion of the optic nerve extends from the optic chiasma to the cranial end of the optic canal and is approximately 1 cm in length (Figs 41.16A and B).

The anterior cerebral artery and the frontal lobe of the brain lie superior to it. As the optic nerve emerges from the cavernous sinus, the internal carotid artery lies lateral to it. The intracanalicular portion of the optic nerve is only 5 to 6 mm in length and lies in the optic canal. As the dural sheath is tightly adhered to the periosteum of the canal, so this portion of the optic nerve is completely rigid. The intraorbital portion of the optic nerve extends from the optic foramen to the posterior surface of the eyeball, 3 mm on the nasal side. It is 3 cm in length. But the distance from the foramen to the eyeball is only 2.5 cm. So, this portion of the optic nerve is loose, lax and tortuous. This tortuosity of the optic nerve permits free movement of the globe in all positions, without detrimenting its function. The dural sheath of the optic nerve fuses anteriorly with the sclera and posteriorly with the periorbita (periosteum) at the optic foramen. The CSF flows freely within this dural sheath around the optic nerve and is in continuity with the CSF of the midbrain. In primary gaze position, the intraorbital portion of the optic nerve is closer to the medial than the lateral rectus muscle and assumes a tortuous course between the posterior pole of the globe and the optic foramen. In abduction and upward gaze, the optic nerve becomes straight. In abduction and downward gaze the optic nerve takes on a S-shaped curve. The intraocular part of the optic nerve is only 1 mm in long, representing the thickness of the sclera where the nerve enters near the posterior pole of the globe (3 mm to the nasal side) (Fig. 41.17).

Motor Nerves to Extraocular Muscles

The three cranial nerves such as the oculomotor (III), trochlear (IV), and abducent (VI) nerves supply the motor functions of the extraocular muscles of the eyeball. The trochlear nerve supplies the superior oblique muscle, and the abducent supplies the lateral rectus muscle. The remaining

Fig. 41.18: Nerves within the orbit

four extraocular muscles and the levator palpebrae superioris are supplied by the oculomotor nerve. The oculomotor nerve also carries the parasympathetic fibres for the sphincter muscles of the iris and the ciliary muscles. The dilator muscles of the iris is supplied by the sympathetic fibres carried by the nasociliary nerve. The motor nerve to the four rectus muscles and the inferior oblique muscle enter their respective muscle bellies from within the muscle cone. Whereas, the trochlear nerve remains outside the cone and enters its supplying muscle, named the superior oblique through its superolateral edge. This anatomic difference explains the cause of delayed onset of akinesia of this muscle, following a small volume of intraconal local anaesthetic injection.

Oculomotor nerve

It supplies all the extraocular muscles, except the superior oblique and the lateral rectus. It also supplies the parasympathetic fibres to the sphincter pupillae and ciliary muscles which are intraocular. So, the functional components of oculomotor nerve are:

i. Somatic efferent for the movement of the eyeball,
ii. General visceral efferent for accomodation and contraction of the pupil (these fibres come from Edinger-Westphal nucleus),
iii. General somatic afferent for the proprioceptive impulses from the muscles of the eyeball (Fig. 41.18).

The oculomotor nerve emerges from the interpeduncular sulcus on the ventral surface of the brainstem by 15 to 20 rootlets which then quickly coalesce into a single trunk. It then passes between the posterior cerebral and superior cerebellar arteries and traverses through the lateral wall of cavernous sinus but above the trochlear nerve. It divides here into superior and inferior branches, and then these two divisioins enter into the intraconal space of the orbit through the intermediate part (oculomotor foramen) of the superior orbital fissure. The nasociliary nerve and the sympathetic twig to the ciliary ganglion lie between these two divisions of the oculomotor nerve, and the abducent nerve lies lateral to them. The superior division of oculomotor nerve runs lateral to the optic nerve and supplies the superior rectus and the LPS muscle. The inferior division of the oculomotor nerve divides again mainly into three branches such as (i) the nerve to medial rectus, (ii) the nerve to inferior rectus, and (iii) the nerve to inferior oblique. The nerve to medial rectus passes inferior to the optic nerve. The nerve to inferior rectus passes downwards and enters the muscle from its upper aspect. The nerve to inferior oblique passes in between the inferior rectus and the lateral rectus and supplies the muscle from its posterior border. It also gives a thick branch to the ciliary ganglion. This branch carries the preganglionic parasympathetic fibres to the ciliary muscles and the sphincter pupillae.

Trochlear nerve

This 4th cranial nerve is the longest and the thinnest of all the cranial nerves. It first exits from the dorsum of the brain stem. Then it winds around the brain stem and traverses along the lateral wall of the

cavernous sinus inferior to the oculomotor nerve. After that it, enters the orbit through the superior orbital fissure, outside of the annulus of Zinn. In the orbit it passes forward near the roof and supplies the superior oblique muscle from its orbital surface. As the motor supply of the superior oblique muscle is from the outside of the cone of rectus muscles, so there may be some retained activity of the superior oblique muscle (intortion), following a small volume of intraconal local anaesthetic injection. The functional components of the trochlear nerve are: (i) the somatic efferent for the movement of eyeball and (ii) the somatic afferent for the proprioceptive impulses from the superior oblique muscle. At the cavernous sinus the fibres carrying the proprioceptive impulses leave the trochlear nerve and join the ophthalmic division of the trigeminal nerve. These fibres relay into the mesencephalic nucleus of the trigeminal nerve.

Abducent nerve

The abducent nerve is designated as the 6th cranial nerve and supplies the lateral rectus muscle only. It emerges from the CNS at the groove which is situated between the medulla and the pons (pontomedullary junction). Then, it ascends on the brainstem and makes a sharp bend over the petrous part of the temporal bone. After that it enters the cavernous sinus where it lies between the internal carotid artery medially and the trigeminal ganglion laterally. In the laterval wall of the cavernous sinus the nerve lies inferior to the oculomotor and trochlear nerves, but internal carotid artery lies superomedial to it. During the intracavernous course, the abducent nerve is joined by some branches from the sympathetic nerve which supplies the dilator pupillae. Then, the abducent nerve enters the intraconal space of the orbit through the superior orbital fissure but within the common tendinous ring, lying inferolateral to the oculomotor and the nasociliary nerve. It supplies only the lateral rectus muscle from its ocular surface (Fig. 41.19).

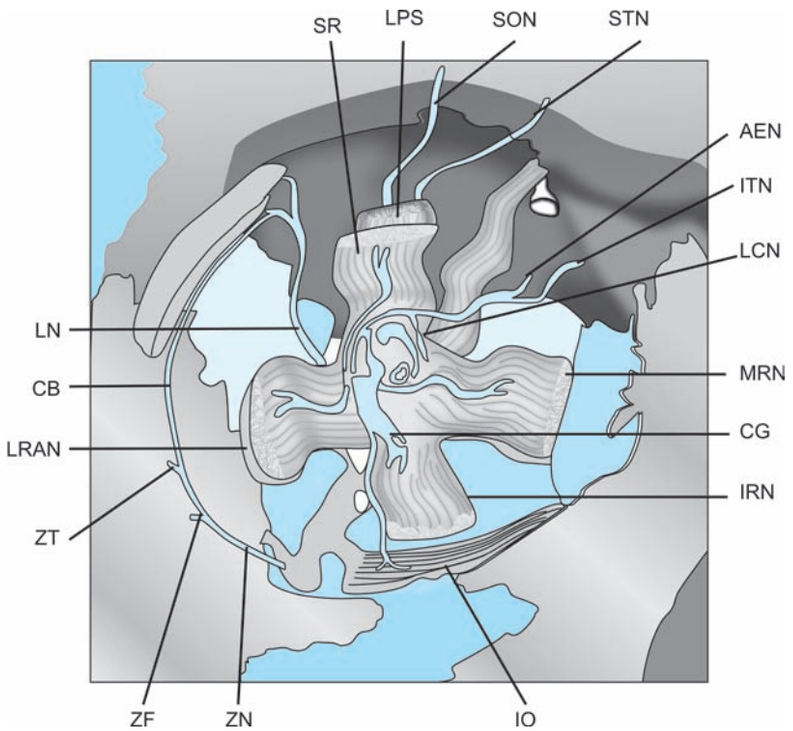
Trigeminal Nerve

The trigeminal nerve is the 5th and the largest cranial nerve. It is the nerve of the 1st brachial arch. The functional components of the trigeminal nerve are: (i) general somatic afferent which carries the sensation from the eyeball, lacrimal gland, conjunctiva, whole of the face, anterior half of the scalp, the auricle and the oral and nasal cavities, (ii) efferent fibres carrying motor to the muscles of mastication, tensor veli palatini, tensor tympani, the mylohyoid and the anterior belly of digastric muscle.

It arises from the ventral surface of the pons by two roots: a small motor root and a larger sensory root. These two roots then run forwards towards a notch at the upper margin of the petrous part of the temporal bone. After crossing the superior border of the petrous bone, the two roots then enter the middle cranial fossa to join the trigeminal ganglion. This trigeminal Gasserian ganglion is the sensory ganglion of trigeminal nerve. The sensory fibres are relayed and rearranged within this ganglion and gives emergence to the ophthalmic nerve, maxillary nerve and mandibular branche (only sensory part of the mandibular nerve) to form the mandibular nerve. The motor root passes inferior to the ganglion, and joins with mandibular branches to form the mandibular nerve.

Ophthalmic nerve

It is completely a sensory and is the smallest division of the trigeminal nerve. It supplies the eyeball, lacrimal gland,



SR – Superior rectus, LPS – Levator palpebrae superioris, SON – Superior orbital nerve, AEN – Anterior ethmoidal nerve, ITN – Infratrochlear nerve, LCN – Long ciliary nerve, MRN – Medial rectus and nerve, CG – Ciliary ganglion, IRN – Inferior rectus and nerve, IO – Inferior oblique, ZN – Zygomatic nerve, ZF – Zygomatico facial nerve, ZT – Zygomaticotemporal nerve, LRAN – Lateral rectus and abducent nerve, CB – Communicating branch, LN – Lacrimal nerve

Fig. 41.19: Orbital nerves from the front

conjunctiva, eyelids, forehead, scalp, nasal mucosa and the skin of the nose. After arising from the trigeminal ganglion, it runs forwards through the lateral wall of the cavernous sinus but below the oculomotor and the trochlear nerve. In the front of the cavernous sinus, the ophthalmic nerve then divides into three branches such as the lacrimal, frontal, nasociliary nerve which pass separately through the superior orbital fissure. The lacrimal and frontal nerves pass outside of the annulus of Zinn and the nasociliary nerve passes through the annulus of Zinn of superior orbital fissure (Fig. 41.20).

The lacrimal nerve enters the orbit as the lateral most structure through the surperior orbital fissure. Then, it runs forwards along the upper border of the lateral rectus muscle to enter the posterior border of the lacrimal gland. Besides supplying the secretomotor fibres to the lacrimal gland, it also innervates the most lateral part of the skin of the upper eyelid and adjacent conjunctiva. The lacrimal nerve also receives a branch from the zygomatico-temporal nerve. This branch carries the post-ganglionic parasympathetic fibres which are secretomotor to the lacrimal gland. The origin of this preganglionic parasympathetic fibres is in the lacrimatory nucleus which is situated in the lower part of the pons. The fibres arising from this nucleus first run through the nervous intermedius part of the facial nerve. Then, they run through the greater petrosal branch of the facial nerve and joins with the deep petrosal nerve to form the nerve of the pterygoid canal. Here the fibres make connection with the post-ganglionic fibres in the pterygopalatine ganglion. Then the postganglionic fibres arising from the pterygopalatine ganglion enter the maxillary nerve and passes through its zygomatic branch and then its zygomaticotemporal branch to join the lacrimal nerve.

The frontal nerve which is a branch of the ophthalmic division of the trigeminal nerve enters the orbit through the supraorbital fissure above the anular tendon and traverses between the LPS and the periosteum. At the midway between the apex and the anterior margin of the orbit, it divides into two branches: supraorbital and supratrochlear. The supratrochlear nerve runs anteromedially above the trochlea and supplies the skin of the upper medial part of the upper eyelid, medial conjunctiva and the skin of the scalp. The supraorbital nerve passes forwards and emerges at the front of the orbit, either through the supraorbital foramen (20%) or notch (80%). It provides sensation to the rest of the forehead, anterior 2/3 of the scalp, the skin of the upper central part of the eyelid and the adjacent conjunctiva. Thus, the peripheral conjunctival sensation is mediated via the lacrimal and the frontal nerves, both of which do not course through the intraconal space. So, incomplete conjunctival anaesthesia may result from a small volume of intraconal local anaesthetic injection.

The nasociliary branch of the ophthalmic division of trigeminal nerve passes through the annulus of Zinn. Then, it enters the intraconal space and sends a communicating branch to the ciliary ganglion. As it passes over the optic nerve, the long ciliary nerves (3 or 4 in number) are given off from it. These long ciliary nerves accompany the short ciliary nerves and then pierce the sclera close to the optic nerve. In addition to the afferent sensation from the iris, ciliary body, cornea and the central bulbur conjunctiva, these nerves also carry the sympathetic motor fibres to the dilator pupillae muscle. After passing over the optic nerve, the nasociliary nerve runs along the medial orbital wall in close relationship with the ophthalmic artery. Here, it gives off the anterior and posterior ethmoidal branches which pass through their respective foramina on the medial orbital wall and supply the mucosa of the ethmoidal sinuses and the nasal cavity. The most anterior division of the nasociliary nerve is the infra- trochlear nerve. It runs along the superior border of the medial rectus muscle and penetrates the orbital septum to innervate the skin of the side of the nose, the medial side of the skin of the lower

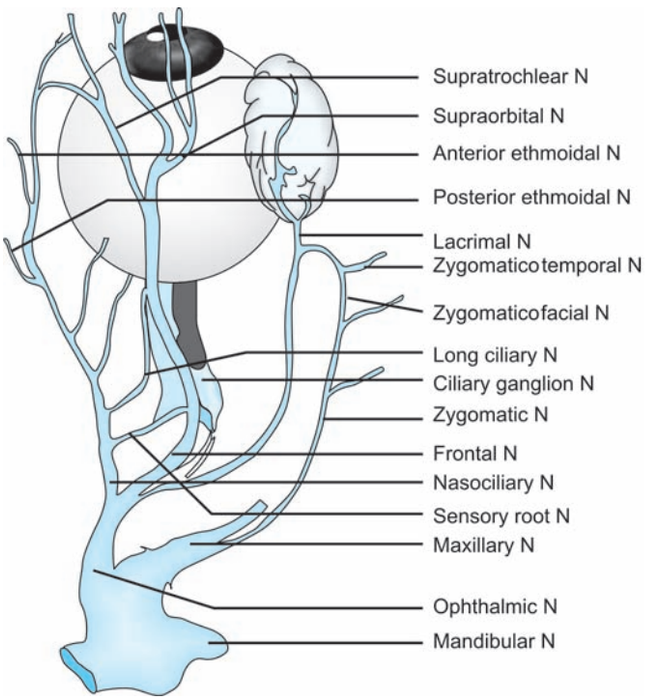


Fig. 41.20: Nerve supply of the orbit

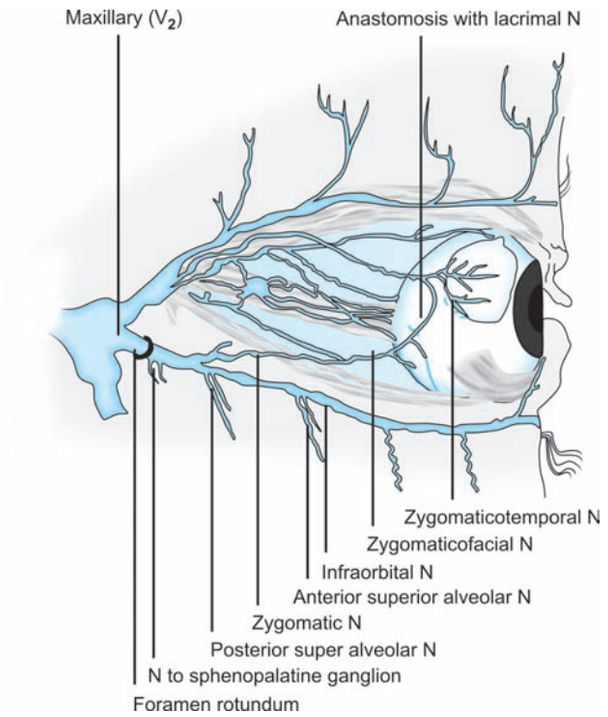

Fig. 41.21: Nerves of the orbit

eyelid, the adjacent conjunctiva and also the lacrimal sac (Fig. 41.21).

Maxillary nerve

The maxillary nerve is the second division of the trigeminal nerve. It is completely a sensory nerve supplying the middle portion of face, anterior temporal region, lower eyelid and the upperlip. It also supplies the sensation to the upper gums and teeth, the mucous membrane of upper mouth, nasopharynx and the maxillary sinuses. After emerging from the trigeminal ganglia, it runs forwards through the lateral wall of the cavernous sinus. Then, it exits from the cranial cavity through the foramen rotundum and enters the pterygopalatine fossa. Here, it sends branches to the pterygopalatine ganglion. After crossing the pterygopalatine fossa, the maxillary nerve enters the orbit through the infraorbital fissure, where it is known as the infraorbital nerve. Passing anteriorly, this nerve lies in the infraorbital groove. Then, it descends through the infraorbital canal to reach the front of the face at the infraorbital foramen which is situated 1 cm below the midpoint of the infraorbital rim. The infraorbital nerve supplies the skin of the lower eyelid, nose, upperlip and the central part of the face. In the pterygopalatine fossa the maxillary nerve gives off its zygomatic branch. This branch then enters the orbit through the infraorbital fissure and divides into zygomatico-facial and zygomatico-temporal nerves. The former exits through a foramen which bears the same name and supplies the skin overlying the malar bone. The later also travels a short distance along the lateral orbital wall. Then, it exits through a foramen, bearing the same name and innervates the skin of the anterior temporal region.

The preganglionic parasympathetic secretomotor fibres to the lacrimal gland emerge from the brainstem with the facial nerve. Then, it is transferred to the trigeminal nerve by a complex pathway and travels through the maxillary nerve. It relays in another peripheral ganglion of the parasympathetic system, named the sphenopalatine ganglion. This ganglion lies in the pterygopalatine fossa. From the ganglion, the postganglionic parasympathetic fibres reach the lacrimal gland, via the interconnections between the zygomatico-temporal and the lacrimal nerve.

There is a great anatomical proximity of the central and peripheral orbital nerves, with their shared innervating adipose tissue compartments and the skin. This explains easily the widespread area of the peripheral sensory block, associated with the intraorbital regional anaesthesia. The spread of to intraorbital regional anaesthetic block the frontal nerve complex in the superior orbit and the maxillary nerve complex in the inferior orbit results in a unilateral loss of sensation, which extends from near the occiput above to the upper lip below, and from the mid-line of the nose to the anterior temporal region laterally, including anaesthesia of the mucosa of the upper mouth and teeth and the nasal cavity. So, patients usually experience unilateral nasal stiffness or nasal block, andfeel that their nose is running.

Mandibular nerve

The detailed anatomy of the mandibular nerve has no direct importance to an ophthalmic anaesthetist. So, it will not be discussed here in detail.

Facial Nerve

It is the VII cranial nerve and is the nerve for the 2nd brachial arch. The functional components of facial nerve are:

i. Efferent fibres for all the facial muscles of face,
ii. General visceral parasympathetic efferent fibres for the submandibular and sublingual salivery glands and also for the lacrimal, nasal, palatine and the pharyngeal glands,
iii. Special visceral afferent fibres for taste sensations from the presulcal area of the tongue (anterior 2/3) and palate,

iv. General somatic afferent fibres from the concha of the auricle.

Among all the functional components of the facial nerve, only the efferent component for the the facial muscles is of the main interest to an ophthalmic anaesthetist (Fig. 41.22).

Facial nerve originates in the pons. Then, it exits from the base of the skull at the stylomastoid foramen in close proximity to the glossopharyngeal, vagus and spinal accessory nerves which are emerging from the jugular foramen. Here, the whole branchiomotor component of the facial nerve comes out, except the fibres going to the stapedius muscle. The landmark of the stylomastoid foramen is 2 cm deep and medial to the anterior border of the mastoid process. So, block of the facial nerve at this level results in a complete hemifacial akinesia and spread of injected local anaesthetic agent to the other adjacent major cranial nerves. After its exits from the stylomastoid foramen, the facial nerve first crosses the styloid process of the temporal bone. Then it passes under the external auditory meatus and enters the substance of the parotid gland through its posterior border. At this level, the facial nerve supplies the occipitalis, auricularis posterior and superior (through its posterior auricular branch), stylohyoid and the posterior belly of diagastric muscles. Inside the parotid gland the facial nerve divides first into two main divisions and then subsequently into several branches such as temporal, zygomatic, buccal, mandibular and cervical. However, the pattern of this break-up and distribution of the branches of the facial nerve within the parotid gland varies greatly between individuals. The temporal branch supplies the intrinsic muscles on the lateral surface of the auricle and the auricularis anterior, auricularis superior, frontalis, orbicularis oculi, and corrugator muscles. The zygomatic branch supplies the orbicularis oculi. The buccal branch supplies buccinator, small muscles of the nose, levator anguli oris, levator labi superioris and zygomaticus major. The mandibular branch supplies the depressor anguli oris, depressor labi inferioris and mentalis muscle. The cervical branch supplies only the platysma muscle (Table 41.1).

The fibres carrying the secretomotor and special sense (taste) component of the facial nerve are discussed in table. The effarent or motor components of the facial nerve, which hold the interest of an ophthalmic anaesthetist are the upper branches of the facial nerve such as the temporal and the zygomatic branches. This is because they innervate the forehead and the eyebrow musculature (frontalis) and the three components of the orbicularis oculi. It is also important to remember that all the facial muscles which are supplied by the facial nerve are innervated from their deep surface. So, block of the peripheral distribution of the terminal fibres of the facial nerve depends on the block technique. This is because if local anaesthetic drugs are injected superficial to the facial muscles, then they may not spread to their deep surface effectively. So, this will frequently cause poor abolition of their muscles action. Usually, the orbital rim, the zygomatic arch, the mastoid process and the temporomandibular joint form the important bony landmarks which are used for the peripheral facial nerve blocks (Fig. 41.23).

APPLIED ANATOMY

The matrix of the connective tissues of orbit supports the different structures of it, allows the dynamic function of the

eye-ball and limits the spread of the locally injected anaesthetic agents. The sensory anaesthesia of globe and conjunction results from the conduction blockade of intraorbital part of the ophthalmic branch of trigeminal nerve. On the other hand, globe akinesia is achieved by the conduction blockade of the intraorbital portions of the cranial nerves, such as III (oculomotor), IV (trochlear) and VI (abducent) nerves.

The branches of oculomotor nerve enters the muscle bellies of the four rectus muscles from their conal surfaces, 1 to 1.5 cm anterior from the apex of the orbit . The local anaesthetic agents have to reach at least 5 to 10 mm exposed segment of these motor nerves in the posterior intraconal space to produce sensory block and akinesia of the muscles supplied by them. So, when the local anaesthetic agent is injected intraconally, it achieves the motor block more easily with a small volume than when an extraconal method is used. The motor branch of the oculomotor nerve which supplies the inferior oblique runs a long intraconal course. Therefore, it is most easily blocked by the intraconal injection. On the other hand, the trochlear nerve which runs a short intraorbital, but long extraconal course before entering the muscle at its superolateral edge, is most resistant to intraconal local anaesthetic injection.

The autonomic and the sensory nerves have a longer course within the orbit from their point of entry at the apex to the globe and their supplying structures than the motor nerves. So, the local anaesthetic agents have a greater access to these sensory and autonomic nerves and produce a faster block than their motor component. The corneal and perilimbal sensation is mediated through the nasociliary nerve which lies within the cone of muscles. So, the intraconal injection effectively produces anaesthesia of the cornea and the conjunctiva immediately surrounding it. The lacrimal, frontal and infraorbital nerves, suppling the peripheral conjunctiva, run outside the muscle cone. So, surgical pain may be experienced in this area, following a solely intraconal block.

BLOOD VESSELS OF THE EYE AND THE ORBIT

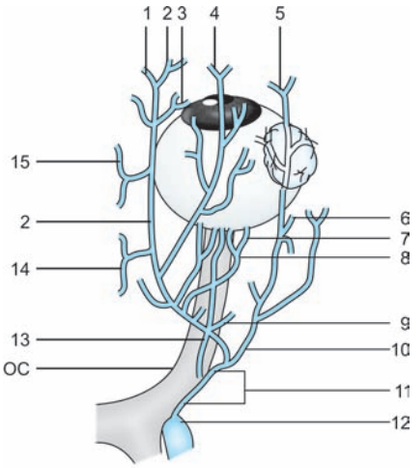
Generally, in the body arteries and veins travel together. But, in the orbit the arteries and veins behave differently. They run independently according to their anatomical distribution. The veins of the orbit do not accompany their corresponding arterial system, but rather take their own course and direction. The arteries of the orbit radiate from the apex towards their target organs, and perforate the connective tissue septa while passing from one compartment to the next. However, the veins run circularly and are confined to the connective tissue septa, without perforating it. In general, the arteries are located centrally in the intraconal space at the apex of the orbit, and superiorly at the anterior part of the orbit. Whereas veins are located peripherally, mainly outside of the intraconal area. The posterior part of the intraconal area has a high arterial density with addition of some venous drainage system from the retina. Considering the arteries and veins as a common entity, the posterior orbit on the lateral side has the greatest vascular constellation, whereas in the anterior orbit most of the vessels are found medially.

Arteries

There is much variability between the individuals, regarding the anatomical layout of the orbital arterial system. The orbital arterial system predominantly consists of the ophthalmic artery which is the branch of internal carotid artery. There are also variations of contributions in supplying the orbital arterial system from the external carotid artery.

The ophthalmic artery arises from the internal carotid artery when this vessel emerges from the root of the cavernous sinus, medial to the anterior clinoid process. Then, the ophthalmic artery enters the orbit through the optic canal, infero-lateral to the optic nerve and both of them lie in a common sheath of dura. In the orbit it pierces out the duramater, winds around the lateral side of the optic nerve and then passes forward and medially above it but below the ciliary ganglion (in 80%) between the superior ophthalmic vein in front and the nasociliary nerve behind. In 20% cases the ophthalmic artery does not pass above, rather lies underneath the optic nerve which is a more vulnerable position of it for injury by needle, directed towards the orbital apex during the local block (Fig. 41.24).

When the ophthalmic artery lies below the optic nerve, it gives off the first branch, called the central retinal artery. It pierces the dural sheath of the optic nerve, usually from its inferomedial aspect and 1 to 2.5 cm posterior to the globe, to reach the centre of the optic nerve. This tiny vital artery then runs forward within the core of the optic nerve and emerges at the optic disc where it divides into multiple retinal arteries supplying the retina. When the ophthalmic artery turns round and reach above the optic nerve, then it gives off the second branch, named the lacrimal artery. The lacrimal artery passes forward along



1. Dorsal nasal artery, 2. Supratrochlear artery, 3. Medial palpebral artery, 4. Supraorbital artery, 5. Lateral palpebral branch, 6. Zygomatic branch, 7. Long and short posterior arteries, 8. Muscular branch of lacrimal artery, 9. Muscular branches of ophthalmic artery, 10. Lacrimal artery, 11. Ophthalmic artery, 12. Internal carotid artery, OC-Optic canal, 13. Central retinal artery, 14. Posterior ethmoidal artery, 15. Anterior ethmoidal artery.

Fig. 41.24: Arterial supply to the orbit

the upper border of the lateral rectus muscle and terminates as superior and inferior lateral palpebral arteries for each eyelid. These superior and inferior lateral palpebral arteries anastomose with the medial superior and inferior palpebral arteries. In its course, the lacrimal artery gives of multiple branches such as the muscular, zygomatic and recurrent meningeal arteries and branches to the lacrimal gland. The recurrent meningeal branch passes back through the superior orbital fissure, and anastomoses with the middle meningeal artery.

When the ophthalmic artery turns nasally above the optic nerve, it gives off some muscular branches to the rectus muscles, and the long and short posterior ciliary arteries. These long and short posterior ciliary arteries enter the globe after piercing sclera in association with the long and short ciliary nerves, close to the optic nerve. The long posterior ciliary arteries usually are two in number. They course forward within the globe, deep to the sclera and supply the anterior part of the uveal tract. The multiple short posterior ciliary arteries also pierce the sclera like the long posterior ciliary artery, and supply the choroidal coat of the eye and the ciliary body. The anterior ciliary arteries arise from the different muscular arterial branches, and enter the globe close to the limbus. They supply the anterior parts of the uveal tract.

The ophthalmic artery then reaches the medial wall of the orbit and passes forward along the this wall between the medial rectus and the superior oblique muscles. At the medial end of the upper eyelid the ophthalmic artery divides into two terminal branches, the supratrochlear (sometimes called the frontal artery) and the dorsal nasal artery. After the ciliary arteries are given off when the ophthalmic artery touches the medial wall of the orbit, it gives off a branch, named the supraorbital artery. This branch courses forward with the nerves of the same name. After the supraorbital artery, the ophthalmic artery while passing along the medial wall of the orbit gives off the following branches: posterior ethmoidal artery, anterior ethmoidal artery, and the superior and inferior medial palpebral artery. The ethmoidal arteries, as they exit through their respective foramina, anchor the ophthalmic artery to the medial wall of the orbit.

During regional anaesthesia any needle should not be introduced into this posterior 1.5 cm of the orbital apex. This is because large vessels are located there which may be the potential sources of any vision-threatening bleeding. These areas also contain vital structures, such as the optic nerve and the extraocular muscle's origins which are tightly packed there and may be subjected to serious damage due to bleeding or direct injury from the needle tip. There are, however, three adipose tissue compartments in the anterior and midorbital area, which are relatively avascular and are so preferred sites for local anaesthetic injection. These compartments are : inferotemporal, superotemporal and medial. The superotemporal space extends from the sagittal plane of the lateral limbus close to the roof and about 3 cm behind the orbital rim. In the medial space the needle entry point should be at the extreme medial end of the palpebral fissure on the nasal side of the caruncle. The needle should be directed upto the maximum distance of 2.5 cm in the transverse plane and 5 degrees medial to the direct sagittal plane. The superonasal quadrant should be avoided as an injection site, because it contains the end arteries of the ophthalmic artery, large venous connections between the facial angular vein and the superior orbital vein, and the trochlear mechanism of the superior oblique muscle. The transconjunctival injection is less likely to produce significant ecchymosis in comparison to the transcutaneous route.

Veins

The two principal veins that drain blood from the eyeball and other orbital structures are: the superior ophthalmic vein and the inferior ophthalmic vein. Among these two, the former is the most constant structure. The superior ophthalmic vein is formed by the confluence of major tributaries of the superior orbital vein, supratrochlear vein and the angular facial vein. The angular facial vein descends lateral to the nose, with the angular artery. It is subcutaneous and is often visible as a blue ridge, until it pierces the orbicularis oculi muscle. This vein complicates the surgical approaches to the lacrimal sac. It (the angular vein) is continuous with the facial vein and communicates freely with the cavernous sinus through the superior ophthalmic vein. After its formation, the superior ophthalmic vein runs backward along the medial boarder of the superior rectus muscle from where it enters the intraconal space. In the conal space, it runs further backward and laterally in a hammock-like structure of the connective tissue septa which is suspended under the superior rectus muscle, between it and the optic nerve. It again exits the intraconal space at the

lateral border of the superior rectus muscle. Here, it runs backward in the direction of the superior orbital fissure, through which it gains access to the cavernous sinus above the annulus. During its course, it accompanies the ophthalmic artery and receives tributaries that corresponds with the branches of the accompanying artery.

The inferior ophthalmic vein which is also called the inferior orbital vein begins at the floor of the orbit and collects the blood from the inferior orbital muscles, lacrimal sac and eyelids. It drains in the cavernous sinus either directly or after joining with the superior ophthalmic vein. It communicates with the pterygoid venous plexus through the inferior orbital fissure.

Other veins of the orbit and globe are: vortex vein, central retinal vein, middle ophthalmic vein and medial ophthalmic vein. The vortex veins are usually four or more in number. The superomedial vortex veins drain into the first part of the superior ophthalmic vein, while the superolateral vortex veins enter its third part. The inferior vortex veins join to form the inferior venous plexus. The central retinal vein leaves the optic sheath and joins the network of venules from the sheath. It drains usually in the superior ophthalmic vein. The middle ophthalmic vein arises near the lateral side of the medial rectus. It drains in the inferior venous network and joins the confluence of the superior ophthalmic vein with the cavernous sinus.

REGIONAL VERSUS GENERAL ANAESTHESIA

The term regional anaesthesia (RA) signifies the conduction block of a specific nerve or a group of nerves of a region by local anaesthetic agents. Whereas, the term local anaesthesia should be restricted to the technique of infiltration of local anaesthetic agent in a area of local tissue, resulting in blockade of only the nerve endings. On the other hand, topical anaesthesia implies to the action of local anaesthetic agents, when it is applied on the surface of epithelial tissues. After the discovery of cocaine as a local anaesthetic agent, the topical and regional anaesthesia became the cornerstone of many ophthalmic surgery. But, cocaine had many complications and in few cases was only taken as an alternative to GA which was at that time also not so improved and had a high mortality rate. After cocaine, many other local anesthetic agents were also discovered. These had no such problems like cocaine and hence established the local anaesthesia as first choice over GA in ophthalmology up to 1950. During that period with firm establishment of RA in ophthalmic surgeries as first choice, some ophthalmic surgeons still preferred GA, even though it was not so improved during those years. The causes behind their perference to GA over RA are : (i) Some surgeons did not believe in RA as local anaesthetic agents had just been developed, (ii) Some surgeons were not mentally prepared to wait for the local anaesthetic agent to act. (iii) Some surgeons thought that postoperative results were better with GA than RA, and (iv) Simply, some surgeons did not like to operate on a conscious patient.

Then, between 1950 and 1960 a swing back to GA from RA for most of the ophthalmic surgeries had again occurred. This is because improved drugs, machines and techniques for GA became available. During that period surgeons were also comfortable to perform surgeries under GA, as ophthalmic surgical techniques were not so improved matching with RA and surgical complication rates were high under RA. But, in the last part of that century and over the last two decades RA has been again supplanting GA for many ophthalmic surgical procedures. This is because surgical techniques were improved with the help of modern surgical equipments of higher technology. Thus, the average surgical time for cataract extraction and other complicated surgical procedures has markedly decreased and this may be one of the causes for preferring RA over GA, recently. This surgical improvement, in combination with the efficient scheduling of operation time and the predominant use of out-patient surgical facilities have made a high volume of patients-turnover possible. So, this form of practice again dictates itself to RA techniques, prohibiting GA for most of the ophthalmic surgeries, except in certain special cases.

Stress is a common and almost unavoidable factor during the perioperative period of ophthalmic surgeries performed under RA. It is associated with the release of catecholamines, cortisol and glucose in the circulation, and this is evidenced by the signs of tachycardia, hypertension and elevated blood glucose level. The increased plasma level of catecholamines in patients undergoing ophthalmic surgery under RA resulted primarily from the endogenous sources and sometimes secondarily (less important) from the exogenous sources. It is found that as an exogenous source 10 ml of local anaesthetic solution containing 1:2,00,000 epinephrine (5 µg/ml) causes no untoward clinical effect. It is also found that entry of a patient into the operating area for block or RA is the most significant stress factor, than the performance of block itself. So, for the perioperative management of a patient who is scheduled for ophthalmic surgery under RA adequate counselling during the first meeting with him is extremely important for successful attenuation of stress. This can be performed efficiently by repeated reassurance, preoperative visit with the anaesthetist, booklet, video, tape, etc. Many patients appreciate music as a distraction, before giving block. The simple act of having a staff member holding the hand of a patient during RA and surgery has a considerable calming effect. In extreme cases, judicious use of benzodiazepine (midazolam) orally or intravenously may be useful to reduce the stress response. But in an ambulatory setting the use of preoperative sedative medications

should be such that it allows the patients to be discharged promptly after completion of surgery (Table 41.2).

For a small percentage of elderly patients who are benefited from preoperative sedation, fine judgement is required to select the correct drug and dosage of sedative agent which are to produce only a calming effect, but remains alert and cooperative without respiratory depression. The advantages of RA over GA can be negated rapidly with the excessive use of sedation. The combination of RA with heavy sedation may produce a less satisfactory outcome than either methods on their own.

The time spent by an anaesthetist for establishing a good rapport with the patient is more effective in removing anxiety than depending on the pharmacological methods. To perform RA efficiently and successfully, the anaesthetist must have certain personality traits and good communication skills. This enables him to gain the patients' trust rapidly. This will also educate the patients, regarding the experiences that they have to face during operation. Thus property treated and prepared patients scheduled for ophthalmic surgery under RA will have a minimal anxiety and have a low incidence of perioperative complications. Sometimes, absence of such a skill in an anaesthetist may force him to take the decision in favour of GA.

Table 41.2: Respective advantages of regional and general anaesthesia. Advantage of one type of anaesthesia is a disadvantage for the other and vice versa

Regional anaesthesia (RA)

- Simple technique,
- Early recovery,
- Less hospital stay,
- Early discharge,
- Quick turnover,
- Less expensive,
- Better postoperative analgesia,
- Avoidance of oculocardiac reflex,
- No loss of control of patient,
- Less physiological change,
- Absence of respiratory depression,
- Full mental status retained,
- No risk of malignant hyperthermia.

General anaesthesia (GA)

- Complete control of patient,
- Risk of globe perforation is nil,
- Risk of intraorbital haemorrhage is nil,
- Risks of myotoxicity, nerve injury are nil,
- Risk of allergy to local anaesthetic agent is nil,
- Applicable to all ages,
- Preferable for teaching of surgery methods for trainees.

There is also a widespread of opinion that patients do better under RA than GA. But, scientifically it is very hard to prove, except in some specific cases. Multiple, major retrospective and prospective non-randomized studies have failed to favour one method of anaesthesia over the other. On the other hand, cataract surgeries which constitutes the main bulk of ophthalmic surgeries are more frequently performed on elderly patients. The more elderly a patient, the higher is the intrinsic risk of death. This should be added to the risk of death which is associated with the clinical intervention. The elderly patients are associated with multiple systemic diseases such as hypertension, coronary arterial disease, COPD, diabetes mellitus, obesity, etc. These are also added to the operative risk and presents an additional challenges to the operating team. It is also demonstrated that complication rate correlates well with the number of the associated diseases, rather than the age of the patient.

All the patients scheduled for ophthalmic surgery under GA or RA require proper preoperative assessment and preparation. They also need an open discussion regarding the risks and complications of anaesthesia and surgery which is based on a thorough history and physical examination. The whole system requires cooperation among the patients, their relatives, their family doctors, surgeons and the anaesthetists. A list of medications, currently taken by the patients is also required. Because it ensures that essential therapy can be continued through the time of surgery and potential drug interaction can also be anticipated. Necessary preoperative laboratory and radiological investigations should be done only when these are indicated, and appropriate for that particular patient or according to the ASA guidelines. Whatever is the method of anaesthesia regional or general, every effort should be made to have the patients in the best possible medical condition prior to surgery. Most ophthalmic surgeries are nonemergency. Therefore, the date of surgery should usually be postponed, until the medical status of each patient becomes optimal.

The decision of whether general or regional anaesthesia should be selected, is based on the consensus among the team members who are involved in the surgery including the patient. The choice of anaesthetic technique is usually predicted by the team's previous experience for that type of surgery on a particular group of patient (Table 41.3).

Whether RA or GA, the skill of application of the technique is more important for patient's morbidity and mortality than any academic discussion of the merits or demerits of the this two anaesthetic technique RA and GA. However, a high standard peri operative monitoring and anaesthetic skill must be maintained for both forms of anaesthesia. Usually, it is a common practice to select sick patients for RA, because they are unfit for GA. But it should be kept in mind that RA should be an alternative to GA for the more fit and healthy patients, and RA should always not be considered as an alternative means of anaesthesia for operating on unfit patients. This is because unfit patients do not co-operate well even under RA for prolonged periods. Thus, the tragedy is that the patients who are unfit for GA cannot be selected under RA, and vice-versa.

Before selecting the patients for GA, few things can be tried or followed which may help to perform surgery under RA instead of GA. For example in the management of patients with mild to moderate degrees of senile dementia or mental

Table 41.3: Contraindication to regional and general anaesthesia with decreasing order of importance from absolute at the top of the table. Contraindication of RA is indication to GA and vice versa

Regional anaesthesia (RA)
Refusal of informed consent by the patient
Surgeon preference for GA
Surgery for open eye injury
Prolonged surgery (more than 2 hours)
Children up to the age of early teens
Unsuitable psychological status
Psychiatric disorders
Uncooperative patient
Mental retardation
Senile dementia
Communication barrier
Language
Deafness
Head tremor or movement
Parkinsonism
Tardive dyskinesia
Inability to lie flat
Severe arthritis
Respiratory diseases
Cardiac diseases
Claustrophobia
Previous complication from RA
High myopia
Inexperience of anaesthetist on RA
True allergy to local anaesthetic agent
Patients on anticoagulants
Needle phobia
Intractable cough
General anaesthesia (GA)
Refusal of informed consent by the patient
Severe medical condition, ASA III or IV
History of difficult airway
History of serious adverse effect from previous GA History of malignant hyperthermia
Muscle diseases
Dystrophia myotonica
Myasthenia gravis
Haemoglobinopathies
COPD
History of porphyria
History of atypical pseudocholinesterase

retardation who are presented for ophthalmic surgeries under RA, a family member can hold hands with the patient and give verbal support in the operating room. It also acts in the same fashion in the presence of a language barrier, where communication with the patient becomes impossible which results in the choice of general anaesthesia. In such situations a family member can be recruited to interpret the language. When a patient with slight tremor of head is scheduled for ophthalmic surgery under RA, then Intravenous sedation in titrable doses can control the Parkinsonian head tremors effectively. Incomplete block can be best managed by further supplementation of drug. Because operation in the presence of partial regional anaesthesia or block failure puts the patients in a severe unpleasant and stressful experience. Use of IV sedation which is not up to the level of GA and is used to cover the block failure or partial block is hazardous and inappropriate. In such situations, full GA with all precautions and monitoring should be the real answer.

In the past, when the ophthalmic surgeries were performed under conventional GA then it was the traditional domain of an anaesthetist, while local regional block was the domain of an ophthalmologist. The ophthalmologists were also considerably reluctant to permit anaesthetists to perform the orbital regional anaesthesia. This is because, they believed that only the physicians of their own discipline had the necessary elaborate anatomical and technical knowledge to avoid serious complications during regional block. But, for the last two decades a change has been under way due to many reported or unreported deaths during RA by ophthalmologists. So, at present in many developed and under-developed countries idea to improve the patient care by increasing the involvement of an anaesthetist, including administration of regional block by them, has been given official sanction. The various commonly used methods of RA for ophthalmic surgeries are all completely blind procedures. So, multiple serious complications have been reported, following RA by efficient persons of both the disciplines. It does not depend on the person of any particular discipline who is administering the block. On the other hand, there is an obivious added disadvantage when acts both as an ophthalmic surgeon together with giving a complete attention to the patient's medical condition during surgery under RA, especially in the absence of an anaesthetist who can continuously monitor the patient. He can never give his undivided attention to the general condition of the patient which an anaesthetist can. Moreover, in the event of an emergency and serious cardiopulmonary complications, anaesthetists are more familiar with them and can perform better and more efficient cardiopulmonary resuscitative measures than their surgical colleagues. There is also no inherent reason why an anaesthetist who is proficient in various regional anaesthesia ouside the orbit should not become efficient in ophthalmic cases, too.

TECHNIQUE OF ORBITAL REGIONAL ANAESTHESIA

History

The history of anaesthesia for ophthalmic surgery dates back to over 2500 years from present date. The earliest authentic writings on this subject were those of Susruta who was an ancient Indian surgeon. He first described cataract surgery by couching, around 600 BC. Couching is nothing but pushing back the lens in the vitreous cavity by a blunt pressure on the eyeball. He also outlined the use of inhalational anaesthesia for this method but the name of the inhalational agent was not known and also described aseptic techniques. Later, Egyptian and Assyrian surgeons described the use of carotid compression to produce transient unconsciousness by cerebral ischaemia under which couching was performed. In the first century of AD, Dioscorides produced a soporific sponge from an extract of mandrate, boiled in wine and was used to produce unconsciousness.

After that twelve hundred years had passed without any advancement in the science of ophthalmic surgery and anaesthesia. Then, in the 13th century, a Spanish alchemist described a liquid which was produced by the mixture of sulphuric acid and alcohol to make the patient unconscious after inhalation of this liquid. He called this mixture as 'sweet vitriol'. But, in 1730, this substance was renamed as ether. However, during this period nobody except this alchemist knew the anaesthetic property of this compound. In 1818, Faraday discovered its anaesthetic effects accidentally. Up to that period, all the ophthalmic surgeries, mainly the cataract were done under GA produced by excessive consumption of alcohol, opium, etc.

In 1855, Gaedcke first extracted crude alkaloid from the leaves of cocoa plant. Then, 5 years later, it was purified and named as cocaine by Neiman. He noted that cocaine numbed the nerves of the tongue and deprived it from the feeling of taste. 25 years later, in 1884, Koller in collaboration with Sigmund Freud first used cocaine as a topical anaesthetic agent for minor surgery only of the conjunctiva. News of this discovery rapidly spread across the whole world. Then, in New York city an ophthalmologist named Dr Herman Knapp used cocaine in all the type of ophthalmic surgery by injecting if in the orbital cavity and published his work in December of the same year. This publication also inlcuded his own work on retrobulbar injection of cocaine. He had done this for painless enucleation of an eyeball. But, subsequently serious toxic effects and death were experienced by the other surgeon with the use of cocaine which was injected in large doses for nerve blocks, particularly in general surgery. This dettered the other ophthalmologists from using cocaine for regional anaesthesia in ophthalmic surgeries, until well up to the twentieth century. But, topical anaesthesia using cocaine continued, apparently successfully, for minor conjunction surgical procedures and all other ophthalmic surgeries were done under G.A.

During the early part of the twentieth century adrenaline (in 1901) and procaine (in 1905) were discovered. After that, various and much safer regional anaesthetic techniques were developed in general surgery which was accomplished with larger doses of local anaesthetic agents other than cocaine. But, unfortunately this was not introduced into the ophthalmological practice for many years. Then, in 1914, Van Lint first reported his classical facial nerve block technique, using procaine. This removed the problem of suddenly high rise of IOP by forceful contraction of the orbicularis oculi muscle, during ophthalmic surgery. This akinesia of facial muscles were commonly used as an adjuvent to the topical anaesthesia for corneal and conjunctival surgeries and was in routine practice until 1930. Later, retrobulbar techniques in conjunction with facial nerve block for ophthalmic regional anaesthesia using procaine became wide spread instead of topical. Although, this retrobulbar block using cocaine as the local anaesthetic agent was first done in 1884 by Knapp, but he failed to popularize this method, until 1930.

From 1934 to 1964, Atkinson published many articles on regional anaesthesia for ophthalmic surgery. At this time, hyaluronidase was not available. He used only procaine and adrenaline. In 1936, he convinced all the opthalmologists that for best results the injection should be given within the muscle cone and just posterior to the globe. Atkinson also advocated that the inferotemporal quadrant is relativley avascular and the safe route for needle introduction into the orbit for regional block. During his period, many other persons like Lowenstein, Swan, Gifford, O'Brien, etc. also worked on the retrobulbar block by using procaine with different size, length and position of the needle and also with different volumes of the drugs. Then, came the peribulbar method which was also described long ago, in 1914 by Allen. But, this technique did not come into common ophthalmic practice, until 1986.

The whole scenario of this ophthalmic regional anaesthesia practice was changed dramatically after the lignocaine was synthesized by Lofgren and Lundqvist in 1943 and after the introduction of hyaluronidase around 1956. Lignocaine was first used clinically after its synthesis by Gordh in 1947. Then with the intorduction of mepivacaine in 1957 and its chemical modification such as bupivacaine in 1963, the stage was rightly set for dependable clinical ophthalmic regional anaesthesia practice to cover a wide range of ophthalmic surgical procedures and to provide greatly improved postoperative analgesia.

Practical Management and Patient Preparation

An anaesthetist who is totally devoting his practice on ophthalmic anaesthesia should have a thorough knowledge regarding the anatomy of orbit and eyeball, the physiology of eye and the pharmacology of the ocular and local anaesthetic drugs. It will enormously help him to prevent any criticism and opposition from any ophthalmologist during any complication which may occur of the fine of administration of RA. The anaesthetist who also wants to engage himself in this type of work is always encouraged to meet and observe some highly specialised ophthalmic centres which are operated by qualified personnel with wide experience and vast knowledge on this subject. The goal of each such practitioner is to build up an experimental database by himself from which later increasingly good judgement may result.

During ophthalmic operation, the required anaesthetic technique (RA or GA) is mainly dictated by the type of surgery, the surgeon's particular preference to the type of anaesthesia for that surgery and the wishes of the patient. So, a good understanding between the anaesthetist and the ophthalmologist's preference to the type

of anaesthesia for this surgery is essential. For example, some surgeons quarrel for complete akinesia, while some surgeons do not during cataract extraction. Again, it is not necessary or desirable in all the cases. Achievement of complete akinesia demands a higher volume of injected local anaesthetic agent, which may increase the intraorbital and subsequently the intraoccur pressure. This may also be of great disadvantage to some surgeons. Again, most surgeons may prefer globe hypotony. But, some surgeons may not prefer it and there may be certain situations where this becomes undesirable.

On the other hand, ophthalmic surgeons who are operating under regional anaesthesia must know how to deal with an awake patient on the operating table. It is unwise for an ophthalmic surgeon to ask repeatedly whether the patient is feeling pain or not. If the achievement of complete motor akinesia is used as the yard stick of block effectiveness, then pain will not be experienced. This is because motor fibres are blocked only after the block of sensory fibres. In such situations, appreciation of touch and tissue movement by the patient (proprioceptive sensation) may be interpreted wrongly as pain in the nervous patients. If the local anaesthesia is not adequate, then it is usually not difficult to recognise it by an anaesthetist. But if it is not i.e. when the block is very good then it is a bad practise to take suggesstion from the patient. Again, it will make the patient feel that the surgeon does not have the required confidence on the surgery and anaesthesia. The surgeon who knows better and trusts a carefully selected anaesthetic team by himself should start the operation without any confusion. At the same time, he should be aware of any significant non-verbal responses due to pain on the part of the patient.

Most of the patients presenting for ophthalmic surgery are at the extremes of age. Again, majority of eye surgeries consist of cataract extraction and are performed as day-cases under local anaesthesia. As most patients are elderly, they have many serious systemic diseases. So, preoperative assessement and preparation of the patient undergoing ophthalmic surgery under regional anaesthesia is same as that of general anaesthesia. On the other hand, in many centres, patients undergoing cataract extraction under RA do not warrant routine investigations. But, more stress is given on the psychological aspect of the patient for preoperative preparation. All the patients should receive a careful explanation of the procedure, that lies ahead on the day of surgery.

Whatever may be the type of surgery and anaesthesia (even topical) an informed consent from the patient is mandatory. During the period of preanaesthetic examination, preparation and taking consent, the patients should be given the opportunity to ask questions and receive answers. Premedication may or may not be indicated. Care should be taken during application of sedative premedication on very elderly patients. Oral sedation may produce pleasure in some patients, but some may complain of vertigo and dislike it. But as a whole, the use of short acting oral benzodiazepines as premedication is beneficial for most of the patients.

The preoperative fasting protocol for regional anaesthetist is similar to that of general anaesthesia. Clear fluid may be given 3 hours before sending the patient to the anaesthsia room. But, some clinics or hospitals maintain their own fasting protocol for regional anaesthesia. They do not routinely make starve such patients and provide a light meal 2 to 3 hours before operation, thinking that it is less disruptive for the elderly population and also facilitates better diabetic control. Regular medications should be continued up to and also on the day of surgery, including anti-hypertensives, anti-diabetics, anti-coagulants, anti-inflamatory, anti-asthamatic drugs, etc. Prophylactic antibiotic are generally not considered necessary for patients with cardiac lesions, undergoing routine anterior chamber (cataract) surgery. In patients receiving anticoagulant therapy, INR should be kept less than 2.5. Whenever required, the anticoagulant therapy should be adjusted to reduce the INR to less than 2.5. If this is considered inappropriate, e.g. in patients with artificial heart valve, then the relative risks of GA must be considered. An alternative option is to use the subtenon's approach or just topical anaesthesia.

Preoperatively, the axial length of the eyeball should always be measured in all cases. In severe myopic patients (axial length > 26 mm) the globe often has a long anteroposterior diameter (sausage-shaped eye ball). This increases the likelihood of globe perforation during regional anaesthesia which is diagnosed by sudden pain during injection, loss of vision, poor red reflex or vitreous hemorrhage. So, where axial length is greater than 26 mm, then single medial canthus injection, subtenon's approach, topical anaesthesia or GA should be considered. Hearing aids and dentures are left in place during RA.

It is a very good practice to set up a venous line routinely for all patients. Though, it is not a part of a planned routine intravenous therapy, but will be helpful in the event of an unplanned emergency intervention, calling for intravenous therapy. Good record keeping of every patient is essential. This includes medical history, health status of the patient, type and length of the surgical procedure, surgical complications, anaesthetic procedure and patient's reaction to it, etc. Anaesthetic record will include : used anaesthetic drugs, its volume and concentration, sites of injection, increased intraorbital pressure due to injection, decompression procedures, etc. Parameters of all the vital signs should also be measured and recorded. A foolproof system of checking of all the drugs and equipments in the anaesthetic room and operating theatre is essential. It will help to avoid dangerous errors and damage to the patients, particularly during emergency. It will also help in smooth and safe functioning of the whole

unit in operating suit. Personal or self-confidence of an anaesthetist is also acquired with repeated use of different regional anaesthetic techniques and tackling their complications. This in-turn will help the patients to be more stable, reassured and less dependent on sedative premedicant drugs.

History of claustrophobia is also very important. Because, many patients undergoing ophthalmic surgery are bothered to some degree with surgical drapes which encroach on their face. In such circumstances, alternative draping techniques or light intravenous sedation will be helpful. In extreme situations, general anaesthesia is indicated.

No patient should be left unattended in anaesthesia room and OT. Engagement of all the patients with light conversation by both the anaesthetist and the surgeon during both administration of anaesthesia and surgery is considered a good practice. Patients should be encouraged to express any difficulties on their part. By doing so, they act as their own monitor and are more reliable than any electronic gadget. While a surgeon is working with a particular patient, then conversation with a staff or an the anaesthetist or with another surgeon regarding other patients is inappropriate. This is because it is thought that this patient is not getting proper attention.

Most of the patients undergoing ophthalmic surgery are elderly. They are frequently suffering from arthritis, spondylytis, kyphosis, osteoporosis, etc, which are sometimes painful. So, it is frequently impossible for them to accomodate on the operating table for prolonged period-which have little or no head rest. Hence, intraoperative posture of a patient is very important. Ophthalmic surgeons usually prefer the patient's head in a horizontal plane under the microscope. But, the peculiar ophthalmic table with little or no head rest make it difficult for elderly patients to accomodate their head in this horizontal plane. This can be achieved by the necessary number of pillows under the occiput on the OT table.

Types of Surgeries which can be Undertaken Under RA

Usually, the type of surgery is not an important factor for selection of regional or general anaesthesia. Any type of surgery, except a few, can be performed under any type of anaesthesia. But most of the ophthalmic surgeries are performed under RA, except a few where intraorbital injection is contraindicated or topical cornea-conjunctival anaesthesia is not appropriate, or RA cannot be provided due to the patients health factors such as ASA III and ASA IV group of patients, The RA is also not applicable for ophthalmic surgeries in paediatric, psychiatric, cerebral palsy group of patients, etc. whose long list are given in table. The long list of surgeries which can be performed safely using regional anaesthesia are: cataract extraction with or without intraocular lens implantation, corneal transplantations, trabeculectomy, strabismus repair, lid surgeries, oculoplastic surgeries, vitreo-retinal surgeries, etc. But the main limitation of regional anaesthesia is its fixed time frame. Duration of operations extending beyond 2 to 2.5 hours tend to be rather difficult under RA. This difficulty is more applicable for conscious elderly patients who have cervical spondylosis or increased frequency of micturition due to enlarged prostate, or any other cause for which he is unable to lie supine for prolonged period. For regional anaesthesia a wide range of local anaesthetic drugs are now available, with which the duration of safe therapeutic time-window usually can be predictably planned. For example, 10 ml of 2% lignocaine with 1:2,00,000 adrenaline and 7.5 turbidity units of hyaluronidase per ml will produce a dependable 60 to 90 minutes of therapeutic time-window for complete akinesia. For surgical procedures lasting for 2 to 3 hours, such as vitro-retinal surgeries, long acting agents like bupivacaine or etidocaine should be the agent of choice. Because, both of these agents produce a therapeutic time-window of about 2 to 3 hours.

Retrobulbar or Intraconal Block

'Retrobulbar' or 'intraconal' are two clinically interchangeable word, because both usually signify the same space. But the 'retrobulbar' is a more vague term, as it indicates any space with in the orbit but behind the globe (or bulb) and may not be within the geometric confines of the four rectus muscles. Whereas the term intraconal block exactly signifies that the needle tip and the injection placement is within that space which is confined by the four rectus muscles. On the other hand, when the needle tip is placed and the local anaesthetic agent is deposited within the orbit, but not within the geometric confines of the cone of the rectus muscles, then it is called the peribulbar or periconal or periocular block. The peribulbar block may be posterior or anterior to the equator of the globe. When the peribulbar block is placed posterior to the equator of the globe, then it is called the posterior peribulbar or periconal block and when the peribulbar block is placed anterior to the equator of the globe, then it is called the anterior peribulbar block. The intraconal area is always posterior to the globe. So, there is no need to mention the word 'posterior' during its use. On the contrary, during the use of the name 'peribulbar' we can fix the word posterior with it, as there is also a peribulbar space anterior to the equator of the globe (Fig. 41.25).

During the intraconal or retrobulbar block, a straight needle with different lengths and sizes (discussed later), mounted on a syringe containing the chosen anaesthetic mixture is introduced within the orbit either transconjunctivally or transcutaneously. This site of introduction is through the inferotemporal quadrant of the orbit which commences at the junction of the lateral third and medial two-thirds of the inferior orbital rim. The safety of the retrobulbar block mainly depends on the proximity of the needle tip to the orbital wall at the

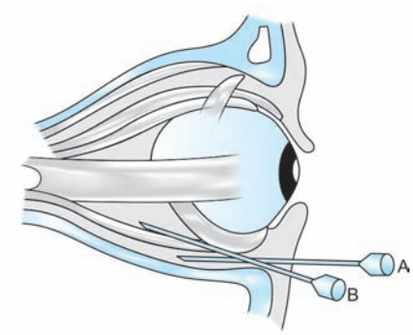


Fig. 41.25: Transcutaneous approach of intraconal block through inferotemporal space. In position A, the path of the needle is followed close to the orbital floor until the equator of globe is crossed. Then, in position B of the needle the angle of direction is changed upward and medially and is advanced to enter the intraconal space, posterior to globe

time of first entry and until the globe equator is passed. Initially, the inferotemporal orbital rim is palpated by the finger and its relationship to the globe is noted, including the orientation of the equator of the globe to the lateral orbital rim.

When the transconjunctival route is chosen for the retrobulbar block through the inferotemporal quadrant, then the tip of the needle enters the orbit just behind the inferior tarsal plate at the lower orbital rim. But, if transcutaneous route is used, then the lower lid is not retracted and the needle entry point would be inferior to the lower tarsal plate. The needle runs first parallel and close to the orbital floor with slight medial direction. In this direction when the needle crosses the equator of the globe, the angle of direction of the needle tip is adjusted upwards, medially and posteriorly as if the tip enters the cone of the muscles posterior to the globe. After crossing the equator for this direction the needle tip should be aimed at an imaginary point behind the globe on the axis formed by the central pupil and the macula in primary gaze position. During the advancement of the needle in the retrobulbar space, great care should be taken to avoid crossing the mid-sagittal plane of the globe. During either transconjunctival or transcutaneous route the tip of the needle should always run inferior to the lower border of the lateral rectus muscle, till it crosses the equator. During advancement of the needle the globe should be observed continuously to detect any rotation or movement that may indicate fixation of the needle in the sclera (Fig. 41.26).

The needle then enters the intraconal space by piercing the intermuscular septum, just inferior to the lower border of the lateral rectus muscle. During the advancement of needle the continuous observation of the relationship between the shaft and hub junction of the needle and the plane of the iris usually establishes an appropriate depth of insertion of the needle within the orbit.

The inferotemporal space for retrobulbar or peribulbar block is chosen for three reasons because :

i. It is relatively most avascular. The other two low vascular areas are superotemporal and medial compartment.
ii. The lateral orbital rim is set back from the line of the equator of the globe at the inferotemporal region.
iii. The space between the globe and the orbital rim for placement of the needle in deeper orbital structures is widest here.

To avoid trauma to the inferior oblique muscle or its motor nerve the inferotemporal needle placement should be lateral to the sagital plane of the lateral limbus. During injection the deposition of local anaesthetic agents directly into any of the extraocular muscles should be diligently avoided. Otherwise, direct muscle injury from the needle prick and myotoxicity from the local anaesthetic agent may result in a prolonged diplopia which may even become permanent.

Following negative aspiration test of blood the injection is performed, confirming the absence of abnormal resistance or the presence of atypical discomfort. If anyone is suspected, then the needle tip should be relocated. While injecting the drug, monitoring should be done visually and / or digitally for the increasing intraorbital volume and the intraconal pressure. The 3 to 4 ml of local anaesthetic mixture is injected very slowly over 2 minutes. Proper placement of the needle is indicated by bulging of the superior orbital sulcus which is accompanied by the filling out of upper eyelid crease and some degree of ptosis with proptosis. After injection is completed, the needle is withdrawn and a check for the bleeding is made. If there is any bleeding or sudden abnormal increase in the intraorbital pressure, then immediate digital compression over the eyeball should be instituted to minimize any potential complication from high intraorbital pressure which has built up in the orbit. During introduction of the needle, no attempt is made to contact with the bone of the orbital floor. This is because the tip of the needle may enter the infraorbital canal or fissure resulting in unpleasant infraorbital nerve paresthesia (Fig. 41.27).

Following injection, a period of gentle message or decompression by 'pinky' for about 2 to 5 minutes is done. Then, the effectiveness of the block is assessed by checking the globe movements, superior

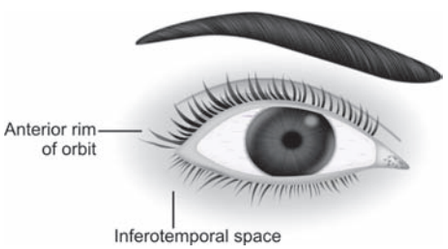

Fig. 41.26: The inferotemporal space which is wide and recommended for needle entry site for regional block

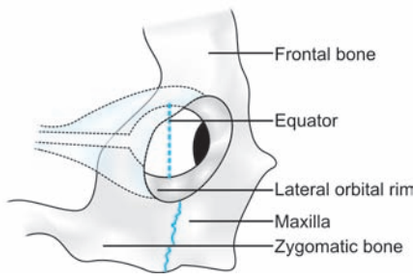

Fig. 41.27: The lateral orbital rim which is set back in line with the globe of equator. Thus, it makes the inferotemporal approach the route of choice for regional block

levator activity and orbicularis oculi function. If there is any ineffective block, then it can be completed by supplementation. The supplementing injections are : medial periconal injection and/or superotemporal periconal injection (which are discussed later).

The complications of retrobulbar intraconal block are:

i. Globe perforation (0.1 to 7%),
ii. Intravascular injection,
iii. Intraorbital haemorrhage (1%),
iv. Penetration and injection within the optic nerve sheath (0.3%) with resulting optic nerve damage, subarachnoid spread of local anaesthetic agent, brain stem paresis and cardiopulmonary arrest.

So, retrobulbar intraconal block for ocular surgeries is not recommended any more.

Peribulbar or Periconal or Periocular Block

In this method of ophthalmic regional anaesthesia, local anaesthetic agents are deposited outside the cone of the rectus muscles, but within the orbit and posterior to globe. So, it may be called as the posterior peribulbar block. When the local anaesthetic agents are deposited anterior to the equator of the globe and obviously outside the cone of the muscles, then it is called the anterior peribulbar block (Fig. 41.28).

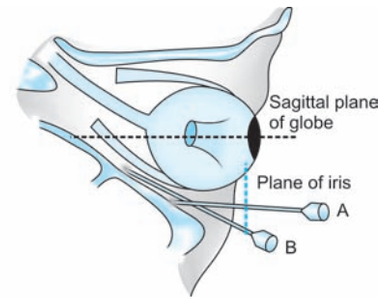

Fig. 41.28: Transcutaneous approach of periconal block through inferotemporal space. A 24 G 24 mm needle enters the orbit close to the bone (A). The needle then passes backwards in sagittal plane parallel to the orbital floor (B). It crosses the equation of globe up to a depth when the needle hub junction reach the plane of iris. This technique is equally applicable for transconjunctival route

The peribulbar or periconal block was first described as early as in 1914 by Allen. But it came into common practice only in 1986. Davis and Mandel first published papers on this method of peribulbar block. They used two routes : one below and one above the globe. Both the routes were chosen at the inferior and superior orbital margins respectively through the inferotemporal and the superotemporal quadrant of the orbit up to 3.5 cm, where near about 10 ml of the local anaesthetic solution was injected. Through both the routes the needles were directed to the floor or the roof of the orbit respectively, but not to the axis joining the centre of the pupil and the macula. Then, Bloomberg did more work on the peribulbar block. He entered the orbit only through the inferotemporal route, and the needle was directed to the floor of the orbit. In this method, there was a controversy regarding the failure rate and incidence of subsequent supplemental block. In some studies only 5% patients required supplemental upper superotemporal quadrant injection to achieve complete globe akinesia, while many studies reported up to 50% failure rate.

At that time, many other techniques of peribulbar block were also tried using many routes (inferotemporal, superotemporal, medial periconal, etc.) at a time in different permutation and combination, using needle of different lengths and sizes. They have a wide variation in results. Among all the combinations, three-needle-technique is the best, requiring only 5% supplemetation through the medial periconal route. This three-needle-technique consists of (i) preliminary subcutaneous or subpalpebral conjunctival (lower) infiltration of local anaesthetic agent which is followed by (ii) a second infratemporal intraconal injection and (iii) lastly a superotemporal periconal injection. But, whichever peribulbar technique is used, it is important to note that there is insufficient space between the lateral rectus and the lateral wall and the inferior rectus and the inferior wall of the orbit. So, true periconal block is very difficult or may be theoretical in inferotemporal quadrant.

After the introduction of the periconal block, many variations of this technique have developed which have already been discussed. But, the difference between the peribulbar and the retrobulbar block is that in peribulbar block the onset of akinesia is considerably slower, the volume requirement is greater and the supplementation rate is higher. In both the retrobulbar and peribulbar block the young patients are more resistant to total akinesia and analgesia of the globe and peribulbar tissue than the elderly. This is because the more dense connective tissues in the young patients hinder the access of the anaesthetic solution to the sensory and motor nerves, which are situated both in the intraconal and periconal spaces.

There are three main routes for peribulbar block :

i. Inferotemporal (most commonly used),
ii. Medial periconal,
iii. Superotemporal.

Types of needles

There are volume of discussion regarding the types of needles used for regional anaesthesia in ophthmology. But, the traditional teaching favours the use of dull tipped, intermediate size (gauge) needle. It has the advantage of pushing the blood vessels aside, rather than traumatizing them and the tissue planes are more accurately felt. There is also a common believe among the ophthalmologists, though it is not true, that it is more difficult to penetrate the globe and the optic nerve sheath with a blunt or dull tipped needle. But, multiple studies have shown that penetration or perforation of the eyeball by a dull needle (if it occurs) causes more serious damage than when a fine or sharp (i.e. of higher gauge) needle is used. Thus, it questions the arguments which advocate the use of blunt needles. Any needle, blunt or sharp, advanced blindly within the orbit has the potential of causing serious complications such as

globe perforation, optic nerve injury, and retrobulbar haemorrhage. Therefore, any serious practitioner of ophthalmic regional anaesthesia must keep a thorough knowledge of the anatomy and the contents of the orbit, rather than choosing the blunt or sharp needle. It is also found that pain and tactile discrimination is progresively reduced by decreasing the needle width, i.e, increasing the gauge (size). This is because, the increased resistance caused by a blunt needle is no more appreciated here due to the increased preload at the tip of the fine needle.

Special attention should also be paid to the length of any needle which enters beyond the orbital rim. However, at any circumstance, the intraorbital distance of 31 mm as measured from the orbital rim should never be exceeded. During the medial direction of the needle which advances from the inferotemporal entry point should be such that the mid sagittal plane of the eyeball should never be crossed. All the needles placed periconally or intraconally should be oriented tangentially with the bevelled opening facing towards the globe.

The force required to inject the local anaesthetic agent at a given rate through a given needle, mounted on a larger syringe, is more than a smaller syringe. This is because, a larger syringe has a greater plunger cross-sectinal area than a smaller one. So, a change in resistance while injecting 10 ml of the drug is more easily felt by the injecting finger when smaller size syringes are used. Here the fingers serve as a transducer. It relays information to the sensory cortex of an anaesthesiologist. The ability to detect the change in resistance during injection, (more or less easily), is very important for the avoidance of complications.

Facial Nerve Block

Before the era of retrobulbar and peribulbar block, the techniques of combining the corneoconjunctival topical anaesthesia with transcutaneous 7th cranial nerve block was in vogue. The facial nerve block causes the paralysis of orbicularis oculi muscle and prevents the squeezing or movements of the eyelids. During that period various methods of 7th cranial nerve block were introduced by Van Lint, Wright, O'Brien, Atkinson, Nabath & Rehman and Spaeth, etc. But, among these Van Lint is the most distal and Nabath-Rehman is the most proximal site of block for the facial nerve after its emergence from the base of the skull at the stylomastoid foramen. In Van Lint block the local anaesthetic drug is injected directly deep to the orbicularis oculi muscle and close to the bone at the lateral angle of the eye.

Before the days of hyaluronidase and the development of decompression devices, a small volume retrobular block with facial nerve paralysis at the stylomastoid foramen was the only choice for most of the ophthalmic surgeries under regional anaesthesia. But, with the discovery of hyaluronidase and the decompression devices the peribulbar block allows the injection of a large amount of local anaesthetic agent into the orbit. It has been observed that an effective spread of this adequate amount of local anaesthetic agent from the orbit through the orbital septum causes akinesia of the orbicularis oculi muscle, which makes the block of the 7th cranial nerve at the stylomastoid foramen unnecessary. The local anaesthetic drug spreads out from the orbit with the help of hyaluronidase into the deep plane of the orbicularis oculi muscle and abolishes the activity of lid closure by conduction blockade of the terminal divisions of 7th cranial nerve, entering from the muscle's deep surface. Thus, in the technique of peribulbar block using hyaluronidase and large amount of local anaesthetic agent in vast majority of cases sufficient blockade of the lid closure muscular activity is achieved. Hence, the painful transcutaneous 7th cranial nerve block through the sensitive facial skin is avoided and found to be unnecessary. So, the historical and traditional concept of globe akinesia and anaesthesia by retrobulbar injection and orbicularis muscle akinesia by direct separate intervention of the 7th cranial nerve after its emergence from the skull is not needed now. In an occassional patient who exhibits strong recruitment of the more peripheral fibres of the orbicularis oculi muscle and / or exibits excessive use of brow musculature, then only supplemental transcutaneous blocking of the orbicularis oculi by Van Lint method may be necessary.

Combined Retrobulbar (Intraconal) and Peribulbar (Periconal) Method

Multiple distinct techniques of injection for regional anaesthesia of orbit were studied. From this it was determined that a method of combining an initial intraconal (best through inferotemporal route) injection with a secondary periconal (best medialpericonal) injection is the most suited for the rapid turnover in day case ophthalmic practice. Alternatively, a technique with solely periconal placement of the local anaesthetic agent may be a more prudent practice for the relatively inexperienced practitoner.

This combined method consists of a preliminary injection of the local anaesthetic mixture, diluted with balanced salt solution, at subjunctional or subcutaneous level by a 30 G needle to anaesthetize the local area. It is followed by two full strength local anaesthetic injections in retrobulbar and peribulbar space. The first is an inferotemporal intraconal injection and the second is a medial periconal injection. The rational behind this three-needle – technique is to provide effective (i.e low supplementation rate) and safe (low complication rate) local anaesthesia and akinesia according to the requirements. This method is virtually pain-free. As a result preoperative and intraoperative sedation are usually not necessary, except a good rapport and assurance to the patient. This no-sedation approach avoids the problem of patients falling into a deep sleep during surgery and awakening precipitously with potential detrimental effects on the surgery in hand.

Inferolateral Periconal Block

This is the most commonly used technique for peribulbar or periconal block. Sometimes, it is supplemented with medial and / or superotemporal periconal block. This is because a single inferolateral injection is often inadequate and may not be predictable for complete anaesthesia and akinesia of globe.

After proper examination of the patient, an IV line is accessed and monitoring is started as a standard rule. If mild sedation is indicated, then it is administered by midazolam (0.5 to 1.5 mg) and /or fentanyl (50 µg) or sufentanil (150 µg). Topical local anaesthetic drops are instiled to anaesthetize the palpebral conjunctiva. For this purpose, 1% amethocaine or 2% xylocaine is sufficient, but it may cloud the cornea. So, 0.4% oxybuprocaine or 0.5% proxymetacaine may be a better alternative. This topical anaesthesia of the conjunctiva is only necessary for the transconjunctival route of the inferotemporal periconal block. The junction of the medial 2/3rd and lateral 1/3rd of the inferior orbital rim is palpated with the nondominant hand and a groove is felt at the junction of the maxilla and the zygoma. Just lateral to this point and 1 mm above the orbital rim a standard hypodermic needle (25G, 25 mm), mounted on a 10 ml syringe is inserted and passed slowly backwards perpendicular to all the planes. Needle entry can be either subcutaneous or transconjunctival (by retraction of the lower lid). If the needle tip touches the bone, it is redirected slightly superomedially to follow the orbital floor once more, i.e at a 10 degree angle with the transverse plane. The needle is advanced till its tip reaches the level of the posterior pole of the globe (i.e. until the hub reaches the plane of the iris).

The globe should be observed carefully for any sign of rotation during needle insertion into the orbit, indicating scleral contact. In such situation every temptation to wriggle the needle to confirm scleral engagement should be avoided. Because, this may increase the risk of haemorrhage if perforation of globe occurs. After proper positioning of the needle and aspiration, 6 to 8 ml of the local anaesthetic agent is injected slowly and at the same time the globe should be palpated with the other hand to assess the tension. If the globe becomes tensed or proptosed or the upper eye lid droops, then the injection should be stopped. Because, this likely indicates the retrobulbar injection, requiring much smaller volume of local anaesthetic agent. After completion of the injection the needle is slowly withdrawn and a small volume of the local anaesthetic solution is deposited under the orbicularis oculi muscle of the lower lid when the needle is withdrawn. Then, digital massage or a compression device (Hanon's Balloon) should be applied to dissipate the local anaesthetic solution within the orbital tissue, which quickly normalises the IOP. The block is assessed after 5 to 10 minutes and a second injection is repeated if a greater degree of akinesia and analgesia is required. In modern ophthalmic practice a completely akinetic eye is less often required and a second injection doubles the risk of complication. So, the required extent of the block should be discussed with the surgeon beforehand.

The larger volumes of local anaesthetic drugs which is required for peribulbar block tend to cause proptosis and a temporary increase in IOP. However, in the intact globe this has no significance. But, it becomes problematic when the globe is opened for surgery. After the dissipation of the drug in the surrounding orbital tissue with the passing of time, the raised IOP usually disappears. Alternatively, digital massage by the fingers or application of the Hanon's Balloon on the eyeball helps in dissipation of the drug. The Hanon's Balloon is a type of tamponade which is applied on the eyeball at a set pressure of 25 mm of Hg. This compresses the eyeball and transiently increases the IOP further. During compression, the volume of blood and aqueous in the eye is reduced. After release of the tamponade, the 'empty' eye becomes hypotonic and remains so for about 15 minutes, until the blood and aqueous volumes are re-established.

Medial Periconal Block

Here, the injection of local anaesthetic agent is administered into the fat compartment which is situated on the nasal side of the medial rectus muscle. This block has distinct advantages due to the relative avascularity of this region and the peculiar arrangement of the connective tissue in this area. Local anaesthetic mixture, injected into this area spreads to the orbital apex posteriorly, but its spread is restricted laterally by the intraconal compartment. Subsequently, the drug spreads anteriorly through the two hernial orifices which are situated above and below the medial check ligament of the connective tissue diaphragm that surrounds the globe just near its equator. The drug also passes through the orbital septum into the upper and lower eyelid in the tissue plane deep to the orbicularis oculi muscle. Here, the fine terminal motor branches of the 7th cranial nerve are readily blocked. Superiorly the access of local anaesthetic agent to the motor nerve supply of the superior oblique, superior rectus and levator complex is also facilitated. The injection of the local anaesthetic agent in this space also promotes the spread of the drug to the lacrimal and frontal nerves and the peripheral conjunctiva. Thus, it effectivley abolishes the intraoperative discomfort which is sometimes observed in the low-volume, solely intraconal technique.

The entry point of the needle for the medial periconal block is the small depression immediately medial to the caruncle. Caruncle is the specialized portion of the conjunctiva which occupies the extreme medial end of the palpebral fissure. Caruncle lies medial to the sagittal plane of the medial equator of the globe in almost all patients. So, there is no chance of perforation of the sclera by a needle when it enters

through this point. The needle should be passed in the transverse plane, directed towards the midline of the skull at the occiput. The medial compartment is 5 to 10 mm wide anteriorly at the equator of the globe, and 3 to 5 mm wide at the posterior surface of the eye. Then, it rapidly becomes narrower as the medial rectus muscle reaches its bony origin posteriorly. The needle must avoid the penetration of the medial rectus muscle, because injection of local anaesthetic agent directly into the muscle could result in myotoxicity with resultant prolonged paralysis or paresis. If there is any doubt, then the needle tip should hit the periosteum of the medial wall of the orbit, and withdrawn slightly to redirect with a lesser medial inclination. This allows the needle tip to be free in the fatty tissue the medial compartment. If the above mentioned guidelines are obeyed, then the entry of needle in the medial rectus muscle directly will not occur.

After proper placement of the needle volume of 2 to 4 ml of the drug is injected into this space. This volume of drug depends on the degree of supplementation block required, aiming at not to impede the desired goal of intraocular hypotomy. The residual activity of the extraocular musculature which persists even after the initial inferotemporal intraconal block is effectively abolished within 3 to 5 minutes in most cases, following the medial compartmental block.

Though, this compartment is relatively avascular but it contains a portion of the superior ophthalmic vein, the anterior ethmoidal artery, and the supra and infra trochlear arteries. But, they lie above the needle entry point. These vessels are traumatized if the needle enters through the supero-nasal quadrant of the orbit. In such situation the incidence of bleeding by a 30G and 31 mm needle is negligible and always minor in nature. As a whole, the medial periconal block is an effective and safe method of supplementation of the primary inferotemporal block. It is painless because, the needle entry point which is innervated by the nasociliary nerve, lies inside the cone of the muscles and is relatively well-blocked by the previous inferotemporal intraconal injection.

Supero-temporal Periconal Block

It mainly affects the superior rectus and the levator palpebrae superioris muscle. Even after the primary inferotemporal block, sometimes the acitvities of these muscles are retained. The explanation of this failure is that the injection of local anaesthetic agent through the inferotemporal region does not reach in sufficient quantities to the branches of the oculomotor nerve which supplies these muscles. Such a situation may arise, because the connective tissue hammock for the superior ophthalmic vein is usually well-developed in some individuals. This is partially permeable to the LA agent and prevents it from accessing the nerve in the central core of this compartment. So, by the superotemporal block the access of local anaesthetic to the nerve, supplying the muscle, like superior rectus and levator palpebrae superioris from above is possible.

The point of entry of needle for this block is the superior orbital rim and 3 to 4 mm lateral to the sagittal plane of the lateral limbus. Thus, this relatively avascular area lies between lacrimal vessels on the temporal side and the supra-orbital vessels on the medial side. The needle is inserted tangentially from above the globe which is directly towards the roof of the orbit with the eye to be blocked held closed. After making the first bony contact with the orbital roof, the needle is redirected 5 degree medially. Then, it is inserted posteriorly till the depth of 31 mm from the superior orbital rim is reached. Following negative aspiration test the 3 to 4 ml of local anaesthetic solution is injected in this position with the aim of not increasing the intraorbital pressure excessively. This superotemporal supplemental block is needed only in 5 to 10% cases (Fig. 41.29).

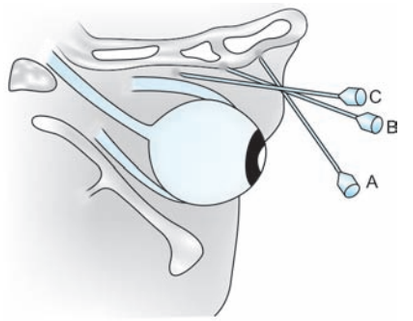

Fig. 41.29: The supero temporal periconal block.The needle is inserted through the superotemporal route and is aimed up towards the roof of the orbit A. Then the needle tip walks along the periorbit of the orbit in a curved line fashion, until the needle tip is at a depth of 24 to 30 mm. At this point injection is made with usual precautions. It is seuperotemporal block

RECENT REGIONAL ANAESTHETIC TECHNIQUES FOR OPHTHALMIC SURGERIES

The large incision cataract surgery, constituting the main bulk of all the ophthalmic operations done in the past, required complete extra ocular muscular paralysis (or akinesia) including orbicularis occuli to avoid the loss of globe contents by muscular contraction during surgery. But the recent small-incision, closed-system surgical technique for cataract extraction does not require complete akinesia or extra occur muscular paralysis. Rather, it may require only surface anaesthesia which is solely confined to the anterior part of the eyeball. So, the concept of alternative non a kinetic methods of regional anaesthesia for cataract extraction surgery has been introduced.

These are:

i. Subconjunctival injection of the local anaesthetic agent,
ii. Sub-Tenon's block,
iii. Topical corne-conjunctival anaesthesia.

But these newer methods of RA are not universally applicable to all the patients for cataract surgery. This is because of the different patient's temperament, different

lens pathology and personal variations of surgical skill.

