In a hospital or extended-care setting it is difficult to provide patients with the time needed to rest and sleep. The most effective treatment for sleep disturbances is to eliminate factors that disrupt the sleep pattern. You need to plan care to avoid waking patients for nonessential tasks. Do this by scheduling assessments, treatments, procedures, and routines for times when patients are awake. For example, if a patient's physical condition has been stable, avoid waking him or her to check vital signs, unless ordered. Allowing patients to determine the timing and methods of delivery of basic care measures promotes rest. Do not give baths and routine hygiene measures during the night for nursing convenience. Draw blood samples at a time when the patient is awake. Unless maintaining the therapeutic blood level of a drug is essential, give medications during waking hours. Work with the radiology department and other support services to schedule diagnostic studies and therapies at intervals that allow patients time for rest. Always try to provide the patient with 2 to 3 hours of uninterrupted sleep during the night.

When the patient's condition demands more frequent monitoring, plan activities to allow extended rest periods. A nurse instructs assistive personnel in the coordination of patient care to reduce patient disturbances. This means planning activities so that the patient has as long as an hour or more to rest quietly rather than having a nurse or other personnel return to the room every few minutes. For example, if a patient needs frequent dressing changes, is receiving intravenous therapy, and has drainage tubes from several sites, do not make a separate trip into the room to check each problem. Instead use a single visit to perform all three tasks. Become the patient's advocate for promoting optimal sleep. This means becoming a gatekeeper by postponing or rescheduling visits by family or by questioning the frequency of certain procedures.

Promoting Safety

Patients with OSA are at risk for complications while in the hospital. Surgery and anesthesia disrupt normal sleep patterns (see [Chapter 50](#)). After surgery patients reach deep levels of REM sleep. This deep sleep causes muscle relaxation that leads to OSA. Patients with OSA who are given opioid analgesics after surgery have an increased risk of developing

airway obstruction because the medications suppress normal arousal mechanisms. These patients often need ventilator support in the postoperative period because of the increased risk of respiratory complications. Monitor the patient's airway, respiratory rate and depth, and breath sounds frequently after surgery.

Recommend lifestyle changes to patients with OSA, changes such as sleep hygiene, alcohol moderation, smoking cessation, and a weight-loss program (McNicholas, 2017). Teach the patient to elevate the head of the bed and use a side or prone position for sleep. Use pillows to prevent a supine position.

If patients normally use a continuous positive airway pressure (CPAP) machine at home because of sleep apnea, it is important that they bring their home equipment with them to the hospital and use it every night. Check to make sure the mask fits snugly and is put on correctly so that the positive pressure is maintained (Schub, 2016). In patients with sleep apnea who have surgery and receive general anesthesia, the anesthesia in combination with pain medications used after surgery reduces the patient's defenses against airway obstruction. After surgery the patient achieves very deep levels of REM sleep that lead to muscle relaxation and airway obstruction. Use pain medication carefully in these patients. These patients need ventilator support in the postoperative period because OSA is linked to increased postoperative respiratory complications. Monitor the patient's breathing and oxygen saturation levels regularly (see Chapter 29). Notify the health care provider right away if the patient is difficult to arouse or is having trouble breathing.

Patients who experience EDS can fall asleep while sitting up in a chair or wheelchair. Position patients so that they do not fall out of the chair when sleeping. Elevating their feet on an ottoman or small bench may help to position them safely. A pillow placed in the patient's lap offers some support. If a patient enjoys leaning over an over-bed table while sitting in a chair, be sure that the table is locked and secure. Do not use safety belts because they are considered restraints (see Chapter 27).

Stress Reduction

Patients who are hospitalized for extensive diagnostic testing often have difficulty resting or sleeping because of uncertainty about their health. Giving patients control over their health care minimizes uncertainty and anxiety. Providing information about the purpose of procedures and routines and answering questions gives patients the peace of mind needed to rest or fall asleep. Take time to sit and talk with your patients who are

unable to sleep to determine the factors keeping them awake. Providing comfort measures such as back rubs also help patients relax more thoroughly. If a sedative is indicated, confer with the patient's health care provider to be sure that the lowest dose is used initially. Discontinuing a sedative as soon as possible prevents a dependence that seriously disrupts the normal sleep cycle. Older adults' metabolism of drugs is slow, making them more vulnerable to the side effects of sedatives, hypnotics, antianxiety drugs, or analgesics.

Restorative or Continuing Care

The nursing interventions implemented in the acute care setting are also used in the restorative or continuing care environment. Controlling the environment, especially noise; establishing periods of rest and sleep; and promoting comfort are important considerations. Nursing interventions related to stress reduction and controlling physiological disturbances are also implemented in these settings. Helping a patient achieve restful sleep in this environment sometimes takes time.

Maintaining Activity

Limit the time residents spend in bed whenever possible. In long-term care settings, serve meals in the resident dining area. Make sure residents are up in a chair for meals and for personal hygiene activities. It is also important to keep the residents involved in planned social activities (e.g., card playing or arts and crafts). Regular exercise keeps people active and stimulated. It is also ideal to limit daytime napping to 30 minutes or less. Short naps taken in the midafternoon increase alertness and cognitive ability. Research has shown that exposure to natural sunlight for 2 hours a day improved the sleep quality of residents in a nursing home ([Duzgun and Akyol, 2017](#)).

Residents with dementia often have disrupted sleep-wake cycles. They often become easily fatigued and experience periods of insomnia ([Meiner and Yeager, 2019](#)). In this situation shorten activities and visits to allow patients to maintain an adequate energy level. If a patient wakes up during the night, keeping the lights at a low level and using soothing techniques such as quiet music or a back rub promote returning to sleep.

Controlling Physiological Disturbances

As a nurse you learn to control symptoms of physical illness that disrupt sleep. For example, a patient with respiratory abnormalities sleeps with

two pillows or in a semi-sitting position to ease the effort to breathe. He or she benefits from taking prescribed bronchodilators before sleep to prevent airway obstruction. A patient with a hiatal hernia also needs special care. After meals he or she often experiences a burning sensation as a result of gastric reflux. To prevent sleep disturbances, have the patient eat a small meal several hours before bedtime and sleep in a semi-sitting position. Time medications to relieve pain, nausea, or other recurrent symptoms so that the drug takes effect at bedtime. Remove or change any irritants against the patient's skin such as moist dressings or drainage tubes.

Pharmacological Approaches

The liberal use of drugs to manage insomnia is quite common in American culture. CNS stimulants such as amphetamines, caffeine, nicotine, terbutaline, theophylline, and modafinil need to be used sparingly and under medical management (Burchum and Rosenthal, 2019). In addition, withdrawal from CNS depressants such as alcohol, barbiturates, tricyclic antidepressants (amitriptyline, imipramine, and doxepin), and triazolam causes insomnia. Consult with pharmacists and health care providers about managing doses.

Medications that induce sleep are called **hypnotics**. **Sedatives** are medications that produce a calming or soothing effect (Burchum and Rosenthal, 2019). A patient who takes sleep medications needs to know about their proper use and their risks and possible side effects. Long-term use of anti-anxiety, sedative, or hypnotic agents disrupts sleep and leads to more serious problems. The FDA requires that the product labels of all sleep medications contain safety information related to the potential adverse effects of severe allergic reactions; severe facial swelling; and complex sleep behaviors such as sleep-driving, making phone calls, and preparing and eating food while asleep (USFDA, 2018).

Benzodiazepines and benzodiazepine-like drugs are commonly used to treat sleep problems and are intended for short-term use (Avidan and Neubauer, 2017). The benzodiazepine-like drugs are the treatment of choice for insomnia because of improved efficacy and safety of use (Burchum and Rosenthal, 2019). Experts recommend a low dose of a short-acting medication such as zolpidem (Ambien) for short-term use (no longer than 2 to 3 weeks) (Burchum and Rosenthal, 2019). These drugs cause fewer problems with dependence and abuse and fewer rebound insomnia and hangover effects than benzodiazepines.

The benzodiazepines cause relaxation, antianxiety, and hypnotic effects by facilitating the action of neurons in the CNS that suppress responsiveness to stimulation, thereby decreasing levels of arousal (Burchum and Rosenthal, 2019). Short-acting benzodiazepines (e.g., oxazepam, lorazepam, or temazepam) at the lowest possible dose for short-term treatment of insomnia are recommended. Initial doses are small, and increments are added gradually, based on patient response, for a limited time. Warn patients not to take more than the prescribed dose, especially if the medication seems to become less effective after initial use. The use of benzodiazepines in older adults is potentially dangerous because of the tendency of the drugs to remain active in the body for a longer time. As a result, they also cause respiratory depression; next-day sedation; amnesia; rebound insomnia; and impaired motor functioning and coordination, which leads to an increased risk of falls (Picton et al., 2018). If older patients who were recently continent, ambulatory, and alert become incontinent or confused and/or demonstrate impaired mobility, the use of benzodiazepines needs to be considered as a possible cause.

Administer benzodiazepines cautiously to children under 12 years of age. These medications are contraindicated in infants less than 6 months old. Patients who are pregnant need to avoid them because their use is associated with risk of congenital anomalies. Mothers who are breastfeeding do not receive the drugs because they are excreted in breast milk. Raise these issues with patients' health care providers if you are concerned about the safety of a prescribed medication.

Trazodone is a serotonin antagonist and reuptake inhibitor (SARI) antidepressant often used in patients with depression or anxiety and insomnia. The most common side effects are daytime grogginess and orthostatic hypotension. Low-dose trazodone is often used as an alternative to benzodiazepines, especially in older patients.

Regular use of any sleep medication often leads to tolerance and withdrawal. Rebound insomnia is a problem after stopping a medication, particularly the benzodiazepines (Avidan and Neubauer, 2017). Immediately administering a sleeping medication when a hospitalized patient complains of being unable to sleep does the patient more harm than good. Consider alternative approaches to promote sleep first. Routine monitoring of patient response to sleeping medications is important.

• Evaluation

Through the Patient's Eyes

The patient is the source for evaluating whether expectations about sleep are met. Each patient has a unique need for sleep and rest. He or she is the only one who knows whether sleep problems are improved and which interventions or therapies are most successful in promoting sleep (Fig. 43.6). It is important to ask the patient if his or her sleep needs have been met. For example, ask the patient, "Are you feeling more rested?" or "Can you tell me if you believe that we've done all we can to help improve your sleep?" or "Which interventions have been most effective in helping you sleep?" If expectations have not been met, you need to spend more time trying to understand the patient's needs and preferences. Working closely with the patient and bed partner enables you to redefine expectations that can be met realistically within the limits of the patient's condition and treatment.

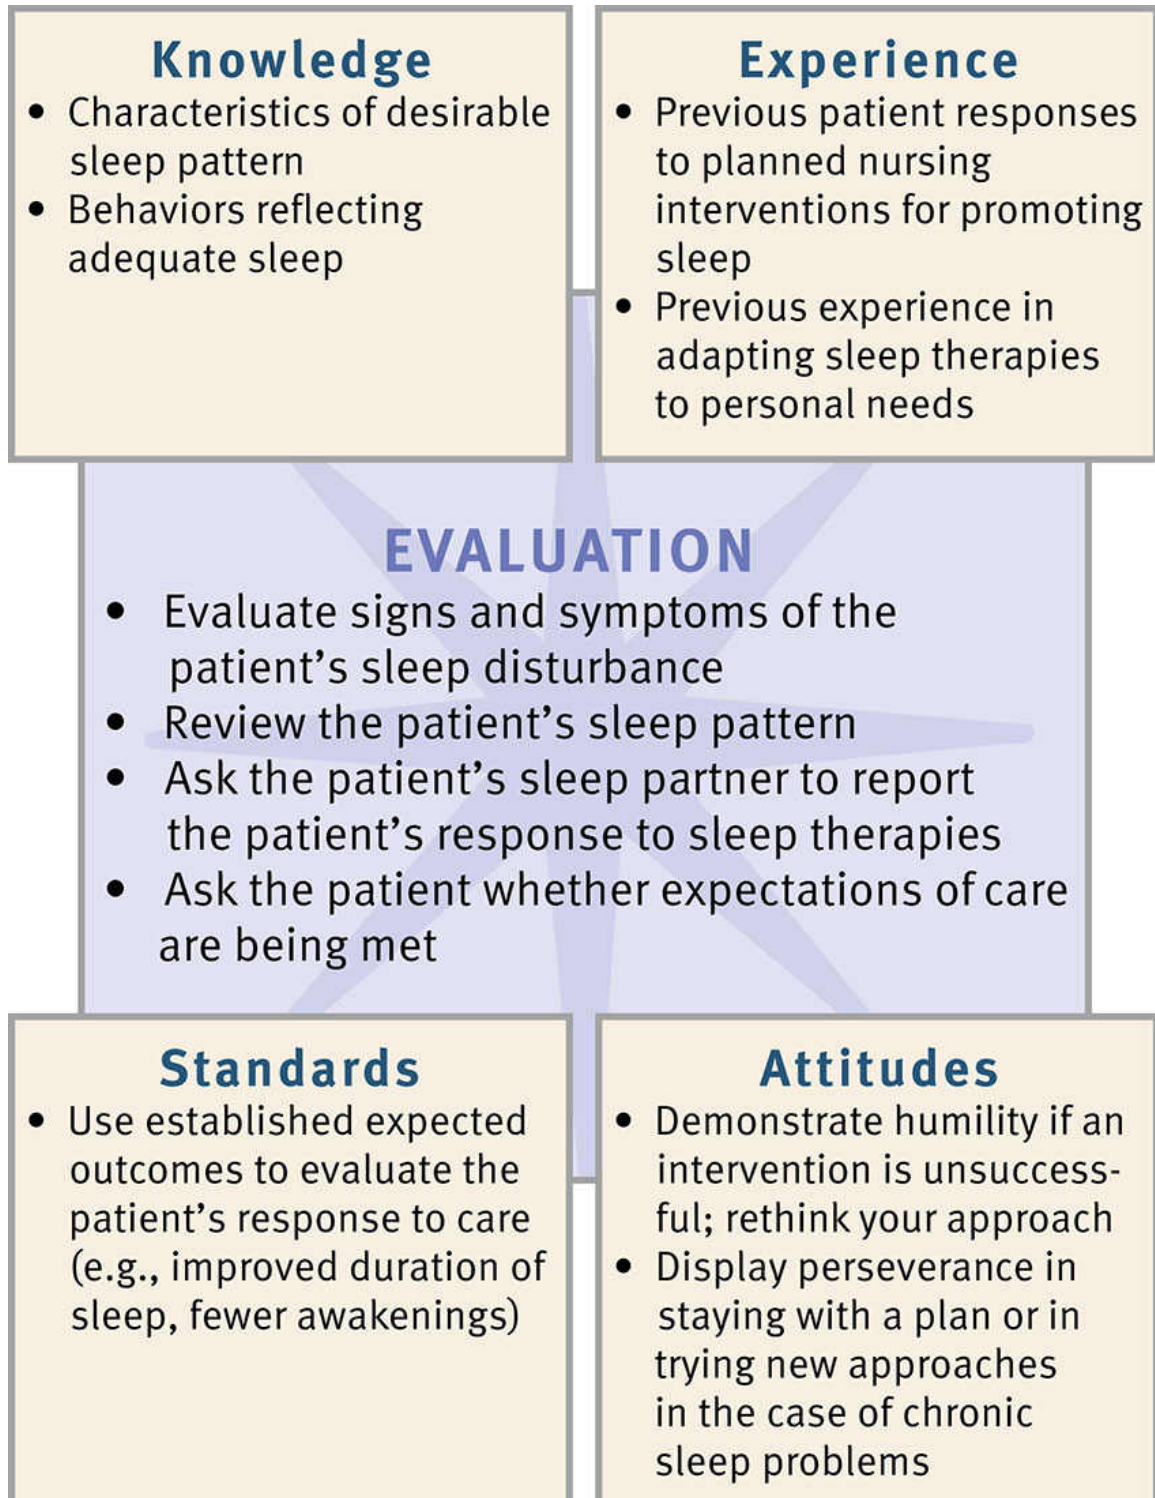

FIG. 43.6 Critical thinking model for sleep evaluation.

Patient Outcomes

To evaluate the effectiveness of your nursing care, make comparisons with baseline assessment data to evaluate whether your patient's sleep has improved. Determine whether expected outcomes have been met. Use evaluative measures shortly after a therapy has been implemented (e.g., observing whether a patient falls asleep after reducing noise and darkening a room). Use other evaluative measures after a patient wakes from sleep (e.g., asking him or her to describe the number of awakenings during the previous night). The patient and bed partner usually provide accurate evaluative information. Over longer periods use assessment tools such as the visual analog or sleep-rating scale to determine whether sleep has progressively improved or changed.

Also evaluate the level of understanding that patients or family caregivers gain after receiving instruction in sleep habits. You measure adherence to these practices during a home visit, when you are able to observe the environment. When expected outcomes are not met, revise the nursing measures or expected outcomes based on the patient's needs or preferences. When outcomes are not met, ask questions such as:

- Are you able to fall asleep within 20 minutes of getting in bed?
- Describe how well you sleep when you exercise.
- Does the use of quiet music at bedtime help you to relax?
- Do you feel rested when you wake up?

If you have successfully developed a good relationship with a patient and a therapeutic plan of care, subtle behaviors often indicate the level of the patient's satisfaction. Note the absence of signs of sleep problems such as lethargy, frequent yawning, or position changes in the patient. You are effective in promoting rest and sleep if the patient's goals and expectations are met.

Key Points

- The 24-hour sleep-wake cycle is a circadian rhythm that influences physiological function and behavior.
- The control and regulation of sleep depend on a balance among regulators within the CNS.

- During a typical night's sleep, a person passes through four to five complete sleep cycles. Each sleep cycle contains three NREM stages of sleep and a period of REM sleep; time in each stage varies.
- Sleep provides physiological and psychological restoration.
- Sleep requirements vary by age, with neonates sleeping on average 16 hours a day and older adults needing 7 to 8 hours of sleep a night.
- The hectic pace of a person's lifestyle, emotional and psychological stress, and alcohol ingestion frequently disrupt the sleep pattern.
- An environment with a darkened room, reduced noise, comfortable bed, and good ventilation promotes sleep.
- A regular bedtime routine of relaxing activities prepares a person physically and mentally for sleep.
- The most common type of sleep disorder is insomnia. Characteristics of insomnia include the inability to fall asleep, to remain asleep during the night, or to go back to sleep after waking up earlier than desired.
- If a patient's sleep is adequate, assess his or her usual bedtime, normal bedtime ritual, preferred environment for sleeping, and usual preferred rising time.
- When planning interventions to promote sleep, consider the usual characteristics of the patient's home environment and normal lifestyle.
- Important nursing interventions for promoting sleep in the hospitalized patient are to establish periods for uninterrupted sleep and rest and to control noise levels.
- Use your patient's self-report to determine whether sleep was restful.

Reflective Learning

- Reflect on your own sleep hygiene practices. What changes can you make to improve your sleep practices?
- Ask your patient about his or her sleep quality since being in the hospital. How has your patient's sleep been affected?
- Working with two to three of your peers, develop a program on improving sleep for students in college. Offer the program on your campus.

Review Questions

1. A nurse is developing a plan for a patient who was diagnosed with narcolepsy. Which interventions should the nurse include on the plan? (Select all that apply.)
 1. Take brief, 20-minute naps no more than twice a day.
 2. Drink a glass of wine with dinner.
 3. Eat a large meal at lunch rather than dinner.
 4. Establish a regular exercise program.
 5. Teach the patient about the side effects of modafinil.
2. Which statements from a patient indicate an understanding of behaviors that will promote sleep? (Select all that apply.)
 1. "I will not watch television in bed."
 2. "I will not drink caffeine later in the day."
 3. "A short nap late in the evening will lead to a more restful night of sleep."
 4. "I am going to start eating dinner closer to my bedtime"
 5. "I will start to exercise regularly during the day."
3. A 72-year-old patient asks the nurse about using an over-the-counter antihistamine as a sleeping pill to help her get to sleep.

What is the nurse's best response?

1. "Antihistamines are better than prescription medications because prescription medications can cause a lot of problems."
 2. "Antihistamines should not be used because they can cause confusion and increase your risk of falls."
 3. "Antihistamines are effective sleep aids because they do not have many side effects."
 4. "Over-the-counter medications when combined with sleep-hygiene measures are a good plan for sleep."
4. Which nursing intervention(s) best promote(s) effective sleep in an older adult? (Select all that apply.)
1. Limit fluids 2 to 4 hours before sleep.
 2. Ensure that the room is completely dark.
 3. Ensure that the room temperature is comfortably cool.
 4. Provide warm covers.
 5. Encourage walking an hour before going to bed.
5. Which statement made by the patient indicates an understanding of sleep-hygiene practices?
1. "I usually drink a cup of warm milk in the evening to help me sleep."
 2. "If I exercise right before bedtime, I will be tired and fall asleep faster."
 3. "I know it does not matter what time I go to bed as long as I am tired."
 4. "If I use hypnotics for a long time, my insomnia will be cured."
6. Which nursing interventions are appropriate to include in a plan of care to promote sleep for patients who are hospitalized? (Select all that apply.)

1. Give patients a cup of coffee 1 hour before bedtime.
 2. Plan vital signs to be taken before the patients are asleep.
 3. Turn television on 15 minutes before bedtime.
 4. Have patients follow at-home bedtime schedule.
 5. Close the door to patients' rooms at bedtime.
7. The nurse is contacting the health care provider about a patient's sleep problem. Place the steps of the SBAR (situation, background, assessment, recommendation) in the correct order.
1. Mrs. Dodd, 46 years old, was admitted 3 days ago following a motor vehicle accident. She is in balanced skeletal traction for a fractured left femur. She is having difficulty falling asleep.
 2. "Dr. Smithson, this is Pam, the nurse caring for Mrs. Dodd. I'm calling because Mrs. Dodd is having difficulty sleeping."
 3. "I'm calling to ask if you would order a hypnotic such as zolpidem to use on a prn basis."
 4. Mrs. Dodd is taking her pain medication every 4 hours as ordered and rates her pain as 2 out of 10. Last night she was still awake at 0100. She states that she is comfortable but just can't fall asleep. Her vital signs are BP 124/76, P 78, R 12 and T 37.1°C (98.8°F).
8. Which statement made by a mother being discharged to home with her newborn infant indicates that she understands the discharge teaching related to best sleep practices?
1. "I'll give the baby a bottle to help her fall asleep."
 2. "We'll place the baby on her back to sleep."
 3. "We put the baby's stuffed animals in the crib to make her feel safe."
 4. "I know the baby will not need to be fed until morning."
9. A nurse is taking a sleep history from a patient. Which statement made by the patient needs further follow-up?

1. "I feel refreshed when I wake up in the morning."
2. "I use soft music at night to help me relax."
3. "It takes me about 45 to 60 minutes to fall asleep."
4. "I take the pain medication for my leg pain about 30 minutes before I go to bed."

10. Which sleep-hygiene actions at bedtime can the nurse delegate to assistive personnel? (Select all that apply.)

1. Giving the patient a back rub
2. Turning on quiet music
3. Dimming the lights in the patient's room
4. Giving a patient a cup of coffee
5. Monitoring for the effect of the sleeping medication that was given

Pain Management

OBJECTIVES

- Describe the physiology of nociceptive pain.
- List the characteristics used to differentiate categories of pain.
- Identify the various factors that influence pain.
- Explain how cultural factors influence the pain experience.
- Demonstrate how to assess a patient experiencing pain.
- Contrast the characteristics of acute pain with those of chronic pain
- Explain the nursing guidelines for administering analgesics safely
- Explain various nonpharmacological and pharmacological approaches to treating pain.
- Identify barriers to effective pain management.
- Evaluate a patient's response to pain interventions.

Pain is a universal but individual experience and a condition that nurses encounter among patients in all settings. It is the most common reason for seeking health care, yet it is often underrecognized, misunderstood, and inadequately treated. A person in pain often feels distress or suffering and seeks relief. One of the major challenges of pain is that as a nurse you cannot see or feel a patient's pain. It is purely subjective. No two people experience pain in the same way, and no two painful events create identical responses or feelings in a person. The International Association for the Study of Pain (IASP) defines it as "an unpleasant, subjective sensory *and* emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (IASP, 2017). In the "Declaration of Montreal," the IASP declared that access to pain management is a fundamental human right (IASP, 2018a).

Nurses are legally and ethically responsible for assessing and managing pain ([American Nurses Association, 2018](#)). Recently there has been a call for increased coordination of pain research and pain management across the United States in response to various deficiencies in pain care identified in the [Institute of Medicine's 2011](#) report, *Relieving Pain in America*. The opioid crisis added another dimension to the urgency in identifying ways to effectively reduce pain while protecting patients from harm ([CDC, 2016](#)). With the aim of enhancing pain research efforts and promoting collaboration across governmental agencies, a federal advisory committee, the Interagency Pain Research Coordinating Committee (IPRCC), was commissioned by the [Department of Health and Human Services \(DHHS, 2016\)](#). In 2016, the IPRCC and DHHS published the National Pain Strategy, a broad-ranging plan to change how the nation perceives and manages pain ([DHHS, 2016](#)). Following this report, the IPRCC published the Federal Pain Research Strategy, which provides a long-term strategic plan to guide federal agencies that support pain research and advance the science to better understand pain and improve pain care ([IPRCC, 2018](#)). Many of the recommendations directly address the need to improve systems of care for pain management and increase resources to prevent and treat substance use disorders, which disproportionately affect patients with chronic pain conditions.

Pain management needs to be patient centered, with nurses practicing patient advocacy, empowerment, compassion, and respect. Caring for patients in pain requires recognition that pain can and should be relieved. Effective communication among the patient, family, and professional caregivers is essential to achieve adequate pain management. Recognition of the subjective nature of pain and respect for the patient in pain are demonstrated when a nurse accepts McCaffery's classic definition: "Pain is whatever the experiencing person says it is, existing whenever he says it does" ([Pasero and McCaffery, 2011](#)). Effective pain management improves quality of life, reduces physical discomfort, promotes earlier mobilization and return to previous baseline functional activity levels, results in fewer hospital and clinic visits, and decreases hospital lengths of stay, resulting in lower health care costs.

Scientific Knowledge Base

Nature of Pain

The pain experience is complex, involving more than a single physiological sensation caused by a specific stimulus. It has physical, emotional, and cognitive components. It is subjective and highly individualized. It depletes a person's energy and may contribute to chronic fatigue. It interferes with interpersonal relationships and influences the meaning of life. Left untreated, it may lead to serious physical, psychological, social, and financial consequences. Pain itself cannot be measured objectively. Only the patient knows whether pain is present and how the experience feels. However, careful assessment is critical as you assess the behaviors and physiological changes associated with pain. It is not the responsibility of a patient to prove that he or she is in pain; it is your responsibility to assess a patient's condition and accept his or her subjective report.

Physiology of Pain

In contrast to pain being a first-person, subjective perception, **nociception** is defined as an observable activity in the nervous system in response to an adequate stimulus (third-person perspective) (Treede, 2018). Normal or nociceptive pain is the protective physiologic series of events that bring awareness of actual or potential tissue damage. There are four physiological processes of nociception: transduction, transmission, perception, and modulation (Das, 2015). A patient in pain cannot discriminate among the processes. Understanding each process helps you recognize factors that cause pain, symptoms that accompany it, and the rationale for selected therapies.

Transduction

Thermal, chemical, or mechanical stimuli can cause nociceptive pain when the amount of stimuli is strong enough to meet the activation threshold of nociceptors, which are specialized nerve endings distributed throughout the skin, muscles, joints, and viscera. Nociceptors are classified by the type of stimuli they respond to, and some nociceptors respond to multiple types of stimuli (polymodal nociceptors). **Transduction** is the process whereby an activated nociceptor converts energy produced by these stimuli (e.g., exposure to pressure or a hot surface) into an action potential.

Once transduction is complete, **transmission** of the nociceptive impulse begins.

Inflammation caused by disease processes or cellular damage resulting from thermal, mechanical, or chemical stimuli cause the release of vasoactive and pro-nociceptive mediators such as prostaglandins, bradykinin, substance P, and histamine (Box 44.1). These substances directly affect the nerve fibers, lowering the threshold required to activate nociceptors and generating action potentials across the synaptic cleft, a process known as peripheral sensitization (Starkweather et al., 2016) (Fig. 44.1). Peripheral sensitization, which lowers the threshold for causing an action potential within the peripheral afferent neurons, can also result from changes in receptors, ion channels, and the amount neurotransmitters released.

Box 44.1 Neurophysiology of Pain: Neuroregulators

Neurotransmitters (Excitatory)

Prostaglandins

- Generated from the breakdown of phospholipids in cell membranes
- Thought to increase sensitivity to pain

Bradykinin

- Released from plasma that leaks from surrounding blood vessels at the site of tissue injury
- Binds to receptors on peripheral nerves, increasing pain stimuli
- Binds to cells that cause the chain reaction producing prostaglandins

Substance P

- Found in pain neurons of dorsal horn (excitatory peptide)
- Needed to transmit pain impulses from periphery to higher brain centers
- Causes vasodilation and edema

Histamine

- Produced by mast cells, causing capillary dilation and increased capillary permeability

Serotonin

- Released from the brainstem and dorsal horn to inhibit pain transmission

Neuromodulators (Inhibitory)

- Are the natural supply of morphinelike substances in the body
- Activated by stress and pain
- Located within the brain, spinal cord, and gastrointestinal tract
- Cause analgesia when they attach to opiate receptors in the brain
- Present in higher levels in people who have less pain than others with a similar injury

FIG. 44.1 Chemical synapses involve transmitter chemicals (neurotransmitters) that signal postsynaptic cells.
 From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.

Transmission

Each nociceptor has an axon composed of peripheral afferent nerve fibers that are either myelinated (A-delta fibers) or unmyelinated (C fibers). The nociceptive impulses are transmitted from the periphery to the spinal cord via the peripheral afferent fibers to the dorsal root ganglia and the superficial lamina I/II of the dorsal horn of the spinal cord. The fast-transmitting myelinated A-delta fibers transmit sharp, localized nociceptive information, whereas the smaller-diameter unmyelinated C

fibers relay impulses that are dull, achy, and poorly localized. For example, after stepping on a nail, a person initially feels a sharp, localized pain, which is a result of A-fiber transmission, or first pain. Within a few seconds the whole foot aches from C-fiber transmission, or second pain (Steeds, 2016).

The A-delta fibers transmit nociceptive impulses from the dorsal horn to the interior deeper laminae (III-IV) of the spinal cord and higher centers of the brain by way of the spinothalamic tracts (Fig. 44.2). Dorsal horn neurons carrying nociceptive input include projection neurons, local interneurons, and propriospinal neurons. Many of the projection neurons have axons that cross the midline and ascend to multiple areas of the brain, including the thalamus, gray matter of the cerebral cortex, the pons, and parts of the medullary reticular formation. It is through this cellular system of communication (action potentials carrying nociceptive input) that pain, arising from any area of the body including the nerve or areas of the brain itself, can be perceived by the individual.

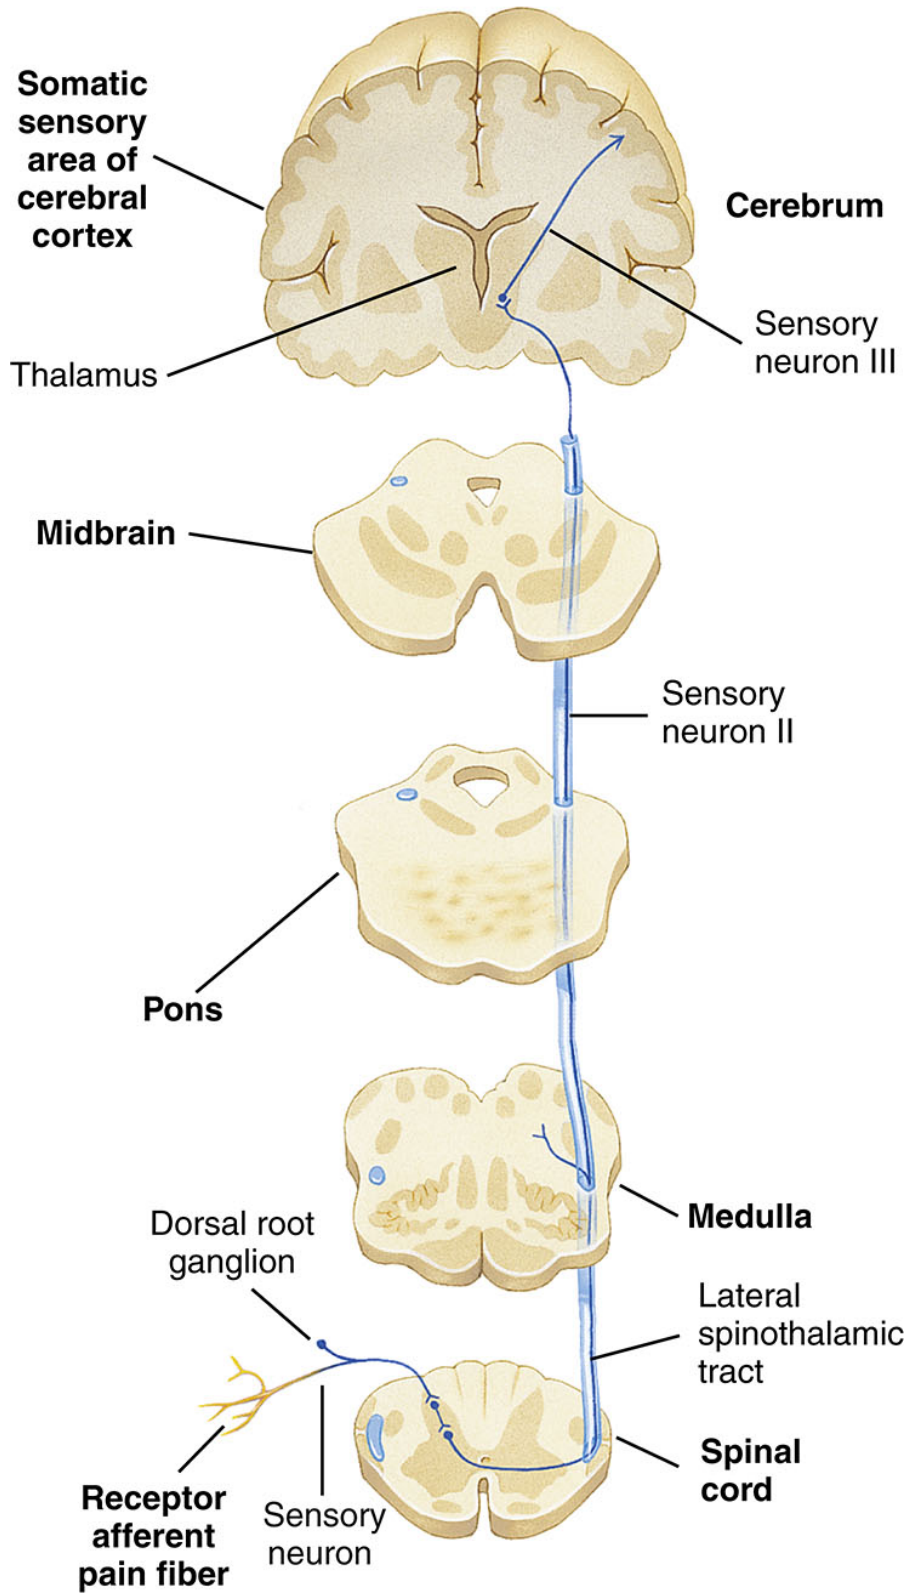

FIG. 44.2 Spinothalamic pathway that conducts pain stimuli to the brain.

Perception

Once a pain stimulus reaches the cerebral cortex, the brain interprets the quality of the pain and processes information from past experience, knowledge, and cultural associations in the perception of the pain (Fenton et al., 2015). Perception is the point at which a person is aware of nociceptive impulses and perceives pain. The somatosensory cortex identifies the location and intensity of pain, whereas the association cortex, primarily the limbic system, determines how a person feels about it. There is no single pain center.

As a person becomes aware of pain, a complex reaction occurs. Psychological and cognitive factors interact with neurophysiological ones. Perception gives awareness and meaning to pain, resulting in a reaction. The reaction to pain includes the physiological and behavioral responses that occur after an individual perceives pain.

Modulation

Projection neurons activate endogenous descending inhibitory mediators (see Box 44.1), such as endorphins (endogenous opioids), serotonin, norepinephrine, and gamma-aminobutyric acid (GABA), that aid in producing an analgesic effect. These mediators hinder the transmission of nociceptive impulses in the dorsal horn neurons. This inhibition of the pain impulse is the fourth and last phase of the normal pain process known as **modulation** (Pasero and McCaffery, 2011). Modulation can also occur through peripheral and/or central sensitization, resulting in increased perception of pain (Bourne et al., 2014). Afferent nerve fibers sensitized by vasoactive and pronociceptive mediators lower the threshold of activation and result in continuous nociceptive input to dorsal horn neurons and central sensitization. Clinical manifestations of central sensitization include expansion of the pain beyond the initial location, exaggerated response to noxious stimuli known as hyperalgesia, and pain in response to normally non-noxious stimuli, also called allodynia.