Subconjunctival Block

In this subconjunctival block (first technique) a small amount of the local anaesthetic agent is injected under the conjunctiva near the superior limbus and this technique is used mainly for the anterior segmental surgery. This technique is also combined with the intracameral injection of a preservative free lignocaine (xylocard). But, in these subconjunctival and topical corneoconjunctival techniques (described below) which is combined with or without intracameral injections of LA agent, anaesthesia is not as complete as with the standard intraorbital blocks. The iris and the ciliary body retain their sensation and akinesia is not a feature. So, many ophthalmologists do not prefer this technique. Because, avoidance of intraconal or periconal block for fear of complications allows exposure to the greater risk of performing intraocular surgery in the presence of extraocular muscle activity.

Sub-Tenon's Block

The sub-Tenon's block was first introduced by Swan in 1956 and was then used extensively after 1960. At that time he suggested that the Sub-Tenon's block produced better iris and anterior segment anaesthesia than a subconjunctival injection. But, the eyeball mobility is usually retained which depends on the volume of LA drug. Subsequently this technique gained popularity as an easy, safe and effective alternative to the retro and peribulbar anaesthesia. It has the advantages of avoiding a needle blindly into the orbit and so has no appreciable risks of the complications which are discussed later.

This technique involves the dissection of a space beneath the Tenon's capsule and passing a blunt curved cannula (Southampton's cannula) into this space beyond the equator of eyeball to deposit the local anaesthetic agent there. It effectively blocks the ciliary ganglion with the long and short ciliary nerves. If larger volumes of local anaesthetic agent is deposited more posteriorly, then it may block the motor nerves and the extraconal branches of the ophthalmic and maxillary nerves. Thus, this large volume of local anaesthetic agent produces complete anaesthesia of the eyeball. During this procedure first the conjunctiva is anaesthetised by topical anaesthesia. This is followed by a small incision on the conjunctiva at the inferolateral quadrant of the globe which is then dissected up to the plane between the sclera and Tenon's capsule. Here the Tenon's capsule is recognised by the white, avascular structure, easily distinguished from the vascular sclera. Then, a blunt curved Southampton's canula is passed backwards beyond the equator through this incision and 3 to 5 ml of the local anaesthetic solution is deposited there. If the canula is placed subconjunctivally, then an attempt to push in the local anaesthetic agent shall immediately make it apparent by chemosis. Following the deposition of local anaesthetic solution beneath the Tenon's capsule by the canula, the LA agent spreads mainly into the anterior intraconal space and produces anaesthesia. The degree of akinesia of the extraocular muscles produced by this subtenon's injection is proportional to the volume of local anaesthetic solution. The peripheral orbital anaesthesia, such as peripheral conjunctiva, lids, etc, is usually incomplete by this to be of block. So, supplemental local anaesthetic injection may sometimes be necessary to achieve the patient comfort or to complete the surgery. Intravenous sedation is often used during surgery, following this method of anaesthesia. Sub-Tenon's block can be used safely in patients where the axial length of globe is more than 26 mm and intraorbital block is more risky. It is also the block of choice in anticoagulated patients, since any bleeding point can be canterized directly. It may be more easily performed by the surgeon, though it is now being increasingly performed by the anaesthesiologist too.

Topical Anaesthesia

Throughout the whole 19th century and the first few decades of the twentieth century, cocaine was the only available local anaesthetic agent. At that period, it was only used in retrobulbar injection and in different general surgeries. But due to its high toxicity, cocaine was abandoned from retrobulbar injection. Then, it was used solely for topical corneo-conjunctival anaesthesia, albeit without the advantages of modern surgical technology which was not developed during that period. However, history is repeating itself. So, after cocaine many good local anaesthetic agents have been developed with more development of sophisticated technology for cataract extraction by very small sclerocorneal incision. Therefore, now reintroduced by Fichman topical anaesthesia by newer local anaesthetic agents is again being commonly used for cataract extraction. For cataract surgery under topical corneo-conjunctival anaesthesia, critical selection of subjects is important and there must be a continuous and open dialogue between the surgeon and the patient throughout the operation. This is because as the eyeball of the patient is not paralysed, so surgeons have to verbally guide the position of the eyeball of patient continuously. This topical corneoconjunctival anaesthesia is most applicable for only cataract extraction by phacoemulsification with or without foldable lens in a very cooperative patients. For topical corneo-conjunctival anaesthesia, the most commonly used drugs are 0.5% bupivacaine and 2% lignocaine.They are very effective, but may sting initially and cloud the cornea. So the newly developed local anaesthetic agents, such as 0.4% oxyprocaine and 0.5% proxymetacaine are considered superior. This topical method cannot be used in patients with language barrier, deafness, dementia and obviously

in children. Dense or trauma-induced cataracts, small pupils failing to dilate, macular degeneration, etc. cannot be managed with this type of topical corneo-conjunctival anaesthesia alone. They are best managed with the other forms of intraorbital regional anaesthesia.

The clear advantages of topical corneo-conjunctival anaesthesia are :

i. Appeal for no-needle procedure,
ii. Avoidance of complications caused by intraorbital injection,
iii. Early visual rehabilitation, especially in patients with only one-sighted eye,
iv. Suitability for patients on anticoagulant medication,
v. The patient's ability to look at any direction directed by the surgeon, which facilitates the surgery also etc.

Junior surgeons still do not prefer this technique and are happier to perform surgery under akinetic block-anaesthesia as they are less experienced regarding the use of topical conrea conjuctional anaesthesia. Patients having cataract surgery under topical corneo-conjunctival anaesthesia require more psychological preparation and oral anxiolytic premedication. The topical agent best suited for this method is 2% lignocaine without preservative. Unlike cataract extraction under intraorbital regional anaesthesia, there is no reduction of optic nerve function in topical anaesthesia. Hence, an awareness of the brightness of the microscope light may be distrubing enough to some patients.This problem can usually be overcome by starting with reduced illumination of the microscope and bringing it up gradually. The iris and ciliary muscles retain their sensation. So, intraoperative use of intracameral miotic agents may precipitate discomfort from ciliary muscle spasm. This can also be prevented by intracameral injection of the local anaesthetic agent, or by avoiding the touching of iris by operating instruments (Table 41.4).

RECENT GUIDELINES FOR ANAESTHETIST IN OPHTHALMIC SURGERY

In 1993, the Royal College of Anaesthetists and the College of Ophthalmologists published certain guidelines on the roles and responsibilities of the anaesthesiologists during ophthalmic surgery under local and topical anaesthesia. The guide line said that the presence of an anaesthesiologist is mandatory to monitor the patient's general condition throughout the operation and to give resuscitation as and when required. In addition, it was also recommended that the anaesthesiologist should be whole responsible for providing sedation when necessary, administering local anaesthesia or block and providing IV access. These recommendations are also applied to simple infiltration anaesthesia for extraocular surgery.

In 2001, these above guidelines were updated with further certain recommendations. These are :

i. Local anaesthesia can also be administered by appropriately trained staff.
ii. Surgeons may administer topical, subconjunctival or sub-Tenons anaesthesia, but an anaesthetist must be present.
iii. An anaesthetist must be available when surgery is performed under retro or peribulbal anaesthesia.
iv. An anaesthetist must be pressent and have sole responsibility if sedation is required.

Table 41.4: Qualities in a surgeon required to select topical anaesthesia

1.	Senior surgeons.
2.	Vast experiences regarding scleral tunnel and intracapsular phacoemulsification.
3.	Good communication skill with the patient.
4.	Appropriate mental makeup to perform the surgery under topical anaesthesia.
5.	Willingness to talk continuously with their patients during the procedures, are most suited for this anaesthetic technique.

SPECIFIC SURGICAL PROCEDURES AND MODIFICATION OF REGIONAL ANAESTHESIA

Today, though most of the ophthalmic surgeries are performed under regional anaesthesia and follow a generalised rule, still some specific ophthalmic surgical procedures may need certain modifications of this regional anaesthetic technique according to their necessity.

For example, secondary intraocular lens implantation in aphakic patients require more surgical time than the standard cataract extraction and intraocular lens implantation procedure. So, it warrants for the selection of more long-acting local anaesthetic agents.

Trabeculectomy usually needs complete akinesia and sensory anaesthesia of the globe. So, topical anaesthesia has no place in such type of surgery. For trabeculectomy operation intraconal or periconal block is the idea RA. But sub-Tenon's block may be an alternative to the intraconal and periconal anaesthesia for trabeculectomy. If there is presence of any bleb of previous trabeculectomy operation, then no external pressure for intraorbital decompression after retro or peribulbar block should be used. Cataract surgery may be combined with trabeculectomy or trabeculectomy may be designed alone to reduce the intraocular pressure in glaucoma. But, in the management of only glaucoma by trabeculectomy the orbital decompression devices are after interconal block best omitted. During surgery of glaucoma instead of intra operative control of 10p the normal intraocular pressure is usually achieved by: careful preoperative control of higher intraocular pressure (by acetazolamide and/or topical β-blocker), perioperative induction of osmotic diuresis with mannitol, using low volume of local anaesthetic agents for intraorbital block incorporating hyaluronidase in the anaesthetic mixture and allowing sufficient time (at least 15 minutes) to pass between the

completion of block and the commencement of surgery.

The strabismus (squint) surgery usually requires full akinesia and deep sensory anaesthesia of the globe by intraorbital intraconal and/or periconal block. But, many other methods of RA have also been described including sub Tenon's, topical, or non-akinetic periconal block for squint surgery.

For refractive keratoplasty procedures, including Excimer laser keratectomy, topical surface anaesthesia by 2% lignocaine is sufficient. But, these surgical procedures are associated with moderate postoperative discomfort or pain for 24 to 36 hours. So this can be postoperatively managed by conjunctival instillations of topical NSAID preparation combined with the use of bandage contact lens.

For corneal grafting the regional anaesthetic technique requires a dependable therapeutic time window of 1 to 2 hours with full akinesia and sensory anaesthesia of the eyeball including both the lids. So, intraconal and/or periconal block with a large volume of long-acting anaesthetic agents is the choice for this type of surgery. Large volume of anaesthetic agents result in an increased intraorbital and subsequently increased intraocular pressure. This can be reduced by preoperative induction of osmotic diuresis by mannitol. An orbital decompression device is also used to reduce the intraoccular pressure. By the use of hyaluronidase and by giving sufficient time between the completion of block and the commencement of surgery, ocular hypotony can be produced.

Epikeratophakia and keratomileusis require a long therapeutic window of 2 to 2.5 hours with full globe akinesia and sensory anaesthesia, including both the eyelid. In both these cases, the moderately potent systemic analgesics are also required postoperatively for about 48 hours. So, appropriate agents should be used with proper postoperative care. During RA the anaesthesiologist should avoid production of conjunctival chemosis, if possible.

Photocoagulation is done with argon laser and it is very painful in an unanaesthetized eye. At the same time the slight globe movement may momentarily expose the relatively healthy part of the retina to iatrogenic injury. So, complete akinetic orbital regional anaesthesia is required for patient's safety and also for surgeon's comfort. Hence, intraconal and /or periconal block is used for this type of surgery. But, some surgeons prefer sub-Tenon's technique also.

Oculoplastic surgeries are also commonly performed under regional anaesthesia and the principles are same as those for other ophthalmic regional anaesthesia in general. However, in oculoplastic surgeries higher concentration of adrenaline is used with the mixture of local anaesthetic agent to reduce bleeding.

For vitreoretinal surgery under regional anaesthesia a more prolonged therapeutic time window is necessary. So, intraconal and/or periconal block by a sufficient amount of long actinglocal anaesthetic agent is advocated. Adrenaline is also usually used to prolong the duration of action of the local anaesthetic agent and to reduce the blood concentration of it, as the large amount of drug is used. The duration of the planned surgery in itself may dictate in favour of general anaesthesia or a combined regional anaesthesia and intravenous sedation technique in the interest of patient's comfort.

COMPLICATIONS OF ORBITAL REGIONAL ANAESTHESIA

The complications of orbital regional anaesthesia may be acute or delayed in onset. Again, it may be systemic or is only confined to the orbit and its contents. The complications of this orbital regional anaesthesia may also range from a trivial one to something serious, such as the death of a patient of drugs. The orbital regional anaesthetic complications are sometimes directly related to the local anaesthetic drugs or may be due to the technique of administeration. The orbital regional anaesthesia, sometimes, indirectly invites the complications resulting from sedative or narcotic drugs and from general anaesthesia but only if they are combined with the previous one in case of inadequate or failed block. In many centres, patients usually receive sedative or narcotic drugs to facilitate the incomplete regional anaesthetic technique, or inadequate psychological preparation of the patient. But, sedatives or narcotics are often unnecessary. Because intravenous medications are only rarely required, if the patients are psychologically properly prepared and regional anaesthesia is adequate. Thus, the side effects and complications related to the use and misuse of these sedatives, narcotics, or general anaesthetic drugs are minimized. The most appropriate management of an inadequate block is supplementation of it by further injection of local anaesthetic agent, rather than the suppression of reflex reactivity with systemic medications such as sedatives or narcotics.

In the past and before the firm establishment of peribulbar technique for better ophthalmic RA with the help of hyaluronidase, the desired goal of complete global and adnexal anaesthesia with akinesia and concurrent global hypotony is achieved only by a two-injection method which is described below and had become the traditionally accepted technique. This two injection method was combining the deposition of a small volume of local anaesthetic agent near the apex of the orbit (retrobulbar) with the block of 7th cranial nerve at some point along its extracranial path. But recently, the introduction of hyaluronidase, peribulbar block and orbital decompression devices allow a larger volume of local anaesthetic drug to be injected into the orbital cavity for complete block. This avoids the necessity to block the 7th cranial nerve, because an adequate volume of drug spreads through the orbital septum to paralyse the orbicularis oculi.

Table 41.5 Complications of ophthalmic regional anaesthesia

1. Globe perforation

   Causes trauma to the retina or chroid. Diagnosed by hypotomy of globe, intravitrol haemorrhage, retinal detachment, retinal tear at the point of perforation, loss of vision, etc.

2. Venous haemorrhage

   Caused by puncture of any orbital vein. Diagnosed by retrobulbar haematoma which progresses less slowly than arterial haemorrhage. Haematoma produces proptosis, tight globe subconjunctival haemorrhage ecchymosis, etc.

3. Arterial haemorrhage

   Caused by puncture of any orbital artery. Produces same picture like venous haemorrhage but very rapidly progressing (acute).

4. Optic nerve injury

   Caused by direct needle injury to the nerve or ischaemic compression by haematoma. Diagnosed by optic atrophy, optic nerve head swelling, visual field defects, permanent loss of vision, etc.

5. Intravessel injection

   Caused by direct injection of LA agent in vein or artery. Produces increased systemic levels of local anaesthetic or cerebral levels of local anaesthetic. Diagnosed by dizziness, drowsiness, confusion, twitching, convulsion, unconsciousness, hypotension, bradycardia, apnoea, coma, cardiac arrest.

6. Deposition of LA agent in subarachnoid space

   Caused by needle penetration of optic nerve sheath and direct spread of LA agent in the central CSF. Diagnosed by vertigo, deafness, aphasia, facial palsy shivering, convulsion, hemiplegia, paraplegia, quadriplegsia, loss of consciousness, apnoea, hypotension, bradycardia, cardiac arrest.

7. Oculocardiac reflex

   Caused by dull or blunt needle and rapid injection of drug in a fixed orbital space. Diagnosed by bradycardia, hypotension, loss of consciousness and cardiac arrest.

However, as larger volume of drugs are used, it is easy to understand the mechanisms causing complications in ophthalmic RA.

Safe regional anaesthesia can be accomplished by both the intraconal and periconal techniques. But, serious complications can arise from both the techniques, if carried out incorrectly. So, it cannot be said that one is better than the other. Although, there are definite description of both the intraconal and periconal techniques for orbital RA, but recently multiple exhaustive studies have failed to find out any evidence of a closed 'cone', consisting of the four rectus muscles and their interconnecting intermuscular septa, thus creating a distinct cone like compartments in the posterior part of globe. So, it can be concluded that the concept of discrete intraconal and periconal compartments are erroneous (Table 41.5).

The advancement of needle by an anaesthetist within the confines of the orbital cavity for regional ophthalmic anaesthesia is essentially a blind procedure. So, it has the potential of serious complications. Therfore, the perception of changes of tissue planes during the advancement of needle is very important for safe regional anaesthesia. But, it is an acquired skill which requires experience and continuous practice to reduce the rate of complications. The traditional teaching of placing an inferotemporal needle intraconally with the globe elevated and adducted i.e. 'up and in' position (Atkinson technique) has largely been abandoned now. Because, in this position the optic nerve is brought easily closer to the needle tip and the macular area is further exposed to the damage. So, optic nerve sheath penetration, optic nerve trauma and globe penetration by the needle may result in this position of the globe more frequently. Further, the posterior pole of the globe is more endangered, particularly in the ovoid shaped globes of myopic patients in such 'up and in' position. But, many of the serious complications can be avoided by having the patients eyes directed in the primary gaze position during the needle placement and subsequent injecton. However this has been substantiated by CT-scanning and MRI.

Special attention should also be paid to the length and direction of the needle which enters the orbital cavity beyond the rim. Longer needles which is more than 31 mm may reach the orbital apex where the vessels are numerous and of larger lumen. Again, at the apex the optic nerve and vessels are less mobile. So, the retrobulbar hemorrhage or optic nerve trauma may result more frequently, if the needle tip approaches more towards the apex. Thus, while it is possible to get a beautiful block with a small volume of drug of it is injected at the apex of the orbit, but the risks increase many-fold. So, a distance of 31 mm within the orbit as measured from the orbital rim should never be crossed. Also, a needle which is advanced from the inferotemporal entry site should not be allowed to pass the mid-sagittal plane of the eyeball. All the needles used for intraconal and / or periconal injection should also be directed obliquely to the globe with the bevelled opening facing the eyeball. This tangential or oblique alignment of needle is most easily achieved through the transcutaneous route by putting a finger between the globe and the inferior orbital rim over the lower eye-lid than the transconjunctival route. This is because the finger pushes the globe upwards and makes more room for the needle in the inferotemporal quadrant. The finger also helps to assess the size of the globe, the distance of the equator from the inferior orbital rim, and guide the direction of the needle tangentially. If a tangentially aligned needle touches the sclera, still globe penetration is less likely to occur than when a needle approaches at

an acute angle. Having placed the needle at a desired depth, if there is an increased resistance which is more than expected during pushing the drug, then it is imperative to reposition the tip of the needle first, rather than inject against this resistance.

Blocking of the main trunk of the facial nerve after its exit from the stylomastoid foramen may be associated with the unilateral blocking of vagus, glossopharyngeal and spinal accessary nerve which are also coming out from the base of the skull near the stylomastoid foramen, causing difficulty in swallowing and respiratory distress. So, for facial nerve block at the stylomastoid foramen it is wise not to go deeper than the recommended 12 mm depth from the skin and to avoid hyaluronidase. Thus, bilateral facial nerve block at the stylomastoid foramen should never be allowed. Another vital structure near the stylomastoid foramen is the internal carotid artery which can also be injured by the deeper placement of needle.

There is a communication or continuation of the subarachnoid space of the optic nerve with that of the chiasma and the subarachnoid space, which surrounds the pons and the mid-brain. The dural sheath at the apex of the orbit and along the optic nerve is not impervious to local anaesthetic agents. So, the local anaesthetic agents deposited in the orbital cavity can easily diffuse into the subarachnoid space which surround the optic nerve. This is evidenced by the incidence of temporary ipsilateral amaurosis (loss of vision, especially that occurring without apparent lesion of the eye), following intraorbital block. Studies of cortical visual evoked potential also indicate temporary suppression of the optic nerve conduction which is greater with intraconal blockade, than with the periconal block. All these points favour the theory of absorption of local anaesthetic agents in the CSF bathing the optic nerve and extension of it to the CNS with the brainstem anaesthesia following intraorbital block. This was explained and was first published in mid 1980's, although there was previous knowledge of this meningeal pathway. About 4 to 5% of patients undergoing cataract extraction under regional anaesthesia generate emergency calls for an anaesthetist. Among these, the direct cerebral spread of local anaesthetic agent from the orbit is very important. The effect of spread of the local anaesthetic agent in the CNS during the intraconal or periconal block depends on the amount of drug entering the CNS and the specific area of CNS to which it has spread. Usually, the patient describes the symptoms about 2 to 3 minutes after the intraorbital injection. Frequently, the peak is reached at about 10 to 15 minutes and resolves over 1 to 2 hours. The clinical picture of the spread of local anaesthetic agent in the CNS is protean and produces signs and symptoms which vary from mild confusion to marked shivering or convulsions. The clinical pictures may also show the bilateral brainstem nerve palsies, including hemi or para or even quadriplegia and with or without loss of consciousness. In extreme cases, the clinical picture shows apnoea with marked cardiovascular instabilty. As this is a potential complication which may occur in any intraorbital block, so patients should not be covered with drapes for surgery until 20 minutes have passed after completion of block. Otherwise, identification and corrective treatment may be dangerously delayed and serious sequelae including death could obviously result. Central spread of the local anaesthetic agent should be suspected, if there is onset of any of the following signs and symptoms, such as : mental confusion, signs of extraocular paresis or amaurosis of the contralateral eye, shivering, convulsion, nausea or vomitting, dysphagia, sudden changes in the vital cardiovascular signs, dyspnoea or respiratory depression, etc. Treatment of this serious complication includes : ventilatory support with oxygen, intravenous fluid, pharmacological circulatory support with vagolytics and vasopressors and anticonvulsants with close vital sign monitoring. The traditional Atkinson's technique with elevated and adducted globe during inferotemporal needle placement increases the chances of cerebral spread of local anaesthetic agent. Because, this position places the optic nerve with its subarachnoid space in close ploximity to the advancing needle. On the other hand, 'down and out' position of the globe advocated by some anaesthetist, where the optic nerve is less vulnerable has the disadvantage of bringing the approaching inferotemporal needle into the field of vision of the patient. So this may be frightening to the patient. However, the 'down and in' position of the globe which places the anterior part of the optic nerve in a safer position in the intraconal space and the needle is away from the field of vision of the patient, is more acceptable to avoid this complication. Whatever may be the reason, the avoidance of deep penetration of the orbit by needle during any technique, is the key factor for both to prevent the cerebral spread of LA agent and avoid other serious complications of regional anaesthesia. Maximum penetration of the needle from the orbital rim should not be more than 31 mm. Modern regional anaesthetic techniques avoid deep orbital placement of the needle and instead advocate accurate site of injection at the limited orbital depth, using increased volume of drug in order to achieve the critical blocking concentration at the apex.

The true incidence of scleral penetration (entry wound only) and perforation (entrance and exit wound) are not known, because most of the cases are not reported. So, the reported incidence ranges from none in a series of 3000 peribulbar (periconal) anaesthesia to 1 in a series of 10,000 combined peri and intraconal anaesthesia to 3 in a series of 3000 intraconal block. But, it is definite that the incidence is higher in both myopic patients and intraconal block. Myopic patients with posterior staphyloma are particularly at higher risk.

Patients presenting for retinal detachment and radial keratotomy also have higher propensity of scleral perforation due to large globe, like myopes. Recessed eyes, tight lower eyelids, small orbital cavity, etc. are more challenging situations and are at an increased risk of scleral penetration. In such situations, periconal needle placement may be safer than intraconal placement of the needle. When someone does not believe in the difference between the periconal and intraconal block, they just try to direct the needle tip towards the orbital floor during the placement of needle through inferotemporal route and roof during the superotemporal route to avoid this complication. A safe pre-requisite to perform the regional anaesthesia of the orbit is to know the exact axial length of the eyeball prior to block. This warns one about the higher risks in larger than average sizes of eyes. In cataract surgery the precise axial length of the eyeball is usually available from biometry which is done to calculate the power of the intraocular lens. But, in other than cataract procedures where axial length is not precisely known, then close attention to the dioptre power of the patient's spectacles or contact lenses will provide valuable clues to the globe dimensions. USG of patients with suspected straphyloma and high myopia is also effective in reducing this complication rates. In such situations, it is prudent to perform periconal method and/or intraconal injection (if it is absolutely necessary) with patient's gaze directed downard and outward or to opt for general anaesthesia. Penetration or perforation of eyeball caused by thick blunt needles, though incidence is low, results in more serious and permanent damage than when such injuries result from the use of fine disposable ones. Fine disposable needles which are less painful for the patient have been proved to be relatively safe than the blunt needles in respect to the postpenetration management. More than 50% of all the iatrogenic globe perforations go unsuspected at the time of their occurrence. The event of perforation may be suspected if there is hypotomy, vitreous haemorrhage, poor red reflex, etc. Patients may complain of marked pain during the occurrence of perforation, particularly if the local anaesthetic agent is injected intraocularly. Fundoscopy confirms the diagnosis. Globe perforation involving only retinal tears with minimum blood in vitreous can be managed with laser photocoagulation, cryotherapy or sometimes by close observation only. When much blood is present in the vitreous cavity, then emergency vitrectomy may be indicated. Without surgical intervention, this severe vitreous haemorrhage frequently leads to proliferative vitreoretinopathy and subsequent detachment of the retina, where prompt surgical treatment is indicated. Actually, the appropriate management of scleral penetration and perforation is complex (Table 41.6).

Intraorbital bleeding is another common complication of ophthalmic regional anaesthesia. It may be manifested as retrobulbar haemorrhage, peribulbar hemorrhage, subconjunctival haemorrhage, lid ecchymoses, etc. Retrobulbar or peribulbar haemorrhage varies in severity. It may be small enough and go unrecognized or is severe enough which results in a loss of vision due to tamponade of the small nutrient vessels of the optic nerve. This explains those cases of profound visual loss where the findings of retinal vascular occlusion were not seen but late optic atrophy had developed. Loss of vision may also occur due to tamponade of the central retinal artery from massive retrobulbar or peribulbar haemorrhage. Some retrobulbar haemorrhage are of venous origin and spread slowly. Whereas, arterial haemorrhage produces rapid and tight orbital swelling, marked proptosis, immobility of the globe, massive blood staining of the lids and conjunctiva, etc. Due to the increased intraorbital pressure from arterial bleeding, serious impairment of the vascular supply to the retina and globe may result. Anterior orbital hemorrhage, subconjunctival bleeding and lid ecchymoses are also the most disconcerning sequelae of the intraconal or periconal anaesthesia. These commonly cause the patient and his family to make complain. Nevertheless, even if bruising occurs, then the patients and the accompanying person should be informed. In such circumstances reassurance should be given to them that the surgical outcome will not be affected at all and the bruising will clear away spontaneously within a few days. The anterior orbit has less vessels than the posterior orbit. Three anterior orbital locations are relatively avascular. These are inferotemporal, superotemporal and the nasal side of the medial rectus muscle. So,

Table 41.6: What we shall do and what we shall not?

1. When we shall use inferotemporal route for intraorbital block, we must maintain the primary gaze position of the eyeball or at least the 'down and out' or the 'down and in' position of the eyeball. 'Up and in' or Atkinson position should not be used during inferotemporal route for fear of optic nerve injury.
2. Needles more than 31 mm approaching the orbital apex should not be used. The length of the needle should always be below 31 mm and better if it be 24 to 27 mm.
3. The axial length of the eyeball should always be measured or known before introducing any needle in the orbit. So, don't fail to measure or check the axial length of eyeball.
4. Always avascular injection sites should be used. So, vascular superonasal quadrant should be avoided.
5. Extra precaution should always be taken for patients having staphyloma, scleral buckle, coloboma, etc. Failure to take history of previous surgical intervention (scleral buckling which increases the axial length of eyeball) or to check for any global anomalies may cause serious disaster.
6. During practice of regional anaesthesia in ophthalmology, everybody must execute his highest knowledge in orbital anatomy. Don't attempt any regional block in ophthalmology without proper anatomical knowledge.
7. We should always try to avoid direct injection into the extraocular muscles.
8. We will always use time honoured regional technique with well-thought volume and concentration of local anaesthetic agent. We will not use unnecessary newer technique and unnecessary higher volume and concentration of local anaesthetic agent.

by using fine needles and confining the needle prick within these three locations and not going beyond 31 mm from the orbital rim posteriorly, we can reduce the incidence and severity of the intraorbital bleeding. If it occurs, it may be minimized by constant vigilence for any sign of bleeding immediately following needle withdrawl and by rapid application of digital pressure with a gauge pad, applied to the closed lids. Other management of retrobulbar haemorrhage are osmotic diuresis and lateral canthotomy, which allows drainage of the blood and decompression of the orbit. So, surgeons should be informed immediately and the pulsation of the central retinal artery should be assessed. The superonasal area should be avoided for needle insertion, because the complex trochlear mechanism of the superior oblique muscles is located there.

Prolonged malfunction of the extraocular muscle may also sometimes occur after the regional anaesthesia of the orbit. Among these the diplopia and ptosis are common which may last for 24 to 48 hours postoperatively, when long-acting local anaesthetic agents have been used in higher concentration and in large volume. When these persist for long period and fail to recover, it may give evidence of toxic changes of the muscles by local anaesthetic agents. Where the recovery is delayed for more than 6 weeks, 25% of the change becomes permanent. It is indeed pathetic, when a patient who has come for a perfect optical result, ends up with devastating diplopia because the eyes are misaligned. Local anaesthetic agents containing hyaluronidase and/or adrenaline may be more myotoxic than plain local anaesthetic solutions. Higher concentration of local anaesthetic agents is more likely to result in a more intense myotoxicity. Another common cause of prolonged malfunction of the extraocular muscle is direct intramuscular injection of the local anaesthetic agent of any concentration.

Ptosis is also a very common complication after ophthalmic RA. This postoperative ptosis is of multifactorial origin.

Table 41.7: Some factors responsible for muscle damage and ptosis

1. Pressure applied to the globe and upper lid,
2. Oedema of the eyelid,
3. Traction on the superior rectus muscle complex,
4. Pressure exerted by the lid speculum,
5. Prolonged postoperative patching.

Among these, the injection of local anaesthetic agent directly into the levator palpebrae superioris muscle plays an important role. The toxic damage of the muscle fibres from local anaesthetic agent which is not injected directly into the muscle may also account for many cases of transient and permanent ptosis (Table 41.7).

Most postoperative ptosis also occurs in patients in whom the levator aponeurotic apparatus was already pathological beforehand and the RA only serves to accelerate the preexisting condition. The preexisting degenerative conditions of the aponeurosis of the levator palpebrae superioris which usually accelerate the postanaesthetic ptosis include : disinsertion in the tarsal plate, dehiscence and rarefaction of the aponeurosis. Many of these lids with the above mentioned pathologies would have become ptotic, even if surgery and RA had not been performed. The RA has just accelerated the pathological process. A low incidence of postoperative ptosis is seen in surgeries which are done under general anaesthesia than with local anaesthesia. Surgical correction of such postoperative ptosis is done when there is only interference with the vision. But, it should be delyed for 6 months, until a self correction of certain limit occurs and a stable state has been reached. So, it is very prudent and should be a routine practice to check the positions of the eyelid margins above the central cornea before embarking on sugery and is documented with photography, if needed. Patients also should be informed beforehand about the possbility of ptosis which may be temporary or permanent after surgery. Written consent for surgery acknowledging this complication of ptosis should also be taken.

Exposure of anaesthetized cornea and subsequently its abrasion are also very common complications of ophthalmic regional anaesthesia. Abrasion is seen as a dull nonreflective patch or as a positive area by fluorescein staining. So, care must be taken to protect the cornea by occlusive dressing, during the whole perioperative period. An occlusive dressing should be used after anaesthesia to seal the eyelids shut, until their full function and reflexes have recovered. The time of recovery will depend on the duration of action of the chosen anaesthetic drug. On the other hand, a prolonged patch can provide a moist atmosphere beneath the gauge as an ideal culture medium for organism to grow. That's why some experienced surgeons do not use patch over the eye postoperatively, especially after small wound phacoemulsification cataract extraction with foldable intraocular lens implantation under solely topical anaesthesia. But, the safety of this decision from the point of view of risks of superficial corneal damage would depend on the degree of the recovery from anaesthesia. After recovery from anaesthesia, corneal abrasion (if it occurs) is manifested as pain, foreign body sensation, tearing, conjunctivitis and photophobia. Pain is also made worse by blinking. Management of corneal abrasion consists of covering the eye with an antibiotic eye ointment. But, topical applications of anaesthetic drops and steroids over the cornea to reduce pain is contraindicated, because they impair the healing of wound.

OCULOCARDIAC REFLEX (OCR)

OCR is a trigeminovagal reflex which is manifested by cardiac arrhythmias such as bradycardia, nodal rhythm, ectopic beats, ventricular fibrillation, asystole, etc. in response to vagal stimulation. Although the most common manifestation of this reflex is sinus bradycardia, but virtually

any cardiac dysrhythmia such as nodal, junctional, atrial or any serious ventricular arrhythmia may occur. This oculocardiac reflex was first described by Aschner and Dagini by two simultaneous but independent reports in 1908. The impulses for OCR usually arise from the stretch and pressure receptors which are present throughout the globe and orbit. The afferent pathway of the reflex first goes through the long and short ciliary nerves to the ciliary ganglion. Then, it passes to the gasserian ganglion along the ophthalmic division of the trigeminal nerve (the 5th cranial nerve). Ultimately, these afferent pathways terminate at the main trigeminal sensory nucleus which is situated on the floor of the 4th ventricle. The efferent pathway comes down by the vagus nerve and ends at the cardiovascular centre, respiratory centre and vomiting centre, causing negative ionotropic effects, negative chronotropic effects, conduction defects, vomiting, sinus arrest and/or respiratory arrest. So, the term 'Oculocardiac Reflex' should be changed to 'Oculomedullary Reflex', consisting of oculocardiac, oculorespiratory and oculoemetic reflexes.

The OCR may be triggered by many factors such as pressure on the eyeball, traction on the extraocular muscles, orbital haematoma or many other. Traction on the medial rectus produces more marked effects than the traction on other muscles. The reflex seems to be most active in children. So, the OCR occurs most often during strabismus surgery in children. But it may also occur occasionally during retinal surgery or at the time of injection of the intraorbital block. The reported incidence of OCR varies considerably from 30 to 90%. Because, it depends on the intensity of observation and the definition of arrhythmias. Transient cardiac arrest may occur as frequently as 1 in 2000 cases of strabismus surgery. The force and the type of stimulus usually influence the incidence of OCR. The more acute, stronger and sustained will be the stimulus and the more sensitive will be the patient, the more likely is the OCR to occur. Therefore, ECG should always be monitored continuously during ophthalmic surgery. The OCR ceases when the stimulus (from pressure or traction) ends. So the surgeon and the anaesthesiologist should not hesitate to communicate each other during any procedure involving the possibility of an OCR.

Intramuscular atropine or glycopyrrolate as premedication are not very effective in preventing the oculocardiac reflex, compared to the intravenous administration. Atropine in the dose of 0.02 mg/Kg through IV prior to surgery will reduce the incidence of OCR by 5 to 15%. Intravenous glycopyrrolate in the dose of 0.01 mg/Kg, is preferred than atropine as it causes less tachycardia. Hypercarbia increases the sensitivity to the reflex, and an anaesthetic technique such as controlled ventilation rather than spontaneous ventilation might be preferred.

The first step of treating OCR is to stop the production of stimulus by surgeon, before the arrhythmia progresses to sinus arrest. Fortunately, the repeated and sustained stimulation usually causes the OCR to become fatigue. If arrhythmias persist, then treatment with atropine (20 µg/Kg IV) and injection of local anaesthetic agent into the eye muscle may be necessary. If the patient still remains sensitive to the manipulations of the extraocular muscles, then the anaesthesiologist should check the adequacy of the depth of general anaesthesia, the existence of normocarbia and the gentleness of surgical manipulation. If the dysrhythmia is fast or ventricular in origin, then surgery should be stopped immediately. Then, we should wait for the return of normal rhythm before giving atropine, otherwise may provoke ventricular tachycardia or fibrillation.

INTRAOCULAR PRESSURE (IOP) AND ANAESTHESIA

IOP is the result of a dynamic balance between the production of aqueous humour by ciliary body in the posterior chamber and its eventual elimination by the episcleral venous system via the spaces of Fontana and the canal of Schlemm at the iridocorneal angle. So, the most important factors which influence on IOP are: the production and movement of aqueous humour, the changes in choroidal blood volume, the central venous pressure and the extraocular muscle tone. The normal IOP is approximately 15 to 20 mm of Hg.

The ciliary body lies behind the root of the iris and consists of two parts. The posterior muscular part is called the pars plana. The muscle in this part has three important functions. The most important of which is to relax the suspensory ligament of the lens. Thus, the lens becomes more spherical and allows accomodation of near vision. Secondly, it exerts tension on the scleral spur. This widens the spaces in the trabecular meshwork and thus facilitates the drainage of aqueous humour. A third and minor action of this muscle is as dilator of the iris. The pars plana is the favoured site for the sclerotomies through which insertion of instruments into the eye is done during vitreoretinal surgery. The anterior part of the ciliary body is thrown into about 70 folds and is called the pars plicata. Here, the stroma is highly vascular and is richly supplied by fenestrated capillaries. It is from these folds that the aqueous humour is secreted. The aqueous humour is produced at a rate of about 2 µl/minute.

After secretion the aqueous humour circulates freely from posterior chamber to the anterior chamber around the free margin of the iris. If there is any increase in venous pressure, or decrease in the cross-sectional area of the spaces of Fontana, then there is increase in the resistance to outflow of aqueous humour which increases IOP. Mydriatic drugs relax the ciliary muscles and close the iridocorneal angle at Fontana's spaces. Thereby, they increase the IOP. Coughing, straining and Valsalva manouevers significantly increase the CVP. Thus, they decrease the

outflow of aqueous humour from the Schlemm's canal into the episcleral venous system and increases the IOP.

The uveal tract is the intermediate vascular coat of the globe lying between the sclera and retina. It consists of the choroid, ciliary body and iris. The choroid coat is present in the posterior 5/6th of the eyeball and is juxtaposed to the sclera. It extends forward up to the ora serrata of the retina. It is chocolate-brown in colour and is highly vascular. Choroid is being fed by the branches of the short posterior ciliary arteries and is drained by a venous network which ultimately converges into four or five vortex veins. The vortex veins pierce the sclera 5 to 8 mm posterior to the equator of the globe. One of the these is located at the lateral border of the inferior rectus muscle and 5 mm posterior to the equator. It may be the source of intraorbital bleeding during the inferotemporal needle placement. The choroid is responsible for the nutirtion of the outer layer of retina. The inner layer of retina receives its blood supply from the central retinal artery. The vascularity of the choroid layer increases with systemic venous congestion, arterial hypertension, hypoxia and hypercarbia. The sclera and the choroid are loosely adherent and separated by a potential suprachoroidal space which may fill with blood during an expulsive or suprachoroidal hemorrhage. This is a dreaded surgical complication.

The choroidal blood flow or its volume affects the IOP significantly. But, it is usually autoregulated over a wide range of systemic systolic pressure to keep the IOP stable. The sudden increase in systolic blood pressure causes a transient increase in choroidal blood volume and the IOP. Hypotension (systolic blood pressure < 90 mm of Hg) reduces the choroidal volume and subsequently decreases the IOP. During an open eye surgery IOP usually remains lower than normal. But a sudden increase in the choroidal blood volume can force the vitreous gel forward into the anterior chamber and also cause the prolapse of iris. Any cause which increases the CVP increases the choroidal blood volume and its pressure and thus elevates the IOP. Choroidal circulation, choroidal pressure and subsequently IOP is also sensitive to the changes of partial pressure of oxygen. So, hypoxia increases the choroidal circulation and its volume by vasodilatation and increases the IOP. Respiratory acidosis and hypercarbia also increases the choroidal blood flow by vasodilatation and, therefore, elevates the IOP. Hypocarbia decreases IOP through vasoconstriction of the choroidal blood vessels, and decrease in the formation of aqueous humour through reduced carbonic anhydrase activity. The IOP is also controlled by CNS through the neurovascularly mediated responses and extraocular muscle tone. These are usually depressed by barbiturates, volatile inhaled anaesthetics and nondepolarizing muscle relaxants. It is also found that IOP is more directly related to CVP than the arterial pressure. So, a slight head up tilt during the intraocular surgery reduces the IOP due to any cause. External pressure on the eyeball initially increases the IOP. But, this increased IOP promotes increased outflow of aqueous humour and thus returns IOP towards normal (Fig. 41.30).

In general, the most anaesthetic agents except ketamine and succinylcholine relax the extraocular muscle tone, depress the CNS, improve the outflow of aqueous humour, lower the venous and arterial pressure and thus reduce the IOP. Inducing agents such as thiopentone and propofol also lower IOP by depressing the CNS and improving the outflow of aqueous humour. Antisialagogues such as atropine and glycopyrrolate, given as premedication through IV or in route have no significant effect IOP. However, when these drugs are applied topically on the eye, they cause mydriasis and increase IOP. But, neostigmine and atropine combination which are used to reverse the nondepolarizing muscle relaxants do not increase the IOP. On the other hand, laryngoscopy and intubation or extubation elevate the IOP. However, the mechanism of it is not clear, but is probably related to the sympathetic cardiovascular responses to tracheal intubation or extubation. Several attempts have been advocated to attenuate the IOP response, related to the laryngoscopy and intubation or extubation. These are: pretreatment with IV lignocaine, narcotics and β-blockers. Oral administration of any centrally acting antihypertensive drug, such as, clondine in the dose of 5 µg/Kg of body weight and given 2 hours before induction of anaesthesia will blunt the IOP response to intubation. Benzodiazepines, administered intravenously, reduce the IOP but not when administered orally. On the other hand, narcotics do not decrease the IOP, even in glaucoma. The effect of ketamine on IOP is controversial. Early studies show an increase in IOP after an

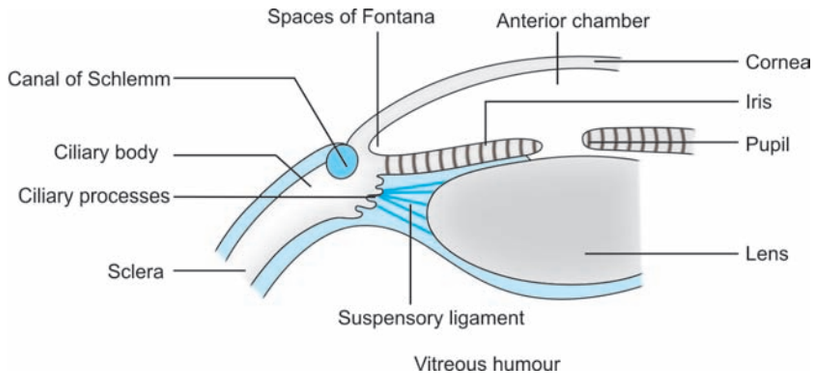

Fig. 41.30: Circulation of aqueous humour

IV administration of ketamine. But when ketamine is used after premedication with BDZ, then IOP does not elevate.

All the nondepolarizing muscle relaxants lower the IOP. But, succinylcholine causes a significant and transient rise in IOP, though the mechanism is not clear. It is definite that an increased IOP by succinylcholine is not due to mere fasciculations of the extraocular muscles as sectioning of recti do not prevent the increase in IOP. So, it may be due to the direct effect of succinylcholine on the choroidal blood volume or on the formation of the aqueous humor.

During retinal surgery the ophthalmologists, sometimes, inject gases into the vitreal cavity to tamponade the retina. The gases commonly used for this purpose are C_3F_8 (carbonoctofluorine) and SF_6 (sulphur hexafluride). They are inert, very insoluble in water and poorly diffusible. N_2O is 117 times more diffusible than SF_6 and so it enters into the gas bubble very rapidly. If administration of N_2O is continued after injection of C_3F_8 or SF_6 gas into the vitreal cavity, then the size of the injected gas bubble rapidly increases and becomes about three times of its original size. Thus, IOP increases from normal 15 to 30 mm of Hg. This may result in occlusion of the retinal artery and loss of vision. Both, the bubble size and the IOP will then decrease and become normal within 15 minutes of discontinuation of N_2O by 90 % elimination from the lungs. This rapid and wide variation in bubble size during general anaesthesia by N_2O may adversely affect the result of the surgery. This outcome is more affected, if hypotension occurs during general anaesthesia. So, administration of N_2O should be discontinued at least 20 minutes before the institution of an intravitreal injection of C_3F_8 or SF_6 gases. Bubble size and IOP would then remain stable. So, some anaesthetists avoid N_2O altogether, when intravitreal injection of gas is planned. SF_6 gas remains in the vitreal cavity for at least 10 days. Other gases remain in the vitreal cavity for as long as 20 to 30 days. So, N_2O should always be avoided in any patient returning for retinal resurgery within 3 to 4 weeks of undergoing intravitreal injection of gases. Patients with intravitreal gas bubbles may also risk ocular damage during air travel. This is because, if patients having intraocular air volumes of only 0.25 cc, were subjected to pressures simulating that inside a commercial aeroplane, there would be an average rise of IOP by 40 mm of Hg. This will again decrease to lower than normal, after return to preflight pressures.

FACTORS AFFECTING THE IOP

These are analogus to the factors affecting ICP (intracranial pressure). The factors which affect the IOP are:

i. Head up or down position.
ii. Volume of aqueous humour determined by the balance of production and drainage.
iii. The tone of extraocular muscles.
iv. Choroidal blood volume, determined by the balance of arterial flow and venous drainage.
v. Mannitol and acetazolamide: Mannitol in the dose of 0.5 gm/Kg IV reduces the IOP by withdrawing fluid from the vitreous. Acetazolamide in the dose of 500 mg orally or IV reduces the IOP by reducing the production of aqueous by the ciliary body.
vi. Anaesthetic factors.

Anaesthetic factors increasing IOP

i. External compression on the globe by face mask which is applied tightly.
ii. Laryngoscopy – through pressure response or from straining in an inadequately relaxed patient.
iii. Suxamethonium – through its effect on extraocular muscles.
iv. Large volume of local anaesthetics placed in the orbit. The effect here is also transient. The ↑IOP can be reduced by different decompression method.

Anaesthetic factors decreasing IOP

i. Inducing agents like thiopentone and propofol. They act by reducing the arterial and venous pressure.
ii. All non-depolarizing muscle relaxants. They act by reducing the extraocular muscle tone.
iii. Head up tilt (> 15°) by assisting venous drainage.
iv. Hypocapnia by reducing the choroidal blood volume by vasoconstriction of choidal vessels.

RETINOPATHY OF PREMATURITY (ROP)

As the neonatal care has been improved due to the advancement of technology, so more and more premature infants now survive. Therefore, the incidence of retinopathy of prematurity is gradually increasing. It has a complex cause with many aetiologies. Previously, it was thought that the ROP was only associated with hyperoxic conditions during neonatal care. But, the full-term non-hyperoxic neonates and infants can also have this condition just like premature infants who have never had O_2 therapy. So, it is decided that ROP may also be associated with factors such as hypoxia, hypocarbia, hypercarbia, sepsis, apnoea, etc., other than hypoxia. The ROP still occurs, despite the efforts in the neonatal intensive care unit to control and monitor the O_2 delivery. ROP also occurs even when the capillary PO_2 is kept between 35 to 40 mm of Hg and P_aO_2 is maintained between 50 to 70 mm of Hg in premature infants. So, the problem for the anaesthetists who is giving general anaesthesia to a premature infant is to balance the risk between the hypoxic damage and prolonged exposure to high O_2 concentration, causing ROP. Although, there is no convincing evidence that ROP has always occured solely because of high O_2 concentration, given during anaesthesia, still prolonged exposure to high intraoperative concentration of O_2 is best avoided during the period of retinal immaturity, i.e. until

8 months of age. P_aO_2 is maintained between 60 to 90 mm of Hg by keeping SPO_2 in pulse – oximetry between 90 to 95%.

GENERAL ANAESTHESIA FOR OPHTHALMIC SURGERY

The list of indications of GA for ophthalmic surgery has been tabled before. The main aim of GA in ophthalmic surgery is to minimise the increase in IOP and keep the patient motionless, while maintaining cardiovascular stability. But, deep anaesthesia should be avoided as the main population in ophthalmic surgery is likely to be elderly with several co-morbidities. GA is provided, unless there are overwhelming risks. Then, the patients and their attendants are informed about the risks and GA is provided only if they accept them. Always a risk-benefit ratio has to be calculated, keeping in mind that ophthalmic surgeries are not life-saving. The preoperative assessment and preparation for GA in the patients scheduled for ophthalmic surgeries follow the same guidelines as GA for other sugeries.

A Standard Technique of General Anaesthesia which is usually Followed for Ophthalmic Surgeries

i. IV induction by propofol or thiopentone. Ketamine is used only if properly indicated.
ii. Non-depolarizing muscle relaxants are preferred. Succinylchoilne can be used only if it is properly indicated.
iii. Airway is maintained by ET tube or LMA.
iv. Ventilation is maintained by IPPV or spontaneous ventilation.
v. Maintenance of anaesthesia is by O_2 with air/N_2O/propofol infusion by TCI/volatile inhalational agents. N_2O should be avoided in vitreoretinal surgeries, especially if SF_6 or C_3F_8 gases are used.
vi. Analgesia is provided with fentanyl/alfentanyl/sufentanyl/remifentany, etcl.
vii. Use of glycopyrrolate as antisialagogue is preferred in ophthalmic surgeries. It reduces the volume of saliva which often produces cough, laryngospasm, etc.
viii. Airway should be secured properly as access to the airway is limited by the surgical drapes, instrument trolleys, and other equipments overlying in this area. Most importantly, there prevails a low threshold for moving every one out of the way to inspect the airway when some problem is suspected.
ix. Which is the better or safe for ophthalmic surgeries – an ET tube or a LMA? This is a potent question which is often asked. Unless contraindicated, the LMA is ideal for ophthalmic surgeries as it avoides laryngoscopy with the consequent adverse effects of it on IOP. It produces minimal stimulation once is *in situ* and permits a lighter anaesthesia. The quality of emergence is also superior, ET-tude and very smooth in case of LMA. 10% Lignocaine is usually sprayed in the larynx during endotracheal intubation. But unfortunately, its effect is very short-lived and so may no longer be effective during extubation. Extubation of ET-tube in a deep plane or administration of a bolus dose of IV lignocaine (1 mg/Kg BW) or propofol (0.5 mg/Kg BW/min) just before extubation are some of the methods which are often opted for smooth extubation. It is better not to lighten the plane of anaesthesia before completion of surgery and the removal of the typical stick-drapes used in ophthalmic surgeries. If a peribulbar block is not used, drape removal may well be the most stimulating part of the procedure. During extubation emergence hypertension and a concomitant rise in IOP can be managed by the use of IV lignocaine and / or β-blocker.
x. Choice between the IPPV and spontaneous ventilation is another important question in ophthalmic surgeries. For minor and extraocular surgeries the spontaneous ventilation is acceptable. Controlled ventilation or IPPV has a number of advantages in intraocular and other major ophthalmic surgeries. It allows a more precise control of CO_2, reducing the IOP and desensitizing the oculomedullary reflex. It also allows the benefits of a balanced anaesthesia technique. IPPV by LMA is also uneventful. But, high pressure (> 15 cm of H_2O) with risk of gastric insufflation should be avoided. CO_2 waveform should always be monitored. Any change in the waveform usually heralds a change in ventilation, before it is clinically apparent (malpositioned LMA, inadequate muscle relaxation, etc.). Nerve stimulators should be routinely used for ophthalmic surgeries, because coughing and gagging are less well tolerated by ophthalmic surgeons, than their colleagues of other surgical streams.
xi. If local block is used as a supplement to GA, it should be administered only after induction. However, since the principal benefit of a local block is the avoidance of GA. But when it is used in addition to GA. Then the risk-benefit ratio is now altered. So, it may no longer be justified now. But, many anaesthesiologists still use a local block in addtion to GA, especially in ophthalmic surgeries, because it allows a very good control of patients even with lesser anaesthestic drugs and most importantly it provides better postoperative analgesia.

42 Kidney and Anaesthesia

INTRODUCTION

The kidneys are a pair of essential excretory organ which form urine, eliminate nitrogenous waste products from blood produced during protein metabolism, and maintain the electrolyte and water balance of the body. In it the fluid that resembles plasma is ultra-filtered through capillaries of glomeruli and is collected in the Bowman's capsule. It then passes down the renal tubule and its volume is reduced by the reabsorption of water. The composition of this glomerular filtrate while passing through the renal tubule is also altered by the process of tubular reabsorption and secretion of different solutes to form finally the urine whose composition may vary according to the circumstances. Many homeostatic mechanisms also try to alter the compositions of plasma or ECF by changing the composition of urine. In addition, the kidneys also secrete the renin for autoregulation of renal blood flow and blood pressure, erythroprotein for maturation of red blood cells and 1,25, hydroxycholecalciferol for the control of calcium metabolism which may modify the action of parathyroid hormone. Thus, the kidneys also subserve the function of endocrine organs. The other endocrine part of kidney include the interstitial tissue of the medulla. These cells are called the 'type I medullary interstitial cells'. They secret prostaglandin, predominantly PGE_2. The PGE_2 is also secreted by the cells of collecting duct. Prostacyclin (PGI_2) and other prostaglandins are also secreted by the afferent arterioles and glomeruli.

STRUCTURE OF KIDNEY

Structure of kidney can be studied under two headings – macroscopic and microscopic.

Macroscopic Structure

On coronal section, macroscopically the kidney presents two parts – inner renal sinus and outer renal substance itself. The outer renal substance itself again consists of two parts such as inner medulla and outer cortex.

Medulla

In coronal section the medulla presents 8 to 18 striated, pale and conical masses which are called the renal pyramids. Each pyramid has a base directed to the cortex and an apex projected into the renal sinus. This apex of renal pyramid projected in the renal sinus is called the renal papilla. Each renal papilla of renal pyramid is perforated by 16 to 20 ducts of Bellini. The renal sinus which receives renal papilla is called the calyx minor. As a rule only one calyx minor receives 1 to 3 renal papillae. Each renal pyramid, capped with the adjoining renal cortex on its outer surface forms the lobe of the kidney. There are many striations on the pyramids which are due to the following factors:

i. Loops of Henle (LOH) with their descending and ascending limbs: These long renal tubules are derived from the glomeruli which are situated in the cortex but near the medulla (juxta – medullary glomeruli) and are plunged into the substance of the pyramids. The longest loops even extended close to the renal papilla. The shortest loops which are derived from the most superficial cortical nephrons does not extend upto the medulla or if extend it reaches only close to the basal zone of the pyramid. This U shaped long loops of Henle of justa medullary glomeruli with the vasa recta act as counter current osmotic multiplier system and are responsible for maintaining the graded osmolarity of the interstitial fluid of renal pyramids or parenchyma. The apex of this pyramid is hypertoic, whereas the body is isotonic and the base of the pyramid is hypotonic to the plasma.
ii. Collecting tubules and ducts of Bellini from base to the apex the pyramids are traversed by the collecting tubules and ducts of bellini. When the collecting ducts and the ducts of Bellini pass through the hypertonic apical zone of pyramid, the urine becomes concentrated and hypertonic and is collected in the minor calyces.
iii. Arteriolae recti and venae recti: These vessels are also called the vasa recta. Arteriolae recti are the wide bored straight vessels, derived from the efferent glomerular arterioles of juxta medullary glomeruli and descend by the side of the loop of Henle. Then they break up into many straight capillaries which are arranged longitudinally and surround

the loops of Henle and finally return to the arcuate veins by the ascending venae recti. The descending and ascending vasa recta are so close to each other and the blood flow through them is so sluggish that they exchange osmolarity amongest themself and do not disturb the osmolarity (hyper) of the renal pyramid or parenchyma. This is explained by the fact that arteriolae recti (descending vasa recta) are only permeable to solutes, but not water. On the otherhand, venae recti (ascending vasa recta) is only permeable to water and not solutes. So, it drains away the water and maintains the gradient of osmolarity in the interstitium of medulla. Thus, the blood vessels of the pyramids act as counter current osmotic exchanger (Fig. 42.1).

Cortex

The outer portion of the renal substancesituated above the renal medulla is called the renal cortex. This renal cortex is granular in appearance (not striated) and consists of cortical arches and renal columns.

Cortical arches are the area of cortex which intervene between the bases of the pyramids and the surface of the kidney. Each cortical arch again consists of numerous cortical rays and smooth parts in between them. Each ray is a narrow conical mass like small pyramid. The apex of each ray is directed to the surface of kidney and the base is continuous with the striations of the pyramid. Each cortical ray is occupied by collecting tubules and the commencement of duct of Bellini. The interlobular blood vessels pass outwards along the each side of these cortical rays. The convoluted plain part of the cortex is the area which intervene between the adjacent cortical rays. These are occupied by the nephrons which consist of renal corpuscles and renal tubules with different convoluted parts of it. The renal corpuscles and tubules are arranged into 13 or more superimposed layers. The nephrons situated in the superficial portions of the cortex is called the cortical nephrons and their glomeruli are called the cortical glomeruli. The renal tubules of these cortical nephron and the capillaries around them remain confined within the cortex. On the other hand, the nephrons which are situated in the cortex, but close to the medulla are called the juxta medullary nephrons and their glomeruli are called the juxta medullary glomeruli. Their corresponding loop of Henle are long and extend into the pyramid of medulla with the straight capillaries (vasa recta) around them.

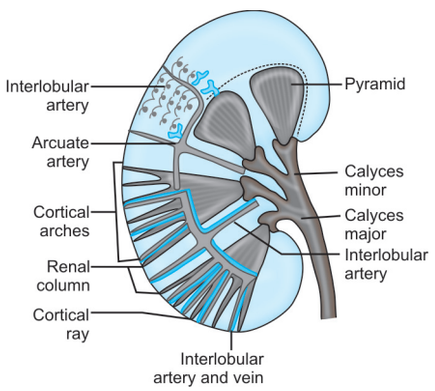

Fig. 42.1: Macroscopic structure of kidney in coronal section

Renal columns of the cortex are the areas which intervene between the adjacent cortical arches. These also extend into the medulla between the two pyramids. It contains nil or few renal corpuscles and is traversed mainly by the interlobar blood vessels.

Blood supply of kidney

Each kidney is supplied by a renal artery which is a branch of abdominal aorta. Each renal artery after its origin from the aorta reaches the hilum of respective kidney and divides into anterior and posterior trunk. The anterior trunk again subdivides into four segmental arteries and the posterior trunk continues as a separate segmental artery (i.e. there are 5 segmental arteries). These segmental arteries again divide into lobar branches which further divides into interlobar branches of arteries. These interlobar arteries then pierce the substance of kidney and run through the renal columns between the adjacent pyramids. At the junction of the cortex and the medulla these interlobar arteries divide dichotomously into arcuate arteries which run as an arch over the base of the pyramids. These arcuate arteries do not anastomose with one another. From these arcuate arteries numerous interlobular arteries arise and runs outward towards the surface of the kidney through cortex by the sides of the cortical rays. Then the extreme terminal branches of the interlobular arteries ramify beneath the renal capsule to form a subcapsular plexus (Fig. 42.2).

Each interlobular artery when it runs through the cortex by the side of the cortical rays gives origin to a number of afferent glomerular arterioles from its sides at different directions. Each afferent glomerular arteriole then forms a glomerular capillary plexus in the Bowman's capsule of cortical glomeruli. Efferent glomerular arterioles arise from these cortical glomerular capillary plexus and are somewhat narrower in diameter than their corresponding afferent arterioles. Efferent arterioles after their origin from the glomeruli of superficial zone of cortex breaks up into peritubular plexus around their corresponding renal tubules. They are usually confined within the cortex. The efferent arterioles arising from the glomeruli which are situated in the superficial part of the renal cortex do not go deep into the medulla and do not take part in the counter current multiplier system. Blood from the cortical peritubular arterial plexus then empties into the interlobular veins which again drain into the arcuate vein and finally drains into the inferior vena cava after passing successively through the arcuate, interlobar, lobar, and renal veins which correspnds with the arteries.

About 15% of the afferent glomerular arterioles arising from the base of the interlobular arteries form glomerular capillary plexus in the juxta medullary glomeruli. These glomeruli are larger and lesser in function than the superficial cortical glomeruli. The diameter of efferent arteriole

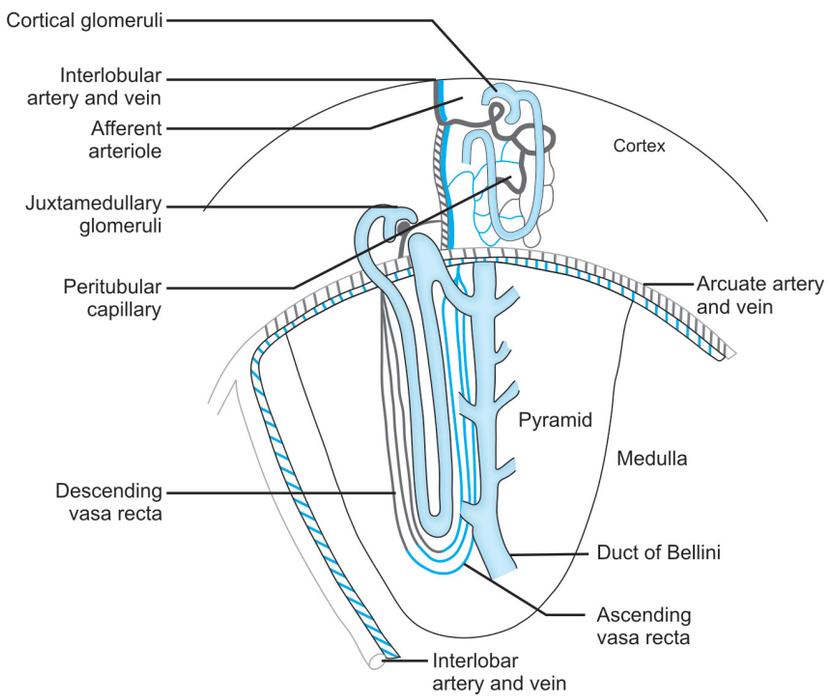

Fig. 42.2: Microscopic structure of kidney

arising from these juxtamedullary glomerular plexus is either equal or slightly larger than their corresponding afferent arteriole and goes deep straight into the renal pyramids. These straight arterioles which are a continuation of the efferent arterioles of the juxtamedullary glomeruli divide further into 20 or more straight branches (vasa recta) and later breaks up into capillary plexus (peritubular capillaries) around the renal tubule which also arise from the corresponding juxtamedullary glomeruli and goes deep into the renal medulla. These capillary plexuses then return to the arcuate veins at the corticomedullary junction by forming some straight veins. These straight arterioles which arise from these efferent arteriole of juxtamedullary glomeruli are called the descending vasa recta. The straight venules arising from the peritubular plexus, drain into the arcuate veins are called the ascending vasa recta. In the medulla these straight vessels and their divisions run parallel to one another and with the renal tubules. Thus, these straight vascular pattern with the renal tubules arising from the juxtamedullary glomeruli form the structural basis of the counter current multiplier system of the renal pyramid. This is because the endothelial linings of the glomeruli capillary plexus, cortical peritubular capillaries and the ascending vasa rectae are fenestrated, but the endothelial lining of descending vasa recta are not fenestrated and lined by continuous endothelial cells.

Nerve supply of kidney

The kidneys are supplied by both the sympathetic and parasympathetic nerves. The efferent sympathetic preganglionic innervation of kidney comes from the lower three thoracic and upper one or two lumbar segment of the spinal cord. The post ganglionic efferent sympathetic fibres are then derived from the sympathetic chain and passes through the coeliac and renal plexus. The sympathetic fibres are distributed primarily to the afferent and efferent arterioles, the proximal and the distal tubules, and the juxtaglomerular cells. In addition, the sympathetic fibres also deeply enter the renal parenchyma and supply the thick ascending limb of LOH. The afferent sympathetic fibres carrying the nociceptive pain sensation from kidney also run parallel to the efferent sympathetic fibres and enter the lower thoracic and upper lumbar segment of spinal cord, through their respective dorsal nerve roots. Other renal afferent sympathetic fibres presumably mediate a reflex, called renorenal reflex which causes decrease in efferent nerve activity and subsequently increase in the excretion of Na^+ and water in one kidney, in response to the increase in ureteral pressure in another kidney.

Both the kidneys also get the parasympathetic innervation through the vagus nerve, but its function is uncertain.

Microscopic Structure

The kidney is composed of numerous nephrons. These nephrons consists of closely packed glomeruli and their tortuous uriniferous tubules which are held together by connecting tissue stroma. This glomeruli and their uriniferous tubules consists of physiologically two parts such as secreting part which is developed from the matanephros and the collecting part which is developed from the ureteric bud. The secreting part includes the nephron consisting of renal corpuscles (glomerulus) and renal tubules and the collecting part includes the collecting tubules and ducts of Bellini.

Nephrons

The total number of nephrons in each human kidney is near about 1 to 1.3 million and forms the structural and functional unit of it. The size of each kidney is determined largely by the number of nephrons, they contain. The length of each nephron varies between 5 to 5.5 cm and consists of two parts – (i) renal corpuscles (or glomerulus) for filtration, and (ii) renal tubules for selective reabsorption and secretion. The nephrons are classified

under two broad groups – cortical nephrons (85%) and juxtamedullary nephrons (15%). The cortical nephrons are primarily responsible for the absorption of Na^+ and juxtamedullary nephrons are primarily responsible for reabsorption of water by counter current mechanism.

Renal corpuscles (glomerulus)

Renal corpuscles are also called as the Malpighian body and consists of a plexus of capillaries (called glomerular capillary plexus) and a Bowman's capsule into which this capillary plexus invaginates. The renal corpuscles are 200 µm in diameter. They are mainly located in the cortical arches and a few in the renal columns.

Glomerular capillary plexus

It is a lobulated tuft of capillary plexus and is formed by an afferent and slightly narrower efferent arteriole. This tuft of capillary plexus projects into the Bowman's capsule and is invested by the visceral layer of the latter. About 50 intercommunicating lobules are present in each glomerular capillary plexus and each lobule consists of few capillary loops which are virtually suspended in the capsular space by a mesentry, derived from the visceral layer of Bowman's capsule. This mesentry for capillary loop contains some mesangial cells which are phagocytic and contractile in nature. This mesentry also contains some acellular matrix. The contractility of these mesangial cells is due to their cytoplasmic content of some myosin like filaments and angiotensin II receptors at their surface. This suggests they have immense role in the control of blood flow through the glomerular capillary loop. They also take part in the regulation of glomerular filtration, in the secretion of various substances and also take up immune complexes. These mesangial cells are involved in the production of glomerular disease.

The afferent and efferent glomerular arterioles are approximated to each other and form the vascular pole of the nephron. The ascending limb of the loop of Henle returns to this vascular pole of the corresponding mother nephron (this happens in case of juxtamedullary nephron only, in case of cortical nephron the distal convoluted tubule comes in close contact with the vascular pole) in close contact with the afferent glomerular arteriole. Usually, the efferent arteriole is somewhat narrower than the afferent one, So it increases the hydrostatic pressure of the glomerular capillary plexus to the extent of about 60 mm of Hg and help in filtration.

Bowman's capsule

It is nothing but the dilated, blind, upper end of the renal tubule in which the glomerular tuft of capillaries invaginate. Thus, Bowman's capsule consists of a parietal layer, a visceral layer in which glomerular plexus invaginates and a capsular space which is filled with glomerular filtrate. The parietal layer of Bowman's capsule is made by a single continuous layer of flattened epithelium, resting on a basement membrane. The visceral layer is made up of a discontinuous large polyhedral cells resting on a basement membrane. These large polyhedral cells are called the 'podocytes'. From the cell body of this podocyte numerous major processes pass outwards parallel to the basement membrane. Then each major process gives rise to a number of minor processes which are attached to the basement membrane by expanded foot plates of pedicles. These foot plates or the minor processes overlap on one another to form a diaphragm with numerous slits. Therefore, when viewed from the capsular space, the podocyte cells present stellate appearance (Fig. 42.3).

Thus, the structures intervening between the blood of glomerular capillaries and the intracapsular space of Bowman's capsule are the following from within outwards:

i. Fenestrated flattened endothelial layer of capillaries with numerous pores. The pore size is about 160°A.
ii. A continuous, but porous basement membrane upon which rests the capillary endothelium. The thickness of this basement membrane is about 0.33 µm. It is formed by the interlacement of fine reticular fibres which are held together by some amorphous materials. Average pore size of the basement membrane is about 110°A.
iii. Fenestrated layer of podocytes with its processes and foot plates. The pores within this layer are arranged like zip fastener between the cell processes or foot plates. The diameter of pores in this layer is about 70°A.

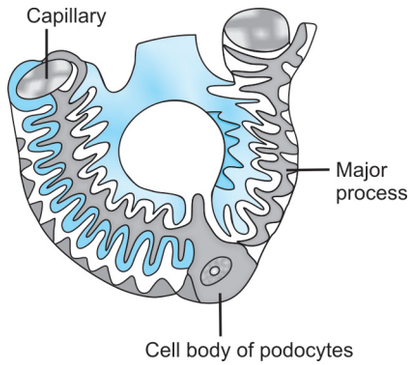

Fig. 42.3: The podocytes or glomerular epithelial cells lining the visceral layer of Bowman's capsule

The glomerular basement membrane which is situated between the capillary endothelium and the podocytes acts as a true membrane for ultrafilter. It allows the filtration of water with simple solutes of low molecular weight which are present in plasma. Therefore, the glomerular filtrate consists essentially of true plasma minus macromolecules of proteins, droplets of lipid and blood cells. Constituents of plasma which are of 68,000 molecular weight or above are held back by this basement membrane. It is also postulated that filtration through the structures intervening between the blood of glomerular capillaries and the Bowman's capsular space is governed by the electrostatic force. As for example, the matrix of the basement membrane which acts as the filtration barrier is negatively charged due to the presence of acidic glycoproteins and this opposes the passage of negatively charged molecules such as albumin (Fig. 42.4).

The diameter of each renal corpuscles (glomerulus) is about 0.2 mm and the total filtration surface area of the glomeruli of both kidneys averages about 1·5 sq.meters. The net glomerular filtration pressure in each renal corpuscles is equal to the glomerular blood pressure (60 mm of Hg) minus colloid osmotic pressure of plasma (32 mm of Hg) and Bowman capsular hydrostatic pressure (18 mm of Hg). Therefore, the net filtration pressure of human kidney comes to about 10 mm of Hg (60 − 32 − 18 = 10). Colloidal osmotic pressure of the ultra filtrate in Bowman's capsule is not taken into account for the calculation of net filtration pressure as there is no protein.

About 1700 litres of blood circulate through all the glomeruli of both the kidneys in 24 hours. Therefore, with a net filtration pressure of about 10 mm of Hg, about 170 litres of ultra filtrate are collected into the Bowman's capsular space in 24 hours. After abundant reabsorption of this filtrate by the renal tubules only about 1.5 litres of urine is formed in 24 hours. When such values are considered in minutes, then it is found that out of 650 ml normal plasma flow through both kidneys per minute, the glomerular filtration rate comes to about only 125 ml/minute. Therefore, filtration coefficient at the filtration pressure of 1 mm of Hg is 12.5 ml.

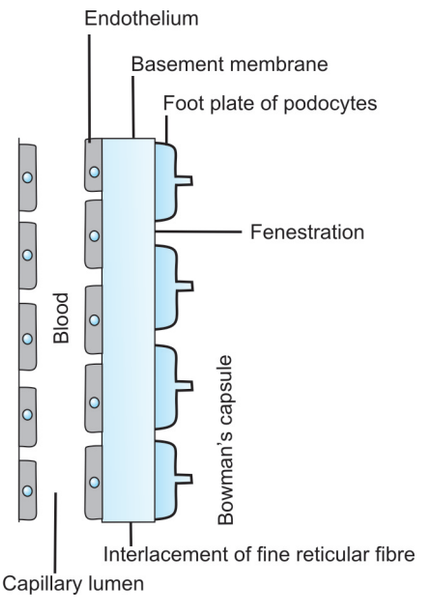

Fig. 42.4: The structures intervening between the blood of glomerular capillaries and the intracapsular space of Bowman's capsule

Renal Tubules

Bowman's capsule is continuous distally as a thin tubular structure which is called the renal tubule. Each renal tubule consist of the following parts such as proximal convoluted tubule, loop of Henle with descending and ascending limbs (or descending loop of Henle, loop of Henle, ascending loop of Henle), distal convoluted tubule and collecting tubule.

Proximal convoluted tubule (PT)

Each proximal convoluted tubule is about 69 µm in diameter and lined by a single layer of truncated columnar epithelial cells, resting on a basement membrane. The nucleus of each of these of these cells is basal in position and the cytoplasm is acidophilic. The luminal surface of each of these cells presents a brush border due to the presence of numerous microvilli. This brush border is rich in alkaline phophatase which helps in active absorption of glucose from the glomerular filtrate. The basal zone of these tubular epithelial cell presents numerous cytoplasmic infoldings. The mitochondrias in each cell are arranged radially at the basal zone in between these cytoplasmic infoldings. Close to the apical zone near the luminal surface the tubular cells are connected to one another by tight junction, but rest of the lateral surfaces of the cells are separated by intercellular clefts. The cytoplasm of the tubular cells contain acid phosphatase (in membrane bound lysosomes) which help in the hydrolysis of low molecular weight proteins into amino acid, when the former is absorbed directly from the glomerular filtrate through the tubular cells by pinocytosis. The cytoplasm of tubular cells also contains a number of enzymes like cytochrome oxidase, succinic dehydrogenase, acid phosphatase, glucose-6-phosphatase etc. which suggests active transport of some ions and small molecules from the tubular lumen in to the peritubular capillary plexus against concentration gradients through these cells (Fact file -I).

The proximal tubules allow active reabsorption of sodium (Na^+) and then subsequent reabsorption of potassium (K^+), chloride (Cl^-), calcium (Ca^{2+}), bicarbonate (HCO_3^-), phosphate, glucose, and amino acids etc. along with the absorption of Na^+. Here, water is absorbed passively as a solvent of the solute along the osmotic gradients through the specialized water channel present on the opieal surface of tubular cells which is composed of membrane protein called aquapronin-I. So, it is known as the obligatory reabsorption of water. Thus about 60 to 70% of the glomerular filtrate is absorbed from the

FACT FILE - I

Regulation of Na^+ reabsorption:

In the renal tubule, the reabsorption of Na^+ plays a major role in the reabsorption and secretion of other ions such as H^+, K^+, Cl^-, SO_4^{2-}, PO_4^{2-}, HCO_3^-, glucose, amino acids, organic acids and other substances across the walls of the tubule. For this, various pumps, cotransporter, antitransporter (or exchanger), channels, etc. are involved. At the capillary side Na^+ is actively pumped out of the tubular cell by Na^+-K^+ ATPase system, which extrudes 3 Na^+ in exchange of 2 K^+. Then, subsequently Na+ moves from the tubular lumen into the tubular epithelial cell by cotransporter or antiporter system in PT, thick portion of the ascending limb of LOH, DT and CD. The tubular cells are connected by tight junctions at their luminal end, but there is space between the cells along the rest of their lateral border. Much of the Na^+ is actively transported into these spaces through the cell and then into the capillary. The remaining portion of Na^+ is transported through the capillary side of tubular cells and then in the capillary blood. Principally Na^+ is reabsorbed at the luminal surface of tubular cells by Na^+-H^+ antitransporter at PT, Na^+-K^+-Cl^- cotransporter at thick ascending limb of LOH, Na^+-Cl^- cotransporter at DT and ENaC (sodium channel) in CD. This ENaC or Na^+ channel is the site of action of alsosterone and homeostatic adjustment in Na^+ balance.

proximal tubules. During absorption and passing through the PT although the volume of the filtrate is reduced, but the fluid remains isotonic to the blood or plasma. After absorption from the tubular lumen into the cell, the absorption of Na^+ then actively takes place at the basal zone of the columnar cells of PT by the active $Na^+ – K^+$ ATPase pump which is present on the capillary side of cell membrane. The energy of this action is derived from the ATP of the mitochondria of the proximal tubular cell. As a result more sodium with water, as a solvent, rush passively into the cytoplasm of the proximal tubular columnar cells from the tubular lumen to replenish the loss within the cell (Fig. 42.5).

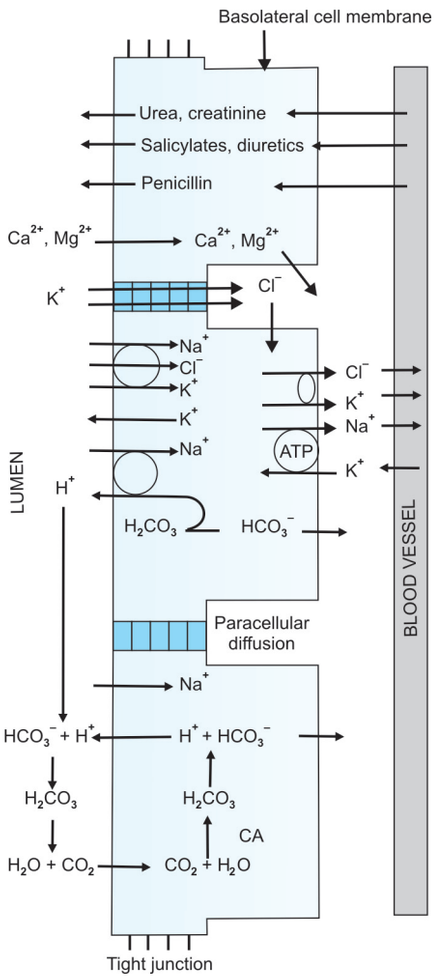

Fig. 42.5: Mechanism of secretion and absorption in proximal tubular cells

The fluid entering the proximal tubule from Bowman's capsule has a composition similar to that of plasma except for the absence of protein. But, as the proximal tubule is considered to be the bulk reabsorber of the glomerular filtrate, so it is responsible for reducing the volume of glomerular filtrate by approximately 65%. The 70% of sodium and chloride, 90% of calcium bicarbonate and magnesium, and 100% of glucose, phosphate, and amino acids all are reabsorbed with in proximal convoluted tubules. The main ion to be reabsorbed in PT is Na^+, on which the reabsorption of other ions depend.

Sodium is reabsorbed through the proximal tubular cells both by passively and actively. Passive reabsorption of sodium through the luminal surface of the tubular cells occur by two gradients: chemical and electrical. In chemical gradient reabsorption process the intracellular Na^+ concentration in the proximal tubular cells is 30 $m.molL^{-1}$ which is considerably less than the concentration of Na^+ in the tubular fluid which is about 140 m.mol/L and creates a chemical gradient for the reabsorption of it. Therefore, the Na^+ travels down the chemical gradient from the tubular lumen into the tubular cell. In electrical passive reabsorption process the electrical potential difference between the tubular cells and the lumen acts which is −70 mV. This creates an electrical gradient for the positively charged sodium ions to travel from the lumen into the cell.

It is already stated that after entry of Na^+ into the cell by passive chemical or electrical gradient, it is actively pumped out of the proximal tubular cell through their basal surfaces into the capillaries by Na^+-K^+-ATPase pump. But, in the proximal tubule this reabsorption of Na^+ is facilitated by angiotensin II and norepinephrine, while fenoldopam and dopamine inhibits it. Thus, Na^+-K^+-ATPase system situated at the capillary side of the cell membrane of proximal tubular cells provides energy indirectly for reabsorption of most of other solutes through the luminal end of these cell membrane. The net loss of intracellular +ve charges due to the absorption of Na^+ from the proximal tubular cells into the capillary blood also favours the absorption of other cations such as K^+, Ca^{2+}, Mg^{2+}, etc. from the tubular lumen into the proximal tubular cells. At the luminal side of the cell membrane of proximal tubular cells, the reabsorption of Na^+ is coupled with the secretion of H^+ by counter or antitransporter system. This secretion of H^+ into the proximal tubular lumen again helps in 90% reabsorption of filtered HCO_3^- from the lumen into the cell. Chloride (Cl^-) is also absorbed actively from the PT cells into the capillary blood by the K^+-Cl^- cotransporter system situated at the capillary side of the cell membrane of proximal tubular cells. As a result further absorption of Cl^- from the lumen in the proximal tubular cells is occurred passively following its concentration gradient. But unlike other solutes, Cl^- also traverses through the tight junction between the two adjacent proximal tubular cells. Most of the other substances also first traverse through the luminar side of the proximal tubular cells and then cross the cell membrane at the basolateral side to enter the renal interstitium, before entering the peritubular capillaries.

Other than reabsorption, proximal tubule is also capable of secreting some cations and anions. These cations are cimetidine, creatinine, quinidine, etc.; and anions are urea, salicylate, penicillin, ketoacids, diuretics, etc. But they share the same pumping mechanisms and one interfere the secretion of other. These pumps also play major role, in the excretion of many circulating toxins and X-ray dyes (Fact file-II).

Loop of Henle (LOH)

The LOH is the part of nephron which is situated next to the proximal tubule. It consists of three parts such as the thin descending limb, the thin ascending limb and the thick

FACT FILE - II

Regulation of K^+ reabsorption and excretion:

Maximum portion of the filtered K^+ of the glomerular filtrate is reabsorbed in PT, though some K^+ is secreted in this portion of the renal tubule. But the net result is maximum absorption. The thin descending limb of LOH is not permeable to K^+, whereas the thin ascending limb of LOH is permeable to K^+ like Na^+. In this thin descending and ascending limb of LOH, there is no Na^+-K^+-ATPase pump. So, in this portion of renal tubule, reabsorption or secretion of K^+ depends on the concentration gradient between the interstitium and tubular fluid. The thick ascending limb of LOH also absorbs and secrets K^+, but the net effect is more absorption than secretion. As a whole, in the absence of any complicating factors or diseases, the amount of reabsorption of K^+ is equal to the amount of K^+ filtered and the amount of K^+ secreted is approximately equal to the amount of K^+ intake. Thus, the K^+ balance of the body is maintained. The rate of K^+ secretion is parallel to the rate of flow of the tubular fluid through the distal portion of the nephron. Because with rapid flow, there is less opportunity for the tubular K^+ concentration to rise to a value that stops further secretion. In the collecing duct (CD), Na^+ is reabsorbed and K^+ is secreted, but there is no fixed one for one exchange and also much of the K^+ movement is passive. As Na^+ is reabsorbed in association with secretion of H^+, so there is competition of secretion between K^+ and H^+ for absorption of Na^+. Secretion of K^+ is decreased when the quantity of Na^+ reaching the distal tubule is reduced or when secretion of H^+ is increased.

ascending limb. The thick ascending limb is again divided into two parts – medullary portion and cortical portion. The nephron situated in the renal cortex (cortical nephron) have small LOH and does not contain the thin ascending limb. Contrary the nephrons situated in cortex near the medulla (juxtamedullary nephron) have the long LOH which goes deeps in to the medulla and contains the medullary and cortical portion of thick ascending limb of LOH. The LOH of juxta medullary nephron maintains a hypertonic medullary interstitium by counter current multipler mechanism. Among the parts of LOH, only the thick ascending part is metabolically active to absorb different solutes and has Na^+-K^+-ATPase pump. Contrary, the other parts of LOH are not metabolically active and only reabsorb Na^+

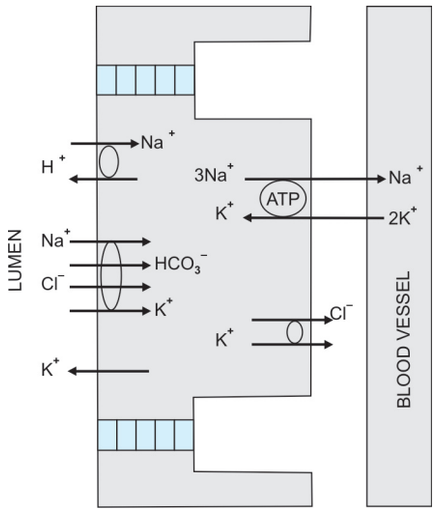

Fig. 42.6: Mechanism of secretion and reabsorption in the thick ascending limb of Henle (LOH)

or water passively, according to the concentration or osmotic gradient between the tubular fluid and interstitial tissue of kidney. The thin decending limb is permeable to H_2O and impermeable to Na^+, therefore it reabsorbs H_2O but not Na^+. Whereas the thin ascending limb is impermeable to H_2O and permeable to Na^+. Therefore it reabsorbs Na^+ but not water (Fig. 42.6).