A protective reflex response also occurs with pain (Fig. 44.3). A-delta fibers send sensory impulses to the spinal cord, where they synapse with spinal motor neurons. The motor impulses travel via a reflex arc along efferent (motor) nerve fibers back to a peripheral muscle near the site of stimulation, thus bypassing the brain. Contraction of the muscle leads to a protective withdrawal from the source of pain. For example, when you accidentally touch a hot iron, you feel a burning sensation, but your hand also reflexively withdraws from the surface of the iron. Pain perception

requires consciousness and an intact central nervous system. Common factors that disrupt the pain process include trauma, drugs, tumor growth, and metabolic disorders.

FIG. 44.3 Protective reflex to pain stimulus.

Gate-Control Theory of Pain

Melzack and Wall's gate-control theory (1965) was the first to suggest that pain has emotional and cognitive components in addition to physical sensations. The theory explains how rubbing an injured area can reduce pain. The small-diameter fibers activated by noxious stimuli open the gate to pain transmission, and the large-diameter fibers have inhibitory effects to shut the gate. Rubbing the injured area promotes proprioceptive large-diameter fiber input and therefore inhibits further transmission of pain signals from small-diameter nerves to the brain. [Melzack \(1999\)](#) later proposed the neuromatrix theory of pain, postulating that each individual possesses a genetically determined neural matrix that develops and is

modulated by sensory input, making pain perception unique to each individual.

Physiological Responses

As pain impulses ascend the spinal cord toward the brainstem and thalamus, the stress response stimulates the autonomic nervous system (ANS). Pain of low-to-moderate intensity and superficial pain elicit the fight-or-flight reaction of the general adaptation syndrome (see [Chapter 37](#)). Stimulation of the sympathetic branch of the ANS results in physiological responses ([Table 44.1](#)). Continuous, severe, or deep pain typically involving the visceral organs (e.g., with a myocardial infarction or colic from gallbladder or renal stones) activates the parasympathetic nervous system. Except in cases of severe traumatic pain, which cause a person to go into shock, most people adapt to their pain reflexively, and their physical signs return to normal baseline. Note that normal is not the same for each individual. Thus patients in pain do *not* always have changes in their vital signs. Changes in vital signs more often indicate problems other than pain ([Manocha and Taneja, 2016](#)).

TABLE 44.1

Physiological Reactions to Pain

Response	Cause or Effect
Sympathetic Stimulation ^a	
Dilation of bronchial tubes and increased respiratory rate	Provides increased oxygen intake
Increased heart rate	Provides increased oxygen transport
Peripheral vasoconstriction (pallor, elevation in blood pressure)	Elevates blood pressure with shift of blood supply from periphery and viscera to skeletal muscles and brain
Increased blood glucose level	Provides additional energy
Increased cortisol level (short term)	Heightened memory functions, a burst of increased immunity, and lower sensitivity to pain
Diaphoresis	Controls body temperature during stress
Increased muscle tension	Prepares muscles for action
Dilation of pupils	Affords better vision
Decreased gastrointestinal motility	Frees energy for more immediate activity
Parasympathetic Stimulation ^b	
Pallor	Causes blood supply to shift away from periphery
Nausea and vomiting	Vagus nerve sends impulses to chemoreceptor trigger zone in the brain
Decreased heart rate and blood pressure	Results from vagal stimulation
Rapid, irregular breathing	Causes body defenses to fail under prolonged stress of pain

^a Pain of low-to-moderate intensity and superficial pain.

^b Severe or deep pain.

Behavioral Responses

The pain response is complex, influenced by a person's culture, pain experiences, perception of pain, and ability to manage stress. If left untreated or unrelieved, pain significantly alters quality of life with physical and psychological consequences; this phenomenon is referred to as high-impact pain (Dahlhamer et al., 2018). The widespread effects of pain support why effective pain management is essential. Some patients choose not to report pain if they believe that it inconveniences others or if it signals loss of self-control. Others endure severe pain without asking for assistance. Clenching the teeth, facial grimacing, holding or guarding the painful part, and bent posture are common indications of acute pain. Chronic pain can affect a patient's activity (eating, sleeping, socialization), thinking (confusion, forgetfulness), emotions (anger, depression, irritability), quality of life, and productivity (IOM, 2011). You soon learn to recognize patterns of behavior that reflect pain even when patients offer no verbal report, especially those with dementia or other cognitive changes.

Recognizing a patient's unique response to pain allows you to assess the success of pain-management therapies. Encourage your patients to accept pain-relieving measures so that they remain active and continue to maintain daily activities. A patient's ability to tolerate pain significantly influences your perceptions of the degree of his or her discomfort. Patients who have a low **pain tolerance** (level of pain a person is willing to accept) are sometimes inaccurately perceived as complainers. Teach patients the importance of reporting their pain sooner rather than later to facilitate better control and optimal functional status.

Acute and Chronic Pain

Pain is categorized by duration (acute or chronic) or pathological condition (e.g., cancer or neuropathic). The two types of pain that you observe in patients are acute (transient) and chronic (persistent), which includes cancer and noncancer pain.

Acute/Transient Pain

Acute pain is protective, usually has an identifiable cause, is of short duration, and has limited tissue damage and emotional response. It is common after acute injury, disease, or surgery. Acute pain warns people of injury or disease; thus it is protective. It eventually resolves, with or without treatment, after an injured area heals. Patients in acute pain are

frightened and anxious and expect relief quickly. It is self-limiting; therefore a patient knows that an end is in sight. Because acute pain has a predictable ending (healing) and an identifiable cause, health team members are usually willing to treat it aggressively.

Acute pain seriously threatens a patient's recovery by hampering his or her ability to become active and involved in self-care. This results in prolonged hospitalization from complications such as physical and emotional exhaustion, immobility, sleep deprivation, and pulmonary complications. Physical and psychological progress is delayed as long as acute pain persists because a patient focuses all energy on pain relief. Efforts aimed at teaching and motivating a patient toward self-care can be hindered until the pain is managed successfully. Complete pain relief is not always achievable, but reducing pain to a tolerable level is a realistic goal. A primary nursing goal is to provide pain relief that allows patients to participate in their recovery, prevent complications, and improve functional status. Unrelieved acute pain can progress to chronic pain.

Chronic/Persistent Noncancer Pain

Chronic pain affects more than 50 million American adults, and among those affected, nearly 20 million live with high-impact chronic pain (Dahlhamer et al., 2018). Unlike acute pain, **chronic pain** is not protective and thus serves no purpose, but it has a dramatic effect on a person's quality of life. Chronic noncancer pain is ongoing or recurrent pain that lasts beyond the usual course of an acute illness or the healing of an injury (more than 3 to 6 months) and that adversely affects an individual's well-being (ACPA, 2018). It does not always have an identifiable cause and leads to great personal suffering. Examples of chronic noncancer pain include arthritis, low back pain, headache, fibromyalgia, and peripheral neuropathy. It may result from an initial injury such as a back sprain, or there may be an ongoing cause such as illness. Chronic noncancer pain may be viewed as a disease since it has a distinct pathology that causes changes throughout the nervous system that may worsen over time. It has significant psychological and cognitive effects and can constitute a serious, separate disease entity itself. Chronic noncancer pain is usually non-life threatening. In some cases an injured area healed long ago, yet the pain is ongoing and does not respond to treatment.

The possible unknown cause of chronic pain, combined with ineffective treatments and the unrelenting nature and uncertainty of its duration, frustrates a patient, frequently leading to psychological depression and even suicide. Chronic pain is a major cause of psychological and physical

disability, leading to problems such as job loss, inability to perform simple daily activities, sexual dysfunction, and social isolation. The goal of treating chronic noncancer pain is to improve functional status with a multimodality plan.

The person with chronic noncancer pain often experiences pain that may not have the same physiological response as acute pain; however, the subjective reports and interference with activities of daily living (ADLs), socialization, and ability to perform work duties is very real. Patients often suffer more with time because of physical and mental exhaustion.

Associated symptoms of chronic pain include fatigue, insomnia, anorexia, weight loss, apathy, hopelessness, depression, and anger. Chronic pain creates the uncertainty of how one will feel from day to day. A person with chronic noncancer pain often does not show obvious symptoms and does not adapt to the pain. Often a person with chronic pain who consults with numerous health care providers is labeled a drug seeker when he or she is actually seeking adequate pain relief. Nurses need to discourage patients from having multiple health care providers for treating pain and encourage the use of both pharmacological and nonpharmacological management. Pain centers specialize in diagnostic testing and in noninvasive and invasive treatments that patients may be able to obtain from their general health care providers.

Chronic Episodic Pain

Pain that occurs sporadically over an extended period of time is episodic pain. Pain episodes last for hours, days, or weeks. An example of chronic episodic pain is the migraine headache that occurs up to 14 days per month compared with chronic migraine, which occurs more than 15 days per month ([Katsarava et al., 2012](#)).

Cancer Pain

Not all patients with cancer experience pain. Cancer pain can be relieved often with simple interventions in 90% of patients ([Burchum and Rosenthal, 2019](#)). Some patients with cancer experience acute and/or chronic pain. The pain is normal (nociceptive), resulting from stimulus of an undamaged nerve, and/or neuropathic, arising from abnormal or damaged pain nerves ([Table 44.2](#)). Cancer pain is usually caused by tumor progression and related pathological processes, invasive procedures, toxicities of chemotherapy, and infection. A patient senses pain at the actual site of the tumor or distant to the site, called *referred pain*. Always

completely assess reports of new pain by a patient with existing pain. Despite the availability and wide use of effective therapies and updated guidelines from reliable leading professional societies, the undertreatment of cancer pain is still frequent (Burchum and Rosenthal, 2019). Research shows that approximately one-third of patients who receive treatment for pain still do not receive pain medication proportional to their pain intensity (Greco et al., 2014).

TABLE 44.2

Classification of Pain By Inferred Pathology

Nociceptive Pain	Neuropathic Pain
<p>I. <i>Nociceptive pain</i>: Normal stimulation of special peripheral nerve endings—called <i>nociceptors</i>; usually responsive to nonopioids and/or opioids.</p> <p>A. <i>Somatic pain</i>: Comes from bone, joint, muscle, skin, or connective tissue; is usually aching or throbbing in quality and well localized</p> <p>B. <i>Visceral pain</i>: Arises from visceral organs such as the gastrointestinal tract and pancreas; is sometimes subdivided:</p> <ol style="list-style-type: none"> 1. Tumor involvement of organ capsule that causes aching and fairly well-localized pain. 2. Obstruction of hollow viscus, which causes intermittent cramping and poorly localized pain. 	<p>II. <i>Neuropathic pain</i>: Pain caused by a lesion or disease of the somatosensory nervous system; treatment usually includes adjuvant analgesics.</p> <p>A. Centrally generated pain</p> <ol style="list-style-type: none"> 1. <i>Deafferentation pain</i>: Injury to either the peripheral or central nervous system. <i>Examples</i>: Phantom pain indicates injury to the peripheral nervous system; burning pain below the level of a spinal cord lesion reflects injury to the central nervous system. 2. <i>Sympathetically maintained pain</i>: Associated with impaired regulation of the autonomic nervous system. <i>Examples</i>: Pain is associated with complex regional pain syndrome, type I, type II. <p>B. Peripherally generated pain</p> <ol style="list-style-type: none"> 1. <i>Painful polyneuropathies</i>: Pain felt along the distribution of many peripheral nerves. <i>Examples</i>: Diabetic neuropathy, alcohol-nutritional neuropathy, and Guillain-Barré syndrome. 2. <i>Painful mononeuropathies</i>: Usually associated with a known peripheral nerve injury; pain is felt at least partly along the distribution of the damaged nerve. <i>Examples</i>: Nerve root compression, nerve entrapment, trigeminal neuralgia.

From Pasero C, McCaffery M: *Pain assessment and pharmacologic management*, St Louis, 2011, Mosby.

Idiopathic Pain

Idiopathic pain is chronic pain in the absence of an identifiable physical or psychological cause or pain perceived as excessive for the extent of an organic pathological condition. An example of idiopathic pain is complex regional pain syndrome (CRPS). Research is needed to better identify the causes of idiopathic pain to identify more effective treatments.

REFLECT NOW

A nurse is caring for one patient who is experiencing acute abdominal pain related to appendicitis and another patient who is experiencing abdominal pain related to ovarian cancer. Compare the pain of these two patients. How might the patients' pain be similar? How might they be different?

Nursing Knowledge Base

Nursing knowledge of pain mechanisms and interventions continues to grow through nursing research. This section explores factors that influence the pain experience.

Knowledge, Attitudes, and Beliefs

Attitudes of nurses and other health care providers affect pain management. The traditional medical model of illness generates attitudes about pain. This model suggests that physical problems result from physical causes. Thus pain is a physical response to organic dysfunction. When there is no obvious source of pain (e.g., the patient with chronic low back pain or neuropathies), health care providers sometimes stereotype patients with pain as malingerers, complainers, or difficult patients.

Studies of nurses' attitudes regarding pain management show that a nurse's personal opinion about a patient's self-report of pain affects pain assessment and titration of medication doses. It has been shown that nurses' assessment of pain intensity often underestimates patients' pain reports (Goulet et al., 2013; Desai et al., 2014). Also, nurses may infer cues on pain severity solely from how pain is treated and then use the cues when making symptom judgments, often leading to underestimation and overestimation of pain (Dekel et al., 2016). Patients with a high self-report of pain, even when nurses are aware of their pain experience and analgesic treatment, are vulnerable to underestimation and hence to pain undertreatment (Dekel et al., 2016). Also, patients with a low self-report of pain are subject to overestimation and thus are exposed to overtreatment with potential treatment hazards. A number of nurse and patient variables, including cultural (e.g., gender, age, education), knowledge, and patient diagnosis, contribute to the differences in pain ratings. A study showed that patients treated by nurses who have postgraduate training and/or attend continuous education programs and who have greater autonomy in modifying pain treatment protocols experience better quality of care (Tomaszek and Debska, 2018).

Nurses' assumptions about patients in pain seriously limit their ability to offer pain relief. Biases based on culture, education, and experience influence everyone. Too often nurses allow misconceptions about pain (Box 44.2) to affect their willingness to intervene. Clinical practices can also play a role. For example, when there are conditions of symptom uncertainty and ambiguous clinical judgment, nurses may incorrectly use

medical evidence cues alone and follow established clinical protocols or pathways that may simplify clinical decisions but will bias pain estimation (Dekel et al., 2016). Some nurses avoid acknowledging a patient's pain because of their own fear and denial. They do not believe a patient's report of pain if he or she does not appear to be in pain. A nurse is entitled to personal beliefs; however, he or she must *accept* a patient's report of pain, act according to professional guidelines, standards, and position statements, and individualize appropriate policies and procedures, protocols, and evidence-based research findings (American Nurses Association, 2018).

Box 44.2 Common Biases and Misconceptions About Pain

The following statements are *false*:

- Patients who abuse substances (e.g., use drugs or alcohol) overreact to discomforts.
- Patients with minor illnesses have less pain than those with severe physical alteration.
- Administering analgesics regularly leads to drug addiction.
- The amount of tissue damage in an injury accurately indicates pain intensity.
- Health care personnel are the best authorities on the nature of a patient's pain.
- Psychogenic pain is not real.
- Chronic pain is psychological.
- Patients who are hospitalized experience pain.
- Patients who cannot speak do not feel pain.

To help a patient gain pain relief, it is important to view the experience through the patient's eyes. Acknowledging a personal prejudice or misconception helps to address patient problems more professionally. When one becomes an active, knowledgeable observer of a patient in pain, it is possible to more objectively analyze the pain experience. The patient makes the diagnosis that pain is present, and the nurse provides interventions that ultimately offer relief.

Factors Influencing Pain

Pain is a complex process, involving physiological, social, spiritual, psychological, and cultural influences. Thus each individual's pain experience is different. Consider all factors that affect a patient in pain to ensure a holistic approach to the assessment and care of the patient. Some of these factors are modifiable, things that can change, while others are nonmodifiable, such as age. Nursing interventions target the modifiable factors, such as attention, fear, and anxiety, by providing patients and families with the knowledge and skills to cope with pain.

Physiological Factors

Age

Age influences the pain experience. It is important to consider how a painful event affects a patient developmentally. For example pain may prevent an adolescent from engaging socially with friends. A middle-aged adult may be unable to continue work in cases when pain is severe. It is particularly important to recognize how developmental differences affect how infants and older adults react to pain. Young children have trouble understanding pain, its meaning, and the procedures that cause it. If they have not developed full vocabularies, they have difficulty with verbally describing and expressing pain to parents or caregivers. Toddlers and preschoolers are unable to recall explanations about pain or to associate it with experiences that may be unrelated to the painful condition. With these developmental considerations in mind, it is necessary to adapt approaches for assessing a child's pain (e.g., what to ask, including what to ask parents) and to learn which behaviors to observe and how to prepare a child for a painful medical procedure.

Pain is not an inevitable part of aging. Likewise pain perception does not decrease with age. However, older adults have a greater likelihood of developing pathological conditions, which are accompanied by acute and chronic pain. Persistent pain may be associated with impaired physical function, falls, diminished appetite, dysmobility, impaired sleep, depression, anxiety, agitation and delirium, as well as more subtle decrements in cognitive function ([Galicia-Castillo and Weiner, 2019](#)). In addition, age-related changes and increased frailty may lead to a less predictable response to analgesics, increased sensitivity to medications, and potentially harmful drug effects ([O'Sullivan et al., 2017](#)). Serious impairment of functional status often accompanies pain in older patients.

It potentially reduces mobility, ADLs, involvement in social activities and physical activity, and activity tolerance. The presence of pain in an older adult requires aggressive assessment, diagnosis, and management (Box 44.3).

Box 44.3 Focus on Older Adults Factors Influencing Pain in Older Adults

- With aging, muscle mass decreases, body fat increases, and percentage of body water decreases. This increases the concentration of water-soluble drugs such as morphine given in normal doses. The volume of distribution for fat-soluble drugs such as fentanyl increases (Burchum and Rosenthal, 2019).
- Older adults frequently eat poorly, resulting in low serum albumin levels. Many analgesics are highly protein bound. In the presence of low serum albumin, more free drug (active form) is available, thus increasing the risk for side effects or toxic effects (Burchum and Rosenthal, 2019; Tracy and Sean Morrison, 2013).
- A decline of liver and renal function naturally occurs with aging. This results in reduced metabolism and excretion of drugs. Thus, older adults often experience a greater peak effect and longer duration of analgesics (Abdulla, 2013).
- Pain is common in the advanced stages of many chronic diseases, including heart failure, end-stage renal disease, and chronic obstructive pulmonary disease. In addition, millions of joint repair and replacement surgeries are performed annually in the United States, and an important minority of patients undergoing these procedures report chronic pain despite surgery (Reid et al., 2015).
- Age-related changes in the skin such as thinning and loss of elasticity affect the absorption rate of topical analgesics.

The ability of older patients to interpret pain is sometimes complicated. They often suffer from multiple diseases with symptoms that affect similar parts of the body. This requires you to make detailed assessments when the source of pain is unclear. Different diseases sometimes cause similar symptoms. For example, chest pain does not always indicate a heart attack; it also is a symptom of arthritis of the spine or an abdominal disorder.

When older adults experience cognitive impairment and confusion, they have difficulty in recalling pain experiences and in providing detailed explanations of their pain (Pasero and McCaffery, 2011). It is necessary to address misconceptions about pain management in the very young and in older adults before intervening for a patient (Tables 44.3 and 44.4).

TABLE 44.3

Pain in Infants

Misconception	Correction
Infants cannot feel pain.	Infants have the anatomical and functional requirements for pain processing by mid- to late gestation.
Infants are less sensitive to pain than older children and adults.	Term neonates have the same sensitivity to pain as older infants and children. Preterm neonates have a greater sensitivity to pain than term neonates or older children.
Infants cannot express pain.	Although infants cannot verbalize pain, they respond with behavioral cues and physiological indicators that are observable.
Infants must learn about pain from previous painful experiences.	Pain requires no prior experience; infants do not need to learn it from earlier painful experience. It occurs with the first insult.
You cannot accurately assess pain in infants.	You use behavioral cues (e.g., facial expressions, cry, body movements) and physiological indicators of pain (e.g., changes in vital signs) to reliably and validly assess pain in infants.
You cannot safely give analgesics and anesthetics to infants and neonates because of their immature capacity to metabolize and eliminate drugs and their sensitivity to opioid-induced respiratory depression.	Infants are very sensitive to drugs. Response to drugs is often intense and prolonged. Absorption is faster than expected. Dosages of drugs excreted by the kidneys need to be reduced (Burchum and Rosenthal, 2019). Prescribers carefully select the medication, dosage, administration route, and time. Nurses monitor frequently for desired and undesired effects. They also follow medication orders to titrate and wean medications to minimize adverse effects.

TABLE 44.4**Misconceptions About Pain in Older Adults**

Misconception	Correction
Pain is a natural outcome of growing old.	Older adults are at greater risk (as much as twofold) than younger adults for many painful conditions; however, pain is not an inevitable result of aging.
Pain perception, or sensitivity, decreases with age.	This assumption is unsafe. Although there is evidence that emotional suffering specifically related to pain may be less in older than in younger patients, no scientific basis exists for the claim that a decrease in perception of pain occurs with age or that age dulls sensitivity to pain.
If the older patient does not report pain, he or she does not have pain.	Older patients commonly underreport pain. Reasons include expecting to have pain with increasing age; not wanting to alarm loved ones; being fearful of losing their independence; not wanting to distract, anger, or bother caregivers; and believing that caregivers know they have pain and are doing all they can to relieve it. The absence of a report of pain does not mean the absence of pain.
If an older patient appears to be occupied, asleep, or otherwise distracted from pain, he or she does not have pain.	Older patients often believe that it is unacceptable to show pain and have learned to use a variety of ways to cope with it (e.g., many patients use distraction successfully for short periods of time). Sleeping is sometimes a coping strategy; alternately, it indicates exhaustion, not pain relief. Do not make assumptions about the presence or absence of pain solely on the basis of a patient's behavior.
The potential side effects of opioids make them too dangerous to use to relieve pain in older adults.	In most cases nonopioids are preferred to opioids for noncancer pain, but opioids can be used safely for older adults with moderate-to-severe cancer pain. Although the opioid-naïve older adult is usually more sensitive to opioids, this does not justify withholding their use in pain management. Analgesics should be initiated at the lowest effective dose and titrated to achieve pain control with minimal adverse effects; this requires frequent reassessment of patients for pain relief and side effects as doses are adjusted (Galicia-Castillo and Weiner, 2019).
Patients with Alzheimer's disease and other cognitive impairments do not feel pain, and their reports of pain are most likely invalid.	No evidence exists that older adults who are cognitively impaired experience less pain or that their reports of pain are less valid than those of individuals with intact cognitive function (Horgas, 2018). Patients with dementia or other deficits of cognition most likely suffer significant unrelieved pain and discomfort. The best approach to assessment is to accept a patient's report of pain and use relevant pain assessment tools.
Older patients report more pain as they age.	Even though older patients experience a higher incidence of painful conditions such as arthritis, osteoporosis, peripheral vascular disease, and cancer than younger patients, studies show that they underreport pain. Many older adults grew up valuing the ability to "grin and bear it" (Pasero and McCaffery, 2011).

Fatigue

Fatigue heightens the perception of pain and decreases coping abilities. If it occurs along with sleeplessness, the perception of pain is even greater. Pain is often experienced less after a restful sleep than at the end of a long day.

Genes

Research on healthy human subjects suggests that genetic information passed on by parents possibly increases or decreases a person's sensitivity to pain and determines **pain threshold** or tolerance. Recent advances in the study of genetics and pain have shown that even slight changes in deoxyribonucleic acid (DNA) or expression of genes could partly explain individual differences in pain. Numerous genetic risk factors have been identified for pain in musculoskeletal, neuropathic, and vascular conditions, as well as migraine ([Zorina-Lichtenwalter et al., 2016](#)) Genetic influences have been shown to play a role in sensitivity, perception, and expression of pain in a variety of conditions ([James, 2013](#)). As a nurse you may encourage patients who have persistent pain syndromes to seek genetic counseling.

Neurological Function

A patient's neurological function influences the pain experience. Any factor that interrupts or influences normal pain reception or perception (e.g., spinal cord injury, peripheral neuropathy, or neurological disease) affects a patient's awareness of and response to pain. Some pharmacological agents (analgesics, sedatives, and anesthetics) influence pain perception and response because of the manner in which they affect the nervous system.

Social Factors

Previous Experience

Each person learns from painful experiences. Prior experience does not mean that a person accepts pain more easily in the future. Previous frequent episodes of pain without relief or bouts of severe pain cause anxiety or fear. In contrast, if a person repeatedly experiences the same type of pain that was relieved successfully in the past, he or she finds it easier to interpret the pain sensation. As a result, the patient is better prepared to take necessary actions to relieve the pain.

When a patient has no experience with a painful condition, the first perception of pain often impairs the ability to cope. For example, after abdominal surgery patients often experience severe incisional pain for several days. Unless a patient knows that this is a common occurrence following surgery, the onset of pain seems like a serious complication. Rather than participate actively in postoperative breathing exercises (see [Chapter 50](#)), the patient lies immobile in bed and breathes shallowly because of fear that something is not right. In the preoperative and anticipatory phase of the pain experience, you need to prepare a patient with a clear explanation of the type of pain to expect and methods to reduce it. This usually results in a reduced perception of pain.

Family and Social Network

People in pain often depend on family members or close friends for support, assistance, or protection. Although pain still exists, the presence of family or friends can often make the experience less stressful. Conversation with family is a useful distraction. The presence of parents is especially important for children experiencing pain.

Spiritual Factors

Spirituality is an active search for meaning in situations (see [Chapter 35](#)). Spiritual beliefs affect the way patients view or cope with pain. Research has shown accumulating evidence that interventions that address spirituality have benefits for individuals' physical and emotional health, including the relief of pain ([Siddall et al., 2015](#)).

Patients often ask spiritually based questions, such as "Why has this happened to me?" or "Why am I suffering?" Spiritual pain goes beyond what we can see. "Why has God done this to me?" "Is this suffering teaching me something?" Other spiritual concerns include loss of independence and becoming a burden to family. Recall that pain is an experience that has physical *and* emotional components. Patients who deal with persistent pain using positive spiritual coping practices such as looking to a higher being for strength and support adjust better to pain and have significantly better mental health ([Siddall et al., 2015](#)). Providing support for patients to utilize their spiritual practices is essential for pain management.

Psychological Factors

Attention

The degree to which a patient focuses attention on pain influences his or her perception. Increased attention is associated with increased pain, whereas distraction is associated with a diminished pain response. This concept is one that nurses apply in various pain-relief interventions such as relaxation, guided imagery, and massage. By focusing patients' attention and concentration on other stimuli, their perception of pain declines (see [Chapter 32](#)).

Anxiety and Fear

A person perceives pain differently if it suggests a threat, loss, punishment, or challenge. For example, a woman in labor perceives pain differently than a woman with a history of cancer who is experiencing a new pain and fearing recurrence. In addition, the degree and quality of pain perceived by a patient influence its meaning. The relationship between pain and anxiety and fear is complex. Both emotions often increase the perception of pain, and pain causes feelings of anxiety and fear. It is difficult to separate the two sensations.

Critically ill or injured patients who perceive a lack of control over their environment and their care have high anxiety levels. This anxiety leads to serious pain-management problems. Pharmacological and nonpharmacological approaches to the management of anxiety are appropriate; however, anxiolytic medications are not a substitute for analgesia ([Pasero and McCaffery, 2011](#)).

Coping Style

Pain is a lonely experience that often causes patients to feel a loss of control. Coping style influences the ability to deal with it (see [Chapter 37](#)). People with internal loci of control perceive themselves as having control over events in their lives and the outcomes such as pain. They ask questions, desire information, and make choices about treatment. In contrast, people with external loci of control perceive that other factors in their lives, such as nurses, are responsible for the outcome of events. These patients follow directions and are more passive in managing their pain. Learn to understand patients' coping resources during painful experiences so that you can incorporate these into your plan of care. For example, a patient who does not ask for pain medication but shows behavioral signs of discomfort might require you to be more responsive in offering prn medications on time.

Cultural Factors

The meaning that a person associates with pain affects the experience of pain and how one adapts to it. This is often closely associated with a person's cultural background, including age, education, race, and familial factors. Cultural beliefs and values affect how individuals cope with pain. They learn what is expected and accepted by their culture, including how to react to pain.

An example comes from a qualitative study conducted among members of a South African culture. The study found gender differences among members of the groups interviewed; the expression or acknowledgment of pain could almost be described as a cultural taboo associated with weakness and a lack of honor and courage among men (Nortje and Albertyn, 2015). Historical folklore, songs, and poems describing the stories of fallen heroes and ancestors were often used to train African children to deal with pain in a stoic and resilient manner.

A study has shown that cultural values regarding work and family play a large role in Hispanic Americans' pain behaviors (Hollingshead et al., 2016). In that study, Mexican-American men reported enduring pain in order to support and provide for their families, whereas Mexican-American women reported enduring pain to care for and nurture their families. When pain threatens an individual's family or work role, an individual may not necessarily seek pain care but instead attempt to endure the discomfort to stay independent and productive.

Health care providers often mistakenly assume that everyone responds to pain in the same way. Different meanings and attitudes are associated with pain across various cultural groups. An understanding of the cultural meaning of pain helps you design culturally sensitive care for people with pain.

Culture affects pain expression. Some people believe that it is natural to be demonstrative about pain. Others tend to be more introverted. When a person moves to another country, it is important to know to what extent the individual has assimilated into his or her new home. For example, if several generations of a Hispanic patient's family have lived in the United States, the influence of the Spanish culture may be limited, whereas newly immigrated patients still often embrace their cultural norms.

As a nurse, explore the impact of cultural differences on a patient's pain experience and make adjustments to the plan of care (Box 44.4). Ask whether the patient has had previous bad experiences with pain management. Work with a patient and family to learn their cultural beliefs, values, and preferences to adequately assess and manage pain (see

Chapter 9). Find a culturally appropriate assessment tool, and communicate the use of that tool to other health care providers in an effort to provide culturally competent care.

Box 44.4 **Cultural Aspects of Care Assessing Pain in Culturally Diverse Patients**

Pain is a biopsychosocial phenomenon. Culture shapes the experience of pain, including its expression and a patient's behaviors, or coping responses. For example, an individual from a higher socioeconomic group has more resources for managing pain and is more likely to adapt behaviors that will lessen pain. Several research studies have shown that people in the lowest as compared with the highest socioeconomic class are more likely to feel disabled through pain (Dahlhamer et al., 2018). A recent literature review demonstrated that Hispanic Americans face numerous barriers to seeking and receiving pain care, including financial limitations, lack of insurance, language barriers, and immigration status (Hollingshead et al., 2016). Culture also affects a person's choice of lay remedies, help-seeking activities, and receptivity to medical treatment. Some health care providers undertreat pain because they do not understand the cultural effects on the perception of pain intensity. Nurses care for patients with pain from a variety of cultural backgrounds; thus you need to develop strategies to assess and manage pain in culturally diverse patients.

Implications for Patient-Centered Care

- Use culturally appropriate assessment tools, such as tools written in the patient's native language, to assess pain (CDC, 2019).
- Assess a patient's health literacy level because this affects your ability to provide appropriate education about pain management and therapies (CDC, 2019). Spanish-speaking Hispanic-American patients report difficulty in describing their pain experiences to providers and report better pain control when a Spanish-language translator is present (Hollingshead et al., 2016).
- Recognize variations in subjective responses to pain. Undertreatment or overtreatment might occur if members of the health care team are unaware of the cultural norms associated with pain and pain expression, since pain is subjective (Nortjé and Albertyn, 2015).

- Be sensitive to variations in communication styles. Some cultures believe that nonverbal expression of pain is sufficient to describe the pain experience, whereas others assume that if pain medication is appropriate, the nurse will bring it; thus asking is inappropriate.
- Understand that expression of pain is unacceptable within certain cultures. Some patients believe that asking for help indicates a lack of respect, whereas others believe acknowledging pain is a sign of weakness.
- Pain is personal and related to religious beliefs. Some cultures consider suffering a part of life to be endured to enter heaven.
- Use knowledge of biological variations of pain. Significant differences in drug metabolism, dosing requirements, therapeutic response, and adverse effects occur in cultural groups. A wide range of responses is also possible within this group. Therefore assess each patient's response to pain medication carefully.
- Develop a personal awareness of your own values and beliefs that affect your responses to patients' reports of pain.

Factors Impacted By Pain

Quality of Life

Pain affects a patient's daily activities and quality of life. Pain affects an individual's ability to provide self-care, work, perform at school, and interact socially with friends and family. Chronic pain is a major public health problem, producing significant economic and social burdens that affect the patient, family, and social circles ([Dueñas et al., 2016](#)). The biopsychosocial model for chronic pain offers a valuable framework for understanding how a variety of factors can contribute to chronic pain and ultimately the quality of an individual's life.

Self-Care

Pain can readily limit how a person is able to perform the activities of self-care, including activities of daily living (ADLs) and instrumental activities of daily living (IADLs) (e.g., shopping and house cleaning). Pain is often debilitating. Research shows a strong correlation between chronic pain and reduced physical activity ([Lerman et al., 2015](#)). In addition, most individuals who experienced chronic pain in one study suffered different limitations affecting the ability to perform intense physical exercise, walk,

perform domestic chores, participate in social activities, and maintain an independent lifestyle (Dueñas et al., 2016).

Work

Pain, both acute and chronic, affects how a person performs at work or in the case of students, school. Research has shown that patients who are affected by pain present problems of absenteeism. Not only must individuals often change their occupational duties or positions, but they may also end up losing their jobs as a result of their pain symptoms (Dueñas et al., 2016). When a person is unable to perform as he or she expects, the threatened loss can result in loss of sleep, change in eating habits, depression, and fear of loss of independence.

Social Support

Support from family and friends is critical for a patient who is experiencing pain. But when a person has pain, the members of the family are also affected. Pain will restrict an individual's leisure activities and social contacts. Social isolation becomes a common problem. The negative emotions, irritability, and feelings of anger that affect patients in pain have a negative impact on interpersonal relationships and the levels of stress in families and social connections. When a family caregiver becomes involved in the care of a patient with chronic pain, the quality of the caregiver's life can decline (Dueñas et al., 2016).

REFLECT NOW

Modifiable and nonmodifiable factors can influence pain. Helping the patient and the patient's family to understand that mood, coping strategies, and the social environment can all have positive and negative influences on pain and functional outcomes is important. What type of modifiable and nonmodifiable factors that affect pain can you identify in a family member you know who had pain or a patient for whom you have provided care?

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. To make clinical judgments, you anticipate the information you need, analyze the data, and make decisions regarding patient care. A patient's condition or situation is always changing. During assessment consider all critical thinking elements that lead to appropriate nursing diagnoses.

Knowledge of pain physiology and the many factors that influence pain help you manage a patient's pain. Previous experience in caring for patients with pain sharpens your assessment skills and ability to choose effective therapies. Critical thinking attitudes and intellectual standards ensure the aggressive assessment, creative planning, and thorough evaluation needed to obtain an acceptable level of patient pain relief while balancing treatment benefits with treatment-associated risks. Successful pain management does not necessarily mean pain elimination but rather attainment of a mutually agreed-on pain-relief goal that allows patients to control their pain instead of the pain controlling them.

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care. Nurses approach pain management systematically to understand and treat a patient's pain. Successful management of pain depends on establishing a relationship of trust among health care providers, patient, and family. Pain management extends beyond relief, encompassing ways to improve or maintain a patient's quality of life and ability to work productively, enjoy recreation, and function normally in the family and society.

The [American Nurses Association \(ANA, 2018\)](#) upholds that pain assessment and pain management are within the scope of every nurse's practice. Thus the ANA offers a certification examination in pain management to staff nurses (<http://www.aspmn.org/certification>). Several clinical guidelines are available for managing pain in specific disorders. Guidelines are available through the American Pain Society (APS) on the management of pain in the primary care setting; sickle cell pain; cancer pain in adults and children; and pain in osteoarthritis, rheumatoid arthritis, and juvenile chronic arthritis. Sigma Theta Tau International offers guidelines for the older adult on its website (www.geriatricpain.org). In addition, the American Academy of Pain Medicine (<http://www.painmed.org/library/clinical-guidelines/>) and Centers for Disease Control and Prevention (<https://www.cdc.gov/drugoverdose/prescribing/guideline.html>) post a variety of pain-management guidelines.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. A comprehensive assessment of pain aims to gather information about the cause of a person's pain and determine its effect on his or her ability to function.

Through the Patient's Eyes

Many people view pain as a part of life. Some patients experience it for hours or days before seeking health care assistance. They often expect and even accept a certain amount of pain while being hospitalized. It is

important to learn a patient's own values and beliefs about the management of pain and recognize that patient expectations will influence your ability to achieve outcomes in its management (QSEN, 2019). Asking a patient about his or her tolerable pain level is a first step in helping a patient to regain control. Assessing previous pain experiences and effective home interventions provides a foundation on which you can build. Patients expect nurses to accept their reports of pain and be prompt in meeting their pain needs.