The thick ascending part of LOH is impermeable to water, because water channel aquaporin is not expressed in this segment, but Na^+, K^+, HCO_3^- and Cl^- are reabsorbed. The reabsorption of K^+, HCO_3^- and Cl^- are coupled with reabsorption of Na^+ which still results from the Na^+-K^+-ATPase activity on the capillary side of the tubular cell membrane. The water impermeable thick ascending limb of LOH is also called the diluting segment of nephron. This is because as the Na^+ and other solutes are reabsorbed from this segment of tubular lumen, then only water remains in this part of tubule and reduce the osmolality of tubular fluid. Like the cells of the proximal tubule as the Na^+ is reabsorbed actively into the capillary blood through the cell membrane of capillary side by ATPase activity, then the Na^+ from the lumen is further absorbed through the cell membrane of the luminal side. This is coupled with the secretion of H^+ into the lumen by the Na^+-H^+ antiporter systemwhich helps in the absorption of Na^+ and exeretion of H^+. Another important symporter system which is present on the luminar side of cell membrane couples the reabsorption of K^+, Cl^- and HCO_3^- along with the reabsorption of Na^+ across the luminal side of cell. This is the major site of action of loop diuretics which inhibit the reabsorption of Na^+ along with the water at the thick ascending limb of loop of Henle. As the concentration of K^+ in the tubular lumen of this segment is much lower than Na^+ and Cl^- concentration so there is need for K^+ to be recycled in this segment. It means K^+ should be secreted in the tubular lumen and reabsorbed. Ca^{2+} and Mg^{2+} are also reabsrobed from this thick ascending limb of LOH. At this segment of renal tubule the reabsorption of Ca^{2+} is controlled by PTH (parathyroid hormone). The fluid leaving the thick ascending limb of LOH is hypotonic whose osmolality varies between 100 to 200 m.mol/L. On the otherhand, the interstitium surrounding the tip of LOH is hypertonic. Therefore a couter current multiplier mechanism is established between the tubular fluid in LOH and the interstitium of kidney which increase gradually with the increase of the depth of medulla from cortex. This couter current mechanism includes the collecting tubules, LOH and their capillaries. This LOH accounts for another 15% absorption of glomerular filtrate.

Distal (convoluted) tubules

This portion of the renal tubule lies next to the cortical portion of thick ascending limb of LOH. The tubular cells in this portion are tightly attached with each other and maintains a relative impermeability to both water and Na^+. The distal tubule receives hypo osmolar fluid from the thick ascending portion of LOH and slightly modifies its composition (Fig. 42.7).

This segment has less capacity for Na^+ reabsorption than the segment before it, but

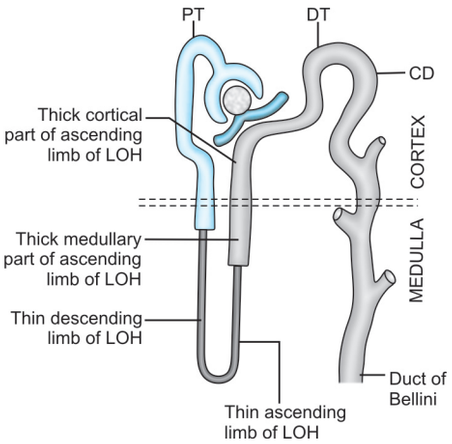

Fig. 42.7: Nephron
PT = Proximal tubule, LOH = Loop of Henle, DT = Distal tubule, CD = Collecting duct

it shows considerable capacity to adapt it in the face of incerased Na^+ load from the earlier part of nephron. This portion of the renal tubule accounts for about 5% reabsorption of glomerular filtrate. This reabsorption include Na^+, K^+, Cl^-, Ca^{2+} etc. Like other parts of nephron the reabsorption of Na^+ in this part is also associated with Na^+-K^+-ATPase activity on the capillary side of the tubular cells. But on the luminal side of te tubular cells Na^+ is absorbed from the lumen by the concentration gradient created by the absorption of it in the capillary blood by Na^+ - K^+ ATPase system, and Cl^- is reabsorbed by the Na^+- Cl^- cotransporter system. Na^+ reabsorption in this segment is directly proportional to the amount of Na^+ delivered in this part of tubule from the LOH. In this portion of renal tubule the reabsorption of Na^+ and Ca^{2+} is controlled by aldosterone and parathyroid hormone (PTH), respectively (Fact file - III).

Collecting tubule (CT) or duct

This portion of the renal tubule also can be divided into cortical and medullary portion which normally accounts for the reabsorption of last 13 to 13.5% of glomerular filtrate, and finally form and modify the composition of urine.

The cortical portion of CT has two types of cells – principal cells (P cells) and intercalated cells (I cells). The P cells primarily reabsorb Na^+ and secret K^+ with the help of aldosterone, whereas I cells are responsible for the acid-base regulations. Aldosterone enhances the Na^+-K^+-ATPase activity on the capillary end of the P cells in this part of nephron and increase the active reabsorption of Na^+ at the capillary side and passive reabsorption of it at the luminal side of tubular cell with subsequent indirect secretion of K^+ in the tubular lumen. Aldosterone also enhances the H^+ secreting ATPase acitivity on the luminal border of I cells and increases the secretion of H^+. Unlike PT, secretion of H^+ in this part of renal tubule is independent of reabsorption of Na^+. Because in this part of renal tubule most of the H^+ is secreted actively by an ATPase driven proton pump, where aldosterone acts and increases or decreases its secretion. So, hyperaldosteronism is associated with alkalosis. These I cells are like the parietal cells of stomach and contains abundant carbonic anhydrase (CA) enzyme which also helps in the formation of H^+. These I cells additionally also have a luminal H^+-K^+-ATPase pump which secretes H^+ in the exchange of absorption of K^+. As these I cells help in the regulation of acid base balance, they also have anion exchange protein (such as Cl^--HCO_3^- exchanger) which are capable of preventing the reabsorption of HCO_3^- in exchange of Cl^- in response to large alkaline loads. With Cl^- the Na^+ and water is also absorbed, but the absorption of water is in excess than Na^+ and makes the tubular fluid from hypoosmolar to iso-osmolar (Fig. 42.8).

FACT FILE - III

Reabsorption and excretion of HCO_3^- :
The amount of reabsorption and secretion of HCO_3^- is proportional to the amount of filtration in Bowman's capsule and the acid-base status of the individual. The concentration of HCO_3^- in the plasma and consequently in the glomerular filtrate is normally about 24 m.mol/L. The process of reabsorption of HCO_3^- does not involve any direct transport system in the tubular cells. Because HCO_3^- is not permeable to cell membrane. For absorption of HCO_3^- most of the secreted H^+ reacts with HCO_3^- to form H_2CO_3. Then this H_2CO_3 breaks down to form CO_2 and H_2O. In most of the tubular cells (except the distal tubule and collecting tubule) there is presence of carbonic anhydrase (CA) in luminal border. Thus this CA facilitates the formation of CO_2 and H_2O. Then the CO_2 as it diffuses readily across all the biological cell membrane and so enters the tubular cells. In the cell, CO_2 again reacts with H_2O to form H_2CO_3 which further breaks down to yield HCO_3^- and H^+. Then this HCO_3^- passes to the blood and H^+ goes to the lumen. This is the mechanism by which HCO_3^- is absorbed. For each mole of HCO_3^- removed from the tubular fluid, one mole of HCO_3^- diffuses from the tubular cells into the blood but these two HCO_3^- ions are not the same.
In acidosis, when the plasma HCO_3^- concentration is low, then all the filtered HCO_3^- is reabsorbed through tubule by the use of secreted H^+ ion. The excess of H^+ ion after neutralisation of HCO_3^- is excreted through urine and the urine becomes acidic. The excess of H^+ also react with NH_3 and form NH_4^+ which is excreted through urine. But, in alkalosis when the plasma HCO_3^- concentration is high above the normal level, then some filtered HCO_3^- appears in the urine after neutralisation of all the H^+ and the urine becomes alkaline. The normal HCO_3^- level in plasma is 24 to 27 m.mol/L.

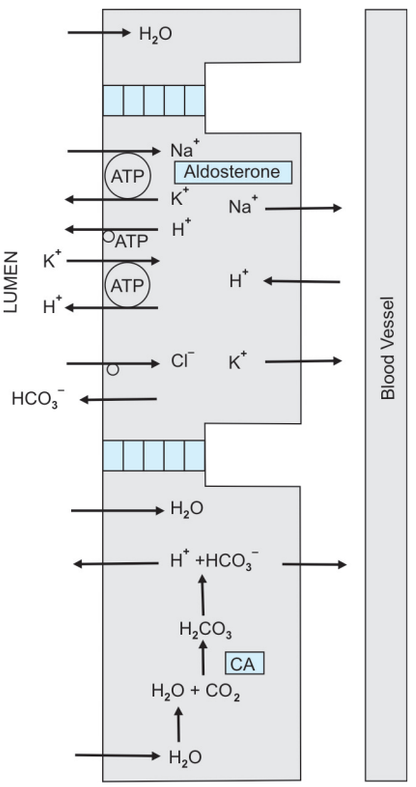

Fig. 42.8: Mechanism of secretion and reabsorption of the cortical portion of collecting tubule (CT)

The medullary portion of CT runs down through the hypertonic interstitium of medulla and joins with other CT to form the duct of Bellini which empties at the tip of the pyramid. This medullary portion of CT is the principal site of action of ADH or arginine vasopressin (AVP). Therefore, permeability of water in this portion of CT is entirely dependent on the presence of ADH. This ADH acts through V receptors which are situated on the special water channel called aquaporin 2. These V receptors are also responsible for increase the vascular resistance. Dehydration increases ADH secretion and increases the permeability of luminal surface of this portion of CT to water. As a result more and more water is reabsorbed and concentrated urine is formed whose osmolality varies upto 1400 m.osm/L. On the Contrary, proper hydration inhibits the secretion of ADH and permeability of this portion of CT to water is lost. This results in non absorption of water and diluted urine whose osmolality varies between 100 to 200 m.osm/L. In the absence of ADH (diabetes insipidus) the osmolality of urine may come down to 30 m.osm/L. This medullary portion of CT also contains P and I cells. Like cortical portion P cells here also regulate the reabsorption of Na^+ by the help of aldosterone and I cells regulate the acid base balance by secreting H^+ in the form of titrable acids of phosphates ($H_2PO_4^-$) and ammonium ions (NH_4^+).

Urea contributes to the establishment of osmotic gradient in the medullary interstitial tissues. Thus, it helps to form a concentrated urine in the collecting duct. The mechanism is like that the fluid entering the distal tubule is hypoosmolal (100 m.osm/L). In the collecting tubule the osmolality of the tubular fluid returns to that of plasma (300 m.osm/L) due to absorption of water by ADH. But unlike the contents of PT, the solute component of DT largely consist of urea, creatinine and other excreted compounds. In the presence of ADH water moves out of the CT and the tubular fluid becomes hypertonic and the urea becomes highly concentrated. In the presence of ADH, the innermost part of medullary CT becomes permeable to urea also. Thus, urea then diffuses out deeply into the medullary interstitium and subsequently the amount of urea in the urine varies with the amount of urea filtered. This in turn varies with the dietary intake of protein. Therefore, high protein diet increases the ability of the kidney to concentrate the urine (Table 42.1).

Table 42.1: Functional divisions of nephron

A. Glomerulus	:	Ultrafiltration
B. Proximal tubule		
Absorption	:	Water, sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphates, urea, uric acid, glucose, protein, amino acid
Secretion	:	Ammonia products, some anions and cations
C. Loop of Henle		
Absorption	:	Water, sodium, potassium, chloride, calcium, magnesium.
Secretion	:	Nil
D. Distal tubule		
Absorption	:	Water, sodium, potasium, chloride, bicarbonate, calcium.
Secretion	:	Hydrogen ion, potassium, calcium.
E. Collecting duct		
Absorption	:	Water, sodium, potassium, chloride, bicarbonate.
Secretion	:	Hydrogen ion, potassium, ammonia products.
F. Juxtaglomerular apparatus	:	Secretion of renin

Juxtaglomerular apparatus or complex (JGA)

The renal tubule after making a sharp bend at the loop of Henle ascends upwards and reaches again near to its mother glomerulus from which the renal tubule arises. Here, the renal tubule rests between its afferent and efferent arterioles, forming juxta glomerulus apparatus. Thus, the JGA is formed by the afferent arteriole, efferent arteriole, renal tubule (thick ascending limb of LOH or distal tubule) and the intervening tissue resting between them. In this junction or JGA, the smooth muscle cells of afferent arterioles are modified and called the juxtaglomerular (JG) cells. The epithelial cells of renal tubule in this junction are also modified and are called the macula densa cells. The specialised mesangial cells, entangled between the afferent arteriole, efferent arteriole and renal tubules also takes part in the formation of JGA and are called the Lacis cells. Thus, the JGA is consisted of: granular juxtaglomerular cells of afferent arteriole, macula densa cells of thick ascending limb of LOH or distal tubule, and agranular interstitial cells of Lacis. The JGA is thought to be related with some way in control of circulating blood volume, BP, renal blood flow, salt balance, and erythropoiesis (Fig. 42.9).

The JG cells are deeply innervated by the sympathetic nervous system and contain baroreceptors. This responds to the changes of pressure of afferent arteriole and regulate the blood flow through glomerulus and subsequently GFR. These JG cells also contain an enzyme, named renin. The secretion of this renin is determined by the degree of stretching of the afferent arteriole, Na^+ concentration of macula densa cells and β-adrenergic stimulation. After the release of renin in response to hypotension, it acts on a special circulating protein in the blood stream, named angiotensinogen

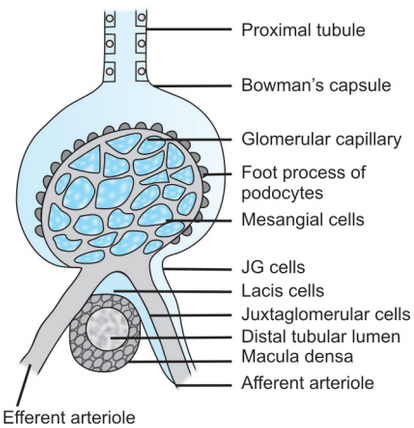

Fig. 42.9: Juxtaglomerular apparatus

which is synthesized by the liver. By the action of renin, angiotensinogen is converted to inert angiotensin I (decapeptide) which is then rapidly converted to angiotensin II (octapeptide) in the lungs by the angiotensin converting enzyme (ACE). This angiotensin II plays a major role in the secretion of aldosterone, control of BP, blood flow in the kidney and formation of volume of urine. Angiotensin II is also formed locally in the kidney and there is the presence of angotensin II receptors which controls the absorption of Na^+ through renal tubules other than aldosterone. Except kidneys and lungs there are also other extrarenal sites where renin and angiotensin II are synthesized locally. These are vascular endothelium, brain tissue and adrenal gland. Angiotensin II modulates the tone of afferent and efferent arterioles and subsequently maintain the GFR. It is also known that under hypoxic state or following haemorrhage, a hormone named erythropoietin is formed in the blood by the interaction of renal erythropoietin factor (REF) with the plasma globulin. This erythropoietin stimutes the process of erythropoiesis. This REF is secreted by JG cells.

The cells of macula densa appear to have chemoreceptor function. It senses the concentration of NaCl in the tubular lumen of thick ascending limb of LOH or distal tubule and regulate the secretion of aldosterone from adrenal gland which in turn regulate the reabsorption of Na^+. The function of Lacis cells is still unknown. (Fact files- IV, V, VI, and VII)

RENAL CIRCULATION OR BLOOD FLOW (RBF)

Both the kidneys receive 20 to 25% of the total cardiac output as their blood supply. This results in total 1 to 1.5 L/min of blood flow through both the kidneys. There is much discrepancy regarding the flow of blood, delivery of O_2 and the consumption of O_2 between the renal cortex and medulla. Approximately, 80% of the total blood flow of each kidney goes to the cortical nephron in superficial cortex and only 15% reach the juxtamedullary nephron in juxtamedullary cortex. The medulla receives only the remaining 5% of the total renal blood flow. The average O_2 tension in medulla is about 10 to 15 mm of Hg. Whereas the O_2 tension in renal cortex is 50 mm of Hg. This indicates that renal cortex has high blood flow, but extracts little O_2 than medulla. This is because cortex is metabolically less active than medulla as it is concerned mainly for filtration function. Whereas, the renal medulla is metabolically more active than cortex as it is mainly concerned for reabsorption of more solute and water to maintain high osmotic gradient of interstitium and to concentrate the urine respectively (Table 42.2).

Table 42.2: Distribution of RBF between the medulla and cortex

	Medulla	*Cortex*
Blood flow (ml/min/gm)	0.05	5
% of RBF	5	95
PO_2 (mm of Hg)	10	50
O_2 extraction ratio	0.8	0·2

FACT FILE- IV

Excretion of water through urine:

Every day normally about 150 to 180 L of fluid is ultra-filtered through all the glomeruli of both the kidneys. But the average daily urine formation varies between 1 to 1.5 L. In adverse situation this volume of urine may come down to 500 ml or may go upto 23 L (diabetes insipidus). On the other hand the same load of solute is excreted in 24 hours within this varying volume of urine with the varying osmolality which varies from 1400 m.osm/L to 30 m.osm/L. Normally among this ultra-filtrate, 87% of water is reabsorbed mandatarily. The reabsorption of remaining 23% varies without affecting the excretion of total solute. When the urine is concentrated the water is reabsorbed in excess of solute. On the otherhand, when it is diluted water is lost in excess of solute. The key regulator of this water absorption and excretion is ADH (vasopressin) which acts on the collecting duct.

In the PT, water moves out of the tubule along with the osmotic gradient which is set up by the active transport of solutes and thus isotonicity is maintained. Therefore, the tubular fluid passing at the end of PT is isotonic or iso-osmotic. About 65% of the filtered water and 65% of the filtered solute is absorbed in the PT. In the thin descending and ascending limb of LOH, there is no system of pump for active transport of Na^+. The thin descending limb of LOH is permeable to water, whereas the thin ascending limb of LOH is permeable to Na^+only. On the other hand, there is graded increase in the osmolality of interstitium of renal medulla from outer cortex to the tip of pyramid. Therefore, the fluid flowing down the descending limb of LOH gradually becomes hypertonic as water moves out of this part of renal tubule into the hypertonic interstitium. Then this hypertonic fluid gradually becomes hypotonic as it flows up the thin ascending limb of LOH, because in this portion only Na^+ moves out, leaving water in the tubule.

In the thick ascending part of the limb of LOH active Na^+ transport system is present and is also impermeable to water. Therefore, fluid passing up the thick ascending limb of LOH gradually becomes more dilute and when it reaches the top it becomes maximum hypotonic in relation to plasma. During passing through loop of Henle (LOH), 15% of filtered water is removed. So, approximately next 20% of the filtered water enters the distal tubule (DT). DT is less permeable to water, but more permeable to solutes. So, continuous removal of solute in excess of water from DT further dilutes the fluid in this segment of nephron. 5% of filtered water is removed in this segment.

The collecting duct (CD) has two portion - cortical and medullary. The cortical portion of the CD receives hypotonic fluid from DT. Vasopressin or ADH secreting from the posterior pituitary acts on this portion of renal tubule i.e. CD. In the presence of enough vasopressin maximum antidiuretics occurs. Therefore, maximum amount of water moves out of hypotonic fluid in cortical portion of collecting duct and enters into the interstitium of cortex. Thus here the tubular fluid becomes isotonic. In this fashion 10% of filtered fluid is removed in the cortical portion of CD. Next, isotonic fluid enters the medullary portion of CD. Here, additional 3.5% or more of the filtrate is reabsorbed in the hypertonic interstitium of medulla and produce concentrated urine. In human being, the osmolality of urine may reach 1400m.osm/L which is 5 times greater than that of plasma with total 99.5% of filtered water being absorbed.

In the absence of ADH or vasopressin (AVP), CD is impermeable to water. The fluid in CD, therefore, remains hypotonic and large amount of tubular fluid flow into the renal pelvis. In human being in such circumstances, the urine osmolality may be as low as 30 m.osm/L.

FACT FILE - V

Excretion of H^+ and acidification of urine :

The cells of the proximal tubule, thick ascending limb of LOH, distal tubule and the collecting duct secrete H^+, like the cells of gastric gland. This secretion of H^+ primarily involves the Na^+-H^+ antiporter system situated on the luminal side of cell membrane of the tubular cells. This Na^+-H^+ antiporter system acts as secondary to Na^+-K^+ ATPase system on the capillary end of tubular cells which lowers the intracellular Na^+ concentration and subsequent entry of Na^+ from the tubular lumen coupled with extrusion of H^+. This H^+ comes from the intracellular dissociation of H_2CO_3 which is formed by the reaction of CO_2 and H_2O. The HCO_3^- formed from dissociation of H_2CO_3 diffuses back into the interstitial fluid. Thus for each H^+ secreted one Na^+ and one HCO_3^- enter the interstitial fluid and is preserved in body.

In respiratory acidosis, there is more CO_2 in the body, which produces more H_2CO_3, and more H^+ and HCO_3^-. This means more H^+ is excreted through urine and urine becomes acidic. The excess HCO_3^- produced from excess CO_2 is preserved in body and produce compensatory metabolic alkalosis. In respiratory alkalosis the reverse is occurred. There is less CO_2 due to more washout through lungs. This leads to less H_2CO_3 and subsequently less H^+ and HCO_3^- which leads to less excretion of H^+ and urine becomes alkaline (metabolic acidosis). In metabolic acidosis there is more formation of H^+ in the body. So, there is more excretion of H^+ through urine and urine becomes acidic. Subsequently, due to more H^+ there is more consumption of HCO_3^- and more formation of CO_2 and H_2O. This excess CO_2 is excreted through lungs (compensatory metabolic alkalosis). on the contrary, in metabolic alkalosis (e.g. vomiting) the reverse is occurred. There is less H^+ or more HCO_3^- in the body. Therefore, the body tries to preserve the H^+ and less excretion of it. Thus, urine becomes alkaline. Due to less H^+ there is less consumption of HCO_3^- and less formation of CO_2. This causes less excretion of CO_2 through lungs (compensatory respiratory acidosis).

The amount of H^+ secreted in the tubular fluid depends upon the pH of it. If the pH of tubular fluid is 4.5 i.e. an H^+concentration in it is 1000 times more than plasma, then secretion of H^+ stops. Thus, the pH of urine which goes upto maximum is 4.5. This is normally reached in the collecting ducts. If there is no buffer in the renal tubules which neutralise the H^+, then pH will rise rapidly and the secretion of H^+ will stop. There are three important buffer in tubular fluid which remove the free H^+ and permits more H^+ to be secreted. These are HCO_3^- forming CO_2 and H_2O, HPO_4^{2-} forming $H_2PO_4^-$ and NH_3 forming NH_4^+. Among these HCO_3^- is most important which maximum neutralises the H^+. This is because the concentration of HCO_3^- in plasma and subsequently in glomerular filtrate is normally about 24 mEq/L, whereas that of phosphate is only 1.5 mEq/L. The secreted H^+ reacts with diabasic phosphate (HPO_4^{2-}) to form monobasic phosphate ($H_2PO_4^-$). This happens to the greatest extent in the distal tubules and collecting ducts. Because it is here that the phosphate which escapes proximal reabsorption is greatly concentrated by the reabsorption of water. The reaction of H^+ and NH_3 occurs maximally in the proximal and distal tubules.

Each H^+ that reacts with the above mentioned buffer such as $H_2PO_4^-$ and NH_3 constitutes or called the titrable acidity of urine. Because this is measured by determining the amount of alkali which is needed to change the urinary pH to 7.4 which is the pH of glomerular filtrate or plasma. But it does not measure the HCO_3^- part, because it is converted to CO_2 and H_2O. It measures the other two fractions of acid secreted.

FACT FILE - VI

Secretion of ammonia:

Multiple reactions in the renal tubular cells produce NH_4^+. Among these the principal reaction is conversion of glutamine to glutamate with one molecule of NH_4^+. This reaction is catalysed by glutaminase which is abundant in renal tubular cells. Glutamate is again converted to α-ketoglutamate by the help of enzyme glutamic dehydrogenase, when more NH_4^+ is produced. Subsequently, metabolism of α-ketoglutamate utilises $2H^+$ and makes free $2HCO_3^-$. In the tubular cells NH_4^+ remains in equilibrium with NH_3 and H^+. pK value of this equilibrium is 9. So in acidosis this equilibrium shifts towards NH_3 and therefore more NH_3 is produced from NH_4^+. Then this NH_3 enters the tubular fluid, because NH_3 is lipid soluble and diffuses across the cell membrane down its concentration gradient. In the tubular fluid it reacts with H^+ and form NH_4^+ which remains in the urine. Thus, excretion of NH_4^+ causes further removal of H^+ from tubular fluid and consequently further enhancement of secretion of H^+.

$$\text{Glutamine} \xrightarrow{\text{Glutaminase}} \text{Glutamate} + NH_4^+$$

$$\text{Glutamate} \xrightarrow[\text{dehydrogenase}]{\text{Glutamic}} \alpha\text{-ketoglutamate} + NH_4^+$$

$$NH_4^+ \rightleftharpoons NH_3 + H^+$$

FACT FILE - VII

The medullary concentration of solutes and osmolality (1400 m.osm/L) is very high. This is because (i) the ascending limb of loop of Henle (LOH) actively reabsorbs Na^+ and Cl^-, but not water into the interstitium of medulla and (ii) large amount of urea enter the deeper part of medulla from the collecting duct. This is because the cortical and the outer medullary part of the collecting duct are the sites of passive diffusion of water, but impermeable to urea. So, the urea gradually becomes concentrated in the collecting duct of deeper medulla, which is permeable to it and moves passively down its concentration gradient. Again the high concentration of urea, Na^+ and Cl^- in the deeper medulla are not washed out, because blood flow in this portion (medulla) is low and the configuration of capillaries (vasa recta) allows countercurrent exchange. Thus all these factors cause the gradual increase of tonicity from outer cortex to medulla.

On the contrary, the renal medulla has little blood flow (to maintain osmotic gradient) and extracts large amount of O_2 (due to high metabolic acitivity) than cortex. Therefore, severe hypoxia and necrosis could develop first in the medulla, sparing the cortex during compromised circulation. Thus, in conclusion we can say that kidney is such an organ where O_2 consumption is primarily determined by the blood flow, but not by the metabolic activity or O_2 demand. Whereas, in other organs the blood flow is primarily determined by the O_2 demand and the subsequent consumption of it by this tissue which again depends on its metabolic activity. In adverse condition the sympathoadrenal response tries to redistribute the flow of blood from the cortex to the medullary area by cortical vasoconstriction, mediated by the increased level of catecholamines and angiotensin II.

When the mean systemic arterial pressure (MAP) is 100 mm of Hg, then the glomerular capillary pressure at the afferent arteriole is about 40 mm of Hg. This pressure further drops to only 1 to 2 mm of Hg at the efferent end of arteriole after the blood flows through the glomerular capillaries. Then, it drops much at the peritubular capillaries and comes down to about

10 mm of Hg. Therefore, the glomerular capillary pressure gradient which is similar to the pressure of afferent arteriole is about 40% of the mean systemic blood pressure.

Regulation of Renal Blood Flow (RBF)

The renal blood flow is regulated by some very complex mechanisms which are interplayed by several factors such as autoregulation (intrinsic), tuboglomerular feed back (reflex), hormones and nerves.

Intrinsic autoregulation of RBF

The RBF usually remain autoregulated between the mean systemic arterial pressure of 80 to 200 mm of Hg. This is due to the changes in renal vascular resistance in response to the changes of pressure within this value and keeps the RBF relatively constant. This type of autoregulation is also seen in other organs such as brain, liver, heart, etc., and several factors contribute to it. This autoregulation is also present in denervated, isolated, perfused and transplanted kidney, but it can be prevented by administration of drugs which paralyses the vascular smooth muscles. Thus, it indicates that this autoregulation is an intrinsic myogenic response of afferent arterioles (vasoconstriction and dilatation) to the changes in blood pressure which keeps the RBF constant. This intrinsic myogenic response to regulate the RBF is nothing but the direct contractile response of the smooth muscles of the afferent arteriole to stretch, mediated by the baroreceptors. Nitric oxide (NO) may also be involved in this intrinsic autoregulation of RBF. The RBF is generally decreased or autoregulation fails when the MAP falls below the 80 mm of Hg. Outside this limit the autoregulation of RBF becomes pressure dependent i.e. when the pressure increases, RBF decreases and vice versa. Glomerular capillary pressure and subsequently the filtration pressure gradient comes down to zero and filtration ceases when the MAP falls to 40 to 50 mm of Hg (Fact file - VIII).

FACT FILE - VIII

The release of renin from juxtaglomerular apparatus is controlled by several mechanisms. A reduction in renal artery perfusion pressure stimulate the baroreceptors in afferent arterioles. Then, subsequent stimulation of sympathetic nerve and increasd circulating catecholamines act on α and β adrenergic receptors on the afferent arteriole which produces vasoconstriction and simultaneously causes release of renin. The cells of medulla densa also sense the increased concentration of Na^+ in the tubular fluid and triggers the release of renin from the afferent arteriole in hypotension. Thus, this tubuloglomerular reflex appears to play a role in modulating GFR, during normal and abnormal renal function through feed back loop. Hence, renin secretion is stimulated by actual hypovolaemia (haemorrhage, duresis, Na^+ loss etc.) and relative hypovolaemia or decreased perfusion (heart failure, IPPV, sepsis etc.).

Regulation by tubuloglomerular feedback mechanism

This tubuloglomerular feedback reflex is very important to maintain the renal circulation and subsequently the GFR, over a wide range of variation of perfusion pressure. Although, the mechanism of this reflex is very poorly understood, but still the macula densa cell is thought to be responsible for controlling this reflex by changing the tone of afferent arteriole and subsequently the RBF with pressure gradient of glomerular capillary. This tubuloglomerular reflex is nothing but the changes of RBF and GFR with the changes of flow of fluid through the renal tubules, mainly the thick ascending limb of LOH and distal tubule. Increase in tubular flow through the thick ascending limb of LOH or DT reduces the RBF and GFR, whereas decrease in tubular flow increase the RBF and GFR. Thus, it is completely a compensatory mechanism.

During hypotension when the thick ascending limb of LOH becomes ischaemic, then reabsorption of NaCl through this part of renal tubule ceases and delivery of NaCl to macula densa cells is increased. This causes increased release of renin and angiotensin II from afferent arteriole and triggers the arteriolar constriction and decreased GFR. During overhydration the reverse occurs. Thus, the tubuloglomerular reflex mechanism induces the oliguria, conserve intravascular volume and protects the organism from dehydration. Another probable mechanism of tubuloglomerular reflex is local release of adenosine. It inhibits the release of renin and dilate the afferent glomerular arteriole. In dehydration the release of adenosin is inhibited and the secretion of renin is increased which causes constriction of afferent arteriole and decrease of GFR. In overhydration the opposite occurs and GFR is increased.

Hormonal regulation

For this type of autoregulation two important hormones, named renin and angiotensin II come into play for action. During any circumstances such as in hypotension, surgical stress, trauma, severe sepsis, etc.; there is stimulation of sympathetic system and secretion of these two hormones (first renin and then conversion of renin to angiotensin) which causes the afferent arteriolar constriction and reduces the RBF with reduction of GFR. Thus, they preserve the ECF volume. Both the afferent and efferent arterioles are constricted, but as because the efferent arterioles are smaller, so its resistance becomes greater than that of the afferent arterioles and minimum GFR, therefore, tends to be preserved. This autoregulation can also be carried out by adrenal catecholamines such as epinephrine, norepinephrine and by aldosterone. Angiotensin induced secretion of vasoconstrictive prostaglandin F_2 is also responsible for this autoregulation. Inhibition of synthesis of PGF_2 by NSAID can thus block this autoregulation (Fact file-IX).

Renal synthesis of some vasodilating prostaglandins such as PGE_2, PGI_2, etc. is also an important protective mechanism during the period of systemic hypotension and renal ischaemia. Another local hormone, named ANP (arterial natriuretic peptide) is secreted from the arterial

FACT FILE- IX

Two mutually dependent but opposing neuro hormonal system is present in the kidney which control the BP, intravascular volume and concentration of salt with water homeostasis, by a complex set of interactions. Among these the renin - angiotensin II - aldosterone - ADH system acts against the hypovolaemia and hypotensin by promoting vasoconstriction (renin and angiotensin) and salt and water retention (aldosterone and ADH). On the otherhand, the another system including bradykinins, some prostaglandins and ANP protect against hypervolaemia and hypertension by producing vasodilatation and excretion of salt and water.

myocytes. It is a direct smooth muscle dilator and antagonise the vasoconstrictive action of epinephrine, norepinephrine and angiotensin II. It preferentially constricts the efferent arterioles and dilates the afferent arterioles. It, thus, effectively increases the GFR and protects the kidney during hypotension. ANP also inhibits the release of aldosterone, induced by renin and angiotensin II and its (aldosterone) action on renal tubules (Fig. 42.10).

Neuronal regulation

Sympathetic system innervates the juxtaglomerular cells through β_1-receptors. It also innervates the general renal vasculature with afferent and efferent arterioles through the α_1 and α_2-receptors. Both these receptors mediate vasoconstriction and is responsible for the stress induced reduction in GFR. The action of sympathetic nerves on juxtaglomerular cells is also mediated by the β_1-receptors and causes increased secretion of renin. The proximal and distal tubules and the thick ascending limb of LOH are thickly innervated by sympathetic nerves. Here, α_1-receptor is responsible for reabsorption of Na^+ in proximal tubules. Whereas, α_2-receptors inhibits the reabsorption of Na^+ and promotes the excretion of H_2O. There is also D_1 and D_2 receptor in kidney. Activation of D_1 receptor directly dilates the afferent arterioles. Whereas, the activation of D_2 receptors, situated on the presynaptic membrane of postganglionic neurone inhibit the release of norepinephrine and indirectly dilates the afferent arterioles. Thus, dopamine (acting on both D_1 and D_2 receptors) and fenoldepam (acting only on D_1 receptor) cause the dilatation of afferent glomerular arteriole and increases the GFR (Fact file- X).

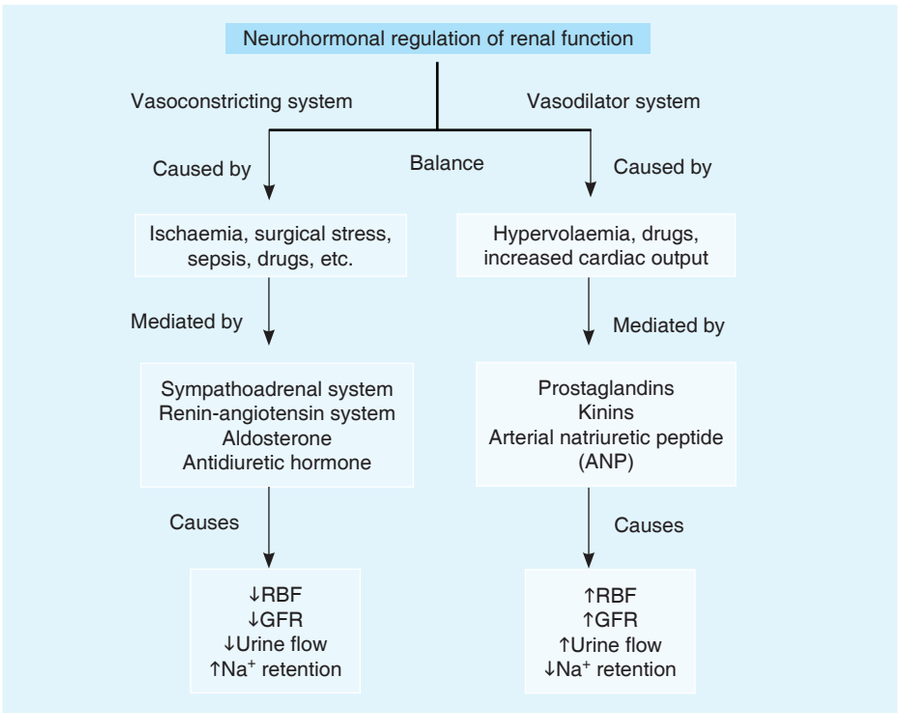

Fig. 42.10: Neurohormonal regulation of renal function

Measurement of RBF

Renal blood flow can be measured by indicator dilution technique, radiolabeled tracers, doppler USG, electromagnetic procedure, or by some other types of flowmeter. It can also be measured by applying the Fick principle. For Fick principle, a nontoxic substance which is completely cleared by the kidney and not metabolised or stored or produced by body or kidney and does not itself affect the RBF is used. By Fick method, first renal plasma flow (RPF) is measured, and then from it renal blood flow (RBF) is calculated. This is because the kidney ultra-filters the plasma and RPF is equal to the amount of substance excreted per unit of time divided by the renal arteriovenous concentration difference of that substance. Therefore, the RPF = UV/A − RV. Here, U is the urinary concentration of substance which is used to measure the RBF, V is the urinary flow rate, A is the arterial plasma concentration of that substance and

FACT FILE - X

Mild adrenergic stimulation (initial stage of humoral and neural autoregulation) causes activation of α-receptor and produce only preferential glomerular efferent arteriolar constriction. This preserves the filtration fraction and GFR, still in the face of hypotension and decreased RBF. This α-adrenergic stimulation occurs through renin-angiotensin system. Therefore, the importance of this protective mechanism is lost and GFR is reduced if ACE inhibitor is used in patients with hypotension, renal insufficiency and renal artery stenosis. Contrary, severe α-adrenergic stimulation (late stage of hormonal and neural autoregulation) causes predominant constriction of afferent arteriole and decreases GFR with RBF. This can be opposed by α-adrenergic blockade.

RV is the renal venous plasma concentration of that substance.

RPF is measured by using PAH (para amino hippuric acid) through IV route. PAH is used to measure RPF, because it is physiologically inert, nontoxic, filtered completely at the glomerulus, secreted through renal tubule, and eliminated completely from the plasma by single passage through kidney. When PAH is infused at low doses, 90% of it is removed by a single circulation through kidney. It is, therefore, become easy to calculate the RPF by dividing the amount of PAH in urine by the plasma PAH level, ignoring its level in renal venous blood. Peripheral venous plasma can be used for plasma PAH level, because its (PAH) concentration is essentially identical to that in arterial plasma, reaching the kidney. Thus, the value obtained is called the effective renal plasma flow (ERPF) which does not need to measure the renal venous plasma PAH level. Therefore, ERPF = UV/P_{PAH}, where P_{PAH} is plasma PAH level. This also indicates the clearance of PAH like the clearance of insulin and creatine. In human, the average ERPF value is 700 ml/min.

Example:

Urinary concentration of PAH (U) is 14.4 mg/ml
Urine output (V) is 1 ml/minute
Plasma concentration of PAH is 0.02 mg/ml
Therefore, ERPF = 14.4 × 1/0.02 = 720 ml/min
This ERPF can be converted to actual RPF
This can be done by: ERPF / excretion ratio of PAH = 720 / 0.9 (excretion ratio of PAH is 0.9) = 800 ml/minute
Therefore, the actual RPF = 800 ml/minute
RBF is calculated from RPF from the following formula:
RBF = RPF ÷ (1 − Haematocrit value)
= 800 ÷ (1 − 0.45) [Normal haematocrit value is 45%]
= 800 ÷ 0.55
= 1454.5 ml/minute

Therefore, renal blood flow (RBF) is 1454.5 ml/minute.

GLOMERULAR FILTRATION

Usually, both the kidney receive total blood flow of 1.2 to 1.3 L/min which is about 25% of the total cardiac output. But, out of this only 125 ml/min or 7.5 L/hour or 180 L/day of fluid is filtered by the glomerulus and only 1 to 2 L/day of urine is formed. Therefore, 99% or more of glomerular filtrate is reabsorbed in renal tubules. It is estimated that to clear the nitrogenous waste products, produced during metabolism throughout the whole day, at least 400 to 500 ml of urine per day is required to be formed mandatorily. For reabsorption of glomerular filtrate in renal tubules the counter current multiplier exchanger system is a critical component which help the kidney's ability to excrete or conserve the salt and water. The Na^+ and water reabsorption by kidney depend on the hypertonicity of the medullary interstitium which again depends on the maintenance of normal renal blood flow. The major hormonal influences determining the conservation or loss of filtered Na^+ and water are aldosterone, ADH, ANP and the renal prostaglandin. At the filtration rate of 125 ml/min, the kidney filter an amount of fluid which is 4 times of the total body water, 15 times of the ECF volume and 60 times of the plasma volume per day.

Like the capillary of other parts of body, the filtration in glomerular capillary is also governed by four forces opposing to each other. These four forces are: glomerular capillary hydrostatic pressure (C_H), glomerular capillary oncotic pressure (C_{ON}), hydrostatic pressure in Bowman's capsule (B_H) and oncotic pressure in Bowman's capsule (B_{ON}). Therefore, the effective glomerular filtration pressure is: $(C_H - B_H) - (C_{ON} - B_{ON})$ and GFR = $K_f [(C_H - B_H) - (C_{ON} - B_{ON})]$, where K_f is the glomerular ultrafiltration coefficient. The K_f depends mainly on 4 factors. These factors are the permeability of glomerular capillary, charge of the filtrate substances, size of the filtration pore and size of the capillary bed. Therefore, GFR depends upon on these above mentioned factors which determine the filtration coefficient and the hydrostatic and oncotic pressure of the glomerular capillary and Bowman's capsular fluid (Table 42.3).

Capillary permeability is different at the different parts of our body. Permeability of glomerular capillary is 40 to 50 times more than that of the skeletal muscle. Substances with molecular diameter of smaller than 4 nm are freely filtered out through the glomerular capillary. Whereas substances with molecular diameter of greater than 8 nm are not at all filtered out. Therefore, filtration of substances with molecular diameter between 4 to 8 nm is inversely proportional to their molecular size.

GFR also depends on the charge of the filtered substances. Glomerular capillary itself is negatively charged and it is due to the presence of sialoprotein (a special type of protein). So, the –ve charge of the capillary bed repel the –ve charged

Table 42.3: Factors affecting the GFR

A.	**Changes in hydrostatic pressure of glomerular capillary**
	Changes in systemic blood pressure
	Contraction of afferent or efferent arteriole
B.	**Changes in oncotic pressure of glomerular capillary**
	Hypoprotinaemia
	Dehydration
C.	**Changes in hydrostatic pressure of Bowman's capsule**
	Obstruction in urinary passage
D.	**Changes in oncotic pressure of Bowman's capsule**
	Oncotic pressure in Bowman's capsule is negligible as the ultrafiltrate does not contain any protein or very minimum amount.
E.	**Changes in permeability coefficient**
	Changes in surface area for effective filtration
	Changes in permeability of glomerular capillary
F.	**Changes in renal blood flow**

substances in blood and reduces their filtration. Hence, filtration of −ve charged substances of 4 nm molecular diameter is more or less half than that of neutral charged substances of the same molecular diameter. On the contrary, filtration of the +ve charged substance of 7 nm molecular diameter is greater than the neutral and −ve charged substances of the same molecular diameter. This probably explains why the normally −ve charged albumin with molecular diameter of 6 to 7 nm has concentration in glomerular filtrate of only 0.1 to 0.2% of its plasma concentration. This is far less than the expected higher concentration in glomerular filtrate calculated on the basis of the molecular diameter alone. The total amount of protein in the urine is usually less than 100 mg/day. However, most of this is not filtered, but comes from the shed tubular cells. In nephritis the −ve charge of the glomerular capillary bed is lost and then albuminuria can occur without any increase in the size of the pores of the filtration membrane.

The sizes of the pores on the filtration membrane of capillary bed depend on the contraction of mesangial cell. The increase in contraction of these mesangial cells decrease the size of the pores and K_f. Many agents such as angiotensin II, epinephrine, norepinephrine, vasopressin, thromboxane A_2, PGF_2, leukotrines, etc., also induce contraction of the mesangial cells and decrease filtration. Whereas ANP, dopamine, PGE_2, etc., relax these cells and increase the size of pores with increased filtration.

The hydrostatic and oncotic pressure of the glomerular capillary blood and Bowman's capsular fluid also alter the GFR. Afferent glomerular arterioles are short and arise directly from the interlobular arteries. Further, in the downstream the efferent arterioles also have relatively high resistance. Therefore, the hydrostatic pressure of glomerular capillary is much higher than that of the capillaries inother part of the body. This glomerular capillary hydrostatic pressure which is the main filtration pressure is opposed by the hydrostatic pressure in Bowman's capsule. This is further opposed by the oncotic pressure gradient across the glomerular capillary bed i.e. $C_{ON} - B_{ON}$. Usually B_{ON} is negligible as there is no protein in the capsular filtrate. So, the equation of GFR can be rewritten as:

$$GFR = K_f [(C_H - B_H) - C_{ON}]$$

The net filtration pressure at the afferent end of glomerular capillary is 16 mm of Hg. But it gradually falls to zero and a filtration equilibrium is reached at the effarent end of glomerular capillary. This is due to the gradual leaving of fluid and other solute, except protein from the capillary bed and, therefore, gradual increase in oncotic pressure of capillary blood due to increased concentration of serum protein passes through the glomerular capillary. Due to the autoregulation, change in renal vascular resistance tries to stabilize the filtration pressure. But, when the MAP drops below this autoregulatory range, then GFR falls sharply. The GFR is maintained when the efferent arteriolar constriction is greater than that of the afferent arteriole, but constriction of both the arterioles decrease the GFR (Table 42.4).

Table 42.4: Net filtration pressure at the afferent and effarent end of the glomerular capillary

Net filtration pressure = $C_H - B_H - C_{ON}$
C_H = Hydrostatic pressure in glomerular capillary, B_H = Plasma oncotic pressure in glomerular capillary, C_{ON} = Hydrostatic pressure in Bowman's capsule

	Afferent end (mm of Hg)	*Effarent end (mm of Hg)*
CH	45	44
BH	−10	−10
CON	−25	−34
Net filtration pressure	10	0

Measurement of GFR

The normal value of GFR varies between 120 to 130 ml/minute. It is usualy about 20% of RPF. GFR is usually measured by inulin or creatinine. Creatinine is a break down product of phosphocreatine which normally present in muscle. Whereas inulin is a fructose polysaccharide with molecular weight of 5200. The measurement of GFR by inulin or creatinine is also called inulin or creatinine clearance, respectively. Inulin is completely filtered by glomerular capillary but it is neither secreted, nor reabsorbed by renal tubules. Therefore, the use of inulin gives very accurate result of GFR (or inulin clearance). Whereas, the use of creatinine to measure GFR (creatinine clearance) tends to overestimate the result, because though it is completely filtered but small amount of it is secreted through renal tubule. In addition, determination of plasma creatinine is inaccurate at low creatinine level. This is because the method used to estimate plasma creatinine also measures the small amount of other plasma constituents such as chromogens. In spite of this, creatinine clearance is frequently measured in patients to estimate the GFR accurately. This is because it is more practical, easy and the value matches quite well with the value of GFR, measured by inulin. This is also true, because although $U_{CR} \times V$ is high as a result of tubular secretion, but the value of P_{CR} is also high as a result of nonspecific chromogens. Therefore, the two errors cancel each other. Hence, the measurement of endogenous creatinine clearance is a worthwhile index of renal function. The creatinine clearance (C_{CR}) is measured by the following formula:

$$C_{CR} = U_{CR} \times V / P_{CR}$$

U_{CR} = creatinine concentration in urine, V = urinary flow rate, P_{CR} = creatinine concentration in plasma.

Example

U_{CR} = 35 mg/ml, V = 0.9 ml/minute, P_{CR} = 0.25 mg/ml

Therefore, $C_{CR} = 35 \times 0.9 / 0.25 = 126$ ml/minute

The ratio of GFR to RPF is called the filtration fraction and is usually 20%.

ASSESSMENT OF RENAL FUNCTIONS

Generally the kidney performs three principal functions in the body. These are: (i) excretion of potentially toxic and non-toxic metabolic end products, (ii) regulation of water and electrolyte balance and (iii) production of hormones. Direct assessment of all these renal functions are practically impossible and also simultaneously direct on-line evaluation of these renal functions are limited. Most of the renal functions are, therefore, assessed indirectly. Furthermore, these assessments of renal function are not simple and are very expensive. On the otherhand, the readily available tests fail to accurately reflect the status of kidney in large percentage of patients, especially the elderly, malnourished and dehydrated individuals.

Kidneys perform their functions through glomerulus and renal tubules. So, renal functions are divided into glomerular and tubular functions. But this classification is arbitary, because in any renal diseases both these functions are impaired simultaneously. On the contrary, fortunately any standard test performed for renal functions evaluate both the glomerular and tubular functions. Furthermore, it is also important to remember that most of the renal function tests are insensitive to detect the early renal dysfunction. Therefore, the subsequent serial results are more helpful than a single result (Table 42.5).

Table 42.5: Tests used to evaluate renal function

Glomerular function
Blood urea nitrogen (BUN) [Normal value: 10 - 20 mg/dl]
Plasma creatinine [Normal value: 0.5-1.5 mg/dl]
GFR or creatinine clearance [Normal value: 120 - 130 ml/min
Proteinuria [Normal value: < 100 mg/day]
Renal tubular function
Urine osmolality [Normal value: 30-140 m.Osm/L]
Urine specific gravity [Normal value: 1.003 - 1.030]
Excretion of Na^+ through urine [Normal value: < 40 m.mol/L]
Renal glycosuria
Cellular cast
Urinary lysozyme

The most common tests for renal function are urine analysis, measurement of blood urea nitrogen (BUN) in plasma, estimation of serum creatinine level, creatinine clearance, etc. Many other intravenous tests, urography, renal ultrasound, renal MRI, renal CT and renal biopsy etc. may also be performed to diagnose the renal pathology, responsible for renal dysfunction.

Urine analysis

Information from urine analysis should be interpreted very cautiously to assess the renal function, because there are many flaws. The urine analysis includes: the measurement of urine output, the measurement of urinary osmolality and specific gravity, and the microscopical examination.

The estimation of urine output is an indirect parameter for assessment of renal function. This is because many prerenal factors directly and profoundly affect the urine output without the presence of any renal dysfunction. For example, oliguria due to severe systemic hypotension and subsequently reduced renal perfusion without any renal parenchymal dysfunction or any obstruction at any where on the passage of urine on one hand and polyuria due to central diabetes insipidus without any impairment of renal function on the otherside, make it obvious that urine output does not always specifically reflect the renal function. This is more true intraoperatively when the several other factors such as increased secretion of ADH, aldosterone, catecholamines, angiotensin, etc., due to stress affect decrease the output of urine with normal renal function.

Still, the measurement of urine output as a primary indicator of renal function is important in certain situations, where anuria can develop due to some parenchymal diseases of kidney or due to impaired renal blood flow for any cause that may lead to renal dysfunction. The evidence of formation of urine, regardless of its amount, suggest that there is adequate blood flow to the kidney. The intraoperative oliguria does not always indicate impaired renal function and if is not due to impaired renal function, it does not correlate (if the cause is prerenal) with increased BUN and creatinine level or decreased creatinine clearance. The level of nitrogenous waste in blood depends on its production and its clearance through kidney. On the other hand, the renal clearance depends on renal blood flow and glomerular filtration. In the circumstances of reduced renal blood flow, kidney concentrate the glomerular ultra-filtrate, so that at maximal concentration at least 400 to 500 ml of urine can be excreted which is required to clear the daily obligatory nitrogenous waste (Table 42.6).

Table 42.6: Difference in urinary indices of patients with oliguria due to prerenal, renal and physiological causes

Indices	*Renal causes*	*Prerenal causes*	*Physiological causes*
Urinary osmolality (m.osm/kg)	200-300	> 450	> 700
Urine / plasma osmolality	< 1.5	> 2	> 2.5
Urinary Na^+ concentration (m.mol/L)	> 40	< 20	< 10
Fractional Na^+ excretion (%)	> 1	< 1	< 0.5
Urine and plasma creatinine ratio	< 20	> 40	> 60
Specific gravity of urine	1.010-1.015	> 1.015	> 1.024
Urine and plasma urea ratio	> 3 (rarely > 10)	> 20	> 100

During analysis of urine, the measurement of specific gravity and osmolality of urine are also used as parameter to assess the renal function. This indicates the tubular function only, i.e. concentration capacity. In specific gravity the mass of 1 ml of urine is compared to the mass of 1 ml of distilled water. Whereas, in osmolality the number of osmotically active particles in solution is measured. Usually, the osmolality force governs the movement of fluid throughout the body and also in kidney. Therefore, the measurement of osmolality of urine is more superior than the measurement of specific gravity as a test of renal function. In poor renal perfusion due to reduced circulation (prerenal azotemia), kidneys try to concentrate the urine. Therefore, its osmolality and specific gravity may go up above 500 m.osmol/kg of H_2O and 1.03, respectively. Whereas, in acute tubular necrosis (renal tubular dysfunction) urine osmolality and specific gravity may go below 350 m.osmol/kg of H_2O and 1.01, respectively. Thus, it makes an important guide line to differentiate the causes of low urine output due to renal from prerenal causes. Still, the measurement of osmolality and specific gravity of urine is nonspecific for diagnosis of renal dysfunction. Because there are many other factors which affect the osmolality and specific gravity of urine, other than renal dysfunction. These are the presence of protein, glucose, mannitol, dextrose, antibiotics in urine and use of diuretics, etc.

Haematuria which is defined as more than 2 RBC per high power field of centrifused urine indicates glomerular diseases, or trauma to the kidney, ureter, lower urinary tract, etc. If urine test is positive for blood, but there is no RBC, it indicates the presence of free haemoglobin in urine (haemoglobinuria). Urine normally may contain hyaline or granular cast, but presence of cellular cast confirms pathological condition of kidney. Trace proteinuria may be a normal finding. Whereas 3 to 4+ proteinuria suggests glomerular disease as proteins are not prevented from filtration. Patient without renal disease may excrete upto 100 mg of protein per day, but greater amount may be present after heavy exercise or after prolonged standing. Massive proteinuria with protein content above 500 to 700 mg/day is always abnormal and indicates severe glomerular damage. However, proteinuria may also be due to: (i) failure of tubular reabsorption of small amount of protein that is normally filtered, (ii) abnormally increased concentration of normal plasma protein, (iii) the presence of abnormal plasma proteins which are excreted through urine. Pyuria indicates infection at any level of genitourinary system.

Measurement of urinary pH may assist in the diagnosis of some acids base disturbances in body, but determination of pH from a single sample of urine has no value. Presence of glycosuria without hyperglycaemia suggests proximal tubular damage. Normal urinary lysozyme level is less than 1.9 mg/ml. Urinary level of it above 5 mg/ml indicates significant renal tubular disease (Table 42.7).

Estimation of BUN

Like urine analysis, estimation of BUN (blood urea nitrogen) is a commonly performed test to asses the renal function. The level of BUN greater than 50 to 60 mg/dl indicates the renal disease, unless proved otherwise. But abnormalities in the level of BUN indicates the renal dysfunction which is already advanced. As urea is filtered and then partially reabsorbed and secreted, so BUN level is not a sensitive index of GFR or renal dysfunction. The level of BUN is also elevated during low circulatory states such as congestive heart failure, dehydration, etc. This is due to the increased reabsorption of filtered urea for renal hypoperfusion. The reabsorption of urea is greater, approximately 60% of the filtered load, when urinay flow is low and only about 40% when this flow is high. There are other multiple nonrenal conditions where BUN level is increased. These are: high protein diet, GI bleeding, large haematoma, increased tissue breakdown in high catabolic state of body such as sepsis, high fever, starvation, steroid therapy (due to increased protein catabolism), etc. On the otherhand, the BUN level may remain within normal range despite significant reduction of GFR, if there is liver disease which causes decreased synthesis of urea.

Table 42.7: Factors that influence the result of renal function

- Variable protein intake
- Dehydration
- Degree of catabolism
- GI bleeding
- Skeletal muscle mass
- Advanced age
- Timing of measurement of urine volume

Estimation of plasma creatinine

Like BUN, plasma creatinine level is also measured to assess the renal function (mainly GFR). In a normal individual, daily a constant amount of creatinine is produced in body from creatine – phosphate, present in muscle. It is excreted by filtration through kidney. Therefore, a muscular individual may have high plasma creatinine level, though GFR is normal. On the otherhand, an individual with low muscular mass may have normal creatinine value, despite significant reduction of GFR. Thus, like BUN increased plasma creatinine level is also a late sign of renal dysfunction. This is because GFR must often be reduced as much as 50% before the elevation of creatinine concentration reach the abnormal level. Further, this is more true for individual with reduced muscle mass who has already low creatinine value. As creatinine is a product of skeletal muscle's protein catabolism, so it is formed at lower rate in elderly and women than young and male persons. Consequently, plasma creatinine level does not accurately reflect the magnitude of loss of nephron. Because creatinine production is directly proportional to the

muscle mass and indirectly proportional to the nephron loss. Therefore, many chronically ill, wasted, elderly patients may have palsma creatine value in normal range, though there is reduced renal concentrating ability and GFR.

Measurement of creatinine clearance

The excretion of creatinine from plasma by glomeruli measure or reflect the ability of glomeruli to filter it. This is called the creatinine clearance. It gives the more useful result than the only plasma creatinine value to quantify the renal reserve. From the only plasma creatinine level (without measuring the urinary concentration of it which is needed to measure the creatinine clearance rate as described before) the creatinine clearance can also be measured with reasonable accuracy by the following formula:

Creatinine clearance = [(140 – Age) × Body weight in kg] ÷ [72 × Plasma creatinine value]

But, the precise measurement of creatinine clearance (using the formula $C_{CR} = U_{CR} \times V/P_{CR}$) require collection of urine samples for a fixed time say 24 hours or 2 hours. 24 hours urine collection gives more accurate results than the 2 hours collection. This is because the changing hydration of a patient invalidates the result calculated from the short term collection of urine volume (2 hours) which varies greatly. On the otherhand, for a patient with acute renal failure a test that requires 24 hours collection of urine is often impractical. Creatinine clearance may also be used to differentiate the prerenal azotaemia from acute tubular necrosis (ATN) or renal azotaemia. In the postoperative period, a creatinine clearance value which is < 25 ml/minute, measuring over 2 hours appears to be a good and early predictor of impaired renal function (Fact file - XI).

FACT FILE - XI

Creatinine (anhydride of creatine) is mostly formed from the breakdown of creatine phosphate which is present in the muscle. This process is not catalysed by any enzymes and is irreversible. It is formed within the muscle itself. So, liver diseases do not affect the blood creatinine level. It is considered as a waste product and serves practically no function in the body. It is a no-threshold substance and is filtered completely by glomeruli. A small amount of creatinine is also secreted by the tubular cells in the urine. Its excretion is not related to exogenous food protein. The normal plasma value of creatinine is 0.7 to 2 mg/dl. This level is very constant and is considered to be pathological when its value increases above 2 mg/dl. Usually about 1.2 to 2 gm of creatinine is excreted in 24 hours urine. This amount is remarkably constant for a particular individual. It is related to muscle bulk and is higher in muscular persons. Creatinine excretion increases in fevers, starvation, carbohydrate free diet and in diabetes mellitus.

Creatinine represents the waste products of creatine metabolism. It arises in the body (muscle) from creatine during the spontaneous breakdown of creatine phosphate. Therefore, creatinine level increases during excessive muscle dstruction releasing creatine or due to failure of creatine being properly phosphorylated. So, creatinine excretion is independent of exogenous food protein and is considered as in index of endogenous protein metabolism. Due to any inborn metabolic disorders creatine does not convert to creatinine and appears in urine. This is known as creatinuria. Usually a small amount of creatine is excreted through urine along with creatinine. But it gradually diappears as the maturity advances.

Miscellaneous tests

Except the above mentioned tests, there are other tests which may be used to take an overview about the renal functions. Among these, some are not so reliable but only few are very promising. For example, the urine-plasma creatinine ratio and the urine-plasma urea ratio or index were initially introduced as a very promising methods for evaluation of patients with suspected acute tubular necrosis or renal dysfunction. But subsequently these tests show the lack of reliability and have more prognostic than diagnostic value.

The concentrating capacity of renal tubules also can be assessed by measuring the urinary Na^+ concentration and fractional excretion of Na^+ (FENa). If these two values go above 40 mEq/L and 1 respectively, it indicates acute tubular necrosis. On the contrary in hypotension ADH induced increased Na^+ reabsorption leads to a decrease in urinary Na^+ concentration < 20 m.Eq/L and FENa < 1 in prerenal azotemia which indicates the fallacy of this test. Some other tests of tubular function such as concentrating ability, ability to excrete water load and ability to excrete acid through kidney are valuable in some circumstances.

More accurate measurement of GFR is now most easily undertaken by ascertaining the clearance of ^{51}Cr-labelled EDTA. This has largely replaced the estimation of inulin and creatinine clearance in clinical practice.

ANAESTHESIA AND RENAL FUNCTION

Anaesthesia and any surgery have enormous impact on renal function. This can be caused directly or indirectly by affecting the renal physiology due to the changes in the levels of different hormones, electrolytes, body water, cardiac output, RBF, pH, etc. In general, the anaesthesia results in decrease in RBF and subsequently results in deterioration of renal function due to the decreased GFR. The likely mechanism of this deterioration of renal function induced by anaesthesia includes the loss of renal autoregulation, increased neurohormonal factors (ADH, vasopressin, renin, angiotensin) and increased neuroendocrine response. This inturn decrease the excretion of nitrogenous wastes, electrolytes, H^+, anaesthetic and other drugs, and conservation of body fluid etc. Decreased excretion of anaesthetic and other drugs lead to prolongation of their effect. On the other hand, anaesthetic agents also affect the renal function directly. This is mainly applicable for volatile anaesthetic agents such as methoxyflurane which produces many nephrotoxic metabolites in our body after its administration. IV anaesthetic agents have minimal direct effects on kidney. They deteriorates the renal function indirectly by reducing the RBF. Among

the anaesthetic agents which are mostly concerned about the renal function are: IV anaesthetic agents, inhalational agents, muscle relaxants and its reversal.

Intravenous Anaesthetic Agents

In patients with impaired renal functions, the CNS depressant effect of intravenous anaesthetic agents are exaggerated. This is because they are mostly protein (albumin) bound and in renal dysfunction as the level of albumin is reduced, so most of the drug remains in unbound free form and theri actions are enaggenated . In addition, the renal dysfunction is frequently associated with acidosis which increases the unionized form of drug, as their pK value acts usually at the physiological range of plasma. The unionized form of the drug is more lipid soluble. Therefore it causes higher drug concentration in CNS. Hence, the thiopentone which remains as 15% unbound free and un-ionized form in normal individual, increases to 30% in chronic renal failure. Therefore, the induction and maintenance dose of thiopentone should be reduced in uraemic patients. On the other hand, as the metabolism of thiopentone in liver remains unchanged in renal dysfunction patient, so the amount of it which is necessary to produce and maintain anaesthesia is reduced. The same consideration is also true for the methohexitone, although metabolism of it plays a slight greater role in termination of its therapeutic effect than thiopentone. On the other hand, the reversal of effect of ultra-short acting barbiturate such as thiopentone will depend only on redistribution and hepatic metabolism, but very little or nil on the elimination through kidney. Therefore, the recovery from thiopentone in a renal dysfunction patient is not affected.

However, it is surprising that in a renal dysfunction patient the pharmacodynamics and pharmacokinetics of a new I V anaesthetic agent such as propofol do not change and is very safe to use. Ketamine should be avoided in renal failure patient. Because it causes exaggerated reaction to coexisting hypertension and tachycardia in renal failure patient, where they are already present. However, ketamine is reported to minimally affect the renal function directly. It also tries to preserve the renal function during haemorrhage and hypovolaemia. For benodiazepines the increased free fraction of these drugs due to decreased protein binding also increases its CNS sensitivity. Further, due to impairment of excretion caused by renal dysfunction there is accumulation of active metabolites of some long acting BZD such as diazepam lorazapam, oxazepam, etc. and prolongs their clinical effect.

For narcotics the same is true as barbiturates and BZDs. As the protein binding capacity is reduced in renal dysfunctional patient, the unbound level of morphine and its active metabolites such as morphine-6-glucoronite (non toxic) in plasma increases and predisposes the patient to more and prolonged respiratory depression. Meperidine (pethidine) has a toxic metabolite, named normeperidine (norpethidine). So, it is not recommended for use by repeated bolus doses or through infusion in renal failure patient due to gradual accumulation of these toxic metabolites which are excreted through kidney. The pharmacogenetic and pharmacodynamic effects of alfentanil and fentanyl are appeared to be unaffected by the renal dysfunction. Further, fentanyl has short half-life and its metabolites are inactive. So, these agents are good choice in patient with renal disease.

Drugs with antidopaminergic activity such as metoclopramide, phenothiazines, etc., may impair the renal response of dopamine when it is used as protection for kidney. Use of analgesic drug such as ketorolac inhibits the synthesis of which have renal vasodialating property prostaglandin of renal origin. This is especially important in patients with high level of angiotensin II and norepinephrine which causes renal vasoconstriction. Thus, it attenuates the renal protective response and decreases GFR, producing or enaggerating renal dysfunction. ACE inhibitors also block the protective effect of angiotensin II and causes additional reduction in GFR during anaesthesia. Thus, it potentiates the detrimental effect of anaesthetic agent on renal perfusion.

Volatile Anaesthetic Agents

Indirectly the volatile anaesthetic agents affect the renal function by eliminating the renal autoregulation and reducing the RBF and GFR, with decreased urine output. All these haemodynamic changes, produced by volatile anaesthetic agents are dose dependent and can be attenuated by adequate preoperative hydration which probably helps to maintain the better renal perfusion.

On the otherhand, the volatile anaesthetic agents also directly affect the renal functions by their nephrotoxic metabolites which are formed by liver and excreted through kidney. Though 99% of volatile anaesthetic agents are excreted out through the lungs, still to some extent all the inhaled anaesthetics are biotransformed to nephrotoxic metabolites during their metabolism in liver. Impaired renal function does not alter the pharmacodynamics and pharmacokinetic effect of any volatile anaesthetic agents, but the agents affect the function of kidney. So, from the point of view of selecting a volatile anaesthetic agent one should be careful regarding the effect of agent on kidney which may make further detorioration of its function than the effect of renal dysfunction on the haemodynamic and pharmacodynamic effect of the agent.

All the modern volatile anaesthetic agents such as methoxyflurane, enflurane, halothane, isoflurane, sevoflurane and desflurane are halogenated compounds, containing mainly fluorine. These fluorinated volatile anaesthetic compounds produce inorganic fluorides as their metabolites which are nephrotoxic. These inorganic fluoride induced nephrotoxicity depends on the type of volatile agent used and the duration of their exposure. The threshold

level of nephrotoxicity of these inorganic fluorides are 50 M/L. The amount of inorganic fluoride below these level does not produce nephrotoxicity. In impaired renal function methoxyflurane is absolutely contraindicated, because it is extensively biotransformed into inorganic fluoride and oxalic acid due to its metabolism in the liver. This inorganic fluoride induced nephrotoxicity caused by volatile agents includes an inability to concentrate the urine in response to ADH, leading to polyuria, hypernatraemia and increased serum osmolality. Other halogenated volatile agents are metabolised in body duirng their use to inorganic fluoride, but their levels are below the threshold level. For example, after 3 to 4 hours of use of enflurane, the inorganic fluoride level in plasma is 20 ± 5 μM/L. Again obesity is associated with production of higher level of inorganic fluorides following enflurane anaesthesia. Whereas the plasma fluoride level after the use of isoflurane and halothane increases to only 3 to 4 μM/L and 1 to 2 μM/L respectively. Therefore, the use of isoflurane and halothane is a better alternative in renal failure patient. Recently introduced volatile anaesthetic agent is desflurane. It is highly volatile and boiling point is 19°C (near the room temperature). But it is very stable in sodalime and also resists degradation by liver. So, the mean inorganic fluoride concentration after 1 hour exposure of desflurane at the dose of 1 MAC is only 1 μM/L or less. On the other hand, sevoflurane is very unstable in sodalime which decomposes it. It is also biotransformed in liver. So after prolonged exposure of sevoflurane, the level of nephrotoxic inorganic fluoride may reach upto 50 μM/L, but still there is no report of gross change of renal function in humans, after its prolonged use.

Muscle Relaxant

The level of plasma cholinesterase is reduced in severe renal dysfunction patient, but the value is rarely so low to cause prolonged action of succinylcholine. Therefore, it can be used without difficulty in patient with decreased or absent renal function. Succinylcholine is metabolised by plasma cholinesterase to nontoxic succinic acid and choline. The metabolic precursor of these two compounds is succinylmonocholine which is excreted through kidney. Hence, prolonged use of succinylcholine by infusions or repeated bolus doses should be avoided in patient with renal failure. The use of succinylcholine is associated with the transient rise of plasma K^+ level to 0.5 to 0.7 mEq/L. This rise may be as great as 5 to 7 mEq/L in burn, trauma or neurologically injured patient. In renal failure patient the level of plasma K^+ also remains high. Hence, the use of succinylcholine in renal failure patient with this high level of plasma K^+ can cause cardiovascular collapse. So, the use of succinylcholine in severe renal failure patient is inadvisable, unless the patient undergone dialysis within 24 hours prior to anaesthesia and surgery. Still succinylcholine is the agent of choice for rapid sequence induction and intubation for difficult airway (as its onset of action is not delayed and duration of action is not prolonged in renal dysfunction patient), if the plasma K^+ level permits. In majority of patients with renal failure, a single dose of succinylcholine is considered safe, provided the serum K^+ level is below 5 mEq/L.

The two nondepolarising muscle relaxants such as atracurium and its derivative cisatracurium are broken down in plasma by enzymatic ester hydrolysis and by nonenzymatic alkaline degradation (Hofmann elimination) to their inactive products. Therefore, they are not dependent on renal excretion for their termination of action. Hence, the indices of these two muscle relaxants such as onset, duration and recovery are same in patient with normal and with severely impaired renal function. So, they appear to be the neuromuscular blocking agent of choice for renal failure patients. Severe renal dysfunction does not prolong the neuromuscular blocking effect of these two agents, even when is given by constant infusion over several days. Laudanosine is one of the important metabolic end products of atracurium and cisatracurium which may cause convulsion. This laudanosine is excreted through kidney. But fortunately the risk of convulsion from accumulation of laudanosine in renal failure patient after continuous infusion in ICU has not been reported.

Vecuronium is another nondepolarising muscle relaxant which is 70 to 80% metabolised in liver and the remaining 20 to 30% is excreted as mother compound through kidney. Hence, in patients with renal failure the normal intubation and maintenance doses should be reduced and the intermittent dosing interval should be increased. One of the metabolites of vecuronium is 3-desacetyl vecuronium which is pharmacologically active. Hence, continuous infusions of vecuronium is not recommended in renal failure patient in fear of accumulation of its active metabolites.

Another short acting nondepolarising muscle relaxant is mivacurium which is metabolised by plasma cholinesterase, but slowly than succinylcholine. Therefore, as the level of plasma cholinesterase is reduced in impaired renal function or after dialysis, so the duration of action of it is prolonged by another 10 to 15 minutes. But the use of this drug in renal failure patient is not a contraindication. This agent can be used cautiously with lower doses. The clearance of rocuronium is not changed in renal failure patient, but the elimination half-life is increased. This is due to the increase in volume of distribution in renal dysfunction. Therefore, there is somewhat longer duration of action of rocuronium in renal failure.

Other long acting non-depolarising muscle relaxants such as pancuronium, doxacurium, pipercuronium, etc.; show reduced clearance, increased elimination half-life and prolonged duration of action in patients with renal disease. Therefore, if

possible these agents should be avoided or can be used with lower doses and longer dosing interval. Use of any neuromuscular agent in presence of renal dysfunction should be monitored by nerve stimulator.

The anticholinesterases such as neostigmine, edrophonium and physostigmine are excreted mainly through kidney. Among these the 50% of neostigmine and 70% of edrophonium and physostigmine are excreted unchanged by urine. So, in renal dysfunction their actions are prolonged, but this is matched with the prolonged action of neuromuscular blocking agents.

Anaesthetic Procedure

Before operation it is not always possible to become certain whether the patient has any renal disease or not. The best way to know the presence or absence of renal disease is past medical history. The physical findings are often minimum until renal disease is far advanced. This is because until approximately 50% of renal function is lost, the laboratory results remain within normal limits, except the creatine clearance. Patient with this 50% loss of renal function are said to have decreased renal reserve and their anaestheitc management is same as that of the patients with normal renal functions (Table 42.8).

For renal dysfunction two terms are used – renal insufficiency and renal failure. The renal insufficiency is characterised by mild anaemia, mild azotaemia, slight decrease of urine concentration ability. During anaesthesia of this category of patients, attention is paid to avoid the conditions which may further deteriorate the renal function. On the other hand, the renal failure is said to be present when patients have hypocalcaemia, hypernatraemia, hyperphosphataemia, hyperchloraemia, hyperkalaemia, progressive anaemia and loss of urinary, concentrating or diluting, ability. In these renal failure group of patients the plasma creatinine value and creatinine clearance vary between 3.5 to 4 mg/dl and 15 to 20 ml/minute, respectively. They are also unable to adapt to the rapid changes in fluid balance. Hence, they run the risk of becoming acutely hypovolaemic or fluid overload and the clinical condition of these patients are uncertain. The aim of anaesthetic management of these category of patients is directed at avoiding the deterioration of renal function which will cause them to become grossly uraemic and require haemodialysis. Drugs which are excreted through kidney should completely be avoided or if is required at all, they should be given very cautiously in decreased doses or at prolonged intervals.

If the patients lack the significant medical history focussing on renal disease and its function, then the routine preoperative blood tests and urine analysis for screening is sufficient for early identification of renal disease or its dysfunction. In screening, if renal dysfunction is thought to be present, then the more precise methods of assessing the degree of deterioration of renal function are necessary. Therefore, the laboratory tests useful for preoperative evaluation of renal functions are as follows: urine analysis (including output, appearance, pH, specific gravity, protein content etc.), blood tests (includig Hb%, coagulation profile, electrolytes, pH, BUN, creatinine etc.), ECG, chest X-ray etc. If necessary, other renal function tests such as creatinine clearance and GFR should also be measured. Among these many are described before and those which are not described before are mentioned below.

Table 42.8 : Manifestations of renal dysfunction

- Hyperkalaemia
- Hyponatraemia
- Hypocalcaemia
- Hyperchloraemia
- Hyperphosphataemia
- Metabolic acidosis
- Anaemia
- Coagulopathies
- Unpredictable intravascular fluid volume status
- Hypertension
- Congestive heart failure

Haematocrit

Anaemia is a common finding for renal diseases and severity of it depends on the depth of renal dysfunction. It is due to the decreased production of erythropoietin (erythropoiesis stimulating factor). The Haematocrit value running between 25 to 30% is appeared to be well tolerated and does not always need blood transfusion, because it is associated with unnecessary several disadvantages such as volume overload, hyperkalaemia, viral infections, etc. If this haematocrit value is thought not to be justified for the proposed surgery or is poorly tolerated due to some systemic diseases such as cardiac disease, then blood transfusion should not be withheld (Table 42.9).

Coagulation profile

Haemorrhagic episodes remains the major risk factor contributing to the morbidity and mortality, associated with anaemia in renal dysfunction patient. Prothrombin time (PT) and partial thromboplastin time (PTT) remains usually normal in such patient, though they have increased tendency to bleed. Hence, the bleeding time

Table 42.9: Treatment of coagulopathy due to renal failure

Drug	*Dose*	*Onset of action*	*Peak effect*	*Duration of action*
Cryoprecipitate	10-15 units IV over 15-30 minutes	< 1 - 2 hours	6 - 12 hours	12 - 24 hours
Desmopressin	0.3-0.6 µg/kg IV or SC	< 1 - 2 hours	2 - 4 hours	4 - 8 hours
Estrogen	0.6 mg/kg/day	6 hours	6 - 7 days	15 days

(BT) is the best screening test for this group of patient that correlates well with the tendency to bleed in renal dysfunction patient. The treatment of uraemic bleeding usually includes the adminstration of cryoprecipitate plasma which provides factor VIII or administration of desmopressin (1-desamino-8-D-arginine vasopressin or DDAVP). The DDAVP is an analogue of ADH and increases the circulating level of factor VIII. Thus, it decreases the bleeding. The maximal effect of desmopressin is found within 2 to 4 hours after administration and lasts for 6 to 8 hours. It acts by increasing or changing the platelet membrane receptor binding capacity with the factor VIII and making a more active complex. Although, cryoprecipitate plasma and desmopressin can correct BT and the surgical procedure can be performed without excessive bleeding in renal failure patient, but the effects of both these drugs lasts only for few hours. Therefore, if prolonged effect is desired then conjugated oestrogen may be given in the dose of 0.6 mg/kg/day through IV. Repeated daily administration of oestrogen for 5 days decreases BT within 6 hours and this lasts for 15 days. Administration of erythropoietin also decreases the BT. It probably acts by increasing the erythropoiesis which acts like blood transfusion.

Electrolytes and acid-base status

As a preoperative checkup, the plasma Na^+, K^+, HCO_3^-, pH, BUN and creatinine level of a patient suffering from renal dysfunction should be checked routinely. If plasma Na^+ level is <125 m.mol/L, K^+ level is > 5.5 m.mol/L and both are associated with hypoalbuminaemia and acidosis, then the patient should be put under haemodialysis to control all these parameters, before induction of anaesthesia. Among these the plasma K^+ concentration is most important. So, if dialysis is performed 24 hours before surgery, still plasma K^+ level should be checked just before induction of anaesthesia. This is because plasma K^+ level is changed very rapidly than that of other electrolytes. In emergency circumstances, if dialysis can not be instituted immediately before anaesthesia and surgery, then the plasma K^+ level can be controlled by administration of IV glucose with insulin. Hyperventilation after induction and intubation may also decrease the plasma K^+ level by about 0.5 m.mol/L for every 10 mm of Hg reduction of P_aCO_2 level. Renal dysfunction is also associated with acidosis (low HCO_3^- level). Control of this acidosis by IV administration of bicarbonate also control the plasma K^+ level. But to control this acidosis and hyperkalaemia, bicarbonate should be infused very slowly, keeping in mind that rapid administration of it may precipitate overt symptoms of hypocalcaemia. If serum bicarbonate level is very low, i.e. between 12 to 15 m.mol/L then anion gap acidosis, for example ketoacidosis, should be thought. In renal dysfunction as the GFR is reduced, so the filtration of glucose is also reduced. Therefore, control of plasma glucose level, especially in diabetic patient is very difficult. Furthermore, an increase in plasma glucose level causes increase in plasma K^+ level. If plasma BUN level goes > 100 mg/dl, then dialysis should be performed 12 to 24 hours before any anaesthesia and surgery. It will help to remove the waste products and excess fluid. It will also help to control the K^+ and Na^+ level and acidosis (Table 42.10).

ECG and Chest X-ray

Renal dysfunction is associated with electrolytes imbalance, mainly K^+ and Na^+. Therefore, ECG in patients with renal failure often reveals conduction abnormalities and arrhythmias. Hence, continuous perioperative ECG monitoring is mandatory during anaesthesia of a renal failure patient.

Preanaesthetic chest radiograph also should always be obtained in patient suffering from renal dysfunction. Because renal failure is commonly associated with pulmonary infection, congestion, oedema, pleural or pericardial effusion, etc.

Premedication

For premedication before any anaesthesia and surgery in a renal dysfunction patient benzodiazepines are the most commonly used agents for sedation and anxiolysis. But caution must be exercised by reducing the dose and avoiding the repeated administration, as they may cause the excessive and prolonged sedation. Other premedicant such as H_2 blocker (ranitidine) or proton pump inhibitor (omeprazole) and prokinetic agent (metoclopramide) may be used safely in renal dysfunction patient, but their dose should be reduced appropriately. On the otherhand, use of these agents is mandatory in renal dysfunction patients,

Table 42.10: Management of hyperkalaemia

Type of treatment	*Dose*	*Onset of action*	*Mechanism of action*	*Side effects*
Sodium bicarbonate	50 - 100m.mol IV	Short	Shifting of K^+ into cells	Na^+ overload
Glucose & insulin	50 ml of 50% glucose solution with 10 unit soluble insulin	6-8 hours	Shifting of K^+ into cells	Hypo or hyperglycaemia
Calcium gluconate	10 - 20 ml of 10% solution IV	Short	Directly antagonize the effects of K^+ on the heart	Arrhythmia
Dialysis	–	According to severity of renal dysfunction	Directly remove K^+ from the body	Require vascular access
Ion exchange	–	- Do -	- Do -	Na^+ overload

because gastric emptying time is delayed in uraemia. Patients who are already under chronic steroid therapy should receive steroid preoperatively and in higher doses than previous one. This is because the long term use of steroid impair the stress response and therefore higher doses are needed. The dose of anticholinergic agents such as atropine and glycopyrrolate also should be reduced accordingly as they are partially excreted through urine.

Monitoring

Routine monitoring devices which are used in other patients should also be applied here to the renal dysfunction patient. Among these the ECG is very important to detect conduction abnormalities and arrhythmias which are commonly associated with hyperkalaemia, found in renal failure. BP cuff should not be used on the same extremity in which arterio venous fistula for dialysis is performed. This is because the fistula can be blocked by thrombosis during inflation of cuff. Special monitoring such as intra-arterial BP monitoring, CVP monitoring, pulmonary arterial pressure monitoring, etc. are needed according to the severity of renal dysfunction. A peripheral nerve stimulator may also be useful to avoid excessive dose of muscle relaxant with prolonged neuromuscular blockade.

Induction of anaesthesia

The commonly used inducing agents such as thiopentone and propofol has hypotensive effect which may be exaggerated in patients suffering from renal dysfunction. So, an anaesthetist must be careful about it and the incidence of severe hypotension can be reduced by reducing the dose of the above mentioned inducing agents and maintaining the adequate intravascular volume status prior to induction. In this regard, ketamine is safe and the agent of choice in severly ill patient, provided there is no hypertension which is commonly associated with renal dysfunction. The Rapid sequence induction and intubation is preferred in severe renal failure patient, because of the delayed gastric emptying and the risk of aspiration. If succinylcholine is contraindicated due to hyperkalaemia, a quick acting nondepolarising muscle relaxant that does not depend on the kidney for its clearance may be used. But, unfortunately, such ideal agent is not, available. Therefore, atracurium, cistracurium, rocuronium, mivacuronium, etc; are the better choice. Laryngoscopy should be brief, because prolonged apnoea and hypoxia may lead to respiratory acidosis which may aggravate the existing hyperkalaemia. After intubation slight hyperventilation is preferred, because it can correct acidosis and subsequent hyperkalaemia if these are present.

Maintenance of anaesthesia

After induction and intubation, general anaesthesia is maintained by N_2O and volatile anaesthetic agents. Among the volatile anaesthetic agents methoxyflurane, enflurane are contraindicated and sevoflurane is best avoided in patients with impaired renal function, the cause of which is discussed before. Therefore, isoflrane and halothane is the agent of choice as volatile anaesthetic agent. Opioids such as fentanyl, sufentanil and remifentanil can be used safely in conjugation with volatile anaesthetic agents. During maintenance of anaesthesia slight hyperventilation is better, the reason of which is also discussed before. On the otherhand, excessive hyperventilation is not desirable which is more applicable in anaemic patients only. This is because respiratory alkalosis, resulting from hyperventilation may shift the O_2 dissociation curve to the left and thus affect the O_2 unloading to the tissue. During artificial mechanical ventilation, intrathoracic pressure should be maintained at optimim level by appropriately adjusting the respiratory rate, tidal volume and I:E ratio. Otherwise, increased intrathoracic pressure may decrease the cardiac output and further deteriorates the renal function by decreasing the perfusion in kidney. The intraoperative severe hypertension can be controlled by infusion of nitroglycerine and nitroprusside. Cyanide toxicity following prolonged infusion of nitroprusside is unlikely in patient suffering from renal failure. This is due to decreased excretion of thiosulfate through kidney which facilitates the conversion of cyanide to thiocyanate.

During maintenance of general anaesthesia, intraoperative monitoring of renal function is important. This can be performed by measuring the urine output. Oliguria or anuria should be recognised promptly and treated immediately which may thus avoid the development of acute renal failure. If there is any suspicion of acute renal failure, then rapid infusion of 500 ml of normal saline as bolus and a small dose of frusemide (0.1 to 0.2 mg/kg), if intravascular volume is adequate, is effective. Still, if the urine output does not increase, then the intravascular volume status and cardiac output are monitored by invasive monitoring such as CVP and PWAP. Once the filling pressure is optimised by IV fluid and the urine output does not increase by frusemide, then dopamine in the dose of 1 to 2 µg/kg/minute is used to increase the renal blood flow and urine output. Sometimes, severe hypotension refractory to adequate intravascular volume repletion may occur in severe renal failure and dialysis patient which is due to autonomic dysfunction. This is generally treated by increasing the dose of dopamine (5 µg/Kg/minute) which increases the cardiac function and renal blood flow or by noradrenaline (Fig. 42.11).

Postoperative care

The Postoperative care of a patient suffering from renal dysfunction is similar to that of other patients, except some special points. Hyper or hypokalaemia usually occur during the first 24 hours of postoperative period in renal failure patient which depends on the severity of failure. So, electrolytes level should be checked

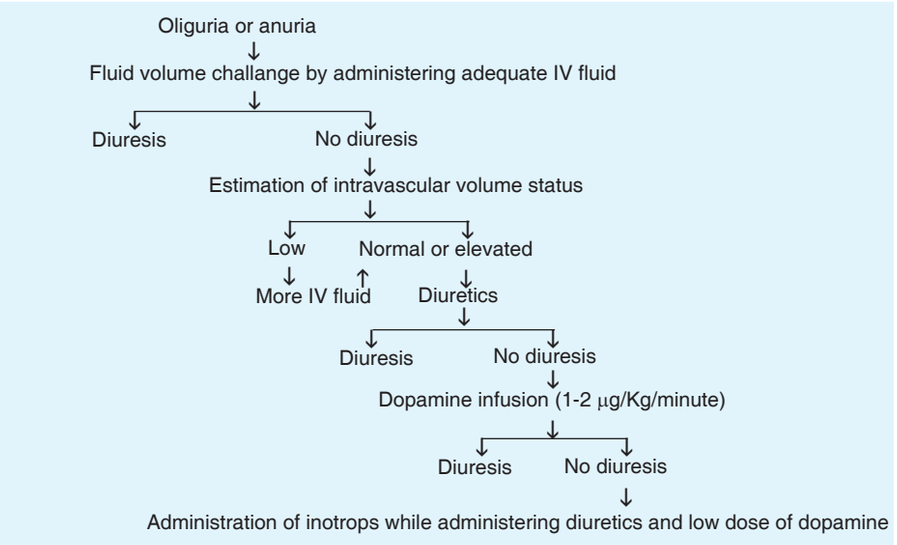

Fig. 42.11: Management of oliguria in renal dysfunction

routinely in recovery room and measures should be taken accordingly. Continuous ECG monitoring is essential for the detection of any conduction abnormalities and arrhythmias which is common due to electrolyte disturbances during the first 24 hours of postoperative period in a renal dysfunction patient. PCA using fentanyl is the best method of postoperative analgesia for patients with impaired renal function. Regional analgesic technique is very helpful for postoperative analgesia, if coagulation profile remains within normal limit. If a patient with history of impaired renal function shows skeletal muscular weakness, then partial reversal of the action of muscle relaxant should be thought. So, neuromuscular conduction should be monitored by nerve stimulator and if necessary additional dose of anticholinesterase with anticholinergic agent can be administered. Postoperative renal failure patient may suffer from hypertension or hypotension. So, blood pressure should be monitored closely and the recovery room sister is informed regarding the site of AV fistula used for dialysis to avoid the inadvertent placement of BP cuff on the same extremity.

43 Orthopaedic Anaesthesia

INTRODUCTION

It is very interesting to mention that only this subspeciality of anaesthesia experiences a large varieties of anaesthetic techniques or procedures such as GA, RA, combination of GA and RA, different types of nerve block, IV regional anaesthesia, only sedation, monitored anaesthetic care, etc, which the other specialities of anaesthesia do not. Also the orthopaedic anaesthesia encompasses a great range of patients extending from a child with congenital skeletal deformities requiring surgery and anaesthesia to an young adult with multiple trauma or fracture to a very old person with multiorgan problems coming with fractured neck femur etc. The degree of surgical complexity also vary from minor surgical manipulation of a joint which has limited mobility due to scars, fibrosis or adhesions, etc. to minor finger surgery to hemipelvectomy. There is also huge advancement in orthopaedic surgical technique which is gradually making it lesser to lesser invasive procedure and this is due to the development of CT scan, MRI, and computer. This causes only the overnight stays or the same day discharge of patient. Otherwise, they were kept admitted for many days after surgery which was done before. All these have great implication on anaesthesia. The other pecularities of orthopaedic surgeries that anaesthetists have to face are: (i) the different positions of the patient to facilitate the surgery which has many implications on on patients and subsequently on anaesthesia, (ii) the use of tourniquate which has many complications, though has many advantages, (iii) the use of orthopaedic cement and its bad consequences, (iv) the venous, fat and air embolism which are very common for orthopaedic surgery, (v) the amount of blood loss which may vary from few drops to 2 litres and blood transfusion related complications. So, different types of techniques are adapted to reduce the blood loss during major orthopaedic surgery such as induced hypotension, haemodilution, cell saver technique, etc. which have their own intrinsic complication and have to tackle by the anaesthetist. It is also very interesting that some orthopaedic surgeries are very short and some are very long and complex in nature requiring extensive monitoring such as intra arterial pressure monitoring, central venous pressure monitoring, transoesophageal echo cardiography, etc. Therefore, the rate of perioperative morbidity and mortality in orthopaedic surgeries vary greatly and is different from other surgical discipline (Table 43.1).

Some patients seeking orthopaedic surgery also have rheumatoid arthrities, alkylosing spondylits, etc. which affect the cervical, thoracic and lumbar spinal vertebrae with the other bony joints of the body.

Table 43.1: Causes of atlantoaxial instability

- Down's syndrome
- Adult rheumatoid arthritis
- Juvenile rheumatoid arthritis
- Ankylosing spondyitis
- Fractured cervical spine
- Morquio disease (mucopolysaccharidosis)

These patients may also have instability of cervical spine or atlantoaxial joint and can make the airway management difficult. In rheumatoid arthritis the damage of atlantoaxial joint is developed from the erosion of ligaments by rheumatoid involvement of the bursae around the odontoid process of C_2 vertebra. So, iatrogenic acute subluxation of joint between C_1 and C_2 vertebra may occur by the flexion of neck during intubation and it may result in cord compression or sudden death. Hence, during anaesthetic management of these type of patients previous diagnosis of this type of ailment is essential and all the precaution should be taken which must prevent flexion of the neck and maintain the stability of cervical spine. Therefore, orthopaedic anaesthesia sometimes demands a high degree of skilled airway management facility requiring fibreoptic laryngoscope, flexible bronchoscope, intubating LMA and all the other accessories to offset the movement of cervical spine during intubation.

Ankylosing spondylitis is more common in men than women and involves the ossification of ligaments of joints at their attachment to the bone. Progressive ankylosis also involves the cartilages of joint and intervertebral disc with diminution of spaces. Thus the vertebral column gradually becomes fused, making lumbar epidural or spinal anaesthesia difficult or impossible. Due to ankylosing spondylities sometimes the positioning of patient also becomes very painful while he is awake for central neuroaxial block. Similarly, there is also some choice between

the axillary and the interscalene route of brachial plexus block for regional anaesthesia of upper extremity when the patient is suffering from severe ankylosis of shoulder joint. The difficulty of positioning the patient or extremities may also arise from fractures, joint deformities, or unstable vertebrae which influence the mode of anaesthesia. Sometimes, it is very helpful to exercise the position preoperatively while the patient is awake.

Arthritis and ankylosis affecting the temperomandibular joint may also restrict the opening of mouth and can cause visualization of larynx difficult. These diseases may also affect the cricoarytenoid joint and may leave the vocal cord with limited mobility and restricted glottic opening. All these may produce difficulty of tracheal intubation. On the otherhand, as both the rheumatoid arthiritis and ankylosis spondylities are systemic disease, hence they may also affect the different organs or systems of body other than bones and joints causing different diseases. These are cardiac valvular lesions, ischaemic heart disease, pericarditis, pulmonary interstitial fibrosis, etc. However, these patients also have an impaired immune system, wasted musculature and underlying hypermetabolism which will contribute to an increased rate of postoperative infections and other complications (Table 43.2).

Many patients admitted for orthopaedic surgeries have the history of corticosteroid therapy in the past. Therefore, it has become routine for many anaesthetist to administer a large dose of glucocorticoids on the day of surgery with the aim to avoid the risk of acute adrenal insufficiency. But many anaesthetist oppose this view and their arguments are that: (i) The acute adrenal insufficiency causing unwanted hypotension is rare and can be better treated after it occurs than taking prophylactic measures. (ii) Preoperative large dose of corticosteroid may impair wound healing and immune function. Thus, it causes more harm to patient than good. (iii) The previous history of steroid therapy does not always predict the occurance of adrenocortical deficiency and thus it is impossible to select the patient who should receive the prophylactic steroid therapy without previous testing of adrenal response. (iv) The daily dose of corticosteroid is sufficient unless the severity of surgical stress warrants larger doses.

Table 43.2: Systemic manifestations of rheumatoid arthritis

CVS	Pericardial effusion, conduction defects, myocarditis, valvular defects, coronary arteritis, etc.
Respiratory system	Interstitial pulmonary fibrosis, pleural effusion, etc.
Others	Anaemia, thrombocytopaenia, adrenal insufficiency, impaired immune system, etc.

Some Specific Problems Related to Orthopaedic Surgeries and Anaesthesia

As discussed previously, the orthopaedic surgeries have some specific problems which are not found in other subspecialities of surgical discipline. So, the anaesthetists have to face these problems only or more frequently during orthopaedic anaesthesia. These problems are: tourniquet, bone cement, embolism, DVT, blood loss, and position of patient.

Tourniquet

It is frequently used in orthopaedic surgeries around the upper and lower extrimities to reduce or eliminate the intraoperative blood loss and to provide a clear surgical field. Though it is very useful, but is not completely devoid of problems, because it produces many changes in body such as haemodynamic, metabolic, embolic, pain, neurological damage, etc which are detrimental to patients. When the tourniquet is applied and inflated above the systolic pressure to get the blood less dry surgical field, then the distal tissue is cut off from its O_2 supply. So, within 8 to 10 minutes of application of tourniquet the partial pressure of O_2 in the mitochondria of the cells of ischaemic tissue falls to zero and anaerobic metabolism begins. Thus the stored NAD and creatine phosphate in the cell of ischaemic tissue decreases and is completely depleted within 60 minutes. Hence, the pH of tissue distal to the tourniquet rapidly falls < 6. Thereafter, the developed cellular hypoxia and acidosis cause the release of myoglobin, intracellular enzymes and K^+ from the muscle cells into the circulation. Subsequently the endothelial integrity of blood vessels is also lost. This is due to the release of thromboxane and tissue oedema supervens. Gradually after that the ischaemic portion of extremities becomes cool and approaches the room temperature.

Application of tourniquet is also associated with some haemodynamic changes in body. This is due to the exsanguination of limb before the application and inflation of tourniquet which causes a sudden shift of large volume of blood from the peripheral compartment to the central compartment. But usually in healthy adult patient this suddn shifting of huge amount of blood from peripheral compartment to central compartment does not produce any significant haemodynamic effect except a small increase in central venous and arterial pressure. However, in patient with poor ventricular compliance and with extensive vericose vein where tourniquet is applied over this limb may experience a considerable increase in pulmonary artery pressure. Also the bilateral application of tourniquet at a time and exsanguination of both the limbs before its application may cause the shift of a greater amount of blood with higher rise of CVP and systemic blood pressure that may not be sometimes tolerated in healthy patients causing failure. For the proper function of the tourniquet the inflation pressure within it should be raised to about 50 to 100 mm of Hg above the present mean arterial blood pressure which is needed to block the arterial flow. Then BP of a patient may increase after surgical incision or due to any cause

during intraoperative period. Therefore, the BP measured during preinduction preparation of patient is not always a reliable guide to set the pressure of the tourniquet during intraoperative period. Hence, the tourniquet pressure should be changed according to the intraoperative blood pressure of the patient. The time of application of tourniquet and the periodic pressure within it should be noted on the anaesthetic record. Like all the other medical devices, the pneumatic tourniquet also requires regular preoperative periodic check up and calibration.

For the proper functioning of tourniquet, the width of the cuff of it should be more than the half of the diameter of the limb. Because it will improve the transmission of cuff pressure to the deeper tissue and occludes the artery better. For the good functioning of tourniquet it should also be placed over a smoothly applied cotton padding around the limb. This will prevent the damage of underlying skin caused by tourniquet. It will have to be kept in mind that antiseptic solution used to prepare the skin of surgical site should not spread under the tourniquet. Otherwise it may cause chemical burn to the skin.

Within 30 minutes of inflating the tourniquet the conduction of impulses through the nerve (affarent and effarent) also ceases and it may also contribute to anaesthesia at the surgical site other than the action of anaesthetic agents on CNS. Due to tourniquet as the extremity is isolated from the central circulation and becomes cool, so it also reduces the sensation. The neurological and vascular problems arise when the tourniquet is inflated for prolonged period (> 2 hours) or when the excessive inflation pressure is applied. After the speculated time or when the surgery is over, then the tourniquet is deflated and the ischaemic limb is again reperfused from itself with the reduction of central venous pressure and arterial blood pressure. Sometimes this reduction of systemic BP becomes excessive and may result in cardiac arrest. The other contributing factors for this cardiac arrest associated with tourniquet may be the excessive blood loss from the surgical site or the circulatory effects of metabolites (e.g. thromboxane) from the ischaemic limb after the deflation of tourniquet. Washout of the accumulated metabolic wastes from the ischaemic limb into general circulation also increases P_aCO_2, $ETCO_2$, serum lactate and serum K^+ level. These metabolites can increase the minute ventilation in spontaneously ventilated patient.

Some patients receiving spinal, epidural, IV regional or brachial plexus block feel pain at the site of tourniquet before the level of anaesthesia recedes from the site of tourniquet where it is applied (tested by the pin prick). This pain occurs inconsistantly and comes at intervals. Similarly some patients undergoing GA also feel pain after inflation of tourniquet. This tourniquet pain is reflected by the sudden unexplained intraoperative hypertension after one hour of the application of tourniquet. The mechanism of this tourniquet's pain is not exactly known. Still the probable explanation is that it is the unmyelinated, slow conducting fine sympathetic C nerve fibres which are relatively resistant to the local anaesthetic agent and carry this pain sensation. However this is an explanation only for RA. The explanation in GA is given below. But this argument is sometimes contradicted by the following observation that tourniquet pain from lower extrimity is still experienced despite blockade up to the level of T_4 spinal segment and stellate ganglion block cannot ameliorate this pain from the upper extremity.

The management of intraoperative hypertension due to this pain from tourniquet during GA is very difficult. This is because attempts to relieve this pain with IV narcotics and increasing the dose of inhaled anaesthetics are not always successful. This pain can only be relieved by deflating the tourniquet for 10 to 15 minutes and then reinflating it. Thus this correlates well the relief of pain with the correction of cellular acidosis and also explains the another mechanism of this tourniquet pain in GA. The uncontrolled intraoperative hypertension due to tourniquet pain which cannot be managed by increasing the dose of narcotics and inhaled anaesthetics can usually be managed by vasodilator agents such as IV nitroprusside, nitroglycerine, or nifedipine, etc. The tourniquet pain under spinal or epidural anaesthesia sometimes becomes so severe that patient may need supplemental analgesia or light GA, despite the regional block is adequate for surgical incision.

Now, after multiple studies it is also observed that the tourniquet pain is mainly related to the quality or intensity of neural block than the level of the block. This is confirmed by the observation that tourniquate pain also can be relieved during continuous regional block by increasing the density of block by increasing the concentration of local anaesthetic agent or by adding some opioids with LA agent or by adding bicarbonate to LA agent which increases the fraction of the drug present as free base. It is also found that hypobaric and isobaric spinal technique result in lower incidence of tourniquet pain than the hyperbaric technique, even when the drugs, dose, and dermatome levels are same.

Bone (methacrylate) cement

Chemically the bone cement is a complex polymethylmethacrylate compound and is frequently used in joint arthroplasty. It acts only by helping strong binding between the metal prosthetic device and the cancellous or medullary part of the patient's bone. It also acts as a space filler which improve the fitting of implanted prosthetic device in the marrow cavity of the bone. However, the quality of interface between the cement and the bone is improved, if there is no layer of blood covering the bone surface when the cement is applied. So, some anaesthetists use hypotensive anaesthesia during the use of cement. But it has some disadvantages which are described below and are not routinely used.

Mixing of the solid methylmethacrylate polymer powder with the liquid methylmethacrylate monomer produces this polymethylmethacrylate compound which is known as cement. This is an exothermic reaction and leads to hardening and expansion of the cement substance. During preparation and hardening of this bone cement a strong pungent vapour is given off which produces some air pollution in operating theatre. This exothermic reaction also may cause some risk of thermal injury to the patient's tissues.

The major concern regarding the use of bone cement during joint arthroplasty is the pulmonary and cardiovascular responses of the patient. These responses are increased pulmonary vascular resistance, development of pulmonary hypertension, reduced cardiac output, hypotension, cardiac arrhythmias, and even cardiac arrest. These cardiovascular responses of patient during the use of bone cement may be due to the indirect and/or direct effect of cement. However, the indirect effect is more important than the direct effect of cement. The indirect effect of cement is due to the embolization of bone marrow into the right side of the heart and direct effect is due to the toxic effect of cement itself. In the indirect effect as the cement improves the fitting between the prosthetic device and the walls of the marrow cavity, it increases the intramedullary pressure, because during curing of cement in the marrow cavity it expands in volume. Thus, it forces out the remaining bone marrow contents or substances into the bloodstream and produces catastrophic pulmonary embolism of bone-marrow with the above mentioned complications. It is proved by the transoesophageal echocardiography (TEE) which shows the continuous raining of echogenic substances (pieces of bone marrow) in the right side of the heart after the application of cement. Sometimes, few large emboli may be observed in the right side of the heart, obstructing completely the right ventricular outflow tract and leading to acute right sided heart failure, reduced cardiac output, hypotension and cardiac arrest. Small emboli of bone marrow travers the right ventricle and embolises in the lung. These may increase the pulmonary artery pressure and intrapulmonary shunt. In patients with patent foramen ovale these emboli may pass into the systemic circulation through this foramen and cause systemic embolic manifestation such as infarction, stroke, etc. This is also proved by the fact that insertion of the stem of femoral prosthesis into the marrow cavity of femur increases the intramedullary pressure > 1 atmosphere and produces more entry of the medullary contents into the bloodstream than the only act of cementing of the acetabular prosthesis which is shown by echocardiography. It is also found that the emboli during prosthesis of hip is larger in size than the other joint arthroplasties such as knee. In patients undergoing total knee replacement surgery this reaction is not seen until the tourniquet is deflated which also prove the above explanation. However, this entry of bone marrow contents into the circulation is not so severe during other orthopaedic surgeries using bone cement such as surgeries on the proximal humerous. Also these reactions are not as common or as severe in prothesis where cement is not used. This increase in intramedullary pressure by bone cement not only causes the embolisation of the bone marrow contents, but also causes the embolisation of fat and air into the femoral venous channels.

The direct toxic effect of bone cement on the cardiovascular system of patient is due to the vasodilating and decreased systemic vascular resistance effect of the monomer component of the cement. It also release thromboplastin which trigger the aggregation of platelet and, the formation of microthrombus in the lungs. Thus it causes cardiovascular instability.

Therefore, the clinical symptoms of bone cement implantation is due to the embolic manifestation in lungs and direct toxic effect on CVS, all of which include pulmonary hypertension, hypoxia, hypotension, decreased cardiac output, cardiac arrhythmias and even cardiac arrest. As most of the hypotension after the use of cement results from the impaired left ventricular filling which is due to the pulmonary embolism and increased PVR, so the previous existing hypovolaemia will further impair the left ventricular filling and aggravate the hypotension leading to cardiac arrest. Hence, the management of the cardiovascular response of bone cement includes: increase in FiO_2, maintenance of euvolaemia before the use of cement, continuous monitoring of BP, and the use of vasopressor if necessary. The other measures which also can prevent the cardiovascular responses of cement during the joint arthroplasty are: the use of a plug previously into the marrow cavity of the femoral shaft that will limit the distal spread of cement in the femur, waiting for cement to become more viscus before its insertion, making a vent hole in the distal femur which will decrease the intramedullary pressure, vacuum drainage of marrow substances from the proximal femur during riming, performing a high pressure lavage in the distal femoral shaft which will remove the debris, or adopting some procedures where cement is not necessary.

Another major drawback of the use of bone cement during arthroplastic surgery is the delayed gradual loosening of prosthesis and it is due to the breakage of cement in small pieces over the years into the marrow cavity. In cementless arthroplastic surgeries, the natural bone grows slowly and fits the implants tightly. So, cementless arthroplasty last longer and advantageous for younger and active group of patients where healthy active bone will be formed, though the full recovery is slow and prolonged. Therefore, the bone cement for arthroplastic surgery is preferred where the chance of active healthy bone formation is less such as older (> 80 years) and less active patients who are suffering from osteoporosis or other diseases.

Hence, the use of bone cement depends on the patient's status, surgical technique, and the type of joint to be replaced. In modern practice, the articular surface is made up of plastic, ceramic, or metal.

Fat embolism

It means the appearance of fat globules in the bloodstream. The incidence of fat embolism is as much as 90% for the victims of major trauma. But the majority of cases remains subclinical and are only detected by the active investigations of serum or urine for the evidence of macroscopic fat globules. An association between the age and the incidence of fat embolism may be seen. Its incidence is low in the very young group of patient and much higher in the very old subject. When the fat embolism is manifested clinically, then it is known as the fat embolic syndrome (FES). However, the incidence of FES is rare (1 to 2%), but is fatal with high mortality rate (10 to 20%) when it occurs. It classically presents as the triad of pulmonary symptoms, CNS symptoms and cutaneous symptoms such as dyspnoea, confusions and cutaneous petechiae. But, the clinical diagnosis of FES is based on the major or minor criteria described in the (Table 43.3). It usually appears within 72 hours following the major orthopaedic surgeries or trauma. This syndrome can also be seen following parenteral feeding with lipid infusion or during liposuction. A full blown FES has cutaneous, CNS, pulmonary, and haemodynamic manifestations with less clincal effects on the other organs, depending on the site of embolic events.

Table 43.3: Diagnostic criteria of fat embolism

Major criteria	*Minor criteria*
PaO_2 < 60 mm of Hg	Tachycardia (HR >120/m
↑ PVR	Fat in urine
↑ Pulmonary artery pressure	Fat in sputum
Pulmonary oedema	Emboli in fundoscopic examination
Petechiae	Thrombocytopenia

Till now two theories of fat embolism have been advanced for its pathogenesis. Among them, the most widely accepted theory for the aetiology of fat embolism is the mechanical tissue trauma which forces out the fat globules, (released by the disruption of fat cells), into the circulation through tear in medullary vessels. This is proved by the fact that malignancy of long bones causes higher incidence of fat or marrow embolism. This is because the enlarged venous sinuses caused by malignant tumour permit greater access of fat globules into the circulation. Another alternative theory of fat embolism is that the circulating fat globules in the vessels result from the aggregation of the increased circulating free fatty acid (FFA) molecule due to the changes in the fatty acid metabolism for tramuma or surgery.

Regardless of the theories and the sources of fat globules in circulation, the clinical manifestation of fat embolism which is known as FES are due to the result of the deposition of fat particles at different organs and as well as the activation of some enzymes (particularly lipase) that lead to the capillary damage, endothelial leakage and release of many vasoactive substances such as prostaglandins, amines, etc. All these lead to the cutaneous manifestation (petechiae, mainly over neck, back, chest, trunk), pulmonary manifestation (ARDS), CNS manifestation (confusion, agitation, stupor, coma), CVS manifestation (due to pulmonary manifestation caused by fat embolism in pulmonary vasculature), ophthalmic manifestation (retinal exudate due to capillary leakage which is seen by fundoscopic examination as cotton wool), etc. It must also be considered that for systemic manifestation of fat embolism there must be a patent foramen ovale or intrapulmonary shunt which bypass the pulmonary filtration system and contribute the passage of fat globules directly into the systemic circulation.

The first step of diagnosis for early FES is a high index of suspicion. So, during anaesthesia for patients with higher risk and increased chances of incidence of FES attention should be focussed on the early signs and symptoms of FES and on the alterations of the normal physiology which indicate that fat embolism is occuring. The signs of pulmonary fat embolism during GA include ↓$ETCO_2$, ↑P_aCO_2, ↑pulmonary arterial pressure, ↓cardiac output, hypotension, etc. which are like the pulmonary embolism of bone marrow substance during the use of cement in arthroplasty. For diagnosis of cutaneous involvement of FES petechiae can be obvious. It can be further confirmed by retinal fundoscopic examination if cotton wool exudates are found. The clinical diagnosis of pulmonary involvement of FES may range from mild hypoxia with normal chest findings to mild hypoxia with wheezing, crepitations, secretions, etc. to full blown picture of ARDS. The diagnosis of cardiovascular involvement of FES depends on the stage of evolution. An early CVS finding in FES is only nonspecific tachycardia and right heart ECG changes which may pass later to severe hypotension, cyanosis, and left ventricular failure. Later DIC can result. Fat embolism to the specific parts of brain can cause seizure activity and predict serious FES. Coma can evolve from ischaemia, hypoxia and embolism to the key areas of brain stem.

There is no specific laboratory test which absolutely confirm the diagnosis of FES. The serum lipase activity may be elevated in majority of cases of FES, but bears no relationship to the severity of disease process. A large number of cases of fat embolsim will detect the fat globules in sputum, serum, or urine. But this test is too sensitive to use as an indicator of serious FES. Different coagulation abnormalities as the part of DIC may be present. There is general agreement that an unexplained low P_aO_2 (< 60 mm of Hg) which is not linked to other pathology is highly suggestive of FES. Patients with A-a O_2 tension gradients greater than 100 mm of Hg represent a high

probability of severe FES. It is also reported that bronchial lavage has both diagnostic and therapeutic value in FES.

The first step of the treatment of clinically manifested fat embolism (FES) is to minimise the factors which contribute to this process such as the decreased manipulation of fractures, decreased reaming of medullary canal, increased immobilisation of fractured long bones, etc. The second step of treatment of this disease process is supportive which are designed to decrease the impact of changes due to fat emboli. This includes the support of pulmonary and cardiovascular system according to necessary. Support of the pulmonary system will be the key factor for the survival of patient with severe FES. The principal objective of this support is adequate oxygenation of the tissues particularly the CVS, CNS, and other end organs. This is accomplished by the optimum support of cardiac output and adjustment of ventilation to achieve the best possible O_2 delivery to the tissues with the lowest possible FiO_2 to avoid injury of the pulmonary parenchyma from high FiO_2 for prolonged period (O_2 toxicity). This mandates the optimum PEEP, adequate cardiac output, proper patient's sedation and supportive mechanical ventilation. The defect of coagulation system must be treated based on the accurate assessment of the step of defects. For example the thrombocytopenia is treated by platelets. Decreased labile clotting factor or factor V (this factor is necessary for conversion of prothrombin into thrombin and is used up during clotting) is managed by fresh frozen plasma. Decreased fibrin level is maintained by pooled cryoprecipitate. The clinical situation where the laboratory results have long return intervals also can be managed by thromboelastogram and sonoclot devices which can provide accurate information and direct therapy. As the pathology of FES mainly involves the inflammatory reaction to the lungs and other tissues, so it is rational to use high doses of steroid for their profound anti-inflammatory property and to decrease the release of tissue activating factor from cellular injury (vasoactive substances). Previously for the management of FES, ethyl alcohol was used with the aim to decrease the activity of lipase. But now its use is abandoned as it had no effect. Similarly, the dextran and heparin was used previously to consolidate the fat. But recently these treatments are also ineffective and abandoned. Further they may contribute to the instability of coagulation system.

Deep venous thrombosis (DVT)

Pulmonary embolism (PE) originating from the clots of deep venous system by the process of thrombosis (deep venous thrombosis or DVT) may be the leading cause of morbidity and mortality following trauma or orthopaedic surgeries on the pelvis and lower extremities. The incidence of DVT is usually determined by a number of factors. These are: advanced age (> 60 years), prolonged bed rest or immobility, obesity, use of pneumatic tourniquet, prolonged surgery (> 30 minutes), surgery on pelvis or lower extremities, prior history of DVT or PE, malignancy, etc. Decreased fibrinolysis or release of plasminogen activating factors secondary to the inflated tourniquet are also the cause of tourniquet related DVT.

The risk of DVT and embolism from immobilisation of patient increases with the duration of immobilisation. The risk of DVT and embolism from upper extremity is very uncommon and is only related to trauma but not to surgeries. The use of oral contraceptive pill among the young woman patients also doubles the normal low incidence rate of DVT. The incidence of DVT in lower extremity (e.g. knee) following orthopaedic surgery using tourniquet and without any prophylactic measures varies between 40 to 60% which is demonstrated by venogram. This incidence is more high in pelvic fracture and this is due to the direct trauma of pelvic venous structure. Whereas the incidence of clinically significant PE following hip surgery is only 20 to 30%, among which only 1 to 2% becomes fatal. Although the clinical detection of DVT most often occurs between the 3rd and 5th day of surgery, but many clots are present in subclinical stage from earlier. This can only be detected by radiolabelled fibrinogen immediately after the surgical procedure. The likely major pathophysiological mechanism of DVT include the venous stasis and decreased fibrinolytic activity leading to hyper coagulable state which is further influenced by hormone related to pain or surgical stress. These facts comprise the triad of DVT which include : the change in constitutions of blood, the change in vessel wall and the change in flow of blood. Therefore, the prophylaxis of DVT acts at any of these steps.

Like fat embolism, the diagnosis of DVT is also triggered by the high index of suspicion in patients of high risked group. The first step of diagnosis of DVT is clinical examination. But, unfortunately the diagnosis of DVT by clinical examination alone may frequently overlook the presence of thrombosis which is sufficient to cause embolization and morbidity. So, the other more accurate methods of diagnosis are gradually evolved. The gold standard for diagnosis of DVT is the contrast venogram. This is only performed by cannulation of the distal vein on the involved limb and then the injection of contrast dye into that canulated vein to get the radiological picture of that venous system. This contrast venogram has very high detection and very low false negative rate. But its invasive nature, high cost, patient's discomfort, difficulty during cannulation and sometimes the chance of contrast media to cause thromboembolic disease itself leads to the search of ultrasound technique for diagnosis of DVT. The ultrasound technique diagnose the presence of thrombi in the venous system noninvasively by detecting the altered flow of blood in the venous system. Unfortunately, however, in ultrasound technique the false negative rate is very high. This is because of the

absence of a preoperative baseline study to compare with the postoperative picture and if the study is not performed by the same specialist pre and postoperatively, and also especially if the patient is obese.

Next, the radioactive fibrinogen study for the diagnosis of DVT also has high false negative and false positive rate. Another technique for diagnosis of DVT such as impedence plethysmography has also high detection but low false negative rate. But technically it is not very simple for clinical application. Therefore, in specialised centre performing major orthopaedic surgeries and when the suspicion is very high, then the combined approach of clinical examination, ultrasonography and venography is usually performed.

The prophylaxis for DVT is certainly more appealing than the treatment of it and its sequelae such as PE, cerebral embolism, coronary embolism, etc. This is because the institution of postoperative therapy in an established case of DVT by full dose of heparin may increase the bleeding at surgical site and therefore the morbidity by formation of haematoma at the operative site and at the spinal or epidural level. The treatment of an established case of DVT also increases the chance of postoperative infection, the length of hospitalisation, the cost, etc. Therefore, the prophylaxis of DVT has immense importance than its treatment. The prophylaxis of DVT is performed by interfering with the steps that lead to thromboembolic manifestation. These include : physical measures, antithrombotic drugs, and some modification of surgical and anaesthetic techniques. Among the physical measures the compressive elastic stocking or the intermittent compressive pneumatic stocking are most effective. This is because they more readily simulate the normal muscular contraction which helps in venous pumping from the lower extrimity. These should be applied prior to the surgical preparation and during the surgical procedure. The old electrical stimulation and contraction of the calf muscle for prophylaxix of DVT is proved to be no more effective than the simple intermittent compression of the muscle. In the postoperative period the most effective prophylactic physical measure of DVT is ambulation, if possible after orthopaedic surgery.

Many antithrombotic drugs that interact with the coagulation cascade have been used for the prophylaxis of DVT. These drugs are : various concentration of high molecular weight dextran, antiplatelet agent, aspirin, coumarin, heparin, and recently LMWH (low molecular weight heparin). Dextran acts by decreasing the platelet activity and interfering with the fibrin deposition. Despite its initial enthusiastic report, dextran is used now very rarely for the prevention of DVT and not at all for its treatment. Aspirin acts by preventing the adhesion of platelet to the injured vessel wall. It is given orally or rectally. It is not so effective in preventing the formation of thrombus, because the concentration of aspirin necessary to achieve the antiplatelet activity for antithyrombotic effect increases the intraoperative blood loss and causes the higher incidence of wound haematoma formation post operatively. However, among the antiplatelet agents only the dipyridamole is used as prophylaxis for DVT. It acts in the same way as aspirin or other prostaglandin synthetase inhibitor and has the same disadvantage like aspirin which is discussed above.

Coumarin (warfarin) is the most commonly used drug for the prophylaxis of DVT in high risk patients. It is usually used at the evening following surgery or at the next morning. The therapeutic end point of administration of coumarin (warfarin) is increasing the PT by 50% over the control value. The use of coumarin preoperatively is abandoned now, because it also increases the intraoperative bleeding. When DVT occurs inspite of the use of coumarin, then heparin is started as an acute course. Later coumarin is reinstated for maintenance.

Heparin acts by activating the plasma antithrombin III. At low concentration of heparin, factor Xa mediated conversion of prothrombin to thrombin is selectively affected (antithrombin activity). The anticoagulant action of heparin is exerted mainly by the inhibition of factor Xa as well as inhibition of thrombin (IIa) mediated conversion of fibrinogen to fibrin. For the treatment of DVT or pulmonary and systemic embolism such as cerebral embolism, coronary embolism, etc, the full anticoagulating dose of heparin is used. But this is too dangerous for prophylaxis of DVT, because of the fear of excessive bleeding, formation of haematoma, and other of haemorrhagic events elsewhere in the body. So, the idea of low dose of heparin has been evolved. It is administered in the dose of 5000 unit 8 hourly through subcutaneous route which only interfere the formation of clot at the site of injured vessel. In the majority of cases PT or PTT is not prolonged. But, as the result is not absolutely guaranteed, so it may rise concern in spinal and epidural block and most anaesthetist feel that evaluation of PT/PTT is mandatory prior to performing any central neuroaxial block, even in a patient receiving low dose SC heparin as prophylaxis.

Refined heparin preparations containing only the smaller molecules of it, called LMWH, has less effect on the platelet function than standard heparin. So, it has the same antithrombotic quality but less direct effect on coagulation and give the effective DVT prophylaxis with the decreased risk of postoperative bleeding and haematoma formation. The PT/PTT is also not prolonged by LMWH. Therefore, unless the patient pose any exceptionally high risk which demand the anticoagulant treatment preoperatively, all these anticoagulants should be started few hours after surgery only to prevent the excessive intraoperative surgical bleeding and prophylaxis of DVT.

Though it is generally agreed that preoperative full anticoagulation or fibrinolytic

therapy provide an unacceptable risk for spinal or epidural haematoma formation following regional anaesthesia, but still there is some controversy regarding the danger of patients who is receiving the low dose of anticoagulation preparation as prophylaxis preoperativley and undergoing regional anaesthesia – spinal and epidural. However, it is agreed that placement of spinal or epidural needle or catheter should generally not be undertaken 8 to 10 hours after administration of minidose of unfractioned heparin through SC route or within 12 to 24 hours of LMWH. Concomitant use of antiplatelet agent with heparin may further increase the risk of spinal or epidural haematoma formation. It is also interesting to mention that regional anaesthesia with continuous postoperative analgesia can mask the signs and symptoms of an expanding haematoma resulting cord compression (back pain, muscular weakness, etc.) and thus delaying the diagnosis and treatment.

It is an established fact that there is less incidence of DVT among the patients who are undergoing orthopaedic surgeries of pelvis or lower extremities under spinal or epidural anaesthesia compared to GA. There is also more reduction of incidence of DVT when the regional anaesthetic technique is extended postoperatively as continuous epidural infusion for postoperative analgesia. However, the method of detection of DVT must be the same with either venogram or radio labelled fibrinogen uptake. The probable theories about the decrease in thromboembolic manifestation associated with regional anaesthesia is that it improves the blood flow in microcirculation due to the effect of sympathectomy, as venous stasis is the known cause of DVT. Another probable threory is that pain or stress response inhibit fibrinolysis and thus regional anaesthesia is associated with this increase in fibrinolytic activity and reduction of the incidence of DVT. Some works have also established that there is an increase in DVT when blood loss is higher. Therefore, as regional anaesthesia is known to decrease the blood loss, this also causes the decrease in incidence of DVT.

Blood loss

Major orthopaedic surgeries are associated with significant amount of bloos loss. But the blood loss during orthopaedic surgeries is somewhat different from the blood loss in other specialities of surgery. This is because in major orthopaedic surgery the large amount of blood is lost from the raw bone and muscle surfaces which limits the surgeon's ability to control it directly and allows much of the shed blood to escape the method of retrive by suction catheter and gauze sponges, and it also continues after the closure of surgical wound. It is also proved by the radio isotope studied that the actual amount of blood loss in major orthopaedic surgery is 50% higher than the amount which is estimated clinically. Thus, the surgeons and anaesthetists always underestimate the blood loss during major orthopaedic surgeries. There are also many factors which increase the loss of blood during orthopaedic surgeries. These are: previous surgeries, large area of raw bones, proximal site of operation where tourniquet cannot be applied, presence of infection at the operative site, previous radiation at the operative site, surgeon's technique, etc. The reduction of blood loss during orthopaedic surgeries has many benefits to the patient. It reduces the exposure of patient to donated blood (homologus banked blood) and transmission of fatat viral disease such as hapatitis, HIV, and protozoal disease such as malaria, etc. The use of donated blood may have other harmful effects which can also be reduced by decreasing the blood loss. The intra operative decrease in blood loss also causes the reduction in postoperative infections, improved surgical results, better binding of cement to the bone, etc.

There are different methods by which the intraoperative blood loss and/or donation of homologus banked blood during orthopaedic surgeries can be reduced. These may begin with the use of tourniquet, preservation of normothermia, intraoperative haemodilution etc, and end with the predonation of autologus blood, induced hypotension, conduction anaesthesia, use of cell saver, progressive use of erythropoietin, use of antifibrinolytic agent, etc. In practice, the combination of several of these modalities is most effective in reducing the blood loss and subsequently reducing the incidense of homologus blood transfusion. Cell savers are expensive and have certain risks. So, they are used selectively in the operating room for major spinal surgery. Antifibrinolytic drugs such as tranexamic acid and aprotinin, and postoperative cell salvage are probably best used when the expected blood loss exceeds 2 litres. But it is warranted in minor procedure due to the risks of aprotinin. It acts by inhibiting the fibrinolytic pathway and intrinsic coagulation pathway by decreasing the activation of plasminogen. Thus it reduces the intraoperative blood loss. However, it is usually reserved for high risk cases (coagulopathies) or revision arthroplasty or bilateral hip arthroplasty. This is becaue it has high propensity to produce immunological sensitization. However, the use of aprotinin does no increase the incidence of DVT or PE.

A pneumatic tourniquet placed proximal to the site of surgery on extremities and inflated to occlude the arterial blood flow at the operative site eliminates the intraoperative blood loss. But, the significant loss of blood will occur postoperatively when the tourniquet is removed. So, some surgeons routinely deflate or remove the tourniquet before closing the wound to control the postoperative bleeding. The another method for the reduction of intraoperative blood loss is avoidance of hypothermia. This is based on the finding that mild hypothermia (35°C) is associated with an average increase of 500 ml of blood loss during single total hip arthroplasty.

Haemodilution and maintenance of normal blood volume with normal blood

pressure of a patient by administering cell free fluids such as saline, starch solution, albumin solution, etc. is also a common method of managing the blood loss and reducing the use of banked blood (homologous transfusions). When the patient's haemoglobin concentration falls between 6 to 7 gm/dl, then the anaesthesiologists must determine whether patient's risk due to inadequate oxygenation caused by anaemia will justify the transfusion of blood on not.

The transfusion of banked blood can be replaced by more safer autologous transfusion. This can be arranged by collecting the blood from surgical field or donating by patient and preserving preoperatively. This autologous transfusion of blood will remove the adverse effects of homologus transfusion for which the intraoperative reduction of blood loss is attempted. Recently much attention has been directed at the using of synthetic erythropoietein factor to increase the red cell mass of patient preoperatively. It is used in the dose of 600 IU/Kg subcutaneously weekly beginning 3 weeks before surgery. It increases the red cell mass by enhancing the production of it by stimulating the division and maturation of megaloblast in bone marrow. Therefore, it increases the number of collected autologous blood unit and reduces the amount of homologous blood transfusion.

During orthopaedic surgeries under regional or general anaesthesia intraoperative blood loss from raw oozing surfaces also can be reduced by the induced hypotension. This can be achieved by high spinal or epidural anaesthesia or by using Na-nitroprusside and nitroglycerine during GA and maintaining the BP at lower level such as MAP at 50 to 60 mm of Hg. But many patients scheduled for orthopaedic surgeries are old enough and may present relative contraindications to this type of hypotensive anaesthesia. The high regional anaesthesia produces patient's discomfort and it can be ameliorated by combining it with GA. Now, it is suggested that the combination of high level spinal or epidural anaesthesia with GA is safer and may be applied as a method of reducing blood loss during orthopaedic surgeries.

Positioning of patient

For different orthopaedic surgeries different position of the patient is needed. Further, different positioning places the patients at the risk of varieties of injury, but mainly nerves by compressions. Therefore, an anaesthetist must be aware of it and almost try to prevent their occurances. An awake patient will not tolerate this compressive nerve injury for long time, because pain and restlessness caused by the ischaemia of nerve will trigger the patient to correct its position spontaneously. But, in the sedated or anaesthetised patient this is not possible. So, different nerves and other structures such as blood vessels, skin, muscles, etc, are more liable to injury during anaesthesia. If a patient incurs nerve injury during anaesthesia and surgery, then the anaesthetist will be held responsible for it, whether the injury is related to the position, surgery, or other causes (Fig. 43.1).

The principal means of brachial plexus injury under GA is stretching. This is because of the hypermobility of upper extremity, the long course of nerves in the plexus, the extreme mobility of neck, and some points of fixation of this plexus of nerves during formation. When the patient's arm is constantly held for long time in excessive abducted position with flexion and rotation of neck to the contralateral side, then it puts the brachial plexus under stretching and subsequent ischaemia. Here the head of the humerus acts as a pivotal point against which the stretching of nerves occur. In another circumstances if the humerus is allowed to fall posteriorly against the trunk in supine position then it also causes the excessive stretching of nerves in the brachial plexus and injury. When the patient is kept in lateral position, then the brachial plexus is also at risk for both the dependent and the non dependent limb with more risk to the first one. This is because in dependent limb the plexus is compressed between two bony structures, i.e. the rib cage and the head of the humerus. So, in order to avoid this compression injury of brachial plexus the weight of the patient's thorax must be kept off the humerus and a roll of foam or towel of proper size should be placed in the axilla. The vascular integrity of dependent arm should also be checked by pulse oximeter. But it does not always guarantee the integrity of brachial plexus. In prone position, there is more danger to the ipsilateral brachial plexus, if the head is rotated toward the contralateral side, placing the brachial plexus under stretch at its origin. In the postoperative period the diagnosis of brachial plexus injury is first suspected, if the patient has unusual pain in the neck and the upper arm on the first postoperatvie day. This pain may be accompanied by numbness and loss of motor function. It can affect the entire brachial plexus (C_5 to T_1), but commonly it involves only the upper roots (C_5 to C_7, Erb's palsy) with the involvement of upper arm and forearm, and less commonly the lower roots (C_8 to T_1) with the involvement of hand (Fig. 43.2).

Just immediately above the elbow the ulnar nerve is situated very superficially in the olecranon notch. So, direct compression at this place can render the ulnar nerve ischaemic and after prolonged ischaemia

Fig. 43.1: Stretching of brachial plexus due to excessive abduction of arm and flexion and rotation of neck

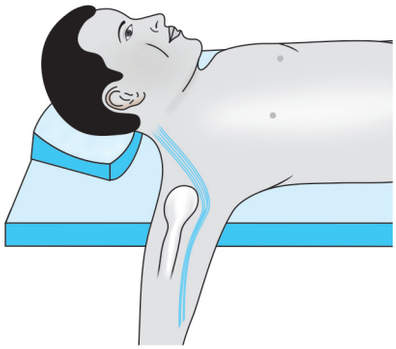

Fig. 43.2: Stretching of brachial plexus due to hanging of hand below the table

neuropraxia can occur. For a patient under GA the ulnar nerve is highly susceptible to injury at this site in supine posture by the edge of the table. So it must be always positioned such that direct compression of the ulnar nerve does not occur. The ulnar nerve injury may be detected in the post-operative period as a weak grip strength of hand. By specific examination it is found that the weakness is localised only to the ulnar function of the hand. Depending on how high the lesion is, there may be weakness of the wrist flexors also. The intrinsic muscles of the hand supplied by ulnar nerve will be weak and finger dexterity will be poor. Abduction and opposition of the 5th finger may be weak. There may be sensory deficit over the ulnar fingers and palm. In complete lesion of nerve there is no regeneration. So, there is wasting and contracture of the the intrinsic muscles, resulting in claw hand (Fig. 43.3).

The saphenous nerve is very superficial at the region of the upper part of the leg. So, this nerve is also more susceptible to injury at this site by compressions when the patient is positioned in lithotomy position by some devices like the picture for knee immobilization during arthroscopy. The compression injury of the saphenous nerve produces only the sensory loss over the distribution of this nerve on leg and foot. The saphenous nerve of the dependent leg is also at risk from pressure injury when the patient is kept in lateral position for prolonged period (Fig. 43.4).

Normally, in supine position the sciatic nerve is protected from compressisn injury by the muscles of the buttock. However, in supine position especially in thin and malnourshied patients or due to any position of buttock in normal individual over the edge of a positioning device can result in compression injury of the sciatic nerve. The incorrect application of the lateral position of patient also can put the sciatic nerve of dependent side liable to injury by the edge of the table, or by any positioning devices or other irregular surfaces due to direct compressions over the lateral gluteal surfaces. Intramuscular injection in the buttock should be performed in the superior and medial location to minimise the possibility of intraneural injection of the sciatic nerve, as it emerges from the pyriformis. Trauma to the branches of sciatic nerve is also possible. For example the common peroneal nerve is very superficial and liable to direct pressure injury as it sweeps around the head of the fibula just below the joint line of knee. This occurs in dependent leg when the patient is kept for prolonged period in lateral position or during lithotomy position when the leg is kept medial to the stand which is erected to hold the leg in hanging position (Fig. 43.5).

When the sciatic nerve injury occurs, then all the muscles below the knee will be paralyzed or becomes weak and numbmess of the anterolateral part of the calf and foot, except the spahenous area will also occur. When the injury of common peroneal nerve occurs, then the loss of dorsiflexion of the ankle (foot drop) is accompanied by the anterolateral numbness of the calf and the medial planter side of the foot. Deep peroneal injury also involves foot drop and numbness of the dorsum of foot. Posteriar tibial nerve injury results in numbness of the plantar surface of the foot, toes and the lateral edge of foot, combined with weakened plantar flexion.

Of all the positions chosen for orthopaedic surgery, the prone position is the lest physiological for the patient under anaesthesia. The prone position brings a hot of challenges to an anaesthetist depending on the types of surgery and anaesthesia selected. GA presents different issues from RA and LA with or without sedation. There is definite problem for ventilation and excessive surgical bleeding in prone position. In addition to the risk of injury to nerve, the prone position may also precipitate the risk of injury to the muscle and skin also. The direct prolonged contact of bed with the body during prone position is sometimes associated with isolated lesion by pressure of different terminal branches of the facial nerve, bracial plexus, femoral and

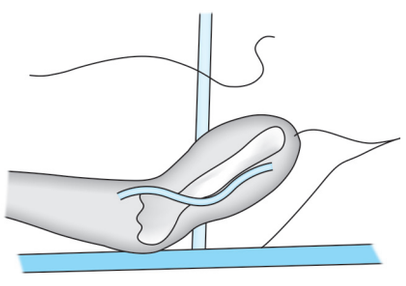

Fig. 43.3: Compression of radial nerve

Fig. 43.4: Compression of saphenous nerve on the medial side of the leg below knee by iron stand

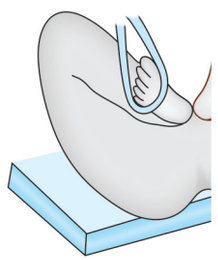

Fig. 43.5: Compression of common peroneal nerve over the head of fibula

other nerves. Different positioning devices that facilitate the prone position also can injure the different nerves or their branches. Curved frames that allows the abdomen to hang freely may also place direct pressure on the lower abdomen. But care should be taken to avoid direct pressure to the ilioinguinal and illiohypogastric nerve in the region of iliac crest (Table 43.4).

The use of tourniquet is also a risk factor for nerve injury. So, the size of the cuff, proper placement of it, padding and the duration of cuff inflation are the all important consideration. Inflation of tourniquet for more than 2 hours increases the risk of ischaemic injury to the underlying muscle and nerve. However, the nerve of upper extrimity is more sensitive to injury by tourniquet than that of lower extrimity.

When the fractured table is used for some orthopaedic surgeries with the patient in supine position, then all the risks of injury arising from supine position will persist and the other extra risks for this type of table also will be added. The purpose of the fractured OT table is to immobilize the patient's lower extremities and also to allow some rotation and traction of leg which will facilitate the surgery. After anaesthesia the patient is shifted from a regular bed to the fractured table. The trunk and hips are placed in supine position and the legs hang freely, supported by the heels. Longitudinal traction is applied and counter traction is indirectly imposed at a fixed postplaced between the patient's leg. Thus potential injury of lower extremities can occur from traction and counter traction or due to other positions caused by the fractured table. The post is placed at the perineum. So the external genitalia, especially of male are at increased risk of injury from compression by the post.

Table 43.4: Problems faced by anaesthetist during prone position of patient

Airway	Dislodgement of ET tube
	Kinking of ET tube
Nerves	Stretching or compression of brachial plexus
	Compression of ulnar nerve
	Compression of common peroneal nerve
	Gross hyperextension or hyperflexion of neck
	External pressure on eyes
	Excessive rotation of neck
Others	Kinking or obstruction of blood vessels
	Excessive lordosis

INDIVIDUAL ORTHOPAEDIC SURGERY

Total Hip Replacement (THR) or Arthroplasty

Most of the patients who are advised for THR surgery are usually suffered from osteoarthiritis, rheumatoid arthiritis, avascular necrosis of the bones of hip joint, etc., and it is for these diseases they are advised for such surgery. Osteoarthiritis is a degenerative process and affects not only the hip joint for which the patient is put for surgery, but also affects the articular surfaces of the bones of other joints. But among all the joints, the hip and knee are mostly affected. Bones of the vertebral column are also affected by osteoarthiritis. So, making different positions of the patient during THR surgeries and also positioning of neck during intubations is very difficult which is important to an anaesthetist. This is because excessive movement of vertebrae due to positioning or intubation can cause nerve root compression or disc prolapse.

Unlike osteoarthiritis, rheumatoid arthiritis is an immune mediated disease and affects the synovial membrane of joints instead of the articular surfaces. It affects multiple joints including hip, knee, vertebrae, shoulder, and some small joints of hands and legs. It becomes a concern to an anaesthetist when it involves the cervical vertebra and temperomandibular joint. When cervical vertebrae are involved, it causes sublaxation of atlantoaxial joint. Atlantoaxial sublaxation is important to an anaesthetist because during the flexion of neck for intubation the odontoid process may protrude into the foramen magnum and can compress the spinal cord or brainstem causing serious injury or death. Rheumatoid arthritis is also a concern to an anaesthetist because it may produce difficulty in intubation due to involvement of temperomandibular joint. Sublaxation of the atlantoaxial joint can be diagnosed radiologically. So, during preoperative evolution all the patients suffering from severe rheumatoid arthiritis and getting steroid or methotrexate as medication must have the lateral radiograph of neck in both the position of flexion and extension. If the atlantoaxial instability exceeds 5 mm, then intubation should be performed by awake fibreoptic laryngoscope or other techniques with out any movement of the neck. Rheumatoid arthirits also have the systemic involvement affecting the immune, haematology, pulmonary and cardiovascular system, which have immense implications on anaesthesia. Sometimes, patients with rheumatoid arthritis suffer from severe deformities which make the insertion of invasive catheters and even gaining an intravenous line a challenge.

The surgical procedure of THR involves the prosthetic replacement of acetabulum and the femoral head. It includes the procedures such as: (i) Reaming of acetabulum and insertion of prosthetic acetabular cap with or without cement, (ii) Dislocation and removal of femoral head, and (iii) Reaming of femur and insertion of prosthetic femoral head into the shaft with or without cement. The anaesthetic consideration of THR involves the general principles of orthopaedic surgeries which are discussed under the heading of 'introduction' and 'specific problems related to orthopaedic surgery'. Among these the three potential life threatening complications of THR are: Intra and postoperative haemorrhage, bone cement implantation syndrome and DVT.

THR is a major surgical procedure and takes 2 to 3 hours as intraoperative time. The expected perioperative blood

loss during THR is 1 to 1·5 litre and the position of patient to facilitate the surgery is lateral (more common) or supine. To maintain the lateral position of patient an anaesthetist must discuss with surgeron regarding the proper placement of anterior pelvic brace. Because if it is placed too far caudally it will exert much pressure on the femoral triangle of the dependent leg of patient causing venous or arterial obstruction. On the other hand, if it is placed too far cranially, it will also press the patient's abdomen too forcefully and can limit the movement of diaphragm causing impairment of respiration. THR surgery is particularly amenable to RA with slight sedation or full GA. But the technique may be influenced by the patient's wishes and its medical status. In RA, postdural puncture headache is very rare with 25G needle as the procedure involves mainly the older age group of patients.

As THR is a major surgery and may involve many complication, so intraoperative monitoring of patient by invasive arterial line, transoesophageal echocardiography, $ETCO_2$, etc may be considered. These are more applicable for revision arthroplasty after prior surgery, or bilateral hip arthroplasty, or very sick patient. But, unless, the patient is at particular risk due to severe illness, then intraoperative monitoring by measuring BP with an arm cuff and measuring urine output with a bladder catheter is usually sufficient for cardiovascular system. Embolic phenomenon most frequently occurs during the insertion of femoral prosthesis or at the end of surgery when the hip is relocated. This is because during relocation of leg emboli formed by the contents of bone marrow are dislodged from the previously obstructed femoral vein. More emboli occur in patient when cement is used for THR than when it is not used. Therefore, uncemented THR is preferred for patient at higher risk of FES. The measures taken to avoid the embolic manifestations include omitting cement, high pressure wash out of femoral canal to remove debris (potential microemboli), and drilling a venting hole in the distal part of the femur to relieve intramedullary pressure. Increased pulmonary artery pressure at the time of cementing the femoral prosthesis is the usual finding during THR surgery. So, many anaesthetists increase the FiO_2 prior to cementing. Careful maintenance of blood volume at the time of the placement of prosthesis and hip relocation attenuates the chance of decrease in BP due to bone marrow emboli. Severe hypotension during THR reflects large emboli in pulmonary artery causing large increase in PVR, decreased cardiac output and resultant right heart failure or severe reaction from cement. So, immediate inotropic support is recommended. As DVT is prevalent after THR, so all the measures to prevent this complication should be taken when managing THR. This is already discussed before and among these regional anaesthesia is important. So, THR should better be performed under spinal or epidural block.

Blood loss in THR is expected to be large and may increase to about 2 litres or above in case of revision of prior arthroplasty. It depends on many factors such as the surgical technique used, the skill of surgeon, and the type of prosthesis chosen, etc. This losses of blood can be reduced by deliberately inducing controlled hypotension. So, a combination of RA (like continuous lumbar epidural or single shot spinal with or without narcotic) with anaesthetic level upto T_4 and light GA could be employed. With mean arterial pressure maintaining at 50 to 60 mm of Hg the intraoperative blood loss can be reduced to less than 300 to 500 ml. Thus, by providing dry surgical field, controlled hypotension also improves the result of THR using cement and make short the duration of surgery. If deliberate hypotension is contraindicated due to any reason, then deliberate haemodilution and/or preoperative preservation of autologuous blood unit can prevent the intraoperative transfusion of banked blood. Preoperative administrations of recombinant human erythropoietin represents an another alternative for perioperative allogenic blood transfusion. Maintenance of normal body temperature is also an another mean to reduce the intraoperative blood loss. Preoperative insertion of epidural catheter and diluted local anaesthetic solution with or without opiates greatly facilitates the postoperative pain management in THR. This may extend for 48 to 72 hours.

Total hip replacement of both the sides at the same time is a longer and more invasive procedure than THR of one side. So, they are associated with more haemodynamic changes particularly if cement is used. Therefore, in such situation consideration should be given to direct arterial pressure monitoring, access to large bore venous system for quick transfusion, and other full haemodynamic monitoring, especially in elderly frail patient. The amount of blood loss may go above 2 litres. It can safely be performed in one anaesthetic sitting if there is no significant PE of bone marrow contents after insertion of the first femoral component. Monitoring of pulmonary artery pressure may indicate pulmonary embolization by a rise in pulmonary artery pressure and fall in cardiac output. The normal pulmonary artery pressure is 200 dyne × s × cm^{-5}. If it rises above normal, then the plan for surgery of contralateral side should be postponed. Recently, synthetic prosthetic system is available which does not require cement and therefore cementless hip arthroplasty of both sides at one sitting does not require monitoring of pulmonary artery pressure.

Hip Fracture

Usually there are two types of hip fracture: Intracapsular and extracapsular. Intracapsular fracture is again of two types — subcapital and transcervical, and extracapsular fracture is again of three types — base of the femoral neck, intertrochanteric, and subtrochanteric. In general, the intracapsular fracture is associated with less amount

of blood loss (400 ml) than the extracapsular fracture (800 ml). Most patients coming with hip fracture for surgery and anaesthesia are aged, frail and suffering from many concomitant systemic diseases such as osteoporosis, IHD, COPD, hypertension, diabetes mellitus, cerebral vascular diseases, psychiatric disorders, etc. In such group of patients the common cause of hip fracture is indirect trauma due to fall. But, occassionally young patients may also present with hip fracture and this is mainly due to direct accidental trauma. The patients presenting with hip fracture are often severly dehydrated. This is because of occult blood loss, use of diuretics in case of hypertensive patient, inadequate oral intake in psychiatric patients, delayed rescue after accident and trauma, etc. They also present with a false normal or borderline normal haematocrit value and it is due to dehydration and haemoconcentration or actual anaemia due to occult blood loss. It is also very important to know the cause of fall or cause of accident which may be stroke, MI, cardiac arrhythmia, etc. resulting in hip fracture. Because all these have imanse effect on anaesthesia (Fig. 43.6).

Generally, the operative decision for hip fracture is taken in the hope of getting the older patient out of the bed as much as quick possible in order to reduce the bad effects of prolonged staying in bed. These bad effects due to prolonged staying in bed include the bed sore, pneumonia, thromboembolic manifestation, etc. However, emergency surgery for hip fracture is not undertaken and is usually performed after one or two days, during which period the patient is treated for the concomitant diseases and is also prepared for surgery. However, more delay in surgery does not increase the mortality, but increase only the morbidity which are mainly related to the lungs and skin. Sometimes, during preoperative evaluation the examination of mental status of patient is very important. This is because: dementia patients are not suitable for RA, mental illness is associated with delayed recovery and increased mortality, they cannot be communicated during perioperative period, and others which are discussed in the chapter 'Psychiatric diseases and anaesthesia'. The hip fractured patients are more likely to be hypoxaemic than expected for their age. This may probably due to the result of occult fat embolism. Many studies have reported that the rate of mortality following hip fracture may vary from 10 to 15% during admission in hospital and 20 to 25% at the end of 1 year. The significant predicting factor for this mortality include : old age > 85 years, pulmonary complications, infection, depressed mental function, etc.

The choice between GA and RA for fractured hip surgery is also extensively studied and is tilted towards the later like other orthopaedic surgeries. This is because RA is associated with decreased thromboembolic manifestation, induced hypotension facilitating surgery, reduced blood loss, postoperative analgesia, more prompt return to the preoperative mental state, lower mortality rate in the early postoperative period, etc. However, in recent studies it is found that the mortality rates after 1 to 2 months following RA or GA is more or less same. There is also a general impression that RA is less associated with postoperative confusion and mental impairment than GA but it is only in the absence of previous psychiatric disease and if excessive sedation are not used perioperatively. However, recent studies do not confirm it and shows that both the type of anaesthesia (general and regional) produce the same postoperative confusion and mental impairment. The postoperative confusion correlates best with the presence of preoperative confusion, presence of preoperative hypoxaemia, and the use of drugs with anticholinergic effects, but not on the mode of anaesthesia. The mode of anaesthesia in fractured hip also depends on the type of surgery which varies from close reduction with surface traction to open reduction with different types of internal fixation such as cannulated screw fixation, intramedullary Gamma nail, extramedullary sliding screw and plates, etc. according to the site of fracture, degree of displacement, patient's status, etc.

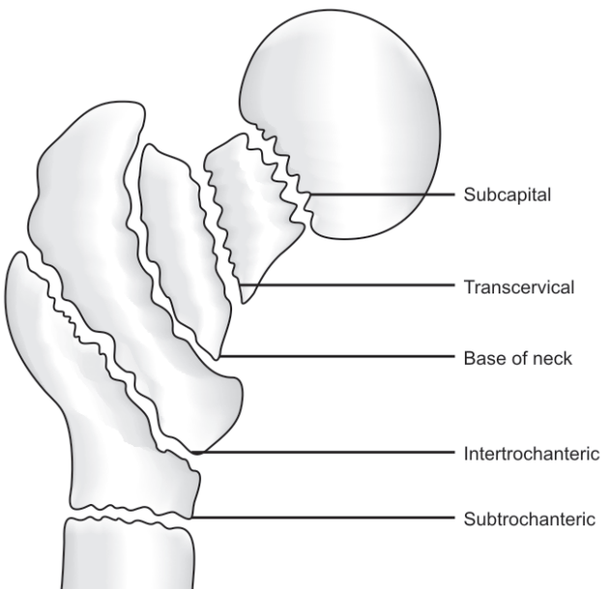

Fig. 43.6: This figure shows different types of fracture of the head of femur

Total Knee Arthroplasty (TKA)

The anaesthetic consideration of TKA is more or less similar to THR surgery. RA offers several advantages to the patients

undergoing such surgery and therefore is preferred. The usual position of the patient for TKA is supine and tourniquet is commonly used to reduce the blood loss. So, there is more chance of DVT and other thromboembolic manifestation than THR, and the prophylactic measures do not seem to reduce the incidence of these problems. When the TKA using cement is performed under tourniquet then the syndrome of ↑PVR, ↓CO, systemic hypotension, etc. which are usually found after the use of cement is delayed until the tourniquet is deflated at the end of surgery. Otherwise, when tourniquet is not used this syndrome may begin immediately after the insertion of prosthesis. The patient may suffer from the combined effects of embolism arising from cement, blood clot, fat or marrow debris and blood loss. This can be diagnosed by TEE showing emboli in RV, increased pulmonary artery pressure, hypotension, and hypoxaemia. Large emboli greater than 5 mm produces fatal consequences and is more commonly associated with tourniquet. So, the vital signs of patient should be monitored continuously in the perioperative period especially after insertion of prosthesis or deflation of tourniquet when bone cement is used and the patient is treated with O_2, fluid, pressure agents as required. Sick patients or with cardiovascular diseases who might not be able to compensate adequately for these events during TKA should be monitored extensively by invasive method and ventilators should be kept ready at hand.

Recently, many studies are showing their result that the complication rate and initial recovery of knee movement is better when TKA is performed without tourniquet. The expected blood loss in single TKA is about 1 to 1·5 litres. The use of tourniquet reduces this intraoperative blood loss, but may be the same after deflation of tourniquet. Deliberate hypotension reduces the perioperative blood loss, but may increase the incidence of PE.

The surgical insult caused by single TKA is usually tolerated by most of the healthy patients who do not have serious pulmonary and cardiovascular diseases. On the other hand, bilateral TKA in one sitting is associated with double amount of blood loss, requiring subsequent blood transfusion, and double the risk of PE. Therefore, the decision of TKA in both legs in one sitting will depend on the patient's health status, invasiveness of monitoring and the outcome of surgery of one leg. It is better to stage the bilateral TKA procedure into two when performed in one sitting, so that the second part does not begin until it is seen that there is no complication after the first phase of TKA procedure.

Postoperative pain following TKA is more severe than THR. Therefore, effective postoperative analgesia is essential for early physical rehabilitation after TKA. This will in turn prevent the joint adhesions and increases the movement. Non-cooperative patients will not do exercise even with good postoperative analgesia. So, there should be a balance between the pain control and the cooperative patient willing to do exercise. The preoperative placement of epidural catheter is the best way for postoperative pain management and physiotherapy. For this 0·2% ropivacaine infusion at the rate of 10 ml/Hour will provide good analgesia with minimum motor blockade. Alternatively, placement of an indwelling catheter in femoral sheath may be performed for postoperative analgesia. Through this catheter 0·2% ropivacaine or 0·25% bupivacaine can be used continuously at the rate of 5 to 10 ml/hour for good analgesia with minimum motor block.

Knee Arthroscopy

The surgeries of knee joint that can be done through arthroscopy include menisectomy, ligament repairs, replacement of cruciate ligaments, removal of loose foreign bodies, etc. The typical patients undergoing knee arthroscopic surgeries are young healthy adult, usually atheletes. However, it is also performed on aged persons with multiple medical problems. All forms of anaesthesia as an outpatient basis is suitable for knee arthroscopic surgery. So, it may vary from GA to spinal anaesthesia using fine pencil point needle to combined spinal epidural anaesthesia to femoral block. Less invasive and least prolonged procedure also can be performed with the intraarticular injection of local anaesthetic solution. Absorption of local anaesthetic (LA) agent from joint surface is slow and addition of epinephrine in this local anaesthetic solution will further decrease its absorption. Therefore, blood concentration of LA agent will be always minimum and 30 ml of 0·5% bupivacaine with or without epinephrine is safe. If blood less field is required for arthroscopic surgery then tourniquet should be applied and mode of anaesthesia also should be changed accordingly.

Closed Treatment of Fracture, Joint Manipulation and Reduction of Dislocation

The management of these group of patients are more or less similar. As the procedures are very brief, so GA is often preferred to regional techniques. The later is chosen for elderly patients with multiple medical problems and full stomach. For example, reduction of Colles's fracture in an elderly patient can be achieved by intravenous regional anaesthesia or brachial plexus block. If GA is chosen then violent fasciculation by succinylcholine which may disturb some fractures should be avoided. Whatever may be the type of anaesthesia profound muscle relaxation is mandatory. This will allow the surgeon to distinguish between the limitation of joint movement due to anatomical cause or muscle guarding. Thus, short acting IV anaesthetics and small dose of succinylcholine is effective. If surgical lesions permit then intra-articular injection of LA may provide some postoperative analgesia after joint manipulation.

44 Anaesthesia for Surgeries of the Genitourinary Tract

INTRODUCTION

About 15 to 20% of all anaesthetic procedures are undergone for genitourinary tract surgeries. With a drastic revolution in technology and introduction of fibreoptic instrumentation, complicated urological procedures have become common. Patients undergoing genitourinary tract surgeries are usually elderly, with multiple, coexisting medical disorders, thus making anaesthesia more challenging. The commonly used lithotomy position, the approach through the transurethral route, the extracorporeal shock waves used in lithotripsy and other radical methods make the procedures more complicated. Proper and meticulous preoperative evaluation of the patient, understanding the surgical procedure, being acquainted with the surgical skill and estimating the approximate time of surgery – helps the anaesthesiologist to formulate the best anaesthetic plan.

The anaesthetic plan for all genitourinary tract surgeries partly depends on the innervation of the area (Table 44.1).

Motor suply of the bladder is by the parasympathetic nerves. Sensation of fullness and stretching of the bladder is carried by the afferent parasympathetic fibres. Sympathetic fibres carry the pain, touch and temperature sensations. Pain from the ureter and kidney is felt in the low back area, flanks, scrotal, labial and ilioinguinal areas, i.e. along the innervation of the 10th thoracic nerve mainly, but also extending to the second lumbar regions. Nerves from the lumbosacral area innervates the prostate.

Some important genitourinary procedures shall be discussed now, to help further understanding of the subject.

CYSTOSCOPY

One of the most commonly performed genitourinary procedure is cystoscopy. Introduction of the flexible fibreoptic scope have made this procedure very easy to perform.

Indications

Urinary obstruction, haematuria and recurrent urinary obstruction are most common indications for cystoscopy. Bladder tumour biopsies and resection, renal stones extraction and placement of ureteric stents are also done through a cystoscope. Retrograde pyelograms are also performed through a cystoscope.

Position

The most commonly used position for genitourinary procedures is the lithotomy position, which may be accompanied by the trendelenburg (head-down) position. Improper positioning of the patient may cause severe iatrogenic complcations. The patient lies supine and straps, holders, stirrups or supports hold the legs in position. These supports should be padded to prevent nerve injuries. The legs should hang freely. Pressure of the straps on the lateral part of the leg causes injury to the common peroneal nerve, with loss of dorsiflexion of the foot. Pressure of the straps medially on the leg injuries the saphenous nerve, causing numbness along the medial calf. The obturator and the femoral nerves may be damaged by too much flexion of the thigh. Extreme flexion of the thigh may also damage the sciatic nerve. Prolonged lithotomy position often presents with a compartment syndrome of the inferior extremities, with rhabdomyolysis.

Table 44.1: Level of regional anaesthesia required for surgeries of different structures of the genitourinary tract

Urethra		S2 - S4
Bladder	Dome	T11 - L2
	Lower tract	S2 - S4
Ureter		T10
Prostate		T11 - L2 and S2-S4

Various physiological changes are associated with the lithotomy position, which makes the work of the anaesthesiologist more demanding. Congestive cardiac failure is often exaggerated, as raising of the legs increase venous return and blood pressure though cardiac output remains almost unchanged. Lowering of the legs similarly decreases the venous return and the blood pressure. This hypotension is further increased by regional or general anaesthesia, due to vasodilatation. So blood pressure measurement and monitoring is essential before and after positioning of the patient in the lithotomy position. Lung atelectasis and hypoxia is common as functional residual capacity decreases, which is further aggravated by the trendelenburg position.

Anaesthesia

Age of the patient, gender and indication for cystoscopy decides on the plan

of anaesthesia. Cystoscopy in children is always performed under general anaesthesia. Short urethra in females allows the procedure to be performed under topical anaesthesia, with viscous lidocaine, with or without sedation, but only for diagnostic purposes. All cystoscopies for therapeutic or operative purposes are preferred under general anaesthesia. In males, cystoscopies for diagnostic as well as operative purposes are done under general or regional anaesthesia.

General anaesthesia is preferred by most anaesthesiologists for cystoscopy, due to the short duration of the procedure (about 18-20 minutes). Patients are usually very apprehensive and so they too prefer general anaesthesia. LMA (laryngeal mask airway) is usually used. Oxygen saturation is closely monitored in all patients.

Regional anaesthesia may also be opted. Either spinal or epidural anaesthesia may be preferred, though most anaesthesiologists like spinal anaesthesia, as epidural anaesthesia takes 20 minutes to provide satisfactory blockade whereas spinal anaesthesia takes just 4-5 minutes. All cystoscopies can be done with a sensory block up to T10. Most anaesthesiologists believe that the sensory block by the hyperbaric local anaesthetic agent, used for regional block should be well "fixed", before putting the patient in lithotomy position, as that may raise the level of the sensory block. But, there is no substantial evidence to prove this.

Obturator reflex is not abolished by regional anaesthesia. Muscle paralysis in general anaesthesia is needed to block the obturator reflex (electrocautery of the lateral bladder wall stimulates the obturator nerve, which causes external rotation and adduction of the though).

TRANSURETHRAL PROSTATECTOMY (TURP)

Transurethral prostatectomy is the most commonly adopted operative procedure for either benign or malignant hypertrophy of the prostate, in elderly men. Prostatic enlargement leads to urinary bladder neck obstruction.

Indications

The patients present with recurrent urinary infections, persistent haematuria or even impaired renal function. TURP is preferred in patients with a prostate gland volume less that 45-50 ml. Larger volumes require alternative aproaches like suprapubic prostatectomy or perineal prostatectomy. TURP is also the procedure of choice in patients with prostatic carcinoma and helps to relieve the urinary obstruction.

Position

The usual lithotomy position.

Anaesthesia

Most patients are elderly and have coexisting pulmonary, cardiac or renal diseases. No wonder TURP carries a 0.5-7% mortatity rate, even today. Preoperative evaluation and optimising of the patient presenting for TURP is of utmost importance to an anaesthesiologist (Table 44.2).

Spinal anaesthesia is the choice of most anaesthesiologists, though other forms of regional anaesthesia like epidural block may be opted for too. Block up to T10 sensory level is enough to make the patient, surgeon and anaesthesiologist comfortable. Regional anaesthesia is contraindicated only when there is possibility of lumbar metastasis of prostatic cancer and then GA is preferred (Table 44.3).

TURP Procedure

A cystoscope, more precisely a resectoscope is introduced, which has a cutting and coagulating wire loop. By passing a cutting current through this loop, hypertrophic prostatic tissue is resected and removed from the medial and the lateral lobes, under continuous irrigation and direct visualisation. Continuous irrigation is used to distend the bladder, remove the resected materials and clear the field of surgery.

Complications

Here are some of the major complications in TURP:

i. TURP syndrome
ii. Bladder perforation
iii. Haemorrhage
iv. Bacteraemia and septicaemia
v. Coagulopathy – DIC (Disseminated intravascular coagulopathy)
vi Hypothermia
vii. Rarely death due to myucardial infarction, renal failure or pulmonary oedema.

TURP Syndrome

The prostate has a network of large venous sinuses, which open up during

Table 44.2: Comparison of regional anaesthesia over GA in TURP

1. Regional anaesthesia does not mask the signs and symptoms of TURP syndrome, unlike GA
2. Regional anaesthesia does not mask the signs and symptoms of bladder perforation, unlike GA
3. Regional anaesthesia decreases the incidence of postoperative venous thrombosis.
4. Reversal and recovery from general anaesthesia is delayed due to hyponatraemia, caused by TURP syndrome.
5. GA is preferred in cases of lumbar metastasis of prostate cancer.

Table 44.3: Essential intraoperative and early postoperative monitoring in patients of TURP

1. Mental status: Any alteration detects early signs of TURP and bladder perforation.
2. Arterial oxygen saturation: A decrease detects fluid overload.
3. Temperature: To detect hypothermia.
4. ECG: To detect ischaemic changes.
5. Blood chemistry: Haemodilution may decrease the haematocrit values.
6. Blood loss: Larger prostatic volume (> 45 ml) and longer operative procedures (> 1.5 hours) may require blood transfusion, as controlling prostatic bleeding is often difficult. So blood should be cross-matched and arranged.

transurethral resection and cause absorption of the irrigating fluid into the systemic circulation.This results in a set of manifestations, commonly referred to as the TURP syndrome, which may become evident intraoperatively or in the early postoperative period. If not treated instantaneously and with utmost care, fatality is not uncommon. The amount of irrigating fluid absorbed depend a number of factors, listed below (Table 44.4).

The irrigating fluid should be nonelectrolytic because electrolyte solutions disperse the electrocautery current, passing through the loop of wire. Visibility is best with water, but can cause severe water intoxication on absorption. Water also causes lysis of red blood cells due to its hypotonicity. Water irrigation is used only for resection of bladder tumours. To increase the osmolality of the irrigating fluid mannitol, glycine, sorbitol, urea, etc. have been added to it, but one has to be careful. These solutes and their metabolites should be nontoxic and easily excretable (Table 44.5).

Hyponatraemia occurs due to intravascular absorption of any non-electrolytic irrigating fluid, due to its hypotonicity. The CNS symptoms of TURP syndrome are usually due to hyponatraemia, which causes metabolic encephalopathy, which in turn is caused by cerebral oedema. Clinical manifestations of hyponatraemia appear only when the serum sodium concentration falls below 120 mEq/L (Table 44.6).

Glycine is commonly added to the irrigating fluid for TURP, to increase its osmolality to plasma level. Hyperglycinemia due to intravascular absorption of this irrigating fluid, is also responsible for most of the CNS symptoms. Visual disturbances like transient blindness has been reported, but the vision usually returns back to normal within 24 hours. Normal plasma glycine level is about 12-15 mg/L and may increase to 900-1000 mg/L after TURP. CNS symptoms of glycine is because it is an inhibitory neurotransmitter in the CNS. It also acts on the retinal receptors to cause transient blindness. Glycine also causes cerebral oedema.

Ammonia is a metabolic product of glycine degradation. Hyperammonaemia causes seizure and coma in TURP patients, by increasing the concentration of neurotransmitter in the brain. Normal ammonia level in blood is 5-50 µmol/L and may exceed 100-150 µmol/L in TURP patients.

Dextrose or sorbitol in irrigating fluid may cause hyperglycaemia (Table 44.7).

Mannitol does not undergo metabolism in the body. It causes osmotic diuresis, increases fluid overload and may cause congestive cardiac failure or pulmonary oedema.

The absorption of the irrigating fluid may be intravascular or extravascular. Intravascular absorption occurs when the hydrostatic pressure of the irrigating fluid (the height of the irrigating fluid above the open venous channels of the prostate) is more than the pressure inside the venous sinusoids of the prostate. Extravascular absorption of the irrigating fluid occurs only when the prostatic capsule is perforated during surgery and it effects the haemostasis. Extravascular diffusion of the irrigating fluid along with excretion through the kidney, decreases the severity of complications due to intravascular absorption (Table 44.8).

Treatment of the TURP syndrome

The treatment of TURP syndrome depends on the early detection and severity of symptoms. Patients should be closely

Table 44.4: Factors on which absorption of irrigating fluid depends

1.	Duration of the surgical procedure.
2.	Type, nature and amount of fluid used for irrigation.
3.	Hydrostatic pressure of the irrigating fluid.
4.	Number, size and pressure in the venous channels opened up in the prostate.
5.	Skill of the surgeon.

Table 44.5: Common irrigating fluids used in TURP

Plain water
Glycine solution (1.5% - 230 mOsm/L)
Mixture of sorbitol (2.7%) and mannitol (0.54% - 195 mOsm/L)
Sorbitol solution (3.3%)
Mannitol solution (3%)
Dextrose solution (2.5 - 4%)
Urea solution (1%)

Table 44.6: Characteristics of an ideal irrigating fluid in TURP

1.	It should be isotonic.
2.	It should be nonhaemolytic.
3.	It should be nontoxic.
4.	It should be nonelectrolytic.
5.	It shouldnot be easily metabolised.
6.	It should allow clear visibility.
7.	It should not affect the osmolality.
8.	It should be rapidly metabolised.
9.	It should be an osmotic diuretic.