When assessing pain, be sensitive to the level of discomfort and determine which level will allow your patient to function. For example, when caring for a patient with pain, ask, "Which level of pain will allow you to walk down the hall?" The patient answers that walking is possible when pain is at a level of 2 on a scale of 0 to 10, with 0 being no pain and 10 being worst pain imaginable. You then plan therapies to decrease the patient's pain to that level. Be sure that he or she is a partner in making decisions about the best approaches for managing pain.

Another aspect of assessing pain through the patient's eyes is to determine his or her health literacy. People who struggle to find a range of words to talk about their pain lack the ability to use language for symptom relief. Psychologists suggest that having a wide vocabulary with which to describe pain symptoms helps equip a person to better manage pain and reduce distress. Many agencies have assessment tools that allow you to get a more accurate measure of a patient's literacy skills.

If pain is acute or severe, it is unlikely that a patient is able to provide a detailed description of the entire experience. During an episode of acute pain, streamline your assessment and assess its location, severity, and quality. Collect a more detailed acute pain assessment when a patient is more comfortable (Box 44.5). For patients with chronic pain, a thorough pain assessment includes affective, cognitive, behavioral, spiritual, and social dimensions. In the home care setting family members can assess pain by using the ABCs of pain assessment and management (Box 44.6).

Box 44.5 Nursing Assessment Questions

Current Pain: (Modify Assessment for Patient's Age, Cognitive Ability, Culture, Language, and Other Factors)

Palliative or Provocative factors: What makes your pain worse? What makes it better?

Quality: Describe your pain for me.

Relief measures: What do you take at home to gain pain relief? What makes your pain go away?

Region (location): Show me where you hurt.

Severity: On a scale of 0 to 10, how bad is your pain now?

- What is the worst pain you have had in the past 24 hours?
- What is the average pain you have had in the past 24 hours?

Timing: Do you have pain all of the time, only at certain times, or only on certain days?

U: Effect of pain: What are you not able to do because of your pain?

- With whom do you live, and how do they help you when you have pain?

Current Medications

- Which medications/herbs are you taking now?
- Tell me how these medications and herbs affect your pain?
- What approaches other than medications have you tried to relieve the pain?
- Have you ever used recreational drugs or alcohol to alleviate pain?

Activity

- What level of daily exercise can you maintain with your pain?
- Which type of movement increases or relieves your pain?
- Which type of activities do you now avoid because of your pain?

Box 44.6 Routine Clinical Approach to Pain

Assessment and Management: ABCDE

A: **Ask** about pain regularly. Assess pain systematically.

- B: **Believe** patient and family in their report of pain and what relieves it.
- C: **Choose** pain control options appropriate for the patient, family, and setting.
- D: **Deliver** interventions in a timely, logical, and coordinated fashion.
- E: **Empower** patients and their families. Enable them to control their course to the greatest extent possible.

From Jacox A, et al: *Management of cancer pain*, Clinical Practice Guideline No. 9, AHCPR Publication No. 94-0592, Rockville, MD, 1994, Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services.

Because pain is dynamic, accurate assessment requires you to monitor it on a regular basis along with other vital signs. Some institutions treat it as the fifth vital sign. Pain assessment is *not* simply a number. Relying solely on a number fails to capture the multidimensionality of pain and may be unsafe, particularly when the number fails to reflect the entire pain experience or when a patient does not understand the use of the selected pain-rating scale. Pain assessment is a nursing responsibility. However, assistive personnel (AP), physical therapists, social workers, and others also screen for pain by asking patients whether they are uncomfortable or in pain. When pain is noted by any care provider, it is essential that a nurse be informed immediately so that he or she can make a thorough assessment to confirm the patient's discomfort and provide appropriate treatment.

The ability to establish a nursing diagnosis, decide on appropriate interventions, and evaluate a patient's response (outcomes) to interventions depends on the fundamental activity of a factual, timely, accurate pain assessment (Fig. 44.4). The core of this complex activity is the exploration of the pain experience through the eyes of the patient. Nurses use a variety of tools to assess nociceptive and neuropathic pain. In selecting a tool to be used with a patient, be aware of the clinical usefulness, reliability, and validity of the tool in that specific patient population. For example, a tool that has been validated for use with preverbal children may not have validity or reliability for use with adults. Assessment tools (or scales) are available for use with a number of different patient populations, including critically ill adults, young children, or adults with advanced dementia. The goal in using these tools

is to identify how much pain exists, not to identify how much pain the patient tolerates.

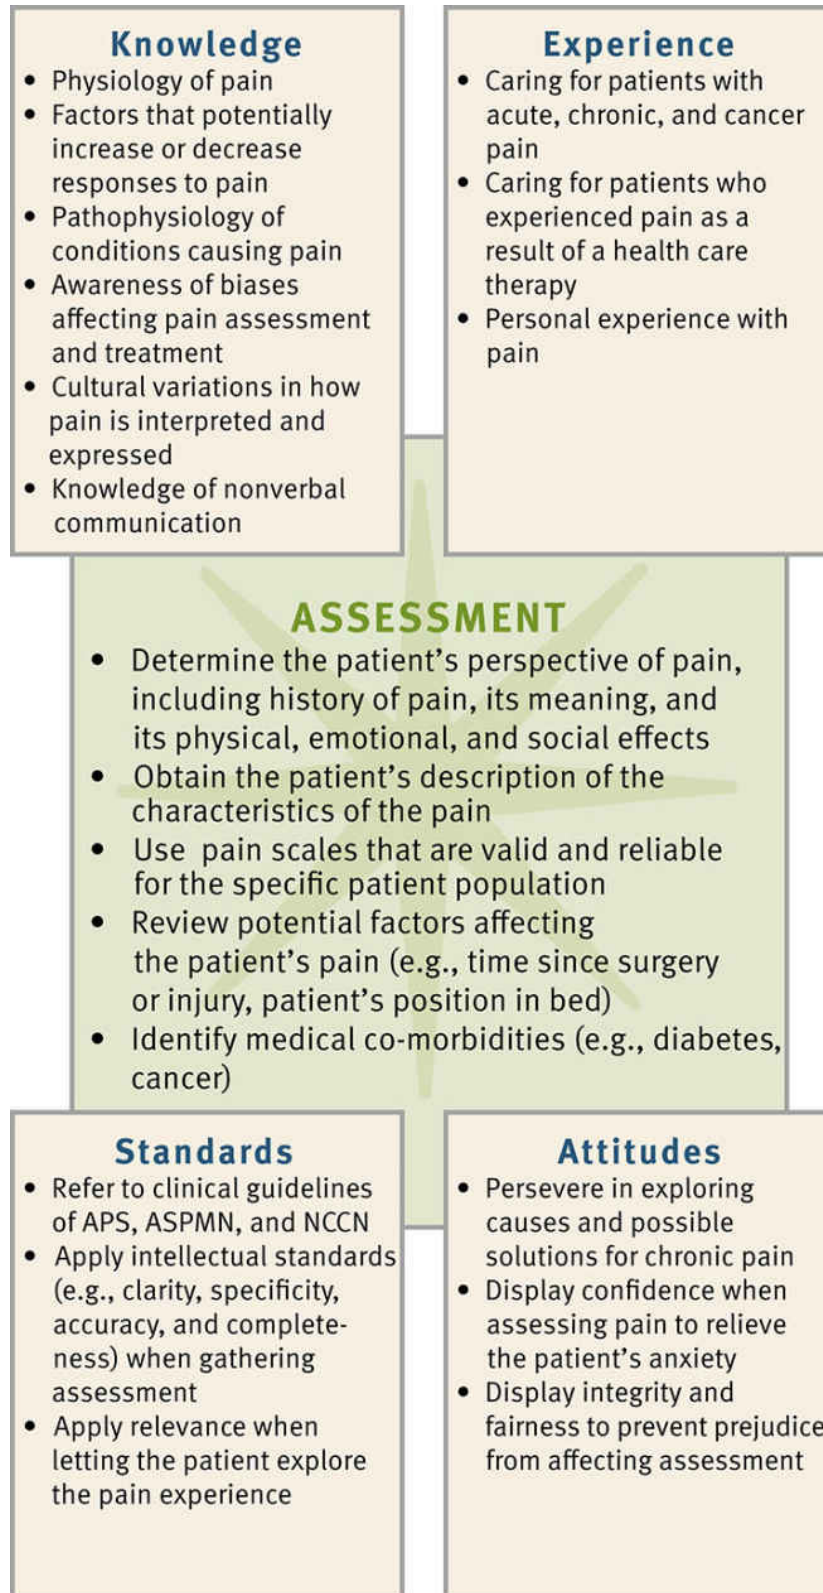

FIG. 44.4 Critical thinking model for pain assessment. *APS*, American Pain Society; *ASPMN*, American Society for Pain Management Nursing; *NCCN*, National Comprehensive Cancer Network.

It is necessary to be aware of possible errors in pain assessment (Box 44.7). Using the right tools and methods helps to avoid errors and ensures the selection of the right pain interventions. Failure of clinicians to accurately assess a patient's pain, accept the findings, and treat the report is a common cause of unrelieved pain and suffering.

Box 44.7 Possible Sources for Error in Pain

Assessment

- Bias, which causes nurses to consistently overestimate or underestimate the pain that patients experience
- Vague, closed-ended, or unclear assessment questions, which lead to unreliable assessment data
- Use of pain assessment tools that are not evidence based or validated for a particular patient population
- Use of medical terms that patients with low health literacy cannot understand
- Patients who do not always provide complete, relevant, and accurate pain information
- Patients who are cognitively impaired and unable to use pain scales

Patient's Expression of Pain

A patient's self-report of pain is the single most reliable indicator of its existence and intensity (Pasero and McCaffery, 2011). Pain is individualistic. Many patients fail to report or discuss discomfort. At the same time many nurses believe that patients report pain if they have it. If patients sense that you doubt their pain exists, they share little information about their pain experience or minimize their report. Establish a caring therapeutic relationship with the patient to promote open communication. Simple measures, such as sitting when talking to patients about pain, let them know that you are sincerely concerned about their pain.

Patients unable to communicate effectively often require special attention during assessment. Infants and children, people who are developmentally delayed, patients who are psychotic, a patient who is critically ill or at end of life, patients with dementia, and patients who are aphasic or do not speak English all require different approaches. Clinical

practice recommendations have been developed for the use of behavior-assessment pain tools with patients who are cognitively impaired (Box 44.8). However, you need to understand that the number obtained when using a pain-behavior scale is a behavior score, not a pain-intensity rating (Pasero and McCaffery, 2011). These tools identify the presence of pain but do not determine its intensity.

Box 44.8 Evidence-Based Practice Pain Assessment in the Nonverbal Patient

PICOT Question: In elderly nonverbal patients, which pain-assessment tool is most effective in determining presence of pain?

Evidence Summary

A common misconception is that individuals who are nonverbal as a result of dementia or cognitive impairments do not experience pain. These patients often present with atypical manifestations of pain caused by pathophysiological changes in the brain. Manifestations often include fearful expressions, combativeness, and resistance to care (Atee et al., 2017). An evidence-based position statement and clinical practice recommendations for pain assessment in patients who are nonverbal was developed by the Hartford Institute for Geriatric Nursing and the Alzheimer's Association (Horgas, 2018). No single assessment strategy, such as interpretation of behaviors, pathology, or estimates of pain by others, is sufficient by itself in determining the presence of pain in a patient who is unable to communicate. However, initial assessment can be performed by using self-assessment with a numeric rating scale or verbal descriptor scale (Horgas, 2017).

A number of tools have been developed to assess for the presence of pain in adults who are cognitively impaired. Although research studies have demonstrated that these tools can be used to determine the presence of pain, there has been little evidence to determine whether they can be used to identify pain intensity. Commonly used instruments include the Abbey Pain Scale, Pain Assessment in Advanced Dementia Scale (PAINAD), and Noncommunicative Patient's Pain Assessment Instrument (NOPPAIN) to recognize the presence or absence of pain and provide a rating of pain severity in older people with impaired cognition. An electronic pain assessment tool (ePAT) app was recently developed to provide point-of-care facial recognition technology for detecting facial

micro-expression indicative of pain, as well as the presence of pain-related behaviors under five additional domains (voice, movement, behavior, activity, and body) (Atee, 2017). An analysis revealed a sensitivity of 96.1% and accuracy of 95% (Hoti et al., 2018). This assessment supports the clinical usefulness of the ePAT for identifying pain in patients with moderate to severe dementia.

Application to Nursing Practice

- Attempt a self-report of pain using simple yes/no responses or vocalizations or a numerical rating scale (Chow et al., 2016).
- Search for potential causes of pain (Horgas, 2018). Examples include pain associated with intravenous insertion site infiltrations, abdominal cramping and fullness, urinary retention, or prolonged pressure on body parts associated with immobility.
- Assume that pain is present after ruling out other problems (infection, constipation) that cause pain.
- Identify pathological conditions or procedures that cause pain.
- Observe patient behaviors and list behaviors (e.g., facial expressions, vocalizations, body movements, changes in interactions or mental status) that indicate pain (Horgas, 2018).
- Ask family members, parents, or caregivers for a surrogate report.
- Use behavioral pain assessment tools.
- Use evidence-based tools to ensure appropriate pain assessment (Horgas, 2018).
- Use the PAINAD to assess pain in patients with advanced dementia (Horgas, 2018).

Patients with cognitive impairments require insightful assessment approaches involving close observation of vocal response, facial movements (e.g., grimacing, clenched teeth), and body movements (e.g., restlessness, pacing). Also assess social interaction (e.g., does the patient avoid conversation?). Patients who are critically ill and have a clouded sensorium or the presence of nasogastric tubes or artificial airways require specific questions that they can answer with a nod of the head or by writing out a response. If a patient speaks a different language, pain assessment is difficult and requires the assistance of a professional interpreter.

Physical Examination

When a patient is in pain, conduct a focused physical and neurological examination and observe for nonverbal responses to pain (e.g., grimacing, rigid body posture, limping, frowning, or crying) (see [Chapter 30](#)).

Examine the affected painful area to see whether palpation or manipulation of the site increases pain. Assess the patient's cognitive status and ability to respond appropriately to questions. Also assess a patient's mobility/balance, especially in older adults with persistent pain. Mobility assessment is critical because of the potential impact of pain and some analgesics on the risk for falling ([Galicia-Castillo and Weiner, 2019](#)).

Characteristics of Pain

Assessment of the characteristics of pain allows you to understand the type of pain, its pattern, and the types of interventions that bring relief. Use of assessment tools to quantify the extent and degree of pain depends on a patient being cognitively alert enough to be able to understand and follow instructions.

Timing (Onset, Duration, and Pattern)

Ask questions to determine the onset, duration, and time sequence of pain. When did it begin? How long has it lasted? Does it occur at the same time each day? Is it intermittent, constant, or a combination? How often does it recur? It is sometimes easier to diagnose the nature of pain by identifying time factors. Knowing the time cycle or pattern of pain helps you intervene before the pain occurs or worsens (see [Box 44.5](#)).

Location

Ask a patient to describe or point to all areas of discomfort to assess pain location. To localize the pain specifically, have him or her trace the area from the most severe point outward. This is difficult to do if pain is diffuse or involves several sites or parts of the body. Do not assume that your patient's pain always occurs in the same location. When describing pain location to other health care providers, use anatomical landmarks and descriptive terminology. The statement "Pain is localized in the upper right abdominal quadrant" is more specific than "The patient states the pain is in the abdomen." Pain classified by location can be further classified as superficial or cutaneous, deep or visceral, referred, or radiating ([Table 44.5](#)).

TABLE 44.5**Classification of Pain By Location**

Location	Characteristics	Examples of Causes
Superficial or Cutaneous		
Pain resulting from stimulation of skin	Pain is of short duration and localized. It usually is a sharp sensation.	Needlestick; small cut or laceration
Deep or Visceral		
Pain resulting from stimulation of internal organs	Pain is diffuse and radiates in several directions. Duration varies, but it usually lasts longer than superficial pain. Pain is sharp, dull, or unique to organ involved.	Crushing sensation (e.g., angina pectoris); burning sensation (e.g., gastric ulcer)
Referred		
Common in visceral pain because many organs themselves have no pain receptors (The entrance of sensory neurons from affected organ into same spinal cord segment as neurons from areas where individual feels pain causes perception of pain in unaffected areas.)	Pain is in part of body separate from source of pain and assumes any characteristic.	Myocardial infarction, which causes referred pain to the jaw, left arm, and left shoulder; kidney stones, which refer pain to groin
Radiating		
Sensation of pain extending from initial site of injury to another body part	Pain feels as though it travels down or along body part. It is intermittent or constant.	Low back pain from ruptured intravertebral disk accompanied by pain radiating down leg from sciatic nerve irritation

Severity

One of the most subjective and therefore most useful characteristics for reporting pain is its severity. Nurses teach patients how to use pain scales to help them communicate pain severity or intensity. Many scales are available in several languages to aid nurses when a professional interpreter is not present. The purpose of using a pain scale is to identify a patient's perception of pain intensity over time so that the effectiveness of interventions can be evaluated (Pasero and McCaffery, 2011). It is important to select the scale that is appropriate for a patient's age, language, condition, and ability and to ensure that the patient understands how to use it.

Pain Scales

A numerical rating scale (NRS) requires patients to rate pain on an 11-point line of 0 to 10, with 0 representing no pain and 10 representing the worst pain the patient can imagine (Fig. 44.5A). The scale has been found to be very effective in many populations, including youth with disabilities (Miró et al., 2016). This scale is also used to assess pain intensity before and after therapeutic interventions. A verbal descriptive scale (VDS) consists of a line with two- to six-word descriptors equally spaced along the line (Fig. 44.5B). Show a patient the scale and ask him or her to choose

the descriptor that best represents the severity of pain. A visual analog scale (VAS) consists of a straight line without labeled subdivisions (Fig. 44.5C). The straight line shows a continuum of intensity and has labeled end points. A patient indicates pain by marking the appropriate point on the line. Use a scale to measure the current severity of a patient’s pain. Also ask patients to rate their average pain and the worst pain they have had in the past 24 hours. This information allows you to see trends in pain severity.

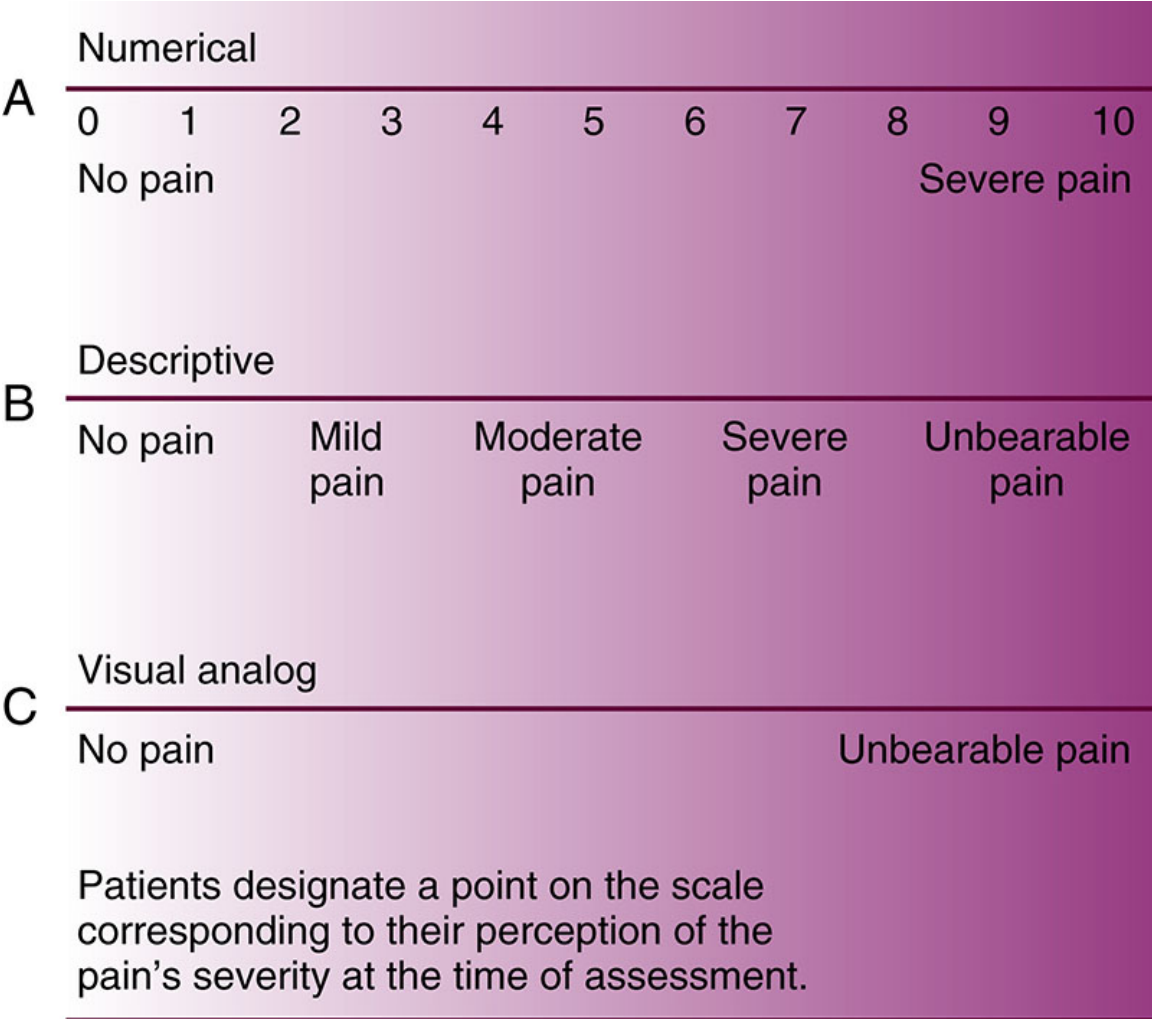

FIG. 44.5 Sample pain scales. **A**, Numerical. **B**, Verbal descriptive. **C**, Visual analog.

Another pain scale, originally developed for children to assess pain, is now used worldwide with people ages 3 and older ([Faces of Pain Care, 2016](#)). The Wong-Baker Faces Pain Rating Scale (FPS-revised) provides a

pictorial representation of pain intensity (Fig. 44.6) (Wong and Baker, 1988; IASP, 2018b). Young children do not always know what the word *pain* means; therefore assessment requires you to use words such as *owie*, *boo-boo*, or *hurt*. However, the “faces” scale has been shown through research to be very reliable and valid in measuring pain severity. Also, a recent study among adults from a developing country showed the “faces” scale to be preferred over the NRS (Pathak et al., 2018). Such self-report measures of pain are most often used for children older than 3 to 4 years, but even 2-year-olds can report pain (Hockenberry and Wilson, 2019). As children develop, newer cognitive skills such as measurement and classification mature so that school-age children can use the NRS to assess pain (Hockenberry and Wilson, 2019). Another popular pain scale shown to be valid and reliable is the Oucher pain scale (0-10) (Beyer et al., 1992). It uses a series of photographic images of faces in varying degrees of distress (Fig. 44.7). A child points to a face on the tool, thus simplifying the task of describing the pain. Different forms of the Oucher pain scale have been developed for specific ethnic groups, including Asian, Hispanic, and African American. A good pain scale is easy to use, understandable, and not time consuming. If a patient is able to read and understand a scale easily, the pain description is more accurate. If patients use a hearing aid or glasses, be sure that they are using them when answering pain-assessment questions or marking a pain scale. Once you select a scale that works for a patient, be sure to use it consistently. Do not use a pain scale to compare the pain of one patient with that of another.

Brief word instructions: Point to each face using the words to describe the pain intensity. Ask the child to choose face that best describes own pain and record the appropriate number.

The Asian versions of the Oucher scale [male and female] were developed

Quality

There is no common or specific pain vocabulary in general use. Patients describe pain in their own way. A study conducted in 1990 showed that Hispanics, American Indians, blacks, and whites all rated *pain* as the most intense term, followed by *hurt*; *ache* was the least intense (Gaston-Johansson et al., 1990). The research is dated, but it shows the importance of not assuming that one patient perceives pain differently from another only on the basis of cultural background. Assess the terms that patients use to describe their discomfort; then use these words consistently to obtain an accurate report. For example, say, "Tell me what your discomfort feels like. What do you call it?" The patient may describe the pain as crushing, throbbing, sharp, or dull. For example, if it is dull, when you return to the patient, ask if it is still "dull." It is always more accurate to have patients describe the pain in their own words whenever possible.

There is some consistency in the way people describe certain types of pain. The pain associated with a myocardial infarction is often described as crushing or viselike, whereas the pain of a surgical incision is often described as dull, aching, and throbbing, indicating nociceptive pain. Neuropathic pain is usually pricking pain, burning, electric-like, or numbness (Colloca et al, 2017). When a patient's descriptions fit the pattern forming in the assessment, you then make a clearer analysis of the nature and type of pain. This leads to more appropriate pain management because you treat nociceptive and neuropathic pain differently.

Aggravating and Precipitating Factors

Various factors or conditions precipitate or aggravate pain. Ask a patient to describe activities that cause or aggravate pain, such as physical movement, positions, drinking coffee or alcohol, urination, swallowing, eating food, or psychological stress. Also ask them to demonstrate actions that cause a painful response, such as coughing or turning a certain way. Some symptoms (depression, anxiety, fatigue, sedation, anorexia, sleep disruption, spiritual distress, and guilt) cause a worsening of pain or may be aggravated by it. Assess for these associated symptoms and evaluate their effects on the patient's pain perception. After identifying specific aggravating or precipitating factors, it is easier to plan interventions to avoid worsening the pain.

Relief Measures

Ask patients how they relieve their pain, such as changing position, using ritualistic behavior (pacing, rocking, or rubbing), eating, meditating, praying, or applying heat or cold to a painful site. Encourage patients to continue using their own pain-relieving measures if they are effective and appropriate to the cause of pain. Patients gain trust when they know that nurses are willing to try their relief measures, especially in the home setting. Patients gain a sense of control over the pain instead of the pain controlling them. Identify all the patient's health care providers (e.g., internist, orthopedist, acupuncturist, chiropractor, or dentist) in addition to assessing relief measures.

Effects of Pain on the Patient

Pain alters a person's lifestyle and psychological well-being. For example, chronic/persistent pain causes suffering, loss of control, loneliness, exhaustion, and an impaired quality of life. To understand a pain experience, ask the patient what the pain prevents him or her from doing.

Behavioral Effects

When a patient has pain, assess verbalization, vocal response, facial and body movements, and social interaction. A verbal report of pain is a vital part of assessment. You need to be willing to listen and understand. When a patient is unable to communicate pain, it is especially important for you to be alert for behaviors that indicate it ([Box 44.9](#)).

Box 44.9 Behavioral Indicators of Effects of Pain

Vocalizations

- Moaning
- Crying
- Gasping
- Grunting

Facial Expressions

- Grimace
- Clenched teeth
- Wrinkled forehead
- Tightly closed or widely opened eyes or mouth
- Lip biting

Body Movement

- Restlessness
- Immobilization
- Muscle tension
- Increased hand and finger movements
- Pacing activities
- Rhythmic or rubbing motions
- Protective movement of body parts
- Grabbing or holding a body part

Social Interaction

- Avoidance of conversation
- Focus only on activities for pain relief
- Avoidance of social contacts
- Reduced attention span
- Reduced interaction with environment

The nonverbal expression of pain either supports or contradicts other information about it. If a woman in labor reports that her labor pains are occurring more frequently and if she begins to massage her abdomen more often, this confirms her report. If a patient reports severe abdominal pain but continues to grasp the chest, a more detailed assessment is probably needed.

Influence on Activities of Daily Living

Patients who live with daily pain or have prolonged pain during a hospitalization are less able to participate in routine activities, which

results in physical deconditioning. This deconditioning can slow a patient's recovery (see [Chapter 38](#)). Assessment of these changes reveals the extent of a patients' disabilities and adjustments necessary to help them participate in self-care. The primary goal of the nurse is to improve patient function.

Ask a patient whether pain interferes with sleep. Some patients experience difficulty in falling asleep and/or staying asleep. The pain may awaken the patient during the night and make it hard to fall back to sleep.

Depending on the location of the pain, some patients have difficulty independently performing ADLs. For example, some pain restricts mobility to the point at which a patient is no longer able to bathe in a bathtub or dress himself or herself. Some patients with severe arthritis find it painful to grasp eating utensils or lower themselves to a toilet seat. Assess the patient's need for help with self-care activities, determine whether a family caregiver provides assistance at home, and collaborate with members of the health care team (e.g., physical and occupational therapy).

Pain sometimes impairs the ability to maintain normal sexual relations. Physical conditions such as arthritis or back pain may prevent patients from assuming usual positions during intercourse. Pain or fatigue may reduce a patient's desire for sex. Include the extent to which pain affects the patient's usual sexual activity (i.e., physically unable or reduced desire) in your assessment.

Pain threatens a person's ability to work. The more physical activity required in a job, the greater the risk of discomfort when the pain is associated with movement. Pain related to emotional stress increases in individuals whose jobs involve stressful decision making. Assess the work that patients do and their abilities to function in their jobs. Assess the daily chores of homemakers in the same manner as the duties involved in jobs outside the home. Also assess whether it is necessary for patients to stop activity occasionally because of pain, and help them select ways to minimize or control it so that they are able to remain productive.

Include an assessment of the effect of pain on social activities. Some pain is so debilitating that the patient becomes too exhausted to socialize. Identify a patient's normal social activities, the extent to which activities have been disrupted, and the desire to participate in these activities.

Concomitant Symptoms

Concomitant symptoms occur with pain and usually increase a patient's pain severity. Examples include nausea, headache, dizziness, urge to

urinate, constipation, depression, and restlessness. Certain types of pain have predictable concomitant symptoms. For example, severe rectal pain often leads to constipation. These symptoms are as much a problem to a patient as the pain itself.

REFLECT NOW

Consider a patient you recently cared for in a clinical experience or consider a time when you experienced a painful condition. In what way did pain limit your daily activities/the activities of the patient? How did you or the patient adapt to those limitations?

• Nursing Diagnosis

An accurate nursing diagnosis may be made only after you perform a complete assessment. The development of accurate nursing diagnoses for a patient in pain results from thorough data collection and analysis ([Box 44.10](#)). Careful assessment reveals the presence or a potential for pain. Be sure that your assessment includes the patient's history of recent procedures or preexisting painful conditions.

Box 44.10 Nursing Diagnostic Process Chronic Pain

Assessment Activities	Assessment Findings
Have patient describe pain intensity.	Pain is constant; patient verbally reports 5 on a scale of 0 to 10
Assess onset and location of pain.	Present for 7 months in lower lumbar area
Observe patient behaviors.	Grimaces and grunts when sitting, rubs flanks frequently; reduced movement in upper trunk and legs
Assess effect of pain on activities of daily living (ADLs).	Appetite poor; gets little sleep; difficulty dressing
Review medical history.	Previous trauma; effectiveness of past pain-control measures

The nursing diagnosis focuses on the specific nature of a patient's pain to identify the most relevant types of interventions for alleviating it and improving the patient's function. *Acute Pain related to physical trauma* and *Acute Pain related to natural childbirth processes* require very different nursing interventions. Accurate identification of related factors for problem-focused or negative nursing diagnoses helps you choose appropriate nursing interventions. You will sometimes use this information to identify interventions that treat or modify the related factor or risk for the diagnosis to be resolved. For example, interventions for *Acute Pain related to physical trauma* usually require pharmacological intervention, whereas *Acute Pain related to natural childbirth processes* is sometimes managed more appropriately with nonpharmacological interventions, such as controlled breathing techniques.

A pain assessment often directs you to identify additional diagnoses other than that of *Acute* or *Chronic Pain*. The extent to which pain affects a patient's function and general state of health determines whether other nursing diagnoses are relevant. For example, your assessment reveals that a patient reports having pain of the hands and shoulders and has difficulty removing or fastening necessary items of clothing. The patient has had osteoarthritis for over 3 years with persistent discomfort and weakness of the upper extremities. The nursing diagnoses for this patient are *Self-Care Deficit; Impaired Ability to Dress* and *Chronic Pain*. The diagnosis of *Self-Care Deficit; Impaired Ability to Dress* requires involvement by members of the interprofessional health care team to provide the patient with assistive devices for performing self-care. Examples of other diagnoses that may be related to pain follow:

- *Difficulty Coping*
- *Fatigue*

- *Impaired Mobility*
- *Impaired Sleep*
- *Social Isolation*

• **Planning**

During the planning step of the nursing process, analyze information from multiple sources, including the patient, family, and other health care providers. Critical thinking ensures that a patient's plan of care (see the [Nursing Care Plan](#)) integrates all that is known about the individual and key critical thinking elements ([Fig. 44.8](#)). Professional standards are especially important to consider when developing a plan of care. These standards establish evidence-based guidelines for selecting effective nursing interventions. Professional standards of care regarding pain management are available as agency policies or through professional organizations such as the American Society for Pain Management Nursing (ASPMN).

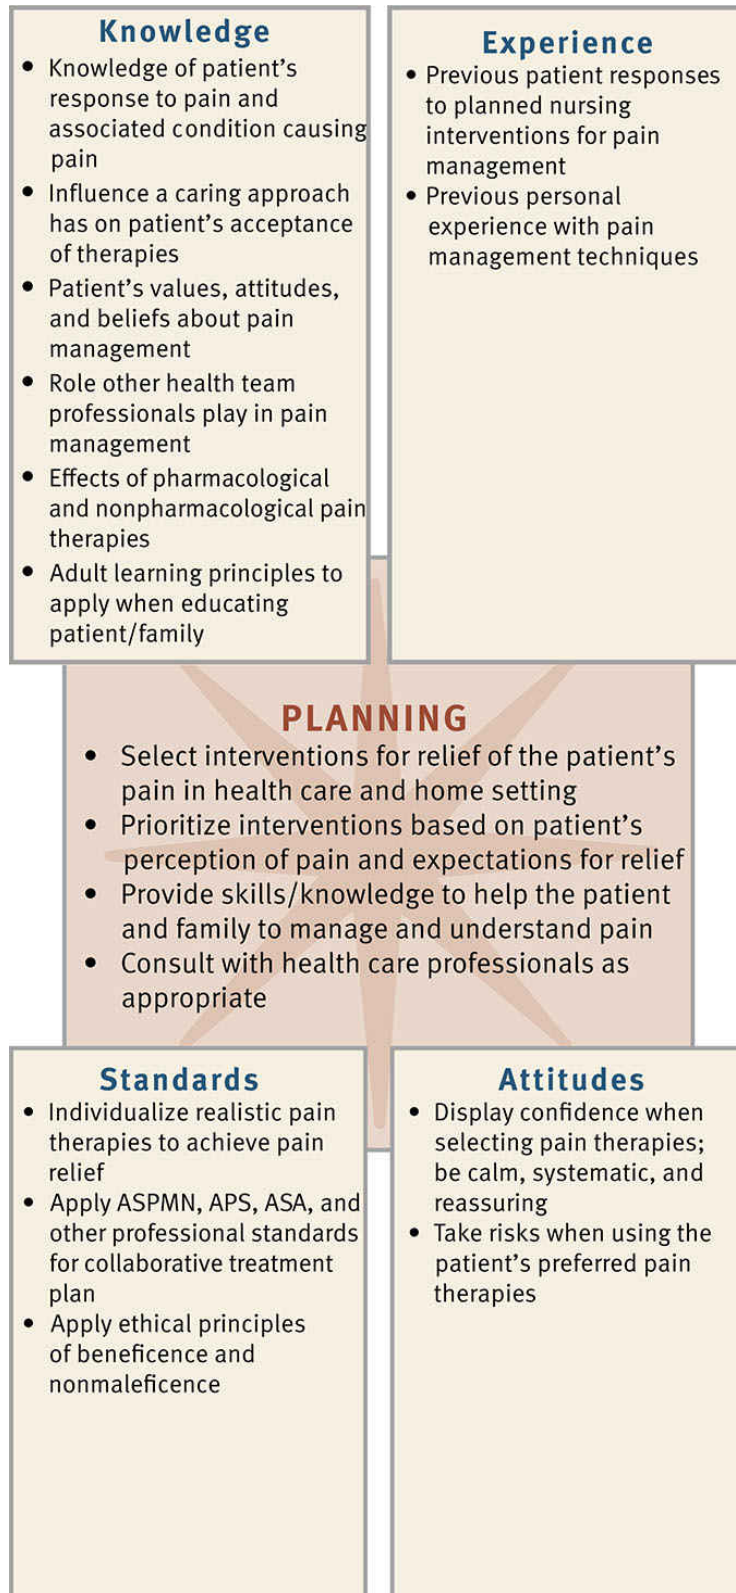

FIG. 44.8 Critical thinking model for pain management planning. APS, American Pain Society; ASPMN, American Society Pain Management Nursing; ASA, American Society of Anesthesiologists.

Another strategy for planning care is using a concept map. Patients who are in pain frequently have interrelated problems. As one problem gets worse, other aspects of a patient's level of health also change. A concept map helps you determine how the nursing diagnoses are interrelated with one another and linked to the patient's medical diagnosis. This eventually allows you to also see how interventions are related for different diagnoses. See the example for Mrs. Mays' plan of care ([Fig. 44.9](#)). Identifying the relationships between diagnoses and interventions helps you develop a holistic and patient-centered plan of care.

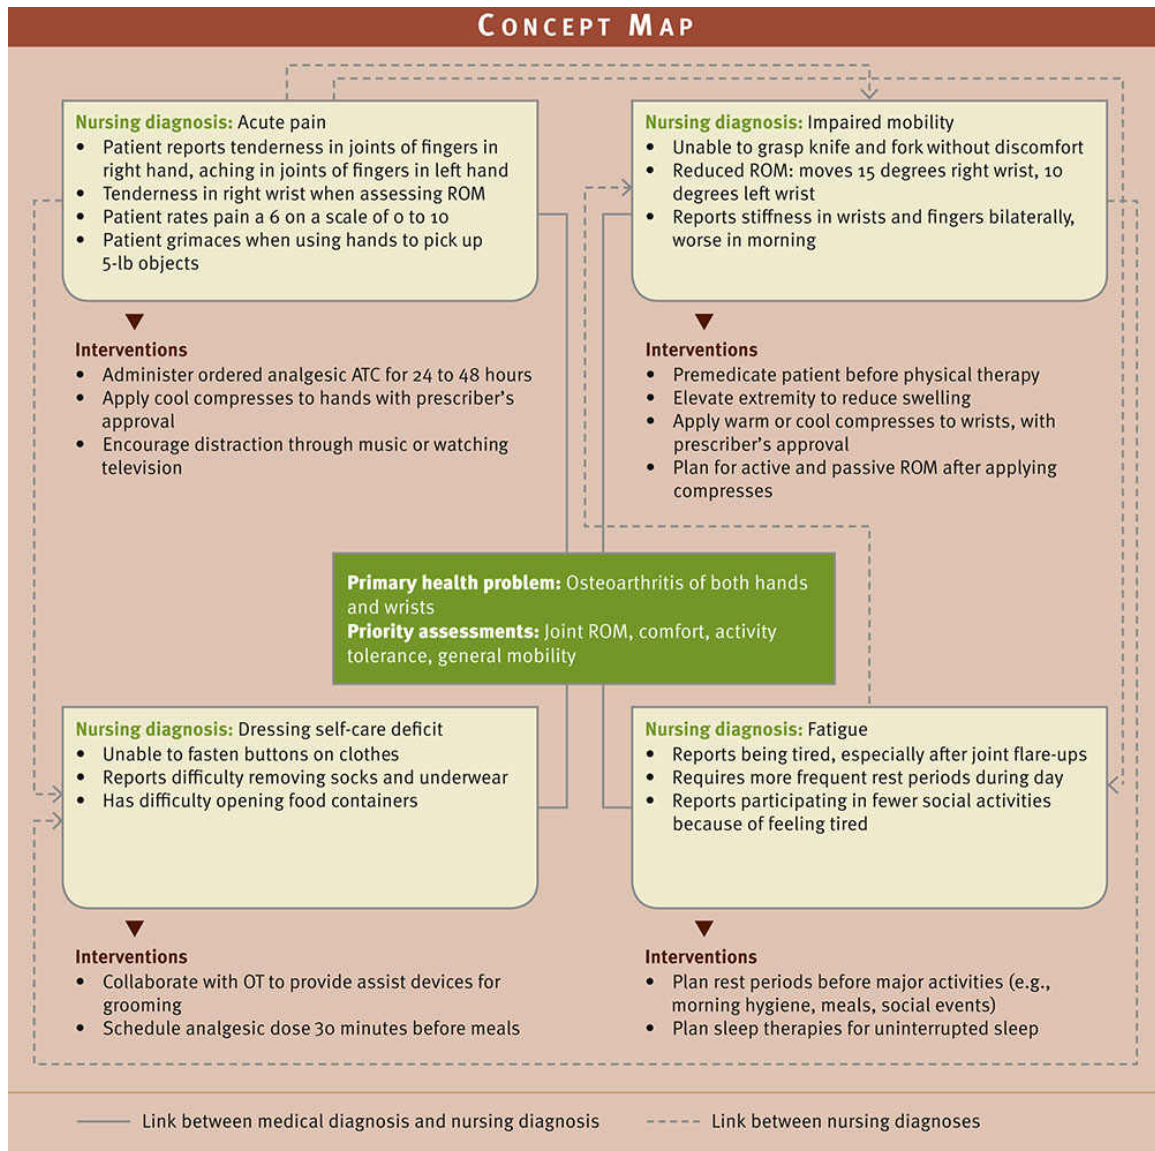

FIG. 44.9 Concept map for Mrs. Mays. ATC, Around the clock; OT, occupational therapist; ROM, range of motion.

Goals and Outcomes

Because the pain experience is so closely connected to a patient's perceptions, beliefs, and attitudes, it is essential that your plan include goals of care accepted by the patient. A patient-centered plan will more likely promote the patient's optimal function. Partner with the patient to determine relevant and realistic expectations for pain relief. Decide on a mutually acceptable level of pain that allows return of function. Make sure that the patient understands that complete pain relief may not be possible

but that every effort will be made to allow him or her to safely reach a pain level that allows for maximum function.

Nursing Care Plan

Acute Pain

Assessment

Mrs. Mays, 72 years old, was diagnosed with a cancerous tumor in her left lung 2 months ago. She takes ibuprofen on an as-needed (prn) basis to manage her arthritis pain. She is admitted to the hospital with uncontrollable pain in her chest, shortness of breath, and possible pneumonia.

Assessment Activities	Assessment Findings ^a
Ask Mrs. Mays what she did at home to control her pain.	Her pain rapidly escalated over several hours from a 3 to a 10 on a scale of 0 to 10, so she doubled her ibuprofen and went to bed, but this did not help.
Ask Mrs. Mays to describe the pain she is having now.	She is having sharp, stabbing constant pain on the lower left side of her chest.
Ask Mrs. Mays to rate her pain on a scale of 0 to 10.	She rates her pain at a 7.
Ask Mrs. Mays what has helped and worsened her pain.	She responds that her pain decreases when she stays still and takes shallow breaths. It is worsened by activity (e.g., walking, completing ADLS), deeper breaths, and coughing.
Observe Mrs. Mays' nonverbal behavior.	She is restless, is unable to stay focused, her muscles tense, and she is frowning during the history taking.

^a **Assessment findings** are shown in bold type.

Nursing Diagnosis:

Acute pain related to abrupt onset of pulmonary inflammation

Planning

Goals	Expected Outcomes (NOC) ^b
	Pain Control
Mrs. Mays will perceive a tolerable level of pain before discharge.	Mrs. Mays reports chest pain at target goal of 3 or below. Mrs. Mays demonstrates use of nonpharmacologic therapies.
	Pain: Disruptive Effects
Mrs. Mays will actively participate in activities of daily living (ADLs).	Mrs. Mays reports sleeping for 5 to 6 hours without interruption from pain. Mrs. Mays completes her own hygiene with minimal assistance. Mrs. Mays walks the hallway with her husband every 4 hours for 15 minutes.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Pain Management: Acute	
Begin around-the-clock (ATC) prescribed dose of opioid and co-analgesic.	Severe acute pain requires immediate-release opioid (US Dept of Veterans Affairs, 2017). Most opioids may be given around the clock (ATC) for continuous pain. ATC dosing is recommended after an optimal dose is established by dose titration (National Pharmaceutical Council, 2001)
Consult with health care provider for providing a multimodal pharmacological regimen	Combining analgesics with at least two different mechanisms of action can optimize pain control.
Have patient select nonpharmacological interventions that have relieved her pain in the past (e.g., distraction, music, simple relaxation therapy) or that are acceptable to her.	Nonpharmacological approaches augment pharmacological therapy and help patients improve quality of life and decrease anxiety and depression (Tick et al., 2018).
Teach spouse how to perform slow-stroke back massage when pain has lessened.	Slow-stroke back massage is easy to do, takes a short time, and induces relaxation (Tick et al., 2018). Not likely effective during most acute pain.

^c Intervention classification labels from Bulechek GM, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Ask Mrs. Mays if she has attained her pain-relief goal most of the time.	She responds, "My pain usually runs around a 3, except when I start coughing or walking."	Mrs. Mays reports an acceptable level of pain.
Observe Mrs. Mays performing ADLs, walking, and during sleep.	Mrs. Mays is dressed for breakfast, walking the hallway every 4 hours with her husband. The night nurse's notes indicate that she slept through the night.	Ability to perform ADLs and sleep has improved. Continue to monitor.
Ask Mr. Mays if he was able to give his wife a back rub.	Mr. Mays reported that she did not want a back rub but preferred to have her feet rubbed, which he was happy to do. "She said it made her feel more relaxed."	Nonpharmacological intervention was successful but needs to be changed from back rub to foot rub in the nursing care plan.

It is important to remember that a successful plan of care requires a therapeutic relationship with a patient and family to focus on a relevant education plan. Helping patients learn how to manage their pain is always a goal of care. You help best by listening to the patient's concerns, needs, and understanding of available pain-relief measures. A patient knows the most about his or her pain and is an important partner in selecting successful pain therapies.

An indication of the success of a plan of care is determined through attainment of goals and outcomes. For example, for the goal "the patient will achieve a satisfactory level of pain relief within 24 hours," the following are possible outcomes:

- Reports that pain is a 3 or less on a scale of 0 to 10
- Avoids factors that intensify pain
- Uses pain-relief measures safely
- Is able to dress self

REFLECT NOW

In addition to goals for reducing pain intensity, goals should be set with patients concerning their physiological, affective, cognitive, behavioral, spiritual, and social functioning with the use of pharmacological and nonpharmacological management strategies. Why is it important to address these other domains of pain rather than just focusing on reducing pain intensity?

Setting Priorities

When setting priorities in pain management, consider the type of pain the patient is experiencing and the effect that it has on function and quality of life. The primary goal often is to decrease pain to help the patient improve function. Any episode of acute pain is a priority because of its potential effects on physical and psychological function. In addition, acute pain may cause the interruption or delay of other important therapies (e.g., ambulation, physical therapy, or a planned diagnostic procedure). For less acute pain, work with the patient to select interventions that are appropriate and relevant. For example, if an analgesic is relieving acute pain, turn your attention to how the pain is affecting the patient's activity, appetite, and sleep. What other therapies can you provide? Priorities change as a patient's pain experience changes.

Teamwork and Collaboration

A comprehensive plan includes the collaboration of a variety of members from the health care team, including advanced practice nurses, doctors of pharmacology (PharmDs), physical therapists, occupational therapists, physicians, social workers, psychologists, and clergy. An oncology or pain clinical nurse specialist is very familiar with pharmacological and nonpharmacological interventions that are most effective for chronic/persistent pain. PharmDs are knowledgeable about pharmacological treatments of pain. Physical therapists plan exercises that strengthen muscle groups and lessen pain in affected areas. Occupational

therapists devise splints to support painful body parts and plan approaches for performing ADLs. Physicians are familiar with pharmacological interventions, and some are skilled in interventional pain procedures such as nerve blocks and spinal cord stimulator implantations. Social workers and psychologists may offer cognitive behavioral therapy or mindfulness training for pain relief. Clergy members help patients focus on spiritual health by helping patients find the meaning of their pain. It is important to also involve family caregivers in the plan of care. They will often administer care in the home after discharge. If the pain-management plan is unsuccessful in achieving the identified pain-relief goal(s), talk with the patient's health care provider about revising it. Consultation with a pain expert is sometimes necessary.

• Implementation

Pain therapy requires an individualized approach, perhaps more so than any other patient problem. The nurse, patient, and frequently the family are partners in pain management. You are responsible for administering and monitoring therapies ordered by health care providers for pain relief and independently providing measures that complement those prescribed. Generally try the least invasive or safest therapy first along with previously used successful patient remedies. If you question a medical therapy, consult with the health care provider.

Your ability to show compassionate care toward patients has the potential for maximizing their pain control. You can help a patient minimize pain through caring behaviors such as listening, offering a gentle touch, and responding promptly to a pain request.

Health Promotion

When providing pain-relief measures, apply these guidelines for individualizing pain therapy:

- Use different types of pain-relief measures. Persistent pain is multifactorial, requiring an approach that addresses a variety of etiologies and includes pharmacological and nonpharmacological strategies ([Galicia-Castillo and Weiner, 2019](#)).
- Be willing to use more than one type of pain relief measure as appropriate.
- Use measures that the patient believes are effective.
- Keep an open mind about ways to relieve pain.

- Keep trying. When efforts at pain relief fail, do not abandon the patient but reassess the situation. Persistent pain is treatable, with improvement anticipated, but it is not curable ([Galicia-Castillo and Weiner, 2019](#)).
- Although pain may not be totally eliminated, substantial improvement in function is realistic ([Galicia-Castillo and Weiner, 2019](#)).

Maintaining Wellness

Patients are better prepared to handle almost any situation when they understand it. The experience of pain and its related therapies is no exception. However, patients with moderate-to-severe pain are not always able to participate in decision making until the pain is controlled at an acceptable level. Once you accomplish this, you can begin teaching.

Pain often affects a patient's ability to sleep and remain asleep. Consider consulting with a health care provider on appropriate medications for the patient, and try nonpharmacological interventions to promote sleep (see [Chapter 43](#)). Instruct patients not to use medications that promote sleep as a substitute for pain relief.

Health literacy significantly affects a patient's pain experience and understanding of pain-management strategies. Low health literacy poses significant barriers to optimal pain management. In a study of patients with chronic pain, patients with low health literacy were found to have low overall pain medication knowledge and did not know where to find health care professionals to help them with their pain ([Devraj et al., 2013](#)). The patients in the study also lacked knowledge about nonpharmacological approaches to pain management and did not know which nonprescription pain medications could provide pain relief. In another study Spanish-speaking Hispanic Americans commonly reported difficulties in describing their pain experience and problems in understanding clinical recommendations from non-Spanish-speaking health care providers ([Hollingshead et al., 2016](#)).

Research conducted with patients with chronic back pain and other patient groups provides evidence for why educational materials and approaches must be adapted so that they are suited for patients with low health literacy. In addition, combat any cultural norms that may stop patients from talking about pain at all. Stoicism (suffering without verbalizing complaint) not only potentially obscures dangerous signs about which you should know, but also denies people the opportunity to use labels as a tool to cope with pain. Help patients find words to describe

their pain when they are experiencing difficulty explaining it on their own (Pasero and McCaffery, 2011). Because pain affects physical and mental functioning, holistic health approaches are important interventions. Holistic health is an ongoing state of wellness that involves taking care of the whole person: body, mind, spirit, and emotions. To achieve optimal health and well-being, it is necessary to have balance of all of the interdependent elements of the whole person (Matthews-Kozanecka, 2014).

Patients actively participate in their own well-being whenever possible. Common holistic health approaches include wellness education, regular exercise, rest, relaxation techniques (see Chapter 32), attention to good hygiene practices and nutrition, and management of interpersonal relationships. When a person develops pain, offer nonpharmacological strategies. Several nonpharmacological interventions are nurse initiated.

Nonpharmacological Pain-Relief Interventions

Nonpharmacological interventions can be used alone or in combination with pharmacological measures. However, in the case of moderate to severe acute pain, nonpharmacological therapies should not be used in place of pharmacological therapies. A number of nonpharmacological interventions are available for lessening pain. Evidence-based therapies include acupuncture and massage, osteopathic and chiropractic manipulation, cognitive-behavioral intervention, meditative movement and mind-body interventions, and dietary and self-management approaches to pain management (see Chapter 32) (Tick et al., 2018). Researchers suggest that these evidence-based nonpharmacological interventions should be used routinely to provide a comprehensive plan for pain management, although the effectiveness may vary depending on the type of pain that the patient is experiencing and the patient's belief in the therapy. Both active (physical movement) and passive nonpharmacological strategies can target different pathways for pain relief while increasing physical functioning. For example, cognitive-behavioral interventions change patients' perceptions of pain, alter pain behavior, and provide patients with a greater sense of control. Distraction, prayer, mindfulness, relaxation, guided imagery, music, and **biofeedback** are examples of therapies frequently initiated by nurses (US Department of Veterans Affairs, 2017).

Physical approaches aim to provide pain relief, correct physical dysfunction, alter physiological responses, and reduce fear associated with pain-related immobility. Complementary and alternative medicine (CAM)

therapies such as therapeutic touch and mindfulness meditation help to alleviate pain in some patients (see [Chapter 32](#)). An evidence-based practice protocol for pain management in older adults recommends these guidelines for nonpharmacological therapies ([Abdulla et al., 2013](#)):

- Tailor nonpharmacological techniques to the individual.
- Cognitive behavioral strategies may be inappropriate for the cognitively impaired.
- Physical pain-relief strategies (e.g., heat, cold, transcutaneous electrical nerve stimulation [TENS]) focus on promoting comfort and altering physiological responses to pain and are generally safe and effective.

Relaxation and Guided Imagery

Relaxation and **guided imagery** allow patients to alter affective-motivational and cognitive pain perception. **Relaxation** is mental and physical freedom from tension or stress that provides individuals a sense of self-control. You use relaxation techniques at any phase of health or illness. Physiological and behavioral changes associated with relaxation include decreased pulse, blood pressure, and respirations; heightened awareness; decreased oxygen consumption; a sense of peace; and decreased muscle tension and metabolic rate ([Tick et al., 2018](#)). Relaxation techniques include meditation, yoga, Zen, guided imagery, and progressive relaxation exercises (see [Chapter 32](#)). For effective relaxation, teach techniques only when a patient is not distracted by acute discomfort. Sometimes a combination of these techniques is needed to achieve optimal pain relief. With practice the patient performs relaxation exercises independently.

Distraction

The reticular activating system inhibits painful stimuli if a person receives sufficient or excessive sensory input. With sufficient sensory stimuli, a person ignores or becomes unaware of pain. People who are bored or in isolation have only their pain to think about and thus perceive it more acutely. Distraction directs a patient's attention to something other than pain and thus reduces awareness of it. A disadvantage of distraction is that, if it works, health care providers or family members may question the existence or severity of the pain. Distraction works best for short, intense pain lasting a few minutes such as during an invasive procedure or while

waiting for an analgesic to work. Use activities enjoyed by the patient as distractions (e.g., singing, praying, listening to music, or playing games).

Music

Music therapy may be useful in treating acute or chronic pain, stress, anxiety, fatigue, and depression (Korhan et al., 2014; American Music Therapy Association [AMTA], 2019). It diverts a person's attention away from the pain and creates a relaxation response. Specifically, music therapy can result in physiological changes, including improved respiration, lower blood pressure, improved cardiac output, reduced heart rate, and reduced muscle tension (AMTA, 2019). Music creates positive changes in mood and emotional states and allows patients to actively participate in treatment. It can be used with relaxation to help patients cue positive visual imagery. Music therapy uses all kinds of music. It is important to let patients select the types of music they prefer. Music produces an altered state of consciousness through sound, silence, space, and time. Therapeutic sessions usually last 20 to 30 minutes (Tick et al., 2018). Patients may use earphones to enhance their concentration on the music. This allows them to adjust the volume without interrupting other patients or staff. Evidence shows that music contributes to the pain relief of hospitalized patients and may decrease the use of analgesics in some postoperative patients (Cole and LoBiondo-Wood, 2014; Tick et al., 2018).

Cutaneous Stimulation

Stimulation of the skin through a massage, warm bath, cold application, or **transcutaneous electrical nerve stimulation (TENS)** may reduce pain perception. How **cutaneous stimulation** works is unclear. One suggestion is that it causes release of endorphins, thus blocking the transmission of painful stimuli. The gate-control theory suggests that cutaneous stimulation activates larger, faster-transmitting A-beta sensory nerve fibers. This closes the gate, thus decreasing pain transmission through small-diameter C fibers (Melzack and Wall, 1965).

Cutaneous stimulation gives patients and families some control over pain symptoms and treatment in the home. Using it properly helps to reduce muscle tension, resulting in less pain. When using cutaneous stimulation, eliminate sources of environmental noise, help the patient to assume a comfortable position, and explain the purpose of the therapy. Do not use it directly on sensitive skin areas (e.g., burns, bruises, skin rashes, inflammation, and underlying bone fractures).

Massage produces physical and mental relaxation, reduces pain, and enhances the effectiveness of pain medication. Massaging the back, shoulders, hands, and/or feet for 3 to 5 minutes relaxes muscles and promotes sleep and comfort (Tick et al., 2018). Massages communicate caring and are easy for family members or other health care personnel to learn (Box 44.11).

Box 44.11 Procedural Guidelines Massage

Delegation and Collaboration

Assessment of a patient's pain cannot be delegated to assistive personnel (AP). The skill of massage can be delegated to AP. The nurse directs the AP by:

- Identifying and explaining when massage can work best for a patient.
- Explaining how to adapt use of massage to patient restrictions (e.g., massage in side-lying versus prone position).
- Instructing to report worsening of a patient's pain.

Equipment

Lotion or oil (consider lavender aromatherapy lotion [non-alcohol-based]), sheet, bath towel

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Perform hand hygiene. Perform complete pain assessment.
3. Assess character of patient's respirations.
4. Review health care provider's orders for pain relief (if required by agency).
5. Review medical record for any restrictions in patient's mobility or positioning.
6. Assess patient's and/or family caregiver's knowledge, experience, and health literacy level.
7. Assess patient's language level and values he or she has regarding alternative pain-relief approaches. Identify descriptive terms that

you will use when guiding patient through relaxation during massage.

8. Dim room lights and/or turn on soft music according to patient preference.

CLINICAL DECISION: *Massage is contraindicated in cases of muscle, bone, or joint injury; bruised, swollen, or inflamed areas.*

9. Place patient in comfortable position such as prone or side-lying. Have patients with difficulty breathing lie on side of bed with head of bed elevated.
10. Adjust bed to comfortable position for you; lower upper side rail on side where you are standing. Drape patient to expose only area that you will massage.
11. Ensure that patient is not allergic to lotion. Warm lotion in hands or place bottle in basin of warm water. **Note:** If you massage head and scalp, delay use of lotion until completed.
12. Choose stroke technique based on desired effect or body part.

CLINICAL DECISION: Use very gentle massage with patients who are unable to communicate, and monitor nonverbal behavior because they cannot tell you if massage becomes uncomfortable.

- a. Effleurage: massaging upward and outward from vertebral column and back again (see illustration). Smooths and extends muscles; improves lymph and venous circulation.
 - b. Pétrissage: kneading tense muscle groups (see illustration). Promotes relaxation and stimulates local circulation.
 - c. Friction: strong circular strokes bring blood to skin surface. Increases local circulation and loosens tight muscles.
13. Encourage patient to breathe deeply and relax during massage.
 14. Standing behind patient, stimulate scalp and temples.

STEP 12A Effleurage.

STEP 12B Pétrissage.

15. Supporting patient's head, use friction to rub muscles at base of head.
16. Reposition if needed. With patient in supine position, massage hands and arms as appropriate.
 - a. Support hand and apply friction to palm using both thumbs.
 - b. Support base of finger and work each finger in corkscrew-like motion.

- c. Complete hand massage using effleurage strokes from fingertips to wrist.
- d. Knead muscles of forearm and upper arm between thumb and forefinger.

17. After determining that patient has no neck injury or condition that contraindicates neck manipulation, massage neck as appropriate:

- a. Place patient prone unless contraindicated.
- b. Knead each neck muscle between thumb and forefinger.
- c. Gently stretch neck by placing one hand on top of shoulders and other at base of head. Gently move hands away from one another.

18. Massage back as appropriate:

- a. Assist patient to prone position unless contraindicated; side-lying position is an option.
- b. Do not allow hands to leave patient's skin.

STEP 18C Circular massage of the back.

- c. Apply hands first to sacral area; massage in circular motion. Stroke upward from buttocks to shoulders. Massage over scapulae with smooth, firm stroke. Continue in one smooth stroke to upper arms and laterally along sides of back down to iliac crest (see illustration). Continue massage pattern for 3 minutes.
- d. Use effleurage along muscles of spine in upward and outward motion.

- e. Use pétrissage on muscles of each shoulder toward front of patient.
 - f. Use palms in upward and outward circular motion from lower buttocks to neck.
 - g. Knead muscles of upper back and shoulder between thumb and forefinger.
 - h. Use both hands to knead muscles up one side of back and then the other.
 - i. End massage with long, stroking effleurage movements.
19. Massage feet as appropriate:
- a. Place patient in supine position.
 - b. Hold foot firmly. Support ankle with one hand or support sides of foot with each hand while performing massage.
 - c. Make circular motions with thumb and fingers around bones of ankle and top of foot.
 - d. Trace space between tendons with firm finger pressure, moving from toe to ankle.
 - e. Massage sides and top of each toe.
 - f. Use top of fist to make circular motions on bottom of foot.
 - g. Knead sides of foot between index finger and thumb.
 - h. Conclude with firm, sweeping motions over top and bottom of foot.
20. Tell patient that you are ending massage.
21. When procedure is complete, instruct patient to relax and inhale deeply and exhale slowly. Caution him or her to move slowly after resting a few minutes.
22. Wipe excess lotion or oil from patient's body with bath towel.
23. Observe character of respirations, body position, facial expression, tone of voice, mood, mannerisms, verbalization of discomfort.
24. Ask patient to use pain rating scale to rate comfort level; compare with patient's goal.
25. Observe patient perform pain-control measures.
26. Perform teach-back: "I want to ensure you know how to perform massage for your husband. Show me how you would massage his back and feet."
27. Record in EHR or printed record patient's response to massage.

Cold and heat applications (see [Chapter 48](#)) relieve pain and promote healing. The selection of heat-versus-cold interventions varies with patients' conditions ([Tick et al., 2018](#)). For example, moist heat helps to

relieve the pain from a tension headache, and cold applications reduce the acute pain from inflamed joints. When using any form of heat or cold application, instruct the patient to avoid injury to the skin by checking the temperature and not applying cold or heat directly to the skin. Especially at risk for injury are patients with diabetic neuropathies, spinal cord or other neurological disorders, older adults, and patients who are confused.

Ice massage is effective for acute pain relief. It involves the use of a large ice cube or a small paper cup filled with water and frozen (water rises out of the cup as it freezes to create a smooth surface of ice for massage). A nurse or the patient applies the ice with firm pressure to the skin, which is covered with a lightweight cloth. Then use a slow, steady circular massage over the area. Apply cold within a 6-inch circular area near the pain site or on the opposite side of the body corresponding to the pain site. Limit application to 5 minutes or until the patient feels numbness. Application near the actual site of pain tends to work best, and it can be applied several times each hour to help reduce pain (Tick et al., 2018). Cold is effective for tooth or mouth pain when you place the ice on the web of the hand between the thumb and index finger. This point on the hand is an **acupressure** point that influences nerve pathways to the face and head. Cold applications are also effective before vaccine injections (Taddio et al., 2015).

Heat application is more effective for patients with chronic pain. Chapter 48 discusses in detail the types of heat devices (e.g., warm compresses and commercial heat packs) that are safe to use. Never place a heat application in a microwave unless it is directed by the manufacturer. Then follow directions carefully. Teach patients to check the temperature of a compress carefully and not to lie on the heating element because burning can occur.

Another form of cutaneous stimulation is TENS, involving stimulation of the skin with a mild electrical current passed through external electrodes. A TENS unit consists of a battery-powered transmitter, lead wires, and electrodes. TENS works both peripherally and centrally: centrally it acts by activating sites in the spinal cord and brainstem that use opioid and serotonin receptors; peripherally neuroreceptors at the site of the TENS application produce analgesia (Tick et al., 2018). It can be applied at various frequencies (<10 Hz to >50 Hz) and intensity (sensory versus motor). Stimulation intensity has been shown to be the critical factor in TENS efficacy. A TENS unit requires a health care provider's order that identifies the site for the TENS electrode placement. Remove any hair or skin preparations before attaching the electrodes. Then place

the electrodes directly over or near the pain site. Turn the transmitter on to the ordered level when the patient feels pain. The TENS creates a buzzing or tingling sensation. After assessing the patient's tolerance, he or she can then turn on the transmitter and adjust the intensity and quality of skin stimulation until pain relief occurs. TENS is effective for acute, emergent, and postsurgical and procedural pain control ([Tick et al., 2018](#)).

Herbals

Many patients use herbals and dietary supplements such as echinacea, ginseng, ginkgo biloba, and garlic despite conflicting research evidence supporting their use in pain relief. Significant attention has been paid to the potential benefits of glucosamine and chondroitin in the treatment of pain from osteoarthritis, but the evidence suggests that chondroitin isn't helpful for pain from osteoarthritis of the knee or hip, and it is unclear whether glucosamine helps with osteoarthritis knee pain or whether either supplement lessens osteoarthritis pain in other joints ([NIH, 2014](#)). Herbal supplements may interact with prescribed analgesics and condition-specific medications. For example, glucosamine and chondroitin supplements may interact with the anticoagulant drug warfarin and increase the risk of bleeding ([NIH, 2014](#)). Thus it is important to ask patients to report to their health care provider all of the substances taken to relieve pain (see [Chapter 32](#)).

Reducing Pain Perception and Reception

One simple way to promote comfort is to remove or prevent painful stimuli ([Box 44.12](#)). This is especially important for patients who are immobilized or who have difficulty expressing themselves. For example, your patient becomes constipated and has abdominal distention and cramping. You intervene to ensure that the normal elimination process continues: increasing fluids, ambulating the patient, and/or requesting stool softeners or laxatives. Another example involves reducing pain perception during procedures using techniques such as proper patient positioning and coaching to perform progressive muscle relaxation. Always consider the patient's condition, aspects of the procedure that are uncomfortable, and techniques to avoid causing pain. In a patient with severe arthritic knee pain who has severe discomfort during any extreme flexion of the knee, take precautions before walking the patient to the bathroom. Use an elevated toilet seat to allow him or her to sit and rise with minimal discomfort.

Box 44.12 Controlling Painful Stimuli in Patient's Environment

- Tighten and smooth wrinkled bed linen.
- Reposition patient anatomically to relieve any pressure points according to individual preferences or requirements.
- Reposition patient to avoid lying on tubing (e.g., intravenous tubing, chest tubes).
- Loosen constricting bandages (unless specifically applied as a pressure dressing).
- Change wet dressings and linens.
- Check temperature of hot or cold applications, including bath water.
- Lift patient in bed – do not pull. Use safe patient-handling lift devices and techniques.
- Position patient correctly on a bedpan.
- Avoid exposing skin or mucous membranes to irritants (e.g., urine, stool, wound drainage).
- Keep patients clean, dry, and turned if needed. Use urinary incontinence pads if indicated.
- Prevent urinary retention by keeping Foley catheters patent and free flowing if in use, while also monitoring urinary output.
- Prevent constipation with fluids, diet, exercise, and stimulant laxatives if needed.

Acute Care

Nurses often care for patients who have acute pain resulting from invasive procedures (e.g., surgery) or trauma. Many professional organizations such as the APS, [American Society of Anesthesiologists \(ASA, 2010\)](#), and the [ASPMN and ANA \(2016\)](#) have published guidelines and position papers related to acute pain management. The key to success is ongoing pain assessment and evaluation of the efficacy of interventions. Does the patient feel relief? Are there any unacceptable side effects from therapies? It is the responsibility of the health care team to collaborate to find the combination of therapy that works best for a patient.

Pharmacological Pain Therapies

Many pharmacological agents are available to provide pain relief. Your judgment in the use and management of analgesics with or without other pain therapies ensures the best pain relief possible. Unfortunately the ideal analgesic (i.e., one that provides highly effective pain relief without significant risks or side effects) has yet to be developed.

Analgesics

Analgesics are the most common and effective method of pain relief. Nurses need to understand the medications available for pain relief, indications for use and pharmacological effects, and risks for addiction. Reassure patients that treatment of pain is necessary to aid recovery and that nonpharmacological strategies can be used to augment the effectiveness of analgesics, healing, and pain relief.

There are three types of analgesics: (1) nonopioids, including acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs); (2) **opioids** (traditionally called *narcotics*); and (3) **adjuvants** or co-analgesics, a variety of medications that enhance analgesics or have analgesic properties ([US Department of Veterans Affairs, 2017](#)).

Nonopioids. Acetaminophen (Tylenol), considered one of the most tolerated and safest analgesics available, is available in a variety of over-the-counter (OTC) oral medications (e.g., cold and flu remedies) or rectal forms and in an intravenous (IV) preparation (Ofirmev). The analgesic effect of acetaminophen is not entirely clear, but it is believed to have a direct effect on the central nervous system by selectively inhibiting cyclooxygenase, an enzyme needed to make prostaglandins ([Burchum and Rosenthal, 2019](#)). It has limited effects on the peripheral nervous system. Acetaminophen has analgesic and antipyretic properties but no antiinflammatory effects ([Burchum and Rosenthal, 2019](#)). IV acetaminophen (Ofirmev) is effective because it crosses the blood-brain barrier rapidly, thus providing nonopioid analgesia for patients after surgery, especially those who cannot take oral medications. The maximum 24-hour dose is 4 g (the same limitation as aspirin). Acetaminophen is often combined with opioids (e.g., oxycodone, hydrocodone, tramadol) because it reduces the dose of opioid needed to achieve successful pain control. When acetaminophen is combined with an opioid in these products, it is important to recognize the abbreviations that describe the contents of the product. The order and package label often state “name of opioid/acetaminophen (abbreviated as APAP) 5/325” which means that the opioid is 5 mg and the acetaminophen (APAP) is 325 mg per tablet. For

example, oxycodone/APAP 5/325 indicates that each tablet contains 5 mg of oxycodone and 325 mg of acetaminophen. Similar abbreviations are used for combination products of hydrocodone and tramadol.

The major adverse effect of acetaminophen is hepatotoxicity; and, because the drug is so widely used, the Food and Drug Administration (USFDA, 2014) issued an order to limit the amount of acetaminophen in prescription combination products to 325 mg per tablet, capsule, or other dosage unit. Instructions for acetaminophen-containing products such as 1 to 2 tablets every 4 to 6 hours, were not required to change in the order. Higher dosing units continue to be available in OTC products, but the products are required to include dosage labeling information about safety risks, including liver injury and the risks of serious skin rashes. Although some manufacturers have voluntarily reduced the maximum daily acetaminophen dose labeling on their OTC products, the FDA has not reduced the maximum daily dose limit of 4 g for adults. Reduced doses are necessary for inadequate liver function and are recommended to prevent accidental overdose in the outpatient setting. It is important to read and understand these warning labels. Dangerous hepatotoxic overdoses of acetaminophen are treated with acetylcysteine (Burchum and Rosenthal, 2019).

Nonselective NSAIDs such as aspirin, ibuprofen, and naproxen relieve mild-to-moderate acute intermittent pain such as that from headache or muscle strain. Treatment of mild-to-moderate postoperative pain begins with an NSAID unless contraindicated (Chou et al., 2015). NSAIDs act by inhibiting cyclooxygenase (COX), the enzyme that synthesizes prostaglandins and related compounds (Burchum and Rosenthal, 2019). The drugs inhibit cellular responses to inflammation. Most NSAIDs act on peripheral nerve receptors to reduce transmission of pain stimuli and inflammation. Unlike opioids, NSAIDs do not depress the central nervous system, nor do they interfere with bowel or bladder function. However, NSAIDs do increase gastrointestinal irritation because COX normally synthesizes the prostaglandins that protect gastric mucosa. NSAIDs may reduce renal blood flow since COX causes vasodilation to maintain renal blood flow (Burchum and Rosenthal, 2019). Thus NSAID use in the older patient is not recommended because it is associated with more frequent adverse effects (gastrointestinal bleeding as well as renal insufficiency) (American Geriatrics Society Beers Criteria Expert Panel, 2015). Mild-to-moderate musculoskeletal pain in older adults is managed effectively with acetaminophen (Abdulla et al., 2013). Some patients with asthma or an allergy to aspirin are also allergic to NSAIDs (Morales et al., 2015). As with

all OTC medications, patients should be advised to discuss their use of NSAIDs and their pain with their health care provider.

Opioids. Opioid or opioid-like analgesics are prescribed for moderate-to-severe pain. In any acute pain situation, opioids are not always necessary, but with severe trauma and immediately postoperatively, short-term use of opioid medications (3-5 days) is rarely a problem although side effects are most problematic when initiating treatment (ACPA, 2018). The misuse and improper prescribing of opioids has led to a crisis in the United States. Among patients who use opioids for more than 8 days, 13.5% will be on opioids at 1 year; in addition, 30% of persons taking opioids for more than 31 days remain on them at 1 year (ACPA, 2018). Nurses play a key role in monitoring patient response early when opioids are being used and in detecting potential misuse or prolonged unnecessary use. Long-term use can lead to problems with tolerance, loss of benefit from prescribed dosage with time, and escalating usage despite decreases in function and increases in side effects in some individuals (ACPA, 2018). Opioids, however, do play an important role in pain management. Be knowledgeable of the effects of opioids and implications for patient monitoring and management.