Table 44.7: Major physiological changes in TURP syndrome

Circulatory fluid overload
Water intoxication
Hypo-osmolality and hypotonicity
Haemolysis
Solute toxi
Hyponatraemia – from all irrigating fluid
Hyperglycinaemia – from glycine solution
Hyperammonaemia – from glycine solution
Hyperglycaemia – from sorbitol or dextrose solution
Intravascular fluid volume-expansion from mannitol solution

Table 44.8: Common clinical manifestations of TURP syndrome

1.	CNS manifestations - Restlessness, confusion, anxiety, agitation, nausea, disorientation, visual disturbance, seizure and coma.
2.	CVS manifestations - Increased CVP, bradycardia, anginal pain, ischaemic changes in ECG, hypotension, congestive cardiac failure, cyanosis, arrhythmia, etc.
3	Respiratory symptom - Dyspnoea, pulmonary congestion and pulmonary oedema.

monitored. Investigations should be done immediately to evaluate the severity of TURP syndrome. Blood glucose, blood urea, serum creatinine, ECG, glycine and ammonia levels and electrolytes should be evaluated. Hyponatraemia should be corrected to prevent the CNS manifestations with hypertonic saline solution, in patients with normal renal function. In patients with renal failure, dialysis should be started. Hyponatraemia creates acute hypotonia and our aim should be to shift fluid from the intracellular compartment to the extracellular compartment. This helps to decrease cerebral oedema. But one should be careful that rapid correction of hyponatraemia may cause circulatory overload, cerebral haemorrhage or cerebral demyelination. The rate at which hypertonic saline solution is given should not be more than 100 ml/hour and the amount of hypertonic saline solution repuired depends on the level of hyponatraemia. Seizures may be corrected with diazepam (2 to 5 mg), midazolam (2 to 4 mg), thiopental (75 to 100 mg), phenytion (10 to 20 mg/kg) slow IV (at the rate of 50 mg/min). Lasix may be given to correct fluid overload. Transient blindness may evaluated by an ophthalmologist but is usually self limiting. Hyperglycinemia and hyperammonemia doesnot resquire any specific treatment. Hypoxaemia should be avoided. Endotracheal intubation may be advised in very severe cases, mainly to avoid aspiration (Table 44.9).

The dreaded complications of TURP syndrome may be avoided by decreasing the resection time (to maximum 1 hour), by consultation with the surgeon. The procedure should be performed under spinal anaesthesia rather than GA, for early detection and management of symptoms. Hypotension due to spinal anaestiesia should not be corrected with large volume of hypotonic IV fluid, instead vasopressors should be used. 0.9% saline solution is considered best for IV infusion during TURP.

Table 44.9: Signs and symptoms of hyponatraemia

Serum sodium level	*Manifestations*
Below 120 mEq/L	Blood QRS complex, restlessness, disorientation.
Below 114 mEq/L	Nausea, vomting, elevated ST segment.
Below 100 mEq/L	Ventricular febrillation, seizure, coma.

Some other major complications of TURP are explained below.

(a) Bladder perforation

Bladder perforation may be caused by over distension of the bladder with irrigating fluid or by direct injury to the bladder wall by the resectoscope. In most cases the perforation in extraperitoneal and the patient complains of suprapubic, inguinal or periumbilical pain, accompained by nausea. Poor return of the irrigating fluid during the procedure signals extraperitoneal perforation of the bladder. Intraperitonal perforation of the bladder presents with hypotension, bradycardia and acute abdominal symptoms.

(b) Haemorrhage

Thromboplastins released from the prostate during TURP, into the circulation causes DIC (Disseminated intravascular coagulopathy). Diffuse uncontrollable bleeding is often seen in TURP and is tough to manage. Absorption of the irrigating fluid often causes dilutional thrombocytopaenia. Primary fibrinolysis caused by metastatic carcinoma of the prostate due to release of fibrinolytic enzymes from the cancer cells, causes coagulopathy and hence profuse haemorrhage. Laboratory tests confirm the diagnosis and the help of a haematologist is sought for. Heparin, replacement of clotting factors and platelets are used to treat DIC. Primary fibrinolysis is treated with E-aminocaproic acid 5 gm IV, repeated at a dose of 1 gm/hour IV.

(c) Septicaemia

The prostate is a site for bacterial colonisation and chronic infection. Opening up of the venous sinusoids and surgical procedure on the prostate, causes these bacteria to escape into the circulation, leading to bacteraemia and septicaema, or even septic shock may result if neglected. Fever, rigor and tachycardia are the common symptoms. Antibiotics like cephazolin, levofloxacin, gentamycin, etc. are preferred by most surgeons, prophylactically given before TURP, to avoid this complication.

(d) Hypothermia

Large volume of irrigating fluids and intravenous fluids (given to correct hypotension of spinal anaesthesia), given at room temperature, causes acute hypothermia. This often leads to rigor during the postoperative period. But this is best avoided as it may dislodge the clots formed and thus increase chances of acute postoperative haemorrhage. All fluids – whether irrigating or intravenous fluid – should be heated to body temperature to prevent hypothermia.

LITHOTRIPSY

Treatment of stones in the urinary tract has changed drastically in the past few years. The open surgical procedures have been replaced by noninvasive or lesser invasive surgical procedures, using cystoscopes – both rigid and flexible.

Indications

Stones in the urinary bladder and lower part of the ureters are removed by intracorporeal lithotripsy. Intracorporeal lithotripsy may be laser lithotripsy or electrohydraulic lithotripsy. Intracorporeal laser lithotripsy uses a Holmium-YAG laser. Stones in the upper part of the ureters and the kidney are removed by ESWL (Extracorporeal Shock Wave Lithotripsy) or percutaneous nephrolithotomy. Percutaneous nephrolithotomy is used to remove big

stones (more than 2 cm) and hard stones like cystine stones, uric acid stones and calcium oxalate monohydrate stones. It is similar to ureteroscopy, the approach is through a percutaneous sheath over the kidney, with the patient in the prone position.

Mechanism

ESWL comprises of a lithotriptor. The lithotriptor has a spark plug, which is the energy or shockwave generator; a reflector; a concentrator and either a fluoroscope or a ultrasonogram for viewing the stone. A water bath or a conducting gel attaches the generator to the patient. The spark plug produces energy waves repeatedly, which vaporise the water in the water bath, thus creating an external shock wave (sound waves) there. As the acoustic density of the tissue and water is same, these shock waves travel from the water bath into the tissue of the patient's body, without any damage to the tissue or loss of energy. As these extracorporeal shock waves meet a stone, the acoustic density changes (between the tissue and the stone) and energy is released. As these shock waves pass through the stone and leaves it to enter the tissue again, energy is again released. This double power breaks the stone into fragments and the small pieces are washed down the urinary tract. Ureteral stents placed preoperatively with the help of a cystoscope allows larger stones to pass through, without damaging the tissue.

There are three types of shock wave generators used in ESWL (Table 44.10).

In older electrohydrautic lithotriptors, the patient was submerged in a hot water bath on a hydraulic chair. The patient was so placed with the help of two image intensifiers, that an underwater spark plug (energy generator) was the first focus of an elliptical reflector, while the stone was the second focus. Modern lithotriptors generate energy using electromagnetic waves or from piezoelectric crystals. In electromagnetic generators, a metallic plate is placed in front of an electromagnet, the vibration of which produces shock waves. In piezoelectric lithotriptors electric current is passed through ceramic crystals and shock waves are produced when their external dimensions change. Both the electromagnetic and the piezoelectric generators are put in a case filled with water and a plastic membrane or conducting gel couples it to the patient. These newer lithotriptors have facilities for both ultrasonography and fluoroscopy, for localisation of the stones.

Table 44.10: Extracorporeal shock wave generators used in ESWL

Type	*Model*
Electrohydraulic generator	
– With tub	Dornier HM_3
– Tubless	Dornier MFL5000
Electromagnetic generator	Dornier DoLi, Compact Delta, Sigma, Siemens Lithostar, Storz Modulith.
Piezoelectric generator	Wolf Prezolith

Anaesthesia

Lithotripsy by older electrohydraulic lithotriptors using a water bath was painful. 1200-2400 high voltage shock waves were required to pass through. So regional or general anaesthesia was preferred. Newer lithotriptors use 1500-2500 low voltage shock waves, which can be performed even with light sedation.

Continuous epidural anaesthesia was the procedure of choice of most anaesthesiologists previously. Kidney is supplied by T10 to L2. So a T6 sensory block was sufficient for ESWL. Fentanyl was used epidurally for better analgesia. Light IV sedation was used and oxygen supplementation with a face mask or nasal catheter was given. During insertion of the epidural cannula and cathetor minimum air should be put in the epidural space (for testing the loss-of-resistance feeling) and foam tapes should be avoided for fixing of the cannula as both air and foam tapes cause release of energy, when the shock waves pass through them causing tissue damage.

Spinal anaesthesia was avoided because postdural puncture headache was common due to the sitting position of the patient in the hydraulic chair, after the spinal block. A loading volume 1200-1500 ml of lactated Ringers solution is given to the patient IV before hand, to prevent postural hypotension during positioning of the patient, after the regional anaesthesia. Further, 1500-2000 ml of lactated Ringers solution is given along with a diuretic intraoperatively, to increase urinary flow and wash out the stone fragments, clots and debris. Less and calculated fluid is given to patients with low cardiac reserve.

Diaphragmatic movement is not controlled in regional anaesthesia. The movement of the diaphragm during spontaneous respiration may move the stone in and away from the shock waves, thus prolonging the procedure. The patient may be asked to take shallow breaths but that is not always practical, especially when light sedation is administered to calm the patient. So general anaesthesia is prefered by some anaesthesiologists, especially when electrohydraulic lithotriptors with water bath is used. Endotracheal intubation with muscle relaxation is preferred but placing an anaesthetised patient on a hydraulic chair and raising and lowering him to submerge him in a water bath carries its own risks. Newer methods of ESWL require low voltage shock waves and can be done under sedation. Propofol infusion with midazolam and some opioid analgesic is often sufficient.

Monitoring is important in ESWL. ECG leads should be attached with some waterproof dressing. Oxygen saturation should be noted and temperature of the water bath maintained. Pulse and blood pressure monitoring is mandatory for each patient.

Complication

Placing a patient in a heated water bath causes vasodilatation and transient hypotension. The hydrostatic pressure of water

on the inferior extremity and abdomen, causes redistribution of the venous blood centrally. Thus preload is increased and CVP and PCWP raised. Stroke volume increases, cardiac output increases but heart rate remains the same. Subsequently systemic vascular resistance (SVR) rises and cardiac output falls. This increase in venous return can cause congestive cardiac failure in patients with poor cardiac reserve. Shock waves of ESWL can damage the parts of a permanent pacemaker or internal cardiac defibrillator, thus precipitating arythmia in these patients. If the shock waves are synchronised with the R wave of the ECG and the shock waves are generated during the ventricular refractory period (i.e. approximately 20 minutes after the R wave) of the cardiac cycle, arrhythmias may be avoided.

Hydrostatic pressure of water on the chest of the patient decreases the FRC, vital capacity and tidal volume. Thus work of respiration has to be increased. As all respiratory reserves are decreased, hypoxia is quite common.

Table 44.11: Other common surgeries of the genitourinary tract

Laparoscopic procedures	Pyeloplasty Partial nephrectomy
Nephrectomy	Renal cancer
Radical prostatectomy	For adenocarcinoma of prostrate
Cystatectomy	For bladder cancer
Orchiectomy	For testicular cancer
Renal transplantation	

Contraindications and Special Considerations

Pregnancy is a complete contraindication for ESWL. Coagulopathies and anticoagulant therapies are relative contraindications. Aortic aneurysms in the abdomen, especially with calcifications and orthopaedic prosthesis should be kept away from the path of the shock waves. Obesity is a problem for ESWL due to mechanical factors. The temperature of the water in the water bath may affect the body temperature. Lungs and intestine, should be kept away from the path of the shock waves, as air tissue interfaces can dissipate energy and cause tissue damage. Chronic infection and obstruction of the urinary tract below the stone is a contraindication for ESWL. Ecchymosis haematoma, blistering or bruising of the skin is common at the site of treatment. Development of a perinepheric haematoma has also been observed (Table 44.11).

Each has its own special consideration, positioning and complications.

45 Day Case Anaesthesia

INTRODUCTION

Day case anaesthesia in also termed as outpatient anaesthesia or ambulatory anaesthesia. Over the last few decades, day case surgery and according to the need of this surgery the day case ambulatory anaesthesia has grown up at an exponential rate. It is mainly due to the major development of sophisticated surgical equipment advocating more and more minimal invasive surgery and due to the development of newer ultrashort acting anaesthetic drugs which help in quick recovery. A day case or an out patient surgery and anaesthesia is one which is performed on a patient who is admitted only for investigation under anaesthesia or for minor examination under anaesthesia or for operation on a planned non resident basis and who nonetheless requires any overnight indoor facilities for recovery. Today, almost 60% of all the elective surgery and anaesthesia are performed at the outpatient surgical and anaesthesia setting in the form of GA, LA or MAc (monitored anaesthetic care). In USA and UK, over 80% of all the elective surgeries are performed as an outpatient basis and this is likely to increase more and more in near future in response to the economic pressures on the health care market.

For day case anaesthesia while the surgical procedure is same, but the anaesthesia and the nursing care are significantly different from if the same is performed at the in-patient setting. In the day case unit anaesthesiologists are mainly responsible for evaluating, screening, informing and preparing the patients, both by physiologically and psychologically. Specialized skills are required for day case or outpatient anaesthesia, because the patients are discharged to their home soon after their operation. So, at conclusion, we may say that to achieve a pain free ambulatory day case patient, it requires skillful patient selection, experienced anaesthetists and skilled surgeons working coordinately in a day case surgery and anaesthesia unit. The day case surgery and anaesthesia unit is also termed as the cost-effective quality care unit. This is because costs for anaesthesia and surgical procedures are much less in such setting than when the same procedure is performed at the in-patient setting without sacrificing quality. Costs in day case or out-patient anaesthesia unit can be minimised without sacrificing quality by (i) the proper preoperative screening, (ii) unnecessary cancellation of surgery, (iii) decreasing room turn over times, (iv) decreasing stays in post-anaesthesia care unit and (v) reducing unanticipated admission and staffing.

The cost of surgery and anaesthesia on an ambulatory basis has been estimated to be about 25 to 75% less than the similar inpatient procedure. Ambulatory day case surgery and anaesthesia also offers a wide variety of other advantages to all the parties involving patients, surgeons and insurance companies. Patients and their relatives experience less disruption to their personal lives and rapidly return to their daily activities. Patients are also able to recover at home in familiar surroundings. Thus, it provides an additional psychological benefit. There is also a reduced risk of complications such as wound infections (from other patients), deep venous thrombosis, pulmonary embolism, paralytic ileus and pneumonia (nosocomial), etc.

PATIENT SELECTION

Patient's selection for day case surgery and anaesthesia is the most important point, if the maximum use of resources and the smooth running of a unit is to be made. Proper preanaesthetic planning will minimize the unexpected cancellations or unnecessary postoperative admissions. It will also allow for easy access to in-patient services of the outpatient individual when necessary. The selection criteria of patients for day case anaesthesia and surgery should include: (i) the over all medical health of the patient (ASA physical status), (ii) age, (iii) social factors, (v) the surgical procedure, (vi) the limitations of surgical facility (vii) and the limitations of health care providers.

Normally the ASA I and II status patients (for example normal healthy patient with or without minor systemic disease, not interfering with the surgical and anaesthetic procedures or medical conditions that are well controlled by previous therapy such as hypertension or non-insulin dependent diabetes, etc), are included in this unit. But gradually the increasing numbers of medically stable ASA III patients are now included in outpatient surgical and anaesthesia unit due to the use of more and more local and topical anaesthesia and due to the more and more

use of minimally invasive (endoscopic) surgical procedures. Also it is important to notice that some ASA III patients do better in a day case enviornment rather than an in-patient enviornment e.g chemotherapy patients, stable diabetics, etc. But patients with significant cardiovascular or respiratory diseases, insulin dependent diabetes or those with gross obesity, etc., are not suitable for day case anaesthesia. Stable asthmatics are suitable for day case surgery and anaesthesia. Whereas frequent hospitalization, oral steroid therapy and poor control of symptoms of bronchial asthma would suggest unsuitability for day case unit. Stable epileptics on medications are suitable for day case surgery and anaesthesia, but propofol should be avoided if they have a driving license. Undiagnosed hypertensive disease and uncontrolled atrial fibrillation should be reevaluated on the day of surgery and anaesthesia.

Recently in USA, the patients of status of ASA IV are also inculded in day case surgery and anaesthesia. It is based on the findings that (i) there is no obvious relations between the ASA physical status and the rate of major morbidity or mortality after day case surgery and anaesthesia. (ii) It is also found that those with preexisting disease have the same complication rate as healthy patients. (iii) There is also no significant relation between the cause and the effect for pre-existing disease and the incidence of perioperative complications in the ambulatory patients. (iv) Major morbidity occurs less often in the ambulatory surgical population than in the age and gender matched population not having surgery. So, now a wide varieties of surgical procedures can be performed in an out patient basis (Table 45.1).

Duration of surgical procedure also has no impact on out patient surgical and anaesthesia unit as long as the post-operative physiological impairment of patient is at an acceptable level. There is great controversy on corelation between the duration of surgical procedure and anaesthesia with the recovery time. In one study, it is found that there is no correlation between the duration of anaesthesia and the recovery time. In another study, longer anaesthetic procedure is associated with longer recovery time and higher incidence of PONV, necessitating patient's readmission in hospital and overnight observation. So, the general rule is that operations lasting for more than 60 to 90 minutes and those associated with a risk of significant postoperative pain, haemorrhage, excessive fluid shifts and prolonged immobility should not be performed in day case unit. However, recently many oral, plastic, general, gynaecological and orthopaedic surgical procedures, lasting for 2 to 4 hours are now being routinely performed successfully in many ambulatory surgical and anaesthetic unit in USA.

Table 45.1: Common day case surgical procedures

General surgery	Superficial biopsy, abscess drainage, hernia repair, haemorrhoidectomy, laparoscopic cholecystectomy, varicose vein surgery, anal fistula repair, muscle biopsy.
Gynaecology	Superficial biopsy, dilatation and curettage, tubal ligation, polypectomy, hysteroscopy, Bartholin cystectomy.
Orthopaedics	Close reduction, biopsy, arthroscopy, anterior cruciate ligament repair, amputation, carpal tunnel release, excision of ganglion, removal of screw and plate.
Urology	Circumcision, orchidectomy, cystoscopy, lithotripsy, prostate biopsy, orchiopexy, urethral dilatation.
Ophthalmology	Cataract extraction, squint surgery, enucleation, ptosis surgery, chalazion excision, pterygium.
ENT	Tonsillectomy, adenoidectomy, tympanoplasty, rhinoplasty, polypectomy, myringotomy, mastoidectomy, removal of foreign body.
Plastic surgery	Cleft lip repair, skin graft, scar excision, basal cell cancer excision, mammoplasty.
Miscellaneous	Angioplasty, laser treatment, oesophageal dilatation, bone marrow aspiration, lumbar puncture.

Some ambulatory or day case surgical and anaesthetic centres question about the extremes of age (< 6 months and > 70 years) for selection of their patients. The cause is being: (i) the recovery of fine motor and cognitive functions are slower in older patients and (ii) the preterm infants who are less than 48 weeks of post-conceptual age are at a increased risk for apnoeic episodes after anaesthesia. But, the age alone should not be considered as a deterrent factor for the selection of patients for day case surgery and anaesthesia. Still, the infants less than 60 weeks post-conceptual age (gestational plus post natal age) should not be considered for day case surgery and anaesthesia and postanaesthetic apnoea monitoring for at least 12 to 24 hours has been recommended for them. Now, in many centres of developed countries there is no upper age limit for day case anaesthesia. Because there physiological fitness for surgery and anaesthesia is considered first rather than the chronological factor age. This is based on findings that there is no increase in morbidity with increasing age, when only the age factor is considered. However, special attention must be paid to the discharge criteria for that group of patient from day case unit, because recovery of fine motor function and cognitive skills following GA or sedation is slower in the elderly. Children are usually well suited for the ambulatory surgery and anaesthesia unit. This is because those who are treated on a same day basis have less psychological disturbances than those who are admitted on the day before and discharged on the day after surgery.

In some day care surgical and anaesthetic units severely obese patients are not selected. The upper limit of body mass index (BMI) for day case anaesthesia is 30 to 34 [BMI = weight (in kg)/height^2 in meter]. Moderate obesity in itself does not

preclude them from day case surgery and anaesthesia, but does cause unpredictable problems in terms of length of surgery and anaesthesia. BMI alone is not always considered as the ideal tool for assessing the fitness for day care surgery and anaesthesia. Obese patients in a day case unit should be scheduled for surgery at mid morning which will allow time for preoperative antacid therapy to work and will also allow adequate time for recovery. It will also have to remember that obesity may cause many problems to the surgeons or to the anaesthetist which will force them to treat these patients as indoor basis.

A limit is also set for the distance from the hospital to the patient's home during selection of patients for day case anaesthesia and surgery. A responsible adult must be present at home with the patient during the first 24 hours after day case surgery and anaesthesia. All the patients must be escorted to home during postoperative period by a responsible, and well-informed adult. All the patients should be adequately supervised during their recovery at home for a minimum period of 24 hours. Similarly all the patients must have suitable home conditions with adequate toilet facilities and a telephone should be readily available for advice during an emergency. The patient should also live within 1 hour's travelling distance from the hospital.

SURGICAL PROCEDURES

There is a long list of surgical procedures from different discipline of medicine which can be performed at a day case surgical and anaesthesia unit. But always it should be kept in mind that the procedures in which post-operative surgical and anaesthetic complications are likely to occur should be performed as an in-patient basis. The surgical procedures necessitating excessive fluid infusion or blood transfusion should be handled in the hospital's indoor patient setting. Operative procedures requiring prolonged immobilization and parenteral analgesic therapy are not ideally suited for the out-patient unit.

PREOPERATIVE VISIT, ASSESSMENT AND PREPARATION OF PATIENT FOR DAY CASE SURGERY AND ANAESTHESIA

It is already said that preoperative patient selection is the corner stone of running an outpatient anaesthesia and surgery unit. So for selection, preoperative visit of patient to the anaesthetic unit is important. Preoperative visit of patient to the anaesthetic unit has two parts: preoperative assessment and preoperative preparation. Preoperative preparation of patient again consists of pharmacological preparation, nonpharmacological preparation and preparation by information.

Preoperative Visit and Assessment

Preoperative assessment is the part of preoperative preparation of patient before coming to the out-patient anaesthetic unit on the day of surgery. The practice of not preparing the patients prior to the day of anaesthesia and surgery can result in unnecessary delays, last minute cancellation and inadequate patient management. So, the starting point of the day case anaesthetic process is the proper preoperative assessment of patient. Preoperative visit and assessment has also some public educative value, because anaesthetist may present different risks and complications of anaesthesia to the patient and its relatives related to the surgical procedure.

During the preoperative assessment of patient, the time required for taking history can be shortened by the use of pre-anaesthetic questionnaire. By that questionnaire information is usually obtained regarding the patients medical problems, previous operations, drug and family history, etc. and as well as it also provides a general review of the patient. The use of computerized questionnaire prior to pre-operative examination of patient by anaesthetist is more time saving and efficient. Modern computerized questionnaires are more accurate in listing positive and negative information and history than a physician's interview. This also can be used correctly to predict the need for preoperative laboratory testing. This approach has been shown to reduce the number of laboratory tests and result in considerable cost savings. In the near future, interactive screening process will almost certainly become available over the internet.

However, sometimes it is not always possible or practical to examine all the patients in the preanaesthetic unit regardless of their medical conditions prior to surgery. So, many day case institutions find alternative ways to achieve this same goals. Such alternative is, surgeons are asked to screen their own patients at their initial office visit prior to fixing the date of surgery. Patients who are of physical status like ASA I or II and who do not require laboratory testing or are not overly anxious about the surgery, can be seen by the anaesthesiologist on the day of anaesthesia and surgery. The preoperative laboratory investigation component should be tailored according to the patient's need, history, type of surgery and skills or preferences of the anaesthesiologist. Preoperative testing should also be based on the patient's age, history and examinations. The laboratory examinations should not be a lengthy screening procedures. Because it does not always provide benefit to the patient, anaesthetist, surgeon, hospital or society. Indiscriminate laboratory testing also produces a large number of false positive or random abnormal results and among them most of which are ignored by the anaesthesiologist. On the other hand, general physicians may treat these borderline or false positive abnormalities which can lead to patient's harm without any benefit. It is reported in a study that more than 60% of the routinely ordered preoperative laboratory investigation could be eliminated, if

these are tailored solely according to their correct indication. It is also known that only 0·2% of the abnormalities which are reported, might have influence on the perioperative anaesthetic care. Elimination of these unnecessary tests results in cost savings. It is also deplorable that some tests frequently ordered are not recommended at all, while others are not ordered though they are recommended. So, it is recommended that no laboratory tests are needed for active healthy male patients below the age of 40 without any history of previous medical disease and undergoing superficial outdoor surgical procedures such as biopsy, herniorrhaphy, circumcision, cataract, DCR, DCT, etc. For the female patients in this age group (i.e. childbearing age) only Hb or haematocrit estimation should be done. Estimation of haemoglobin or haematocrit value is also appropriate for children under the age of 5 years. Patients with an unexpected Hb concentration of less than 10 g/dl should undergo further evaluation prior to the elective out-patient surgery and anaesthesia, because low Hb concentration may be associated with many diseases that could influence the perioperative mortality and morbidity. Patients with chronic diseases such as diabetes, hypertension, COPD, etc. will require additional laboratory investigations according to the severity of diseases (Fact file- I).

FACT FILE - I

In summary, the following preoperative investigations for day case surgery and anaesthesia should be performed when appropriate. These are:

(i) Full blood count (FBC) only for patients with the possibility of anaemia e.g. bleeding piles, menorrhagia, child-bearing age, etc.

(ii) Sickle cell test in all patients of Afro-Caribbean origin.

(iii) Serum electrolytes and creatinine in patients on diuretics.

(iv) Blood sugar in patients who are diabetic.

(v) ECG in all male patients over the age of 40 years and women over 50 years and younger patients if they have a history of cardiac disease or signs of hypertension, dysrhythmias, diabetes etc.

(vi) X-rays only for patients with COPD, breathlessness, history of severe chest and cardiac disease or for all patients over 70 years of age. Very few day case surgery and anaesthesia patients need a preoperative chest radiograph.

After the preoperative visit in the anaesthetist's room, patients must visit the hospital's business office for financial interview, to familiarize himself and his party with the centre, and to complete all the paper works including the consent form which will effectively prepare the patient for out-patient surgery on the schedule day. This is because outpatients usually dislike to wait for long time before surgery.

Preoperative Preparations

Preoperative preparations have great impact on smooth functioning of an out patient surgical and anaesthetic departments. This is because, if the selected patients are not prepared properly, they might result in unexpected cancellation and great chaos. As for example, BP and blood sugar can go up in unprepared hypertensive and diabetic patient, leading to cancellation and so on so forth. Besides control of medical disorders from which the patient is suffering, the main aim of preoperative preparation in an out patient anaesthetic department is also the alleviation of anxiety of patient. Always a significant amount of anxiety is present among all the patients waiting for surgery. Hence the increased anxiety further increases the release of stress hormone and thus increases the anaesthetic requirement, resulting in prolonged recovery time. High level of anxiety can also be associated with other adverse outcomes such as increased incidence of tachycardia, increased BP, emesis, etc. Again, for day case anaesthesia surgical patients are not given any sedative premedications, because of the fear of prolonged recovery. So, to relieve anxiety patients must be prepared preoperatively by strong assurance. This is called non-pharmacological and informative methods of preanaesthetic preparation. The Pharmacological methods to relative anxiety are only applied when it is absolutely necessary. This excessive anxiety may later precipitate many behavioral problems in patients, especially paediatric group, after surgery. These behavioral problems are: aggression, regression, eating and sleeping disturbances, fears, angers, bed-wetting, increased dependency, etc. One of the key point to reduce this anxiety of a child is to allow the parents in anaesthesia room who will support their child during induction of anaesthesia. This will help in relieving the child's anxiety and producing smooth induction of anaesthesia. Similarly, the parents should be allowed to meet their child in the recovery room as soon as possible. It will also help to reduce the separation anxiety.

Non-pharmacological and informative method of preoperative preparation

An important and first step of non-pharmacological and informative method for preoperative preparation of patient is to visit this anaesthetist's room by patient and its relatives. The rationality behind the nonpharmacological preoperative preparation of patient is that information helps to build expectation and encourage cognitive control over the surgical events. A meeting among the anaesthetist, patient and his family is more effective to reduce anxiety than pre-operative benzodiazepines, barbiturates or any sedatives. Among the information only the perioperative events such as general plan for anaesthesia and surgery, benefits of relaxation, discussion of postoperative pain, hospital stay, etc, should be given. This type of preparation of patient by information will be beneficial, because this reduces uncertainty and subsequently anxiety. Patients may feel better having more control over the situation due to more clearly defined expectations. This will help in reducing the psychological stress factors which is associated with increased incidence of emesis. Information can be given in the form of

booklets or audiovisuals. Relaxation training is also given to reduce the anxiety and postoperative pain, successfully. These methods are economical and have no side effects which is the drawback of drugs or any medications. Patient's motivation and acceptance becomes high in non-pharmacological method than pharmacological one. Overall, a well-informed patient recovers faster and better and experiences less pain. Proper preoperative anaesthetic preparations should also include verbal and written instructions regarding arrival time, place of surgery, fasting instructions, postoperative advice, limitations of driving abilities after anaesthesia and the need for a responsible adult to escort and accompany the patient, while returning back to home.

Pharmacological method

For preoperative pharmacological preparation of patients, the use of drug as premedication for day case anaesthesia is controversial in outpatient anaesthetic unit. But this is not saying about the drugs which are taken preoperatively for medical disorders. The aim of premedications in out- patient anaesthetic department is like that of indoor patients i.e. anxiolysis, sedation, analgesia, amnesia, vagolysis, antiemesis and prevention of aspiration pneumonia. But problem is that the use of sedatives, hypnotics, analgesics, etc. prolongs the recovery time (some studies say) and causes more postoperative nausea and vomiting which are important concerns for out-patient anaesthesia. Also prolonged amnesia of the patient is not desired in the outpatient anaesthesia setting. But, recently many other studies have shown that the use of premedication does not delay the recovery and discharge of patients, although coordination and reaction times may be impaired for 6 to 12 hours. Hence, judicious use of preoperative medication can be extremely beneficial for some outpatients, without increasing morbidity. But, we will have to keep in mind that the choice of agents and timing of premedication for the outpatients requires different considerations than inpatients, with the special attention to specific needs of the patient and pharmacokinetics – pharmacodynamics of the used drug. So, in conclusion, it can be said that the proper choice of drug with its correct dose and timing, balanced with patient's need, actually facilitates the discharge of patient, reduce anaesthetic requirements and lesson the degree of postoperative emesis.

Among the sedatives and hypnotics, now barbiturates are not used as premedicant. This is because of their prolonged postoperative recovery time. So now, benzodiazepines and among them only short acting agents are the drug of choice. So, oral midazolam in the dose of 0.05 mg/kg with a little undiluted sweet fruit juice surpasses all and is used in out patient setting due to its short elimination half-life and lack of significant side effects. The rapid onset of action than other benzodiazepine and water solubility of midazolam offer a number of advantages for day case anaesthesia and surgery. This agent may also be given through IM 30 to 40 minutes before surgery or preferably IV before the induction. Midazolam (1 to 2 mg) given IV prior to the induction of GA reduces anxiety and increases amnesia without prolonging the recovery room stay. It may be associated with impaired postoperative psychomotor skills. Midazolam given orally has been reported to be highly effective for adults, as well as for children, although larger doses of it are required because of the first pass metabolism of midazolam by liver. Intranasal and rectal midazolam are also highly effective routes for administration of it, if the child tolerate them (Table 45.2).

Temazepam in the dose of 10 to 20 mg in adult has also been reported to be an important oral premedicant for out patient anaesthesia. Lorazepam, like diazepam due to its long duration of action is not in choice for day cases. If patient expresses severe anxiety in pre operative visit, then benzodiazepines can be given in a titrable fashion (in the evening at home and in the morning before leaving home). On the day of surgery after admission if severe anxiety is apparent in patient, then IV midazolam is the drug which is most often administered.

Table 45.2: Components of preoperative visit

Preoperative assessment
History
Physical examination
Laboratory investigation
Nonpharmacological preparation
Preparation by information
Counseling for stress and anxiety reduction
Counseling for reduction of pain
Pharmacological preparation
Anxiolysis
Amnesia
Antisialogogue
Antiemetic
Analgesia
Prevention for aspiration pneumonitis

For children, chloral hydrate (40 mg/Kg orally) is reported to increase the calmness and make asleep during induction of anaesthesia compared with midazolam (0·05 mg/Kg orally), alprazolam (0·005 mg/Kg P.O) and placebo. Injection ketamine (2 mg/Kg) given IM to uncooperative children also permit smooth inhalation induction by halothane or sevoflurane after 2 to 3 minutes of its administration. Although early recovery time is unaffected, but home discharge may be delayed by an average of 30 to 40 minutes.

Non selective α_2-agonist such as clonidine and highly selective α_2-agonist such as dexmedetomidine have also been proved to be useful adjunctives as premedication for outpatient anaesthesia. Because they cause sedation, potentiation of the effects of other anaesthetic agent and attenuation of the sympatho adrenal stimulation during intubation and surgery. In addition, dexmedetomidine also has analgesic and

anxiolytic property and reduce the plasma stress hormone level. But still the haemodynamic effects of these drugs limit their use as a primary anaesthetic agent and may prove to be valuable as adjunctive premedicants.

As premedication, opioid analgesics are not so much helpful to reduce the anxiety. This is because there are other better and specific drugs for this purpose, except when patients present with painful conditions. In these circumstances (i.e painful condition) preoperative opioid analgesics as premedicants are beneficial for acute control of pre-operative pain and anxiety, decreasing anaesthetic drug requirements and providing postoperative pain relief. But the drawback of opioid as premedicant is that it is associated with more PONV and slow gastric emptying time. Therefore, it should not be used in patients who are very obese, very old and fragile, and patients with COPD, etc.

PONV is the another common problem for day case anaesthesia. Because it can delay the discharge and may result in unplanned postoperative hospital readmission. So, its management should be started pre-operatively. There are multiple causes of PONV such as: age, gender, menstrual cycle, pregnancy, previous history of nausea and vomiting, anxiety, obesity, anaesthetic agents, type of surgery (laparoscopy, ear surgery, etc.), postoperative pain, movement, hypotension etc. The incidence of postoperative nausea and vomiting is very low in infants and gradually increases with adulthood. It is true that any one drug is not effective in preventing PONV in all conditions. So, a combination of two or three drugs is more successful. Droperidol, an active antagonist of dopamine receptor (D_2), is highly effective against PONV. But, full doses of droperidol as premedication may result in dyskinesia, restlessness and dysphoria which may persist up to 24 hours after surgery. So, these drawbacks limit the use of droperidol as a routine antiemetic premedicant for outpatinet anaesthesia. But, low doses of droperidol is as effective as higher doses in preventing PONV without delaying recovery. Thus, lowest effective dose (judged by anaesthetist) of droperidol is recommended as premedicant for prophylaxis of PONV.

Metoclopramide is another antidopaminergic antiemetic agent (i.e. block the dopamine receptor) which has also gastrokinetic effects and facilitates both the gastric and small bowel motility. It has some antagonistic effect on 5-HT_3 receptor also. It is postulated that metoclopramide is more effective in opioid induced vomiting and especially if it is given at the end of anaesthesia with or without any other antiemetics. But the drawback of metoclopramide is that it causes extrapyramidal side effects, drowsiness, drymouth or urinary retention.

Ondansetron, granisetron, tropisetron are other 5 HT_3 receptor antagonists. They are also effective in preventing nausea and vomiting both when administered alone or in combination with ranitidine and / or metoclopramide. Smaller doses (1 mg) of ondansetron also appear to be effective in prophylaxis of nausea and vomiting. It is especially effective in cytotoxic drug induced vomiting and has no extrapyramidal side effects like metoclopramide. Anticholinergic drugs, such as atropine and glycopyrolate are also used for premedication as they are antisialogogue and vagolytic agent. They also have central antiemetic effects. But some anaesthetists do not use them, because the modern intravenous and inhalational anaesthetic agents are not irritant to the airways and also the postoperative dry mouth is very unpleasant for the patients. They also do not like tachycardia, caused by atropine or glycopyrolate. When antihistamines are used as antiemetics, they act on the vomiting centre by inhibiting the histamine and vestibular pathways. They also cause drowsiness and prolongs recovery time. Extrapyramidal side effects are also commonly associated with these drugs. So antihistamines are not used routinely in out patients anaesthesia department. Benzodiazepines, especially lorazepam also have antiemetic properties. In paediatric population, lorazepam is as effective as droperidol in reducing postoperative nausea and vomiting.

Another important aspect of preoperative preparation of patient for day care anaesthesia is reduction of the risk of pulmonary aspiration. This can be achieved by reducing the volume and increasing the pH of gastric contents. The incidence of pulmonary aspiration in day care surgical patients is very low. It is only 1 in 40,000 and mortality rate is 0.00002. However several studies have found that 50 to 60% of day care patients would be defined as theoretically 'high risk' for aspiration pneumonitis by the traditional criteria where gastric volume is more than 25 ml, with pH less than 2.5, despite an overnight fast. It has also been suggested that all the patients receiving GA by mask or LMA should be protected against the pulmonary aspiration. So, the reduction of volume of gastric contents and increase of pH should be done and this can be achieved by fasting and medication (metoclopramide and H_2 blocker).

However, prolonged fasting does not guarantee an empty stomach (i.e. does not reduce the residual volume which is always present in the stomach) at the time of induction and so the risk of aspiration always persists. Again prolonged fasting (conventional fasting, i.e. 6 to 8 hours) causes moderate to severe hunger and thirst which may contribute significantly to the preoperative anxiety. On the other hand, half-life of clear fluid in stomach is about 11 minutes which justify that prolonged fasting is unnecessary. So, ingestion of 150 ml of water, tea, coffee, apple juice or orange juice (3 ml/kg) as late as 2 to 3 hours before anaesthesia and surgery has no significant effect on residual gastric volume and pH. Instead, it decreases gastric volume, thirst and hunger (especially

in children) and anxiety (mainly children's parents). There are also data to suggest that intake of oral fluids may dilute the already present concentrate gastric secretions and actually stimulate the gastric emptying. So, prolonged fasting causing discomfort to out-patients without any apparent benefit, is not recommended now.

Thus, the starvation instructions for out-patients will be like that: (i) morning lists – no solid food after midnight and free clear fluids up to 6.30 hours, (ii) afternoon lists–no solid food after 6.30 hours and free clear fluids up to 11.30 hour. Preoperative verbal and written instructions are important so that milky drinks are avoided. Only those patients, suspected or known to be at risk for delayed gastric emptying (e.g. diabetes, hiatus hernia, gastroesophageal reflux and gastric outlet obstruction, etc) should be considered for prolonged fasting. H_2 receptor antagonist such as ranitidine and its congeners are effective both in increasing the gastric pH and decreasing gastric volume by inhibiting the gastric acid secretion, though they have no influence on the volume and pH of gastric secretion which is already present in the stomach. Ranitidine is given either orally or parenterally with peak effects occuring within 2 hours. Compared to fasting without ranitidine, patients who receives coffee or orange juice with oral ranitidine, 2 to 3 hours prior to induction of anaesthesia has lower residual gastric volumes, higher pH values and decreased incidence of thirst. It has been suggested that all the patients who receive GA by mask should be protected by H_2 blocker from pulmonary injury by gastric acid component.

The use of metoclopramide in combination with an H_2 blocking drugs increase the gastric pH and decrease the residual gastric volume by increasing the gastric emptying time. However, the metoclopramide also offers an additional advantage by increasing the lower esophageal sphincter tone and thus reducing the chance of regurgitation and aspiration of gastric contents. Molar sodium citrate (0·3 M, 30 ml), a nonparticulate oral antacid is effective in directly raising the gastric pH (less effective than H_2 blocker), but it can increase the gastric volume. This drug can only be useful in combination with metoclopramide when prophylaxis against pulmonary aspiration is desired but only little time is available prior to the operation, as the onset of action of sodium citrate is immediate.

Actually, there is no evidence of any increase in regurgitation and aspiration in day case anaesthesia. So, the routine use of H_2 blocker, metoclopramide or molar sodium citrate is probably unnecessary. However, in those with a history of regurgitation ranitidine (300 mg orally) or omeprazol (40 mg orally) with metoclopramide is appropriate. The ASA task force on preoperative fasting has recommended no routine use of: gastric acid secretion blockers, antiemetics, antacids, gastrointestinal stimulants, anticholinergics or combinations of these medications for patients who have no apparent increased risk for pulmonary aspiration.

NSAIDs, e.g diclofenac 50 to 100 mg which is given orally or rectally or IM reach the peak effect after 1 to 2 hours of administration and are a useful adjunct to preoperative medication, with very few side effects. But the slow release oral preparations of it does not reach the plasma steady state concentrations, until after several doses and are thus not useful for early analgesia.

ORGANISATION OF DAY CASE ANAESTHESIA UNIT

The Day case anaesthesia unit is usually of three types.

i. An unit within the hospital main complex, but with separate OT, ward and staff.
ii. An unit with separate ward, but using the hospital's main OT complex. (No separate OT for day case surgeries and anaesthesia)
iii. An unit remote from the main hospital complex with separate building, OT, ward and staff.

Ideally, the day case surgical and anaesthesia units should have a separate building, but not be far away from the main hospital complex. It should be situated by the side of the in-patient department of the main hospital complex. The ward area of it should be near by of its own operation theatre, to reduce the transport time, particularly when the multiple short operative procedures are to be performed. This arrangements also enable the parents to accompany their children to the anaesthetic room when it is desired.

The ideal separate day case surgical and anaesthesia unit which is situated adjacent to the main hospital complex, must have an separate admission area, an anaesthetia room, an operating theatre, and a fully equipped recovery room. An admission area usually includes a reception area, examination and treatment room, a nurse's station, lavatory and discharge area. The anaesthestia room should be fully equipped too. It should be large enough to allow the free access of an anaesthetist around the patient's trolly to permit the use of local and general anaesthesia. There should be good arrangements for lighting, scavenging, piped gases, suction equipment, anaesthetic machine and all the types of standard monitoring equipment with all emergency drugs. The hazards and risks of general anaesthesia in a day case surgery and anaesthesia unit are not less than that of an in-patient surgery and anaesthesia unit. Indeed, they may be greater and the facilities should be like an in-patient anaesthestisa room. An operation theatre for day case surgery and anaesthesia unit should be of the same specification as the main in-patient's OT. There is always the possibility of a minor surgery, developing unexpectedly into a major operation and this demands that the theatre should be well equipped to deal with any eventuality. Like the main in-patient recovery unit,

the day case recovery room should also be well equipped and staffed properly, for the safe recovery of patients after general anaesthesia.

On the day of anaesthesia and surgery, patients should be admitted in the day case ward with adequate time for history taking and examination (if not done before). The results of prescribed investigaton should be available during preoperative examination and it is noted. Patients should receive an identity tag with the name and necessary information, printed on it. The surgeon should ensure that the indication for surgery is still present, as there may be a long gap between the first clinical examination and the day of surgery. The consent form should be signed, if not already done during the out patient appointment. The names should be entered in the nursing record and the operation site should be marked. A pregnancy test for women of vulnerable age should be performed, if there is any risk of pregnancy.

Technique of Anaesthesia

There is no any separate ideal or special technique for out-patient anaesthesia. General, local or regional anaesthesia which are generally used for indoor patients can be administered safely to day-case patients. But the choice of technique is tailored made and should be determined by the surgical requirements, anaesthetic consideration and the patient's physical status and preference. The ideal general anaesthetic technique for day cases should include rapid and smooth induction, followed by adequate intraoperative amnesia, analgesia and muscle relaxation i.e good surgical condition and good recovery without any side effects. Out-patient or day case anaesthesia delivery system requires the same basic care, safety, efficiency as an inpatient anaesthesia, including the same basic monitoring equipment such as ECG, BP, pulse oximeter, capnograph, temperature, etc. The EEG based monitoring the depth of anaesthesia helps to titrate the hypnotic and sedative effect of anaesthetic agents and thus reduces its dose and rapid recovery.

General anaesthesia

It is the widely choiced anaesthetic technique in outpatient or day case department by surgeons, anaesthetists and patients. For GA, there is no ideal or special separate anaesthetic technique for outpatients. But there is a vast array of pharmacologically active anaesthetic drugs. So when they are combined in a rational manner and carefully titrated, then they can produce the desired general anaesthetic condition for outpatients with an acceptable cost and recovery profile. The aim of GA in outpatient department is to deliver it safely with minimum side effects and rapid recovery. Forsurgical procedures under GA, lasting less than 15 minutes, and which do not require any IV administration of drugs or fluid (i.e. those can be done by only inhalational anaesthesia with spontaneous mask ventilation), then there is no need even for an intravenous line. This is because perioperative fasting even for periods of 10 to 15 hours do not usually result in hypoglycaemia in healthy individual who is more than 5 years old and adult. However, for longer periods or circumstances where the patient has been without oral intake for an excessive period of time (> 10 to 15 hours), an intravenous line is essential for maintenance of fluid balance and glucose haemostasis, as well as facilitating the administration of intravenous anaesthetic and emergency drugs during the perioperative period. But this dictum is not always followed in many developed countries. Therefore, any minor procedure even under topical or local block, IV line is procured with all standard monitoring.

The choice of an inducing agent for GA depends upon the requirement of patient and the preference of anaesthetist. But the aim of selecting any inducing agent in day case anaesthesia is it should ensure a rapid and smooth induction and good immediate recovery with minimal postoperative sequelae, and a rapid return to street fitness. Several agents such as propofol, thiopentone, methohexital, etomidate or any benzodiazepine have been used successfully for induction of anaesthesia in a surgical out patient unit. But propofol has replaced all, due to its favourable recovery profile for out-patients or day case anaesthesia. One of the main advantages of propofol is the ease and rapidity with which patients recover from its effects. Patients are clear–headed and have a lower incidence of PONV when propofol is used. Induction of anaesthesia with propofol is associated with a greater decrease in blood pressure and heart rate than with either thiopentone or methohexital. It is used in the elderly with the reduced dose. Pain on injection of propofol can be significant. But this may be reduced by the addition of lignocaine with propofol, using a large vein, or by cooling the propofol to 4°C.

Thiopentone is characterised by rapid induction without significant side effects. But psychomotor recovery is sometimes delayed and prolonged subjective feelings of tiredness and drowsiness by patients receiving thiopentone are drawbacks to its use in ambulatory anaesthesia. Methohexital is associated with slightly shorter awakening and recovery times than thiopentone. But pharmacokinetic property of it makes its administrations possible only by continuous infusion. Recovery of fine motor skills from methohexital is not complete until 8 to 10 hours is passed after induction. It may also cause pain on IV injection, involuntary muscle movements and hiccup. But the use of small doses of rapid acting opioids (fentanyl, sufentanil, remifentanil) can minimize the side effects of methohexitol without prolonging the recovery. Among the benzodiazepines, midazolam (0.2 to 0.4 mg/Kg, IV) only can be used as an inducing agent for day case anaesthesia (where propofol and thiopental is not indicated), but its onset of

action is slow and recovery is prolonged than propofol and thiopentone. Whereas the onset of action and recovery of midazolam is quicker than other benzodiazepines. Compared to propofol, recovery after flumazenil antagonized midazolam anaesthesia, is still significantly slower.

For day case anaesthesia inhalational induction by halothane or sevoflurane is also an alternative to intravenous induction where intravenous access is very difficult or contraindicated. Inhalational induction should not normally be used for patients with symptom of gastroesophageal reflux or where there is chance of gastric regurgitation and aspiration. In children, inhalational induction is a useful alternative to the standard intravenous induction techniques which is usually adapted in adult patients. But unfortunately, induction by inhalation is more time consuming and many children object to face mask due to apprehension and the pungent smell of the inhaled volatile anaesthetic agents. However, this problem can be reduced by the use of single breath induction technique. Traditionally, volatile anaesthetic agents are considered as superior than intravenous agents for maintenance of anaesthesia. But there is little or no basis for this justification. On the otherhand, combination of intravenous agents for induction and inhalation agents for maintenance of anaesthesia for very short procedures is associated with long recovery time than inhalation agents alone.

For the maintenance of anaesthesia, combination of O_2 and N_2O with minimum concentration of volatile anaesthetic agents is the most popular technique in a day case anaesthesia department. The extreme slow solubility of N_2O (0.46) causes rapid onset and also rapid recovery from its CNS effects and makes it a valuable adjunct for combination with other volatile or IV anaesthetic agents. Thus, it also reduces the requirement of other anaesthetic agents, and helps in early recovery. But, the use of N_2O for maintenance of anaesthesia has been shown to increase the risk of PONV (by increasing the pressure in the middle ear and thus stimulating the vestibular system) and this incidence is more when N_2O is combined with other volatile anaesthetic agents or opioid analgesics. However, minimum concentration of its use reduces the requirement of volatile or opioid agents and reduces the incidence of PONV. In many developed countries N_2O is not used now and it has become obsolete. But still the use of N_2O is standard practice in other developing nations.

For the maintenance of out-patient or day case anaesthesia, the three commonly used volatile anaesthetic agents are halothane, isoflurane and sevoflurane. Among these halothane and sevoflurane are also used for induction as both are non-irritant to the airway. But sevoflurane has the advantages of more rapid induction and recovery with minimal cardiovascular side effects than halothane. However, Sevoflurane causes more PONV than propofol, but less than the other volatile anaesthetic agents. Isofluranes is not used for induction as it is irritant to the airways, but recovery from isoflurane is faster than halothane and produces more stable CV effect than halothane. Ventricular arrhythmias are more likely to occur during halothane anaesthesia. Desflurane also provides stable CVS condition like isoflurane and helps in quick recovery as its solubility (0.42) is less than N_2O. But it possesses airway irritant property and may cause breath holding, laryngospasm, apnoea like isoflurane.

Opioid and nonopioid analgesics are frequently administered in the immediate pre-induction period and during the maintenance of general anaesthesia. They reduce the dose of sedative and hypnotic for induction and thus help in early recovery. Morphine and meperidine are not popular analgesic for outpatient anaesthesia. More potent, rapid, short acting, narcotic analgesics such as fentanyl (2 to 4 µg/kg), sufentanyl (0.25 to 0.5 µg/kg) and remifentanil are popular for day case anaesthesia and is used to attenuate effectively the CV responses to laryngoscopy and intubation. They are also useful supplements to the inhaled anaesthetics during the maintenance of anaesthesia. Some studies have demonstrated improved intraoperative conditions and a more rapid recovery from anaesthesia when fentanyl or one of its newer congeners were administered as a part of N_2O – narcotic – relaxant (balanced) technique. Remifentanil is an esterase – metabolised µ-opioid receptor agonist. Its biological halflife is only 3 to 5 minutes, regardless of the total dose and duration of infusion. It has no accumulation property even after prolonged infusion. So, remifentanil has become very useful in providing profound analgesia for day case surgery and anaesthesia without effecting recovery. However, its short duration of action is a definite disadvantage, if significant and prolonged postoperative analgesia is needed. The choice of opioid analgesic usually depends on the desired duration of effect. If a strong analgesic effect is needed for a brief period, then this is achieved by bolus administration of fentanyl, sufentanil, alfentanil or remifentanil. For a short surgical procedure the addition of fentanyl (50 to 100 µg) does not much affect the recovery from a propofol – N_2O and muscle relaxant combination technique without increasing PONV. In this circumstances alfentanil and remifentanil would have slight advantage. But, fentanyl is a better choice if analgesia is needed to maintain postoperatively. If the strong analgesic effect is needed by repeated bolus injections or a continuous infusion, then remifentanil, fentanyl or sufentanil are the best choice. If patients require moderate analgesia for 2 to 3 hours or more, an injection of morphine is a reasonable alternative to multiple bolus dose of fentanyl, sufentanil or remifentanil. The newer techniques, such as target controlled infusion (TCI) of propofol with or

without the ultrarapid acting opioid such as remifentanil or the use of sevoflurane may confer some advantages. But these have to be balanced against the cost of these agents. TCI of propofol is an intravenous technique for maintenance of intraoperative hypnosis. It takes into account the patient's weight (kg), and the desired drug concentration in blood (μg/ml). An initial target plasma concentration of 4 to 6 μg/ml of propofol is often set and then adjusted appropriately. Subsequently, the infusion rate is calculated by a computer within the pump.

Anaesthesia for day case surgery requires a variety of airway management techniques. This is because of the wide variety of surgical procedures which are performed in the day case surgery. In all this a clear airway is a fundamental requirement for safe anaesthesia. ET intubation causes higher incidence of airway related complications such as soar throat, croup, hoarseness, etc., and a greater morbidity during and after surgery. Thus, ET intubation is not essential or desirable for all outpatient general anaesthesia surgical procedures. For day case anaesthesia of small duration, simple face mask with Guedel airway is sufficient and is commonly used. Spontaneous ventilation via face mask does not result in significant hypercarbia or acidosis for brief procedures. Thus, by avoiding laryngoscopy and intubation, the amount of anaesthetic drugs administered is reduced and a faster recovery with fewer postoperative side effects may be anticipated. So, some anaesthetists have chosen not to intubate a selected group of low risks patients.

Instead of face mask and ET-tube (i.e. where face mask is not appropriate and ET intubation is not desired), LMA also can be used for both the adult and children. Longer procedures may necessitate the use of ET-tube. Thus it is suggested that LMA is superior than face mask for unobstructed spontaneous ventilation, but inferior to ET tube for the management of airway. It can be positioned without direct visualization of larynx and neuromuscular block. Patient is allowed to breath spontaneously throughout the procedure and anaesthesia is maintained continuously by volatile anaesthetic agents by attaching LMA with anaesthetic machine or by TIVA. Compared to anaesthesia with face mask and simple airway, the patients of the LMA group did not have any increased requirements of anaesthetic agents. The other advantages of LMA are: (i) it offers a hands free approach to air way management, allowing the anaesthetist to complete other tasks, (ii) there is decrease in haemodynamic changes during both induction and emergence, (iii) reduced work of breathing compared with the use of ET-tube and spontaneous respiration and (iv) if necessary controlled ventilation also can be performed, but up to a maximum airway pressure of 15-20 cm of H_2O. The disadvantage of LMA is it cannot protect the airway from gastric aspiration and hence it should not be used in patients with high risk of regurgitation, aspiration and upper airway bleeding. Another disadvantage of LMA is that when greater airway pressure is needed for ventilation then there is chance of gastric dilatation and subsequent regurgitation and aspiration of gastric contents.

Although few ambulatory or day case procedures require a secure airway by ET tube, but patients undergoing laparoscopy are often intubated. This is because gas insufflation and the head down position are believed to increase the risk of regurgitation and hypoventilation. But, in some units the patients undergoing small laparoscopic surgery are not intubated. These centres report that the spontaneous ventilation via face mask or LMA in the head down position does not result in significant hypercapnia or acidosis in non-obese patients and not it is associated with reflux of gastric contents. Thus, by avoiding laryngoscopy and intubation for laparoscopic surgery requiring brief period, the amount of anaesthetic drugs administered is decreased and there is a faster recovery with fewer and minor side effects.

For endotracheal intubation during day case anaesthesia, the choice of muscle relaxant depends on the anticipated duration of surgery. Many out-patient surgical and anaesthetic procedures that can be carried out by face mask and without intubation does not require any muscle relaxant. The conditions where face mask or LMA can not be used and intubation is needed, only then muscle relaxant is used to facilitate the tracheal intubation and to optimize the surgical condition. In addition, the use of muscle relaxant decreases the other anaesthetic requirements and shortens the recovery time. Before the introduction of atracuronium, mivacurium and vecuronium, the depolarizing agent succinylcholine was the most popular muscle relaxant for out-patient anaesthesia, both for intubation and maintenance, by infusion or repeated doses (only for short procedure). But as the succinylcholine causes a lot of problems such as hyperkalaemia, arrhythmia, malignant hyperpyrexia, severe muscle pain, etc. so it is now abandoned from the modern anaesthesia, except in certain few indicated cases for outpatient anaesthesia. Therefore, with the availability of many short acting non-depolarizing muscle relaxants such as atracurium, vecuronium and mivacuronium prompt reversal of neuromuscular blockade can be achieved after 15 to 30 minutes of brief surgical procedure. Atracuronium, vecuronium and mivacurium are each metabolized through distinctly different pathways. As atracurium and mivacurium release histamine it should not be used in certain cases. Mivacurium has the shortest duration of action and hence is the ideal for out-patient anaesthesia. But as it undergoes hydrolysis by plasma cholinesterase, so a small number of patients may suffer from prolonged muscle paralysis like succinylcholine and this is because of plasma cholinesterase deficiency. After the use of

recommended tracheal intubating dose of atracuronium or vecuronium, the duration of action (to 95% spontaneous recovery) is roughly 1 hour. Rocuronium may have a role in out-patient anaesthesia like succinylcholine as it has a more rapid onset of action than any of the other non-depolarizing muscle relaxants, providing intubating conditions within 30 to 60 seconds. However, it has a longer duration of action similar to that of vecuronium. Recently, the stereoisomer of atracurium, cisatracurium, has been introduced with similar duration of action to that of atracurium, but without the side effects of histamine release (Fact file- II).

Regional anaesthesia

Regional anaesthesia (spinal or epidural) offers many advantages over GA in day case surgical and anaesthesia unit, such as: (i) less nausea, vomiting, dizziness, lethargy, etc., (ii) no side effects of tracheal intubation, (iii) better postoperative analgesia, (iv) minimal post anaesthetic nursing care, (v) decreased recovery time. Still its use is limited in an out-patient anaesthesia unit due to the occurrance of an unacceptable incidence of post dural puncture headache (PDPH) and lignocaine induced TRI (transient radicular irritation). The actual lack of good alternative to lignocaine for short duration of action without the risk of TRI (incidence is 16 to 20%) has been the subject of recent controversy. Typically the pain of TRI begins within 24 hours after spinal anaesthesia and lasts for approximately 2 days. 5% hyperbaric lignocaine has the highest incidence of TRI. This is amenable to treatment by rest and oral analgesics. Bupivacaine is not associated with TRI. But it is not the first choised agent in a day case unit, because it is long acting. Now, there is an open debate that whether RA is truly safer than GA in out-patient or day case anaesthesia unit or not. Only caudal block may be useful in adult for day case anaesthesia without any debate.

During caudal block, the use of diluted solutions of LA agent (0.125% bupivacaine) with addition of preservative free opiates, ketamine 0.5 mg/kg or clomidine 1 μg/kg may prolong the analgesia for upto 24 hours without any loss of motor function. In caudal block, patient should also be warned about the ambulation difficulties. The caudal epidural anaesthesia is usually employed for anorectal, scrotal, penile, inguinal and some gynaecological surgeries involving lower part of vagina and perineum. This caudal epidural technique is associated with nil or fewer haemodynamic changes, no incidence of PDPH, no urinary retention and provide faster recovery when compared with spinal or lumbar epidural anaesthesia for the same procedures.

PDPH after spinal or epidural anaesthesia should always be differentiated from other causes of pain rather than regional anaesthesia. These are neurologic, vascular, musculoskeletal, metabolic, etc., such as migrane, rapid expansion of brain tumour, intracranial haemorrhage, withdrawal of caffeine, hypoglycaemia, etc. There are different treatment modalities which will relieve the symptoms of PDPH, rather than treating it which has been discussed earlier. Excessive water intake does not decrease the severity of PDPH as it does not increase the production of CSF. Intake of caffeine may sometimes treat mild PDPH. Activity of outpatients should not be limited with mild PDPH.

In children, a regional block is performed immediately after induction of GA. It can reduce the requirement of general anaesthetic drugs, provide postoperative analgesia and allow more rapid recovery due to lesser amount of anaesthetic drugs which are essential for day case anaesthesia. Caudal epidural anaesthesia is an effective technique for children undergoing surgical procedures on lower abdomen, perineum and lower extremity. Combined or individual ilioinguinal and iliohypogastric nerve block or caudal epidural anaesthesia reduce the pain following herniotomy and herniorrhaphy. Postcircumcision pain may be reduced by the block of dorsal nerve of penis or subcutaneous ring block of penis or topical local anaesthetic ointment, over the surgical site.

Peripheral nerve block is an first and excellent choice of anaesthesia for day case patients. For operations on the hand or arm brachial plexus block is the unique, but axillary approach of brachial plexus block is preferable to the supraclavicular approach, because of the risk of producing a pneumothorax which may become apparent only after discharge. The infraclavicular and axillary approaches for brachial plexus block are preferred for surgery on the elbow, forearm and hand. While the interscalene block is more commonly used for shoulder surgery. The coracoid technique for infraclavicular approach of brachial plexus block has been shown to be very effective. This technique avoids the important neurovascular structures in the neck and minimize the risk of pneumothorax. If brachial plexus block is used with GA, then the diluted solution of LA agent (0.25% bupivacaine) is used to minimise

FACT FILE- II

In summary, total intravenous anaesthesia with propofol is widely used for short out patient surgery and anaesthesia. Inhalation of O_2 enriched air will also allow omission of N_2O. Propofol induction with maintenance by isoflurane/sevoflurane is an alternative. Incremental fentanyl (2 to 4 μg/Kg) is often used in divided doses. Whenever possible LMA should be used avoiding intubation, muscle relaxants and reversal agents. LMA for gynaecological laparoscopy and armoured LMA for wisdom teeth extraction and many nasal operatoins can be used safely in many circumstances. Antiemetics are not indicated routinely, but should be reserved for treatment of any PONV or as prophylaxis in those with a history of PONV. Proper hydration reduces the postoperative morbidity such as thirst, dizziness, drowsiness, etc. It is found that a patient who receives 20 ml/Kg IV fluid instead of 2 ml/Kg has less postoperative morbidity. However, this postoperative morbidity also can be reduced by using heated humidifiers, heat and moisture exchangers, etc., which conserve heat and decrease the fluid loss.

the motor block. During the use of brachial plexus block without GA one must take into account the onset time of block during planning of the list. Otherwise it will make unnecessary delay and at the end of the day the list may remain incomplete. Peripheral nerve block is also useful for day case surgery on the legs.

The '3-in-1' block technique (obturator, femoral and lateral femoral cutaneous nerve block) is useful for any type of out-patient knee surgery (such as knee arthroscopy) with excellent postoperative analgesia and a high degree of patient acceptance. Popliteal sciatic nerve block may also be used successfully for surgical procedures on the lower leg and foot in 92% of patients where supplemental anaesthesia is required only in 5% of cases and general anaesthesia in 3% of cases. A nerve block at the level of ankle is also simple and effective for surgery on the foot at day case unit. There are other types of peripheral nerve block which can be used safely as day case anaesthesia.

Intravenous regional anaesthesia (Bier's block) may also be used successfully for upper and lower extremity surgery as day case procedure. This block is generally considered safe when performed by clinicians, who is familiar with this technique and with the safe doses. The most commonly used drug in Bier's block is 40 to 50 ml of 0.5% lignocaine, using a double tourniquet with cuff pressures of 250 mm of Hg or 100 mm of Hg above the systolic blood pressure. Ketorolac and clonidine can also be used with lignocaine which improve the quality of regional anaesthesia and analgesia. Intravenous regional anaesthesia of the leg requires a larger volume of solutions and higher cuff pressures, so it is not frequently used.

Local infiltration of operative site by diluted solutions of local anaesthetic agent is the simplest and safest technique of regional anaesthesia for day case patient. Out-patient arthroscopy of the knee is commonly performed under infiltration local anaesthesia. Different ophthalmic surgeries are also performed by peribulbar or retrobulbar block as day cases. Now cataract surgeries are also done under topical anaesthesia as day case surgery. Inguinal hernia repair can be performed by individual ilionguinal and iliohypogastric nerve block and local infiltration of the surgical site. A combination of local infiltration and intercostal nerve blocks can also be used for day case lithotripsy. There are many other surgical examples which are performed under RA, but cannot be listed fully here.

The injection of local anaesthetic agent is often associated with significant discomfort. So, the use of IV sedation and analgesics (conscious sedation) during the infiltration of local anaesthetic injection is popular. But with the local anaesthetic, only short acting sedative drugs will increase the tolerability. It also must be noted that sedation is a poor adjunct to an imperfect local anaesthetic block. However, judicious use of intermittent midazolam or propofol infusions (TCI 1 to 1.5 µg/ml) can provide good amnesia with few postoperative effects.

Regional anaesthesia is widely used in Europe and North America for day case surgery and anaesthesia. The timing and planning of RA in a day case unit are important. Because blocks take a longer time to wear off, compared with GA. 50, the discharge of patient may be delayed. For spinal block, 25 or 26 gauge pencil point needle and 0.25% heavy bupivacaine (1:1 diluted 0.5% heavy bupivacaine by sterile saline) is used. This gives a similar onset of anaesthesia with shorter discharge time (4 hours versus 6 hours). Epidurals (except caudal) are less suitable for day case anaesthesia. Usually RA is performed early on the day which will allow maximum time for recovery before the discharge and safe ambulation. However, sometimes it is reasonable to discharge the patients with still acting plexus blocks. This is applicable only to brachial, lumbar and sacral plexus block, but not to the spinal and epidural anaesthesia. This will allow the benefit of prolonged postoperative analgesia at home. In such circumstances patients need special instructions for care of the anaesthetized part of the body, so as to avoid the inadvertent damage. For example, this would include a sling for patients with brachial plexus blocks.

Recovery and Discharge

Before discharge proper recovery from anaesthesia (GA or RA) is an important aspect of day case anaesthesia. So, it should be assessed properly. If the assessment is not correct and patients is discharged without full recovery from anaesthesia, then catastrophy can occur. The assessment of patient's recovery from anaesthesia is divided into three phases: early, intermediate and late. Early recovery phase extends from the completion of surgery and the end of anaesthesia to the awakening and returning of the patient to orientation. Endotracheal tube is extubated in this phase and patient is monitored vigilantly. After that patient is transported to the PACU-1 (post-anaesthetic care unit) without unattended. During this early recovery phase in PACU-1, the patient may undergo many rapid physiological changes and so close observation of patient is important. This first post anaesthetic recovery unit should be provided with continuous monitoring of BP, heart rate, respiratory rate, temperature, ECG and SPO_2. In this phase, the patients especially the paediatric population are routinely given O_2. When the patient is sufficiently awake with stable vital signs and responsive to commands, then only he is signed out to the care of recovery room staff. Patients who have received monitored anaesthetic care or only intravenous sedation in minimum doses or regional anaesthesia may not always require supplemental O_2. Patient should be monitored in PACU-1 until he or she is completely

awake, oriented, vital signs are stable and adequate pain relief is achieved. Once the above criterias are achieved and the patient is able to maintain a semisitting position, then the patient is shifted to the second phase of post-anaesthetic care unit, i.e. PACU-II.

This intermediate recovery phase extends from the admission to discharge from the PACU-II. In this recovery phase, patient should be able to sit alone without any support. Gradually he starts to walk and takes oral fluids and should have minimum pain. This second phase of recovery involves lower nursing dependency and the patient is not attached to any monitoring system any more. Proper anaesthetic technique, high quality postoperative analgesic care and prophylaxis of PONV have major impact on the duration of this intermediate recovery phase. Prolonged intermediate recovery phase will fail to discharge the patient in time and will increase the cost of patient's hospital visit. At the end of this phase, patient will be able to walk unaided, tolerate oral fluids without vomiting, have minimal pain and is ready to be discharged from the hospital. Patient's family can participate in this last phase of recovery, when the criteria for 'home readiness' is achieved and patient is discharged.

The last and late recovery phase starts with the patient's return to the home and continues until the full functional recovery is achieved. Most anaesthesia related postoperative side effects such as pain, nausea, vomiting, dizziness, headache, myalgias, etc, usually resolve within first 24 hours after operation. In this period, the patient should be advised to refrain from activities such as driving a car, operating machines and drinking alcohol. However, recovery from surgery itself has the highest impact on the patient's full functional recovery. During discharge, a responsible person should be present to escort the patient to home and both the responsible person and the patient should be given the verbal and written discharge instructions. In some hospitals, patient's general practitioner is communicated over telephonic helpline and is made aware of the operation performed and the requirement for postoperative follow-up.

Discharge criteria

Following a general anaesthesia (GA), it is very difficult to determine when it is safe to discharge a patient from a day case unit. So, the accurate assessment of complete recovery of cognitive, sensory and psychomotor function is important. Because it will help in determining the appropriate time for discharge. Varieties of tests have been advised to assess the recovery from sensory, motor and cognitive function, but there is currently no standardised discharge criteria. The main principles on which basis the patients are discharged from day case unit are: they must have stable vital signs, there is there is no significant nausea vomiting and pain, they are fully oriented and are able to sit and walk unaided. Some tests which are used to assess the recovery of cognitive functions are: processing (mental arithmetic, reaction time); integration (critical fashion flicker test), memory (digit span), and learning (word lists). The test to assess the recovery of sensory functions are: stimulus detection, auditing perception, Maddox wing test. The tests to assess the recovery of psychomotor function are: choice reaction time, the post box test, the Triegger dot test, etc. Although these cognitive, sensory and psychomotor tests can provide adequate information which are sometimes useful in developing practical discharge criteria, but most of these tests are too complex and time consuming to use. So, some simple tests for memory and sensorimotor co-ordination appear to be the most useful indices of recovery. The Bender Gestalt Track Tracer Test is a very reliable, valid, objective, noninvasive, inexpensive test to assess the postoperative recovery that can be easily performed in less than 60 seconds.

The discharge criterias after spinal and epidural anaesthesia is different from GA. It should include the return of normal sensation, muscle strength and proprioception, as well as the return of functions of sympathetic nervous system. After regional anaesthesia, motor and sensory functions return before the return of function of sympathetic nervous system. So, some investigators suggest that patients can be safely discharged when the decrease between the two successive orthostatic mean arterial pressure (MAP) is less than 10% of preanaesthetic level which indicates return of sympathetic function. Prior to ambulation and discharge, patients should also have normal perianal (S_{4-5}) sensation, the ability to plantar flex the foot, and proprioception of the big toe which indicates the free of lowest spinal segment from the effect of local anaesthetic agent.

'Home discharge' criteria

1. Stable vital signs for more than 30 minutes.
2. After the operation there is no new signs and symptoms of complications.
3. No active bleeding.
4. No nausea or vomiting for more than 30 minutes.
5. Able to void.
6. Fully awake and no loss of orientation to person, time and place.
7. Minimal dizziness after sitting for more than 10 minutes.
8. Pain controllable with oral analgesics
9. Intact neurocirculatory function without evidence of swelling or impaired circulation after extremity surgery.
10. Able to eat and drink

Specific discharge criteria

A. *Spinal*

1. Full recovery of motor power and proprioception.
2. Passed urine.
3. Full recovery of autonomic nervous system.

B. *Brachial plexus block*

1. Some regression of motor block.
2. Understanding of protection of partially blocked limb.

C. *Lower limb block*

1. Some regression of motor block.
2. Adequate mobility demonstrated on crutches.
3. Understanding of protection of partially blocked limb.

Postoperative Analgesia

Pain control is an important factor in determining when a patient can be discharged after surgery and anaesthesia from an out-patient unit. So, the pain must be treated rapidly and effectively in order to minimize the delay of discharge. The excessive post-operative pain is usually due to surgery related causes but not due to anaesthetic causes. But the provision of good postoperative analgesia is primarily the responsibility of an anaesthetist. An anaesthetist can do a little for the number of patients requiring readmission for surgical complications, but can play a major role in reducing the readmissions, caused by pain and vomiting. The postoperative pain control should be started from pre or intraoperative period by supplementing any technique of anaesthesia with NSAID, short acting opioid analgesics and local/ regional block intraoperatively. Any type of NSAID can be used, but recently ketorolac is very useful for postoperative analgesia in day case surgery. It is a potent peripherally acting injectable analgesic associated with few CNS side effects. Caudal block, using 0.125% to 0.25% bupivacaine also provides excellent postoperative analgesia in herniorrhaphy, anal operations, perianal operation, hypospadious, circumcision, orchidopexy, etc. In caudal block, care should be taken that muscular strength should not be compromised. Other than caudal block, there are many other types of nerve block by which postoperative analgesic can be provided matching with the day case anaesthetic unit.

Postoperative admission

The reasons for not discharging the patient at time on the day of surgery and overnight admission are:

i. Unexpected surgical or anaesthetic complications, requiring more close postoperative observation.
ii. Unexpectedly more extensive surgery.
iii. Do not fulfil the discharge criteria before the scheduled closure of day case surgical and anaesthesia unit.
iv. Uncontrolled pain and / or PONV.
v. Inadequate social circumstances at the home of patient.

The overall incidence of complicated and not to be in discharged condition after a surgical procedure in a day case unit is 0.5 to 2%. Among these the gynaecology and urology department have the highest readmission rates. The surgical causes for postoperative readmission are three to five times greater than the anaesthetic causes. The most common anaesthetic causes for postoperative readmission are: inadequate recovery, nausea, vomiting, and pain. The anaesthesia related complications responsible for readmission are more frequent with GA than with local or RA with or without sedation. The surgical reasons for readmission include bleeding, extensive surgery, perforated viscus, etc. which needs further treatment.

46 Anaesthesia at Remote Location and for Radiodiagnosis or Radiotherapy

INTRODUCTION

Delivery of anaesthetic care for radiological diagnostic and therapeutic procedures in a room which is not originally designed for such a work and is located faraway from the main OT complex of hospital is called as the anaesthesia at remote location. The potential problems for an anaesthesiologist, providing good anaesthetic care for patients in such remote locations are: (i) poor physical layout of anaesthetic machine, monitoring equipment, gas supply, suction apparatus, emergency drugs, etc. and so subsequently providing poor facility for anaesthesia at remote area, (ii) unfamiliar or outdated anaesthetic equipment because those which are not usually used in main operation theatre are dumped at such remote area in most of the institutions, (iii) working with personnel who are less familiar with the anaesthetic aspects of patient's care and (iv) the remoteness from available intensive critical help. This lack of familiarity of nonanaesthetic personnel, combined with geographic remoteness from the main surgical and critical care suit, means less ancilliary help will be available to an anaesthesiologist when it is needed in emergency.

A few years ago, very few investigations in the radiology department require any form of anaesthesia. But, now due to the advent of many modern noninvasive radiodiagnostic and radiotherapeutic procedures and the development of fast track ambulatory outpatient anaesthesia; there is an increasing demand both by the patient and the radiologist for the use of anaesthesia in radiology department. Any form of anaesthesia i.e. from conscious sedation to deep sedation to GA with various levels of consciousness are used at such remote area. Among them the most common is conscious sedation and it is such a state that where a sedated patient can respond appropriately to verbal command and other stimuli. In conscious sedation the patient can maintain the patency of airway independently by himself and retain his own protective airway reflexes. Deep sedation is a state in which the patient is not easily aroused and the airway reflexes with patency are lost. The deep sedation is more akin to GA and deep sedation outside the OT is a challenge to an anaesthetist. This is because the environment of a radiological department creates a unique problem which will be discussed later. But instead of all these problems, an anaesthetist must attempt to provide service as good as the main OT without compromising the standards, safety and comforts of the patients.

The ASA standards required for basic anaesthetic monitoring at remote locations are:

i. A qualified anaesthetist must be present continuously.
ii. A Continuous source O_2 should always be available. During anaesthesia patient's oxygenation should be measured continuously by monitoring the inspired O_2 concentration (FIO_2) and SPO_2.
iii. Adequacy of ventilation should be evaluated continuously by clinical examination of patient and expired gas analysis for $ETCO_2$ tension.
iv. Disconnection alarms must be used with mechanical ventilators.
v. Circulatory status should always be evaluated by continuous display of ECG and by frequent determination of arterial blood pressure and heart rate.
vi. ET-tube positioning must be verified by frequent auscultation of chest with stethoscope or by continuous measurement of $ETCO_2$ tension.
vii. There should be readily available means to measure the patients temperature continuously.
viii. Have a complete arrangement for management of a situation like 'cardiac arrest' with CPR.
ix. There must have a suction apparatus and scavenging system.
x. There should be good illumination and a good communication system between the anaesthetist, radiologist, and assistant personale.

Indications for Anaesthesia in Radiology Department

The common indications for any time of anaesthesia (monitored anaesthetic care to conscious sedation to deep sedation to GA) for radiodiagnosis and radiotherapy at remote locations are:

i. Infants or uncooperative children.
ii. Older children or adults with psychological, behavioural or movement disorders.
iii. Many interventional procedures performed under CT or MRI

guidance, requiring analgesia, sedation or anaesthesia.

iv. For certain investigations in intubated patients who is already receiving intensive care or acute trauma victims in ICU.

HAZARDS IN RADIOLOGY DEPARTMENT AND GENERAL CONSIDERATIONS

The hazards which the anaesthetists have to face in the radiology department while providing their anaesthesia service can be divided into two main headings: (i) the environment and (ii) the adverse reactions resulting from contrast media.

Environmental Hazards

Poor visibility

The poor visibility due to darkness which is necessary for radiology unit makes difficulties for the anaesthetist. The radiological investigations are usually done under dark surroundings and the anaesthetist may then have problems in delivering good anaesthesia, by observing the patients and monitoring the anaesthetic machines in this dark vicinity. Again, when anaesthetist is asked to move away from the patient during X-ray exposure, then it adds further problems. This problem can be solved by only illuminating anaesthetic machines and monitoring devices and using audible alarm systems. So the use of a shaded angle lamp to illuminate the anaesthetic area and some part of the patient, while minimally interfering the radiologist's ability to see a picture clearly on the image intensifer is every helpful.

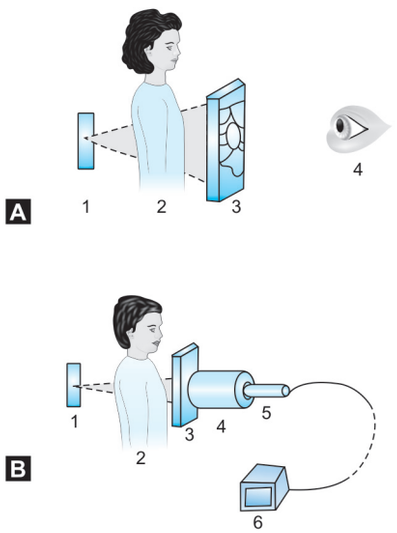
Electrical Hazards

Usually, in the radiology department high voltage apparatuses are used and they often cause malfunctioning of the sophisticated electronic gadgets, used for delivering anaesthesia and monitoring the patient. Unfortunately, it is also often necessary to use an earth lead, attached to the patient, in order to obtain a reasonably interfernce free electrical recording of an ECG. So, if there is any small leakage of current from any of the high voltage radiological equipment which surrounds the patient, then the danger of the patient through this earthing is clear, especially if a central IV line is present. The leakage of current of a few microamperes in these circumstances may precipitate cardiac arrhythmias. But recently, several monitors have been developed which can be used successfully without any outside interference by high voltage radiological equipments (Figs 46.1A and B).

Radiation hazards

X-ray is a form of electromagnetic radiation with wavelength varying between 100 and 0.1 m. This is usually generated by impinging a stream of electrons on certain metals.

The biological effects or hazards of this ionic radiation are caused by the ionisation of tissue cells. This ionization occurs when electrons travel through the tissues and causes physicochemical changes in the molecules of the cells. The two types of potentially harmful physicochemical changes due to ionization occur. These are: (i) somatic effects as for example causing skin burn, dermatitis, leukemia, etc. and (ii) genetic effects resulting in foetal abnormality due to the damage of gonadal cells. The maximum permissible limits of radiation dose for occupationally exposed persons is 50 mSV (milliSieverts) per year or 10 mSV × age for lifetime cumulative dose and 0.5 mSV per month for pregnant woman. So, an anaesthetist who is frequently called upon in the radiology department to anaesthetise the patients should beware of this radiation hazard and must avoid staying in the immediate vicinity during the radiological exposure.



Figs 46.1A and B: A. Simple screening by X-ray; 1 = Tube, 2 = Patient, 3 = Fluorescent screen, 4 = Radiologist, B. Screening with image intensifier and TV link; 1 = Tube, 2 = Patient, 3 = Fluorescent screen, 4 = Image intensifier, 5 = Camera, 6 = Monitor

The X-rays travel in straight line and the intensity of radiation diminishes in direct proportion to the square of the distance from the source. So, an anaesthetist should stand outside the direct line of radiation and as far away as possible from the source as circumstances permit. They also wear protective clothings such as lead apron, thyroid shield, etc. which are helpful in absorbing radiation and preventing exposure to it. Radiation exposure can also be reduced by employing moveable lead lined glass screens between the source of radiation and the anaesthetist and by many other innovative techniques such as allowing patient monitoring to be conducted away from the patient's immediate contact with the use of microphones and close circuit television, etc It is very important to mention that the greatest source of radiation is usually from the fluoroscopy and digital subtraction angiography. The chances of Ionising radiation from a CT scanner is relatively low, because here the X-rays are highly focused.

Space problem

Radiology rooms are so crowded with huge radiological equipments that little space is left for the anaesthetic persons, anaesthetic apparatuses and monitors. So, some compromise has to be made between

the radiological and anaesthetic equipments and the available space. So an anaesthetist should spend adequate time to be familiar with this new environment. Sometimes due to space crisis, access to the patient also becomes difficult and dangerous.

Patient movement

Sometimes during radiotherapy or radiological investigation, an anaesthetised patient moves away a distance of several feet from the anaesthetist and its machine and verities of patient's positions are used for radiological investigation. So, the anaesthetic circuits should be much long, flexible, light weight and tightly anchored to the patient to prevent disconnections during this movement. Therefore, Mapleson D or F anaesthetic circuit has been proved to be very successful and it is because of its length, simplicity and lightness in these circumstances. Further, its length may be easily adjusted to suit the varying distances of movement involved.

Miscellaneous

Truly speaking, anaesthetic equipments used in radiology department are often the oldest in the hospital as previously said. This is because older anaesthetic machines with features that do not meet with the recent standards are usually relegated from the main modern OT complex to the remote area such as radiology unit for anaesthesia. But the practice of using these obsolete equipments in remote locations such as in radiology unit should be condemned. The more tragedy is that It is again often disconnected and moved away to a corner of the radiology room when they are not in use for long period. Also modern monitoring equipments are not readily available in remote area.