Opiates act on higher centers of the brain and spinal cord by binding with opiate receptors to modify perceptions of pain. Examples of opioids include morphine, codeine, hydromorphone, fentanyl, oxycodone, and hydrocodone. Some are available in IV and oral preparations (morphine and hydromorphone), whereas others are available only in oral formulations (oxycodone and hydrocodone). Most are available in a short-acting form, which provides relief for about 4 hours; some are also available in longer-acting preparations (oral morphine, oxycodone, hydromorphone, and a transdermal fentanyl patch).

One out of every two patients taking oral opioids experiences at least one adverse event/effect (Box 44.13). The most common side effects of opioids include nausea, vomiting, constipation, and memory and thought changes (ACPA, 2018). Except for constipation and central nervous system changes, patients usually become tolerant to many of the opioid side effects. To reduce side effects, patients should take the lowest dose of an opioid needed to manage pain. For example, if the prescriber initially ordered oxycodone 10 mg PO every 4 hours and the patient has nausea and is very drowsy, the nurse might suggest that the prescriber reduce the dose to 5 mg. After administration, reassess a patient for the effect of the lowered dose on pain level and side effects. If reducing a dose does not relieve a side effect, confer with the prescriber about a change in the type

of opioid. If side effects persist, it may be necessary to prevent or treat them by administering other medications (antihistamines, antiemetics, stimulants). Constipation should always be anticipated and prevented through diet, hydration, and the use of stool softeners and stimulants as needed.

Box 44.13 Common Opioid Side Effects

Central Nervous System (CNS) Toxicity

- Thought and memory impairment
- Drowsiness, sedation, and sleep disturbance
- Confusion
- Hallucinations, potential for diminished psychomotor performance
- Delirium
- Depression
- Dizziness and seizures

Ocular

- Pupil constriction

Respiratory

- Bradypnea
- Hypoventilation

Cardiac

- Hypotension
- Bradycardia
- Peripheral edema

Gastrointestinal

- Constipation
- Nausea and vomiting
- Delayed gastric emptying

Genitourinary

- Urinary retention

Endocrine

- Hormonal and sexual dysfunction
- Hypoglycemia—reported with tramadol and methadone

Skin

- Pruritus

Immunological

- Immune system impairment possible with chronic use

Musculoskeletal

- Muscle rigidity and contractions
- Osteoporosis

Pregnancy and Breastfeeding

- When at all possible, avoid opioid use during pregnancy to prevent fetal risks

Tolerance

- Over time, increased doses needed to obtain analgesic effect

Withdrawal Syndrome

- Rapid or sudden cessation or marked dose reduction may cause rhinitis, chills, pupil dilation, diarrhea, “gooseflesh”

Adapted from American Chronic Pain Association (ACPA): *ACPA resource guide to chronic pain medication & treatment*, 2018 edition, 2018, https://www.theacpa.org/wp-content/uploads/2018/03/ACPA_Resource_Guide_2018-Final-v2.pdf. Accessed March 27, 2019.

An adverse effect of opioids in opioid-naïve patients (patients who have used opioid around the clock [ATC] *less* than approximately 1 week), as well as in patients on high-dose opioids or who are taking opioids with benzodiazepine medications, is respiratory depression. Sedation always occurs before respiratory depression. Closely monitor for sedation in opioid-naïve patients. Respiratory depression is clinically significant only if there is a decrease in the rate and depth of respirations from a patient’s baseline assessment (Pasero and McCaffery, 2011). It is important for nurses to obtain a complete opioid medication history, including dose, frequency, and duration of use, to determine whether patients are opioid naïve or tolerant. All patients who receive opioids are at risk. However, patients who are opioid naïve (new or restarting opioids), who have a history or show signs of obstructive sleep disorder, who are on high-dose opioids, or who are taking opioids with other sedative medications are at greater risk (US Department of Veterans Affairs, 2017). If an adult patient experiences respiratory depression, administer naloxone (0.4 mg diluted with 9 mL saline) IV push (IVP) at a rate prescribed by health care provider. For initial treatment, IV administration is recommended, and once respiratory depression has been reversed, IM or subcutaneous routes can be used (Burchum and Rosenthal, 2019). Administering naloxone faster than recommended may cause severe pain and serious complications such as hypotension and hypertension, cardiac arrhythmias, dyspnea, and pulmonary edema (Pasero and McCaffery, 2011). Evaluate

patients who receive naloxone every 15 minutes for 2 hours following drug administration because its duration may be less than that of the opioid, and respiratory depression sometimes returns.

One way to maximize pain relief while potentially decreasing opioid use is to administer analgesics around the clock (ATC) or at scheduled times rather than a prn basis. This approach ensures a more constant therapeutic blood level of an analgesic. There are also a variety of extended- or controlled-release oral opioid formulations (dosing intervals of 8, 10, 12, or 24 hours) and transdermal patches (72 hours). These formulations maintain constant serum opioid concentration, minimizing toxic and subtherapeutic concentrations (Burchum and Rosenthal, 2019). An ATC medication lessens the severity of end-of-dose pain, allowing a patient to sleep through the night and reduce “clock watching” for the next dose.

Careful assessment and critical thinking are required to safely administer analgesics (Box 44.14). The current pharmacological approach to acute and chronic pain management is to provide **multimodal analgesia**. Multimodal analgesia combines drugs with at least two different mechanisms of action to optimize pain control. Medications are combined to target different sites in the peripheral or central pain pathways (Fig. 44.10). The use of different agents allows for lower-than-usual doses of each medication, which is a benefit of multimodal analgesia. A multimodal regimen lowers the risk of side effects while providing pain relief that is as good as or even better than could be obtained from each of the medications alone.

Box 44.14 Nursing Principles for Administering Analgesics

ATC, Around the clock; *GI*, gastrointestinal; *NSAIDs*, nonsteroidal antiinflammatory drugs.

Know Patient’s Previous Response to Analgesics

- Determine whether patient has sensitivities or allergies.
- Know whether patient is at risk for using NSAIDs (e.g., history of GI bleeding or renal insufficiency) or opioids (e.g., history of obstructive or central sleep apnea).

- Identify previous doses and routes of analgesic administration to avoid undertreatment.
- Determine whether patient obtained relief.
- Ask whether a nonopioid was as effective as an opioid.

Select Proper Medications When More Than One Is Ordered

- Consult with health care provider to use nonopioid analgesics or opioid combination drugs for mild-to-moderate pain.
- Recommend opioids with nonopioids to provide a multimodal analgesia approach.
- Avoid using multiple opioids with the same duration and mechanism of action.
- Intravenous medications act more quickly and usually relieve severe, acute pain within 1 hour, whereas oral medications take as long as 2 hours to relieve pain.
- Avoid intramuscular analgesics, especially in older adults.
- Recommend use of an opioid with a nonopioid analgesic for severe pain because such combinations treat pain peripherally and centrally.
- For chronic pain give sustained-release oral formulations ATC.

Know Accurate Dosage

- Recall that 4 g is considered the maximum 24-hour dosage for acetaminophen and acetylsalicylic acid (ASA); 3200 mg for ibuprofen.
- Adjust doses as appropriate for children and older patients.
- Large doses of opioids are acceptable in opioid-tolerant patients but not in opioid-naïve patients.
- When titrating an opioid, it is important to titrate to effect or to uncontrollable side effects.

Assess Right Time and Interval for Administration

- Administer analgesics as soon as pain occurs and before it increases in severity.
- An ATC administration schedule is usually best.
- Give analgesics before pain-producing procedures or activities.
- Know the average duration of action for a drug and the time of administration so that the peak effect occurs when the pain is most intense.
- Use extended-release opioid formulations to treat chronic pain.
- Avoid stopping opioids abruptly in patients who are opioid tolerant.

Modified from Centers for Disease Control and Prevention: CDC guideline for prescribing opioids for chronic pain—United States, 2016, *MMWR* 65(1):1-49, 2016.

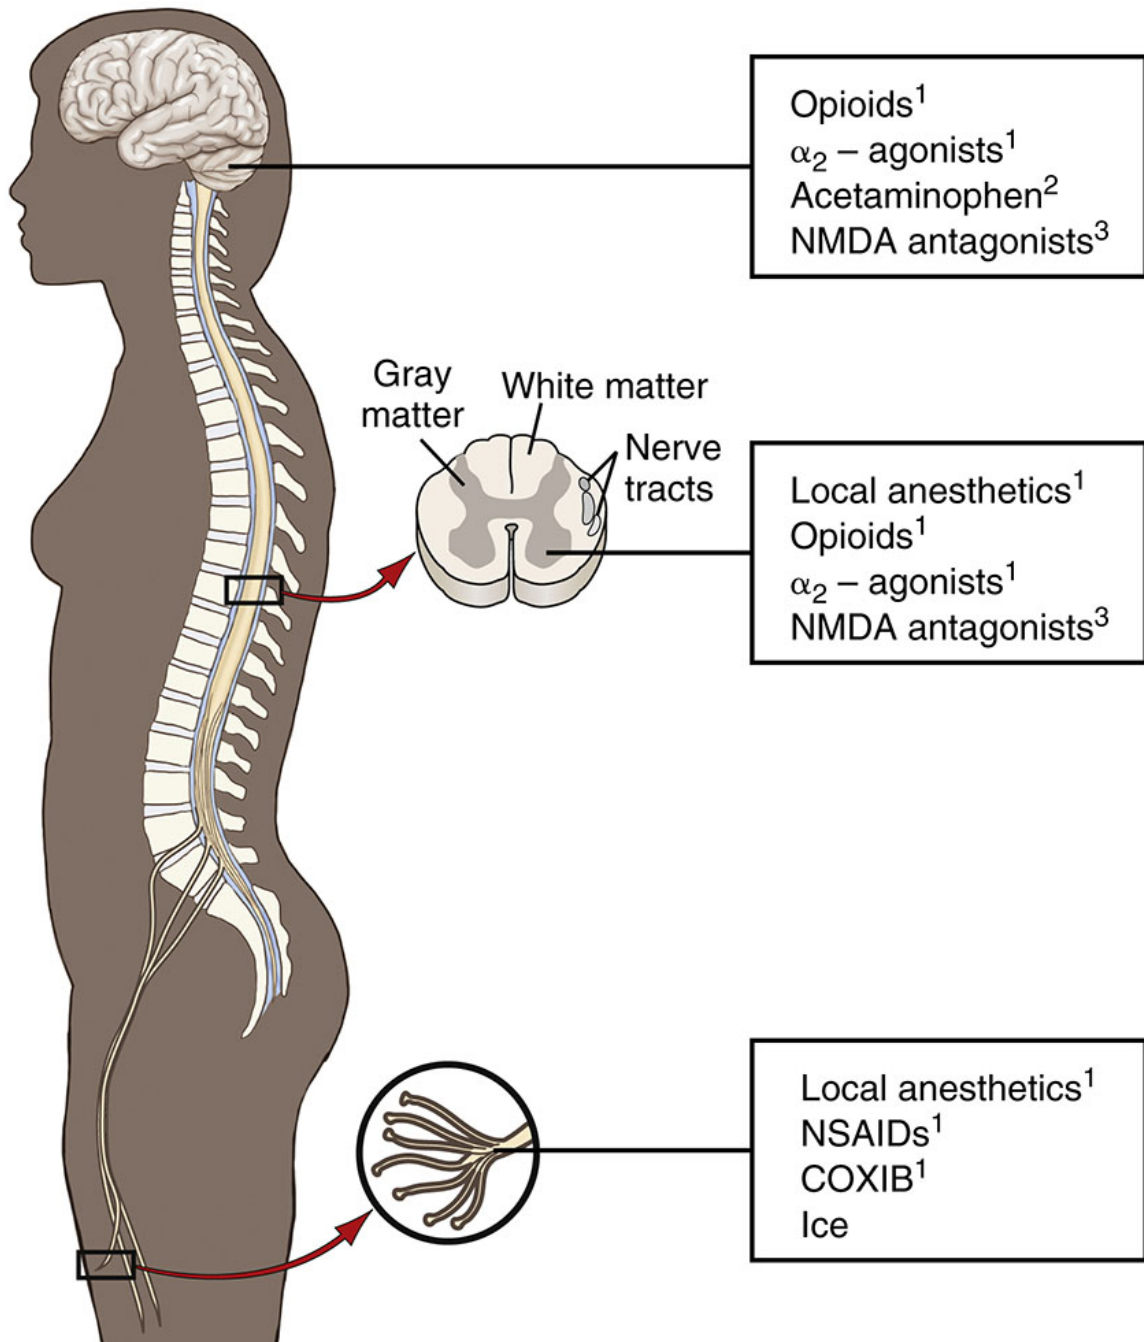

FIG. 44.10 Multimodal analgesia sites of action. (© Elsevier collections.)
 COXIB, Cox-2 inhibitor; NMDA, N-methyl-d-aspartate; NSAID, nonsteroidal antiinflammatory drug. 1. Gottschalk A, Smith DS. New concepts in acute pain therapy: preemptive analgesia. *Am Fam Physician* 63(10):1979-1984, 2001. (<http://www.aafp.org/afp/2001/0515/p1979.html>). 2. Smith HS. Potential analgesic mechanisms of acetaminophen. *Pain Physician* 12:269-280, 2009. (<http://www.painphysicianjournal.com/current/pdf?article=MTE4NA%3D%3D&journal=47>). 3. Sinatra RS, Jahr JS, editors. *The essence of analgesia and analgesics*. New York, 2011, Cambridge University Press.

A person's response to an analgesic is highly individualized. If the pain is caused by inflammation, an NSAID is sometimes as effective as, or more effective than, an opioid. An orally administered analgesic usually has a longer onset and duration of action than an injectable form. In addition, for pain that persists for most of the day, controlled- or extended-release opioid formulations (morphine sulfate extended release, oxycodone sustained/extended release, and methadone) are available for administration every 8 to 12 hours ATC; they are not ordered prn.

When you convert a patient from an IV to an oral form of the same opioid, understand that the dose of the oral opioid is usually much higher than the IV dose because of the first-pass effect. Morphine is inactivated by hepatic metabolism; thus, when taken orally, the drug must pass through the liver on its way to systemic circulation. Much of an oral dose is inactivated during this first pass through the liver. A drug can be completely inactivated on its first pass through the liver, with minimal or no therapeutic effects (Burchum and Rosenthal, 2019). As a result oral doses need to be substantially larger than parenteral doses to achieve equivalent analgesic effects (Burchum and Rosenthal, 2019). Know the comparative potencies of analgesics in oral and injectable form. In addition, know the route of administration most effective for a patient so that controlled, sustained pain relief is achieved. The intramuscular (IM) and subcutaneous routes are painful; absorption is unreliable and thus are generally avoided (Burchum and Rosenthal, 2019). When comparing opioids, equianalgesic charts (i.e., charts converting one opioid to another or parenteral forms of opioids [e.g., morphine to hydromorphone] to oral forms [or vice versa]) should be available on nursing units or by contacting pharmacy staff. There are "smartphone apps" for opioid dosing conversions, but check with the pharmacy staff and agency policies to ensure accuracy before using these electronic conversion tools.

Opioids are usually necessary and effective for acute pain and cancer pain of moderate or severe intensity. The goal of opioid therapy is a reduction in pain intensity to a level of acceptable comfort. In both types of pain, progress toward pain relief is measured by changes in pain-intensity scores. Opioid doses often need to be adjusted up or down according to individual patient circumstances and conditions. A prescriber must carefully individualize drug selection, dosing, and schedule. Many patients are at higher risk for opioid-related adverse drug events (Box 44.15). In addition, morphine-like drugs can interact unfavorably with a number of other medications. For example, morphine-like drugs can interact adversely with CNS depressants, anticholinergic drugs,

hypotensives, and monoamine oxidase inhibitors (Burchum and Rosenthal, 2019).

Box 44.15 Patient Characteristics Associated with Higher Risk for Opioid-Related Adverse Drug Events

- Snoring and sleep apnea or sleep-disordered breathing
- Morbid obesity with high risk of sleep apnea
- Older age
- Significant co-morbidities (cardiac, pulmonary, or major organ failure)
- No recent opioid use
- Increased opioid dose requirement
- Receiving other sedating medications (e.g., antihistamines, antipsychotics)
- Recent surgery, especially thoracic or upper abdominal
- Prolonged general anesthesia
- Smoker

Modified from The Joint Commission: *Sentinel Event Alert: safe use of opioids in hospitals*, Issue 49; August 8, 2012.

http://www.jointcommission.org/assets/1/18/SEA_49_opioids_8_2_12_final.pdf. Accessed March 28, 2019.

Opioid administration in older adults should follow a “start-low” (dose) and “go-slow” (upward dose titration) philosophy (Abdulla et al., 2013). Careful use of multiple drugs together can be seen as potentially helpful. Combining smaller doses of more than one medication may minimize the dose-limiting adverse effects of using a particular single drug (ACPA, 2018). The elderly require special consideration because age-related changes and increased frailty lead to less predictable drug responses, including increased drug sensitivity and severity of side effects (Abdulla et al., 2013). Opioids may place the elderly at increased risk for falls and other injuries. Many elderly patients have multiple co-morbidities and require various medications, placing them at risk for polypharmacy and drug-drug interactions. Dizziness, confusion, and changes in vision are

opioid-related side effects that pose increased safety risks for the elderly; special care must be taken to ensure that the environment is safe and patients are educated about the need for caution. Avoid unintentional medication overdoses by helping an older adult with memory problems receive assistance in creating a safe plan for taking medication (ACPA, 2018). Appropriate interventions may include help from family caregivers, home care medication reconciliation, or using time-of-day labeled pillboxes (that are also kept in a locked safe).

Despite these concerns, elderly patients should receive opioid therapy when needed to treat pain. Carefully selected opioids and doses for all patients, along with patient education and monitoring, are important in providing safe and effective pain management. Box 44.16 offers key steps for the safe use of opioids.

Box 44.16 Key Steps for Safe Opioid Use

- Only fill opioid prescriptions from one health care provider.
- Notify all health care providers about your opioid use. Alert your opioid prescriber about any new medications.
- Inform your health care provider about current/past history of alcohol or substance abuse.
- Follow directions for taking opioids carefully. Do not crush, break, or dissolve pills.
- Reduce the risk of drug interactions. Do not mix opioids with alcohol, antihistamines, barbiturates, benzodiazepines, other sedatives, or muscle relaxants.
- Prevent theft, diversion, and child access to opioids. Keep opioids in a locked box.
- Keep track of when refills are needed to prevent going without medications, which can lead to withdrawal.

Adapted from American Chronic Pain Association (ACPA): *ACPA Resource Guide to Chronic Pain Management*, 2018. https://www.theacpa.org/wp-content/uploads/2018/03/ACPA_Resource_Guide_2018-Final-v2.pdf. Accessed March 28, 2019.

Because there is such a wide variability in patient response to analgesics, as-needed (prn) range orders for opioids (e.g., “morphine 2 to 6 mg IV q2h prn for pain”) are commonly used to provide flexibility in dosing to meet individual patients’ needs (Drew et al., 2018). The Joint Commission requires health care agencies, where permissible, to have range-order policies in place to guide nurses in selecting the most appropriate dose of a medication. Range orders are medication orders in which a dose varies over a prescribed range to provide flexibility in dosing depending on a patient’s condition or situation (Drew et al., 2014). Chapter 31 describes principles of range orders. A proper range order offers specifics (e.g., a patient’s pain severity score) for when a range of doses can be given and gives nurses the flexibility needed to treat patients’ pain in a timely way while allowing for differences in patient response to pain and analgesia. Nurses base decisions about the administration of range orders on a thorough pain assessment and knowledge of the drug to be administered (Drew et al., 2018). Safe and effective range orders consider the patient’s age, pain intensity, pain tolerance, pharmacogenetic profile, renal and liver function, and co-morbidities and prescribe a maximum dose that ranges to 2 to 3 times the lower or minimum dose (Coluzzi, et al., 2016; Drew et al., 2018).

Adjuvants. Co-analgesics or adjuvants are drugs originally developed to treat conditions other than pain but that also have analgesic properties. For example, tricyclic antidepressants (e.g., nortriptyline), anticonvulsants (e.g., gabapentin), and infusional lidocaine successfully treat chronic pain, especially neuropathic pain. Corticosteroids relieve the pain from inflammation and bone metastasis. Other examples of co-analgesics are bisphosphonates and calcitonin for bone pain. Adjuvants have analgesic properties, enhance pain control, or relieve other symptoms associated with neuropathic pain. You give adjuvants alone or with analgesics. Sedatives, anti-anxiety agents, and muscle relaxants have *no* analgesic effect, although they may be effective for their specific indications.

Patient-Controlled Analgesia

When patients depend on nurses for prn analgesia, an erratic cycle of alternating pain and analgesia often occurs. A patient feels pain and asks for medication, but the patient first must be assessed, and then the medication must be obtained and prepared. Under this circumstance analgesia finally occurs in about an hour, but pain relief may last only 30 minutes. Gradually the patient again feels discomfort, and the cycle begins

again. The patient is constantly going in and out of analgesic therapeutic range.

A drug delivery system called **patient-controlled analgesia (PCA)** is a method for pain management that many patients prefer (see Skill 44.1). It is a drug delivery system that allows patients to self-administer opioids (usually morphine, hydromorphone, or fentanyl) with minimal risk of overdose. The goal is to maintain a constant plasma level of analgesic to avoid the problems of prn dosing. Systemic PCA traditionally involves IV or subcutaneous drug administration; however, a controlled analgesia device for oral medications is available. This device allows patients access to their own oral prn medications, including opioids and other analgesics, antiemetics, and anxiolytics, at the bedside.

PCA infusion pumps are portable and computerized and contain a chamber for a syringe or bag that delivers a small, preset dose of opioid (Fig. 44.11). To receive a demand dose, a patient pushes a button attached to the PCA device. The PCA infusion pumps are designed to deliver a specific dose, which is programmed to be available at specific time intervals (usually in the range of 8 to 15 minutes) when the patient activates the delivery button. A limit on the number of doses per hour or a 4-hour interval may also be set. In opioid-naïve patients, do not increase demand or basal dose *and* shorten the interval time simultaneously because this increases the risk for oversedation and respiratory depression. PCA basal doses are also *not* recommended for opioid-naïve patients following surgery because of the possibility for respiratory depression.

FIG. 44.11 Patient-controlled analgesia pump with cassette.
Courtesy Smiths Medical ASD, Inc., St Paul, MN.

Most pumps have locked safety systems that prevent tampering by patients or family members and are generally safe to be managed in the home. For opioid-tolerant patients such as those with cancer pain, a low-dose continuous infusion (basal rate) is sometimes programmed to deliver a steady dose of continuous medication (Pasero and McCaffery, 2011).

There are many benefits to PCA use. The patient gains control over pain, and pain relief does not depend on nurse availability. Patients also have access to medication when they need it. This decreases anxiety and leads to decreased medication use. Small doses of medications are delivered at short intervals, stabilizing serum drug concentrations for sustained pain relief.

Patient preparation and teaching are critical to the safe and effective use of PCA devices (Box 44.17). A patient needs to understand the PCA and be physically able to locate and press the button to deliver a dose. Family members and visitors must be instructed not to “push the button” for the patient (a dangerous action known as “PCA by proxy”), as this bypasses the safety feature of PCA, which requires an awake patient to activate the device. In particular situations, when patients are unable to activate the PCA device, a carefully selected family member or nurse may be authorized to activate the device based on specific criteria. Authorized agent-controlled analgesia (AACAA) guidelines should be used to guide this practice when appropriate (Cooney et al., 2013).

Box 44.17 Patient Teaching

Analgesia

Objective

- Patient will achieve pain control with proper use of the patient-controlled analgesia (PCA) device.

Teaching Strategies

- Teach how to use the PCA before procedures so that patient understands how to use it after awakening from anesthesia or sedation. Include demonstration of use of pump.

- Instruct patient in the purpose of PCA, emphasizing that patient controls medication delivery.
- Explain that the pump reduces risk of overdose.
- Reinforce instruction as needed with teach-back.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Please describe why you are using the PCA device.
- When are you planning on pushing the button?

Programming the settings usually requires independent verification by two nurses to ensure accuracy. Even though patients control administration of analgesics, a nurse's diligence is needed to prevent errors related to programmable PCA devices. Document drug dosages and track medication wastes according to agency policy.

Topical and Transdermal Analgesics

Topical analgesics include prescription and OTC creams, gels, sprays, liquids, patches, or rubs applied on the skin over painful muscles or joints and for peripheral neuropathy ([ACPA, 2018](#)) Commonly used topical agents include NSAID products (ketoprofen patch) and capsaicin and local anesthetics such as lidocaine, prilocaine and diclofenac ([ACPA, 2018](#)). The medications are effective in chronic pain management. Topical agents work locally, have few side effects, and must be applied directly over the painful area.

Transdermal drugs are also applied directly to the skin but have systemic effects and work when applied away from the area of pain ([ACPA, 2018](#)). Transdermal medication in a patch is absorbed through the skin by the bloodstream over a period of time. Examples of analgesic transdermal medications are fentanyl, buprenorphine, and clonidine. [Chapter 31](#) describes the administration of topical and transdermal medications.

The Lidoderm patch is a topical analgesic effective for cutaneous neuropathic pain such as postherpetic neuralgia in adults. Place three patches, cut to size, on and around the pain site using a 12-hour on, 12-hour off schedule ([Pasero and McCaffery, 2011](#)). Products such as ELA-

Max/LMX and eutectic mixture of local anesthetics (EMLA) are available for children. Apply EMLA via a disk or thick cream to the skin 30 to 60 minutes before minor procedures (e.g., IV start, intramuscular injection) or anesthetic infiltration of soft tissue.

Do not place topical or transdermal analgesics on wounds, damaged skin, or the face. Pruritus or burning of the skin or a localized rash is common after topical applications. Application of a topical analgesic to vascular mucous membranes increases the chance of systemic effects such as a change in heart rate. Wear disposable gloves when removing and applying transdermal patches. Lastly, after application, wash your hands thoroughly to avoid getting these products in sensitive areas such as the eyes ([ACPA, 2018](#)).

Local Anesthesia via Injection

Local anesthesia is the local infiltration of an anesthetic medication to induce loss of sensation to a body part. Health care providers often use local anesthesia during brief surgical procedures such as removing a skin lesion or suturing a wound by applying local anesthetics topically on skin and mucous membranes or injecting them subcutaneously or intradermally to anesthetize a body part. **Regional anesthesia** is the injection or infusion of local anesthetics to block a group of sensory nerve fibers. The anesthetics produce temporary loss of sensation by inhibiting nerve conduction. Local anesthetics also block motor and autonomic functions, depending on the amount used and the location and depth of administration. Smaller sensory nerve fibers are more sensitive to local anesthetics than are large motor fibers. As a result, the patient loses sensation before losing motor function; conversely, motor activity returns before sensation.

Perineural Local Anesthetic Infusion

A type of regional anesthesia is the use of perineural injections and infusions of local anesthetic agents to relieve pain. This technique is used for a variety of inpatient and outpatient adult and pediatric surgical procedures. A surgeon places the tip of an unsutured catheter near a nerve or groups of nerves, and the catheter exits from the surgical wound. Infusions of local anesthetics (bupivacaine or ropivacaine) may be run on a pump similar to those used for IV infusions, on ambulatory pumps, or on disposable systems (e.g., On-Q). The pump may be set on demand or continuous mode, and the catheter is usually left in place for 48 hours. Some patients have pump systems that are left in place even after

discharge. Patients learn how to discontinue the pump at home and bring the catheter to the next health care provider visit. Some patients still need oral analgesics, but **perineural infusions** often reduce the total dosage (Chou et al., 2016).

Local anesthetics cause side effects, depending on their absorption into the circulation. The use of local anesthetics in peripheral nerve and epidural infusions (see following paragraph) may block both motor nerves and sensory nerves. This effect resolves within hours of the reduction or discontinuation of an infusion.

Epidural Analgesia

Another pain therapy that often involves the administration of anesthetic agents is **epidural analgesia**, a form of regional anesthesia. Preservative-free opioids are often administered as single agents or in combination with local anesthetics into a patient's epidural space. Epidural analgesia effectively treats acute postoperative pain, rib fracture pain, labor and delivery pain, and chronic cancer pain. Research has shown that adults having surgery under general anesthesia experience fewer postoperative cardiovascular, respiratory, and gastrointestinal complications when receiving epidural analgesia compared with patients receiving systemic analgesia (IV analgesics) (Pöpping et al., 2014). Epidural analgesia controls or reduces severe pain and reduces a patient's overall opioid requirement, thus minimizing adverse effects. It is short or long term, depending on a patient's condition and life expectancy.

The health care provider administers epidural analgesia into the spinal epidural space (Fig. 44.12) by inserting a blunt-tip needle into the level of the vertebral interspace nearest to the area requiring analgesia. He or she advances the catheter into the epidural space, removes the needle, and secures the remainder of the catheter with a dressing while ensuring that the catheter is taped securely. The end of the catheter is capped, or if a continuous infusion is prescribed, it is connected to special tubing and an infusion pump that is designated for epidural infusion. Nurse anesthetists, anesthesiologists, and certified nurses control epidural analgesia, depending on agency policy. Some patients are able to use a technique known as *patient-controlled epidural analgesia (PCEA)*, which allows them to self-administer demand doses of epidural solution when connected to a special administration pump (Chou et al., 2016).

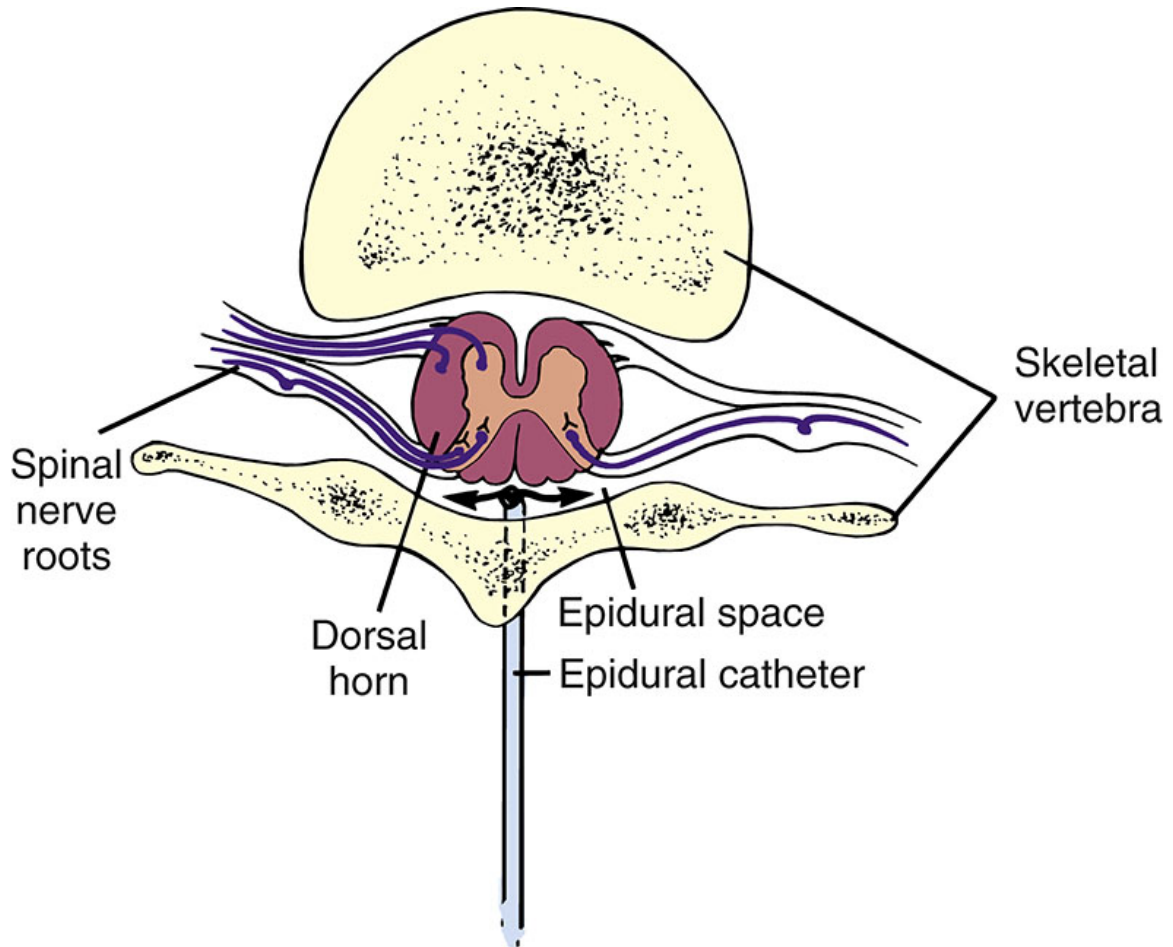

FIG. 44.12 Anatomical drawing of epidural space.

One of the concerns related to the use of peripheral and epidural anesthetic techniques is the risk of bleeding and subsequent hematoma formation near the injection/insertion site. Although relatively uncommon, the risk is increased when patients receive anticoagulant or antiplatelet medications. Safe placement or removal of these injections and catheters is made on the basis of knowledge of the patients' coagulation status and the timing of administration of anticoagulant or antiplatelet medications. Guidelines for the use of anticoagulation in patients with regional anesthesia are available ([Narouze et al., 2015](#)) Because the epidural space is a highly vascular area, patients with epidural catheters are at risk for the development of epidural hematomas, which may lead to ischemia of the spinal cord and if unaddressed, serious neurological complications.

Nursing Implications for Local and Regional Anesthesia

Provide emotional support to patients receiving local or regional anesthesia by explaining the insertion technique and warning patients that

they will temporarily lose sensory function within minutes of injection. Motor and autonomic (bowel and bladder control) function may also be lost quickly, depending on the area anesthetized. It is common for patients to fear paralysis because epidural and spinal injections come close to the spinal cord. To reassure the patient, explain that numbness, tingling, and coldness are common. Catheter insertion should be comfortable because the health care provider should first numb the injection site. Prepare patients for possible discomfort. Before a patient receives an analgesic, check for allergies. Also check to be sure that the drugs (e.g., morphine injection and fentanyl citrate) administered via the epidural catheter are free of potentially neurotoxic substances such as preservatives and additives. Assess vital signs to monitor systemic effects.

After administration of a local or regional anesthetic, protect the patient from injury until full sensory and motor function return. Patients are at risk for injuring an anesthetized body part without knowing it. For patients with topical anesthesia, do not apply heat or cold to numb areas. After an injection into the knee joint, warn the patient to avoid standing without assistance because there is a high risk of falling. With peripheral nerve or epidural local anesthetics, patients may experience sensory loss along with significant motor weakness. Assess patients for sensory and motor nerve blockade, and notify the prescriber when motor blockade is unintended. Protect patients from injury and educate about necessary precautions until full sensory and motor function return. During and after epidural anesthesia a patient stays in bed until motor function returns. Help the patient the first time he or she tries to get out of bed.

When managing epidural infusions, if agency policy allows, connect the catheter to an infusion pump, a port, or a reservoir or cap it off for bolus injections. To reduce the risk of accidental epidural injection of drugs intended for IV use, clearly label the catheter *epidural catheter*. Always administer continuous infusions through appropriately labeled electronic infusion devices for proper control. Because of the catheter location, use surgical asepsis to prevent a serious and potentially fatal infection. Notify a patient's health care provider immediately of any signs or symptoms of infection or pain at the insertion site. Thorough hygiene is necessary during nursing procedures to keep the catheter system clean and dry. Maintain a closed system and prevent catheter disconnection by ensuring tight connections.

Nursing implications for managing epidural analgesia are numerous (Table 44.6). Do not administer supplemental doses of opioids or sedative/hypnotics because of possible additive central nervous system

adverse effects. Monitoring for effects of medications differs, depending on the medication being administered and whether infusions are intermittent or continuous. Complications of epidural opioid use include nausea and vomiting, hypotension, urinary retention, constipation, respiratory depression, and pruritus (Pasero and McCaffery, 2011). When patients receive epidural analgesia, initially monitor them as often as every 15 minutes, including assessment of vital signs, respiratory effort, and skin color. Once stabilized, monitoring occurs every hour in the first 12 to 24 hours and then with less frequency if the patient is stable (refer to agency policy).

TABLE 44.6

Nursing Care for Patients With Epidural Infusions

Goal	Actions
Prevent catheter displacement.	Secure catheter (if not connected to implanted reservoir) carefully to outside skin.
Maintain catheter function.	Check external dressing around catheter site for dampness or discharge. (Leakage of epidural solution may occur if catheter is dislodged.) Use transparent dressing to secure catheter and aid inspection. Inspect catheter for breaks.
Prevent infection.	Use strict aseptic technique when caring for catheter (see Chapter 28). Do not change dressing routinely over site. Inspect insertion site for signs of infection. Follow institutional policies for tubing change.
Monitor for respiratory depression.	Monitor vital signs, especially respirations, and level of consciousness per policy. Use pulse oximetry, end-tidal carbon dioxide, and apnea monitoring.
Prevent undesirable complications.	Assess for hypotension: <ul style="list-style-type: none"> • Ensure adequate hydration and administer prescribed intravenous fluids. • Notify prescriber if significant change in vital signs occurs, and reduce or stop epidural infusion. • Anticipate need for change in epidural solution. Assess for pruritus (itching) and nausea and vomiting associated with use of epidural opioids: <ul style="list-style-type: none"> • Notify prescriber for dose reduction or epidural solution change. • Administer antihistamines and antiemetics as ordered. Assess sensation and motor strength; notify health care provider if deviation from baseline.
Maintain urinary and bowel function.	Monitor intake and output. Assess for bladder and bowel distention. Assess for discomfort, frequency, and urgency.

To minimize bleeding risks and the potential for hematoma formation, do not administer anticoagulant and antiplatelet medications until a pain specialist can verify safe use. To detect development of a possible epidural hematoma, notify the health care provider or pain specialist if the patient develops severe pain at the epidural insertion site or unexplained sensory or motor loss. Also notify the provider who performs the procedure when patients with peripheral nerve injections/catheter have similar signs and symptoms.

Provide thorough patient education about epidural analgesia in terms of the action of the medication and its advantages and disadvantages. Instruct patients about the potential for side effects and advise them to notify you if side effects develop. If the patient requires long-term epidural use, the health care provider tunnels a permanent catheter through the skin. The catheter exits at the patient's side. Teach a patient on long-term therapy how to safely administer home infusions with minimal ongoing nursing intervention, which signs and symptoms need to be reported to the health care provider, and to coordinate with the case manager or social worker to ensure that appropriate home care services are provided.

Invasive Interventions for Pain Relief

When severe pain persists despite medical treatment, available invasive interventions include intrathecal implantable pumps or injections, spinal cord and deep brain stimulation, neuroablative procedures (cordotomy, rhizotomy), trigger point injections, cryoablation, and intraspinal medications (e.g., opioids, steroids, local anesthetics). These techniques are useful for chronic pain. It is unacceptable to tell a patient with severe unrelieved pain that there is "nothing more we can do for you." Refer patients with severe chronic pain to comprehensive pain-management programs whenever possible. These programs offer many different interventional strategies, pharmacological options, physical medicine, and rehabilitation therapies to address the complex needs of patients with chronic pain. When comprehensive pain programs are unavailable, refer patients to a chronic pain-management program.

Pain Management for Procedures

Diagnostic and treatment procedures potentially produce pain and anxiety, both of which should be assessed and treated before a procedure begins. Barriers to successful pain control include numerous patient-specific factors, but perhaps more influential is the lack of acknowledgment by health care providers that pain may occur during or after a procedure. Without this acknowledgment, the necessary anticipation, prevention, and management of potential or actual procedural pain cannot occur (Lee et al., 2014). Many types of routine procedures can cause pain, especially in patients who are critically ill, including turning, wound drain removal, femoral catheter removal, placement of a central line or feeding tube, and changing wound dressings. Common pharmacological agents for managing procedural

comfort include local anesthetics, NSAIDs, acetaminophen, opioids, anxiolytics, and sedatives (Lee et al., 2014). Premedicating patients before painful procedures allows them to cooperate more fully and reduces the experience of pain. Using nonpharmacological therapies such as relaxation techniques, meditation, imagery, and music, in addition to medications, has also been effective in select situations (Lee et al., 2014). When you premedicate a patient before a procedure, keep in mind how long it takes for the onset and peak effect of the analgesic to occur so you can properly time the beginning of the painful procedure to coincide with the medication's peak effect.

Cancer Pain and Chronic Noncancer Pain Management

Cancer pain varies among patients and can be either chronic or acute. A review of research spanning 40 years shows the prevalence of pain ranges from 64% in patients with metastatic, advanced, or terminal phases of the disease; to 59% in patients on anticancer treatment; and up to 40% in patients after curative treatment (Paice et al., 2016). Organizations such as the APS and the National Comprehensive Cancer Network (NCCN) have published guidelines for assessing and treating cancer-related pain. The guidelines support comprehensive and aggressive treatment, including many options for pain relief. The best choice of pain treatment often changes as a patient's condition and the characteristics of pain change. Use multimodal pharmacological strategies and nonpharmacological interventions to optimize pain management (ACPA, 2018).

Many patients with cancer experience **breakthrough cancer pain** (BTCP), a transitory increase in pain in someone who has relatively stable and an adequately controlled level of baseline pain (ACPA, 2018). It occurs either spontaneously or in relation to a specific predictable or unpredictable trigger (Scarborough and Smith, 2018). BTCP is a challenging aspect of cancer because, even though it is self-limiting in nature, its presence has a significant, negative impact on the quality of life of patients and family caregivers (Scarborough and Smith, 2018). Individualized assessment is critical for understanding how BTCP affects a patient's life. A holistic approach to care is often needed (Box 44.18).

Box 44.18 Types of Breakthrough Pain and Treatment

Types of Breakthrough Pain

Incident pain: Pain that is predictable and elicited by specific behaviors or triggers, such as a voluntary act (walking), involuntary act (coughing), or treatments (e.g., wound dressing changes)

End-of-dose failure pain: Pain that occurs toward the end of the usual dosing interval of a regularly scheduled analgesic

Spontaneous pain: Pain that is unpredictable and not associated with any activity or event

Treatment

- Lifestyle changes
- Management of reversible causes
- Modification of pathological processes
- Nonpharmacological management
- Pharmacological management—rescue dose of medication
- Interventional techniques

From Scarborough BM, Smith CB: Optimal pain management for patients with cancer in the modern era, *CA Cancer J Clin* 68(3):182-196, 2018.

In all pain management cases opioids should be used judiciously. The [ACPA \(2018\)](#) reports that the benefits from use of opioids for chronic pain are measured by an increase in the person's level of functioning, a reduction or elimination of pain complaints, a more positive, hopeful attitude, and by minimal or controllable side effects. The use of opioid therapy in patients with chronic pain requires careful patient selection and consideration of the risks and benefits of opioids. For example, to determine whether opioids are beneficial for a patient, it is necessary to assess his or her opioid addiction risk, level of participation in ADLs, physical therapy, family activities, and work-related functions ([CDC, 2016](#)). Family members are often included in office visits to provide input about a patient's functional level. Research has not yet provided clear evidence to support or guide the use of chronic opioid therapy for patients with chronic noncancer pain ([Chou et al., 2015](#)). Use of opioids can increase adverse events and lead to polypharmacy when medications are added to treat side effects of the opioids ([ACPA, 2018](#)). It is recommended that each person with chronic noncancer pain be medically managed individually; medication use should be determined by weighing benefit

compared with other alternatives, cost, potential side effects, and the person's other medical problems (ACPA, 2018).

The World Health Organization (WHO) in 1986 introduced the WHO three-step analgesic ladder as a recommended approach for the slow introduction and upward titration of analgesics for managing pain. This approach has been used worldwide and has been praised for its simplicity and ease of use. However, the ladder has been the object of criticism because of the absence of nonpharmacological therapies in providing analgesia, with modifications suggested in subsequent iterations (US Department of Veterans Affairs, 2017) (Fig. 44.13). The original three-step approach recommended that therapy begin at the first step with the use of nonopioid analgesics and/or adjuvants and progress to the next higher step, using opioids as pain intensity increases.

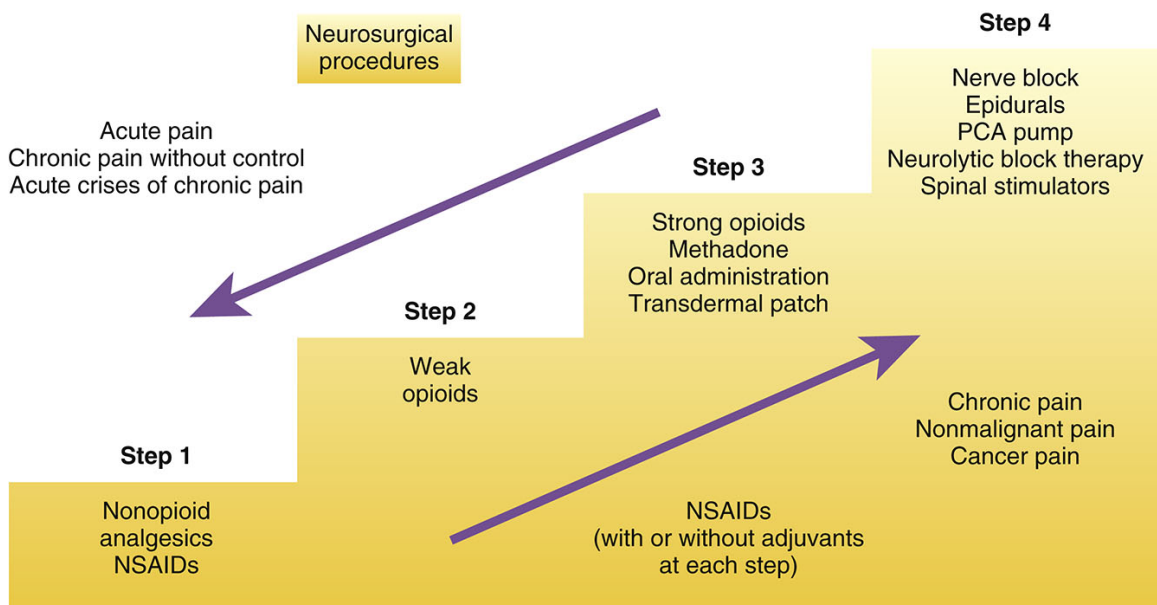

FIG. 44.13 Adaptation of the WHO analgesic ladder. *NSAID*, Nonsteroidal antiinflammatory drug; *PCA*, patient-controlled analgesia. From Vargas-Schaffer G: Is the WHO analgesic ladder still valid?: twenty-four years of experience, *Can Fam Physician* 56:514, 2010.

Modification of the steps aims to facilitate use of the ladder for different pain presentations. A bidirectional approach has been suggested, which adds a step-down approach to the original step-up approach for patients with intense acute pain, uncontrolled cancer pain, and breakthrough pain (Thapa et al., 2011). With this modification, therapy would begin at the third step with the strong opioids and descend down the ladder with

improvement in pain. Another modification includes the addition of a fourth step, which recommends neurosurgical and other invasive procedures and also includes management of pediatric and acute pain in emergency departments and postoperative situations (Vargas-Schaffer, 2010). The fourth step is recommended for the treatment of crises of chronic pain.

Long-acting or controlled-release medications may provide relief for cancer pain, but are not recommended for the treatment of noncancer pain (CDC, 2016). These controlled-release medications (e.g., morphine sulfate extended release and oxycodone HCl) relieve pain for 8 to 12 hours. Long-acting or sustained-release opioids are dosed on a scheduled basis, not prn or “as needed.” Transdermal fentanyl, which is 100 times more potent than morphine, is available for opioid-tolerant patients with cancer or chronic pain. It delivers predetermined doses that provide analgesia for up to 72 hours. The transdermal route is useful when patients are unable to take drugs orally. Patients find the transdermal patch easy to use because it allows for continuous opioid administration without needles or pumps. Self-adhesive patches release the medication slowly over time, achieving effective analgesia. Transdermal fentanyl is not for adult patients who weigh less than 100 lb (too little subcutaneous tissue for absorption) or who are hyperthermic (increases drug absorption). *Do not place heating pads over a patch and never cut a patch.* To dispose of a patch, fold in half, adhesive side onto itself, and flush down the toilet.

All patients on chronic opioid therapy require monitoring and follow-up. Side effects should be anticipated, prevented when possible, and treated when necessary. Over time, patients develop tolerance to the analgesic effect of opioids, requiring higher doses to achieve pain relief. The higher opioid dose is usually not lethal because patients also develop a tolerance to respiratory depression. Less commonly, chronic opioid use may lead to hyperalgesia (increased pain sensitivity). Especially in the case of noncancer pain, monitor patients closely for signs of aberrant opioid-related behaviors such as misuse, abuse, and addiction.

A transmucosal fentanyl “unit” treats breakthrough pain in opioid-tolerant patients. Patients take the medication by placing an opened transmucosal package in their mouth between the buccal mucosa and gums and actively sucking on the medicine. Patients need to let it dissolve in the mouth. Teach patients to not chew it and to allow it to absorb over a 15-minute period, delay swallowing as long as possible, and avoid drinking water or other liquid. A patient should not use more than 1 unit of oral transmucosal fentanyl citrate at a time and no more than 2 units of

oral transmucosal fentanyl citrate during each episode of breakthrough cancer pain. If a patient has more than four episodes of breakthrough cancer pain per day, he or she should contact the health care provider.

Many patients, family members, and health care providers have concerns about the risks of addiction associated with opioid use. The estimated prevalence of prescription opioid abuse and opioid use disorders ranges from less than 1% to 40% due to the limited availability of uniform definitions of what constitutes misuse, abuse, and addiction (Cheatle, 2015). Patients who consult with numerous health care providers may be labeled as drug seekers when they actually may be seeking adequate pain relief. This situation may be associated with behaviors that are indicative of **pseudoaddiction**. Nurses need to discourage patients from “doctor shopping” and having multiple health care providers for treating pain and refer them to pain specialists when effective management cannot be obtained through their general health care providers.

As with constant acute pain, it is necessary to give patients with chronic pain required analgesics on a regular basis. The oral route of administration of analgesic drugs should be used as the first choice (CDC, 2016). The patient with chronic pain may need to take an analgesic ATC, as regular administration maintains therapeutic drug blood levels for ongoing pain control. However, the need for continuation of analgesics should be assessed routinely by the health care provider (CDC, 2016).

Administer analgesics rectally when patients are unable to swallow, have nausea or vomiting, or are near death. This route is contraindicated for patients with diarrhea or cancerous lesions involving the anus or rectum. Morphine, hydromorphone, and oxymorphone are available in suppositories.

Some patients use PCA devices to treat severe cancer pain in the home. PCA devices provide improved, uniform pain control with fewer peaks and valleys in plasma concentration, more effective drug action, and lower drug dosages overall. Patients who usually benefit from continuous infusions include those with severe pain for whom oral and injectable medications provide minimal relief, those with severe nausea and vomiting, and those unable to swallow oral medications.

When a patient receives continuous-drip opioids, ensure the IV access is patent and without complications (see Chapter 42). A central venous catheter, an implanted venous access port, or a peripherally inserted central catheter is usually best for long-term IV infusion. When IV access is poor, the subcutaneous route with a concentrated dose is possible. When

an infusion begins, monitor a patient's sedation level and respiratory status closely during the first 24 hours and with any increases in the infusion rate (follow agency policy). Patients who are placed on continuous analgesic infusions are opioid tolerant; thus respiratory depression is rare.

Building Competency in Patient-Centered Care

You are assigned to make home visits to a 68-year-old female patient who was discharged from the hospital a day ago. The patient has diabetes and underwent a wound debridement of the left leg during hospitalization. When you arrive, the patient describes the pain around the wound as “throbbing” and “never gets much better.” The patient tells you that the NSAID prescribed for wound pain has not worked very well. She states, “I have been taking this medication that I had left over from my surgery last year to help with my pain since this new medication isn’t working.” You note that the medication the patient has been taking is hydrocodone, an oral opioid. What options do you have in helping this patient achieve a realistic and effective approach to managing her pain?

Barriers to Effective Pain Management

Barriers to effective pain management are complex and often involve the patient, the patient's family caregivers, health care providers, and the health care system (Box 44.19). Lack of knowledge and misconceptions about pain and appropriate pain management present significant barriers. Various cultural beliefs about the meaning of pain and pain interventions also pose challenges to effective pain management. Controversy among health care providers exists related to the use of opioid therapy, particularly for the treatment of patients with chronic noncancer pain.

Box 44.19 Barriers to Effective Pain Management

Patient Barriers

- Fear of addiction

- Worry about side effects
- Fear of tolerance (won't be there when I need it)
- Takes too many pills already
- Concern about not being a "good" patient
- Doesn't want to worry family and friends
- May need more tests
- Suffering in silence is expected and needs to suffer to be cured
- Inadequate education
- Reluctance to discuss pain
- Pain inevitable
- Pain part of aging
- Fear of disease progression
- Believes health care providers and nurses are doing all they can
- Just forgets to take analgesics
- Fear of distracting health care providers from treating illness
- Believes health care providers have more important or sicker patients to see

Health Care Provider Barriers

- Inadequate pain-assessment skills
- Concern with addiction or accidental overdose
- Concern with co-morbid mental health conditions
- Opiophobia, fear of opioids
- Fear of legal repercussions
- Patient shows no visible cause of pain
- Belief that patients need to learn to live with pain
- Reluctance to deal with side effects of analgesics
- Not believing patient's report of pain
- Fear that giving a dose will kill patient
- Time constraints
- Inadequate reimbursement
- Belief that opioids "mask" symptoms
- Belief that pain is part of aging

- Overestimation of rates of respiratory depression

Health Care System Barriers

- Concern with creating “addicts”
- Difficulty in filling prescriptions
- Absolute dollar restriction on amount reimbursed for prescriptions
- Mail-order pharmacy restrictions
- Advanced practice nurses not used efficiently
- Poor pain policies and procedures regarding pain management
- Inadequate access to pain clinics
- Poor understanding of economic impact of unrelieved pain

Patients and health care providers often do not understand the differences among **physical dependence, addiction, and drug tolerance** (Box 44.20). Experiencing a physical dependency does not imply addiction, and drug tolerance in and of itself is not the same as addiction. That is not to say that addiction does not occur or that patients who suffer from addiction should not be treated for pain. Patients with addiction and pain should be treated with the same amount of dignity and respect as all other patients, although safety and monitoring are priority concerns. An interprofessional team approach ensures a more effective pain-management plan for a patient with acute pain who also suffers from addiction. Nurses and health care providers need to avoid labeling patients as *drug seeking* because this term is poorly defined and can cause bias and prejudice. If there are concerns that a patient is abusing opioids, they should be voiced to the patient, and the patient’s health care provider should be advised of the concerns. Many patients on long-term opioid medications enter into “pain contracts” that state the expected responsibilities of both the patient and health care provider. If the agreement is violated or other assessments dictate, additional resources may be identified to aid the patient in addressing the addictive illness.

Box 44.20 Definitions Related to the Use of Opioids in Pain Treatment^a

Physical Dependence

A state of adaptation that is manifested by a drug class-specific withdrawal syndrome produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Common symptoms of opioid withdrawal include shaking, chills, abdominal cramps, excessive yawning, and joint pain.

Addiction

A primary chronic neurobiological disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. Addictive behaviors include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Drug Tolerance

A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more effects of the drug over time.

^a Approved by the Boards of Directors of the American Academy of Pain Medicine, the American Pain Society, and the American Society of Addiction Medicine, February 2001 (American Pain Society, 2011).

Placebos

There are many different definitions and interpretations of the terms *placebo* and *placebo effect*. It is generally accepted that **placebos** are pharmacologically inactive preparations or procedures that produce no beneficial or therapeutic effect. Many professional organizations discourage the use of placebos to treat pain. The ethics of therapeutic placebo use is highly controversial; however, evidence suggests that health care providers frequently use placebo treatments, and patients may be open to these interventions under certain situations ([Kisaalita et al., 2016](#)). A study involving a patient-centered approach surveyed patients with chronic musculoskeletal pain about their knowledge and acceptability of placebo analgesic use across different clinical contexts. The survey assessed the role of deception and placebo effectiveness on mood and provider trust. Results showed that participants' acceptability was dependent on the context of an intervention, as placebo treatments were considered acceptable when used as complementary/adjunct treatments and when no other established treatments were available. When there was

no other established treatment for pain relief and patients were involved in deciding the use of placebos, the intervention was more acceptable than when deceptive placebos were used (Kisaalita et al., 2016). Deceptive placebo use jeopardizes the trust between patients and their caregivers. If a placebo is ordered without a patient's understanding of its purpose, question the order. Many health care agencies have policies that limit the use of placebos to only research.

Restorative and Continuing Care

Pain Clinics, Palliative Care, and Hospices

Health professionals recognize pain as a significant health problem. The growth of pain centers, palliative care departments, and hospices designed to manage pain and suffering has increased. The Commission on Accreditation of Rehabilitation Facilities (CARF) accredits chronic pain treatment programs and sets standards for chronic pain management. A comprehensive pain center treats people on an inpatient or outpatient basis. Staff members representing all health care disciplines work with patients to find the most effective pain-relief measures. A comprehensive clinic provides diverse therapies and research into new treatments and training for professionals.

Many hospitals have palliative-care departments to help patients and their family members successfully manage their life-limiting conditions. The goal of palliative care is to help patients manage disease-related symptoms while living life fully with an incurable condition (see [Chapter 36](#)). Patients and their family members need ongoing assistance in managing pain at home. Teaching pain management during discharge and ensuring the continuation of pain management after discharge are essential.

Hospices are programs that care for patients at the end of life (see [Chapter 36](#)). Hospice provides support and care for people in the last stages of incurable disease, with an emphasis on enhancing the quality of remaining life (Cherny et al., 2014). It helps patients who are nearing the end of life to continue to live at home or in a health care setting in comfort and privacy. Pain control is a priority for hospices. Under the guidance of hospice nurses, families learn to monitor patients' symptoms and become the primary caregivers. Some hospice patients become hospitalized such as in the event of a brief acute care crisis or family problem.

Hospice program practices help nurses overcome their fears of contributing to a patient's death when administering large doses of

opioids. The ANA supports aggressive treatment of pain and suffering even if it hastens a patient's death (Fowler, 2015). The ANA position is supported by the ethical principle of double effect, which, when applied to pain at end of life, supports the use of opioids for the purpose of pain relief, despite the risk that a secondary effect may be the hastening of the patient's death from respiratory depression.

Evaluation

Through the Patient's Eyes

Evaluate patients' perceptions of the effectiveness of interventions used to relieve pain. Patients help decide the best times to attempt pain treatments. Essentially they are the best judge of whether a pain-relief intervention works. Often the family is another valuable resource, particularly in the case of a patient with pain who is unable to express discomfort. For patients with chronic pain, consider the effect of the pain intervention on the patient's function when evaluating the patient's perception of his or her response to treatment. You view the pain intervention positively if the intervention results in the patient feeling an improvement in the participation in self-care or activities such as physical therapy. Also ask patients about tolerance to therapy and the overall amount of relief obtained. If patients state that an intervention is unhelpful or even aggravates the discomfort, stop it immediately and seek an alternative. Time and patience are necessary to maximize the effectiveness of pain management. Educate patients about what to expect. For a patient in acute pain, reassure him or her that you will check back frequently to assess for changes in pain level. Continually assess if the character of the patient's pain changes and whether individual interventions are effective.

Patient Outcomes

Evaluation of pain is one of many nursing responsibilities that require effective critical thinking (Fig. 44.14). Evaluate your success in achieving the outcomes of the plan of care. A patient's behavioral responses to pain-relief interventions are not always obvious. Evaluating the effectiveness of a pain intervention requires you to evaluate for change in the severity and quality of the pain. Also be sure to evaluate after an appropriate period of time. For instance, oral medications usually peak in about 1 hour, whereas IVP medications peak in 15 to 30 minutes. Ask a patient whether a medication alleviates the pain when the medication's effect is peaking. Do

not expect the patient to volunteer the information. Evaluate psychological and physiological responses to pain (e.g., check for changes in vital signs and ask questions such as “Tell me how you feel since we gave you your pain medicine.”) It is also important to evaluate whether the patient has any adverse effects from pain therapies.

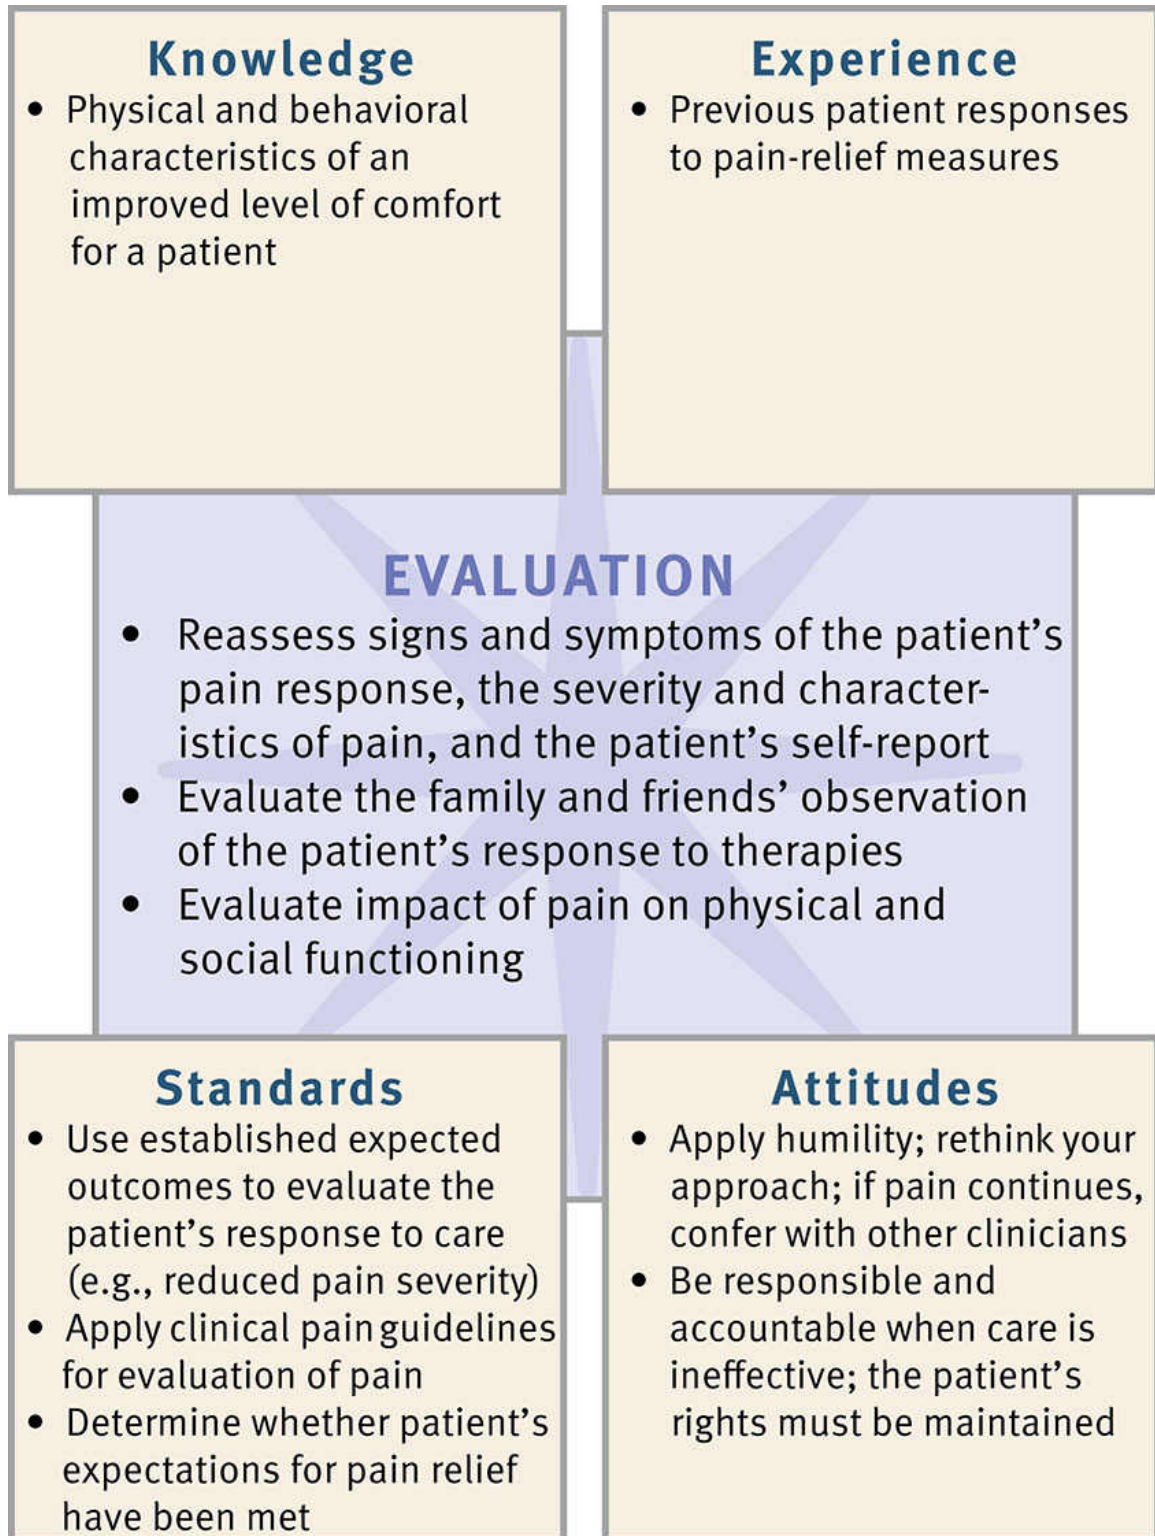

FIG. 44.14 Critical thinking model for pain-management evaluation.

If a patient continues to have discomfort after an intervention, try a different approach. For example, if an analgesic provides only partial

relief, add massage or guided-imagery exercises. Consult with the patient's health care provider about increasing the dose, decreasing the interval between doses, or trying different analgesics. If patient outcomes are not met, ask the patient:

- What is your current pain level?
- How far away is your pain level from your goal?
- Which side effects are you experiencing from your pain medication?
- What have you done to help manage your pain?
- Describe limitations in function that you are experiencing related to uncontrolled pain.
- How is your pain limiting or altering your rest and sleep?

Effective communication of the evaluation of a patient's pain and the response to intervention is facilitated by accurate and thorough documentation. This communication needs to happen from nurse to nurse, shift to shift, and nurse to other health care providers. The nurse caring for the patient has a professional responsibility to report the effectiveness of interventions for managing the patient's pain and evaluation of patient care goals and outcomes. A variety of tools such as a pain flow sheet or diary help centralize information about pain management. The patient expects you to be sensitive to his or her pain and to be attentive in attempts to manage that pain. Effectively communicating with colleagues helps you achieve optimal pain relief for patients. For example, during a hand-off report communicate this information: (1) the patient's current pain rating, (2) the period of time at that level of pain, and (3) what pain rating is acceptable to the patient. Evaluation of pain management requires a patient-centered approach.

Safety Guidelines for Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about the patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care:

- The patient is the only person who should press a PCA button to administer the pain medication.
- Monitor the patient for signs and symptoms of oversedation and respiratory depression.
- Monitor for potential side effects of opioid analgesics.

Skill 44.1. Patient-Controlled Analgesia Delegation and Collaboration

The skill of PCA administration cannot be delegated to assistive personnel (AP). The nurse directs the AP to:

- Notify the nurse if the patient complains of change in status, including unrelieved pain or difficulty awakening.
- Notify the nurse if the patient has questions about the PCA process or equipment.
- Never administer a PCA dose for the patient and to notify the nurse if anyone other than the patient is observed administering a dose for the patient.

Equipment

- PCA pump system and tubing
- Analgesic cartridge or syringe with identification label and time tape (may already be attached and completed by pharmacy)
- Needleless connector
- Antiseptic swab
- Adhesive tape
- Clean gloves (when applicable)
- Opioid reversal agent (e.g., naloxone)
- Equipment for vital signs, pulse oximetry, and capnography
- Medication administration record (MAR)

Step	Rationale
Assessment	
1. Check accuracy and completeness of each MAR or computer printout with health care provider's written medication order. Check patient's name, medication name and dosage, route of administration, lockout period, and frequency of medication (demand, continuous, or both). Recopy or reprint any portion of MAR that is difficult to read.	The order sheet is the most reliable source and only legal record of medications that patient is to receive. Ensures that patient receives the correct medications (Mandrack et al., 2012). Illegible MARs are a source of medication errors.
2. Assess patient's medical and medication history, including drug allergies.	Determines need for medication or possible contraindications for medication administration.
CLINICAL DECISION: When assessing allergies, be aware that nausea is not an allergic reaction and that it can be treated; pruritus alone is not an allergic reaction and is common with opioid use. Pruritus is treatable and does not contraindicate the use of PCA (Masato et al., 2017).	
3. Perform hand hygiene. Perform a complete assessment of character of pain, and measure vital signs.	Reduces transmission of microorganisms. Provides baseline for type and nature of pain condition for determination of efficacy of PCA.
4. Review medication information in drug reference manual or consult with pharmacist if uncertain about any PCA medications to be administered.	Understanding medications before administering them prevents medication errors (Pasero et al., 2015).
5. Assess environment for factors that could contribute to pain (e.g., noise, room temperature).	Elimination of irritating stimuli may help to reduce pain perception.
6. Assess for conditions that predispose patients to unwanted effects from opioids. For example, assess for obstructive sleep apnea syndrome (OSAS) before surgery by anesthesia using the STOP-BANG questionnaire (see Chapter 50) (Gokay et al., 2016) (see agency policy).	Use assessment data to prevent unwanted effects from opioids. For example, known, untreated, or unknown OSAS poses a significant risk for respiratory depression, especially when receiving anesthesia (Gokay et al., 2016). Identification allows treatment teams (surgeon, respiratory therapy, anesthesia) to take appropriate precautions such as making continuous positive airway pressure or bi-level positive airway pressure ventilation devices available.
7. Apply clean gloves. Assess patency of intravenous (IV) access and surrounding tissue for inflammation or swelling (see Chapter 42).	IV line needs to be patent for safe administration of pain medication. Confirmation of placement of IV catheter and integrity of surrounding tissues ensures that medication is safely administered.
8. If patient has had surgery, inspect incision, continuing to wear clean gloves. Gently palpate around area for tenderness. Use sterile gloves if necessary to place hand directly on incision. Remove and dispose of gloves and perform hand hygiene.	Unusual incisional pain, swelling, redness, and/or discharge may indicate infection. Reduces transmission of infection.
9. Assess patient's or family caregiver's knowledge, experience, and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
10. Assess patient's ability to manipulate PCA control and cognitive status for ability to understand purpose of PCA and how to use control device.	Determines patient's competency and ability to use PCA safely and correctly.
11. Assess patient's knowledge and perceived effectiveness of previous pain-management strategies, especially previous PCA use.	Response to pain-control strategies helps identify learning needs and affects patient's willingness to try therapy.
Planning	
1. Provide privacy and prepare bedside environment for patient safety.	Maintains patient comfort and removes barriers that may interfere with procedure.
2. Collect and bring appropriate supplies to the patient's bedside.	Ensures an organized approach.
3. Assist patient into a comfortable position.	
Implementation	
1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Follow "seven rights" for administration of medications (see Chapter 31). Obtain PCA analgesic in module prepared by pharmacy. Check label of medication 2 times—when removed from storage and when preparing for assembly.	Ensures safe and appropriate medication administration. <i>This is the first and second check for accuracy.</i>

Table Continued

Step	Rationale
3. At bedside identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
4. At bedside compare MAR or computer printout with name of medication on drug cartridge. Have second registered nurse (RN) confirm health care provider's order and correct setup of PCA. Second RN should check order and the device independently and not just look at existing setup.	Ensures that correct patient receives right medication. <i>This is the third check for accuracy.</i>
5. Before initiating analgesia, demonstrate function of PCA to patient and family caregiver. This includes education about the use of PCA and verbal and written instruction warning against anyone other than the patient pressing the PCA button (Cooney et al., 2013; Pasero, 2015)	It is important that the patient and family members understand how to use PCA safely. Allows for patient-centered care and improved patient outcomes with pain control (Shindul-Rothschild, 2017).
a. Explain type of medication in device.	Informs patient of therapy to be received.
CLINICAL DECISION: <i>Background basal infusion opioids have been associated with increased risk of nausea, vomiting, and respiratory depression. However, in patients with opioid tolerance, a background basal infusion may be necessary due to the potential for undertreatment and possible opioid withdrawal (Chou et al., 2016).</i>	
b. If a background basal rate is used, explain that device safely administers continuous medication; however, self-initiated small but frequent amounts of medication can be administered for unrelieved pain by using the PCA button.	A background basal infusion delivers a continuous dose of analgesic medication. The PCA pump is programmed to allow additional patient-controlled doses for pain that is not relieved by the continuous infusion (breakthrough pain) (Pasero, 2015).
c. Explain that self-dosing aids in repositioning, walking, coughing, and deep breathing.	Promotes patient's participation in care.
d. Explain that device is programmed to deliver ordered type and dose of pain medication, lockout interval, and 1- to 4-hour dosage limits. Explain how lockout time prevents overdose.	Relieves anxiety in patients who might be concerned about overdosing.
e. Demonstrate to patient how to push medication demand button (see illustration). Instruct family caregiver not to push PCA button to give medication.	Administration by proxy is not recommended in adults (Chou et al., 2016; TJC, 2017).
f. Instruct patient to notify a nurse for possible side effects, problems in gaining pain relief, changes in severity or location of pain, alarm sounding, or questions.	Engages patient as partner in care.
6. Apply clean gloves. Check infuser and patient-control module for accurate labeling or evidence of leaking.	Avoids medication error and injury to patient.
7. Reposition patient to be sure that venipuncture or central line site is accessible.	Ensures unimpeded flow of infusion.
8. Insert drug cartridge into infusion device (see illustration) and prime tubing.	Locks system and prevents air from infusing into IV tubing.
 <p data-bbox="362 1251 621 1266">STEP 5E Patient learns how to press PCA device button.</p>	 <p data-bbox="967 1297 1211 1312">STEP 6 Nurse inserting drug cartridge into PCA device.</p>

Table Continued

Step	Rationale
9. Attach needleless adapter to tubing adapter of patient-controlled module.	Needed to connect with IV line.
10. Wipe injection port of maintenance IV line vigorously with antiseptic swab for 15 seconds and allow to dry.	Minimizes entry of surface microorganisms during needle insertion, reducing risk of catheter-related bloodstream infection.
11. Insert needleless adapter into injection port nearest patient (at Y-site of peripheral IV or central line or connect to its own IV site). There should not be a chance to use PCA tubing for administering IV push with another drug.	Establishes route for medication to enter main IV line. Needleless systems prevent needlestick injuries. Prevents medication interaction and incompatibility.
12. Secure connection and anchor PCA tubing with tape. Label PCA tubing.	Prevents dislodging of needleless adapter from port. Facilitates patient's ability to ambulate. Label prevents error from connecting tubing from different device to PCA.
13. Program computerized PCA pump as ordered to deliver prescribed medication dose and lockout interval. Have second nurse check setting. (Note: Recheck with oncoming RN during shift hand-off to ensure line reconciliation.)	Ensures safe, therapeutic drug administration. With appropriate dose intervals (e.g., 10 min), patient usually experiences an analgesic effect and/or mild sedation before being able to access the next dose; thus, there is lower chance for oversedation and respiratory depression. A second nurse check reduces risk for medication error (Kane-Gill et al., 2017).
14. Administer loading dose of analgesia as prescribed. Manually give 1-time dose or turn on pump and program dose into pump.	Establishes initial level of analgesia.
15. Remove and discard gloves and used supplies in appropriate containers. Dispose of empty cassette or syringe to adhere to institutional policy. Perform hand hygiene.	Reduces transmission of microorganisms. The Federal Controlled Substances Act regulates control and dispensation of opioids for all institutions.
16. If experiencing pain, have patient demonstrate use of PCA system; if not, have patient repeat instructions given earlier.	Repeating instructions reinforces learning. Checking a patient's understanding through return demonstration helps you determine patient's level of understanding and ability to manipulate device.
17. Be sure that venipuncture or central line site is protected and recheck infusion rate before leaving patient.	Ensures patency of IV line.
18. Assist patient into comfortable position.	Patient comfort.
19. Raise side rails (as appropriate) and lower bed to lowest position.	Patient safety precaution.
20. Place nurse call system within patient's reach and instruct patient in its use.	Patient safety precaution.
21. To discontinue PCA:	
a. Check health care provider order for discontinuation. Obtain necessary PCA information from pump for documentation; note date, time, amount infused and amount of drug wasted, and reason for wastage.	Ensures correct documentation of a schedule II drug. Two RNs must witness wastage of opioids (narcotics) and sign record to meet requirements of the Controlled Substances Act for scheduled drugs.
b. Perform hand hygiene and apply clean gloves. Turn off pump. Disconnect PCA tubing from primary IV line, but maintain IV access.	Reduces transmission of microorganisms. Follow health care provider order for maintenance of IV site.
c. Dispose of empty cartridge, tubing and gloves according to agency policy. Remove and dispose of gloves and perform hand hygiene.	Reduces transmission of microorganisms.
d. Follow steps 18-20.	Promotes patient comfort.
Evaluation	
1. Use pain rating scale to evaluate patient's pain intensity following treatments and procedures according to agency policy.	Determines response to PCA dosing. Documenting "PCA in use" or "PCA effective" is not an adequate record of patient's pain level.
2. Observe patient for nausea or pruritus.	Common treatable side effects of opioids.
3. Monitor patient's level of sedation. It is recommended that the Pasero Opioid Sedation Scale (POSS) be used to monitor for unintended patient sedation (Davis et al., 2017; TJC, 2017). Use vital signs, pulse oximetry, and capnography for monitoring. Study findings report nurse observation and administration of the POSS as superior in earlier identification of respiratory depression and oversedation (Chou et al., 2016). Monitoring should be frequent per agency policy and health care provider order (e.g., every 1 to 2 hours for first 12 hours for the first 24-hour period after surgery. Monitor more often at start, during first 24 hours, and at night when hypoventilation and hypoxia tend to occur during sleep.	Patient is at highest risk for oversedation and respiratory distress (OSRD) during the first 24 hours of PCA administration. Although there is low sensitivity for detecting hypoventilation with pulse oximetry when supplemental oxygen is used and evidence is insufficient to firmly recommend capnography (Chou et al., 2016), these interventions are used in monitoring for OSRD and provide important clinical information in your assessment. Excess sedation (difficult to arouse) precedes respiratory depression. Differences in ventilation are observed between wakefulness and sleep, which correlates with states of brain arousal. Opioid-induced respiratory depression is also regulated by sleep-wake mechanisms (Nagappa et al., 2017).