So, an anaesthetist must be very vigilant in checking the anaesthetic machines before every use though it is once upon a time. Empty gas cylinders should be replaced, as soon as it becomes empty. All the anaesthetic and emergency drugs, spare laryngoscope, batteries, suction machine and other routine equipments for anaesthesia should be present and checked. Often the preparations of patients, scheduled for radiological investigation and therapy are inadequate for anaesthesia. Anaesthetic assistance is not up to the mark in remote area and the communication between the radiologist, radiotherapist and the anaesthetist is poor. Recovery rooms too are often nonexistent in such situation.

So, the modern radiology rooms have been designed and built by matching with the up-to-date anaesthetic requirements. These include: O_2 and anaesthetic gas supply through pipeline, wall mounted suction unit, properly placed modern anaesthetic machine with ventilator and monitor, and an anaesthetic supply cart fully equipped with all types of drugs, airway adjuncts, laryngoscope, syringes, etc. Within easy reach, the fully monitoring stack should be placed which can be viewed through a window from outside the scan room. Now, some modern scanners have close circuit television which images the patients in control room as they lie within the tube and allow the constant observation of continuing chest wall movement of patient.

ADVERSE REACTION RESULTING FROM THE INJECTION OF CONTRAST MEDIA

Though the quality of contrast media used for radiodiagnosis have considerably improved in recent years, still their injection may involve a definite morbidity and mortality. The radioopacity of the contrast media is due to its high atomic number which helps to absorb X-ray. The high atomic number of contrast media is due to its containing iodine (atomic number of iodine is 53). The example of oldest contrast media are meglumine, iothalamate, diatrizote, metrizoate, etc. These are toxic, ionized and hyperosmolar. The high osmolarity of these older contrast media is responsible for many of the bad haemodynamic responses. The osmolarity of these old contrast media is usually 4 to 5 times higher than that of the blood. Sometimes, it is as high as 8 times than that of the serum. So, occasionally gross hypervolaemia may result from injections of large amount of these older agents, resulting in depressed myocardial contracility and pulmonary oedema.

Hence, recently the nonionised, highly iodinated, water soluble contrast media which have much lower osmolarity are increasingly used, despite their cost. The examples of these newer agents are: iohexol, iopamidol, ipromide and ioversol. The use of these newer agents as contrast media is associated with much lower incidence and severity of adverse effects. They are typically used in the concentrations which are equivalent to 300 to 320 mg of iodine per ml. The volume of contrast media required for radio diagnosis varies with the preparation, type of investigation, age and the total body weight of patient. But it may be used maximally up to 150 ml. For example for CT of head of an adult 50 to 100 ml, for CT of whole body of an adult 100 to 150 ml, for aortography of an adult 100 ml, for urography 2 to 3 ml/kg, and for child 10+2 ml/kg is used.

The adverse effects encountered with these contrast media include: nausea and vomiting, hypertension, hypotension, bradycardia, bronchospasm, various arrhythmias, pulmonary oedema, and even ventricular fibrillation and cardiac arrest. Most organs or systems are affected, but the CVS and respiratory system are potentially at greatest risk. The adverse reactions usually occur within the first 5 to 10 minutes, following injection. So, it is advised to keep the patient under close observation for first 20 minutes, following injection. These iodine-containing contrast media occasionally also trigger allergic reactions (iodine sensitivity) and rarely anaphylaxis. These agents may cause renal failure in patients who are dehydrated or have impaired renal function. So, adequate hydration should be ensured in patients who have been starved

for prolonged period for GA. Lactic acidosis can be precipated in patients taking bigoanides (metformin) and so these oral hypoglycaemic agents should be stopped 48 hour before the administration of contrast media. DIC also can follow severe hypotensive shock after IV injection of contrast media. The incidence of these complications and severity of it depends on : (i) which agents are used, (ii) the type of investigations performed, (iii) the total dose and speed of injection, and (iv) the most importantly – patient susceptibility. Hypotension, induced by contrast media's reaction, can render the patient unconscious. Convulsions have been reported in patients with a history of epilepsy. Renal failure is a well-documented complication with the use of contrast media, particularly in patients with pre-existing renal disease.

Patients who have experience of previous reactions to contrast media have a higher incidence of potentially severe reactions (anaphylaxis), if they are exposed to these agents again. Pretesting appears to be of little value in the prediction of these reactions that are truly anaphylactic. The increased prevalence and severity of reaction caused by the contrast media can be reduced by pretreatment of patient with prednisolone and diphenhydramine. The mechanisms of these adverse drug reactions are often unclear. Some of these advase effects are immunologically based. But this is not universal. So the treatment of complications due to contrast media is directed at specific components of the patient's reaction. For example, the shock and hypotension is treated by fluid and vasopressor, bronchospasm by bonchodilator, bradycardia by atropine, anaphylaxis by steroid, O_2, adrenaline, etc.

PREANAESTHETIC MANAGEMENT OF PATIENTS UNDERGOING X-RAY INVESTIGATIONS UNDER GENERAL ANAESTHESIA

Preanaesthetic management consisting of assessment and preparations of the patients before any type of anaesthesia in radiology department are often neglected. This is because, unfortunately, many radiological studies have been wrongly regarded as minor procedures where anaesthesia and sedation is given with little importance. But clearly this is not the true, particularly in those patients who are of greater anaesthetic risk due to their age and coexisting medical conditions such as coronary artery disease, respiratory disease, diabetes, obesity, etc. Again unfortunately, the attitude such as 'he is only going for X-ray' prevails among all the staff of radiology department and is not correct for any patient who is going for X-ray under GA. Patients usually come in the morning on the day of investigation. They remain very much anxious because it may be his first experience of anaesthesia. Again huge radiological equipments and surroundings are frightening to them. Also the patient may be anxious about what the X-ray investigation may reveal and about the prospects of subsequent surgery. Anticipation of all these cause anxieties to patients and a brief explanation of the procedure before by the anaesthetist does much to allay the patient's fear, whilst establishing a rapport prior to anaesthesia.

Patients presenting in radiology department are frequently old. They have frequently cardiovascular diseases and because of the association with cigarette smoking also they have the respiratory problems. So, careful control of blood gases is required during cerebral and cardiac angiography. Precise manipulation of the depth of anaesthesia is needed for some radiological procedures which may finish suddenly, once satisfactory films have been taken after a prolonged trial. Yet the patient must be deeply anaesthetised during the injection of contrast media to avoid reflex movement. Such brief movements may be of little inconvenience to a surgeon. But it may easily ruin an X-ray film which may result in multiple X-ray exposure with the patient is repeatedly receiving unnecessary radiation and dangerously large doses of contrast media. So, if patient has to be managed in such circumstances, then a high standard preanaesthetic check up and investigations should be maintained. This includes full clinical examination and all the necessary investigations, including routine Hb%, blood film, urine, chest X-ray ECG and not infrequently pulmonary function tests, according to the patient's history and examination. A normal clotting time is preferable because of the danger of haemorrhage from a relatively large puncture on the wall of blood vessels, left by the radiologists needle, especially if the Seldinger technique is used.

For many arteriography procedures, a preoperative ECG is essential. This is because of the presence of generalised cardiovascular disease. Patients undergoing carotid angiography may present problems with a raised intracranial pressure due to trauma or the presence of a space occupying lesion for which radiography is done. In these patients vomiting, dehydration and consequent electrolyte disturbance due to ↑ICP indicate the need for serum electrolyte investigation. Renal failure patients, presenting for renal angiography require full investigations too. The paediatric patients undergoing any sorts of echocardiography under sedation or GA require a detailed examination and investigations of CVS prior to radiography.

INDIVIDUAL ANAESTHETIC MANAGEMENT IN RADIOLOGY DEPARTMENT

The common procedures for which anaesthetic department is called upon to anaesthetise the patients in radiology department are angiography, computed tomography (CT), magnetic resonance imaging (MRI), doppler and echocardiography and other non invasive procedures. Recently, many invasive radiological procedures are also done quite frequently. The patients are usually children or uncooperative adult who

are suffering from psychiatric diseases, cerebral palsy, down syndrome etc. Patients scheduled for elective scan are rarely normal. So, the indications for anaesthesia for scanning and the nature of the underlying pathology such as developmental delay, epilepsy, malignancy, psychiatric and movement disorders, etc, should be checked properly. Several 'syndromes' with their manifestations on RS and CVS are also not uncommon. The presence of pain and lengthy radiological procedures may also be an indication for anaesthesia in adult advised for radiological investigation. The patients those are brought from ICU for radiological investigation may be non cooperative and critically ill too.

The principal aim of anaesthesia during radio diagnostic or radiotherapeutic procedures is to keep the patient just motionless. So, radiological studies do not demand deep level of anaesthesia as surgical stimulus are not so intense. Therefore, all types of anaesthesia ranging from monitored anaesthetic care (MAC) to conscious sedation to GA may be applied. Most of the times conscious sedation is sufficient to alter the perception of pain and anxiety and keep the patient motionless, while maintaining protective airway reflexes and the ability to respond appropriately to verbal commands.

Benzodiazepines and opioids are frequently used for MAC or conscious sedation. Among the benzodiazepines, midazolam is mostly preferred due to its some definite advantages such as: (i) water solubility, (ii) minimum discomfort during intravenous injection, (iii) no adverse effects on cerebral metabolism and cerebral blood flow, (iv) shorter half-life and (v) lack of its active metabolites. In clinical doses, generally, the midazolam does not produce any significant cardiovascular depression.

Then among the opioids the commonly used opioid is fentanyl (1 to 2 µg/kg). But combination of midazolam and fentanyl can produce significant respiratory and cardiovascular depression. Higher doses of fentanyl can result in chest wall rigidity. Tachyphylaxis to propofol and ketamine have been reported.

Computer Tomography or CT Scanning

As the name implies, it provides a series of computer-integrated tomographic axial slices of different parts of our body. The CT produces a two-dimensional, cross-sectional, transverse images by rotating an X-ray beam around the area which is to be examined. A typical CT scan comprises 20 such transverse sections. It is usually used for the investigation of brain, thorax and abdomen. It has also proved to be valuable in studies of vascular malformation and tumour. Each image is produced by the computer integration of differences in the absorption coefficient of radiation between the different normal and abnormal tissues. The image of the structure under investigation is generated by X-ray and the brightness of each area is proportional to the radiation absorption value of that tissue which is later integrated by computer. Sometimes contrast medium is also used orally or through parenteral route in conjuction with CT scan to enhance the quality of image. In this situation such as when contrast medium is used orally and if GA is needed, then there is higher risk of aspiration. So, in such circumstances the patient should be always intubated (Fig. 46.2).

During CT scan the patient is moved slowly inside the dark tunnel and a gantry rotates around the whole body to cut the transverse slices of the image. Every cutting slice is produced by a single rotation of gantry and thus multiple series of slices are made by several rotation of gantry at interval of 7 mm. The interval of slices can be decreased or increased depending on the diagnostic information sought. The first generation scanners took 4 to 5 minutes for cutting every slice of image. But the newer generation takes only 2 to 4 seconds. The older CT machines scan the slices in a series of discrete steps. While the modern spiral CTs acquire only image data

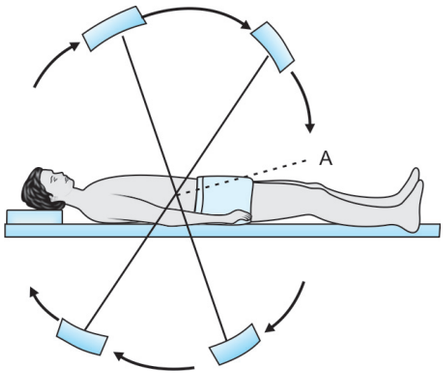


Fig. 46.2: Computer integrated tomography. A is the pivotal point of bar connecting tube and films

by a single continuous pass and later they constitute the image. In modern machines individual scan takes few seconds (2 to 4 sec) and a complete study may require only 5 to 10 minutes. Unlike MRI, in CT scanning the environment does not restrict the use of conventional type of anaesthetic equipment and monitoring. But the space is often limited. So, compact anaesthetic machines and monitors are more practical.

CT scan is a painless noninvasive procedure. So, it does not need any anaesthesia for adults. Only children, uncooperative individual and psychiatric patients need anaesthesia to keep them motionless. Sometimes, critical patients who are brought from ICU for CT scan needs supervision by anaesthetist. GA is usually not needed for them. Sedation is sometimes needed and is sufficient. Only light anaesthesia producing immobility and lack of awareness is required.

A variety of general anaesthetic technique can be used for CT scan by applying inhalation or intravenous agents with spontaneous or controlled ventilation. But the final choice should be determined by the equipment available and the patient's needs, e.g. only maintenance of clear airway, control of raised ICP, respiratory support etc. If there is any antecepated problem regarding clear airway due to falled back tongue under sedation and patient's head is inaccessible during CT scan, then

the airway can be cleared by LMA, provided the patient does not require IPPV or airway protection from aspiration. If intubation is needed for any cause, then every effort should be made to reduce the ICP (especially if the CT is being done for intracranial space occupying lesion) by hyperventilation causing hypocapnia and by avoiding the use of volatile anaesthetics agents.

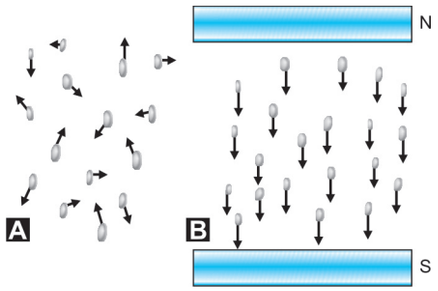
Anaesthetists may have to adopt their own techniques depending on whether the patient is elective or an emergency trauma victim with ongoing blood loss. These latter patients must be treated as if they have full stomach and therefore, sedation is not an option. These patients should be scanned in fully awake condition or be intubated following a rapid sequence induction and intubation, if general anaesthesia is needed. Before laryngoscope and intubation cervical spine (if fractured) should be stabilised. During extreme flexion of head (required for examination of posterior cranial fossa), kinking and disconnection of tube should be cared for.

Positioning and movement of the gantry during the radiological procedure may also cause kinking or disconnection of the anaesthetic circuit. Cannulas, catheters, drains and even ET tubes can be pulled out during the transfer or movement of patient through the scanner. The radiographer should be asked for how far the table will move. There should be always checking that IV lines and breathing circuit have not been snaged with other equipments. CT scanning generates the potentially harmful ionising radiation. So, it is preferable for the anaesthetist to monitor the patient from outside of the scan room. In this circumstance the patient can also be monitored visually through a lead glass window that is supplemented if necessary by closed circuit television. If the anaesthetist observes the patient from the control room, then the monitor's alarm should be a visual one that can be easily seen from the control room. But, if it is necessary for an anaesthetist to remain near the patient, then wearing of appropriate radiation protection gown is advisable. During scanning of thorax and abdomen to reduce the artefacts caused by respiratory movement, the patient may require brief periods of apnoea or breath holding. To achieve this, both the paralysed or spontaneously breathing patients should be ventilated manually and their lungs are held standstill in inspiration phase for few seconds. Patient of intensive care unit requiring CT scans should be managed like any inter-ICU transfer with full monitoring and ventilatory support during transfer.

MRI (Magnetic Resonance Imaging)

It is not based on ionising radiation. It depends on magnetic field and radiofrequency pulses for the production of images. In MRI machine, there is a large magnet in the form of a tube which is capable of accepting the whole length of a human body and creating a huge magnetic field around it. This magnet is approximately 2 metre in length and 500 kg in weight. Within this magnetic tube radiofrequency (RF) transmitting coils which transmit radiomagnetic waves are also incorporated, surrounding the patient. These transmitting coils also act as a receiver to detect the reflected radiofrequency waves from the patient and construct an image (Figs 46.3A and B).

MRI is based on the fact that some atoms which contain unpaired protons or neutrons in their nucleus and simultaneously unpaired electrons in their outer orbit have the potential to act as magnetic dipoles. This property of atom is possessed by the following paramagnetic elements such as ^{1}H, ^{13}C, ^{23}Na, etc. and therefore, they behave like tiny magnets. In this purpose hydrogen atoms of body which contain a single proton are particularly suitable for acting as a tiny magnet and produce an MRI image, since they are normally present in vast numbers in the body tissues. Normally, the hydrogen atoms (which is equivalent to a proton) of our body tissue are arranged in random haphazard fashion. But the use of strong external magnetic field will force a proportion of these atoms to align in a new magnetic axis (parrallel or antiparallel to the applied magnetic filed) from their previous random orientation. The power of external magnetic field used in MRI for clinical practice ranges from 0.15 to 1.5 Texla (1500 to 15000 Gauss) as compared with that of the earth's magnetic field which is only 0.5 Gauss. In addition to the large and costly magnet required for MRI, the machine also uses pulses of radio frequency waves. These radiofrequently waves are generated by RF transmitting coils that closely surround (incorporated in the magnetic tube) the patient. These radio-frequency waves are essential to excite and detect the magnetised aligned hydrogen protons. The pulsed radiofrequency wave displaces the nuclei or protons of hydrogen atom from their new parallel or antiparallel position which was produced by external strong magnetic force. Then again the nuclei or protons return to their previous parallel or antiparallel position produced by the external magnetic force immediately after the pulse ceases. At the same; time they release some energy from tissue as a radio signal which is detected by the same RF transmitting coils, used for transmission of radio frequently waves. Since the returned RF signal is proportional to the concentration of protons of tissue hydrogen atom, so



Figs 46.3A and B: Mechanism of MRI
A. Protons, behaving like tiny bar magnets are oriented randomly.
B. Alignment of protons when immersed in a strong external magnetic field.

it forms the basis for a digital record of the proton content of the tissues by a highly sophisticated computer. The computer creates cross-sestional or three dimensional images from this minute returned radiofrequency signal which is generated when the hydrogen nuclei are flipped in and out of the parallel or antiparallel alignment by a powerful magnetic field with high radiofrequency magnetic pulses. Then using a similar technique which is used in CT, the returning RF signal (captured by RF coils) is converted by computer of MRI into an analogue image presented on a cathode ray tube in varying shades of black and white.

The radio-signal received by RF transmitting coil during MRI scanning is of very low electrical intensity and so is easily subjected to interference from any electronic equipment or anaesthetic monitoring devices. For this reason, MRI scanning area is enclosed within the RF shield which is incorporated usually into the fabric of the MRI imaging suite. The prevention of interference of MRI scanning from anaesthetic monitors is usually made by using isolated power sources or battery, some filters and sometimes enclosing the anaesthetic monitor in its own small RF shield. The provisions for both safe anaesthesia and good MRI image requires specialised anaesthetic equipments and careful organization. Unlike CT, it is not possible to take simply the standard conventional anaesthetic machines and monitors to the MRI room.

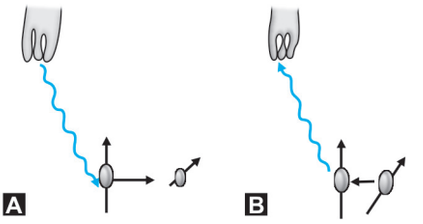
Anaesthetic procedure in an MRI suite creates several problems. Some arise from the effects of magnetic fields of MRI scanners on anaesthetic equipment and some from the effects of anaesthetic equipment on MRI scanner. The MRI image quality is superior to CT scan. It can differentiate clearly between the white and grey matter of brain which is not possible by CT scan. Again, unlike The CT scan which gives picture only in transverse section, MRI can display images in the transverse, sagittal, coronal and oblique planes. Unlike CT scan it is also capable of detecting diseases in the posterior fossa. MRI provides vascular picture without the need of intravenous contrast media. It requires very little patient preparation. As MRI is not an ionising radiation, so it does not produce biologically deleterious effects on patients and other personals present in this room and is non-invasive. MRI also permits evaluations of blood flow, CSF flow, contraction and relaxation of organs, etc. Calcium does not emit signals in the MRI. This lack of calcium signal, however, prevents MRI form detecting any pathological calcification in soft tissue tumour and pathological changes in cortical bone. Another disadvantage of MRI over CT scan is that a relatively long time is required to obtain images. Individual MRI scans may take up to 20 minutes and an entire examination may not take less than 1 hour. The other disadvantages of MRI are that very obese patient cannot be examined in this narrow magnetic tunnel and body surface absorb the RF energy causing increased body temperature. But it is usually unlikely that the patient's temperature will increase by more than 1°C (Figs 46.4A and B).

Anaesthesia and monitoring of patient in the MRI suite poses several unique problems. These are:

i. Need to exclude all the ferromagnetic components surrounding the patient.
ii. Limited patient's access and poor visibility of patient in the MRI tunnel.
iii. Low image quality of MRI due to disturbed radiofrequency (RF) waves caused by anaesthetic electric equipment.
iv. Interference and malfunctioning of anaesthetic monitoring equipment due to high magnetic field of MRI.

Patient acceptance of MRI is generally high. Most adults and small babies (recently well fed and wrapped) tolerate the procedure without sedation. Sedation may be required only in older children and in adults who cannot cooperate.

This sedation may be conscious sedation or deep sedation akin to GA. Conscious



Figs 46.4A and B: A. Effect of radiology pulse from an external coil which displaces magnetised proton from its axis with absorption of energy
B. Return of magnetised proton to its former axis with release of energy as radiofrequency pulse which can be registered by receiving coil and quantified

sedation can be defined as a medically controlled state of depressed consciousness which allow the protective reflexes of airway to be maintained and retains the patient's ability to maintain a patent airway independently. It also permits an appropriate response of the patient to physical stimulation or verbal command. Whereas deep sedation can be defined as a medically controlled state of depressed consciousness which may be accompanied by a partial or complete loss of protective airway reflexes, inability to maintain a patent airway independently and inability to respond purposefully to physical stimulation or verbal command. General anaesthesia (GA) is more or less close to deep sedation. GA is defined as a medically controlled state of unconsciousness accompanied by a loss of protective airway reflexes including the inability to maintain a patent airway independently and the inability to respond purposefully to physical stimulation or verbal command.

Sedation (usually for paediatric group) is usually ensured by chloral hydrate (50 mg/kg orally) or midazolam (0.3 to 0.5 mg/kg orally) or diazepam (0.1 mg/kg orally). For adult, sedation can be maintained by thiopentone or propofol. For each of these group of patients, the requirement of anaesthesia for MRI scan is only immobility.

In order to obtain high quality images, patients need to remain immobile within the confined space of magnetic core for at least 20 minutes. Complex scan may

take much longer time. So, though most patients tolerate the procedure without sedation, still a large number of patients, near about 3% of healthy adults are unable to do this without adjuvent sedation or general anaesthesia.

MRI scanner is very noisy and a patient has to lie for a long time on a thin table in a dark confined space made by tube wihtin this noise. This can cause claustrophobia or anxiety even in adults, necessitating sometimes sedation or anaesthesia. MRI has two implications on anaesthesia: (i) in-accessibility of an anaesthetised patient to an anaesthetist when the body enters totally into the scanner magnetic tunnel and (ii) malfunctioning of anaesthetic feromagnetic monitors in the strong magnetic field of MRI. Within the MRI tunnel, except conscious sedation, in deep sedation (only if it is needed) manual control of the airway of patient is impossible. So, tracheal intubation or laryngeal mask airway is essential to clear the airway of an anaesthetised patient from falling tongue. If the indication of scanning under GA is for suspected raised intracranial pressure or if GA is indicated in a patient with a potentially full stomach, then intubation with positive pressure ventilation is required. The effect of increasing the length of expiratory limb of the Ayre's T-piece has been studied on ventilation. Different studies have shown that with 10 metre long breathing circuit, there is only minimal decrease in tidal volume as a result of circuit compliance. So, it dictates that remote ventilation from outside the scanner room can be performed by using the long Bain circuit or Mapleson-D circuit when the patient is within the MRI room and the anaesthetic machine is outside the MRI room. Maintenance of anaesthesia by volatile anaesthetic agents or propofol infusion have both been employed. However, with the latter the dose requirement can be unpredictable, because infusion pump may malfunction near the strong magnetic field. The use of LMA is gaining popularity in MRI setting, where intubation is not absolutely indicated and is used for only better maintenance of airway. As there is no risk of ionic radiation in MRI, so the anaesthetist can observe the patient from both the ends of the tunnel and can take out the patient quickly if necessary. Due to intense magnetic field the anaesthetic monitoring equipments also do not work properly. Reversely, the ferromagnetic anaesthetic monitoring equipments distort the magnetic field sufficiently to degrade the image. It is also likely that the feromagnetic anaesthetic monitoring equipments are propelled towards the scanner machine and may cause a significant accident, if it makes contact with the patient or staff at a certain speed.

MRI room or suite can be laid out in two fashions for anaesthesia. If the majority of the anaesthetic equipment needs to be kept inside the radiology room, then the MRI compatible instrument should be used. But, usually most of the time, the anaesthetic machine and the monitoring equipments are kept outside the room and long MRI compatible (shielded or nonferromagnetic) anaesthetic circuits, ECG cables, SPO_2 cables, etc. are used and they lead to the patient from outside the room. The disadvantage of this approach includes the need for extra long monitoring leads, breathing tubes and other connections which frequently cause disconnection and leak.

Another common approach is to induce anaesthesia in the induction area adjacent to MRI suite outside the magnetic field using conventional anaesthetic equipments with the patient on a nonferomagnetic table or trolly, made of aluminium or stainless steel (MRI compatible). Then this table is transported with the patient after induction into the MRI room where maintenance of anaesthesia and monitoring are continued using MRI compatible anaesthetic machine and monitoring devices. Protable anaesthetic machine constructed of nonmagnetic material, aluminium gas cylinders and MRI compatible O_2 analyser also are used in MRI suite. Consideration also needs to be given to IV fluid stands, gas cylinders, ventilators, stethoscope, etc. Standard batteries of laryngoscope should be replaced with nonmagnetic lithium batteries if it is used in MRI suite. Laryngeal mask airways without metal spring in the pilot tube valve (armoured) should also be available. Heart rate and respiratory rate can be monitored with an oesophageal stethoscope. If the patient is allowed to breathe spontaneously, then the movement of the reservoir bag may be used as an index of ventilation. The metallic tubing connectors for noninvasive automated arterial pressure monitor should be replaced by nonmetalic connectors. But an extended length of the tubing from the BP cuff to the base unit is associated with some damping of the signal. Invasive monitoring is also possible. But in order to minimize damping the transducer must be kept as close to the patient as the magnetic field will allow. If transducer is kept within the 0.5 mT line, close to the patient then to avoid the damping of radiofrequency filter the use of will limit the interference (Fact file-I).

Patients fitted with a demand cardiac pacemaker should not be exposed to MRI. This is because induced electrical currents within the pacemaker by huge magnetic field may be mistaken for the natural activity of heart and may inhibit the pacemaker output, even in the absence of normal cardiac electrical activity. Other potential problems of the cardiac pacemaker due to MRI include (i) possible reed switch closure or damage, (ii) automatic switch over to an asynchronous mode and (iii) changes of programme, etc. Intracranial metallic vascular clips may be dislodged from the blood vessels due to magnetic induction of clips during the procedure of MRI. Malfunctioning of shunts, wire spiral of ET-tube, automatic implantable cardiac defibrilators and implanted biologic pumps are also other dangers. Metallic

FACT FILE- I

Specific problem and its solution during anaesthesia and monitoring of a patient in the MRI suite is like that:

i. Pulse oximeter must have the fibreoptic signal linking facilities between monitor and the sensor, RF filter and ECG locking device.

ii. ECG must have the RF filter and leads should be placed as close as possible to the centre of the magnetic field.

iii. Metal connection of the blood pressure cuff and pipes should be changed to plastic one for noninvasive monitoring of BP.

iv. Side stream capnography functions satisfactory in MRI unit but the length of the sampling tube may cause significant delay in signal transduction.

v. Precordial or oesophageal stethoscope does not function well. This is because of noise, created by scanner during its operation.

vi. Temperature probe should have RF filters for its proper functioning in MRI unit.

It is to be remembered that monitoring units which function satisfactorily in one MRI unit, produce problems in another MRI suite. This is due to differences in the RF and magnetic field strength employed by the two MRI system. Some centres permit the patient to breathe spontaneously during anaesthesia. But controlled ventilation by neuromuscular blockade is preferred. This is because it not only provides satisfactory gas exchange, but also avoid excessive head, neck, chest and abdominal movement that may interfere the imaging process.

objects such as scissors, stethoscope, BP instrument, cylinder opener, laryngoscope, etc, which are brought in the vicinity of the MRI magnet can literally fly into it and may cause severe injury to the patient and the bystanders.

Electric motors (e.g. in syringe infusion pump) may run erratically and administer wrong doses of drug to the patient. Also any information stored on magnetic media of credit card, bank cards, cassette tape, floppy disc, etc. will be erased by demagnetisation. The magnetic field decreases as distance from the scanner increases. Places beyond the 0.5 mT boundary line or outside of the scanning room can be considered safe. During scanning the noise level may sometimes reach 95 decibel So, ear plugs should be worn, even for anaesthetised patients to avoid the damage of cochlea. Devices, made from stainless steel which is not ferromagnetic can be taken into the scan room. Even weakly ferromagnetic objects such as metallic make up on face or tattoos, etc, can distort the image or be heated by the powerful magnetic field of the MRI machine to a point which can cause burns.

In complying with the minimum perianaesthetic monitoring standards, a balance must be made between the loss of MRI image quality due to electromagnetic interference from the different anaesthetic and monitoring equipments and degradation of the monitor signal quality as a result of the powerful magnetic field of MRI. There are several monitoring systems that are nonferromagnetic and, therefore, are compatible for use in the MRI room. Central capnography is not possible to use in MBI room, because within magnetic field sampling unit will tend to be overheated and would grossly distort the image. Side stream capnography should be used, but it necessitates a long sampling tube to keep the monitor beyond the MRI room or 0.5 mT line. ECG leads can cause the reduction of quality of both the monitor and scan signals. So, telemetric ECG is very useful in an attempt to circumvent this problem which is now available commercially. A liquid crystal display for cardiac monitoring should be used to avoid distortion of cathode ray tracing by the magnet of MRI machine. Recently, surgeries like laparotomies and craniotomies are being carried out with intermittent MRI picture to allow the accurate tomour resection. In such condition, scanners are horseshoe-shaped in design, like C arm with one side open to allow the access to the patient. Here, all the same precautions and principles are applied like the nonoperative MRI except titanium instruments are used.

Angiography

For angiography an arterial catheter is passed directly into the arterial lumen and a contrast medium is injected into the artery that produces image which is viewed by a conventional cut film radiography or by digital subtraction angiography. The arteries of viscera and lower extremities may be approached via the femoral artery, although arterial occlusive disease may require a translumbar approach to the aorta. It is an invasive technique, so the development of CT scan and MRI has now reduced the use of this type of invasive angiography. Also the advent of spiral and double helical CT scanner allows the whole vascular territories to be mapped out within 30 sec. Regarding the angiography MRI produces superior images than CT scanning, including three dimensional pictures and is also sensitive to the detection of flow.

Most of the angiographies are done under local anaesthesia with or without mild sedation. This is because the gaining of vascular access and the injection of contrast media in the vessels may result in the patient's discomfort. So, some patients may get benefit from the judicious administration of analgesics and sedatives. Indications for GA in angiography is same as for CT scan and MRI. The disadvantage of GA for angiography is it prolongs the time taken for investigation, and increase the cost and risk associated with anaesthesia. In GA the another disadvantage is that patient will not be able to react to untoward reactions due to radiocontrast medium, while under LA a conscious patient can describe symptoms and allow the procedure to be stopped immediately. Usually the patients undergoing arteriography to determine the extent of vascular occlusive disease have a higher incidence of serious comorbid conditions such as diabetes mellitus, coronary heart disease, hypertension, renal disease, etc. So, appropriate monitoring and precautions should be taken when applying sedation and

anaesthesia for angiography or CT or MRI scan in this group of patients.

Cerebral angiography

Cerebral angiography is usually done for the diagnosis of arteriovenous malformations, aneurysms or tumours, etc. in the brain where radio opaque contrast medium is given in the carotid artery and a plane or a digital X-ray is taken. It is mostly done under LA. The indications for GA in cerebral angiography are same as that of CT scan or MRI. But most of the patients scheduled for cerebral angiography have increased ICP. So, all the measures have to be taken to prevent the rise of ICP, if the patient requires GA. Smooth induction should be instituted, avoiding coughing, bucking, straining etc. and permitting BP to be well maintained. It is reasonable to employ a technique of controlled ventilation, avoiding the use of volatile anaesthetic agents as they increase the ICP. Hyperventilation produces hypocapnia and it is useful for reduction of ICP. So, during maintenance of anaesthesia reduction of P_aCO_2 by hyperventilation causes vasoconstriction of cerebral vessels resulting in slow cerebral circulation and increased transit time of contrast medium which will improve the delineation of small vascular lesions. The transient hypotension, bradycardia or asystole may occur during cerebral angiography due to contrast dye injection. Acute cerebral oedema has also been reported following injection of contrast media due to the hyperosmolarity of dye and also due to the changes in permeability of endothelium of blood-brain barrier. Other complications of cerebral angiography are haemorrhage which is due to the rupture of lesion or vessel and ischaemia which is due to thromboembolism or vasospasm.

Coronary angiography

Coronary vasculature is visualised by injecting the radioopaque contrast media into the ostium of any coronary artery. Thus, it helps in the determination of the anatomy of coronary artery, or the presence and location of any stenosis, or the detection of coronary vasospasm. Thus, information obtained from coronary angiography dictate further treatment, ranging from simple medical therapy for myocardial ischaemia to angioplasty during angiography to CABG. Though CT and MRI help in the diagnosis of coronary arterial disease, but still coronary angiography is the 'gold standard' method for the diagnosis of coronary arterial disease. During coronary angiography, some interventional procedure can also be performed to improve the coronary blood flow.

During coronary angiography local anaesthesia is provided at the site of the introduction of an arterial catheter which is either around the femoral artery or the brachial artery. Under local anaesthesia, coronary angiography is usually performed by passing a catheter via the femoral artery in a retrograde fashion to the aortic root. Then for the selective angiography injection of contrast medium is done into the ostia of each coronary artery. During coronary angiography, every patient should have an intravenous canula for administration of emergency medicines (if needed); analgesics or sedation. For analgesia, usually fentanyl and for sedation usually midazolam are helpful in reducing the discomfort during injection of contrast media and in maintaining the motionless supine position of patient during long procedures. Any benzodiazepines, given IV slowly, provides adequate sedation for most of the purposes. Sometimes fentanyl and midazolam is supplemented with propofol. Standard anaesthetic monitoring protocol is used during the whole procedure including continuous monitoring of SPO_2, heart rate, respiratory rate, ECG, arterial BP (by directly transduced from the arterial introducer), etc. The infusion of GTN should be readily available for administration, if the patient develops myocardial ischaemia. Supplemental O_2 should be administered to every patient via face mask or nasal cannula. Complications of coronary angiography are more common in patients with severe coronary artery disease and it includes arrhythmias, heart failure and strokes. Local bleeding and haematoma at the site of catheter introduction are the surgical complications. Arrhythmias are not uncommon which is both due to direct stimulation of myocardium by catheter and following injection of contrast media. Bradycardia is also common as the nonspecific ECG changes. Left heart failure is easily induced which is due to the rapid rise in left ventricular end diastolic volume and pressure, caused by the injection of contrast media in bolus. Myocardial infarction has been noted in 0.5% of patients during coronary angiography. Thorough proper pre-operative examination, correction of preexisting arrhythmias where possible, and good control of the serum electrolytes clearly minimizes the potential dangers, during coronary angiography.

Interventional transvascular coronary arterial procedure

Once the presence and location of any coronary arterial block or stenosis is confirmed, a variety of methods or interventional procedures can be employed to improve the myocardial blood flow directly. Heparin is used prior to any angiography and interventional therapeutic procedures. One of the methods or interventional coronary arterial procedure is the percutaneous transluminal coronary angioplasty (PTCA). Here, the stenosed or blocked area of coronary artery is traversed by a balloon-tipped catheter which is introduced through the femoral artery. The balloon is then inflated to dilate the area of stenosis and to remove the block which will increase the coronary blood flow. During balloon inflation, transient coronary artery occlusion can occur. So, patient's haemodynamic status must be closely monitored.

Other interventional coronary arterial procedures are: placement of coronary stents, removal of atheromatous plaque, extracorporeal circulation, etc. Extracorporeal circulation is usually established in patients who are not otherwise candidates for CABG surgery such as those with unacceptably poor ventricular function. It is performed via the femoral artery and vein following GA and systemic heparinisation. The coronary atherotomy may be performed using atherotomy catheter or excimer lasers. During all these procedures different types of ventricular arrhythmias can be precipitated and these haemodynamically unstable arrhythmias can be treated with lignocaine or cardio version. The rupture of coronary artery during these interventional transvascular coronary arterial procedure may result in pericardial tamponade and is treated by emergency pericardiocentesis. The other complications of interventional coronary angiography are coronary artery dissection, coronary artery vascular spasm due to dysfunctional coronary artery endothelium and intraarterial thrombus formation. Once thrombus is formed, then intracoronary injection of urokinase or streptokinase may dissolve the thrombus. Sometimes, accute coronary artery occlusion does not respond to transluminal treatment in cardiac catheterization laboratory. Then it may require emergency CABG. The spectrum of treatment provided in the cardiac catheterisation laboratory is now constantly changing. Various combination of the above described procedures and some new procedures may be performed on individual patient. But it depends on the severity and location of the lesions and the frequency of practice, performed at each individual institution.

Cardiac catheterisation

Cardiac catheterisation is nothing but the placement of catheters in the great vessels or the chambers of heart through transvenous or transarterial route. It helps in determination of cardiac anatomy, valvular anatomy, pulmonary vascular anatomy, pressure measurement in different cardiac chambers and major blood vessels, injection of contrast media for radiological visualisation of various vascular structures, injection of indicator with distal sampling for flow determination (using Fick principle), blood sampling for measurement of O_2 and CO_2 tension to detect the presence and location of shunts, etc. Right side of the heart is accessed via the femoral, brachial, cephalic or internal jugular vein and the left side of the heart is accessed via the femoral or brachial artery. Although, all the above mentioned parameters can be meausred by echo and Doppler cardiography, still cardiac catheterisation is the 'gold standard' technique. For measurement of flow and pressure from different cardiac chambers and subsequently to measure shunt (by O_2 tension), a steady state preanaesthetic cardiovascular and respiratory function is necessary. Any change in flow and pressure in any chamber due to anaesthetic procedure may result in incorrect result for the measurement of shunt. So the arterial O_2 and CO_2 tension should be strictly maintained at the preanaesthetic levels or should not change (if abnormal for that patient) by any anaesthetic technique or by giving O_2. These constraints make anaesthetic management extremely difficult for cardiac catheterisation.

The cardiac catheterisation in adults is done under local anaesthesia and/or sedation produced by midazolam and/or fentanyl and if necessary with propofol. It is frequently performed in conjunction with coronary angiography. O_2 is administered only when O_2 saturation falls below the level of baseline and care must be taken to maintain the present arterial blood gas level if shunts or pulmonary haemodynamics are to be measured. Complications of cardiac catheterisation are similar to that of coronary angiography, because catheter is placed within the cardiac chambers. So, supraventricular and ventricular arrhythmias are very common during this procedure. Hence, anaesthetist must be ready to deal with these acute haemodynamic and/or respiratory instability in patients who may have severe valvular and myocardial dysfunction. Fortunately, however, these cardiac arrhythmias are usually resolved with immediate withdrawal of catheter. Sometimes IV medication, vagal maneuvers or cardioversion may be necessary to terminate these arrhythmias. Other than arrhythmias complications of cardiac catheterisation are: perforation of cardiac chambers, perforation of great vessels, bleeding, haematoma, aortic dissection, embolic phenomenon, etc.

Only children require GA for cardiac catheterisation. Children requiring cardiac catheterisation usually suffer from congenital heart disease and often present with cyanosis, dyspnoea, heart failure, etc. Congenital cardiac anomalies may vary from simple atrial septal defect to complex cardiac defects with shunts at various levels, as for example hypoplastic left heart syndrome with severe ventricular dysfunction etc. Paediatric patients may also have coexisting noncardiac congenital anomalies. So, only when an experienced cardiac anaesthetist is readily available, then it has now become the custom in many institutions to employ GA on children for cardiac catheterisation. During the procedure of cardiac catheterisation the aim of an anaesthetist is to maintain a steady circulatory state. This may require considerable preoperative preparation of patient in close conjunction with the cardiac physicians, surgeons and radiologists. Oxygen, digitalis and diuretic therapy together with the correction of electrolyte imbalance and acidosis should be carried out before cardiac catheterisation when possible. Some infants may be seriously ill and may present with cardiac failure as potential surgical emergencies.

During cardiac catheterisation an ideal anaesthetic technique (i) should not produce any myocardial depression, (ii) should avoid any hypertension / hypotension and tachycardia, (iii) must preserve

normal O_2 tension and maintain normocapnia (to avoid alterations in PVR) while maintaining respiration on air. Even in cyanotic patients, supplemental O_2 is not administered unless O_2 saturation falls below the baseline level. Spontaneous respiration with volatile anaesthetic agents may not be suitable for patients with significant myocardial disease. Controlled ventilation is essential using room air, as long as O_2 saturation does not fall below critical level. Controlled ventilation avoids the increase in P_aCO_2 which is frequently found in spontaneous respiration. As an alternative to volatile anaesthetic agents, patients can be managed with TIVA using various combination of opioids, midazolam, propofol and ketamine. During the procedure of cardiac catheterisation repeated blood gas analysis is essential, because the metabolic acidosis may be the initial sign of low cardiac output state due to myocardial depression. Even mild degrees of metabolic acidosis should be treated in critically ill patients by inotropic therapy. Initially, there was some reluctance in many centres for administering GA and this is because of the disturbances of the normal cardiopulmonary physiology during GA. Sudden cardiorespiratory failure may occur during cardiac catheterisation. Contrast medium in the coronary circulation may cause profound transient changes in the ECG. Therefore, continuous ECG and invasive arterial pressure monitoring should be used to allow rapid assessment of arrhythmias and hypotension for critically ill patients.

ANAESTHESIA FOR RADIOTHERAPY

The indications and the process of management of monitored anaesthetic care (MAC) or conscious sedation or GA for paediatric or adult group of patients for radiotherapy is same as CT and MRI. Radiotherapy in children is usually performed under GA. As the patient had received anaesthesia recently for a diagnostic procedure and then will require anaesthesia more than once for radiotherapy, so, halothane should be avoided. It is also, therefore, desirable to avoid repeated invasive procedures as far as possible and to keep the anaesthetic technique as simple as possible. During anaesthesia in radiotherapy, anaesthetist may be exposed to radiation repeatedly. So, proper precautions should be taken by anaesthetist.

The children usually undergo radiotherapy for variety of reasons, as for example Wilm's tumour, retinoblastoma, acute leukaemia, etc. The implications of radiotherapy on anaesthesia are: (i) as during radiotherapy high doses radiation (X-ray or any other) is administered by linear accelerator, so all staffs should remain outside the room leaving the anaesthetized patient alone. (ii) as radiotherapy needs repeated doses for several weeks, anaesthesia is also given repeatedly. (iii) the anaesthetised child must remain alone and motionless for a short period of time in the radiotherapy room. For that period clinical monitoring should continue and is observed by a close circuit television from the control room. (iv) as radiotherapy is arranged on an outpatient basis, recovery should be fast. (v) Patient's physical status may remain compromised before and it is due to malignant disease which has immense impact on general anaesthesia. (vi) Within the therapeutic radiology department there should have facilities and monitors that must satisfy or exceed the current standards promulgated by the ASA.

The actual process of radiotherapy is of very short duration, i.e. for only 30 to 60 sec. But considerable longer period of anaesthesia is required, i.e. for 20 to 30 minutes, because before treatment begins, the field which is to be irradiated is plotted and marked so that the X-ray can be accurately focussed on the marked radiation side without damaging the surrounding structures. During that period the child has to be remained motionless.

There is no pain in radiotherapy. So, the aim of anaesthesia for radiotherapy is only to keep the patient motionless for a few minutes. This can be achieved by oral sedation. But heavy oral sedation delays recovery time. Injection of ketamine, through IV or IM route is also helpful to keep the baby motionless, provided the patient does not have intracranial lesion. A need to increase the dose of ketamine gradually with successive radiation treatment (tachyphylaxis) may be observed. Intravenous propofol infusion can also be used satisfactorily for the children. Similarly, the increasing dose requirements have also been noted with propofol (tachyphylaxis).

If airway control is difficult during anaesthesia, then LMA can be instituted and anaesthesia can be given by a combination of N_2O, O_2 and volatile anaesthetic agents. In most of the cases LMA is sufficient and endotracheal intubation is rarely necessay. No analgesia is required and relatively light plane of anaesthesia is maintained which allows rapid emergence and recovery. Monitoring of the patient under GA during radiotherapy is only done by seeing the bag movement and by seeing the screens of different monitor through the close circuit camera from control room. A microphone can help to hear the sound of different monitors and also the saturation dictated by the pitch of pulse oximeter.

47 Neuromuscular and Muscular Diseases and Anaesthesia

INTRODUCTION

All the neuromuscular and muscular diseases usually manifest with some obvious clinical symptoms and signs which are mainly related to skeletal muscles. But many patients with some occult state of many of these disorders without any symptoms and signs may also be presented for anaesthesia and is very important to an anaesthetist because they may cause many complications during perioperative period. The most common neuromuscular diseases which an anaesthetist usually encounters during perioperative period are myasthemia gravis and Lambert-Eaton myasthenic syndrome (LEMS). They are presented in OT for treatment of these diseases or for surgical management of other disorders associated with these diseases. Other than neuromuscular diseases, the muscular diseases which are commonly encountered by an anaesthetist during perioperative period are initially divided under three broad headings such as: muscular dystrophies, myotonia and dyskalamic familial periodic paralysis, the subclassification of which will be discussed later.

All these neuromuscular and muscular diseases cause diminished muscle strength and increased sensitivity to neuromuscular blocking agent which predispose the patients to respiratory failure postoperatively. So, thorough understanding of all these neuromuscular and muscular disorders and their potential interactions with various anaesthetic agents is very crucial for an anaesthetist to avoid any morbidity and mortality of patients.

NEUROMUSCULAR DISEASES

Myasthenia Gravis

It is an acquired chronic autoimmune neuromuscular disorder and is characterised by weakness of different skeletal muscles due to the decrease in functioning of nicotinic ACh receptors at their motor end-plate caused by complement mediated destruction or inactivation of it by circulating antibodies which are formed against these receptors. However, the origin of these ACh receptor antibody is still unknown, but the thymus gland is suspected. This is due to the close association of the presence of thymus gland abnormalities with the disease of myasthenia gravis. This is because the muscle like cells (myoid cells) which also bear ACh receptors on their surface are present within the thymus gland and may serve as a source of autoantigen and trigger the autoimmune reaction within the thymus gland producing ACh receptor antibody. The antibody against the ACh receptors is not present in all the cases but found in 80 to 90% of patients with myasthenia gravis (Fig. 47.1).

Myasthenia gravis is not a rare disease, having a prevalance of atleast 1 out of 7500 general population. It affects individuals of all the age groups. But the women are affected more frequently and at early ages than men (3:2). So, the females are affected mainly in the second and third decades and males are affected mainly in fifth and sixth decades of life. Women with myasthenia gravis also experience increased muscular weakness in the last trimester of pregnancy and in the early postpartum period. The babies of myasthenic mothers may also show transient myasthenia for at least 1 to 3 weeks after delivery. This is due to the transplacental transfer of ACh receptors antibody, necessitating sometimes control ventilation in neonate. The disease myasthenia gravis usually runs in relapsing and remitting courses, especially during the early years of the onset of this disease. The Myasthenic patients also have an increased incidence of association with several other medical disorders. For example 10 to 20% of patients who are suffering from myasthenia gravis is associated with the presence of thymoma. Whereas 60 to 70% of patients with myasthenia develop thymic hyperplasia. The other autoimmune disorders which are also present in association with the myasthenia gravis in remaining 10% of patients are

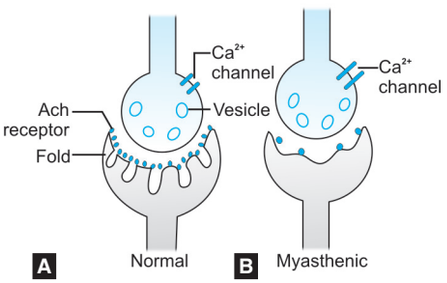


Fig. 47.1: Figure shows the normal A. and myasthenia gravis affected B. neuromuscular junction. In comparison to normal the myasthenic neuromuscular junction has shallow synaptic fold, few acetylcholine receptors and widened synaptic gap

rheumatoid arthritis, hypothyroidism, thyroiditis, Grave's disease, systemic lupus erythematosus, skin diseases, family history of autoimmune disorder, etc. Pernicious anaemia occurs more commonly in patients with myasthenia gravis than in those without that. The myasthenia gravis may also be more commonly associated with myocardiopathy and myocarditis which may result in atrial fibrillation and heart block (Table 47.1).

The cardinal features of myasthenia gravis are increased weakness and easy fatigability of skeletal muscles, but without any loss of tendon reflexes or any impairment of sensation or deficit of other neurological functions. The skeletal muscle strength is maintained at normal level in well rested patients and their atrophy is unlikely. These weakness and fatigability of skeletal muscles is characterised by its increaseness during repeated use and may improve following rest and sleep. The exacerbations and remissions of this muscular weakness usually occur particularly during the first few years after the onset of this disease. Then these remissions and exacerbations rarely occur and muscular weakness become a permanent.

The distribution of skeletal muscular weakness in myasthenia gravis has a characteristic pattern. The cranial muscles such as the muscles of lids and extraocular muscles are often involved most early. So, the ptosis and diplopia are the common initial manifestation of myasthenia gravis. Then difficulty in swallowing may occur and it is due to the result of weakness of the muscles of tongue, palate, pharynx larynx etc, giving rise to nasal regurgitation or aspiration of food, if the cough is ineffectual. This also causes dysarthria (difficulty in speak) and difficulty in clearing secretion from mouth, pharynx and larynx. Any limb muscle may be affected in this disease but it is often the proximal part of the upper limb such as shoulder girdle which is affected most commonly and may be asymetrical on both side. So, the patient is unable to work above the shoulder level such as combing of hair without taking frequent rest. Weakness of pharyngeal and laryngeal muscles during chewing and speaking is most noticeable after prolonged use as in chewing meat or delivery of continuous speech during teaching. If the respiratory muscles become very weak and requires respiratory assistance then the patient is said to be in myasthenic crisis. Infection, stress, electrolyte imbalance, pregnancy, surgery, etc, often cause exacerbation of this disease and may lead to myasthenic crisis. Some drugs such as aminoglycosides, penicillamine and ciprofloxacin usually exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia gravis.

Table 47.1: Classification of myasthenia gravis

Class I	Weakness limited only to extraocular muscles.
Class IIA	Mild weakness to skeletal muscles other than extraocular muscles - mainly bulbar muscles. Respiratory muscles are spared.
Class IIB	Respiratory muscles are involved.
Class III	Moderate weakness of skeletal muscles with rapid deterioration.
Class IV	Acute onset or severe weakness of skeletal muscles. Tracheal intubation and ventilation may be needed.

The diagnosis of myasthenia gravis is suspected on the basis of the history of weakness and easy fatigability of the skeletal muscles in the typical distribution pattern described above. This suspician about diagnosis should always definitely be confirmed before the treatment of myasthenia gravis is undertaken. This is essential because: (i) other treatable conditions such as drugs, hyperthyroidism, Graves' disease, botulism, intracranial mass compressing cranial nerves, etc. may cause muscular weakness and closely resemble myasthenia gravis, (ii) the definite treatment of myasthenia gravis may involve surgery, and (iii) erroneously the prolonged use of drugs for the treatment myasthenia gravis has adverse side effects.

For clinical diagnosis of myasthenia gravis the IV injection of edrophonium (a short acting anticholinesterase whose onset of action is only 30 sec and duration of action is only 5 minutes) is taken as a very valuable diagnostic aid which is known as the Tensilon test. The whole procedure of this test is divided into two parts. In the first part 2 mg of edrophonium is given initially through IV route. Then if definite improvement (examinar should focus on one or more group of weak muscles and evaluate their strength objectively) of any muscle strength is occured, then the test is considered as positive and terminated. If there is no change, then the patient is again given additional 8 mg of edrophonium through IV route. This Tensilon test is divided in two parts, because maximum tests become positive by the initial small dose of edrophonium and does not need the 2nd large dose. Some patients react to this anticholinesterase by subsequent large doses with many adverse effects such as increased salivation, nausea, vomitting, diarrhoea, muscular fasciculation throughout the whole body and rarely syncope. So, the 2nd large dose is omitted if not needed and atropine (0.6 mg) should be given with edrophonium or be kept at hand for IV administration if these symptoms become troublesome.

Instead of edrophonium another long acting anticholinesterase agent such as neostigmine (1 mg) can also be used. However, the advantage of this long acting anticholinesterase is that it better permits more time for detailed evaluation of muscle power. Sometimes, false +ve test occurs with other neurological disorders such as amyotropic lateral sclerosis. Sometimes false-negative or equivocal result may also occur. In such circumstances neostigmine is more helpful than edrophonium by giving more time for evaluation of muscle power. However, virtually in all instances it is desirable to carryout further testing to establish the diagnosis of myasthenia gravis definitively by other investigations

such as EMG, estimation of ACh receptor antibody etc. Positive antiskeletal muscle antibodies suggest the presence of thymoma, but all patients should have a thoracic CT to exclude this condition which may not be visible on plain radiographic examination. Screening for other autoimmune disorders, particularly thyroid disease, is also important.

The principles of treatment of myasthenia gravis are: (i) to maximise the activity of ACh which acts as neurotransmitter on the remaining functional nicotinic ACh receptor at the motor end plate by reducing the activity of cholinesterase which destroys ACH by giving anticholinesterase, and (ii) to abolish or limit the immunological attack on ACh receptor at the motor end plate by surgical thymectomy, immunosuppression (corticosteroids, azathioprine, cyclosporine), and short term immunotherapy (plasma exchange, administration of immunoglobin). Among all these methods anticholinesterase is the first line of treatment for the mild to moderate cases of myasthenia gravis and for this pyridostigmine is the most widely used agent in the dose of 30 to 120 mg 6 hourly, producing an effect in 30 minute and peak effect in 120 minute. During the clinical use of anticholinesterase the muscarinic effect of pyridostigmine (or any anticholinesterase) such as excessive salivation, diarrhoeas, intestinal colic etc, is controlled by the subsequent use of propanthelin with pyridostigmine in the dose of 15 mg or as required. However, the dose and schedule of pyridostigmine should be tailored according to the patient's response, but the maximum dose rarely exceed 120 mg at the interval of every 3 hours. It produces fewer side effects than other anticholinesterase such as neostigmine and 60 mg oral pyridostigmine is equivalent to 2 mg of it through IM or IV route. Higher doses may precipitate cholinergic crisis by producing excessive muscarinic effect and muscular paralysis by blocking motor end plate. This cholinergic crisis is characterised by fasciculation, accentuation of skeletal muscular weakness or muscular paralysis, bradycardia, pallor, sweating, salivation, bronchospasm, miosis, etc. This should be distinguished from severe muscular weakness due to exaccerbation of myasthenia gravis (myasthenic crisis) by the clinical features and if necessary by the injection of a small dose of edrophonium (Table 47.2).

Although anticholinesterase make benefit most of the myasthenic patient, but their effects gradually wane after prolonged treatment and improvements become incomplete. So, thymectomy is the next alternative of the management of myasthenia gravis. But the actual mechanism of action of thymectomy (surgical removal of thymus) in the treatment of myasthenia gravis is still unknown. However there is definite improvement in clinical symptoms and there is decrease in the level of ACh receptor antibody, reducing the dose of immunosuppressive agents or completely eliminating the need for continuing medical treatment. It should be performed in the early stages of this disease leading to a better overall prognosis whether a thymoma is present or not. It should also be performed as soon as possible in any antibody positive patient with symptoms not only confined to the extra ocular muscles and unless the disease has been established for more than 7 years. Generally the myasthenic patients between the ages of puberty and about 50 years are the best candidates for the surgical removal of thymus.

Table 47.2: Diagnosis of myasthenia gravis

History
Weakness of muscle with characteristic distribution .
Ptosis and diplopia.
Fatigue of muscle due to repeated activity.
Muscle weakness improves by rest.
Effects of treatment.
Physical examination
Absence of other neurological defects.
Ptosis, diplopia.
Quantitative testing of muscle strength.
Forward arm abduction time (< 5 minuters)
Laboratory tests
1. *ACh receptor antibody*
If positive then diagnosis is confirmed,
80% positive in generalised myasthenia,
50% positive in ocular myasthenia,
Negative result does not exclude myasthenia.
2. *Tensilon test*
Highly probable of myasthenia if test is unequivocally positive.
3. *Repetitive nerve stimulation*
Decrement of 20% at 3 Hz highly probable of diagnosis.
4. *CT and MRI*
To exclude intracranial lesion.

Before thymectomy for the treatment of myasthenia gravis all the patients should always be prepared preoperatively to optimize the muscular strength, especially of the respiratory muscles. For example, if the patient's vital capacity is less than 2 litres, then plasmapheresis must be performed before surgery to improve the strength of the respiratory muscles. But the immunosuppressive drugs should not be continued (if started) before operation for the possible increased risk of postoperative infection. Endoscopic thymectomy through a small cervical incision is preferred than median strenotomy, because it is associated with smaller incision, less chance of infection and less postoperative pain. The benefit of thymectomy on the myasthenia gravis is not immediate and is typically delayed for months to years.

Immunosuppression by using glucocorticoids, azathioprine, cyclosporine and other immunosuppressive drugs are effective in nearly all patients with myasthenia gravis where the weakness of skeletal muscle is not adequately controlled by anticholinesterase. The choice of these drugs should be guided by their relative risks and benefits in individual patient. But corticosteroids are the most commonly used immunosuppressive agents for the treatment of myasthenia gravis. The improvement of muscle power by corticosteroid is commonly preceeded by marked exacerbations of myasthenic symptoms. So, the treatment should be initiated in hospital

and then is continued at home for months or years. They are also associated with the greatest likelihood of adverse side effects.

The indication for the use of immunoglobulins and plasmapheresis is more or less same, i.e. to produce rapid improvement for brief period during myasthenic crisis and to quickly prepare the patient before any surgery. But their mechanism of action is diferent. In plasmapheresis the antibodies are removed from the patient's circulation. Whereas the mechanism of action of immunoglobulins are not known, because it has no consistant effect on the measurable amount of circulating ACh receptor activity.

Anaesthetic Management

The patients with myasthenia gravis may present for thymectomy which is related to the treatment of this disease or other surgical procedures which are not related to the treatment of myasthenia gravis such as obstetric surgery, general surgery, urological surgery, etc. In all these cases the patient's medical condition mainly the muscular strength should be optimized prior to surgery. So, the myasthenic patients should carefully be evaluated preoperatively giving focus on the affected muscle groups, recent course of the disease, present history of drug therapy and other consisting illness. Patients with bulbar (pharynx, larynx, face, tongue, etc.) muscular and respiratory muscular involvement are at increased risk for postoperative respiratory complications and pulmonary aspiration. So, the proper preoperative preparation of myasthenic patients with immunoglobulins, plasmapheresis, metoclopramide and H_2 blocker may decrease these risks. During the preoperative preparation of myasthenic patients the continuation of anticholinesterase agents which was started before is controversial and should be individualized. The potential problems regarding the preoperative treatment of myasthenic patients by anticholinesterase include the possible drug interaction between it and the other anaesthetic agents mainly muscle relaxants (described later), increased vagal reflexes by anticholinesterase, and the possibility of disruption of bowel anastomosis due to hypersistalsis caused by anticholinesterase during bowel surgery. On the otherhand, patient's muscle power may deteriorate rapidly if the anticholinesterase agents are withheld preoperatively.

Patients with myasthenia gravis are very sensitive to the impairment of respiratory function during perioperative period and it is due to the respiratory muscular weakness or paralysis. So, drugs such as opioids, benzodiazepines, and other similar sedative agents should be used with caution as preoperative medication or is completely omitted if circumstances permits. It is already said that myasthenic patients are at increased risk for postoperative respiratory failure due to the muscular weakness or paralysis. So, the preoperative criteria that are predictive of the need for postoperative ventilatory support following transsternal thymectomy or any major surgery in myasthenic patients are: duration of disease for more than 6 years, the presence of some concomitant lung diseases, the dose of preoperative pyridostigmine is >750 mg/day, peak inspiratory pressure is >20 cm of H_2O, the preoperative vital capacity is < 4 ml/Kg. However, these criterias are less relevant to the endoscopic transcervical thymectomy, because these less invasive surgical procedures have a respiratory sparing effect.

Except thymectomy, in other surgical procedures where myasthenia gravis is present as coexistent disease epidural or spinal anaesthesia is preferred than GA because it avoids the potential problems of increased neuromuscular blocking effect with respiratory depression of muscle relaxant during postoperative period in GA. However, excessive high spinal level of motor blockade can also result in hypoventilation in RA and also should be avoided. During GA the induction in myasthenic patients is usually accomplished by all standard short acting IV anaesthetic agents but in small doses, keeping in mind that the relaxation effect of these inducing drugs on weak respiratory, laryngeal and pharyngeal muscles may be accentuated in such group of patients. Sometimes, tracheal intubation can also be performed without further addition of neuromuscular blocking agent in such patients by taking the advantage of muscular weakness of such disease, and the muscular relaxing effect of intravenous and volatile anaesthetic agents, used during induction. The only volatile anaesthetic agent based anaesthesia is usually sometimes satisfactory for intubation in some myasthenic patients. Because in myasthenic patients the deep anaesthesia produced by volatile anaesthetic agents provide sufficient muscle relaxation for tracheal intubation and intraoperative procedures. So, many anaesthetists try to avoid muscle relaxants and use only volatile anaesthetic agents in patients suffering from myasthenia gravis (Table 47.3).

The response of succinylcholine in myasthenic patients is unpredictable. The patients may show a relative resistance or higher sensitivity and a prolonged effect or an unusual phase II block in response to succinylcholine. The mechanism by which the myasthenic patients are resistant to succinylcholine are not known, but the reduced number of ACh receptor at the motor end plate may be the possible explanation of it. On the otherhand, the anticholinesterase agents such as pyridostigmine not only inhibits the true cholinesterase at the motor end plate, but also inhibits the plasma cholinesterase causing the possibility of higher sensitivity and prolonged effects of succinylcholine. In contrast to succinylcholine, the myasthenic patients always show the high sensitivity to nondepolarizing muscle relaxant and it is due to the decrease in total number of the functional ACh receptors. The balance between the number of functional and nonfunctional ACh receptors determine

Table 47.3: Comparison between myasthenia gravis and myasthenic syndrome

	Myasthenia gravis	*Myasthenic syndrome*
Gender	Myasthenia gravis Females > Males	Myasthenic syndrome Males > Females
Associated pathology	Thymoma, thymus hyperplasia	Small cell carcinoma of lungs
Manifestation	Ocular, bulbar, facial muscles are more commonly affected Arms > Legs Exercise worsens strength No muscle pain Tendon reflex normal	Not common Legs > Arms Exercise improves power Muscle pain Tendon reflex absent
Response to muscle relaxant	Resistant to succinylcholine Sensitive to nondepolarizing agent Good repsonse to anticholinesterase	Sensitive to succinylcholine Sensitive to nondepolarizing agent Poor response to anticholinesterase

the degree of sensitivity of myasthenic patients to the nondepolarizing muscle relaxing agnets. Sometimes the small dose of nondepolarizing agent desired to attenuate the succinylcholine induced fasciculations may produce adequate muscle relaxation for intubation. So, if nondepolarizing agents are required, then small doses of a relatively short acting agent such as cisatracurium and mivacurium are preferred. The potency of atracurium is increased two times in mild to moderate myasthenic patients compared to normal individual. As mivacurium is eliminated rapidly, so it can be titrated easily to achieve the desired level of muscular paralysis with confidence that this can be reversed predictably at the end of surgery. During the whole intraoperative period the neuromuscular blockade should be closely monitored by peripheral nerve stimulator and at the end of surgery the ventilatory function should carefully be evaluated prior to extubation and this is to avoid any postoperative pulmonary complications. Theoretically, the anticholinesterase drugs which are usually taken by the patients during preoperative period may antagonize and decrease the sensitivity of nondepolarizing agents. But practically this does not happen. Conversely, the preoperative corticosteroid therapy may produce resistance to neuromuscular blocking effect of nondepolarizing agents.

Monitoring of the neuromuscular blockade at the wrist or elbow by a peripheral nerve stimulator may over or underestimate the degree of neuromuscular blockade caused by muscle relaxant in patients with myasthenia gravis. So, it is better to monitor the neuromuscular blocking effect of a muscle relaxant at the orbicularis oculi muscle which is most commonly affected in myasthenic patient to avoid any complication. Intraoperative anaesthesia is usually maintained by N_2O and volatile anaesthetic agents which decrease the dose of muscle relaxants or completely eliminate the need for their use. However, if it is absolutely necessary to use the non depolarizing agents, then their initial dose should be reduced to atleast half or two third of the usual dose and the response is observed by nerve stimulator. At the end of surgery it is wise not to extubate, until the patient shows an adequate functional ability for ventilation. It is very interesting in myasthenic patients that the strength of the skeletal muscles often seem adequate during the early postoperative period, but only deteriorate a few hours later.

Lambert-Eaton Myasthenic Syndrome (LEMS)

There are other many conditions like myasthenia gravis which also present with muscle weakness due to transmission defect at the motor end plate. The most common of these is the LEMS which is also a autoimmune disease producing antibodies against the presynaptic voltage gated Ca^{2+} channels and reducing the quantal release of ACh at the motor end plate. This is in contrast to myasthenia gravis which is not due to the defect in quantitative release of ACh, but is due the defect in ACh receptor where the released ACh acts. In a high percentage of cases this condition is usually associated with an underlying malignancy, mainly the small cell carcinoma of lungs where these small carcinoma cells express the identical voltage gated Ca^{2+} channels, serving as a trigger antigen for the autoimmune response. Otherwise, LEMS is also seen with other occult cases of malignancy or as an idiopathic autoimmune disease. As it is an autoimmune disease, so LEMS is also associated with dry mouth, male impotence and other manifestations of autoimmune dysfunction. The cardinal differences (the other differences are tabled) between LEMS and myasthenia gravis are that in the former there is absence of tendon reflexes and the muscle weakness improves with repeated contraction. So, this condition is diagnosed electrophysiologically by the presence of post tetanic potentiation of motor response after stimulation of nerve fibre at the rate of 20 to 30 per second and the investigations are directed towards the detecton of underlying malignancy.

The 3,4, diaminopyridine (DAP) and guanidine hydrochloride are two drugs which increase the release of ACh. So, they can be used in LEMS to improve the muscle power. But the use of guanidine for the treatment of LEMS is limited due

to its hepatotoxic effect. So, the DAP is only used for the treatment of LEMS in most of the countries. Like myasthenia gravis the most patients with LEMS also improve with immunosuppression and/or plasmapheresis by decreasing the level of antibodies against the Ca^{2+} channel. The anticholinesterase agents which are effective in the management of myasthenia gravis do not produce any improvement of muscle strength in myasthenic syndrome. Unlike myasthenia gravis the patients with myasthenic syndrome are sensitive to both the succinylcholine and nondepolarizing neuromuscular blocking agents. So, the potential presence of undiagnosed myasthenic syndrome and the subsequent reduction of the dose of muscle relaxant always should be kept in mind during anaesthetic management of patients with known malignancies or during anaesthetic management of patients for diagnosis of malignancy by bronchoscopy, mediastinoscopy, exploratory thoracotomy for suspected lung cancer. The response of other anaesthetic drugs such as opioids, benzodiazepines, IV inducing agents and volatile anaesthetic agents etc., and intraoperative monitoring in myasthenic syndrome during anaesthetic management of it is similar to that of myasthenia gravis. The postoperative management of myasthenic syndrome is also similar to that of myasthenia gravis.

MUSCULAR DISEASES

Other than the disorders at neuromuscular junction, the skeletal muscles itself is also subjected to a range of disorders with limited spectrum of symptoms and signs. These are initally classified as muscular dystrophies, myotonias, and dyskalemic familial periodic paralysis. Muscular dystrophies are a heterogenous group of hereditary diseases of skeletal muscles. It is characterised by painless degeneration and atrophy of voluntary muscles. So, there is symmetrical progressive weakness and wasting of skeletal muscles but with intact sensation and reflexes, indicating normal skeletal muscle innervation. The main pathology of muscular dystrophy is increased permeability of muscle cell fibres, leading to necrosis, degeneration and fibrosis. The muscular dystrophy is again of different types and according to decreased frequency these are: Duchenne's muscular dystrophy, Becker's muscular dystrophy, myotonic dystrophy, Limb-Girdle dystrophy, fascioscapulohumeral dystrophy, etc.

Muscular Dystrophy

Duchenne's muscular dystrophy

It is also known as the pseudohypertrophic muscular dystrophy and is the most common form among others. It is caused by the mutation of gene which is responsible for producing normal dystrophin. Actually, dystrophin is a protein in nature and is localised to the inner surface of the sarcolemma of muscle fibre. With a glycoprotein molecule it forms a dystrophin glycoprotein complex which confers stability to the sarcolemma. In the absence of this dystrophin protein the sarcolemma of muscle cells or fibres becomes weak and more permeable, leading to tear and a cascade of events causing the death of muscle fibres and necrosis. This chain of events occur repeatedly during the whole life of a patient suffering from Duchenne muscular dystrophy.

The incidence of this type of muscular dystrophy varies between 2 and 3 per 10,000 life births. It is an X-linked recessive disorder. So, the males are affected almost exclusively and the females are usually become carrier. It is present from birth, but becomes apparent between 3 and 6 years of life when they fall frequently on the ground due to muscle weakness while playing with their friends. Running, jumping, hopping, and climbing up the stair are invaribly abnormal. By the age of 6 years this muscle weakness in the patients will become obvious and is characterised by using hands to climb up himself when a child tries to get up from floor (Gower's maneuver) after fall. In younger children the muscles, particularly of the calves are usually enlarged and it is due to true compensatory mascular hypertrophy due to over use. But later the affected muscles become apparently larger as a result of fatty infiltration and this accounts for the designation of this disorder as pseudohypertrophic. The involvement of legs in this disease is more frequent and severe than the arm. After that there is a steady deterioration of the strength of many other skeletal muscles and fixed contractures of joints are developed. By the age of 12 years, most of the patients are confined to a wheel chair and it is due to weakness of large group of muscles and contracture of many joints. Progressively, scoliosis and kyphoscoliosis are also often developed which may be associated with pain. This is due to the unopposed action of antagonistic group of muscles against the affected weak dystrophic groups of muscles in body. Thus, gradually the severe chest deformity associated with scoliosis is developed which impair the pulmonary function that is already previously diminished by muscle weakness. The skeletal muscle atrophy can also predispose to long bone fractures. In this disorder the intellectual impairment is also common, but generally nonprogressive. In patients with muscular dystrophy the degeneration of respiratory muscles also interfers the mechanism of effective coughing and thus causes retention of secretion and frequent pulmonary infection.

Then gradually by the age of years 20, patients are predisposed to serious and sometimes fatal pulmonary infection leading to death. Other causes of death in this muscular disorder include aspiration of food and acute gastric dilatation. The degenerative changes of cardiac muscles is also common in patients with muscular dystrophy. This results in dilated or hypertrophic cardiomyopathy. Mitral

regurgitation may also accompany with muscular dystrophy in 25% cases and this is due to the dysfunction of papillary muscles in ventricle. The characteristic ECG changes associated with muscular dystrophy are : short PR interval, tall R wave in V_1 and deep Q wave in periodical leads. Cardiac failure is also an important cause of death in patients suffering from this type of muscular dystrophy which usually occurs between 15 to 25 years of age.

The level of serum creatine phosphokinase (CK) are invariably elevated and reach between 10 and 100 times of the normal value. This reflects the increased permeability and necrosis of muscle fibres. The female carriers often also have high plasma CK levels though there is no manifestation of this disease. In affected male child the increased level of CK is found at birth. But it declines later with the progress of disease and it is due to the loss of muscle mass. EMG of patients suffering from this type of muscular dystropy demonstrates the features of typical myopathy. The diagnosis of Duchenne's muscular dystrophy is only confirmed by muscle biopsy showing necrosis, degeneration fibrosis and subsequently some regeneration of muscle fibres. The connective tissues replace the lost muscle fibres. The definite diagnosis of Duchenne muscular dystrophy can only be established on the basis of determination of the amount and alteration in the size of dystrophin molecule (present on the sarcolemma of muscle cell) by western blot analysis of muscle specimen taken for biopsy, or analysis of DNA on peripheral blood leucocytes showing deletion and duplication of dystrophin gene. Actually there is no treatment in this disease, but prednisolone in the dose of 0.5 to 1 mg/kg/day has been shown to delay significantly the progress of this disease. However, this is only for 2 to 3 years.

Becker's muscular dystrophy

Like Duchenne's muscular dystrophy, Beoker's muscular dystrophy is also a X-linked recessive disorder with almost same manifestations, but in less severe and delayed form. So, it is often also called as the benign form of the pseudohypertrophic muscular dystrophy. It is less frequent than Duchenne's and the incidence rate is about 3 per 1,00,000 male life births. Till recently it is not known whether these two diseases such as Duchenne's and Becker's muscular dystrophy are the genetically two distinct disorders or not. Like Duchenne's it is also thought to be due to point mutation or deletion of dystrophin gene which is located on the X-chromosome leading to defect in the production of dystrophin protein of sarcolemma of muscle fibre. But the amount of mutation and deletion varies.

The onset of symptoms in Becker's dystrophy occurs usually around 10 years of age, although it may delay to 3rd or 4th decade of life and progress very slowly. The proximal muscles, especially of the lower limbs are first involved and as the disease progresses the weakness spreads to other muscles and becomes more generalized. By definition the patient suffering from Becker muscular dystrophy can ambulate beyond the age of 15 which is not possible in Duchenne's and this is the clinical distinction between the Duchenne's and Becker's muscular dystrophy. Mental retardation may be seen in Becker's dystrophy, but is not as common and severe as in Duchenne's. Cardiac involvement may also occur in this type of dystrophy, leading to heart failure. Though the life expectancy in Becker's muscular dystrophy is reduced than normal, still the most patients reach the 4th or 5th decade of life and some may survive up to their 70s. During diagnosis of Becker's dystrophy the findings from the serum CK measurement, EMG, and muscle biopsy closely resemble with those of Duchenne's dystrophy. But the definite disgnosis of Becker's dystrophy requires western blot analysis of muscle tissue taken by biopsy demostrating dystrophin gene of reduced amount and abnormal size.

Limb-girdle muscular dystrophy

It represents a heterogenous group of more than one muscular disorders which are further classified by the analysis of the molecular genetics. In this type of group of dystrophy each disorder is slowly progressive and benign. The muscular weakness in this type of dystrophy affects both the male and female group of patients with onset varying from 2nd to 5th decades of life. Mainly the muscles of shoulder girdle or hip girdle or both are involved in this disease. So, it is named like that. The distribution of weakness of muscles and the rate of progress of this disease vary from family to family. The respiratory insufficiency from the weakness of diaphragm may occur. In some patients the involvement of cardiac muscle may also result in congestive heart failure or arrhythmia. Intellectual function remains usually normal in this type of muscular disorder. The plasma CK levels are usually elevated. The EMG findings and muscle biopsy represent the characteristic changes in limb girdle dystrophy.

Myotonic dystrophy (or Dystrophia myotonica)

It is the most common form of adult (not childhood) muscular dystrophy and is a multisystem disorder involving many organs other than muscles. The incidence of this disorder varies between 10 and 15 per 1,00,000 live births and both the males and females are affected. It is an autosomal transmitted disease and caused by the expansion of a trinucleotide repeat on chromosome 19. The diagnosis of this myotonic dystrophy is now possible by measuring this repeat.

The myotonic dystrophy usually manifests between the 2nd and 3rd decades of life. During the early stage of this disease process myotonia (slowing of relaxation after contraction of muscle, for example slow relaxation of hand grip following forced voluntary closure) but not weakness is the main manifestation. But as the disease progress the weakness and atrophy

of the muscles become more evident. This weakness and atrophy of the muscles usually affect the cranial group of muscle such as fascial, temporalis, masseter, etc, and result in the typical appearance of face which is known as the 'hatched face'. As opposed to the other muscular dystrophies the distal muscles are more involved than proximal muscles in myotonic dystrophy. So, the weakness of wrist extensors, finger extensors and intrinsic hand muscle impair the function of hand. The weakness of ankle dorsiflexor may cause foot drop. The involvement of the muscles of tongue, palate and pharynx produce dysarrthria of speech, nasal voice and swallowing problems. Some patients have weakness of diaphragm and intercostal muscles, resulting in respiratory in sufficiency. Congenital myotonic dystrophy is rare, and represents a more severe form of this disease and occurs approximately in 25% of infants of affected mothers. It is characterisd by severe fascial and bulbar weakness and neonatal respiratory insufficiency.

Cardiac disturbances occur in most of the patients with myotonic dystrophy. The ECG abnormalities include different types of conduction defects or heart block. Mitral valve prolapse occurs commonly in myotonic dystrophy patients. As in myotonic dystrophy the multiple organ or systems are affected, so it is associated with premature frontal baldness, presenile cataract, multiple endocrine dysfunction (such as thyroid, adrenal, pancreatic and gonadal insufficiency) decreased oesophageal and colonic motility, etc. Uterine atony can prolong labour and will increase the chance of retained placenta.

The diagnosis of myotonic dystrophy can usually be made on the basis of clinical findings. The serum CK level may be normal or mildly elevated. The evidence of myotonia in this type of muscular dystrophy by EMG will readily be found in most cases. Usually the severity of myotonia in patients suffering from myotonic dystrophy is mild and rarely warrant any treatment. But if the treatment is required then it is undertaken by membrane stabilizing agents such as phenytoin, quinidine or procainamide. Among these the phenytoin is the preferred agent, whereas the quinidine and procainamide has the cardiac adverse effects precipitating or worsening conduction defect. The insertion of cardiac pacemaker may be considered in some patients suffering from myotonic dystrophy with unexplained syncope or major conduction abnormalities with evidence of second degree heart block or trifascicular block with marked prolongation of PR interval.

Facioscapulohumeral dystrophy

It is an autosomal dominant disorder due to deletion of DNA in chromosome 4 at locus q35. It affects both the males and females and the incidence varies between 1 and 3 per 1,00,000 live births. The patients usually present with muscular weakness in the 2nd and 3rd decade of life and as the name signifies the weakness is confined primarily to the muscles of face and shoulder girdle. So, there is inability to smile, whistle, fully close the eyes or elevate the arms. The scapular winging becomes apparent with attempts to abduction or forward movement of arm. The muscles of lower limbs are rarely affected and the respiratory muscles are usually spared. Cardiac involvement is also rare in this disease. The serum CK level may be normal or mildly elevated. The EMG usually indicates myopathic pattern. The muscle biopsy also shows the features of myopathy.

Anaesthetic Management

Duchenne's and Becker's muscular dystrophy

The patients with these two diseases of muscular dystrophy usually come for anaesthesia to do muscle biopsy for diagnosis or for correction of progressive orthopaedic deformities caused by these two diseases or for other surgical causes unrelated to these muscular dystrophies. Unlike myasthenia gravis the anaesthetic management of patient associated with these two types of muscular dystrophies is complicated not only for the presence of muscle weakness and paralysis, but also for the presence of associated cardiopulmonary complications due to the presence of these diseases. In these group of patients the hypomotility of GI tract may delay gastric emptying. So, this GI hypomotility further in the presence of weak laryngeal reflexes and respiratory muscular weakness increases the risk of pulmonary aspiration. So, some definite preoperative and intraoperative measures should be taken to avoid this complications. Any sedative or opioid as preoperative medication should also be avoided due to the same reasons.

Succinylcholine should also be avoided in these group of patients and this is because of the fear of rhabdomyolysis, hyperkalaemia, malignant hyperthermia and subsequent cardiac arrest. In some patients sudden ventricular fibrillation leading to cardiac arrest during induction of anaesthesia and intubation using succinylcholine has been proved later to have these type of muscular dystrophies. Patients with these two types of muscular dystrophies also usually exibit higher sensitivity to the nondepolarising muscle relaxant. Malignant hyperthermia has also been observed in these group of patients when succinylcholine and volatile anaesthetic agents are administered. So, RA is always preferred for these group of patients to avoid these unique risks of GA related to these muscular dystrophies. The intraoperative monitoring during anaesthesia of these patients is directed to the early detection of malignant hyperthermia, hyperkalaemia, and cardiac arrhythmia. In the postoperative periods the need for temporary mechanical ventilation for these patients due to the weakness of respiratory muscles should always be kept in mind.

Myotonic dystrophy

The anaesthetic management of patients suffering from myotonic dystrophy

becomes frequently complicated and it is due to the commonly presence of patient's pulmonary and cardiac abnormalities and altered response of these patients to a number of anaesthetic medicines. It is presumed that the asymptomatic patients with myotonic dystrophy also have some degree of cardiomyopathy which may alter the course of anaesthesia. The patients of myotonic dystrophy become very sensitive to sedatives and opioids. So, any small doses of it can cause sudden and prolonged apnoea. Hence, these should be avoided (if possible) as premedicant and should be used in small doses during induction of anaesthesia. Succinylcholine is not used in these patients, because prolonged skeletal muscle contraction, triggered by it, may occur. So, the trismus and contraction of laryngeal muscles can prevent the opening of mouth and may make the intubation difficult. The rigidity of chestwall also may make the ventilation difficult or impossible. Conversely, the response of these myotonic dystrophic patients to nondepolarizing agents is normal. But reversal of neuromuscular blockade by neostigmine can aggravate the myotonia. This is due to the falicitation of depolarization at neuromuscular junction by anticholinesterase. Hence, short acting nondepolarizing agent not requiring reversal such as cisatracurium, mivacurium, etc. are preferred.

There is also a theoretical concern that these patients are susceptible to malignant hyperthermia. Intraoperative maintenance of body temperature and postoperative avoidence of shivering is important for these group of patient, because cold may induce myotonia. Although intraoperative high concentration of volatile anaesthetic agents may abolish myotonic contraction, but it is associated with postoperative shivering and myotonic contraction in postoperative room. In such situations small dose of meperidin can often prevent such shivering and perhaps the myotonic contraction. So, due to these above mentioned complications GA should be avoided in known myotonic dystrophic patients, if not absolutely indicated. Therefore, preoperative diagnosis of myotonic dystrophy is very vital to an anaesthetist. But patients with this disease may be undiagnosed before or he may not divulge intentionally the information preoperatively. Sometimes the diagnosis of myotonic dystrophy comes to light when the patient suffers from prolonged apnoea or myotonia after GA.