Table Continued

Step	Rationale
4. Have patient demonstrate dose delivery.	Evaluates skill in use of PCA.
5. According to agency policy, evaluate number of attempts (number of times patient pushed button), delivery of demand doses (number of times drug actually given and total amount of medication delivered in particular time frame), and basal dose if ordered.	Helps to evaluate effectiveness of PCA dose and frequency in relieving pain. Maintains compliance with Controlled Substances Act.
6. Observe patient initiate self-care.	Demonstrates pain relief.
7. Use Teach-Back: "I want to be sure I explained how the PCA will help with your pain and how you should use the device. Tell me the steps you will use to activate the PCA." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Patient verbalizes continued or worsening discomfort or displays nonverbal behaviors indicative of pain, suggesting that underlying condition has changed or that patient is undermedicated.</p> <ul style="list-style-type: none"> • Perform complete pain reassessment. • Assess for possible complications. • Inspect IV site for possible catheter occlusion or infiltration. • Evaluate number of attempts and deliveries initiated by patient. • Check that maintenance of IV fluid is running continuously. • Evaluate pump for operational problems. • Consult with health care provider. <p>2. Patient is sedated and not easily aroused.</p> <ul style="list-style-type: none"> • Stop PCA. Notify health care provider immediately. • Elevate head of bed 30 degrees unless contraindicated. • Instruct patient to take deep breaths. • Apply oxygen at 2 L/min per nasal cannula (if ordered). • Assess vital signs, oxygen saturation, and/or capnography. Monitor frequently. • Evaluate amount of opioid delivered within the past 4 to 8 hours. • Ask family members if they pressed button without patient's knowledge. • Review MAR for other possible sedating drugs. • Prepare to administer naloxone if signs or symptoms of respiratory depression are noted. <p>3. Patient unable to manipulate PCA device to maintain pain control.</p> <ul style="list-style-type: none"> • Consult with health care provider regarding alternative medication route or possibly a basal (continuous) dose. 	
Recording and Reporting	
<ul style="list-style-type: none"> • Record appropriate drug, concentration, dose (basal and demand), time started, lockout time, and amount of solution infused and remaining per agency policy. Many agencies have a separate flow sheet for PCA documentation. • Record assessment of patient's response to analgesic on PCA medication form, narrative notes, or patient assessment flow sheet (see agency policy), including vital signs, oximetry and capnography results, sedation status, pain rating, and status of vascular access device. • Calculate infused dose: add demand and continuous dose together. • Document your evaluation of patient learning. • During hand-off report, the oncoming and outgoing nurses should inspect and agree with PCA pump programming as a means of medication reconciliation (Kane-Gill, 2017). • Hand-off report should include detailed information regarding vital signs, pulse oximetry and capnography, pain assessment scores, STOP-BANG score for OSAS if done, POSS sedation scores, level of consciousness, anxiety level, and activity level (Chou et al., 2016; Cooney, 2016; Meisenberg et al., 2017). • Nursing research has been reported on the benefit of "safety priming" during hand-off report, such as using words to activate a mental construct, prompting nursing safety-oriented behavior (Groves et al., 2017). An example of safety priming during hand-off report may include the nurse's words to express concern of what may happen (e.g., excess opioid infusion) because of certain behaviors, instead of reporting only factual information. 	

Key Points

- There are four physiological processes of nociceptive pain: transduction, transmission, perception, and modulation.
- Pain is characterized by its duration, location, cause, intensity, and impact on the individual.
- Individual, physiological, psychological, social, cultural, and environment factors influence pain.
- Cultural beliefs affect how individuals cope with pain as they learn what is expected and accepted by their culture, including how to react to pain.
- The assessment of pain incorporates a patient's physiological, affective, cognitive, behavioral, spiritual, and social dimensions.
- Acute pain is protective, usually has an identifiable cause, is of short duration, and has limited tissue damage and emotional response. In contrast, chronic pain is not protective and thus serves no purpose, but it has a dramatic effect on a person's quality of life.
- Active and passive nonpharmacological measures can be used along with analgesics (nonopioid or opioid) and adjuvant medications for the treatment of pain.
- When administering analgesics, consider that opioids given with nonopioids provide a multimodal analgesia approach, but always avoid using multiple opioids with the same duration and mechanism of action.

- Lack of knowledge and misconceptions about pain and appropriate pain management are significant barriers to pain management.
- Evaluation of the response to pain should include pain intensity, as well as side effects, behavior, and functional outcomes.

Reflective Learning

- Think about a patient you cared for who experienced pain. Was your assessment comprehensive?
- What pain medications were ordered for your patient, and how did you ensure the seven rights of medication administration before administering them?
- Describe the monitoring you did and the side effects you observed for with the ordered medications. How did you determine if the patient's pain management plan was effective?

Review Questions

1. Which of the following signs or symptoms in a patient who is opioid-naïve is of greatest concern to the nurse when assessing the patient 1 hour after administering an opioid?
 1. Oxygen saturation of 95%
 2. Difficulty arousing the patient
 3. Respiratory rate of 12 breaths/min
 4. Pain intensity rating of 5 on a scale of 0 to 10

2. A health care provider writes the following order for a patient who is opioid-naïve who returned from the operating room following a total hip replacement: “Fentanyl patch 100 mcg, change every 3 days.” On the basis of this order, the nurse takes the following action:
 1. Calls the health care provider and questions the order
 2. Applies the patch the third postoperative day
 3. Applies the patch as soon as the patient reports pain
 4. Places the patch as close to the hip dressing as possible
3. A patient is being discharged home on an around-the-clock (ATC) opioid for postoperative pain. Because of this order, the nurse anticipates an additional order for which class of medication?
 1. Opioid antagonists
 2. Antiemetics
 3. Stool softeners
 4. Muscle relaxants
4. A new medical resident writes an order for oxycodone CR 10 mg PO q2h prn. Which part of the order does the nurse question?
 1. The drug
 2. The time interval
 3. The dose
 4. The route
5. The nurse reviews a patient’s medical administration record (MAR) and finds that the patient has received oxycodone/acetaminophen (5/325), two tablets PO every 3

hours for the past 3 days. What concerns the nurse the most?

1. The patient's level of pain
 2. The potential for addiction
 3. The amount of daily acetaminophen
 4. The risk for gastrointestinal bleeding
6. When using ice massage for pain relief, which of the following is correct? (Select all that apply.)
1. Apply ice using firm pressure over the skin.
 2. Apply ice for 5 minutes or until numbness occurs.
 3. Apply ice no more than 3 times a day.
 4. Limit application of ice to no longer than 10 minutes.
 5. Use a slow, circular steady massage.
7. A patient with a 3-day history of a stroke that left her confused and unable to communicate returns from interventional radiology following placement of a gastrostomy tube. The patient had been taking hydrocodone/APAP 5/325 up to four tablets/day before her stroke for the past year to manage her arthritic pain. The health care provider's order reads as follows:
"Hydrocodone/APAP 5/325 1 tab, per gastrostomy tube, q4h, prn." Which action by the nurse is most appropriate?
1. No action is required by the nurse because the order is appropriate.
 2. Request to have the order changed to around the clock (ATC) for the first 48 hours.
 3. Ask for a change of medication to meperidine (Demerol) 50 mg IVP, q3h, prn.

4. Begin the hydrocodone/APAP when the patient shows nonverbal symptoms of pain.
8. Place the following steps in the correct order for administration of patient-controlled analgesia:
 1. Insert drug cartridge into infusion device and prime tubing.
 2. Wipe injection port of maintenance IV line vigorously with antiseptic swab for 15 seconds and allow to dry.
 3. Demonstrate to patient how to push medication demand button.
 4. Secure connection and anchor PCA tubing with tape.
 5. Instruct patient to notify a nurse for possible side effects or changes in the severity or location of pain.
 6. Insert needleless adapter into injection port nearest patient.
 7. Apply clean gloves. Check infuser and patient-control module for accurate labeling or evidence of leaking.
 8. Program computerized PCA pump as ordered to deliver prescribed medication dose and lockout interval.
 9. Attach needleless adapter to tubing adapter of patient-controlled module.
9. When teaching a patient about transcutaneous electrical nerve stimulation (TENS), which of the following represent an accurate description of the nonpharmacological therapy? (Select all that apply.)
 1. Turn TENS on before patient feels discomfort.
 2. TENS works peripherally and centrally on nerve receptors.

3. TENS does not require a health care provider order.
4. Remove any skin preparations before attaching TENS electrodes.
5. Placing electrodes directly over or near the pain site works best.

10. Match the characteristics on the left with the appropriate pain category on the right.

	Acute Pain	Chronic Pain
A. Has a protective effect		
B. Lasts more than 3 to 6 months		
C. Usually has identifiable cause		
D. Dramatically affects quality of life		
E. Viewed as a disease		
F. Eventually resolves with or without treatment

Nutrition

OBJECTIVES

- Explain the effects of a well-balanced diet on the body throughout the life span.
- Discuss the process of digestion and absorption.
- Explain the ChooseMyPlate and discuss its value in planning meals for healthy nutrition.
- List the current dietary guidelines for the general population.
- Explain the variance in nutritional requirements throughout the life span.
- Discuss the major methods of nutritional assessment.
- Correctly perform the procedure for initiation and management of enteral feedings.
- Explain the nursing management of enteral feedings.
- Critique the approaches for how to avoid complications of parenteral nutrition.
- Discuss medical nutrition therapy in relation to three medical conditions.
- Discuss how to implement diet counseling and patient teaching in relation to patient expectations.

Nutrition is a basic component of health and is essential for normal growth and development, tissue maintenance and repair, cellular metabolism, and organ function. Adequate access to nutrition is imperative to attain and maintain this component of health. In 2015, nearly 42.2 million Americans lived in a household that lacked access to proper nutrition ([Swinburne et al., 2017](#)). **Food security** is critical for all members of a household. This term means that all household members have access to sufficient, safe, and nutritious food to maintain a healthy lifestyle. Household members should have sufficient food available on a consistent basis and the resources to obtain appropriate food for a nutritious diet. The importance of food security is supported by the US Department of Agriculture, which found that many children in this country live in a home that lacks the access to enough quality food to maintain an active healthy life ([Huang and Barnidge, 2016](#)). Decreased food security or access to healthy nutrition can result in poor patient outcomes such as longer hospital admissions due to delayed healing or adverse effects on health conditions ([Giddens, 2017](#)). Therefore, nutrition and health are interrelated and represent an important concept in nursing practice.

Medical nutrition therapy (MNT) uses nutrition therapy and counseling to manage diseases ([American Dietetic Association, 2019](#)). In some illnesses such as type 1 diabetes mellitus (DM) or mild hypertension, diet therapy is often the major treatment for disease control ([ADA, 2019](#)). Other conditions such as severe inflammatory bowel disease require specialized nutrition support such as enteral nutrition (EN) or parenteral nutrition (PN). Current standards of care promote optimal nutrition in all patients, including a low-fat diet and limiting red meat specifically ([ACS, 2019](#); [AHA, 2018](#)).

The US Department of Health and Human Services (USDHHS) and the Public Health Service established nutritional goals and objectives for

Healthy People 2020 (USDHHS, 2019). *Healthy People 2020* is the United States' contribution to the "Health for All" strategy of the [World Health Organization \(WHO, 2019\)](#). *Healthy People 2020* (Box 45.1) continues the objectives initiated in *Healthy People 2000* and *Healthy People 2010*, with overall goals of promoting health and reducing chronic disease. All nutrition-related objectives include baseline data from which progress is measured. The challenge remains to motivate consumers to put these dietary recommendations into practice.

Box 45.1 Examples of Nutrition Objectives for *Healthy People 2020* Weight and Growth

- Increase proportion of adults who are at a healthy weight (body mass index [BMI] 18.5 to 24.9).
- Reduce the proportion of adults who are obese.
- Reduce the proportion of children (2 to 11 years) who are overweight or obese.

Food and Nutrient Consumption

- Decrease saturated fat intake in population 2 years and older.
- Increase the variety of vegetables and fruit intake in the population 2 years and older.
- Increase grain product intake and consumption of calcium in the population 2 years and older.
- Reduce sodium daily intake in the population 2 years and older.

Iron Deficiency and Anemia

- Reduce prevalence of iron deficiency in children and childbearing women.
- Reduce prevalence of anemia in pregnant women in third trimester to 20%.

Schools, Work Sites, and Nutrition Counseling

- Increase work-site nutrition-education and weight-management program offerings.
- Offer nutrition assessment and individualized planning at primary care sites.
- Increase the percentage of schools that offer nutritious foods and beverages outside of school meals.
- Increase the number of states with nutrition standards for food and beverages provided to preschool-age children in child care.

Food Security

- Increase food security to 94% of households.

Data from US Department of Health and Human Services: *Healthy people 2020*, 2019, <http://www.healthypeople.gov/>.

Scientific Knowledge Base

Nutrients: The Biochemical Units of Nutrition

The body requires fuel to provide energy for cellular metabolism and repair, organ function, growth, and body movement. The **basal metabolic rate (BMR)** is the energy needed at rest to maintain life-sustaining activities (breathing, circulation, heart rate, and temperature) for a specific amount of time. Factors such as age, body mass, gender, fever, starvation, menstruation, illness, injury, infection, activity level, and thyroid function affect energy requirements. The **resting energy expenditure (REE)**, or resting metabolic rate, is the amount of energy you need to consume over a 24-hour period for your body to maintain all of its internal working activities while at rest. Factors that affect metabolism include illness, pregnancy, lactation, and activity level.

When the **kilocalories (kcal)** of the food we eat meet our energy requirements, our weight does not change (Nix, 2017). When the kilocalories ingested exceed our energy demands, we gain weight. Likewise, if the kilocalories ingested fail to meet our energy requirements, we lose weight.

Nutrients are the elements necessary for the normal function of numerous body processes. We meet energy needs through the intake of a variety of nutrients: carbohydrates, proteins, fats, water, vitamins, and minerals. The **nutrient density** of food refers to the proportion of essential nutrients to the number of kilocalories. High-nutrient dense foods such as fruits and vegetables provide a large number of nutrients in relationship to kilocalories. Low-nutrient dense foods such as alcohol or sugar are high in kilocalories but nutrient poor.

Carbohydrates

Carbohydrates, composed of carbon, hydrogen, and oxygen, are the main source of energy in the diet. Each gram of carbohydrate produces 4 kcal/g and serves as the main source of fuel (glucose) for the brain, skeletal muscles during exercise, erythrocyte and leukocyte production, and cell function of the renal medulla. We obtain carbohydrates primarily from plant foods, except for lactose (milk sugar). Carbohydrate classification occurs according to their carbohydrate units, or saccharides.

Monosaccharides such as glucose (dextrose) or fructose do not break down into a more basic carbohydrate unit. Disaccharides such as sucrose, lactose, and maltose are composed of two monosaccharides and water.

Simple carbohydrate is the classification for both monosaccharides and disaccharides; they are found primarily in sugars. Polysaccharides such as glycogen make up carbohydrate units too (i.e., complex carbohydrates). They are insoluble in water and digested to varying degrees. Starches are polysaccharides.

The body is unable to digest some polysaccharides because we do not have enzymes capable of breaking them down. **Fiber**, a polysaccharide, is the structural part of plants that is not broken down by our digestive enzymes. The inability to break down fiber means that it does not contribute calories to the diet. Therefore, insoluble fibers, including cellulose, hemicellulose, and lignin, are not digestible. Soluble fibers dissolve in water and include barley, cereal grains, cornmeal, and oats.

Proteins

Proteins provide a source of energy (4 kcal/g); they are essential for the growth, maintenance, and repair of body tissue. Collagen, hormones, enzymes, immune cells, deoxyribonucleic acid (DNA), and ribonucleic acid (RNA) are all made of protein. In addition, blood clotting, fluid regulation, and acid-base balance require proteins. Proteins transport nutrients and many drugs in the blood. Ingestion of proteins maintains nitrogen balance.

The simplest form of protein is the amino acid, consisting of hydrogen, oxygen, carbon, and nitrogen. Because the body does not synthesize **indispensable amino acids**, we need these to be provided in our diet. Examples of indispensable amino acids are histidine, lysine, and phenylalanine. The body synthesizes **dispensable amino acids**. Examples of amino acids synthesized in the body are alanine, asparagine, and glutamic acid. Amino acids can link together. **Albumin** and **insulin** are simple proteins because they contain only amino acids or their derivatives. The combination of a simple protein with a nonprotein substance produces a complex protein such as lipoprotein, formed by a combination of a lipid and a simple protein.

A complete protein, also called a *high-quality protein*, contains all essential amino acids in sufficient quantity to support growth and maintain nitrogen balance. Most complete proteins come from animal sources, such as fish, poultry, beef, milk, cheese, and eggs, but they can also come from plant sources, such as soy. Incomplete proteins are missing one or more of the nine indispensable amino acids and include grains, seeds and nuts, legumes, and vegetables. Complementary proteins are

pairs of incomplete proteins that, when combined, supply the total amount of protein provided by complete protein sources.

Nitrogen is a byproduct of protein catabolism. Achieving **nitrogen balance** means that the intake and output of nitrogen are equal. When the intake of nitrogen is greater than the output, the body is in positive nitrogen balance. Positive nitrogen balance is required for growth, normal pregnancy, maintenance of lean muscle mass and vital organs, and wound healing. The body uses nitrogen to build, repair, and replace body tissues. Negative nitrogen balance occurs when the body loses more nitrogen than it gains (e.g., with infection, burns, fever, starvation, head injury, and trauma). The increased nitrogen loss is the result of body tissue destruction or loss of nitrogen-containing body fluids. Nutrition during this period needs to provide nutrients to put patients into positive balance for healing.

Protein provides energy, but because its essential role is to promote growth, maintenance, and repair, a diet needs to provide adequate kilocalories from nonprotein sources. When there is sufficient carbohydrate in the diet to meet the energy needs of the body, protein is spared as an energy source.

Fats

Fats (**lipids**) are the most calorie-dense nutrient, providing 9 kcal/g. Fats are composed of triglycerides and fatty acids. **Triglycerides** circulate in the blood and are composed of three fatty acids attached to a glycerol. Fatty acids are composed of chains of carbon and hydrogen atoms with an acid group on one end of the chain and a methyl group at the other. Fatty acids can be *saturated*, in which each carbon in the chain has two attached hydrogen atoms, or *unsaturated*, in which an unequal number of hydrogen atoms are attached and the carbon atoms attach to one another with a double bond. Monounsaturated fatty acids have one double bond, whereas polyunsaturated fatty acids have two or more double carbon bonds. The various types of fatty acids referred to in the dietary guidelines have significance for health and the incidence of disease.

Fatty acids are also classified as essential or nonessential. Linoleic acid, an unsaturated fatty acid, is the only essential fatty acid in humans. Linolenic acid and arachidonic acid, other types of unsaturated fatty acids, are important for metabolic processes. The body manufactures them when linoleic acid is available. Deficiency occurs when fat intake falls below 10% of daily nutrition. Most animal fats have high proportions of saturated

fatty acids, whereas vegetable fats have higher amounts of unsaturated and polyunsaturated fatty acids.

Water

Water is critical because cell function depends on a fluid environment. Water makes up 60% to 70% of total body weight. People who are lean have a greater percent of total body water than those who are obese because muscle contains more water than any other tissue except blood. Infants have the greatest percentage of total body water because of greater surface area, and older people have the least. When deprived of water, a person usually cannot survive for more than a few days.

We meet our fluid needs by drinking liquids and eating solid foods high in water content such as fresh fruits and vegetables. Digestion produces fluid during food oxidation. In a healthy individual fluid intake from all sources equals fluid output through elimination, respiration, and sweating (see [Chapter 41](#) and [Chapter 46](#)). An ill person has an increased need for fluid (e.g., with fever or gastrointestinal [GI] losses). By contrast, he or she also has a decreased ability to excrete fluid (e.g., with cardiopulmonary or renal disease), which often leads to the need for fluid restriction.

Vitamins

Vitamins are organic substances present in small amounts in foods that are essential to normal metabolism. They are chemicals that act as catalysts in biochemical reactions. When there is enough of any specific vitamin to meet the catalytic demands of the body, the rest of the vitamin supply acts as a free chemical and is often toxic to the body. Certain vitamins are currently of interest in their role as antioxidants. These vitamins neutralize substances called *free radicals*, which produce oxidative damage to body cells and tissues. Researchers think that oxidative damage increases a person's risk for various cancers. Antioxidant vitamins include beta-carotene and vitamins A, C, and E (Nix, 2017).

The body is unable to synthesize vitamins in the required amounts. Vitamin synthesis depends on dietary intake. Vitamin content is usually highest in fresh foods that have minimal exposure to heat, air, or water before their use. Vitamin classifications include fat soluble or water soluble.

Fat-Soluble Vitamins

The **fat-soluble vitamins** (A, D, E, and K) are stored in the fatty compartments of the body. People acquire vitamins primarily through dietary intake, although vitamin D also comes from the sun. The body has a high storage capacity for fat-soluble vitamins. As a result, toxicity is possible when a person takes large doses of them. **Hypervitaminosis** of fat-soluble vitamins results from megadoses (intentional or unintentional) of supplemental vitamins, excessive amounts in fortified food, and large intake of fish oils.

Water-Soluble Vitamins

The **water-soluble vitamins** are vitamin C and the B complex (which is eight vitamins). The body does not store water-soluble vitamins; thus, we need them provided in our daily food intake. Water-soluble vitamins absorb easily from the GI tract. Although they are not stored, toxicity can still occur.

Minerals

Minerals are inorganic elements essential to the body as catalysts in biochemical reactions. They are classified as **macrominerals** when the daily requirement is 100 mg or more and **microminerals** or **trace elements** when less than 100 mg is needed daily. Macrominerals help to balance the pH of the body, and specific amounts are necessary in the blood and cells to promote acid-base balance. Interactions occur among trace minerals. For example, excess of one trace mineral sometimes causes deficiency of another. Selenium is a trace element that also has antioxidant properties. Silicon, vanadium, nickel, tin, cadmium, arsenic, aluminum, and boron are trace elements. Arsenic, aluminum, and cadmium can have toxic effects.

Anatomy and Physiology of the Digestive System

Digestion

Digestion of food is the mechanical breakdown that results from chewing, churning, and mixing with fluid and chemical reactions in which food reduces to its simplest form (Grodner, 2020). Each part of the GI system has an important digestive or absorptive function (Fig. 45.1). Enzymes are the protein-like substances that act as catalysts to speed up chemical reactions. They are an essential part of the chemistry of digestion.

FIG. 45.1 Summary of digestive system anatomy/organ function. *HCl*, Hydrochloric acid.

Most enzymes have one specific function. Each enzyme works best at a specific pH. For example, the enzyme amylase in the saliva breaks down starches into sugars. The secretions of the GI tract have very different pH levels. Saliva is relatively neutral, gastric juice is highly acidic, and the secretions of the small intestine are alkaline.

The mechanical, chemical, and hormonal activities of digestion are interdependent. Enzyme activity depends on the mechanical breakdown of food to increase its surface area for chemical action. Hormones regulate the flow of digestive secretions needed for enzyme supply. Physical, chemical, and hormonal factors regulate the secretion of digestive juices and the motility of the GI tract. Nerve stimulation from the

parasympathetic nervous system (e.g., the vagus nerve) increases GI tract action ([Grodner, 2020](#)).

Digestion begins in the mouth, where chewing mechanically breaks down food. The food mixes with saliva, which contains ptyalin (salivary amylase), an enzyme that acts on cooked starch to begin its conversion to maltose. The longer an individual chews food, the more starch digestion occurs in the mouth. Proteins and fats are broken down physically, but remain unchanged chemically because enzymes in the mouth do not react with these nutrients. Chewing reduces food particles to a size suitable for swallowing, and saliva provides lubrication to ease swallowing of the food. The epiglottis is a flap of skin that closes over the trachea as a person swallows to prevent aspiration. Swallowed food enters the esophagus, and wavelike muscular contractions (**peristalsis**) move the food to the base of the esophagus, above the cardiac sphincter. Pressure from a bolus of food at the cardiac sphincter causes it to relax, allowing the food to enter the fundus, or uppermost part, of the stomach.

The chief cells in the stomach secrete pepsinogen, and the pyloric glands secrete gastrin, a hormone that triggers parietal cells to secrete hydrochloric acid (HCl). The parietal cells also secrete HCl and intrinsic factor (IF), which is necessary for absorption of vitamin B₁₂ in the ileum. HCl turns pepsinogen into pepsin, a protein-splitting enzyme. The body produces gastric lipase and amylase to begin fat and starch digestion, respectively. A thick layer of mucus protects the lining of the stomach from autodigestion. Alcohol and aspirin are two substances directly absorbed through the lining of the stomach. The stomach acts as a reservoir where food remains for approximately 3 hours, with a range of 1 to 7 hours.

Food leaves the antrum, or distal stomach, through the pyloric sphincter and enters the duodenum. Food is now an acidic, liquefied mass called **chyme**. Chyme flows into the duodenum and quickly mixes with bile, intestinal juices, and pancreatic secretions. The small intestine secretes the hormones secretin and cholecystinin (CCK). Secretin activates release of bicarbonate from the pancreas, raising the pH of chyme. CCK inhibits further gastrin secretion and initiates release of additional digestive enzymes from the pancreas and gallbladder.

Bile, manufactured in the liver, is then concentrated and stored in the gallbladder. It acts as a detergent because it emulsifies fat to permit enzyme action while suspending fatty acids in solution. Pancreatic secretions contain six enzymes: amylase to digest starch; lipase to break

down emulsified fats; and trypsin, elastase, chymotrypsin, and carboxypeptidase to break down proteins.

Peristalsis continues in the small intestine, mixing the secretions with chyme. The mixture becomes increasingly alkaline, inhibiting the action of the gastric enzymes and promoting the action of the duodenal secretions. Epithelial cells in the small intestinal villi secrete enzymes (e.g., sucrase, lactase, maltase, lipase, and peptidase) to facilitate digestion. The major part of digestion occurs in the small intestine, producing glucose, fructose, and galactose from carbohydrates; amino acids and dipeptides from proteins; and fatty acids, glycerides, and glycerol from lipids. Peristalsis usually takes approximately 5 hours to pass food through the small intestine.

Absorption

The small intestine, lined with fingerlike projections called *villi*, is the primary absorption site for nutrients. Villi increase the surface area available for absorption. The body absorbs nutrients by means of passive diffusion, osmosis, active transport, and pinocytosis (Table 45.1).

TABLE 45.1

Mechanisms for Intestinal Absorption of Nutrients

Mechanism	Definition
Active transport	An energy-dependent process whereby particles move from an area of greater concentration to an area of lesser concentration. A special "carrier" moves the particle across the cell membrane.
Passive diffusion	The force by which particles move outward from an area of greater concentration to one of lesser concentration. The particles do not need a special "carrier" to move outward in all directions.
Osmosis	Movement of water through a semipermeable membrane that separates solutions of different concentrations. Water moves to equalize the concentration pressures on both sides of the membrane.
Pinocytosis	Engulfing of large molecules of nutrients by the absorbing cell when the molecule attaches to the absorbing cell membrane.

Data from Nix S: *Williams' basic nutrition and diet therapy*, ed 15, St Louis, 2017, Mosby.

Absorption of carbohydrates, protein, minerals, and water-soluble vitamins occurs in the small intestine. Then the nutrients are processed in the liver and released into the portal vein circulation. Fatty acids are

absorbed in the lymphatic circulatory systems through lacteal ducts at the center of each microvilli in the small intestine.

Approximately 85% to 90% of water is absorbed in the small intestine (McCance et al., 2019). The GI tract manages approximately 8.5 L of GI secretions and 1.5 L of oral intake daily. The small intestine resorbs 9.5 L, and the colon absorbs approximately 0.4 L. Elimination of the remaining 0.1 L occurs via feces. In addition, electrolytes and minerals are absorbed in the colon, and bacteria synthesize vitamin K and some B-complex vitamins. Finally, feces form for elimination.

Metabolism and Storage of Nutrients

Metabolism refers to all the biochemical reactions within the cells of the body. Metabolic processes are anabolic (building) or catabolic (breaking down). **Anabolism** is the building of more complex biochemical substances by synthesis of nutrients. It occurs when an individual adds lean muscle through diet and exercise. Amino acids are anabolized into tissues, hormones, and enzymes. Normal metabolism and anabolism are physiologically possible when the body is in positive nitrogen balance. **Catabolism** is the breakdown of biochemical substances into simpler substances and occurs during physiological states of negative nitrogen balance. Starvation is an example of catabolism when wasting of body tissues occurs.

Nutrients absorbed in the intestines, including water, transport through the circulatory system to the body tissues. Through the chemical changes of metabolism, the body converts nutrients into a number of required substances. Carbohydrates, protein, and fat metabolism produce chemical energy and maintain a balance between anabolism and catabolism. To carry out the work of the body, the chemical energy produced by metabolism converts to other types of energy by different tissues. Muscle contraction involves mechanical energy, nervous system function involves electrical energy, and the mechanisms of heat production involve thermal energy.

Some of the nutrients required by the body are stored in tissues. The major form of body reserve energy is fat, stored as adipose tissue. Protein is stored in muscle mass. When the energy requirements of the body exceed the energy supplied by ingested nutrients, stored energy is used. Monoglycerides from the digested part of fats convert to glucose by gluconeogenesis. Amino acids are also converted to fat and stored or catabolized into energy through gluconeogenesis. All body cells except red blood cells and neurons oxidize fatty acids into **ketones** for energy when

dietary carbohydrates (glucose) are not adequate. Glycogen, synthesized from glucose, provides energy during brief periods of fasting (e.g., during sleep). It is stored in small reserves in liver and muscle tissue. Nutrient metabolism consists of three main processes:

1. Catabolism of glycogen into glucose, carbon dioxide, and water (glycogenolysis)
2. Anabolism of glucose into glycogen for storage (glycogenesis)
3. Catabolism of amino acids and glycerol into glucose for energy (gluconeogenesis)

Elimination

Chyme moves by peristaltic action through the ileocecal valve into the large intestine, where it becomes feces (see [Chapter 47](#)). Water absorbs in the mucosa as feces move toward the rectum. The longer the material stays in the large intestine, the more water is absorbed, causing the feces to become firmer. Exercise and fiber stimulate peristalsis, and water maintains consistency. Feces contain cellulose and similar indigestible substances, sloughed epithelial cells from the GI tract, digestive secretions, water, and microbes.

Dietary Guidelines

Dietary Reference Intakes

Dietary reference intakes (DRIs) present evidence-based criteria for an acceptable range of amounts of vitamins and nutrients for each gender and age-group ([National Academies of Sciences Engineering Medicine Health and Medicine Division, 2019](#)). There are four components to the DRIs. The estimated average requirement (EAR) is the recommended amount of a nutrient that appears sufficient to maintain a specific body function for 50% of the population on the basis of age and gender. The recommended dietary allowance (RDA) represents the average needs of 98% of the population, not the exact needs of the individual. The adequate intake (AI) is the suggested intake for individuals based on observed or experimentally determined estimates of nutrient intakes and is used when there is not enough evidence to set the RDA. The tolerable upper intake level (UL) is the highest level that likely poses no risk of adverse health events. It is not a recommended level of intake ([NIH, n.d.](#))

Food Guidelines

The US Department of Health and Human Services (USDHHS) and the US Department of Agriculture (USDA) published the *Dietary Guidelines for Americans 2015-2020* and provide average daily consumption guidelines for the five food groups: grains, vegetables, fruits, dairy products, and meats (Box 45.2). These guidelines are for Americans over the age of 2 years. As a nurse, consider the food preferences of patients from different cultural groups, vegetarians, and others when planning diets. The USDA developed the *ChooseMyPlate* program to replace the *My Food Pyramid* program. *ChooseMyPlate* provides a basic guide for making food choices for a healthy lifestyle (Fig. 45.2). It includes guidelines for balancing calories; decreasing portion size; increasing healthy foods; increasing water consumption; and decreasing fats, sodium, and sugars (USDA, 2017a).