Myotonia

It is defined as a type of muscular disorder where tonic spasm of a single muscle or a group of muscles occur and it is probably due to the repeated depolarization of muscle cells or fibres causing contraction, stiffness and impaired relaxation of it. In this disease the skeletal muscles are only involved, but the other organ or systems are not affected like myotonic dystrophy. There is no cardiac involvement in this disease like muscular dystrophy. This disease of myotonia does not progress. So, it does not result in decreased life expectancy. However, in contrary the myotonic dystrophy (described before) is associated with myotonia and other systemic manifestations and muscle weakness. In myotonia there is usually no weakness of muscle, rather the muscles are very well developed due to constant muscular contraction.

In myotonia the contraction of muscles is painless. But still it disables the patients by interferring the movement of extremities and ambulation. In myotonia the stiffness of muscle is often exaggerated by cold, but is characteristically reduced by repeated muscular exercise. The flaccid muscular paralysis in myotonia may be produced by warming the muscles. The EMG is normal at room temperature, but typical myotonic discharges start when the muscles are cooled.

Principally, there are two types of myotonia such as myotonia congenita and paramyotonia congenita. The myotonia congenita is caused by mutation of gene on chromosome 7 at locus q35, resulting defects in function of chloride channel. It has both autosomal dominant and recessive variant. On the otherhand, the paramyotonia congenita is due to the defect of gene on chromosome 17 and is very rare autosomal dominant disorder. The defect of Na^+ channel is associated with this disease and is characterised by paradoxical myotonia, i.e. the myotonia which worsens with repeated muscular activity. So, it is named as paramyotonia congenita. In myotonia the stiffness or contraction of muscles are alleviated by quinine, phenytoin, or mexiletine. Other medications that have been used in the treatment of myotonia include prednisolone, dantrolene, tocainide, etc.

The anaesthetic management of myotonia is complicated by the abnormal responses of patients to the muscle relaxants. The nondepolarizing muscle relaxant paradoxically causes the generalised contraction of muscles such as trismus, contraction of vocal cord, etc, leading to difficult intubation and ventilation. Intraoperative hypothermia may also lead to muscular contraction in myotonia patients. This disease does not cause malignant hyperthermia. Infiltration of muscles with local anaesthetic solutions (diluted) at operative field reduces the myotonic contraction.

Dyskalaemic Familial Periodic Paralysis

It is a spectrum of muscular disorders characterised by the intermittent acute attack of weakness or paralysis of skeletal muscles of limbs. Pecuiliarly it does not affect the respiratory muscles including the cranial and thoracic musculature like muscular dystrophy. The attack usually lasts for few hours and frequent attacks may lead to progressive long-term muscular weakness in some patients. This weakness or paralysis of muscles are due to the loss of excitability of muscle fibres. This is again due to the incomplete depolarization of the resting muscle potential because of either

decrease in K^+ conductance or increase in Na^+ conductance due to the defect in channels of some ions such as Ca^{2+}, Na^+ or K^+ etc. However, both are associated with, fluid and electrolyte disturbances.

This whole spectrum of diseases is classified into primary genetic or congenital and secondary or acquired form. The primary genetic form of this dyskalaemic familial periodic paralysis is inherited as an autosomal dominant traits, but have a number of mozaic variants, resulting indifferent manifestations in different families. The genetic or inherited form is due to the mutation of gene responsible for the voltage gated Ca^{2+}, Na^+ or K^+ ion channels. The inherited defect in voltage gated Ca^{2+} channels is typically associated with low serum K^+ level during periodic attack of weakness or paralysis. On the otherhand the inherited defect in Na^+ channels is typically associated with increased serum K^+ level during the attack of periodic weakness or paralysis. So, both these defects result in hypokalaemia, hyperkalaemia or normokalaemia associated with non excitable muscle membrane causing weakness or paralysis of muscle. This spectrum of diseases is classified according to the clinical manifestations, but not according to the defect of ion channels. This is because it is useful as a guide to the prognosis and therapy, and defect in same channel can cause different clinical pictures and defect in different channels has same clinical picture.

Hypokalaemic form of familial periodic paralysis (Ca^{2+} channelopathy)

This disease is due to the defect of voltage gated Ca^{2+} ion channel and the mechanism of this disease is unrelated to the defect of ion channel at the neuromuscular junction. It is the most common form of familial periodic paralysis and is sometimes associated with hyperthyroidism. It may present at any decade of life between the childhood to adulthood and as the time progresses the frequency of attack increases, although it may subside at later life. The episodes of attack of weakness or paralysis of muscle are most common in the morning, lasting for 3 to 4 hours, but it may last for whole day. This episode of muscular weakness or paralysis is precipitated by heavy exercise or high carbohydrate diet and is characterised by low serum K^+ level. On the contrary the mild exercise actually prevents it. There may be ECG changes consistent with low serum K^+ level. The onset of unexpected skeletal muscular weakness at the postoperative period may suspect familial periodic hypokalaemic paralysis which is with or without additive action from the trailing effects of nondepolarising muscle relaxants used during anaesthesia and surgery. The diagnosis of this disease is usually made from patient's history, family history, EMG and ECG changes, etc. The weakness of skeletal muscle provoked by the infusion of glucose and insulin confirms the diagnosis of this type of familial hypokalaemic periodic paralysis. Barium blocks the K^+ channel. So, consumption of large amount of barium for any diagnostic purposes may precipitate this hypokalaemic familial periodic paralysis. The secondary acquired form of hypokalaemic paralysis caused by the loss of K^+ through kidney and GI tract may also develop and should not be confused with primary genetic cause. An acute attack of this disease is treated with 5 to 10 gm of potassium through oral route, but without glucose. This is because uptake of glucose by cells may increase hypokalaemia and weakness. During the treatment of this familial paralysis of periodic hypokalaemic form, the administration of K^+ through IV route is not recommended, because it may lead to sudden unwanted hyperkalaemia.

Anaesthetic considerations of this hypokalaemic periodic paralysis include the avoidence of factors which trigger the hypokalaemic attacks. These are heavy excercise, cold, heavy carbohydrate diet, etc. So, carbohydrate diet should be avoided 24 hours before surgery in the patients suffering from this disease. The drugs known to cause hypokalaemia by shifting K^+ into the cell such as β-blocker, insulin, etc. should also be avoided. The IV glucose infusion should also be avoided. As succinylcholine increases the serum K^+ level, so it is suitable for this group of patients. In patients with periodic weakness or paralysis, the response of nondepolarizing muscle relaxant is unpredictable. Therefore, the short acting nondepolarizing agents are preferred and the neuromuscular function should be carefully monitored by nerve stimulator. In the intraoperative period if diuresis is needed due to any cause, then K^+ losing diuresis should be avoided for the fear of hypokalaemia. Hence, infusion of mannitol is a better alternative. The RA can safely be applied on these patients.

Hyperkalaemic form of familial periodic paralysis (Na^+ channelopathy)

It is due to the defect of voltage gated Na^+ ion channel and the muscular weakness or paralysis is triggered by the abnormal activation of Na^+ channel with prolonged depolarisation like depolarising muscle relaxant (succinylcholine) which causes prolonged depolarisation at the motor end plate. So, Na^+ with water flow into the cells and K^+ comes out causing hyponatraemia, hyperkalaemia and haemoconcentration. It is manifested during the early childhood of life usually at the morning and these attacks are shorter and more frequent than the hypokalaemic one. The muscular weakness and paralysis is worse during rest after heavy exercise, but mild exercise prevents it. During periodic attacks the serum K^+ level rises above 5 to 6 mEq/L. But remains normal inbetween the attacks. Hypothermia, hypoglycaemia, glucocorticoids, pregnancy, etc, aggravates this condition. The diagnosis of this disease is usually made from patient's history, family history, serum K^+ level during attack, EMG, etc. The skeletal muscle weakness in response to oral administration of K^+

confirms the presence of hyperkalaemic form of periodic paralysis.

The anaesthetic management of hyperkalaemic periodic paralysis includes the avoidance of factors which increase the hyperkalaemic attacks or to take the measures which will decrease the serum K^+ level. So, perioperative voluntary K^+ depletion by frusemide induced diuresis is very important and succinylcholine is contraindicated as it is associated with hyperkalaemia. The potassium containing solutions or the potassium releasing drugs should always be avoided in the perioperative period during anaesthetic management of such patients. Carbohydrate depletion during fasting should be managed by glucose containing IVsolutions. Frequent monitoring of serum concentration of K^+ is indicated during perioperative course of anaesthesia. Careful ECG monitoring is indicated to detect cardiac arrhythmias associated with hyperkalaemia. Hypothermia and shivering trigger the hyperkalaemia. So, the maintenance of body temperature during perioperative period is very important.

48 Malignant Hyperthermia

INTRODUCTION

The term malignant hyperthermia (MH) refers to a clinical syndrome which is characterised by rapidly increasing temperature (as great as 1°C/ 5min), ↑cellular metabolism, ↑O_2 consumption, ↑CO_2 production, metabolic and respiratory acidosis, ↑lactate production, muscular rigidity, ↑sympathetic activity and high mortality. This results from the acute uncontrolled increase in skeletal muscle metabolism that may proceed to severe rhabdomyolysis. It is also defined as a pharmacogenetic disease because the susceptile patients have a genetic predisposition for the development of this syndrome and is not manifested until they are exposed to some triggering pharmacological agents such as mainly the volatile anaesthetic agents and succinylcholine (SCh). There are also many other pharmacological agents which trigger this syndrome.It is also an example of subclinical myopathy that becomes unmasked after exposure to the triggering factors.

There is no doubt that this syndrome had been responsible for many anaesthetic deaths from the middle of the 19th century to the middle of the 20th century since the introduction of ether, chloroform and succinylcholine. But during that period nobody knew about this syndrome. Among these incidences the few remarkable examples are: between 1915 and 1925 one family experienced three anaesthetic deaths from MH featuring muscular rigidity and hyperpyrexia. In 1960 Denborough and Lovell described a 21-year-old Australian who was suffering from an open leg fracture and was more anxious about anaesthesia than surgery, because 10 of his relatives had died due to anaesthesia before. This had given a very good description of anaesthetic reaction leading to death and its inheritance as an autosomal dominant character. Later, this anaesthetic reaction was described as malignant hyperthermia (MH). However, actually the genetic inheritance of MH which has been confirmed recently is more complex than this simple straight forward autosomal dominant veriety. It may be autosomal recessive, multifactorial or unclassified.

In 1966, Wilson first used the term malignant hyperthermia in his book. In the past death related to anaesthesia was not uncommon and the causes of these deaths were multiple including MH. So, this relatively rare cause of death only due to MH during anaesthesia was not given any importance and was not recognised. But, after that as the anaesthesia has become progressively safer, so the high mortality due to MH have become more and more significant. During earlier period the mortality rate due to MH was 70 to 80%. But with earlier diagnosis, increased awareness among anaesthetist, and improvement in monitoring this mortality rate due to MH had dropped significantly to 25%. Then in 1979 with the advent of dandrolene this mortality rate due to MH has further dropped to 5%. When the volatile agents and SCh are considered as the principal cause, then the overall estimated incidence of MH in UK population is approximateley 1 in 8000.

Aetiology

Normally, during muscular contraction the wave of depolarisation moves from the end plate of muscle fibre to the sarcoplasmic reticulum (SR) within the cell through the T-tubules of sarcolemma. At the end of these T-tubules which come in contact with the SR possesses voltage gated Ca^{2+} channel of type I. These are labelled as dihydropyridine receptors (DHPR). Through these Ca^{2+} channels or DHPR small amount of Ca^{2+} ions first enter into the muscle cell from ECF in response to the T-tubular depolarisation. The end of the SR which come in contact with T-tubules also contain ryanodine receptors (RYR). These are also known as the Ca^{2+} efflux channel or foot plate protein and connect between the DHPR of T tubules and SR. With the wave of depolarisation and intracellular entry of small amount of Ca^{2+} from ECF through DHPR, these receptors of T-tubules (i.e. DHPR) make coupling with the RYR of SR and transfers the wave of depolarisation from T-tubules to SR, resulting in the release of huge amount of Ca^{2+} from SR. Thus, the free ionised intracellular Ca^{2+} level within the muscle cell fibre rises from 10^{-7} M to about $10^{-5} \times 5$ M due to depolarisation of SR. Then this increase in intracellular Ca^{2+} removes the inhibition of troponin from the contractile elements of muscle cell causing muscular contraction. After that when contraction of muscle is over then the multiple intracellular Ca^{2+} pumps situated on SR and mitochondria rapidly transfers the free intracellular Ca^{2+} back into the SR causing relaxation. This increased intracellular concentration

of Ca^{2+} also stimulates multiple intracellular function such as ↑ metabolism, ↑ heat production, ↑ enzyme secretion, ↑ hormone secretion, etc.

Now, there is general agreement that the MH is due to the defect or abnormal properties of these RYR (Ryanodine receptor) causing increased release of intracellular Ca^{2+} from SR leading to intense contracture of muscles and marked increase in intracellular metabolism. It is very well known that Ca^{2+} is an important ion controlling different functions of cell. So the loss of this haemostasis of Ca^{2+} causes many abnormal metabolism with in the cells which depend not only on the RYR but on the other organelle of cells such as T-tubules, DHPR, inositol phosphate, oxidation – reduction activity, etc. So, this explains why different chemical agents such as SCh, halothane, etc, trigger the same MH and there is strong evidence of heterogeneity of this syndrome (Fact file-I).

Genetics

Ryanodine receptor (RYR) is the largest known receptor in our body and is four to five times larger than the ACh receptor. In MH the properties of these RYR is altered due to the genetic mutation and these alterations include: increased rate of Ca^{2+} release from SR, changes in the patterns of binding of RYR with DHPR and the effects of Ca^{2+} on this binding and the increased sensitivity of RYR to caffiene which is also known to cause the increased release of Ca^{2+} from SR. It proves that the muscles of an individual susceptible to MH are more sensitive to caffiene.

Ryanodine is a toxic plant alkaloid. It was first extracted by Rogers and his co-workers from a plant named Ryania Speciosa Vahl. It acts on these RYR (from where these receptors get this name) and has profound poisonous effect producing rigidity of skeletal muscle. Later, it was purified and radiolabelled and extensively used in the research of MH. The research to establish the relationship between the RYR gene and MH gets its fuel with the subsequent identification of link between the mutation of RYR gene and MH. There are three forms of RYR (such as RYR_1, RYR_2, RYR_3) and for these three forms of RYR there are three types of genes. But among these only the mutation of RYR_1 gene have been linked to the MH. The gene of RYR responsible for MH is located on human chromosome 19, which is also the genetic coding site of the Ca^{2+} release channel of SR.

At the beginning of research on MH the identification of Hal genes in pig which is responsible for the similar MH syndrome in pig (but not identical and is known as the porcine stress syndrome) is the first step. Then subsequently the identification and localisation of RYR_1 genes on human chromosome 19 at q13-13·2 position and transportation of Hal gene at that place had stimulated intense research of this subject. Gradually, it was found that the gene responsible for MH is not only situated on chromosome 19, but is also situated on the chromosome 1 and 7 and also possibly 3, 5, 17. These many genes are also responsible for the various subunits of DHPR which forms the triadic junction complex with the RYR at the SR. Over the next past 20 years with the revolution in the technique of molecular biology, it has also been possible to study the susceptibility of a family to MH using DNA markers of known chromosomal location.

In swine a single genetic mutation of RYR gene is responsible for all the cases of MH. But in human a series of different mutations or even a lack of any mutation of this RYR gene indicates the heterogenous character of genetic basis of human MH.

Clinical Features

The onset of clinical features of this MH syndrome may be acute and rapid when volatile anaesthetic agents and / or SCh are used in full doses or may be delayed and show for several hours when the inhalational agents have been used in low concentration to prevent the only patients's awareness during anaesthesia and not become evident until the patient enters the recovery room. But once the reaction or pathology of MH is initiated, then the next course of it cannot be stopped by the discontinuation of triggering factors and will must progress to a full blown picture. However, the reaction of MH does never start after the discontinuation of triggering factors.

The affected person had undergone tremendous increase in muscle rigidity and cellular metabolism after the onset of MH due to exposure to volatile anaesthetic agents and/or SCh. This leads to intense production of heat (body temperature may exceed 108°F), increased production of CO_2 (P_aCO_2 may exceed 100 mm Hg) and increased plasma lactate level. This causes metabolic and respiratory acidosis and altered acid base balance. So, the plasma pH may be less than 7. The increase in temperature is the cardinal feature of MH, because muscle is the pathological site of this disease which constitute 40 to 45% of total body weight. Another important feature of MH is MMS (masseter muscle spasm) or whole body muscle rigidity. Associated with this muscular rigidity there is also increased permeability of muscle cell membrane causing increased level of serum K^+, CK and serum myoglobin, leading to hyperkalaemia and myoglobinuria.

FACT FILE - I

MH susceptible skeletal muscle differs from normal muscle in that it is always closer to the loss of control of Ca^{2+} concentration within the muscle fibre. It also involves a generalised alteration in cellular or subcellular membrane permeability. This is an excitation contraction (EC) coupling defect resulting from alteration in the ryanodine receptor (RYR) encoded by gene. It is a heterogenous disorder having 30 mutations in RYR-1 gene. Evaluation of affected families is guided by the measurements of circulating CK, *in vitro* drug induced contracture test and genetic testing of DNA samples.

Sometimes moderate to severe form of rhabdomyolysis may also occur during an acute episode of MH. But milder form of it occurs more often than realised and it would have to kept in an anaesthetist's mind. Due to the false indentification of myoglobin for haemoglobin, the myoglobinuria can be misdiagnosed as haemolysis when a massive shift of fluid occur during an episode of MH.

In exception to other muscles of body, the only masseter and lateral pterygoid muscles contain the slow tonic fibres. So, they sometimes response abnormally to SCh with contracture or spasm when other muscles become flaccid. This abnormal response of masseter muscle may or may not be a part of the MH syndrome. It may occur isolatedly. This spasm of jaw muscles cannot be altered by pretreatment with defasciculating dose of non-depolarising muscle relaxant. It can be graded as tight jaw, rigid jaw and very rigid jaw. When spasm of these jaw muscles is very severe which is designated as 'very rigid jaw' (impossible to open mouth) and especially prolonged then this condition is designated as a separate syndrome named masseter muscle spasm (MMS), and greatly increases the risk of MH (Fact file- II).

This MMS or severe form of masseter spasm caused by SCh is entirely considered as pathological and its causes may include MH, myotonia, or other pathological situations. In the absense of family history the first indication of susceptibility of an individual to MH is this exaggerated response of masseter muscle to a depolarising muscle relaxing agent. When this MMS is associated with rigidity of other body muscles, then the chance of MH is absolute. In such circumstances anaesthesia should be stopped immediately and the treatment for MH should be started.

When the MMS is appeared alone without other manifestations, then the chance of MH is 30%. But when it is associated with the rigidity and damage of other muscles which is evidenced by increased plasma level of CK and myoglobinuria, then this chance of MH associated with MMS is increased to 70 to 80%. The true response of jaw muscles to SCh in MH as opposed to the only exaggerated response of rigidity of jaw muscles to SCh is that the former is associated with metabolic stimulation and the consequences of the loss of sarcolemmal integrity leading to hyperkalaemia and myoglobinaemia. When the clinical signs of MH such as ↑ $ETCO_2$, tachycardia, ↑muscle rigidity, ↑ temperature suggest this syndrome, then the diagnosis of MH is not strong unless more than one abnormal sign is noted. When there is a single suggestive adverse sign, then the diagnosis is usually not MH. If the patient suffering from MH is carefully monitored during the perioperative petriod, then one or more abnormalities will always be detected. A postoperative pyrexia occurring after a normal intraoperative and immediate postoperative period is not always an indication of MH.

Other than MMS increased sympathetic activity due to increased cellular metabolism may frequently be the first sign of MH. This increased sympathetic activity causes tachycardia, sweating, hypertension, tachypnoea, hypoxia, etc. With metabolic exhaustion the cellular permeability may also increase in MH. It may cause generalized oedema including cerebral oedema. As MH progresses to DIC (due to cellular destruction), so cardiac failure and renal failure may also develop. Hyperkalaemia due to increased cellular permeability and acidosis may also cause cardiac arrhythmia, even asystole.

FACT FILE - II

Evaluation of affected families is guided by the measurement of circulating creatine phosphokinase and subsequently by the analysis of drug induced (caffeine, halothane) contracture in muscle biopsy specimen in laboratory. The measurement of plasma creatine phosphokinase (CK) also provides a basic screening test for MH, because it reflects the stability of muscle cell membrane which is distributed in MH. It is elevated to 70 to 80% in affected people. When the plasma CK value is elevated in a close relative of a susceptible person, then this relative is also considered as susceptible to MH, and requiring contracture testing. On the otherhand, the CK value remains normal in the susceptible patients on several occasions. In the same way isolated CK elevations in normal asymptomatic individual are seldom associated with positive contracture test. So, in such circumstances it has no predictable value and muscle biopsy is necessary for contracture study. The contracture study also becomes positive in patients who are suffering from myopathies and not related to MH in any way. Dantrolene should not be given to patient before muscle biopsy, because it may mask the contracture test.

Diagnosis

In the absence of specific drug such as dandrolene the treatment of MH is difficult. But the diagnosis of it during intraoperative period (however not in postoperative period) is more difficult than its treatment. This is becasue the MH is a disorder of cellular metabolism and so the early signs and symptoms of it are masked or subtle during the course of anaesthesia. The diagnosis of MH is also difficult, because the onset of it may sometimes be delayed until the patient is recovered from anaesthesia. During the course of anaesthesia the effects of different anaesthetic drugs on different systems of body may also complicate and confuse the signs of MH and make the diagnosis of it difficult. When the hyperthermia is taken as the important diagnostic point, then this syndrome of MH should also be differentiated from other disorders which have same manifestations such as hyperthermia and increased muscular nigidity and confuse the diagnosis of MH. These include: heat stroke, preoperative atropine, septicaemia, hyperthyroidism, pheochromocytoma, neuroleptic malignant syndrome, pontine haemorrhage, etc. However, the differentiating point is that these above mentioned disorders confusing the diagnosis of MH are not associated with the other clinical and laboratory evidence of MH.

The most important point for the intraoperative diagnosis of MH is the measurement of $ETCO_2$ tension at the constant rate of ventilation. This is because if

ventilation is increased with the increase of $ETCO_2$ tension, then the $ETCO_2$ tension will remain same and the diagnosis of MH will be masked and delayed. However, the other causes increasing the tension of $ETCO_2$ should also be ruled out such as stuck valve, exhausted soda lime, inadequate fresh gas flow, inappropriate breathing circuit, etc. In general MH is not expected in any patient when GA is administered with the help of barbiturates, propofol, N_2O, opiates, benzodiazepines and non-depolarising muscle relaxants. On the other hand, when GA is administered with the help of volatile anaesthetic agents and depolarising agent such as SCh, then the chance of occurrence of MH should always be kept in mind of an anaesthetist and will start to suspect it when the patient will develop undue tachycardia, tachypnoea, increased body temperature, cyanosis, arrhythmia, rigidity of muscle, sweating, molting of skin, etc. Then the diagnosis of MH should be confirmed by the subsequent evaluation of serum pH, hyperkalaemia, arterial blood gases, myoglobinuria, etc.

For the diagnosis of MH, the level of O_2 and CO_2 tension in arterial blood is less important than that of the central venous blood as it is the disease of increased cellular metabolism, and the $ETCO_2$ and central venous CO_2 level are the more accurate reflection of whole body CO_2 stores. In normal condition the level of CO_2 in venous blood is only 5 mm Hg higher than the arterial blood. But in MH this difference will exceed this normal value. The upper limit of the venous PCO_2 and PO_2 is suggested as 55 mm Hg and 35 mm of Hg respectively, provided the arterial PO_2 is higher than 100 mm Hg. If venous PCO_2 is > 60 mm Hg and base deficit is > −5 to −7 mEq/L, then the diagnosis of MH is confirmed. So, from this above discussion it is found that the most important monitoring devices for the early detection of MH are capnography, pulse oximeter, blood gas analysis and ECG. But the most appropriate prerequisite for early diagnosis of MH is an appropriate suspecious mind of an anaesthetist.

Triggering Factors and Diagnosis of Susceptibility

There are many factors which trigger the onset of MH in human being. But, among these the volatile anaesthetic agents and depolarising agent such as SCh are the prime triggering agents. Again, among the volatile anaesthetic agents the halothane is the most potent, while the desflurane and sevoflurane are the less potent triggering agent, causing gradual onset of MH. The onset of MH may be explosive, if SCh is concomitantly used with volatile anaesthetic agents and muscular rigidity is developed within 5 minutes. The response of susceptible patients to the triggering agents such as SCh may be different. It may be only muscular contracture or only increased permeability of muscle cells causing hyperkalaemia and myoglobinuria or increased cellular metabolism in association with the muscular contracture and increased permeability. It is most unlikely that N_2O acts as a triggering factor, because previously it has been used safely and repeatedly in a susceptible individual patient without any evidence of MH. The non-depolarising muscle relaxant is not a triggering agent for MH. Rather they block or at least attentuate the effects of SCh and volatile anaesthetic agents cause MH. Propofol is not a triggering factor for MH. On the other hand, it stabilises the cell membrane of MH affected muscle cells and has opposite effects to those of volatile anaesthetic agents. Like propofol, the other intravenous anaesthetic agents such as thiopentone, benzodiazepines, opioids, ketamine also have no triggering effect causing MH. Previously, it was believed that the amide group of local anaesthetic agents such as lignocaine and others also may trigger MH. But later it was proved that they are safe for patients who are susceptible to MH (Table 48.1).

The predictability of the onset of MH in susceptible persons are not always correct. Because many affected persons have previously experienced the exposure to the triggering factors without the onset of MH. So, from this history, we can not say that this patient is not susceptible to MH during the present course of anaesthesia. On the other hand, many patients suffer from MH during anaesthesia without any exposure to known triggeirng factors. So, from this history, we also always cannot product which patient will develop MH even if triggering agents are not used. All these events dictate that the exact mechanism of triggering of MH by factors during anaesthesia is still unresolved. Recently, two *in vitro* tests were described to diagnose the preanaesthetic susceptibility of an individual to MH. These are the open muscle biopsy and the exposure of some strips of living muscles to halothane and caffeine, producing abnormal contracture response to these two agents. This later test is also known as the *in vitro*

Table 48.1: Classification of drugs according to their potentiality for triggering MH

Unsafe	*Safe*	*Probably safe*
All volatile anaesthetic agents	Benzodiazepines	Tricyclic antidepressants
Succinylcholine	Propofol	Monoamine oxidase inhibitors
Decamethonium	Ketamine, opiates	Phenothiazines
	Barbiturates	Haloperidol
	Metoclopramide	
	Atrope, glycopyrrolate	
	Non-depolarising muscle relaxants	
	All local anaesthetics	
	Epinephrine, norepinephrine	
	Nitrous oxide	
	Neostigmine	

contracture test (IVCT) and offers 93% specificity and 99% sensitivity. This IVCT test is not offered to children who are below 10 years of age as screening for susceptibility to MH. Because in children this test may yield more false negative result. After a patient is diagnosed as susceptible to MH syndrome by IVCT, then a DNA testing for mutations from muscle biopsy should follow. If one is detected as positive, then the other relatives of this person with that mutation are considered to have susceptibility to MH syndrome and do not need IVCT. The result of the use of DNA screening test from biopsied muscle for the diagnosis of susceptibility to MH is not always straight forward. This is due to the marked heterogeneity and the lack of orderly mutations in many families. However, all these tests to diagnose the susceptibility to MH is invasive and destructive. So, recently the noninvasive nuclear magnetic resonance test probably has the greatest promise to diagnose the susceptibility. There are also many diseases which make the individual more susceptible to MH. Among these the myopathies are most important. For example, Duchenne muscular dystrophy may result in an episode of MH after exposure to any triggering factors despite normal contracture testing. Patients with occult myopathies of any type may also have the potentiality to develop rapidly this disastrous anaesthetic event. Other muscular disorders that have inconsistent association with MH include myotonia, neuroleptic malignant syndrome (NMS), sudden infant death syndrome (SIDS), etc (Fact file- III).

All the patients who are suspected to develop MH are referred to higher medical centres which are recognized to tackle this type of patients for anaesthesia and surgery. Because due to any reason the surgery should not be denied to these group of patients only for the fear of uncapability to manage a case of MH if it develops. The key to safe anaesthesia for this type of patient is to avoid the use of triggering factors, mainly SCh and volatile anaesthetic agents. So, the regional anaesthesia is the best option to these individuals who are susceptible to MH as local anaesthetic agents do not trigger it. If GA is required, then it is best provided by barbiturates, propofol, benzodiasepine, N_2O, opiates and non-depolarising muscle relaxant only. Hence, the routine use of TIVA to deliver GA in these patients who are susceptible to MH is more straight forward. However, when a patient who is susceptible to MH is presented with difficult airway, then they are truly exposed to greater risk. This is because in such circumstances either an rapid sequence intubation by SCh or inhalation technique for tubation by volatile anaesthetic agents (due to the fear of failed intubation and failed ventilation if mondepolarizing muscle relaxants is used) cannot be used.

FACT FILE - III

The muscular rigidity which occurs during the onset of MH and is known as contracture is not the normal contraction of it which is the usual form of muscle movement. The process of muscular contraction is reversible, brief and is due to a propagated wave of depolarisation. On the otherhand, the process of contracture is irreversible, nonpropagated and prolonged. In laboratory the degree of contracture of cut muscle fibres in tissue both are used to study the various aspects of MH under the strict guidance of European or North American protocol with different concentration of caffeine and halothane which vary between this protocol.

Theoretically to deliver general anaesthesia on a MH susceptible patient, a dedicated vapour free anaesthetic machine is ideal. But if this is not available, then both the machine and the ventilator is made ready to use for these susceptible patients by removing all the vapourisers from machine and flusing the ventilator with maximum flow of O_2 for at least 30 minutes. As volatile anaesthetic agents are absorbed by the rubber or plastic, so new breathing circuit and face mask should be used mandetarily. If all these preventive measures are taken meticulously and all the well known triggering factors are avoided, then the prophylactic use of dandrolene to avoid the onset of MH is not recommended or required.

Treatment

The keypoint of the treatment of MH after its development is the immediate discontinuation of all the triggering factors as soon as it is diagnosed or suspected. This can be accomplished by quick turning off the vaporiser, and by quick and total eliminating of all volatile anaesthetic agents from the body of patient by hyperventilation and by changing the anaesthetic circuit. If the episode of MH is diagnosed as a fulminate one (venous PCO_2 above 90 mm Hg, base defect less than 5 mEq/L and the rate of increase of temperature 1°C/15 min) then an aggressive therapy should be started immediately to save the life of patient.

Dantrolene is the specific drug for the treatment of MH. It rapidly halts the increase in cellular metabolism and return back the level of catecholamine and K^+ to normal. The dantrolene acts by inhibiting the release of Ca^{2+} from SR, but does not affect the uptake of it by SR and mitochondria. The site of action of dantrolene is at the level of DHPR and interrupt the transmission of impulses from DHPR to RYR. Thus, it decreases the resting level of intracellular Ca^{2+}. In the past it was used in neuromuscular disorders with better results which are due to the increased intracellular Ca^{2+} level from any cause. Then this gives the idea of using dantrolene in MH. It is used in the dose of 2 mg/kg through intravenous route and in fulminate case this dose may be repeated after every 5 minutes up to the maximum dose of 10 mg/kg.

Dantrolene is available now as orange coloured powder in vial. Each vial of it contains 20 mg dantrolene sodium, 3 gm mannitol and NaOH. It is reconstituted prior to the use by mixing it with 60 ml of water. The pH of this preparation is 9 to 10 and this is due to the presence of NaOH.

The high pH of this reconstituted solution (or high alkalinity) helps the dantrolene to dissolve in water. The mannitol is added in this preparation to make the solution isotonic. It is not dissolved by 5% Dextrose solution, because it may lead to salting out effect with greater difficulty in dissolving. If it does not dissolve immediately into water producing a clear yellow to yellow orange colour solution, then it should be heated under tap water or autoclaved for few minutes. During extreme emergency it can be administered through the filter of blood transfusion set without worrying about the crystals of dantrolene. In some fulminant cases of MH the cardiac output falls rapidly. So, it should be given while adequate cardiac output and muscle perfusion is still present. The half-life of dantrolene is 10 to 15 hours. So, it can be repeated after every 10 to 15 hours for several doses. If there is no recurrence of MH, it can be then discontinued.

Though the administration of dantrolene is the key to therapy of MH, but, still the use of other symptomatic therapy to control the body temperature, acid-base balance and renal perfusion etc. which are developed with the onset of MH is also very important. But during this symptomatic therapy of MH an anaesthetist should always keep a notion in his mind that this supportive therapy will not be able to stop the uncontrolled increased metabolism mayhem within the muscle cells or the actual pathology of MH. So, he or she will not be much preoccupied or busy with such supporting symptomatic works neglecting the prime factor in therapy. Hence, active cooling is not a prominant feature. Usually, hyperthermia is tried to control by applying ice sponging all over the whole body and putting ice pack over the axilla and groin, IV infusion of refrigerated crystalloid solution, peritoneal lavage with sterile iced fluids and in extreme cases blood heat exchanger with pump oxygenerator, where this facility is available. The cooling of body only prevents the potentially harmful effect of hyperthermia on other cellular function but it does not stop the pathology of hyperthermia. During cooling it will also have to keep in mind that cooling causes peripheral vasoconstriction which prevents further heat loss and may produce sudden inadvertent hypothermia. So, the cooling should be halted when the body temperature comes down to 38° to 39°C. In such circumstances adequate intravascular fluid load is only the answer. IV methylprednisolone in the dose of 10 mg/kg is also effective vasodilator and has been shown to reduce the muscular contracture (Fact file- IV).

After the discontinuation of volatile anaesthetic agent (if only it is used and the patient develops MH) the patient should be hyperventilated with 100% O_2. This will help to increase the elimination of volatile anaesthetic agents from the patient's body, and compensate the metabolic acidosis. With increased aerobic metabolism within the cell during episode of MH, the CO_2 production will also be increased. This is because of the neutralisation of fixed or noncarbonic acid produced during intracellular metabolism by plasma bicarbonate. Thus, hyperventilation is needed to remove this additional CO_2. Due to hypermetabolism excessive lactate is also formed by skeletal muscle which may result in recurrent metabolic acidosis. This is further corrected by titrating with sodium bicarbonate at the dose of 2 to 4 mEq/kg.

The serum K^+ level should be measured frequently since the onset of MH. If there is alarming hyperkalaemia, then it should be treated immediately but slowly. The best way of treating mild to moderate hyperkalaemia is reversal of MH by proper doses of dantrolene. Otherwise, it is corrected by infusion of dextrose with insulin or ion exchange or haemodialysis (only in refractory case). To correct hyperkalaemia IV calcium can be used, but only when there is impending life threatening arrhythmia. This is because the influx of extracellular Ca^{2+} may further trigger MH response.

MH is associated with myoglobinaemia. This may block the renal tubules leading to renal failure. So, it is essential to maintain the normal urine output at any cost. Hence, all the patients suffering from MH should be catheterised and diuresis is ensured by mannitol or furosemide. Dopamine is also used to increase the renal blood flow which subsequently will increase the urine output in acute phase of illness to prevent renal failure. Myoglobinuria can usually be detected by coca colour urine in first voided specimen. But the increased level of CK due to muscle damage which is diagnostic of myoglobinaemia and subsequently MH takes 24 hours to develop. However, it is obvious that significant amount of myoglobinaemia should have to develop before myoglobinuria has to be detected.

Ultimately DIC develops in a severe fulminating case of MH. It is due to the

FACT FILE- IV

The anaesthetist will response according to the degree of tightness of jaw due to masseter spasm and its duration during induction and intubation after administration of SCh and / or volatile anaesthetic agents. If the mouth is impossible to open and the jaw is very tight, then the anaesthetic procedure should be halted immediately and the patient should be monitored closely for impending MH. The therapy including the use of dantrolene should be started immediately if there is any suggestion of the onset of MH. On the otherhand, if the jaw is moderately tight and the anaesthetist has any suspician of the onset of MH in his mind, then there is two options. First, if the facilities for subsequent monitoring and management of MH (if it occurs) are available, then the anaesthetist can procede the anaesthetic procedure slowly and cautiously with nontriggering agents still the onset of MH is confirmed. Second, the anaesthetist can halt the procedure if he thinks that this medical centre is not well equipped to tackle such cases. Patients who are suffering from fever may have exaggerated reaction to SCh and increased tightness of jaw. So, the patients who develop trismus under the influence of SCh and volatile anaesthetic agents should be screened for susceptibility to MH.

tissue damage, release of thrombopalastin and haemolysis. It is treated according to the standard lines of treatment.

Management of Susceptible Patients

Before anaesthesia and surgery an anaesthetist will must discuss the special anaesthetic problems with the patient who is susceptible to and to his or her relatives. This will make the patient very anxious. So, with this discussion of problems an anaesthetist will also assure the patient and his or her party with the confidence that maximum care will be taken to avoid these problems and if problems occur then the appropriate management of international standard with best drugs, knowledge and skill will also be taken. Hence, the patient will enter the OT in relaxed mind with full confidence that he or she will not die.

If a particular surgery can be performed under RA, then it should be performed under this technique as RA is very safe for the MH susceptible patients. However, if GA is required, then it should be delivered by benzodiazepines, propofol, barbiturates, ketamine, N_2O, opioids, non depolarising muscle relaxant, neostigmine, atropine and glucopyrrolate. However, by any cost volatile anaesthetic agents and depolarising muscle relaxant should be avoided in any concentration, even in the presence of dantrolene. Some susceptible patients develop hypermetabolic state despite all these precautions. Then these patients should be treated by dantrolene and usually they respond. So, the present consensus is that the preoperative use of dantrolene as a prophylactic measure to MH is superfluous in susceptible patients and the avoidance of triggering factors and the only use of non triggering agents are sufficient for the anaesthetic management of MH susceptible patients. But if any anaesthetist wants to use preoperative dantrolene, then it should be given in the dose of 2 mg/kg IV just before induction of anaesthesia. In obstetric susceptible patients this prophylactic dose of dantrolene is given after the cord is clamped. This is becasue if dantrolene is administered before the cord is clamped then the cord blood level of dantrolene may approach to 60 to 70% of the patient's plasma level which may result in floppy child.

49 Neurosurgery and Anaesthesia

INTRODUCTION

Usually the neurosurgical operations are relatively high-risk procedures. The patients who are undergone neurosurgical procedures present many problems to an anaesthesiologist. This is because the soft brain tissue is positioned in a bony skull which acts as a rigid closed box and its functions depend mainly on the ICP which subsequently depends on the cerebral circulation and dynamics of CSF within this closed bony cavity. The diseases for which the patients are presented for neurosurgeries itself interfere this cerebral circulation and dynamics of CSF with flactuation of ICP that predisposes to cerebral ischaemia and, therefore, cerebral damage. For example, an intracranial space occupying lesion causes increased ICP and as the lesion grows the danger increases. The other examples are the patients who are presented for neurosurgeries for subarachnoid haemorrhage may suffer from cerebral vascular spasm and subsequently cerebral ischaemia and infarction. The patients with pituitary diseases who are presented for neurosugery usually suffer from endocrine disorders that increases the risk of anaesthesia during surgery. Anaesthetic drugs also have powerful effects on ICP as they also have immense effects on cerebral circulation and dynamics of CSF.

So, during anaesthesia of neurosurgical procedures an anaesthesiologist needs profound knowledge regarding the physiology of CNS including the cerebral metabolism, cerebral blood flow, dynamics of CSF, intracranial volume, intracranial pressure and the effects of anaesthetic agents on this physiology of CNS, etc. Hence, the goal of this chapter is to provide adequate information to an anaesthesiologist for rational approach during anaesthetic management of intracranial, spinal or any other neurosurgical procedures.

CEREBRAL PHYSIOLOGY

Cerebral Metabolism

The brain has tremendously high rate of energy utilisation, reflecting the high metabolic rate. But, it has very limited energy storage capacity. It is found that 60% of the total cerebral energy utilisation is needed to maintain the electrophysiological function of brain such as depolarisation – repolarisation activity of neuronal cells which is shown in EEG and synthesis, transport and reuptake of neurotransmitter. Another 40% of total cerebral energy utilisation is used to maintain the cellular homeostatic activities of brain tissues including the integrity of cell membrane (i.e. basic functions of cell). The adult human brain weighs about 1350 gm which represents approximately 2% of total body weight. At rest for production of energy the human brain consumes O_2 at an average rate of 3.5 ml/100 gm of brain tissue/min. Therefore, the whole human brain consumes O_2 at the rate of 47 ml/min ($13.5 \times 3.5 = 47$). This represents 20% of the total body O_2 consumption in a minute. The cerebral metabolic O_2 consumption rate ($CMRO_2$) is maximum at the gray matter of cerebral cortex and is parallel with the electrical activity of it.

The neuronal brain cells mainly utilise glucose aerobically as their substrate to produce energy in the form of ATP. Normally, the rate of utilisation of glucose by brain is 5/100 mg of tissue/min. But, during starvation ketone bodies such as β-hydroxybutyric acetate and acetoacetate and acetone also become the substrate for energy production. In the absence of supply of O_2 lactic acid is formed as a result of anaerobic glycolysis with the little production of energy. Therefore, for proper function of brain and for this the continuous supply of huge amount of energy in the form of adequate ATP, two things are needed – glucose and O_2 through circulation of blood. Hence, the failure of adequate supply of any one, i.e. glucose (hypoglycaemia) and O_2 (hypoxia) cause devastating damage to the brain. The interruption of supply of O_2 through circulation for 10 sec in brain tissues results in unconsciousness. If this supply of O_2 cannot be reestablished within 3 to 5 minutes, then irreversible brain damage occurs, as the energy store in neuronal tissue in the form of ATP is very limited. On the contrary, hyperglycaemia (explained later) and hyperboric O_2 (by vasoconstriction) cause global or focal hypoxic brain injury by producing cerebral acidosis and cellular injury.

Cerebral Blood Flow (CBF)

Previously, it is described that energy expenditure by brain tissue is parallel to the cerebral metabolic rate (CMR).

This CMR is also parallel (or directly proportional) to CBF. The normal approximate value of CBF in an healthy adult human is 50 ml/100 gm of tissue/min. Among these as the gray matter is metabolically more active, so here the CBF is estimated to about 30 ml/100 gm of tissue/min. But as the white matter of brain is metabolically less active, so the CBF in this region is estimated to only 20 ml/100 gm of tissue/min. This total CBF including gray matter and white matter is estimated to about 675 ml/min (13.5 × 50 = 675) which is 12 to 15% of total cardiac output. The CBF has a critical value below which level the function of brain deteriates. For example, when the CBF has fallen to approximately 20 ml/100 gm of tissue/min then the evidence of ischaemia of brain in EEG begins to appear. At CBF level of approximately 15 ml/100 gm of tissue/min the cortical EEG becomes isoelectric. However, when the CBF is reduced below 10 ml/100 gm of tissue/min then the irreversible damage of brain occurs.

Regulation of CBF

There are elaborate mechanisms for the regulation of CBF. These include chemical, myogenic (auto), neurogenic and some other extrinsic mechanisms.

Chemical mechanism

The chemical mechanism for the regulation of CBF include the changes in CMR, P_aCO_2, and P_aO_2. It is already stated that increased neuronal activity results in increased cerebral metabolism and this increase in CMR is associated with well matched proportional increase in CBF. For this a variety of metabolic byproducts have been considered to act as intermediaries to increase the cerebral blood flow. These include: H^+ conc, extracellular K^+ and/or Ca^{2+} conc, thromboxane, certain prostaglandins, adenosine, etc. (Fig. 49.1)

CBF also varies directly with the changes in P_aCO_2. But this effect is greatest within the normal range of physiological

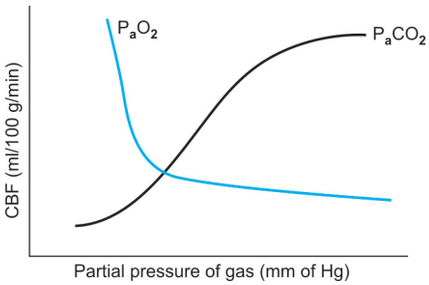

Fig. 49.1: Relationship of CBF with arterial O_2 tension (green line) and arterial CO_2 tension (red line)

changes in P_aCO_2, i.e. between 30 to 70 mm of Hg. Within this range of change in P_aCO_2 the CBF changes by 1 to 2 ml/100 gm of tissue/min for each 1 mm of Hg change in P_aCO_2. This response is attenuated when the P_aCO_2 falls below 25 mm of Hg. This change in CBF caused by P_aCO_2 is due to the changes in pH of ECF (or CSF) of brain, but not due to the changes in H^+ conc which increases in metabolic acidosis. This is because H^+ can not readily cross the blood brain bariers. So this change in P_aCO_2 cause the free CO_2 to diffuse freely across the cerebrovascular endothelium. Thus, acute metabolic acidosis which has where is mainly concerned with the increase in H^+ conc little effect than respiratory acidosis (where CO_2 level mainly increases) on CBF. After 6 to 8 hours the CBF returns to normal in spite of the elevation of P_aCO_2. This is because the pH of ECF of brain gradually normalises due to the adjustment of HCO_3^-. Similarly the reduction in P_aCO_2 reduces the CBF. But several investigations indicate that in normal subjects ischaemia will not occur at P_aCO_2 above 20 mm of Hg. However, physiological alterations of brain function as evidenced by EEG and metabolic abnormalities is observed when P_aCO_2 is reduced below 15 mm of Hg by hyperventilation. So there is little benefit in terms of improvement of ICP, rather it causes harm if P_aCO_2 is reduced lesser than 20 to 25 mm of Hg.

Like P_aCO_2, the P_aO_2 has not much effect on CBF. The changes in P_aO_2 between 60 to 300 mm of Hg have little influence on it. But when P_aO_2 falls below 60 mm of Hg, then CBF increases rapidly. However, this mechanism of vasodilatation caused by hypoxia is not exactly known. But the probable mechanism of this vasodilatation is neurogenic influence which is initiated by peripheral chemoreceptor and direct hypoxic effects on vascular smooth muscles, mediated by lactic acidosis.

Myogenic (auto) regulation or mechanism

Over a wide range of change in mean arterial pressure (MAP) the CBF is maintained automatically by changing the resistance of cerebral vessels (constriction or dilatation) intrinsically. This is called as the myogenic regulation or autoregulation of CBF. In normal human beings the range of MAP through which the CBF is maintained by autoregulation at constant level is 60 to 160 mm of Hg. Above and below this level of MAP the CBF is not autoregulated and becomes pressure dependent and changes (reduce or increase) accordingly in linear fashion. The difference between the MAP and ICP is known as the cerebral perfusion pressure (CPP), which determines the rate of diffusion of substrates into the brain tissue from vessels. When the MAP goes above 160 mm of Hg and autoregulation fails, then ICP rises and CPP falls. The increased MAP beyond autoregulation can disrupt the blood brain barrier. This may result in intracranial haemorrhage and cerebral oedema. The exact mechanism of this autoregulation of CBF is not known. But still it is postulated that the intrinsic characteristic of the smooth muscle of cerebral blood vessles is responsible for this auto regulation of CBF. Another theory is also put forward for this autoregulation of CBF. This is known as the metabolic mechanism. This theory explains that cerebral metabolic demand determines the cerebral arteriolar tone and CBF. Thus, when the brain tissue demands more metabolic

need, then the cerebral vessels dilate and CBF increases and *vice versa*. So, it is also known as the myogenic regulation. This autoregulation or myogenic reflex of CBF is influenced by various pathological processes such as: Intracranial tumours, head injury, many disease processes of cerebral vessels, subarachnoid haemorrhage, volatile anaesthetic agents, vasodilators, etc. This myogenic or autoregulation of CBF is not a fixed one. If a person suffers from chronic essential hypertension for long time, then this autoregulation curve with its upper and lower end shifts to the right. It means the CBF is maintained at higher level of upper and lower range of MAP (Fig. 49.2).

Neurogenic mechanism or regulation

There is strong evidence for extensive innervation of cerebral vessels. These are sympathetic (vasoconstrictive), parasympathetic (vasodilatory), serotonergic, vasoactive intestinal peptidergic (VIP), etc. But the density of innervation decreases with the decrease of vessel's size. So, the neurogenic regulation exists only on the large cerebral vessels. The exact functional significance of this neurogenic regulation of CBF is not known. But, still it may play an important role in some pathological states. For example, in haemorrhagic shock increased sympathetic activity causes lowering of CBF by vasoconstriction at a given MAP than which is found when hypotension is produced by sympatholytic agents. This is probably because during shock the vasoconstrictive effect caused by sympathetic over activity shifts the lower end of autoregulation curve of CBF to the right. The sympathetic and parasympathetic innervation may also play an vital role in regulating CBF during stroke and brain injury.

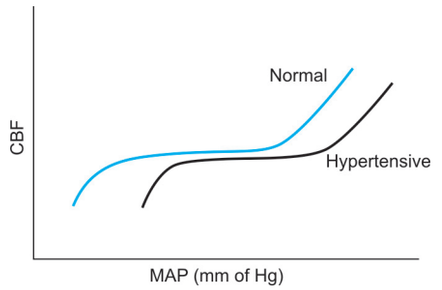

Fig. 49.2: Autoregulation curve of CBF in normal (green) and hypertensive (red) subject. In hypertension, it is shifted to the right

Some extrinsic mechanisms or factors

Temperature

The CMR and subsequently the CBF immensely depend on the temperature of brain tissue. It is found that the CMR and CBF decreases by 5 to 6% for every 1°C reduction of temperature (hypothermia) of brain. So, the CMR and CBF falls to 50% of its original value for reduction of temperature of brain from normal 37°C to 27°C. Then, with further reduction of temperature of brain to 20°C, the EEG which signifies the electrophysiological activity of brain becomes isoelectric with further reduction of CMR and CBF. With further reduction of temperature of brain from 20°C to downwards the CMR will also further decrease with CBF. This is because hypothermia causes decrease in CMR which is associated with both the electrophysiological function and maintenance of basic cellular integrity. The reduction of temperature upto 20°C is responsible for reduction of CMR which is associated with cerebral electrical activity and reduction of temperature below 20°C is responsible for reduction of CMR which is associated with basic cellular activities. In contrast, the anaesthetic agents with deepening of anaesthesia by increasing the dose of it reduce the CMR which is only associated with the electrophysiological function of brain and is evidenced by only EEG. So after the EEG becomes isoelectric with further increase of the dose of anaesthetic agents the CMR and subsequently the CBF will not reduce further. With the reduction of temperature from 27°C to 17°C there is further 50% reduction in CMR and CBF. Therefore, it probably accounts for the brain's tolerance to total circulatory arrest for moderate periods at this level of hypothermia. Hyperthermia has opposite effect to hypothermia or cerebral physiology. Between 37°C to 42°C both the CMR and CBF increase. But above 42°C the CMR again begins to fall. This indicates that 42°C is the threshold level for the toxic effect of hyperthermia and this is due to the neuronal cell damage, resulting from protein (enzymes of cell) degradation due to heat.

Viscosity

One of the single most important determining factor for viscosity of blood is the haematocrit value of it. So, the effect of viscosity of blood on CBF is estimated from the angle of haematocrit level. The viscosity of blood or haematocrit level of it has some influence on CBF. But this is not found within the normal range of haematocrit value (33 to 45%) in a healthy adult individual. But beyond this range the changes in CBF dur to changes in haematocrit value are more substantial. A decrease in haematocrit value (anaemia) improves the CBF. This is due to the decrease in viscosity of blood. On the otherhand, simultaneously it reduces the O_2 carrying capacity of blood to brain. But, practically this occurs after getting the maximum benefit from increased blood flow to brain due to decreased level of haematocrit and viscosity. Thus, anaemia can potentially impair O_2 delivery in brain, but below a certain level of haematocrit value where maximum beneficial effect of increase in CBF has already taken.

The reduction of haematocrit (anaemia) or viscosity increases the CBF by reducing the vascular resistance (i.e. by vasodilatation) in response to low O_2 carrying capacity in blood. This effect of reduction of viscosity on CBF is more important in the case of focal cerebral ischaemia, where local vasodilatation in response to low O_2 delivery is maximum. In this setting reduction of viscosity produced by haemodilution

results in increased CBF in the ischaemic territory. It is also evidenced from different studies that the optimum delivery of P_2 to brain in anaemia can occur at haematocrit value of 30%. Increased haematocrit and viscosity in polycythaemia has opposite effect and reduce CBF.

Vasoactive drug

Many vasoactive drugs such as systemic vasodilators, sympathetic agonists and antagonist, etc; which are used rampantly in anaesthetic practice have some definite effects on CBF. The systemic vasodilators which are used for induced hypotension during anaesthesia practice such as Na-nitroprusside, nitroglycerine, calcium channel blockers, etc, cause cerebral vasodilatation and increase CBF or maintain it at prehypotensive level up to a certain level of MAP which is lower than when it is caused by haemorrhagic shock or any other shock. If hypotension is induced slowly by these agents, then ICP does not rise due to increased CBF. This is probably explained by the shifting of CSF and venous blood (as compensatory mechanism) when changes in increase of CBF occur very slowly. Otherwise, vasodilator drugs will cause increased CBF and increased ICP.

The sympathetic α_1 agonists do not increase CBF, though cause acute increase in MAP. This is probably due to the presence of autoregulation and intact blood brain barrier (BBB). In defective BBB or in the absence of autoregulation these α_1 agonists may increase CBF and ICP tremendously. In case of β agonists it is found that in low doses they have little direct effect on CBF. But in higher doses they definitely increase CMR, coupling with increased CBF. The β blockers probably have no effect on CBF or reduce it with the reduction of CMR. However, the level of circulating plasma catecholamines at the time of administration of β blockers and the status of BBB may influence the effects of these agents on CBF. There is unlikely to have side effects of these agents on patients with intracranial pathology, other than the secondary changes due to reduction in CPP caused by decrease in CBF.

The effect of dopamine on CBF is very interesting. In low doses (2 to 6 µg/Kg/min) it probably causes the dilatation of cerebral vessels and increase in CBF. But there is possibility of vasoconstriction and reduction of CBF in higher doses (6 to 20 µg/Kg/min). In doses lesser than 2 µg/Kg/min dopamine also causes cerebral vasoconstriction.

EFFECTS OF ANAESTHETIC AGENTS ON CEREBRAL PHYSIOLOGY

Except ketamine all the anaesthetic agents reduce the electrical activity of CNS. Therefore, they increase the amount of energy stored in the form of ATP, ADP and phosphocreatine. However, this study of effects of anaesthetic agents on cerebral physiology is difficult. This is because it is often complicated by some other factors during surgery and anaesthesia such as continuous change in MAP due to sympathetic over activity during surgery due to stimuli, concomitant use of many drugs during anaesthesia, continuous change in P_aCO_2 which affect the CBF and subsequently the cerebral blood volume (CBV) during that period, etc. For example, over a wide range with the change in P_aCO_2 (20 to 80 mm of Hg) the CBF also changes by about 0.04 ml/100 gm of brain tissue/min/mm of Hg change in P_aCO_2 provided the MAP remains constant. Thus, in an adult brain weighing about 1.4 Kg this can be an amount to ($14 \times 30 \times 0.04 = 16.8$) 16.8 ml (approximately 17 ml) for every 1 mm of Hg change in P_aCO_2 from 25 to 55 mm of Hg. On the otherhand, this change in CBF is different when the MAP is variable and P_aCO_2 remains a constant factor. It is already stated that autoregulation serves to prevent the MAP related change in CBF and CBV. In the face of rising MAP the cerebral blood vessels constrict to maintain a constant CBF and thus CBV decreases to normal and *vice versa*. But when this autoregulation is impaired by anaesthetic agents or its upper and lower limit (150 mm of Hg and 50 mm of Hg) is exceeded, then the CBF and CBV increase or decrease as arterial pressure increase or decrease.

Intravenous Agents

Barbiturates

They produce dose dependent reduction in CMR and CBF. With the onset of anaesthesia this reduction of CMR and CBF is 30%. But with the deepening of anaesthesia by gradually increasing the doses of barbiturates when the EEG becomes isoelectric, then this reduction of CMR and CBF touches to 50%. However, further increase in dose of barbiturates beyond this point had no effect on CMR, CBF and CBV. This is because barbiturates only cause the reduction in the component of cerebral metabolism which is related only to the neurophysiological activity of brain, but not the component of cerebral metabolism which is related to the basic cellular activity such as ion transport etc. which is responsible for the maintenance of integrity of cell membrane. This is in contrast to hypothermia where both the CMR and CBF is reduced still beyond the point of isoelectric EEG (described before) (Fig. 49.3).

The reduction of CMR by barbiturates is greater than that of CBF. So, there is always some store of metabolic energy during barbiturate anaesthesia as supply (CBF) exceeds the demand (CMR). Barbiturates also cause the constriction of smooth muscles of cerebral blood vessels and is the cause of reduction of CBF along with the reduction of CMR (this mechanism is separate from the reduction of CBF when CMR is reduced due to hypothermia or other causes). But this is found in normal brain tissue. In ischaemic brain tissue barbiturate causes dilatation of vascular

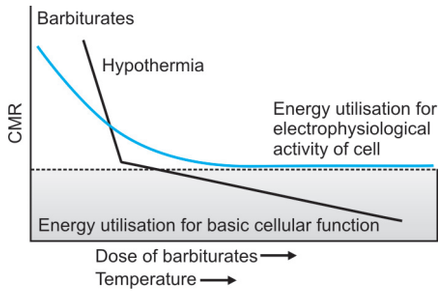

Fig. 49.3: Effects of barbiturates (green line) with increasing dose and gradual lowering of temperature or hypothermia (red line) on CMR. The maximum reduction of CMR that occurs with the increased dose of barbiturate, result in silent EEG. At this point the energy utilisation by cell for electrophysiological activity comes to zero. But the energy utilisation for basic cellular activity remains unchanged which is only reduced by hypothermia

smooth muscle and divert the blood flow from the normal to the ischaemic area of brain which is helpful. It is known as the reverse steal or Robin Hood phenomenon. So, the ischaemic areas of brain get maximum amount of blood supply during barbiturate anaesthesia.

Other than reduction of ICP by reducing CBF in neurosurgeries, the barbiturates also help by facilitating the dynamics of CSF. It helps in absorption of CSF. So the ICP is further reduced and protects the brain from damage by increased ICP and reduction of CPP. Barbiturates have also anticonvulsant property. Thus it prevents convulsion and reduces the CMR along with the reduction of CBF and ICP (convulsion is associated with increased CMR, CBF and ICP), causing decrease in the chance of ischaemia of brain.

Propofol

Like babiturates propofol also reduces the CMR and CBF. These reduction of CMR and CBF caused by propofol are approximately 30% and 50% respectively. Hence, it shows that there is more reduction of CBF than CMR in propofol anaesthesia which is unlike to barbiturates. Thus, it is also helpful in neurosurgery by reducing ICP and protecting brain from ischaemia. Though, propofol causes choreiform and dystonic movements, but it has anticonvulsant property like barbiturates. So, it also protects the brain from ischaemic injury during convulsion. Both autoregulation and CO_2 responsiveness of CBF appear to be preserved during administration of propofol.

Benzodiazepines

Like propofol and barbiturates the benzodiazepines also cause the reduction of CBF and CMR. But the extent of this reduction of CMR and CBF is probably intermediate in position lying between the narcotics (minimal) and barbiturates (maximum). For example, 15 mg diazepam reduces CMR and CBF to 25% provided respiratory depression and increase in P_aCO_2 do not occur.

Narcotics

They have minimal reduction effect on CMR and CBF in the normal unstimulated patients. So, they cannot decrease CMR and CBF especially if there is any factor which increases the $\uparrow P_aCO_2$, $\uparrow$MAP, etc. The CO_2 responsiveness and autoregulation to CBF remain unaffected by narcotics. Regarding the effect of narcotics on ICP it is found that morphine and fentanyl reduce ICP by reducing the CMR, CBF, CBV and CSF pressure. But it is found that sufentanil and alfentanil sometimes increase ICP.

Ketamine

Among all the intravenous anaesthetic agents ketamine is the only one which increases the CMR and subsequently the CBF by dilating the cerebral vessels. Thus it increases the ICP also. It selectively activates the limbic structure and the area of reticular formation, while it selectively depresses the cortical area of brain. Seizure caused by ketamine further increases ICP by increasing CMR and CBF. So it is not beneficial for neurosurgery. Hyperventilation can reduce the elevation of ICP caused ketamine, because CO_2 responsiveness to CBF remains intact by it.

Inhalational Anaesthetic Agents

Volatile agents

The pattern of influence of volatile anaesthetic agents on cerebral physiology is strikingly different from that of the intravenous anaesthetic agents. Here the reduction of CBF does not follow the foot print of the reduction of CMR caused by the volatile anaesthetic agents. All the volatile anaesthetic drugs dilate the cerebral vessels (in contrast to barbiturates and propofol which constrict these vessels). Thus they all increase the CBF and CBV while simultaneously produce dose related reduction in CMR. Hence all the volatile anaesthetic agents increase ICP, especially in patients with reduced intracranial compliance. Regarding the effects of volatile agents on CMR, CBF, CBV and ICP halothane is the most potent and isoflurane is least potent agent. The influence of the newer volatile anaesthetic drugs such as sevoflurane and desflurane on cerebral physiology is more or less similar to that of isoflurane. For example, halothane increases CBF up to 200% compared to 20% produced by isoflurane at the equivalent dose of MAC and similar reduction of BP.

On the otherhand, halothane produces relatively homogenous changes in CBF in brain. Therefore, the CBF is globally increased and CMR is globally decreased by halothane. In contrary, these changes (reduction of CMR and increase in CBF) caused by isoflurane are more heterogenous resulting on increase in CBF in subcortical and hind brain structures than the structures of neocortex. However, for the CMR the reverse is true for isoflurane causing greater reduction in neocortex than that in subcortex and hind brain. All these datas dictate that isoflurane is preferred in neurosurgery, if volatile anaesthetic agents are at all used in the setting of impaired (decrease) intracranial compliance. But that does not indicate that halothane is completely contraindicated

in these circumstances. It is clearly demonstrated that halothane can safely be used in such circumstances if only P_aCO_2 is maintained at normal level by hypo or hyperventilation, the explanation of which is described as follows (Table 49.1).

All these volatile anaesthetic agents abolish the autoregulation of CBF in response to increase or decrease in MAP. So, the CBF changes not in parallel to the changes in MAP. But, after few hours the increased CBV due to increased CBF returns to normal due to compensatory mechanism. However, this time course needed for compensation is dependent on the magnitude of the initial elevation of CBF. It is already previously stated that the reduction of CMR caused by volatile anaesthetic agents is not similar to that of hypothermia. In hypothermia the CMR is further reduced after the EEG becomes isoelectric which is not found in volatile agents and intravenous anaesthetic agents. CO_2 responsiveness to the changes in CBF is well preserved during anaesthesia by all the volatile anaesthetic agents. Therefore, hyper or hypoventilation can control the CBF, CBV and ICP when anaesthesia is provided by volatile anaesthetic agents.

From the above discussion it is learnt that the volatile anaesthetic agents cause uncoupling of the normal relationship between the CBF and CMR, i.e. reduce CMR but increase CBF. So, this aspect of influence of volatile anaesthetics on cerebral physiology is beneficial by preventing ischaemia, especially during the use of isoflurane in neurosurgery. But this beneficial effect is off set by the steal phenomenon, caused by these volatile anaesthetic agents. This steal phenomenon explains that the volatile anaesthetic agents though dilates the vessels of normal brain tissue, but do not dilate the vessels of ischaemic area which are already maximally dilated due to ischaemia. So, the ultimate result is the starved ischaemic area due to the stealing of the supply of blood to normal healthy area of brain. Further, they increase ICP especially in patients with decreaed intracranial compliance, causing further damage to brain.

Sevoflurane	↓↓↓	↑	↑	↑↑
Desflurane	↓↓↓	↑	↑	↑↑
Ketamine	↑	↑↑↑	↑↑	↑↑↑

Nitrous oxide

Nitrous oxide causes vasodilatation of cerebral vessels. This vasodilating effect of N_2O is clinically more significance during neurosurgery in patients who have reduced intracranial compliance. Hence, the available datas till now unequivocally suggest that N_2O produces substantial increase in CBF, CBV and ICP when used alone in neurosurgeries. For example, when N_2O is used alone during removal of intracranial tumours then ICP may rise from the mean value of 10 to 13 mm of Hg to 30 to 40 mm of Hg. But the magnitude of this effect varies considerably according to the presence or absence of other anaesthetic agents such as intravenous or volatile. When N_2O is used in combination with IV anaesthetic agents such as thiopentone, propofol, benzodiazepines, etc. then the vasodilating property of N_2O is completely inhibited or attentuated. So, there is no increase in CBF and ICP. Again during neurosurgery the combination of N_2O and narcotics also have the similar effects. On the contrary, when N_2O is used in combination with volatile anaesthetic agents, then substantial increase in CBF, CBV and ICP is occurred. So, the present status regarding the use of N_2O in neurosurgery is that till now there is no strong adequate evidences to prohibit its use. Hence, N_2O is now widely used in neurosurgery, but in circumstances where ICP is persistently elevated causing tight surgical field, then N_2O should be taken as the responsible factor for this and avoided.

Muscle Relaxants

Depolarising agents

In a lightly anaesthetized patient succinylcholine is found to produce elevation of ICP. This is possibly due to the result of cerebral activation caused by affarent impulses to the brain from muscle spindle during fasciculation. So, this elevation of ICP is found to be maximum after 1 to 3 minutes of administration of succinylcholine and return to base line after 8 to 10 minutes. Thus, the succinylcholine induced elevation of ICP can be attenuated by deepening induction of anaesthesia and preventing fasciculation by using a small defasciculating dose of nondepolarising agent. Hence, its use need not be viewed as contraindication in neurosurgery with elevated ICP, where rapid achievement of skeletal muscle paralysis and intubation by succinylcholine is justified due to any cause such as difficult airway. Little hazard should follow its use if it is administered with proper control of MAP, P_aCO_2, depth of anaesthesia and using the method of defasciculation.

Nondepolarising agents

These agents cannot penetrate the blood brain barrier (BBB). So, they have no direct effect on cerebral vasculatures and the only indirect effect of it on CBF is via the release of histamine by these agents. Histamine decreases MAP by systemic vasodilatation and increases ICP by cerebral vasodilatation. Thus, it can result in reduction of cerebral perfusion pressure (CPP). Among the nondepolarising agents tubucuraine is the most notorious for the release of maximum amount of histamine. But the commonly used nondepolarising agents in clinical anaesthesia such as atracurium,

mivacurium, rocurium, vecuronium, etc. release histamine in lesser quantities. So, their use in neurosurgeries with elevated ICP is clinically inconsequent unless they are administered in large doses which are necessary to achieve rapid intubating condition. The nondepolarising agents which increase MAP such as pancuronium may elevate the ICP. But this is only possible when the rise of this MAP is abrupt and autoregulation is disrupted by the disease processes of CNS for which the surgeries are shouted. On the otherhand, the nondepolarising agents can reduce ICP by decreasing the impedence of cerebral venous outflow by preventing the coughing and straining. In most of the cases during neurosurgery the increase in ICP following the administration of muscle relaxants, laryngoscopy and intubation is due to the hypertensive response for light plain of anaesthesia.

CEREBROSPINAL FLUID (CSF)

A clear, colourless, transparent, modified tissue fluid fills all the ventricles, the whole spinal canal and the total subarachnoid space bathing the whole CNS. This is called the CSF. Its major function is to protect the CNS from trauma and maintain its physiology. The CNS is devoid of lymphatic supply. So, in CNS the CSF replaces the lymph. In a healthy adult human the volume of CSF is about 150 ml. It is continuously formed and absorbed. The normal rate of production of CSF in an healthy adult is about 500 ml/day or 20 ml/hour or 0.3 ml/minute. About 59 to 70% of CSF is produced by the choroid plexus of ventricles, mainly the lateral. The remaining 30% is secreted directly from the ependymal cells lining the ventricles. Yet the smaller quantities is formed by fluid leaking into the surrounding of perivascular space from cerebral vessels. The production of CSF is independent of ICP and everyday it is totally exchanged three times (Fact file I).

After formation from the two lateral ventricles (right and left) the CSF first passes through the foramina of Monro (right and left intraventricular foramina) to the third ventricle which is situated in the midline. Then, it flows through the aqueduct of Sylvius which is a channel in the midbrain to enter the fourth ventricle of medulla. After that from the fourth ventricle the CSF passes through three foraminas to the subarachnoid space. These three foramina are: central one named foramen of Magendie which ends directly into the *cisterna magna* and two lateral ones named the foramen of Luschka which end into the *cisterna pontis* which is situated at the basal aspect of brainstem. From the fourth ventricle the CSF also passes into the central canal of spinal cord. The ciliary movement of the ependymal cells which lines the of ventricles and spinal canal help in the circulation of CSF (Fig. 49.4).

From the subarachnoid space the CSF is absorbed through the arachnoid villi into the veins of cranial cavity, primarily the cerebral venous sinuses. These villi consist of some projections formed by the fused arachnoid membrane and endothelium of venous sinuses. The projections act as valves that permit the bulk direct flow

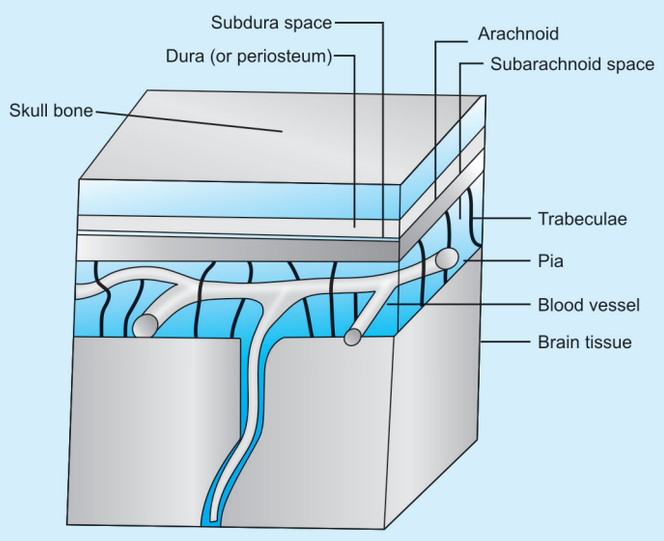
FACT FILE- I

Protective function of CSF

The meninges and CSF protect the brain. In cranial cavity the dura is firmly attached to the bone and acts as a priosteum. But in spinal canal the periosteum and dura is separated by epidural space and this two layers unite at the margin of the foramen magnum. So, epidural space does not extend into the cranial cavity. There is a thin potential space between dura and arachnoid which is known as the subdural space. It contains thin film of fluid. Thus arachnoid is held with dura by surface tension of this thin layer of fluid. The brain with its pia mater covering hangs or floats within the CSF filled subarachnoid space supported by blood vessels, nerve roots and multiple fine fibrous arachnoid trabeculae which pass from arachnoid mater to pia mater through subarachnoid space.

The brain weighs about 1400 gm in air. But in its CSF bath it has net weight of only 50 gm. So, the buoyancy of this organ (brain) in CSF permits these relatively flimsy attachment such as blood vessels, nerve roots and arachnoid trabeculae to suspend it very effectively. When the head receives a blow, the arachnoid mater slides on the dura mater and the brain moves. But this motion is gently checked by the CSF cushion and the arachnoid trabeculae.

Leaking of CSF after lumbar puncture causes severe headache. This is because after removal of more CSF the floating effect of brain in CSF lost. So, it hangs more by the vessels and nerve roots and traction on them stimulates pain fibres.



Different layer from skull bone to brain

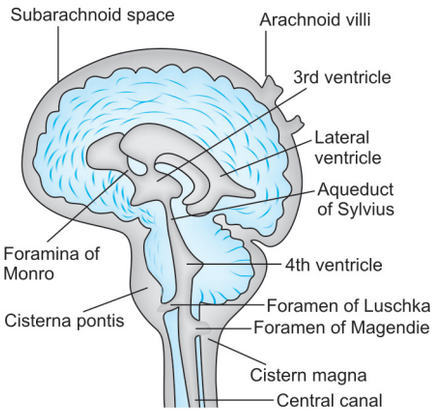


Fig. 49.4: The passage of flow of CSF

of CSF into the venous blood of sinuses. This bulk flow of CSF through these villi accounts for about 500 ml/day. The additional small amount of CSF is also being absorbed by direct diffusion into the cerebral blood vessels and at the nerve root sleeves and by meningeal lymphatics. The large amount of CSF accumulates when the reabsorption capacity of these arachnoid villi is impaired. Then this is called the external or communicating hydrocephalus. On the other hand, when there is obstruction at foramina of Luschlka and Magendie or within the ventricular system, then there is also accumulation of CSF proximal to the block and ventricles are distended. Then this is called the internal or noncommunicating hydrocephalus.

The components of CSF is essentially same as that of ECF of brain. Its formation involves active secretion of Na^+ from choroid plexuses along with water and is isotonic with plasma, though the concentration of K^+, bicarbonate and glucose is low. In comparison to plasma the protein content of CSF is very low and is only due to the small leak of it in perivascular fluid, other than some pathological conditions. The normal CSF pressure which normally reflect the ICP varies between 110 to 130 mm of H_2O. The absorption of CSF which takes place largely in the cranial venous sinuses is proportional to this pressure and inversely proportional to the cerebral venous pressure which is again proportional to the CVP. At a pressure (ICP) of 110 mm of H_2O secretion and absorption of CSF is equal. But below a pressure of approximately 65 mm of H_2O the absorption of CSF stops. The CSF pressure rises on standing, coughing, sneezing, crying, etc. Compressing of internal jugular vein also increases the CSF pressure by inhibiting its flow in the intracranial venous sinuses. It is known as the Queckenstedt's sign. Acetazolamide (carboxy anhydrase inhibitor), diuretics, corticosteroids, vasoconstrictor, etc, decrease the pressure of CSF by attenuating its secretion (Fact file II).

INTRACRANIAL PRESSURE (ICP)

The brain tissue, the blood vessels supplying it and the intracranial part of CSF are all situated in the cranial cavity which is encased by a rigid bony enclosure named the skull. In an adult cranial cavity the brain usually weighs about 1400 gm, the volume of blood is 75 ml and the volume of CSF is 75 ml. They constitute about 80%, 12% and 8% of the total volume of cranial cavity, respectively. Among these the brain tissue and the CSF component is incompressible one and the blood component is compressible one. It is postulated that at any time the total volume of brain tissue, blood and CSF in cranial cavity will remain constant at a certain ICP which is known as the Monro Kellie doctrine. Therefore, any increase in the volume of any one component must be offset by an equivalent decrease in volume of another component of cranial cavity to keep the ICP constant or to prevent the rise of it. As blood is the only compressible component of cranial cavity (CSF is partially compressible), so any increase or decrease of ICP the main burden will come on CBV and *vice versa,* i.e. any change in CVP promptly causes a similar change in ICP (Fig. 49.5).

In the closed cranial cavity the ICP, MAP and CVP interplay within themselves

FACT FILE- II

Blood brain barrier

The cerebral vessels have a number of unique anatomical features. In the capillary wall of choroid plexus there are gaps (65°A) between the endothelial cells which is like the capillaries of other tissues in the body. But the chroid epithelial cells that separate them from CSF are connected to one another by tight junctions. However, in the capillaries of other portion of brain there are tight junction between the endothelial cells (the gap is only 8°A) and limit the passages of substances through this endothelial junction. As a result large molecules such as protein and most ions are prevented from entering the brain's interstitial space. This unique limited exchange of substances into the brain tissue itself is referred to as the blood brain barrier. But some physiologist use this term only to refer to the barrier in the capillary wall of brain tissue and use the term blood CSF barrier to refer to the barrier in the choroid epithelium. However, the barrier are similar and it seems more appropriate to use the term blood brain barrier to refer to both the barriers. There is little evidence that anaesthetic agents alter the function of this blood brain barrier in most of the circumstances. But it has been repeatedly demonstrated that the acute hypertension can breach this barrier.

Multiple transport system (active and carrier mediated) are present in the capillary endothelial cells. Water, CO_2 and O_2 can penetrate the brain easily. So, do the lipid soluble free forms of many substances including anaesthetic drugs. Whereas their protein bound form and all proteins do not. The easy penetration of CO_2 in contrast to slow penetration of H^+ and HCO_3^- has definite physiologic significance in the regulation of respiration. Glucose is the major source of energy for nerve cells. Its passive transport through blood brain barrier is slow. But its transport through the walls of brain capillaries by the glucose transporter GLUT-1 is rapid. The brain contains two forms of GLUT-1 such as GLUT-1, 55K and GLUT-1,45K. Both are encoded by the same gene. Infants with congenital deficiency of GLUT-1 develop low CSF glucose concentration in the presence of normal plasma glucose. So they have seizures and delayed development.

Another important transporter in the cerebral capillaries is Na^+-K^+-$2Cl^-$ transporter. It helps to keep the brain K^+ concentration low. In addition there are specific transporter system for each several organic acids, thyroid hormone, choline, nucleic acids, etc.

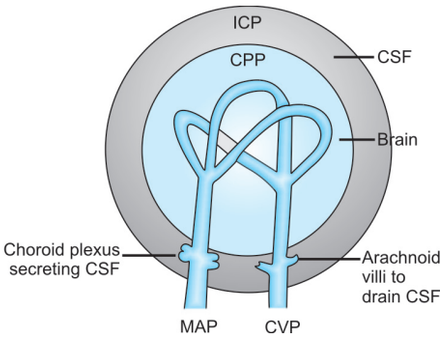

Fig. 49.5: The relationship between the MAP, CVP and ICP. The normal value of ICP is 10 mm of Hg. Elevation of ICP above 30 to 40 mm of Hg significantly compromise the CPP even in the presence of normal MAP. The CPP below 50 mm of Hg shows the EEG. When it is between 20 to 40 mm of Hg, EEG becomes flat. CPP below 20 mm of Hg cause irreversible brain damage

to determine the pressure which help to diffuse the different nutrient substrates and gases from blood to the cerebral tissue. This diffusion pressure in the tissue of brain is known as the cerebral perfusion pressure (CPP). Normally this CPP varies between 80 to 100 mm of Hg. This CPP is the difference between the MAP and ICP or CVP which will be the greater. Due to any condition when CVP exceeds ICP, then CPP will be the difference between MAP and CVP. Thus the CPP = MAP − ICP or MAP − CVP. So any elevation of ICP tremendously reduces the CPP and will impair the cerebral function. Increase in CVP also will decrease CPP by increasing ICP.

Conventionally, the pressure measured in CSF at the supratentorial level from lateral ventricle or over the cortex is considered as ICP. This was first introduced by Lundberg in 1960 and still remains the gold standard technique for the measurement of ICP with which other techniques are compared. In this technique a small catheter or a needle is introduced into the CSF of lateral ventricles and connected to an external standard pressure transducer. This always should be zeroed and calibrated and monitored with currently available electronic display system. During the measurement of ICP the zero reference point of the transducer is important, because CSF pressure is very position dependent. So a standard practice is to calibrate the pressure transducer at the level of the external auditory meatus and to correct the difference in height between the level of heart and head when calculating CPP.

This method of measuring ICP is an invasive one and the complications of this technique are: Infection, haematoma, injury of nerve tissue during passage of catheter through brain, etc. Sometimes a large mass, haematoma, severe brain swelling, etc. may distort the cavity of ventricle and make the introduction of catheter into it very difficult. Other less invasive techniques for measurement of ICP was thought and these include: Threading of a hollow bolt into the skull above a small supracortical dural opening, placement of a subdural catheter, intracranially implanted transducer, etc. (Fig. 49.6).

In lateral recumbent position the CSF pressure measured at the lumbar spinal level very closely approximates with the value supratentorial ICP. The intracranial compliance is measured by determining

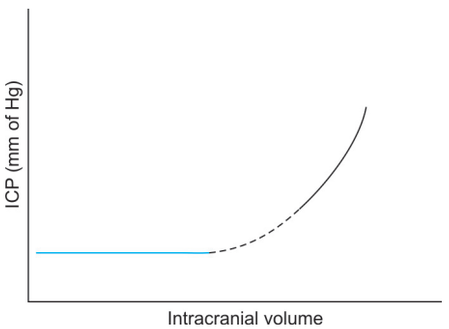

Fig. 49.6: Cerebral compliance curve. Dotted red part of the curve signifies the onset of cerebral ischaemia (focal ischaemia). Then the continuous red part of the curve signifies global ischaemia. In the initial part of the curve (blue line) ICP increases slightly though bulk of brain tissue expands. This buffering is due to the reduction of other intracranial volumes, usually CSF. The rate of increase of ICP is determined by the rate of expansion of intracranial mass, the compliance of CSF space and resistance to CSF absorption

the changes in ICP in response to changes in every unit of intracranial volume. Normally the brain tissue outside the cranial cavity is very much compliant, but this complacency is lost when it is put in a rigid box like skull for protection. So, the initial increase in volume of brain is well compensated without increasing ICP. But when this compensatory mechsnism is lost or exhausted quickly (as there is no scope for much expansion of brain due to rigid bony skull) then further slight increase in the volume of brain tissue will cause precipitous increase in ICP.

There are four compensatory or buffering mechanism which prevent the increase in ICP during increase in intracranial volume. These are: Decrease in CSF production, increase in CSF absorption, displacement of CSF from cranial cavity to spinal compartment, decrease in CBF and CBV. The major causes of increase in intracranial volume and increase in ICP are cerebral oedema due to any trauma, intracranial haemorrhage (extradural, subdural, subarachnoid, within the brain tissue) expansion of CSF or CBV, and growing intracranial mass. The location and the expansion rate of these lesions are the determining factors of the rate of rise of ICP and the rate and the degree of above mentioned compensatory buffering mechanism. So, a lesion situated on the pathways of CSF flow causes a rise in ICP proximal to the block at an accelerated rate by blocking the flow of CSF. Obliteration of CSF pathway can also block the transmission of pressure along the craniospinal axis. So, in this situation the measurement of CSF pressure at the lumbar spinal level does not reflect the actual change in ICP.

Increased ICP causing ischaemia and damage of nervous tissue is the end result of a number of different cerebral pathology. The normal value of ICP at supine position is 10 to 15 mm of Hg. If there is sustained elevation of ICP over 20 mm of Hg, then it is called intracranial hypertension. Although according to definition the elevation of ICP > 20 mm of Hg indicates

a pathological states, but it does not always indicate that this high ICP impair the function and viability of CNS. Becasue the impairment of function and viability of CNS depend directly on the type of pathological process, but not on the intensity of the rise of ICP. The increased ICP impair the function and viability of nerve tissue indirectly by jeopardizing the CBF to nerve tissue. It is also often found that during normal coughing, vomiting, straining, etc. the ICP goes well above 30 mm of Hg without any cerebral dysfunction. With high sustained elevation of ICP there is vascular compression, regional ischaemia and/or intracranial tissue shift which is called herniation of brain. This herniation of brain occurs through one of these four sites such as: Through any defect in the bony skull, under the falx cerebri, through foramen magnum, through tentorium cerebelli (Fig. 49.7).

METHODS OF REDUCTION OF ICP OR STRATEGIES FOR PROTECTION OF BRAIN

The strategies for protection of brain is theoretically most effective if it is started before the onset of ischaemia. But practically this is always not possible due to many socioeconomic reasons. There are different types of injury to brain such as trauma, haemorrhage, thrombosis, infarction, vascular spasm, intracranial mass, etc. But the ultimate insult of all these injuries is the reduction of CBF and ischaemia of brain tissue which stops the function of it. The ischaemia involves a process when the supply of energy falls short below the need of it. In the presence of ischaemia the intracellular enviornment deteriorates (by increase in Ca^{2+} and decrease in pH), cell membrane damages and accumulation of free radicals occur that aggravate the insult of ischaemia. The ischaemic brain injury is usually classified as the complete or gobal and the incomplete or focal one. The best example of complete or global ischaemia is cardiac arrest and the best examples of incomplete or focal ischaemia are thromboembolism, rupture of arteriovenous malformation, subdural haematoma, etc. But whatever (focal or global) may be the cause, the importance lies on the rapidity of development of ischaemic insult. Where the occlution of supply of O_2 and subsequently the supply of energy is not acute, then there is a potential period for manipulation of collateral cerebral blood to attenuate the ischaemic insult.

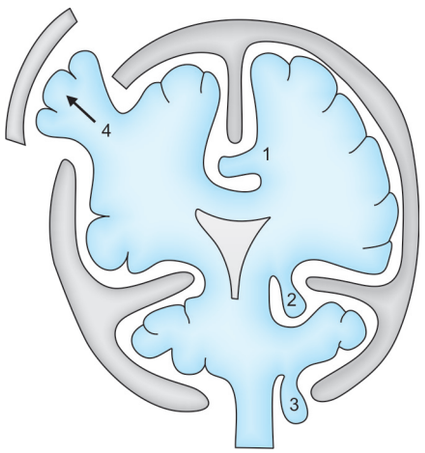

Fig. 49.7: Different herniation site of brain. 1. Under the falx cerebri, 2. Through the tentorium cerebelli, 3. Through the foramen magnum, 4. Through defect in skull.

Whether the insult is focal or global, the goal for the protection of brain from ischaemia are: (i) optimisation of CPP by reducing ICP, by (ii) decreasing in cellular metabolic rate of brain tissue by different methods and (iii) by blocking the action of mediators which cause further cellular injury. There are different methods which helps to reduce the ICP. These are: Cerebral dehydration by using osmotic and loop diuretics, use of corticosteroids, hyperventilation, reduction of cerebral venous pressure, drainage of CSF, surgical decompression, and the use of drugs which increase the cerebral vascular resistance and reduction of CBF. For protection of brain the CMR can be reduced by hypothermia, by anaesthetic agents and by some other specific adjustments. To block the action of different mediators which may cause further cellular injury the corticosteroid is the main stay of treatment.

Reduction of ICP

ICP is reduced by different agents or methods. These are:

Osmotic diuretics

Among the osmotic diuretics the most commonly used drug is 20% mannitol and is used in the dose of 0.25 to 1 gm/Kg average 0.5 gm/Kg) of body weight. It is an inert osmotic agent and preferentially remove more water from brain than other tissues. This is because intact BBB impedes the diffusion of mannitol into the nerve tissue of brain maintaining a strong osmotic diffusion gradient between the nerve tissue and the blood in vessel and withdrawing more water. The decompression action of mannitol on ICP occurs within 10 to 15 minutes after its administration and is independent of its diuretic action. The renal excretion of mannitol and subsequently the osmotic diuresis produced by it occurs within 20 minutes after its administration. This also causes systemic dehydration which also helps to keep the ICP low. Mannitol also reduces ICP by decreasing the formation of CSF. However, with larger doses and repeated administration of mannitol great abnormality in plasma osmolality and electrolyte balance and excessive intravascular volume depletion may occur. Other complications caused by mannitol are congestive heart faliure and rebound increase in ICP. The congestive heart failure is due to the transient initial intravascular hypervolaemia (before onset of diuresis) produced by mannitol as it draws fluid from the extracellular compartment to the intravascular compartment. In pathological conditions when BBB is disrupted, then mannitol itself enters the nerve tissues of brain rapidly (mannitol penetrates the BBB very slowly under normal circumstances)

and potentially can draw water back from circulation into the brain tissue, causing rebound increase in ICP when the plasma concentration of mannitol declines. This rebound increase in ICP can be prevented by restricting the replacement of intravascular volume to about 2/3rd 0.5 gm/Kg of that lost during osmotic diuresis caused by mannitol. Mannitol sometimes also causes transient increase in ICP. This is due to the hyperosmolarity induced dilatation of cerebral and extracerebral vascular smooth muscles (Fact file III).

Mannitol is contraindicated prior to surgical opening of cranium in patients suffering from ruptured cerebral aneurysm, rupture arteriovenous malformation, and sub or extradural haematoma. In such circumstances the osmotic agents (such as the mannitol which is in the collected blood) encourage the further expansion of haematoma (intra or extracerebral) and shrinkage of the healthy brain tissue. In aged patients this sudden shrinkage of brain may rupture the fragile veins entering the sagittal sinus from dura causing further subdural haematoma. Prolonged use of mannitol combined with loop diuretics and fluid restriction may also cause the state of systemic hyperosmolality and electrolyte depletion. The upper limit of hyperosmolality of plasma is 320 mOsm, where beyond this level renal and neurological dysfunction may occur.

FACT FILE - III

Cerebral Oedema

It is defined as the increase in water content of brain and is due to the loss of function of blood brain barrier (BBB). It occurs in three forms — vasogenic, nonvasogenic and interstitial. The vasogenic cerebral oedema is most common and is due to the vascular defect (breakdown of tight junctions between the endothelial cells of cerebral capillaries constituting BBB) allowing the intravascular protein and fluid to escape in the extracellular space of brain parenchyma. The causes of this vascular defect in BBB are trauma, acute hypertension inflammation and endothelial destructive (or vasoactive) substances such as histamine, bradykinin, free readicals, excitating, neurotransmitters, arachidonic acids, etc, releasing from tumour cells. In the pathogenesis of cerebral oedema once the plasma constituents cross the BBB, it draws more water from capillaries and produce swelling. Corticosteroids and Ca^{2+} channel blocker are helpful to reduce this cerebral oedema. Steroids act directly on the capillary endothelial cells by inhibiting the activity of phospholipase A_2 which results in decrease in concentration of lipoxygenase. Ca^{2+} channel blockers act by inhibiting the effect of Ca^{2+} which increase the permiability of capillary endothelium in hypertension.

In nonvasogenic cerebral oedema the integrity of BBB remains intact. The probable explanation of this type of nonvasogenic cerebral oedema are increase in osmolality of brain than that of plasma and toxin. The most common representations of cerebral oedema where brain osmolality increases than plasma osmolality and water is drawn within the brain parenchyma are water intoxication and rapid reduction of blood glucose level during treatment of nonketotic hyperglycaemic coma. The examples of nonvasogenic cerebral oedema where toxin is cause are hepatic encephalopathy, hypoxia, cardiac arrest, different drugs and poisons, etc. The example of interstitial cerebral oedema is obstructive hydrocephalons where over distended ventricles rupture and allow the CSF to enter into the parenchyma of brain.

The clinical manifestation of cerebral oedema is due to the increased ICP. There are no pathognomonic signs and symptoms of increased ICP. The common signs and symptoms are: nausea, vomiting, headache, papilloedema, unilateral dilatation of pupil, paralysis of abducent and occulomotor nerve, etc. In extreme cases there is abnormal ventilatory pattern and loss of consciousness. In such situation clinical examination does not determine the severity of cerebral oedema. So, it is assessed by measuring the ICP directly by measuring the CSF pressure.

The severity and location of cerebral oedema is also assessed by CT scan or MRI. The management of cerebral oedema depends on the pathophysiology of it and several approaches are taken simultaneously. This is because different antioedema measures act synergistically due to different mechanism of action. For example, to reduce the formation of vasogenic cerebral oedema steroid is used to decrease the permiability of BBB and BP is controlled to reduce the hydrostatic pressure which drives the fluid across the capillary wall into the tissue interstitial space. Another example is to increase the reabsorption of oedema fluid in the capillary the osmotic pressure of blood is increased by mannitol.

Loop diuretics

Among the loop diuretics the commonly used agent to reduce ICP is furosemide. It reduces the ICP by three mechanisms: diuresis mediated dehydration of brain like all other tissues reduction of formation of CSF and improved cellular water transport. Its action on brain tissue starts 30 to 45 minutes after intravenous administration. It does not have the problems on CVS such as congestive failure which are inherent to osmotic diuretics. Hence, it is the agent of choice to reduce the ICP in patient suffering from congestive heart failure. In extreme cases the combination of osmotic and loop diuretics is indicated, but it is at the cost of severe intravascular volume and electrolyte depletion. So, the use of these combination is only restricted to patients where there is no pre-existing renal diseases and electrolyte disturbances.

Corticosteroids

These agents are more frequently used to reduce the ICP, which are mainly related to cerebral ischaemia and cerebral oedema. The probable mechanism of action of steroids to reduce ICP are: brain dehydration, inhibition of lysosomal and phospholipase A_2 activity, improvement of the action of BBB, etc. Some thought that the role of corticosteroids to improve the cerebral compliance is still not definitely established. But the general dictum is that the steroids should be used, because if it does not do any good, it does not do any harm. The main drawback of steroids is that it takes hours to be effective in lowering ICP. The side effects during the use of steroids in neurosurgeries are: hyperglycaemia, glycosuria, increased chance of infection, GI bleeding, electrolyte imbalance, etc.

Hyperventilation

In previous discussion it is already stated that lowering of P_aCO_2 has beneficial effect on cerebral insult. It provides this beneficial effect by increasing the cerebral vascular resistance by vasoconstriction

and thus reducing CBF, CBV and ICP. Reduction of P_aCO_2 up to 25 to 30 mmHg by hyperventilation has maximum beneficial effect on ICP with minimum risk of cerebral ischaemia. However, this positive effect of hyperventilation acts till the responsiveness of CO_2 to vascular smooth muscle remains intact. When this reactivity is impaired, (such as during anaesthesia) then hypocapnia may be ineffective in reducing elevated ICP. To control increased ICP the hyperventilation should be initiated as early as possible. Hence, in conscious and cooperative patients with increased ICP hyperventilation is instituted by asking him to take deep and quick repeated breath before induction of anaesthesia during preoxygenation. But if this is not possible, then hyperventilation is immediately started after induction and intubation. So, intubation and hyperventilation is mandatory to reduce ICP in patients with score 7 or less in Glassgow Coma Scale.

Reduction of cerebral venous pressure

When there is impairment of cerebral venous drainage, then the cerebral venous pressure is increased. This increased cerebral venous pressure is associated with increased CBV and increased ICP. So, during neurosurgeries always attempts are made to reduce ICP by removing the factors which impede the venous drainage from brain. Hence, most neurosurgeons prefer to raise the postition of head above the level of chest and avoid any flexion or rotation of neck that impede cerebral venous outflow and cause increased ICP and increased tissue bulk of brain. It is obvious that osmotic diuretics, loop diuretics, hyperventilation, etc. are ineffective in reducing ICP if the cerebral venous drainage is not properly maintained. So, a simple change in head position which impedes the cerebral venous drainage can immediately achieve the desired goal.

Increase in central venous pressure also increases ICP by obstructing the cerebral venous drainage. This is observed in PEEP or any other mode of ventilation where there is potential to increase the intrathoracic pressure causing increased central venous pressure. So, if PEEP is required to improve arterial oxygenation then the rise in P_aO_2 is against the proper cerebral venous drainage and its sequelae. Hence, these two opposite factors have to be balanced. Muscle relaxants can reduce this elevated ICP by decreasing resistance to mechanical ventilation and intrathoracic pressure which impedes the cerebral venous outflow.

Drugs increasing cerebral vascular resistance

Increase in cerebral vascular resistance by vasoconstriction acutely reduces ICP by reducing CBF and CBV. The pharmacological agents causing this effect are propofol, thiopentone, etomidate, lignocaine, etc. However, these drugs receive their best application during induction and maintenance of anaesthesia but not in nonanaesthetised patient. Hyperventilation also reduce ICP by constricting the vessels. But the difference is that these pharmacological agents require coupling between the decrease in CMR caused by these agents and subsequent reduction of CBF, CBV and ICP, which is not seen during the reduction of ICP by hyperventilation. Reduction of ICP by hyperventilation does not decrease CMR, but only constrict the blood vessel and reduce CBF.

Drainage of CSF

Drainage of CSF is a definite method which instantly controls the raised ICP by creating sufficient operative space. This is performed by transdural ventricular CSF tap, prior to dural opening especially when the brain is tight. This is applicable for large supratentorial masses and for decompressing hydrocephalus secondary to posterior fossa tumours. Excessive drainage of CSF through spinal route is also useful for surgery of pituitary lesion, aneurysms, arteriovenous malformation, repair of skull defects, etc. This is performed by introduction of a malleable needle connected with catheter into the lumbar subarachnoid space following induction of anaesthesia. Successful chronic control of high ICP due to hydrocephalus can also be obtained by implanting CSF shunts.

Reduction of secretion of CSF

The reduction of secretion of CSF is an another method of reducing ICP. Approximately 50% of CSF production can be inhibited by acetazolamide. But this effect is transient and has only been used clinically during acute elevation of ICP in chronic hydrocephalus.

Surgical decompression

There are two types of surgical decompression – internal and external. The internal surgical decompression includes complete or partial removal of intracranial tissues or masses. Besides reducing ICP, the internal Surgical decompression can also stop the shifting of brain tissue that are associated with herniation. External surgical decompression includes removal of a portion of skull. But in contrast to internal decompression this external decompression may exaggerate the shifting of brain tissue, while still reduce the ICP. For this reason the external surgical decompression is usually performed only as a last step in the sequence of treating persistent intracranial hypertension.

Protection of Brain

Hypothermia

Hypothermia is justifiably and firmly established as the principal cerebral protective measure in the face of circulatory arrest. This effect is largely due to the reduction of CMR which enhances the cerebral tolerance to the episode of both focal and global ischaemia. Indeed severe hypothermia is often applied for up to 1 to 1½ hours of total circulatory arrest with

little evidence of impairment of neurological function. Hypothermia not only reduce CMR, but also subsequently reduce CBF, CBV, and CSF secretion rate along with ICP. However, this reduction of ICP is more expeditiously accomplished by pharmacological agents and the use of hypothermia to reduce ICP is practised rarely. Pharmacological agents reduce (60%) only that component of CMR which is only associated with the electrical activity of neural cells measured by EEG. Whereas hypothermia causes the reduction of CMR which is responsible for both the electrical (60%) and basal cellular activity (40%). Therefore, hypothermia causes continued decrease in metabolic requirement of nerve cell even after the complete electrical silence of it. A large number of studies have demonstrated that even a mild degree of hypothermia (33° to 35°C) can also offer substantial protection of brain as evidenced by histologically. But Cardiac arrhythmias and a number of other complications related to hypothermia may occur if temperature goes below 28°C. Whenever hypothermia technique is employed to protect the brain, then the use of muscle relaxant and other drugs that centrally suppress shivering may need mechanical ventilation (Fact file IV).

Anaesthetic agents

Previously it is already stated that some anaesthetic agents have protective effect on brain. Among these barbiturates, propofol, etomidate and isoflurane are the most remarkable. With gradual increasing doses they reduce CMR and produce electrical silence. Thus, they eliminate metabolic cost for electrical activity of brain cells. But, like hypothermia they cannot eliminate the metabolic cost for basal cellular activity of neuronal cells of brain. It is also true that like hypothermia these anaesthetic agents are not protective against global ischaemia. Furthermore, their protective effct on brain is not uniform. They are helpful only for focal ischaemia. Other than reduction of CMR, the other mechanisms of protection of brain caused by these anaesthetic agents are: blockade of Na^+ channel, inhibition of free radical formation and inhibition of Ca^{2+} influx. They also protect the brain by reducing ICP by constricting the cerebral vessels and decreasing the CBF and CBV.

Specific adjustments

Among the specific adjustments which have protective value of brain from ischaemia, the Ca^{2+} channel blockers are very important. Further, among the Ca^{2+} channel blockers the nimodipine and nicardipine have been shown to have better neurological outcome if administered following stroke or subarachnoid haemorrhage. But, unfortunately it is not used throughout the whole world uniformly, because still there is some controversy about its positive outcome and nonavailability of parenteral form of these agents. Other agents that have protective effect for brain from ischaemic insult are: dextromethorphan, magnesium, dexmedetomine, etc. Methylprednisolone also has been shown to reduce neurological deficit following spinal cord injury.

Other measures

All the measures which are taken to reduce ICP protect the brain from ischaemic injury. There are also many other measures which protect the brain and reduce the neurological deficit following injury of it. The haematocrit value should be maintained between 30 to 35% for optimum delivery of O_2 to brain tissue. An elevated haematocrit value will reduce CBF because of increased viscosity effect. Lowering of haematocrit value below this optimum level also does not prove effective. Arterial O_2 tension also should be maintained at normal level. The maintenance of high normal CPP is also very important. This is achieved by maintaining normal or slightly

FACT FILE- IV

Pathophysiology of cerebral ischaemia

The brain has very low energy storage capacity, but has very high rate of utilisation of it. So, it is very vulnerable to injury (or ischaemia) in the face of interruption of the supply of energy in the form of substrates such as glucose and O_2. In the pathology of the ischaemic injury of the brain calcium ion acts as a most vital role. All the cellular functions are controlled or mediated by the intracellular Ca^{2+} and its concentration is strictly maintained. Calcium enters the cell through the voltage gated and neurotransmitter gated calcium channel. It is also released from the intracellular storage site such as ER and mitochondria by the action of inositol triphosphate (IP) which is generated by the action of neurotransmitter and the receptor on the cell surface. This intracytoplasmic input of Ca^{2+} is balanced in a narrow range by the extrusion of it from the cytoplasm. This extrusion of Ca^{2+} from the cytoplasm is energy dependent and the processes are: resequestration in ER and mitochondria, extrusion from the cell and inhibition of process that helps to release it from the intracellular storage site.

In ischaemia there is failure of supply of energy (ATP). So, all the energy dependent extrusion processes which help to bring out the Ca^{2+} from cytoplasm are stopped in the absence of ATP. On the otherhand, cerebral ischaemia causes the excessive release of neurotransmitter in the synaptic cleft which activate the influx of Ca^{2+} into the cell through receptor. Thus, in cerebral ischaemia the concentration of intraneuronal Ca^{2+} increases tremendously and over activate the various intracellular enzymatic processes such as lipases, proteases, nucleases, etc. Thus, the over activation of this enzymatic processes cause the structural damage of cell and release of free fatty acid such as arachidonic acid from the cell membrane. Then, this arachidonic acid forms various prostaglandins and leukotrienes with the help of cyclo-oxygenase and lipo-oxygenase and these prostaglandins and leukotrienes bring out all the effects such as vasodilatation, vasoconstriction, change in membrane permeability, leukotaxis, etc., all of which contribute to the evolution of ischaemic insult of neuronal cell of brain tissue.

In the failure of supply of O_2 (ischaemia) lactic acid is formed by the process of anaerobic glycolysis and intracellular pH is decreased. This decrease in intracellular pH further deteriorates the intracellular enviornment and cause injury of neuronal cells. The excessive presence of glucose into the cell stimulate the anaerobic glycolysis and aggravate the lactic acidosis and increase the neuronal injury. So, infusion of glucose solution is not advised in neurosurgery. Thus, lactate formation is an additional element of pathophysiology of cerebral ischaemia.

elevated MAP and avoiding the increase in CVP and ICP. Measures designed to improve CBF is also very important. This is because small increase in CBF have the potential to prolong the survival time of nerve cells.

Hyperglycaemia aggravates the neurological injury following complete or incomplete ischaemia of brain. So, in the presence of cerebral ischaemia withholding of intravenous infusion of glucose containing solution is a standard practice. The plasma glucose level should be maintained below 150 to 180 mg/dl. Still it is in controversy that glucose elevation associated with brain injury may be the result of stress caused by cerebral insult (either traumatic or ischaemic) or hyperglycaemia itself. Hypercapnia and hypocapnia always should be avoided, because both has adverse effects on cerebral injury (ischaemia). Hypercapnia has the potential to worsen the intracellular pH and cause intracerebral steal. On the otherhand, hypocapnia has not generally been proved to be effective in laboratory and clinical setting, inspite of the favourable inverse steal (Robin Hood) effect.

ELECTIVE NON-NEUROSURGICAL PROCEDURES AFTER A STROKE

After a stroke the loss of normal vasomotor responses to P_aCO_2 and MAP (autoregulation) in the early post-insult period is very common. In case of a small infarct this usually persist for 2 weeks, though may last beyond that period depending on the location and the size of infarct. The CBF undergoes marked changes following stroke and the area of both high and low blood flow in brain occur. This is apparent for 2 to 4 weeks. Abnormality in the function of BBB is also found following stroke which is evidenced by accumulation of contrast agent in brain used for CT scan. This is also apparent for approximately 4 weeks in the post-insult period in case of small infarction. However, the histological resolution is not complete for several months and years following stroke which depend on the size and the location of the insult. So, there is no definite statement as to how long elective non-neurosurgical procedures should be deferred following a stroke. But a general agreement is that in case of a small infarct a 6 weeks interval can give some assurances of likely recovery of CO_2 responsiveness, autoregulation MAP and integrity of BBB, though in large infarction this interval may extend up to 6 months. So, at end the conclusion is that it seems reasonable to defer any elective surgery for atleast 6 weeks after small infarction or is performed after 6 weeks from the point at which stable neurosurgical state has been achieved in case of large infarct.

DIFFERENT POSITIONING OF PATIENT DURING NEUROSURGERY

Only for neurosurgeries different pequilar position of patient are required to facilitate the surgical procedures. Among these the supine, prone, lateral and sitting position with their many modifications to a specific procedure are commonly encountered. Certain neurosurgical procedures are long. Hence, some complications only due to these prolonged abnormal position of patient may occur which should be prevented by taking proper care, e.g. good padding of pressure point, avoiding hyperflexion or hyperextension of head, neck and extrimities, etc. During neurosurgical procedures due to prolonged immobilisation of patient in abnormal position the incidence of thromboembolism is also very high which can be lowered by the intraoperative use of pneumatic venous compressive devices on legs and taking other measures.

Supine Position

This position is indicated for frontal, parietal, temporal or sometimes occipital incision with head rotated to one or other side. This rotation of head can impair cerebral venous drainage by obstructing the jugular venous system due to twisting. So, slight reverse Tredelenburg position (10° to 20°) with modest shoulder lift promotes better cerebral venous drainage. In supine position the head is kept at midline without rotating to any side during trans-sphenoidal approach for pituitary and bifrontal craniotomy. For anterior approach to cervical spinal cord this supine position is also used with moderate head traction. In all neurosurgeries, especially for frontal incision, the eyes should be closed and covered properly with thick pad to prevent the antiseptic solution, used for preparation of skin, to come in contact with the eyes.

Lateral Position

This position is used for some special surgeries on spinal cord, and during some surgeries on lateral and posterior cranial fossa. It may be an alternative to supine or prone position and *vice versa*. The main disadvantage of this position is to maintain the stability of patient's trunk exactly in this position for prolonged period because the body is usually inclined automatically due to its weight towards front or backwards. So, sometimes vacuum mattress is used which greatly helps to maintain the patient's body in this position.

Prone Position

This position is used especially for surgery on posterior cranial fossa and for posterior approach of spinal cord. Before positioning to prone, induction of anaesthesia and intubation of patient is done in supine position. Then the patient is turned to prone position carefully with required additional personal. During this positioning from supine to prone the major problem is the maintenance of basic cardiovascular monitoring. Because all the monitoring systems require long cables from the patient's site of attachment to the display modulus which make complicate

this rotation of patient through 180° arc. Frequently they are detached from the patient end or be entangled with each other or give incorrect result due to the movement of patient with continuous buzzing of alarm which distract the attention of anaesthetist from patient in respect to tube position, ventilation, oxygenation, stability of CVS, etc. The Positioning of an anaesthetised patient also may cause circulatory instability. So the total blackout of monitoring during this positioning of patient is also not desirable. Hence, if it occurs then only palpation of peripheral pulses by an anaesthetist during turning of patient from supine to prone can provide a continuous qualitative assessment of cardiovascular status. The ECG contact pads are positioned on the patient's back or side so that patient will not lie on them after positioning.

In prone position if the ET tube comes out of trachea then it is very difficult to reintubate and sometimes it becomes impossible. So, hundred percent full proof fixation of ET tube after intubation is of paramount importance when neurosurgery is done on prone patient. This full proof fixation of tube is again complicated by the inability to use a circumferential tie around the neck which is the location of surgery. So, sometimes to avoid difficulties during turning of patient from supine to prone, awake tracheal intubation in prone position is tried under combination of good local anaesthesia of airway and judicious selection and titration of narcotics or sedatives. Currently this technique is kept reserved only for severely obese patients which cannot be turned from supine to prone after anaesthesia.

After turning the anaesthetised patient from supine to prone position, the head should be kept on a horseshoe shaped rest or on a depression at the head end of the operating table or on a customised disposable head holder. There are many options of supporting the trunk of patient in prone position according to the need of planned operation. First, firm supports are applied under the chest and pelvis, leaving the abdomen free. Second, for lumbar spine surgery the surgeon needs support and fixation of lumbar spine which can be offered by Wilson frame. But whatever may be the support, the compression on abdomen by faulty position should be avoided. Otherwise, the diaphragm will be pushed more towards the thoracic cavity and it will result in increased central venous pressure causing impairment of cerebral venous drainage and engorged epidural veins.

A dreaded complication of prone position during neurosurgery is blindness. This is due to the retinal ischaemia caused by prolonged compression on eyeball in prone position. This may be catalysed by low arterial BP and impaired cerebral venous drainage which will reduce the retinal blood flow and will encourage retinal venous thrombosis. Other pressure points that have to be cared in prone position like eyes are the breasts, genitalias, knees, iliac crest, etc.

Sitting Position

The indications for sitting position in neurosurgery include the lesions in posterior cranial fossa (infratentorial lesions) and posterial cervical spine. However, its use is now diminishing gradually due to the potential serious complications caused by this position, and the presence of alternative position permitting to perform the above mentioned neurosurgeries. The two major hazards which are confronted by patients in sitting position are: the first is due to the influence of gravity on the distribution of intravascular fluid volume, cardiac filling pressure and CPP, and the second is due to (also gravity related) the venous air entrainment resulting in pulmonary and/ or systemic air emboli. Thus, the potential complications caused by sitting position are the venous air embolism (VAE), pneumo-encephalus, circulatory instability, quadriplegia etc. But the sitting position has also many advantages which facilitate the neurosurgical procedures. These are: Better access to midline lesion, low ICP, better venous drainage, better drainage of blood from surgical field by gravity facilitating surgery rather than collecting at the operating site, better drainage of CSF by gravity, less blood loss requiring less blood transfusion, etc. Though its use is gradually diminishing, but it is still used in some centres and some recently developed new neurosurgical procedures find its usefulness (Fig. 49.8).

Actually, the term sitting position is a misnomer. Because the properly done position is nothing but a modified recumbent position where the legs are kept as high as possible which promote better systemic venous drainage (pre-load) and enhance circulatory stability. Recently many modifications are also done of sitting position which permit lowering of head when necessary without taking the patient out of the head holder and not disturbing the continuation of surgery. This is important because it is not always possible to alter the conventional sitting position in the middle of surgery without disturbing it, if VAE is suspected and this will allow precious moments to pass without appropriate treatment is instituted. In sitting position some degree of head flexion is mandatory for better visualisation of surgical site and easy access to the posterior

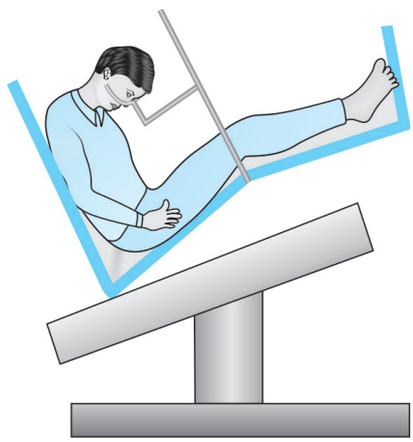

Fig. 49.8: Sitting position of a patient with the head rested on a holder

cranial and spinal structures. But excessive flexion of head has also many disadvantages and should be avoided, maintaining at least a finger breath's distance between the patient's sternum and chin.

Venous Air Embolism (VAE)

In sitting position as the head is positioned above the level of heart, so an open vein and negative intravenous pressure relative to atmospheric pressure during neurosurgery promotes the entry of air in the cerebral venous system causing VAE. The vertical distance between the head and heart varies between 20 to 60 cm in different position of patient during different neurosurgical procedures. So, the incidence of VAE varies as 25, 18, 15 and 10 percent in sitting, lateral, supine and prone position respectively. However, this incidence rate is calculated when the central venous catheter is used for air aspiration and to diagnose VAE. But when the Doppler and other more sensitive monitoring methods are used to diagnose VAE, then the incidence of VAE is increased enormously. For example, this incidence is increased to 50% when Doppler is used to diagnose VAE in suboccipital craniotomy. So, the use of more sensitive monitoring system like Doppler for early diagnosis of VAE also decreases the occurrence of clinically significant VAE (this is because diagnosis at subclinical level make the anaesthetist prompt to take the steps which will prevent the progress of subclinical stage to the clinically significant stage), but increases the reported rate of incidence. Poor surgical technique also increases the incidence of VAE. So, the incidence and the danger of VAE can be reduced only with good monitoring, better surgical and anaesthetic technique and early good communication between the surgeon and the anaesthetist.

Though VAE occurs at any time during craniotomy in any position, but the peak incidence and occurrence time of it is during the sitting position and exposure of bony venous sinusoids at the time of dissection of bone and skin muscles. The maximum incidence of VAE occurs when the major dural sinuses are opened in sitting position. Once air embolism has occurred, the factors which influence the severity are: The volume of air that enters the venous system, the rate of entry, the pressure of the right side of heart, the presence or absence of patent foramen ovale, or VSD, cardiac contractility and the presence or absence of N_2O. The entry of large amount of air within a short period in venous system causes foaming of blood within the heart. This leads to the mechanical obstruction to right ventricular outflow (obstruction to left ventricular outflow occurs if there is patent foramen ovale or VSD) and reflex pulmonary vasoconstriction which results in increased PAP and decrease in the venous return to the left side of heart. Thus, effective pumping action of the left side of the heart is interrupted (cardiac output falls) and cardiovascular collapse is resulted.

The entry of small amount of air in venous system has little clinical significant. It is absorbed at the pulmonary level with little increase of pulmonary arterial pressure (PAP) by reflex mechanism with the release of vasoactive substances which constrict the pulmonary arterial tone. But with the entry of more and more air in venous system and during absorption of it at pulmonary level, the PAP gradually rises coming to a plateau or equilibrium when the entry of air and its maximum absorption capacity by lungs become equal. Crossing this equilibrium causes further increase in PAP, increase in intrapulmonary shunt, decrease in left ventricular output and cardiovascular collapse. The increase in intrapulmonary shunt leads to decline in end tidal CO_2 excretion. Thus, the measurement of $ETPCO_2$ gives an opportunity to detect VAE. The diagnosis of VAE is confirmed by blood gas analysis which shows increased difference in tension between $ETCO_2$ and arterial CO_2, in the absence of recent change in controlled ventilation. Hypoxaemia is the late feaure of VAE and is mainly secondary to the great increase in intrapulmonary shunt.

The use of N_2O as an anaesthetic gas increases the size of intravenous air bubble, because it is 34 times more soluble in blood than N_2 and rapidly diffuses in the air bubbles. Hence, it is suggested that avoidance of N_2O during neurosurgery enhances the safety, especially in sitting position or N_2O should be used only when the sensitive monitor to detect VAE is used and in any suspicion of VAE ventilation with 100% O_2 is immediately instituted, stopping N_2O. With the confirmed diagnosis of VAE attempts are also made to aspirate air from the right side of the heart by central venous catheter which is already placed there for intraoperative monitoring of CVS. The cardiovascular drugs are administered as required to support the circulation. To prevent further entry of air in the venous system the elevation of central venous pressure by elevating airway pressure is not always suggested. This is because it may further reduce the venous return to the heart and may aggravate the cardiovascular instability. The rapid inflation of antigravity G-suit may provide transient cardiovascular support during this critical period by increasing the venous pressure and venous return. After that still if the stability of cardiovascular system is not attained quickly, then the patient is repositioned to supine and cardiopulmonary resuscitation is started as required. Further entry of air in venous system at the surgical site can also be prevented by lowering the head, increasing the cerebral venous pressure by applying compression on internal jugular vein (unilateral or bilateral), packing the wound and flushing the surgical site with sterile saline. So, as soon as the VAE is suspected or diagnosed, then surgeon will be quickly informed and he will immediately flood the operation site with saline. Neck compression is is also given to occlude the neck veins. This will prevent further air

embolism and will cause venous bleeding from the operative site which will allow the surgeon to detect and seal the point at which the air is entering. A central venous catheter should always be placed during neurosurgery in sitting position. Because it will help to aspirate air easily if the above mentioned simple methods fail to prevent large amount of air entering the venous system. It is found that catheter placed in superior vena cava is more helpful to aspirate air than it is placed in the right atrium. The most sensitive method in detecting VAE is the Doppler technique where probe is placed at the right sternal edge between the 3rd and 4th intercostal space. By Doppler method air bubbles as small as 0.5 ml can also be detected. However, the main disadvantages of Doppler in detecting VAE is that its signal is interrupted by the radiofrequency signal of diathermy. Hence, during the peak time of occurrence of VAE, i.e. during the muscle incision and bone work the diathermy is also in full use for this muscle incision and boen work so it will interfre the work of Doppler which is necessary to work at the same time to detect VAE. But the good news is that the newer model of Doppler are now provided with some special filters which are able to reject the diathermy signal and are capable to work without interference.

Pneumoencephalus

It is an another complication of neurosurgery when after dural closure air remains trapped inside the skull and acts as a intracranial mass lesion. Some degree of pneumoencephalus always occurs after neurosurgery in any position, but is found maximum in sitting position (3 to 4 times higher than prone and park bench position). During neurosurgery in sitting position after opening the dura, CSF drains away from the intracranial space and air enters in the cranial cavity like an inverted pop bottle. The air in pneumoencephalus which causes mass effect after the closer of craniotomy wound may be asymptomatic or symptomatic (depending on the amount of air) producing headache, lethargy, confusion, impaired memory, etc. The huge amount of air in pneumoencephalus may also cause shifting of brain tissue along the midline. In the absence of severe symptoms or extensive brain shifting the patient with pneumoencephalus is usually managed conservatively. Because symptoms are commonly non-progressive and resolve after few days in postoperative period. Breathing of 100% O_2 helps to absorb air and tries to resolve pneumoencephalus quickly. Postoperatively the air in pneumoencephalus can be detected both by CT scan and plain X-ray. In the postoperative period if there is expansion of brain due to cerebral oedema (caused by surgical trauma), then the air pocket will be pressurised and may exaggerate the mass effect. Sometimes due to development of tension pneumoencephalus like the tension pneumothorax high pressure may be built-up in the air cavity. The tension penumoencephalus is suspected in patients who shows progressive deterioration of cerebral function or do not awaken following surgery.

N_2O anaesthesia is not contraindicated and can safely be continued until neurosurgery is completed, provided there is no VAE. This is because during surgery with open dura equilibration of N_2O with intracranial air occurs and does not increase ICP. Rather, when the dura is closed at the end of surgery, then the faster reabsorption of N_2O than air reduce the ICP or counter the rise of ICP caused by brain expansion (cerebral oedema) postoperatively.

Cardiovascular instability

Cardiovascular instability evidenced by hypotension is an another complication of sitting position during neurosurgery. It may be mild (when reduction of BP varies between 20 and 30 mmHg) or moderate (when reduction of BP is greater than 50 mmHg) and their incidence is 30% and 5% respectively. So, the preoperative history indicating coronary artery disease, heart failure and cerebrovascular occlusive disease, etc. are contraindication for sitting position during neurosurgery. There are many measures which can prevent the incidence of this hypotension. These are: (i) Slow changes in position from supine to sitting, titrated with the changes in BP, (ii) Use of vasopressor, (iii) Optimum preoperative hydration, (iv) Wrapping of legs with elastic bandages to counteract the gravitational shifting of intravascular blood volume into the lower extramities, and (v) use of antigravity compression device (G-suit). When pins are applied from the head holder to make the head steady in sitting position, then the abrupt elevation of arterial blood pressure occurs and this is due to the stimulus arising from the application of pin on head. The infiltration of the site of pin prick by local anaesthetic agent or addition of bolous dose of IV anaesthetic agent just before application of pin blunt this response of hypertension. However, some anaesthetists apply the pins from headholder to keep the head steady just prior to arrange the patient in sitting position and tries to counteract the hypertension caused by pinprick by hypotension caused by immediate sitting posture.

MONITORING DURING NEURO-ANAESTHESIA

Extensive monitoring during neuroanaesthesia is very important for better outcome, because neurosurgery is frequently complicated by rapid and large amount of blood loss, different positions of patient required for surgery has different special complications, surgeries especially those in the posterior fossa may involve cardiovascular instability, hypotension, etc. So, all the patients undergoing neurosurgery need: (i) a large bore intravenous cannula for rapid transfusion of crystalloid, colloid or blood, (ii) arterial cannulation for beat to beat monitoring of arterial blood

pressure, (iii) central venous cannulation for measurement of central venous pressure and diagnosis of VAE, (iv) cannulation of cerebral ventricle (usually lateral) for measurement of ICP from where CPP can be derived, etc. For correct measurement of CPP the pressure transducer should be placed at the level of the base of the skull for referencing the zero adjustment. In sitting position the pressure transducer which measures the MAP should be placed at the level of the base of the skull to know accurately the pressure by which the blood is forced into the brain. The importance of acurate measurement of CPP is that as little as 5 to 10 mmHg difference in pressure below the critical ischaemic threshold value may cause the brain damage if maintained for prolonged period. The central venous catheter provides measurement of intravascular volume status, diagnose air embolism and evacuate intravascular gas.

In addition to the above mentioned monitorings the measurement of SPO_2, core temperature (preferably nasopharyngeal or oesophageal) and $P_{ET}CO_2$ are also mandatory during neurosurgery. The measurement of O_2 saturation is very important, because the patients undergoing neurosurgical procedures are more sensitive to arterial hypoxaemia and it causes brain swelling (oedema) from hypoxaemia induced hyperaemia. Moreover, many of the conditions for which neurosurgery is shouted is related to focal cerebral ischaemia to which the addition of slight degree of hypoxaemia causes more danger. As it is previously stated that the control of P_aCO_2 is one of the factor of improving the quality of neuroanaesthesia, so the measurement of $P_{ET}CO_2$ is immense importance. It helps to set accurately the levels of ventilation and to monitor the occurance of VAE. At the beginning of surgery the difference between $P_{ET}CO_2$ and P_aCO_2 is measured from capnography and blood gas analysis and then it is repeated throughout the whole intraoperative procedures intermitently. Normally, this difference varies between 2 to 5 mmHg.

The measurement of body core temperature is also important because most of the neurosurgical procedures are prolonged and these prolonged surgeries are associated with large fall in body temperature. This hypothermia causes postoperative shivering producing hypoxaemia, increased intrathoracic pressure, ventilatory impairment, etc. Measurement of oxygen saturation (SPO_2) from internal jugular vein also provides a useful guide to the occurrence of global cerebral ischaemia. The normal range of value SPO_2 in the blood of internal jugular vein is 55 to 85%. Values above this range indicate hyperaemia and values below this range indicate that demand of O_2 is greater than supply of it.

For monitoring of venous air embolism the Doppler technique has already been described. But the transesophageal echocardiography (TEE) is 10 times more sensitive than Doppler technique in detecting VAE. This is because it provides visual representation of air bubble in the right and left side of the heart. It also can detect patent foramen ovale and VSD by detecting air in the left side of the heart. But the disadvantage of TEE is lack of specificity. This is because it can detect fat and blood emboli and cannot differentiate them from air.

Attempts are also taken for the electrophysiological monitoring of brain by analysis of EEG and evoked potential to assess the functional integrity of CNS. But the proper application of these monitoring system depends on the specific area from where the signal is picked up or monitoring is done and recognition of anaesthesia induced changes of this area (depth and dose related changes and changes related to physiological variables such as blood pressure, body temperature and respiratory gas tension).

EEG is very helpful for assessing the adequacy of cerebral perfusion and the depth of anaesthesia, especially during controlled hypotension in neurosurgery and in carotid endarterectomy. The changes in EEG are described as either depression or activation. The EEG depression is manifested by high voltage and low frequency curve and found in deep anaesthesia or cerebral damage. Whereas the EEG activation is manifested by low voltage and high frequency curve, and in found in light anaesthesia or surgical stimulation. Most of the inhalational and intravenous anaesthetic agents cause initial cerebral activation, followed by dose dependent depression of EEG. This is called the biphasic pattern of change in EEG. With the further increase of dose all these anaesthetic agents produce burst suppression with or without changes of EEG to isoelectric level (Electrical silence). With the high dose the desflurane and sevoflurane produce burst suppression, but not the electrical silence. Whereas the isoflurane causes isoelectric EEG. The barbiturates and propofol produce both burst suppression and isoelectric EEG at high doses. Whereas, opioids cause only monophasic dose dependent EEG changes, i.e. depression. Ketamine only causes activation of EEG which is consist of rhythmic high amplitude theta activity. With the increase in dose of ketamine this theta waves are replaced by high amplitude gamma and low amplitude beta waves.

Evoking the response of a nerve, either motor or sensory, after giving a stimulus is called the evoked potential. Analysis of this evoked potential for monitoring of nervous system is more complicated than EEG which does not need any stimulus for its evoking (and recording) and is the difference between the two. All the evoked potential have the latency period which are classified as short, intermediate and long. The evoked potential of intermediate and long latency period arise from the cortex, whereas the evoked potential of short latency period arise from the brainstem, spinal cord and spinal nerves. These short latency evoked potentials are least affected by anaesthetic agents, while the intermediate and long latency evoked potentials are

affected even by the subanaesthetic doses of inhalational and intravenous anaesthetic agents. But evoked potential with long latency period cannot be measured during intraoperative period. So, the short and intermediate latency evoked potential are only used during the intraoperative monitoring of neuroanaesthesia.

There are two types of evoked potential sensory and motor. The sensory evoked potential is again of two types—somatosensory (general sensation) and special (auditory and visual). The motor evoked potential is best useful to assess the adequacy of function of spinal cord during aortic surgery. Whereas the somato-sensory evoked potential is best useful to assess the functional integrity of sensory cortex and dorsal spinal columns carrying the sensory nerve fibres during surgeries on spine and aorta. Among the visual and auditory, the visual evoked potential are easily affected by anaesthetic agents, whereas the auditory evoked potential are the least and last to be affected. The visual evoked potential is usually used to monitor the upper brainstem and optic nerve during surgery on large pituitary tumours. The auditory evoked potential is used to monitor the 8th cranial nerve during surgery in posterior fossa.

All the anaesthetic agents, intravenous and inhalational, depresses (decrease in amplitude and increase in latency) the both motor and sensory evoked potential. But the effect of volatile agents are greater than the intravenous agents. However, among the intravenous anaesthetic agents the barbiturates do not depress the evoked potential, even when the EEG becomes isoelectric. Opioids depress the evoked potential by increasing the period latency, but not decreasing the amplitude.

ANAESTHETIC MANAGEMENT

Anaesthesia for surgery or diagnosis of different neuropathological conditions may be required in OT or in the imaging room for CT scan, MRI, or X-ray. Usually, these patients are very sick. So, proper assessment of these patients for fitness of anaesthesia is very important. In addition many special risk factors arising from neuropathological diseases for which surgery or radiodiagnosis and anaesthesia is shouted must be evaluated as if appropriate anaesthetic procedure can be taken. The most common neuropathological condition for which neuroanaesthesia and neurosurgery is shouted is the intracranial mass. It may be congenital or acquired. The acquired variety again may be again noninfective or infective (cyst or abscess), neoplastic (benign or malignant and primary or secondary), vascular (aneurysm, haematoma, arterio-venous malformation). The primary neoplastic tumour may arise from supporting tissues (meningioma), ependymal cells (ependymoma), glial cells (astrocytoma, medulloblastoma, glioblastoma) or pituitary gland (pituitary adenoma). Astrocytoma and medulloblastoma are the most common primary brain tumour in children. Whereas the most common acquired primary brain tumour in adult are meningioma, glioblastoma, pituitary adenoma. The secondary metastatic brain tumour is also common in adult and the primary sites are lungs and colon. Astrocytoma is a typically benign slow growing tumour in any cerebral hemisphere and medulloblastoma most often arise from cerebellum.

The signs and symptoms of patients with intracranial mass or any space occupying lesion presenting for neuroanaesthesia and surgery depends on the location and the growth rate of this mass or this space occupying lesion and the rate of increase of ICP. A benign slow growing tumour may be asymptomatic for long periods. Whereas a rapidly growing tumour present with a lot of symptoms and signs within a short period before anaesthesia and surgery. Increased ICP is the most likely explanation for signs and symptoms caused by a brain tumour. So, the common symptoms of intracranial mass are headache, nausea and vomiting, convulsions, focal neurological deficit, mental changes, disturbances of consciousness, etc. The supratentorial lesions usually relate to the cerebral hemisphere dysfunction and present as hemiplegia, convulsions, spatial disorientation, dysphagia, etc. Whereas the infratentorial lesions rapidly cause obstructive hydrocephalus and intracranial hypertension. Ataxia, nystagmus, dysarthria and abnormalities in respiratory pattern localize the lesions at posterior fossa.

Preoperative Assessment and Premedication

The preoperative evaluation of a patient with intracranial mass presented for neurosurgery and anaesthesia and anaesthesia is primarily directed towards the establishment of presence or absence of increased ICP and the assessment of neurological status using general and neurological examinations which consist of documentation of the patient's present level of consciousness, any cranial nerve dysfunction, any other gross focal neurological deficit, presence or absence of vomiting, mydriasis, palpilloedema, bradycardia, breathing disturbances, etc. This examination of patient should also be repeated in the OT just prior to the induction of anaesthesia. This is because any changes in patient's neurological status can occur overnight and/or precipitated by premedication. When the spinal surgery is planned, then the preoperative neurological assessment should be focussed on the function of the structures which is controlled by the segment of spinal cord that is involved in the surgical procedure (Table 49.2).

The neurosurgical patients are often dehydrated, hyperglycaemic and have the history of convulsions. Among the factors which contribute to this dehydration include: Decreased fluid intake due to reduced level of consciousness, use of diuretics (osmotic and loop) to reduce ICP, iatrogenic restriction of water input

Table 49.2: Glasgow coma scale

to reduce cerebral oedema, neuroendocrine abnormalities, etc. Patients are often hyperglycaemic because steroids are used in high doses to reduce ICP by decreasing brain oedema. So, the history of preoperative medication should be focussed on the use of diuretics, corticosteroids and the anticonvulsant medications. Laboratory investigations are also should be directed to rule out any electrolyte disturbances caused by diuretics, or hyperglycaemia induced by corticosteroid. Radiological investigations such as CT scan, MRI, straight X-ray must be reviewed to find out any shifting of brain tissue along the midline, the size of the ventricle and the presence or absence of cerebral oedema. The supratentorial lesions are usually presented to an anaesthetist with problems related to increased ICP due to cerebral oedema. Whereas the infratentorial lesions are presents to an anaesthetist with problems related to different surgical position during surgery (prone or sitting), the proximity of surgical site to vital brainstem structures involved in circulatory and respiratory controls, and hydrocephalus.

Premedication before neurosurgery depends on the level of consciousness of the patient. Usually, heavy sedation with or without narcotics is not appropriate in this group of patients. This is because respiratory depression causes increase in P_aCO_2 which may produce cerebral vasodilatation and further increase in ICP. But many patients who have no impairment in the level of consciousness is very apprehensive at the thought of having a neurosurgery and is associated with the increased level of plasma catecholamines. This causes undue hypertension which is obviously dangerous in respect to rupture of an unclipped aneurysm. So, for these group of patients premedication with proper sedation is appropriate which is provided by oral benzodiazepines in titrating doses. Patients who are waiting for spinal surgery due to disk prolapse suffer from acute pain. In this group of patients the use of strong analgesic (narcotic or non narcotic) as premedicant is very valuable.

Induction and Intubation

Induction and intubation are an art in neuroanaesthesia for patients with elevated ICP and compromised cerebral compliance. The aim of an anaesthetist during induction and intubation in neuroanaesthesia is to prevent the elevation of ICP at any cost by maintaining the arterial blood pressure at normal level and controlling ventilation to maintain P_aCO_2 between 30 and 35 mmHg. Arterial hypertension during induction and intubation increases CBF, CBV and ICP. Thus, it decreases the CPP and promotes cerebral ischaemia and oedema. However, excessive reduction of MAP also decreases CPP and impair cerebral function. Some neurosurgical conditions for which anaesthesia and surgery is shouted such as subarachnoid haemorrhage from ruptured aneurysm and head injury, etc. produce local cerebral ischaemia by vasospasm. So, in such circumstances hypotension should be avoided to prevent further increase in ischaemia. During induction the position of patient should be such that the drainage of blood from cerebral veins should not be obstructed.

Before induction all the measures (described before) are taken to reduce ICP, if it is already elevated. At all the stages of induction and intubation procedure the hypoxia, hypercarbia and vasodilating agents should also be avoided at any cost. For induction in neuroanaesthesia the most commonly used agents are thiopentone, propofol and etomidate. Thiopentone and propofol are very useful for this purpose, because both these agents reduce CMR with resultant reduction in CBF and ICP, particularly when an SOL with increased ICP is present. Etomidate also reduces CMR like thiopentone and propofol, but give better cardiovascular stability and is associated with greater rise in MAP during laryngoscopy and intubation than the other two inducing agents. All the cooperative and conscious patients are asked to hyperventilate for hypocapnia during preoxygenation before induction of anaesthesia. After induction the patient is also hyperventilated manually by mask and bag and this can also easily be done with the help of neuromuscular blocking agent which will facilitate later in intubation and will prevent coughing, bucking and straining, all of which will abruptly increase ICP.

In neuroanaesthesia the intubation is usually performed by nondepolarising muscle relaxant. Among these vecuronium, cisatracuranium, rocuronium, etc. provide the greater haemodynamic stability. Preoperative neurological impairment frequently leads to muscle wasting. When this degenerative process of muscle is of recent onset or is chronically progressive, then the use of succinylcholine for intubation is contraindicated. In such circumstances the depolarising agent causes development of severe hyperkalaemia and related arrythmia. Succinylcholine may also increase ICP during fasciculation. So, it is not generally used in neuroanaesthesia. But, succinylcholine is the agent of choice in neuroanaesthesia when there is probability of difficult intubation or risk of aspiration. Intubation should always be attempted, when the peak effect of muscle relaxant is reached and the muscular

relaxation is complete and maximum. Otherwise coughing, bucking, straining, etc. resulting from premature attempts of intubation prior to the establishment of deep muscular relaxation will cause increased ICP due to marked pressure response and increased intrathoracic pressure which impedes the cerebral venous drainage. Laryngoscopy and intubation is associated with acute surge of sympathetic overactivity causing acute hypertension and increased ICP. This acute pressure response during laryngescopy and intubation presents an obvious extra risk to neurosurgical patients with an arterial weakness such as in aneurysm or arteriovenous malformation for haemorrhage. There is also a great danger for patients with vascular tumour. This is because with the acute rise of blood pressure during intubation, the bulk of the tumour also rises causing increase in ICP. Indeed, there is also likely to be an increase in ICP in patients in whom there is no vascular tumour. This is because the rapidity of the pressure response due to intubation exceed the ability of cerebral circulation to be autoregulated (Fact file V).

So, this pressure response related to laryngescopy and intubation should be attenuated at any cost and is usually achieved by the use of any short acting opioids such as fentanyl in the dose of 2 to 3 µg/Kg or any of its congener just prior to induction and intubation. Other measures which attenuate this pressure response are the use of β-blockers (esmolol 0.5 to 1 µg/Kg), or lignocaine (0.5 to 1 mg/Kg IV 90 sec before intubation) or deepening the anaesthesia with the additional dose of thiopentone or propofol. This intubation related pressure response can also be attenuated by hyperventilation with low dose (less than 1 MAC) of isoflurane and sevoflurane. Due to the potentially deleterious effect on cerebral blood flow and ICP the vasodilators such as nitroprusside, calcium channel blockers, nitroglycerine, etc. should generally be avoided, till the dura is opened. The transient hypotension due to any cause during induction and intubation or during the course of anaesthesia is generally treated by incremental doses of vasopressors (noradrenaline, phenylephrine or ephedrine) rather than intravenous fluids.

FACT FILE- V

There are many causes for the subarachnoid haemorrhage (SAH) and among these causes the subarachnoid rupture of intracranial aneurysm (75 to 80%), rupture of arteriovenous malformation (5%), idiopathic (15%) and the rupture of vascular tumours account for the majority. Following SAH the neurological status of a patient is classified by Hunt Hess gradation. This is a follows:

Grade I	Minimum headache, slight nuchal rigidity, or asymptomatic.
Grade II	Moderate to severe headache and nuchal rigidity, cranial nerve palsy (often occulomotor).
Grade III `	Drowsiness, confusion, focal neurological deficit.
Grade IV	Stupor, hemiparesis, early decrebrate rigidity.
Grade V	Deep coma.

The rebleeding (principal cause of death) after spontaneous stoppage of bleeding from ruptured aneurysm and cerebral vasospasm (principal cause of ischaemia) are the two devastating early comlications of SAH following rupture of an aneurysm. So, for grades I to IV the early clipping by surgical intervention within 72 hours of the initial rupture of aneurysm is the management of choice. But, unfortunately this early treatment is technically more difficult due to oedema of tissue and there is less time to stabilise the patient with concomitant medical conditions. If early intervention is not possible, then surgery is often delayed till the risk of maximum vasospasm has decreased. A number of aneurysms are currently treated by endovascular coiling and these patients are very sick with greater number of medical comorbidities.

Cerebral vasospasm following SAH due to ruptured aneurysm or other reasons is the cause of delayed cerebral ischaemia. It can present as neurological continuum form drowsiness to stroke. The aetiology of this cerebal vasospasm following SAH is believed to be due to the presence of blood in subarachnoid space around the circle of Willis in the basal cisterns. So, the blood clot should be removed at the time of clipping of a ruptured aneurysm to decrease the incidence of vasospasm. The signs and symptoms of vasospasm is usually seen is 40% of patients after 5 to 15 days following rupture of an aneurysm. Angiography most early demonstrates vasospasm and surgery is delayed if it is suspected.

The cerebral vasospasm following SAH is usually treated by hypertensive, hypervolaemic haemodilution. This hypervolaemia is achieved by intravenous infusion of crystalloid or colloid solution, maintaining CVP between 8 to 12 mm of Hg and PCWP between 18 to 20 mm of Hg. This hypervolaemia will result in haemodilution with ideal haematocrit value between 27 to 30%. This reduces the viscosity of blood and improves the microcirculation of brain. After the clipping of aneurysm vasopressor (dopamine) is used to induce hypertension maintaining MAP at 20 to 30 mm of Hg above the baseline systolic pressure. This will also counteract cerebral vasospasm and improve circulation. Calcium channel blockers (nimodipine, nicardipine) have also been found to decrease the vasospasm if started within 4 days of SAH. They are not affective if vasospasm is already established.

Maintenance of Anaesthesia

During maintenance of neuroanaesthesia an anaesthetist must concentrate his mind on some important factors which will help him to provide good quality of anaesthesia and avoid many complications. These are: Maintenance of stable arterial BP (no hypertension, no hypotension), avoidance of factors that lead to increased ICP (such as hypoxia, hypercarbia, vasodilating drugs, cerebral venous obstruction), maintenance of adequate CPP, reduction of brain bulk (cerebral swelling), avoidance of cerebral ischaemia, etc. Now, to provide neuroanaesthesia of good quality by maintaining the above mentioned factors a deep plane of anaesthesia is required, sometimes with induced hypotension and hypothermia. But, on the otherhand after surgery rapid recovery of consciousness is essential, so that the level of response can properly be assessed to know the functional integrity of central nervous system. So, the neuroanaesthesia is essential to balance between these two-deep anaesthesia but quick recovery.

After opening the skull and dura (the most painful part of neurosurgery) the part

of neurosurgery which is only confined within the brain matter itself is painless unless the dura is stretched during the handling of brain tissue which is most likely to occur near the points of dural attachment. During neurosurgery the only painful part is the initial craniotomy which includes cutting of the skin, reflecting of the galea, drilling of the bar holes and stripping of the dura or periosteum from the bones. The another painful part of neurosurgery is when the head is held by a head clamp in which pins (mounted in a frame) are fixed into the outer table of the skull. This pain can be ameliorated by giving appropriate analgesic just before the pins are applied or infiltrating the skin by local anaesthetic agent. Hence, in neurosurgery even through the period of pain stimulus is fairly limited, still the neuromuscular blocking agents are used judiciously to maintain the deep plain of anaesthesia. This is because: (i) It helps to prevent any slight intraoperative movements, coughing, bucking and straining, etc. which increases the ICP; (ii) it helps to reduce the dose of anaesthetic agents and quick recovery, (iii) it helps in proper ventilation and reduction of ICP, etc.

Neuroanaesthesia is usually prolonged and lasts for several hours. It is frequently maintained by N_2O, opioids (fentanyl or any of its congener) and nondepolarising muscle relaxant. During the maintenance of neuro anaesthesia the airways, venous access and monitoring lines etc, should be well secured in such a way that an anaesthetist can completely rely on it up to the end of surgery as the clinical monitoring is not possible intraoperatively due to inaccessibility of the upper portion of the patient. Normally, during neuroanaesthesia an armoured ET tube is used to avoid kinking due to the different position of patient. It is fixed in such a fashion that the fixation tape or rope does not produce any pressure on the vein of head and neck and will leave the cerebral venous drainage free. Many anaesthetists like to support the ET tube by orrpharyngeal pack, especially if prone or sitting position is chosen. The placement of tube is also very critical. Because if it is placed too close to the carina, then slight flexion of patient's head and neck to facilitate the surgery will cause the tube to be advanced into any of the main bronchous – right or left. On the otherhand, if it is placed too close to the vocal cord, then slight extension of patient's head and neck will cause the tube to come out of the trachea (Fact file VI).

The intraoperative part of neuroanaesthsia is maintained by hyperventilation, keeping the P_aCO_2 between 30 and 35 mmHg, the cause of which is discussed before. But lowering of P_aCO_2 below 25 mmHg by more and more hyperventilation provides a little additional benefit. Rather it causes some disadvantages by shifting the O_2-Hb dissociation curve to the left which offset the release of O_2 from Hb in tissues. Thus, it causes tissue hypoxia. Hypocapnoea also causes cerebral vasoconstriction and cerebral ischaemia. Wrong ventilating patterns such as PEEP or rapid and small tidal volume ventilation should be avoided. This is because they cause high mean airway pressure which has adverse effect on ICP by increasing CVP. But in severely hypoxic patients due to lung pathology PEEP is used to maintain arterial oxygen tension at normal level to save the life.

All the volatile anaesthetic agents cause the cerebral vasodilatation and increase the cerebral blood flow in different proportions. Thus, they increase the bulk of brain tissue and is not used in neuroanaesthetic. But isoflurane, sevoflurane and desflurane are used by some anaesthetist in low doses below the value of 1 MAC to control the intraoperative persistent hypertension. In such circumstances it is thought that the gradual increase in hypertension may cause more danger than this small dose of volatile agents. However, some anaesthetists have opinion that volatile anaesthetic agents can be used successfully if hyperventilation is maintained at the same time. This is because increase in CBF caused by volatile anaesthetic agents is counteracted by the reduction of CBF caused by hyperventilation. Volatile anaesthetic agents affect the reactivity of cerebral vessels to the changes in P_aCO_2. This affect is greater with isoflurane than sevoflurane. So the decrease in ICP by hyperventilation is more successful in isoflurane anaesthesia than in sevoflurane and desflurane anaesthesia.

Blood loss in neurosurgery is usually less than 500 ml. But sometimes during handling of some vascular tumours such as meningioma, aneurysm, arteriovenous malformation, etc. rapid extensive blood loss may occur. Therefore, the ability of an anaesthetist to replace the blood which is lost and to control the arterial pressure

FACT FILE - VI

With the opening of skull by craniotomy the ICP falls to atmospheric pressure. But, if the factors which was responsible for the increased brain bulk due to increased ICP are still remain active, then it will be difficult for a surgeon to retract the swelled up brain during surgery. Sometimes surgery becomes impossible or increased pressure on oedematous brain by retractor cause neuronal damage. Moreover, if the swelling of brain is marked, then part of it protrudes through the dural incision and tight edges of dura will impair the CBF causing cerebral infarction. It is also true that if there is moderate swelling of brain, then closure of dura at the end of surgery will be difficult causing pressure underneath the dura by swelled brain which also result in cerebral infarction or sometimes the closure of dura becomes impossible.

Therefore, it is important to prevent the increase in brain bulk. This is possible by avoiding the factors (faulty) which help to increase the brain bulk (swelling of brain) and by using drugs which will reduce swelling of brain after it occurs.

The faulty factors which causes swelling of brain are:

1. Poor cerebral venous drainage
   a. Head down position
   b. Jugular venous obstruction
      ↑Intrathoracic pressure
      Neck rotation and tapes around neck
      Bad ventilator setup
   c. PEEP
2. Hypercapnia and hypoxia
3. Inadequate muscle relaxation
4. Arterial hypertension

is important. In neurosurgical patients hyperglycaemia is a common occurrence and this is due to the stress and the use of high doses of corticosteroids to reduce ICP. Hyperglycaemia causes increase in ischaemic brain injury. So, the intraoperative intravenous fluid management should be restricted to only glucose free isotonic crystalloid (normal saline) or colloid solution. But the large amount of crystaloid solutions is avoided in nueurosurgical patients, because it may precipitate severe brain oedema. So, the amount of intraoperative fluid replacement by crystalloid solution should be below the calculated required value. Colloid solutions are generally used to restore the intravascular volume deficit, whereas the isotonic crystalloid solutions are used as a maintenance fluid. Urethral catheterisation is essential during neuroanaesthesia, because it helps to know that diuresis has developed after the use of osmotic diuresis and it also helps in the intravascular fluid management.

Extubation and Emergence from Anaesthesia

At the end of surgery after the dressing of head and bandages are applied, the decision should be taken if the patient remains intubated or is extubated, on the basis of the intactness of the neurological function. If the decision is taken that the patient remains intubated, then more sedation and / or muscle relaxant is added. But if the extubation is decision, then it is a hard task to an anaesthetist. Because it should be very smooth and at any cost coughing, bucking or any other type of straining which may precipitate the intracranial haemorrhage or worsen the cerebral oedema by increasing ICP should be avoided. When the surgical team is moved away from the side of the patient by completing everything, then the anaesthetic team takes this site and the patient with the table is turned back to their original position. Then all the monitoring and the IV lines are checked, and the oropharyngeal pack is removed if it is placed. After that anaesthetic gases are turned off and attempts are made to have the patient breathe spontaneously by reversing the neuromuscular block. When this reverse is judged as complete and the patient is able to take full breathe, then a gentle laryngoscopy should be carried out and the pharynx is cleared quickly from secretion. After that the patient is extubated smoothly.

Some anaesthetists use lignocaine (1 to 1.5 mg/Kg IV) or small dose of thiopentone (20 to 40 mg) or small dose of propofol (20 to 30 mg) 90 seconds before suctioning, in an attempt to suppress the coughing and bucking during extubation. Some anaesthetists use esmolol, verapamil (0.1 mg/Kg) and / or remifentanil (1 µg/Kg) to attenuate the cardiovascular responses during extubation. After extubation rapid awakening and rapid return of cerebral function is desirable, because it helps to assess the neurological function. However, delayed awakening may occur and is due to the overdose of opioid or prolonged use of volatile anaesthetic agents. Postoperative pain after neurosurgery is less severe than the other form of surgeries. So, analgesics should be given very carefully and the overdose of it may confuse the neurological assessment of patient. However, some patients experience severe postoperative pain, especially those who have undergone frontal craniotomy. In such patients adequate analgesia is needed to avoid over sympathetic activity. In the postoperative period after neurosurgery most patients are sent to ICU for close intensive monitoring of neurological, cardiovascular and respiratory function. When the surgery is finished and craniotomy is closed, then some air is frequently left in cranial cavity. This is seen in all the scans or X-ray which are taken on the first postoperative day. Among these 2/3 collections are judged as moderate or large. This incidence comes down to 70% at the end of the first week following surgery. At the end of the 2nd postoperative week 10% collection of air is judged to be moderate and large.

SOME SPECIAL NEUROSURGICAL PROCEDURES

Cerebral Aneurysm

The cerebral vascular aneurysms are usually located at the bifurcations of major cerebral vessels at the base of the brain (circle of Willis) and rupture of it is the most common cause of non-traumatic intracranial haemorrhage. The cerebral aneurysms are diagnosed both in ruptured or unruptured phases. In ruptured aneurysm the bleeding is manifested as subarachnoid, epidural or intracranial haemorrhage and among all the causes of subarachnoid haemorrhage (SAH) the rupture of cerebral aneurysm in subarachnoid space is the most common. The aneurysm is usually manifested as a single one and of different sizes. But only 10 to 20% of patients have more than one aneurysm and those which are larger than 5 to 7 mm in diameter are considered for elective surgical obliteration if it is diagnosed in unruptured state.

The acute mortality following rupture of an aneurysm is very high. Of those that survive from the initial acute insult of haemorrhage, about 10% subsequently die within one week and about next half of the survivors die within next 3 months after the onset of rupture. Further, among these survivors half of the patient have major neurological deficits. Despite successful surgical clipping of a ruptured aneurysm, 1/3 of the patients do not get back the preruptured quality of life. The major causes of this high rate of morbidity and mortality following subarachnoid haemorrhage from ruptured aneurysm are: rebleeding, ischaemic cerebral injury, infarction due to cerebral vasospasm which is the characteristic of SAH, development of hydrocephalus, etc. The cerebral vasospasm following rupture of an aneurysm in subarachnoid space is probably due to the breakdown products of oxyhaemoglobin which causes scavenging

of nitric oxide from the wall of blood vessels and thus block the vasodilating effect of it. The development of hydrocephalus due to the rupture of cerebral aneurysm in subarachnoid space is caused by the interference of absorption of CSF by RBC. The cerebral vasospasm occurs in 25 to 30% of patients and is the major cause of morbidity and mortality following rupture of an cerebral aneurysm in subarachnoid space. So, the Ca^{2+} channel antagonists (nimodipine) are used to prevent this cerebral vasospasm and reduce the morbidity and mortality of SAH following ruptured aneurysm (Fig. 49.9).

Usually most of the patients suffering from aneurysm of cerebral vessels present after rupture. But before rupture the prodromal signs and symptoms of an undiagnosed aneurysm are: Headache, third cranial nerve palsy (most common), visual field defect, convulsion, trigeminal neuralgia, hypothalamic pituitary dysfunction, etc. These are due to the local compression of nerve tissues by expanding aneurysm. The unruptured aneurysm are usually diagnosed incidentally by CT angiography, MRI angiography or simple angiography. The treatment of unruptured intracranial aneurysm are elective surgical clipping following craniotomy or obliteration of it by interventional radiology. These patients are usually of good health and aged between 40 to 50 years.

On the other hand, the ruptured aneurysm presents with acute signs and symptoms which depends on the amount of blood in subarachnoid space. Minor bleeding in the subarachnoid space presents only with slight nuchal rigidity, headache and other minor signs of meningeal irritation. The transient increase in ICP in this type of subarachnoid haemorrhage reduces the pressure gradient across the ruptured aneurysm and subarachnoid space and promotes the tamponade effect on bleeding. So, bleeding from aneurysm is stopped and partial to complete neurological functional recovery may occur spontaneously with this type of subarachnoid haemorrhage. However, more severe bleeding in subarachnoid space may lead to tremendous increase in ICP formation of clot, hrniation of brain, unconsciousness and rapid demise. All these are due to the rapid development of severe intracranial hypertension, precipitous fall in CPP and cerebral ischaemia. These acutely comatosed patients are managed in intensive care unit by proper maintenance of airway, ventilation, oxygenation, etc. In this life threatening condition medical intracranial decompression therapy is instituated immediately which is followed by craniotomy, evacuation of clot and then control of bleeding by clipping of the ruptured aneurysm. However, the lowering of ICP by medical decompression therapy may increase the chance of rebleeding from a ruptured anewrysm by withdrawing the tamponade effect. But it should be kept in mind that this chance of rebleeding should be balanced against the risk of death caused by the extremely high ICP and ischaemia of brain, if ICP is not reduced. So, the general opinion is that ICP should always be reduced by medical intracranial decompression thereby before craniotomy aimed for the clipping of aneurysm (Fact file VII).

The aim of neurosurgery on patients who survive the immediate insult resulting from the acute huge intracranial bleeding due to ruptured aneurysm is to exsanguinate the haemorrhage from the rupture site and prevention of cerebral vasospasm. It is evident that cerebral vasospasm occurs in about 70% of subarachnoid haemorrhage due to the rupture of aneurysm and cerebral ischaemia and/or infarction of brain tissue due to this cerebral vasospasm is

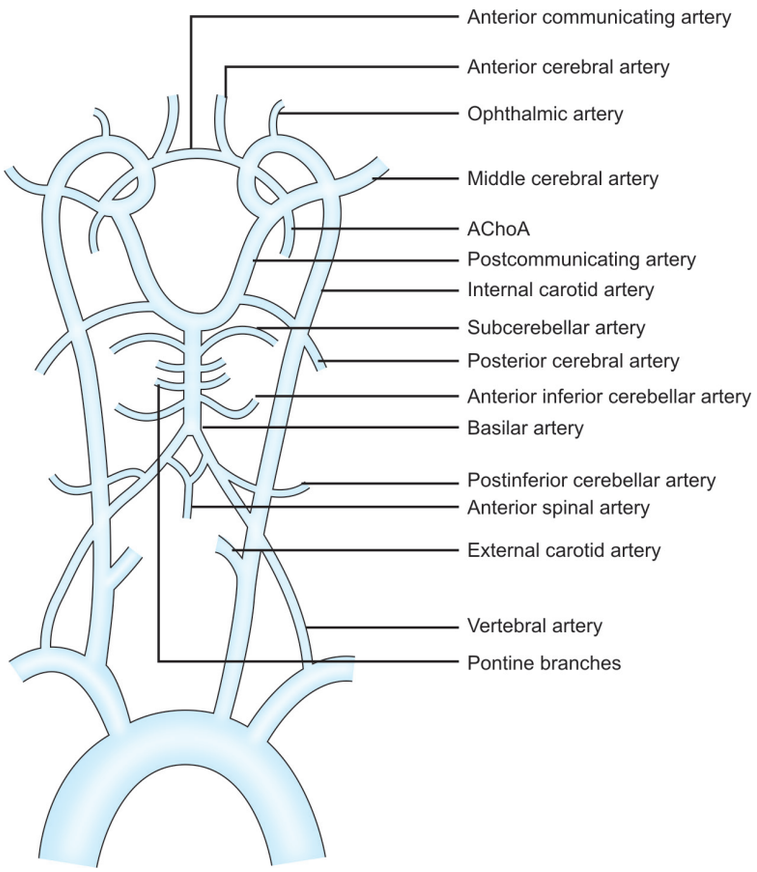

Fig. 49.9: Cerebral arteries

FACT FILE- VII

Arterial supply of brain

The prinicipal arterial flow to the brain in human is by four arteries: two internal carotid arteries and two vertebral arteries. The two vertebral arteries join together at the lower border of pons to form the basilar artery. At the base of the brain the branches of these four main arteries are interconnected forming an arterial circle named the circle of Willis. These interconnection between the branches of four main arteries helps to equalise the pressure in arteries of the two sides. The internal carotid artery, the basilar artery and the vertebral artery give the following branches at the base of the brain.

A. Internal carotid artery:
   Opthalmic a, anterior cerebral a, middle cerebral a, posterior communicating a, anterior choroidal a.
B. Basilar artery:
   Pontine a, labyrinthine a, anterior inferior cerebellar a, superior cerebellar a, posterior cerebral a.
C. Vertebral artery:
   Meningeal a, anterior spinal a, posterior spinal a, posterior inferior cerebellar a, medullary a.

Substances injected into one carotid artery are distributed almost exclusively to the cerebal hemisphere on the same side. This is due to the equal pressure on both sides. Even when it is present the anastomotic channels in the circuit do not permit a very large flow between the two sides. So, obstruction in one carotid artery often causes ischaemia on the same side. There are precapillary anastomoses between the cerebral arterioles. But flow through these colateral channels is generally insufficient to maintain the circulation and prevent the infarction when a cerebral artery is occluded.

responsible for the delayed neurological deficit. If the patient is conscious and ICP is normal, then he is sedated until the anaesthesia is induced. This sedation will help to prevent the rebleeding from ruptured aneurysm by lowering BP. But if the patient is not conscious, then obviously there is no question of sedation. During intraoperative management of aneurysm every attempts should be made to prevent the bleeding or rebleeding (if it is sealed) from the unruptured or ruptured aneurysm. So, arterial blood pressure should be controlled accurately. This is accomplished by avoiding the precipitous increase in arterial BP during laryngoscopy and intubation. Rebleeding from ruptured aneurysm may also be prevented by maintaining a low intra aneurysmal to intracranial transmural pressure gradient, but not much lowering the ICP which acts as a tamponade. The intraoperative severe hypotension (except when induced hypotension is decided) also should be avoided which will aggravate the cerebral ischaemia, already caused by cerebral vasospasm. The patients with subarachnoid haemorrhage from ruptured aneurysm and increased ICP are prone to hypovolaemia and hypotension. So, the liberalization of intake of IV fluid reduces the cerebral ischaemia and mortality due to vasospasm without altering the risk of rebleeding. Thus, restoration of adequate blood volume preoperatively is important, not only for the intraoperative cardiovascular stability, but also for the improvement of neurological function, prior to the neuroanaesthesia and surgery.

During preoperative assessment before neurosurgery and anaesthesia for control of bleeding from ruptured aneurysm by clipping, in addition to neurological finding evaluation of patient should also include the search for other coexisting diseases that may be contraindication for the institution of elective hypotension in the intraoperative period which will facilitate the surgery. The preoperative presence of severe hypertension, renal dysfunction, cardiac diseases, etc may be contraindication to the induced hypotension. The subarachnoid haemorrhage from ruptured aneurysm are also commonly associated with sympathetic overactivity with abnormalities in ECG and arrhythmia. So, these do not necessarily always reflect the underlying cardiac diseases and do not prevent the institution of induced hypotension.

Reduction of MAP in induced hypotension decreases the bleeding from ruptured aneurysm. Thus, it reduces the blood loss, improves the visualization of bleeding site from ruptured anewrysm and facilitates the surgical clipping. Hence, the elective induced hypotension but not up to that level which will cause cerebral ischaemia is useful for aneurysmal surgery. But, it is not without danger, because it may cause ischaemic damage to the brain and other organs. It has been suggested that the MAP should not be reduced more than 50 mm of Hg from the preexisting MAP level. This is because chronic arterial hypertension shifts the hypotensive threshold level for autoregulation of CBF to the right. So, the maximum lower limit of this reduction of BP to which a hypertensive patient can tolerate without producing any cerebral ischaemia is adjusted upward. In addition to recognizing the lower limit of autoregulation, it is also important to understand that this autoregulation takes times. Thus, the slow and controlled induced hypotension is safer than the rapid induction of hypotension.

Sometimes, more profound induced hypotension is required than it is recommended for facilitation of aneurysmal surgery. In such situation when more profound hypotension is used, then their duration should be restricted as less as possible to reduce the ischaemic damage of brain tissue. Recently, the induced hypotension has fallen into disuse. This is because patients with cerebral vasospasm due to subarachnoid haemorrhage have disorder in autoregulation to CBF, causing reduction of CPP and ischaemia of brain. So, induced hypotension in such patients aggravates this ischaemia. During surgery the pressure exerted by the retractors further decreases the local CPP and aggravates ischaemia. So, moderate hypotension combined with intermittent unilateral or bilateral manual carotid artery compression better facilitates the surgery by reducing the intracranial bleeding dramatically. Thus, it avoids the dangers of induced hypotension. Further, the combination of slightly head up position and use of isoflurane in low doses (<1 MAC) enhances the effects of any of the commonly used hypotensive agents and is better than induced hypotension. Recently,

due to some technical improvements and introduction of temporary vascular clips it has enabled the surgeons to cut down the blood flow to the surgical site temporarily during aneurysmal surgery with out applying induced hypotension. On the contrary, the arterial blood pressure of patient is kept at normal or slightly at higher level to protect cerebral perfusion during aneurysmal clipping. During prolonged vascular occlusion or induced excessive hypotension the administration of thiopentone and mild hypothermia may protect the brain from ischaemia. Rarely, for surgery on aneurysm arising from large basilar artery total hypothermic circulatory arrest is used

Carotid Endarterectomy (CEA)

Carotid artery stenosis may be symptomatic or asymptomatic. Asymptomatic carotid stenosis, diagnosed accidentaly by bruits during auscultation with stethoscope, are heard in 5 to 10% of general population. The complication of carotid artery stenosis are mainly TIA and stroke. The CEA is the surgical treatment of both sympmatic and asymptomatic carotid artery stenosis when its lumen's diameter is <70% (1.5 cm). Asymptomatic patients (diagnosed by bruits) are also treated, because they have also the high incidence rate of TIA and stroke than the patient who are without bruits.

Stenosis in carotid artery also induces autoregulation in CBF. So, in an effort to maintain CBF due to the drop of pressure beyond the obstruction the cerebral vasculatures dilate. As the degree of stenosis progresses the cerebral vasculature dilates maximally to a point beyond which they lose the ability of autoregualtion. Then with the further progress of stenosis the CBF will become passive and arterial pressure dependent. So, it is important to maintain intraoperative arterial BP in a patient during CEA operation, because they have no autoregulation to counter the anaesthesia induced hypotension. The normal CBF inhuman is 50 to 60 ml/100 gm/min of tissue (15% of cardicac output) and requirement of O_2 for cerebral metabolism is 3 to 4 ml/100gm/min (20% of whole body O_2 consumption). The reduction of CBF at which level the ischaemia occurs (that is evidenced by EEG) is termed as the critical regional cerebral blood flow (rCBF) and is 18 to 20 ml/min. The surgery of CEA does not cause much fluid shift. So, the introduction of pulmonary artery catheter is not necessary if not otherwise indicated for other causes such as pulmonary hypertension, low ventricular function etc. However, intraarterial pressure monitoring is mandatory during CEA to maintain autoregulation deprived pressure dependent CBF.

During CEA operation the stump pressure which is measured immediately cephalad to the carotid cross clamp does not always provide the reliable information regarding the status of cerebral perfusion. Because it is found that the brain in some patients with stump pressure less than 50 to 60 mm of Hg are adequately perfused, whereas the brain in some patients with adequate stump pressure have suffered cerebral ischaemia. So, in CEA the intraoperative monitoring by evoked potential to judge the integrity of cerebral function, jugular venous or transconjunctival O_2 saturation to know the hyporia at nerve tissue level, transdoppler, echocardiography etc provides better method of monitoring of cerebral perfusion. Although EEG is a highly selective and early indicator of global cortical ischaemia, but it is not applicable in CEA operation. So, no data shows that monitoring by EEG during CEA operation result in better outcome.

The CEA can be performed under both regional and general anaesthesia and these two procedures have both advantages and disadvantages. But the ultimate choice between the RA and GA depends on the patient's stability, surgeon and patient's preference, and surgeon and anaesthetist's experience. The main advantage of doing CEA under RA is the ability to evaluate the adequacy of cerebral perfusion by continuous neurological assessment in a awake cooperative patient. But the disadvantage of RA is that if the patient develops cerebral ischaemia then he or she may lead to disorientation, inadequate ventilation, hypoxia and disturbed surgical field. In such setting immediate rescue induction, followed by ET intubation and institution of GA which provide maximum cerebral protection may prove difficult. The advantages of GA are good control of airway, a quiet undisturbed operation field and ability to provide maximum cerebral protection if ischaemia develops. But the main disadvantages of GA is loss of continuous neurological evaluation like of an awake patient (Fact file VIII).

FACT FILE- VIII

A. Modulation of arginine-NO-GMP system is the central to the changes in cerebral vascular tone, caused by several processes. NO which is responsible for vasodilatation caused by Na-nitroprusside is the mediator of cerebral vasodilatation caused by hypercapnia, ↑CMR, volatile agents and neurogenic stimulation.

B. In normal subject the initial increase in CBV does not result in significant elevation of ICP. This is because there is general tendency for compensatory adjustment by other intracranial compartment such translocation of venous blood and CSF to extracranial vessels, shifting of CSF from cranium to spinal space.

C. Hyperventilation has circulatory side effects requiring consideration. Shallow rapid positive pressure ventilation actually increase mean airway pressure which impedes cerebral venous drainage and increase ICP. Similarly PEEP elevate ICP and reduce MAP. Whereas, ventilation with long expiratory periods result in low mean airway pressure and ↓ICP during hyperventilation. Hypocapnia has no effect on CSF secretion and absorption. Besides reducing ICP, extreme alkalosis caused by hyperventilation impair dissociation of O_2 from Hb at tissue by shifting the curve to left. Respiratory alkalosis also increase O_2 consumption and in the presnce of pulmonary shunting this can reduce arterial oxygenation. Hypocapnia also reduce coronary blood flow. Hypocapnia also lower inotropic sympathetic influence on heart and reduce arterial BP and CPP.