Box 45.2 2015-2020 Dietary Guidelines for Americans: Key Recommendations for the General Population

- Adopt a healthful eating pattern at an appropriate calorie level with a variety of nutrient-dense foods and beverages among all the food groups.
- Maintain body weight in a healthy range.
- Encourage physical activity and decrease sedentary activities.
- Encourage fruits, vegetables, whole-grain products, seafood, and fat-free or low-fat milk.
- Eat a variety of proteins, including lean meats, seafood, poultry, eggs, legumes, nuts, seeds, and soy products.
- Limit saturated fats and trans fats, consuming less than 10% of calories per day from saturated fats.
- Limit added sugar or sweeteners so that less than 10% of calories comes from added sugars.
- Consume less than 2300 milligrams (mg) of sodium per day.
- Choose and prepare foods with little salt, and eat potassium-rich foods.

- Limit intake of alcohol to moderate use (i.e., one drink daily for women and two drinks daily for men).
- Practice food safety to prevent bacterial foodborne illness. Use food-safety principles of Clean, Separate, Cook, and Chill.

Daily Values

The US Food and Drug Administration (FDA) created **daily values** for food labels in response to the 1990 Nutrition Labeling and Education Act (NLEA). The FDA first established two sets of reference values. The referenced daily intakes (RDIs) are the first set, comprising protein, vitamins, and minerals based on the RDA. The daily reference values (DRVs) make up the second set and consist of nutrients such as total fat, saturated fat, cholesterol, carbohydrates, fiber, sodium, and potassium. Combined, both sets make up the daily values used on food labels. Daily values did not replace RDAs but provided a separate, more understandable format for the public. Daily values are based on percentages of a diet consisting of 2000 kcal/day for adults and children 4 years or older.

REFLECT NOW

In your geographic area, identify a population at risk for poor nutrition. What is the population, and what nutritional deficiencies do you believe they are most at risk for having and why?

Nursing Knowledge Base

There are many sociological and psychological factors associated with eating and drinking in all societies. We celebrate holidays and events with food, bring it to those who are grieving, and use it for medicinal purposes. We incorporate food into family traditions and rituals and often associate food with eating behaviors. You need to understand patients' values, beliefs, and attitudes about food and how these values affect food purchase, preparation, and intake to affect eating patterns.

Nutritional requirements depend on many factors. Individual caloric and nutrient requirements vary by stage of development, body composition, activity levels, pregnancy and lactation, and the presence of disease. Registered dietitians (RDs) use predictive equations that take into account some of these factors to estimate patients' nutritional requirements.

Factors Influencing Nutrition

Environmental Factors

Environmental factors beyond the control of individuals contribute to the development of obesity. Obesity is an epidemic in the United States. Presently 68.7% of Americans are overweight or obese ([CDC, 2019](#)). Overweight is defined as having a BMI of 25 to 29, while obesity is defined as a BMI of 30 or greater ([CDC, 2019](#)). Obesity is often associated with a number of factors, such as sedentary lifestyle, overeating, and genetics ([Giddens, 2017](#)). Environmental factors can limit a person's likelihood of healthy eating and participation in exercise or other activities of healthy living. Lack of access to full-service grocery stores, high cost of healthy food, widespread availability of less healthy foods in fast-food restaurants, widespread advertising of less healthy food, and lack of access to safe places to play and exercise are environmental factors that contribute to obesity ([Haug and Barnidge, 2016](#)).

Developmental Needs

Infants Through School-Age

Rapid growth and high protein, vitamin, mineral, and energy requirements mark the developmental stage of infancy. The average birth weight of an American baby is 7 to 7½ lb. (3.2 to 3.4 kg). An infant usually doubles birth weight at 4 to 5 months and triples it at 1 year. Infants need an energy intake of approximately 90 to 110 kcal/kg of body weight per day, with premature infants needing 105 to 130 kcal/kg per day (Nix, 2017). Commercial formulas and human breast milk both provide approximately 20 kcal/oz. A full-term newborn is able to digest and absorb simple carbohydrates, proteins, and a moderate amount of emulsified fat. Infants need about 100 to 120 mL/kg/day of fluid because a large part of total body weight is water.

Breastfeeding

The American Academy of Pediatrics strongly supports breastfeeding for the first 6 months of life and breastfeeding with complementary foods from 6 to 12 months (AAP, 2017). Breastfeeding has multiple benefits for both infant and mother, including fewer food allergies and intolerances; fewer infant infections; easier digestion; convenience, availability, and freshness; temperature always correct; economical because it is less expensive than formula; and increased time for mother and infant interaction.

Formula

Infant formulas contain the approximate nutrient composition of human milk. Protein in the formula is typically whey, soy, cow's milk base, casein hydrolysate, or elemental amino acids. Infants with allergies or an intolerance to cow's milk should consume soy protein-based formulas instead (Nix, 2017).

Infants should not have regular cow's milk during the first year of life. It is too concentrated for an infant's kidneys to manage, increases the risk of milk-product allergies, and is a poor source of iron and vitamins C and E (Nix, 2017). Furthermore, children under 1 year of age should never ingest honey and corn syrup products because they are potential sources of the botulism toxin, which increases the risk of infant death.

Introduction to Solid Food

Breast milk or formula provides sufficient nutrition for the first 4 to 6 months of life. The development of fine-motor skills of the hand and fingers parallels an infant's interest in food and self-feeding. Iron-fortified cereals are typically the first semisolid food to be introduced. For infants 4 to 11 months, cereals are the most important nonmilk source of protein (Hockenberry et al., 2019).

Adding foods to an infant's diet depends on the infant's nutrient needs, physical readiness to handle different forms of foods, and the need to detect and control allergic reactions. Introducing foods that have a high incidence of causing allergic reactions such as wheat, egg white, nuts, citrus juice, and chocolate should happen later in the infant's life (Nix, 2017). In addition, caregivers should introduce new foods one at a time, approximately 4 to 7 days apart, to identify allergies. It is best to introduce new foods before milk or other foods to avoid satiety (Hockenberry et al., 2019).

The growth rate slows during toddler years (1 to 3 years). A toddler needs fewer kilocalories but an increased amount of protein in relation to body weight; consequently, appetite often decreases at 18 months of age. Toddlers exhibit strong food preferences and become picky eaters. Small, frequent meals consisting of breakfast, lunch, and dinner with three interspersed high nutrient–dense snacks help improve nutritional intake (Hockenberry et al., 2019). Calcium and phosphorus are important for healthy bone growth.

Toddlers who consume more than 24 ounces of milk daily in place of other foods sometimes develop milk anemia because milk is a poor source of iron. Toddlers need to drink whole milk until the age of 2 years to make sure that there is adequate intake of fatty acids necessary for brain and neurological development. Avoid certain foods such as hot dogs, hard candy, nuts, grapes, raw vegetables, and popcorn because they present a choking hazard. Dietary requirements for preschoolers (3 to 5 years) are similar to those for toddlers. They consume slightly more than toddlers, and nutrient density is more important than quantity.

School-age children, 6 to 12 years old, grow at a slower and steadier rate, with a gradual decline in energy requirements per unit of body weight. Despite better appetites and more varied food intake,

you need to assess school-age children's diets carefully for adequate protein and vitamins A and C. They often fail to eat a proper breakfast and have unsupervised intake at school. Diets high in fat, sugar, and salt result from too-liberal intake of snack foods. Physical activity level decreases consistently, and consumption of high-calorie, readily available food increases, leading to an increase in childhood obesity ([Haung and Barnidge, 2016](#)).

In the past 10 years, obesity rates have reached a plateau in children and adolescents, although extreme obesity has increased ([Ogden et al., 2016](#)). A combination of factors contributes to the problem, including a diet rich in high-calorie foods, food advertising targeting children, inactivity, genetic predisposition, use of food as a coping mechanism for stress or boredom or as a reward or celebration, and family and socioeconomic factors ([Hockenberry et al., 2019](#)). Childhood obesity contributes to medical problems related to the cardiovascular system, endocrine system, and mental health. With the increase in obesity, the incidence of type 2 diabetes in children is also increasing. Prevention of childhood obesity is critical because of its long-term effects. Family education is an important component in decreasing the prevalence of this problem. Promote healthy food choices and eating in moderation along with increased physical activity.

Adolescents

During adolescence physiological age is a better guide to nutritional needs than chronological age. Energy needs increase to meet greater metabolic demands of growth. Daily requirement of protein also increases. Calcium is essential for the rapid bone growth of adolescence, and girls need a continuous source of iron to replace menstrual losses. Boys also need adequate iron for muscle development. Iodine supports increased thyroid activity, and the use of iodized table salt ensures availability. B-complex vitamins are necessary to support heightened metabolic activity.

Many factors other than nutritional needs influence the adolescent's diet, including concern about body image and appearance, desire for independence, eating at fast-food restaurants, peer pressure, and fad diets. Nutritional deficiencies often occur in

adolescent girls because of dieting and use of oral contraceptives. An adolescent boy's diet is often inadequate in total kilocalories, protein, iron, folic acid, B vitamins, and iodine. Snacks provide approximately 25% of a teenager's total dietary intake. Fast food, particularly value-size or super-size meals, is common and adds extra salt, fat, and kilocalories. Skipping meals or eating meals with unhealthy choices of snacks contributes to nutrient deficiency and obesity (Hockenberry et al., 2019). Furthermore, research on public school lunch programs demonstrates that adolescents have higher BMIs than students enrolled in private school lunch programs (Bogart et al., 2016).

Fortified foods (nutrients added) are important sources of vitamins and minerals. Snack food from the dairy, fruit, and vegetable groups are good choices. To counter obesity, increasing physical activity is often more important than curbing intake. The onset of eating disorders such as **anorexia nervosa** or **bulimia nervosa** often occurs during adolescence. Recognition of eating disorders is essential for early intervention (Box 45.3).

Box 45.3 Diagnostic Criteria for Eating Disorders

Anorexia Nervosa

- Restriction of energy intake relative to requirements, leading to a significantly low body weight in relation to age, sex, developmental trajectory, and physical health
- Intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight
- Disturbance in the way in which one's body weight, size, or shape is experienced; undue influence of body weight or shape on self-evaluation; or persistent lack of recognition of the seriousness of the current low body weight (e.g., the person claims to "feel fat" even when emaciated, believes that one area of the body is "too fat" even when obviously underweight)

Bulimia Nervosa

- Recurrent episodes of binge eating (rapid consumption of a large amount of food in a discrete period of time)
- A feeling of lack of control over eating behavior during eating binges
- Recurrent inappropriate compensatory behaviors to prevent weight gain, such as self-induced vomiting, use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise
- Binge eating and inappropriate compensatory behaviors that both occur, on average, at least once a week for 3 months
- Self-evaluation unduly influenced by body shape and weight

Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision* (Copyright ©2013), American Psychiatric Association.

Sports and regular moderate-to-intense exercise necessitate dietary modification to meet increased energy needs for adolescents.

Carbohydrates, both simple and complex, are the main source of energy, providing 55% to 60% of total daily kilocalories. Protein needs increase to 1 to 1.5 g/kg/day. Fat needs do not increase.

Adequate hydration is very important. Adolescents need to ingest water before and after exercise to prevent dehydration, especially in hot, humid environments. Vitamin and mineral supplements are not required, but intake of iron-rich foods is required to prevent anemia.

Parents have more influence on adolescents' diets than they believe. Effective strategies include limiting the amount of unhealthy food choices kept at home; encouraging smart snacks such as fruits, vegetables, or string cheese; and enhancing the appearance and taste of healthy foods ([Mayo Clinic, 2019](#)). Some ways to promote healthy eating include making healthful food choices more convenient at home and at fast-food restaurants and discouraging adolescents from eating while watching television or using the computer.

Pregnancy occurring within 4 years of menarche places a mother and fetus at risk because of anatomical and physiological immaturity.

Malnutrition at the time of conception increases risk to the adolescent and her fetus. Most teenage girls do not want to gain weight. Counseling related to nutritional needs of pregnancy is often difficult, and teens tolerate suggestions better than rigid directions. The diet of pregnant adolescents is often deficient in calcium, iron, and vitamins A and C. The American College of Obstetricians and Gynecologists recommends prenatal vitamin and mineral supplements.

Young and Middle Adults

There is a reduction in nutrient demands as the growth period ends. Mature adults need nutrients for energy, maintenance, and repair. Energy needs usually decline over the years. Obesity becomes a problem because of decreased physical exercise, dining out more often, and increased ability to afford more luxury foods. Adult women who use oral contraceptives often need extra vitamins. Iron and calcium intake continue to be important.

Pregnancy

Poor nutrition during pregnancy causes low birth weight in infants and decreases chances of survival. Generally, meeting the needs of a fetus is at the expense of the mother. However, if nutrient sources are unavailable, both suffer. The nutritional status of the mother at the time of conception is important. Significant aspects of fetal growth and development often occur before the mother suspects the pregnancy. The energy requirements of pregnancy relate to the mother's body weight and activity. The quality of nutrition during pregnancy is important, and food intake in the first trimester includes balanced parts of essential nutrients with emphasis on quality. Protein intake throughout pregnancy needs to increase to 60 g daily. Calcium intake is especially critical in the third trimester, when fetal bones mineralize. Providing iron supplements to meet the mother's increased blood volume, fetal blood storage, and blood loss during delivery is important.

Folic acid intake is particularly important for DNA synthesis and the growth of red blood cells. Inadequate intake can lead to fetal neural tube defects, anencephaly, or maternal megaloblastic anemia (Nix, 2017). Women of childbearing age need to consume 400 mcg of

folic acid daily, increasing to 600 mcg daily during pregnancy. Prenatal care usually includes vitamin and mineral supplementation to ensure daily intakes; however, pregnant women should not take additional supplements beyond prescribed amounts.

Lactation

Women who are lactating need 500 kcal/day above the usual allowance because the production of milk increases energy requirements. Protein requirements during lactation are greater than those required during pregnancy. The need for calcium remains the same as during pregnancy. There is an increased need for vitamins A and C. Daily intake of water-soluble vitamins (B and C) is necessary to ensure adequate levels in breast milk. Fluid intake needs to be adequate but not excessive. Excretion of caffeine, alcohol, and drugs occurs through breast milk. Therefore mothers who are lactating need to avoid their ingestion.

Older Adults

Adults 65 years and older have a decreased need for energy because their metabolic rate slows with age. However, vitamin and mineral requirements remain unchanged from middle adulthood. Numerous factors influence the nutritional status of the older adult ([Box 45.4](#)). Age-related changes in appetite, taste, smell, and the digestive system affect nutrition ([Touhy and Jett, 2018](#)). For example, older adults often experience a decrease in taste cells that alters food flavor and may decrease intake. Multiple factors contribute to the risk of food insecurity in the older adult. Income is significant because living on a fixed income often reduces the amount of money available to buy food. Health is another important influence that affects a person's desire and ability to eat. Lack of transportation or ability to get to the grocery store because of mobility problems contributes to inability to purchase adequate and nutritious food. Often availability of nutritionally adequate and safe foods is limited or uncertain.

Box 45.4 Focus on Older Adults Factors Affecting Nutritional Status

- Age-related gastrointestinal changes that affect digestion of food and maintenance of nutrition include changes in the teeth and gums, reduced saliva production, atrophy of oral mucosal epithelial cells, increased taste threshold, decreased thirst sensation, reduced gag reflex, and decreased esophageal and colonic peristalsis (Touhy and Jett, 2018).
- The presence of chronic illnesses (e.g., diabetes mellitus, end-stage renal disease, cancer) often affects nutrition intake.
- Adequate nutrition in older adults is affected by multiple causes, such as lifelong eating habits, culture, socialization, income, educational level, physical functional level to meet activities of daily living (ADLs), loss, dentition, and transportation (Touhy and Jett, 2018).
- Adverse effects of medications cause problems such as anorexia, gastrointestinal bleeding, xerostomia, early satiety, and impaired smell and taste perception (Burchum and Rosenthal, 2019).
- Cognitive impairments such as delirium, dementia, and depression affect ability to obtain, prepare, and eat healthy foods.

Maintaining good oral health is significant throughout adulthood, particularly as an individual ages. Difficulty in chewing, missing teeth, having teeth in poor condition, and oral pain result from poor oral health. These often contribute to malnutrition and dehydration in older adults (Touhy and Jett, 2018). Poor oral hygiene and periodontal disease are potential risk factors for systemic diseases such as joint infections, ischemic stroke, cardiovascular disease, DM, and aspiration pneumonia (Touhy and Jett, 2018).

The older adult is often on a therapeutic diet; has difficulty eating because of physical symptoms, lack of teeth, or dentures; or is at risk for drug-nutrient interactions (Table 45.2). Caution older adults to avoid grapefruit and grapefruit juice because they alter absorption of many drugs. Thirst sensation diminishes, leading to inadequate fluid

intake or dehydration (see [Chapter 42](#)). Symptoms of dehydration in older adults include confusion; weakness; hot, dry skin; furrowed tongue; rapid pulse; and high urinary sodium. Some older adults avoid meats because of cost or because they are difficult to chew. Cream soups and meat-based vegetable soups are nutrient-dense sources of protein. Cheese, eggs, and peanut butter are also useful high-protein alternatives. Foods rich in calcium, such as dairy products, green leafy vegetables, soy, nuts, fish (canned sardines and salmon with bones), and fortified grains, help protect against osteoporosis (a decrease of bone mass density) ([NOF, 2019](#)). Screening and treatment are necessary for both older men and women. Vitamin D supplements are important for improving strength and balance, strengthening bone health, and preventing bone fractures and falls. The diet of older adults needs to contain choices from all food groups and often requires a vitamin and mineral supplement. MyPlate for Older Adults addresses the specific nutritional needs for older adults and encourages physical activity (USDA, 2017).

TABLE 45.2**Sample of Drug-Nutrient Interactions^a**

Drug	Effect
Analgesic	
Acetaminophen	Decreased drug absorption with food; overdose associated with liver failure
Aspirin	Absorbed directly through stomach; decreased drug absorption with food; decreased folic acid, vitamins C and K, and iron absorption
Antacid	
Aluminum hydroxide	Decreased phosphate absorption
Sodium bicarbonate	Decreased folic acid absorption
Antiarrhythmic	
Amiodarone (Cordarone)	Taste alteration
Digitalis	Anorexia, decreased renal clearance in older people
Antibiotic	
Penicillin	Decreased drug absorption with food, taste alteration
Cephalosporin	Decreased vitamin K
Rifampin (Rifadin)	Decreased vitamin B ₆ , niacin, vitamin D
Tetracycline	Decreased drug absorption with milk and antacids; decreased nutrient absorption of calcium, riboflavin, vitamin C caused by binding
Trimethoprim/sulfamethoxazole	Decreased folic acid
Anticoagulant	
Warfarin (Coumadin)	Acts as antagonist to vitamin K
Anticonvulsant	
Carbamazepine (Tegretol)	Increased drug absorption with food
Phenytoin (Dilantin)	Decreased calcium absorption; decreased vitamins D and K and folic acid; taste alteration; decreased drug absorption with food
Antidepressant	
Amitriptyline	Appetite stimulant
Clomipramine (Anafranil)	Taste alteration, appetite stimulant
Fluoxetine (Prozac) (selective serotonin reuptake inhibitors [SSRIs])	Taste alteration, anorexia
Antihypertensive	
Captopril (Capoten)	Taste alteration, anorexia
Hydralazine	Enhanced drug absorption with food, decreased vitamin B ₆
Labetalol (Normodyne)	Taste alteration (weight gain for all beta blockers)
Methyldopa	Decreased vitamin B ₁₂ , folic acid, iron
Antiinflammatory	
All steroids	Increased appetite and weight, increased folic acid, decreased calcium (osteoporosis with long-term use); promotes gluconeogenesis of protein
Antiparkinson	
Levodopa (Dopar)	Taste alteration, decreased vitamin B ₆ and drug absorption with food
Antipsychotic	
Chlorpromazine	Increased appetite
Thiothixene	Decreased riboflavin, increased need
Bronchodilator	
Albuterol sulfate	Appetite stimulant
Theophylline	Anorexia
Cholesterol Lowering	
Cholestyramine (Prevalite)	Decreased fat-soluble vitamins (A, D, E, K), vitamin B ₁₂ , iron
Diuretic	
Furosemide (Lasix)	Decreased drug absorption with food
Spirolactone (Aldactone)	Increased drug absorption with food
Thiazides	Decreased magnesium, zinc, and potassium
Laxative	
Mineral oil	Decreased absorption of fat-soluble vitamins (A, D, E, K), carotene
Platelet Aggregate Inhibitor	

Dipyridamole (Persantine)	Decreased drug absorption with food
Potassium Replacement	
Potassium chloride	Decreased vitamin B ₁₂
Tranquilizer	
Benzodiazepines	Increased appetite

^a Not intended to be an exhaustive or all-inclusive list. Always check pharmacology references before administering medications.

Data from Hermann J: *Nutrient and drug interactions*, <http://pods.dasnr.okstate.edu/docushare/dsweb/Get/Document-2458/T-3120web.pdf>. Accessed August 20, 2014; Burcham and Rosenthal: *Lehne's pharmacology for nursing care*, ed 9, St Louis, 2016, Elsevier.

The USDHHS Administration on Aging (AOA) requires states to provide nutritional screening services to older adults who benefit from home-delivered or congregate meal services. This program requires meals to provide at least one-third of the DRI for an older adult and meet the Dietary Guidelines for Americans ([American Dietetic Association, 2019](#)). Homebound older adults with chronic illnesses have additional nutritional risks. They frequently live alone with little or no social or financial resources to help obtain or prepare nutritionally sound meals, contributing to the risk for food insecurity. Approximately 19% of older adults experience some degree of food insecurity resulting from low income or poverty ([American Dietetic Association, 2019](#)). Increased nutritional screening by nurses results in early recognition and treatment of nutritional deficiencies. Undernourishment of older adults often results in health problems that lead to admission to acute care hospitals or long-term care facilities.

Alternative Food Patterns

Long before the FDA issued recommended allowances and guidelines, many people followed special patterns of food intake on the basis of religion ([Table 45.3](#)), cultural background ([Box 45.5](#)), health beliefs, personal preference, or concern for the efficient use of land to produce food. Such special diets are not necessarily more or

less nutritious than diets based on the MyPlate or other nutritional guidelines because good nutrition depends on a balanced intake of all required nutrients.

TABLE 45.3

Religious Dietary Restrictions

Muslim	Christianity	Hinduism	Judaism	Church of Jesus Christ of Latter-Day Saints (Mormons)	Seventh-Day Adventists Church
Pork Alcohol Caffeine Ramadan fasting sunrise to sunset for a month Ritualized methods of animal slaughter required for meat ingestion	Some faiths such as Baptists have minimal or no alcohol Some meatless days may be observed during the calendar year, commonly during Lent	All meats Fish, shellfish with some restrictions Alcohol	Pork Predatory fowl Shellfish (eat only fish with scales) Rare meats Blood (e.g., blood sausage) Mixing of milk or dairy products with meat dishes Must adhere to kosher food preparation methods 24 hr of fasting on Yom Kippur, a day of atonement No leavened bread eaten during Passover (8 days) No cooking on the Sabbath from sundown Friday to sundown Saturday	Alcohol Tobacco Caffeine such as teas, coffees, and sodas	Pork Shellfish Fish Alcohol Caffeine Vegetarian or ovolactovegetarian diets encouraged

Box 45.5 Cultural Aspects of CareNutrition

Food patterns developed as a child, habits, and culture interact to influence food intake. Culture also influences the meaning of food not related to nutrition. Eating is associated with sentiments and feelings such as “good” and “bad.” For example, children are often rewarded for “being good” with a treat such as candy. They then associate candy with “being good.” Food frequently enhances interpersonal relationships and demonstrates love and caring.

Sometimes certain ethnic groups develop genetically related conditions. For example, lactose intolerance, a deficiency of the intestinal enzyme lactase, can be found among Asian-Pacific, African and African American, Native American, Mexican American, Middle Eastern, and Caucasians. Lactose intolerance affects nutrient

absorption. Calcium deficiency often results, causing decreased bone mass density.

The theory of hot and cold foods predominates in many cultures. The origin appears to be from Hippocratic beliefs concerning health and the four humors. Arabs were keepers of this knowledge during the Dark Ages and later influenced the Spanish to adopt this belief system in the later Middle Ages. The foundation of the theory is keeping harmony with nature by balancing “cold,” “hot,” “wet,” and “dry.” Some cultures believe that hot is warmth, strength, and reassurance, whereas cold is menacing and weak. Classification has nothing to do with spiciness but is a symbolic representation of temperature (Giger, 2016). Different cultures also have beliefs about food and special dishes that should be eaten when sick (e.g., chicken soup during illness).

Implications for Patient-Centered Care

- Ask patient or family caregiver to identify the meaning that types of food have for each patient.
- Lactose and other food intolerances unique to specific cultures require diet adaptation to meet nutrient, mineral, and vitamin daily intake requirements.
- When patients use hot and cold foods as part of their cultural health practices, dietary modifications are necessary. Hot foods include rice, grain cereals, alcohol, beef, lamb, chili peppers, chocolate, cheese, temperate zone fruits, eggs, peas, goat’s milk, cornhusks, oils, onions, pork, radishes, and tamales. By contrast, cold foods are beans, citrus fruits, tropical fruits, dairy products, most vegetables, honey, raisins, chicken, fish, and goat.
- Ask patient or family caregiver if there are:
 - Specific conditions such as menstruation, cancer, pneumonia, earache, colds, paralysis, headache, or rheumatism, which are cold illnesses and require hot foods.
 - Other conditions such as pregnancy, fever, infections, diarrhea, rashes, ulcers, liver problems, constipation,

kidney problems, or sore throats, which are hot conditions and require cold foods.

Vegetarian Diet

A common alternative dietary pattern is the vegetarian diet.

Vegetarianism is the consumption of a diet consisting predominantly of plant foods. Some vegetarians are ovo-lacto-vegetarian (avoid meat, fish, and poultry but eat eggs and milk), lacto-vegetarians (drink milk but avoid eggs), or vegans (consume only plant foods). Through careful selection of foods, individuals following a vegetarian diet can meet recommendations for proteins and essential nutrients (Nix, 2017). Children who follow a vegetarian diet are especially at risk for protein and vitamin deficiencies, such as a lack of vitamin B₁₂.

Careful planning helps to ensure a balanced, healthy diet.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis ([Fig. 45.3](#)).

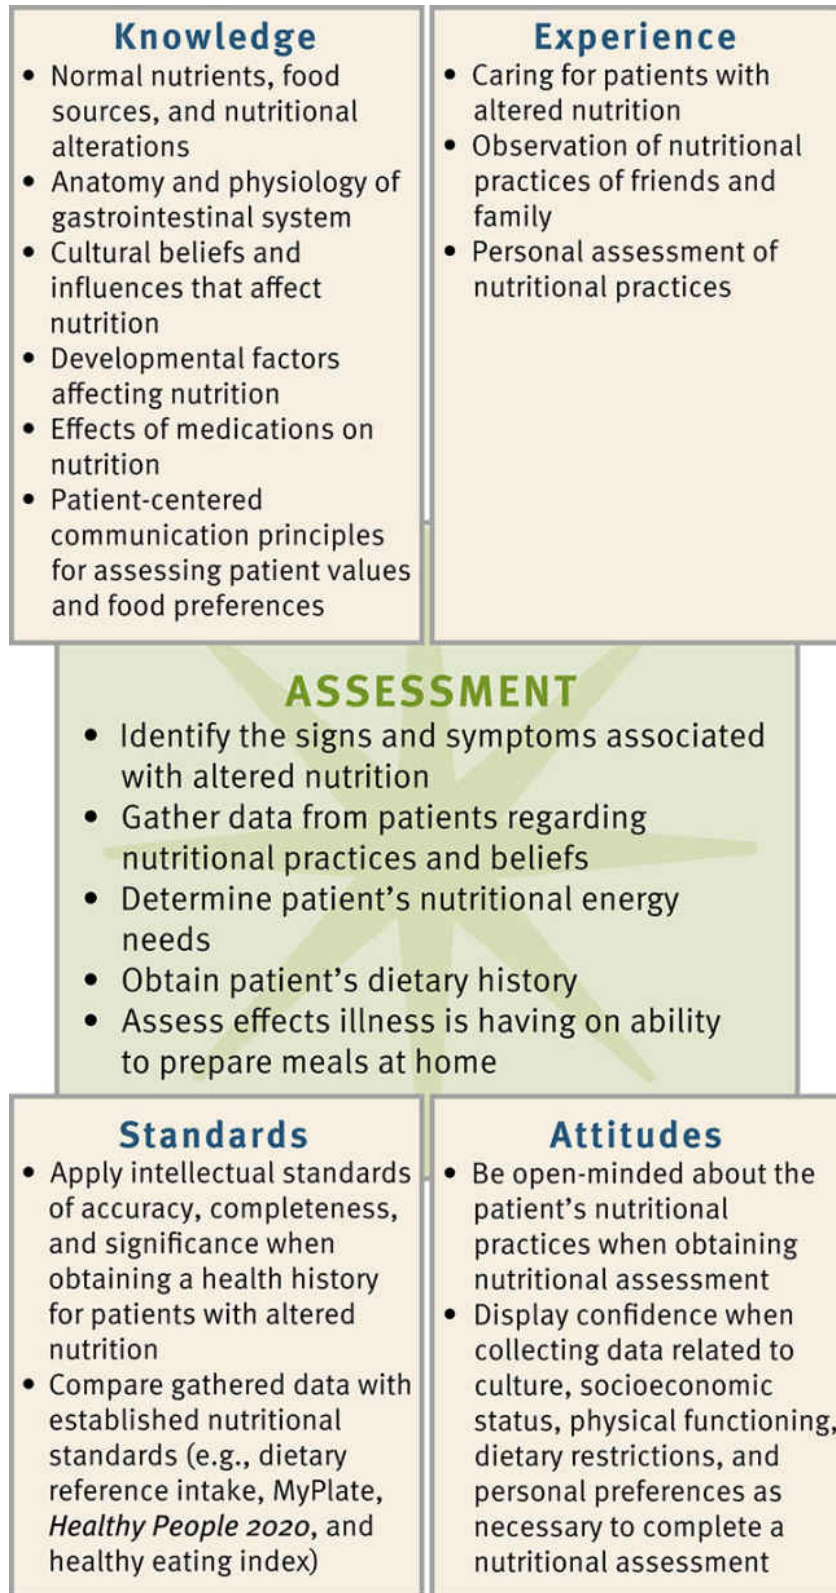

FIG. 45.3 Critical thinking model for nutrition assessment.

Integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients and families regarding customary food preferences and recent diet history. Use of professional standards such as the DRIs, the USDA MyPlate dietary guidelines, and *Healthy People 2020* objectives provide guidelines to assess and maintain patients' nutritional status. Other professional standards by the [AHA \(2018\)](#), the American Diabetes Association ([ADA, 2019](#)), the [ACS \(2019\)](#), and the [American Society for Parenteral and Enteral Guidelines \(2019\)](#) are available. These standards are evidence based and regularly updated for optimal patient care.

REFLECT NOW

What assessment findings in an adolescent child would be indicative of altered nutrition? What are risk factors that lead to altered nutritional status in this age-group?

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Early recognition of patients who are malnourished or at risk has a strong positive influence on both short- and long-term health outcomes. Studies demonstrate a link between malnutrition in adult hospitalized patients and readmission rates, higher mortality rates, and increased cost ([Reed Mangels, 2018](#)). Patients who are malnourished on admission are at greater risk of significant complications such as arrhythmia, skin breakdown, sepsis, or hemorrhage during hospitalization.

Through the Patient's Eyes

Close contact with patients and their families enables you to observe physical status, food intake, food preferences, weight changes, and cultural practices in eating. Always ask patients about their food preferences, values regarding nutrition, and expectations from nutritional therapy. For example, does a patient want to learn about a diet? In attempting to affect eating patterns, you need to understand patients' values, beliefs, and attitudes about food. Assess family traditions and rituals related to food, cultural values and beliefs, and nutritional needs. Determine how these factors affect food purchase, preparation, and intake.

Screening

Assess patients' nutritional status by using the nursing history to gather information about factors that usually influence nutrition. You are in an excellent position to recognize signs of poor nutrition and take steps to initiate change. Nutrition screening is an essential part of an initial assessment. Screening a patient is a quick method of identifying **malnutrition** or risk of malnutrition using simple tools ([McEvelly, 2017](#)). Nutrition screening tools gather data on the current condition and

typically include objective measures such as height, weight, weight change, primary diagnosis, and the presence of other co-morbidities (McEvelly, 2017). Combine multiple objective measures with subjective measures related to nutrition to adequately screen for nutritional problems. Identification of risk factors such as unintentional weight loss, presence of a modified diet, or the presence of altered nutritional symptoms (i.e., nausea, vomiting, diarrhea, and constipation) requires nutritional consultation.

Several standardized nutritional screening tools are available for use in outpatient and inpatient settings. The Subjective Global Assessment (SGA) uses the patient history, weight, and physical assessment data to assess nutritional status (Wittenaar and Ottery, 2017). The SGA is a simple, inexpensive technique that is able to predict nutrition-related complications. The Mini Nutritional Assessment (MNA) (Fig. 45.4) screens older adults in home care programs, nursing homes, and hospitals. The tool has 18 items divided into screening and assessment. If a patient scores 11 or less on the screening part, the health care provider completes the assessment part. A total score of less than 17 indicates protein-energy malnutrition (Agarwalla et al., 2015). Malnutrition screening tools (MSTs) are an effective way to measure nutritional problems for patients in a variety of health care settings.

Mini Nutritional Assessment MNA®

Last name:		First name:		
Sex:	Age:	Weight, kg:	Height, cm:	Date:

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

Screening	
A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties? 0 = severe decrease in food intake 1 = moderate decrease in food intake 2 = no decrease in food intake	<input type="checkbox"/>
B Weight loss during the last 3 months 0 = weight loss greater than 3 kg (6.6 lbs) 1 = does not know 2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs) 3 = no weight loss	<input type="checkbox"/>
C Mobility 0 = bed or chair bound 1 = able to get out of bed / chair but does not go out 2 = goes out	<input type="checkbox"/>
D Has suffered psychological stress or acute disease in the past 3 months? 0 = yes 2 = no	<input type="checkbox"/>
E Neuropsychological problems 0 = severe dementia or depression 1 = mild dementia 2 = no psychological problems	<input type="checkbox"/>
F1 Body Mass Index (BMI) (weight in kg) / (height in m²) 0 = BMI less than 19 1 = BMI 19 to less than 21 2 = BMI 21 to less than 23 3 = BMI 23 or greater	<input type="checkbox"/>
IF BMI IS NOT AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2. DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.	
F2 Calf circumference (CC) in cm 0 = CC less than 31 3 = CC 31 or greater	<input type="checkbox"/>
Screening score (max. 14 points)	<input type="checkbox"/> <input type="checkbox"/>
12-14 points: Normal nutritional status 8-11 points: At risk of malnutrition 0-7 points: Malnourished

FIG. 45.4 Mini Nutritional Assessment (MNA).
 Copyright ©Nestlé, 1994, Revision 2009. N67200 12/99 10M.

Assess patients for malnutrition when they have conditions that interfere with their ability to ingest, digest, or absorb adequate nutrients. Use standardized tools to assess nutritional risks when possible. Congenital anomalies and surgical revisions of the GI tract interfere with normal function. Patients receiving only an IV infusion of 5% or 10% dextrose are at risk for nutritional deficiencies. Chronic diseases or increased metabolic requirements are risk factors for development of nutritional problems. Infants and older adults are at greatest risk.

Anthropometry

Anthropometry is a systematic method of measuring the size and makeup of the body. Nurses obtain height and weight for each patient on hospital admission or entry into any health care setting. If you are unable to measure height with the patient standing, position him or her lying flat in bed as straight as possible with arms folded on the chest and measure him or her lengthwise. Serial measures of weight over time provide more useful information than one measurement. Weigh the patient at the same time each day, on the same scale, and with the same type of clothing or linen. Document the patient's actual weight and compare height and weight with standards for height-weight relationships. An **ideal body weight (IBW)** provides an estimate of what a person should weigh.

Rapid weight gain or loss is important to note because it usually reflects fluid shifts. One pint or 500 mL of fluid equals 1 lb (0.45 kg). For example, for a patient with renal failure, a weight increase of 2 lb (0.90 kg) in 24 hours is significant because it usually indicates that the patient has retained 1 L (1000 mL) of fluid.

Other anthropometric measurements often obtained by RDs help identify nutritional problems. These include the ratio of height-to-wrist circumference, mid-upper arm circumference (MAC), triceps skinfold (TSF), and mid-upper arm muscle circumference (MAMC). An RD compares values for MAC, TSF, and MAMC to standards and calculates them as a percentage of the standard. Changes in values for an individual over weeks to months are of greater significance than isolated measurements (Nix, 2017).

Body mass index (BMI) measures weight corrected for height and serves as an alternative to traditional height-weight relationships. Calculate BMI by dividing a patient's weight in kilograms by height in meters squared: weight (kg) divided by height² (m²). For example, a patient who weighs 165 lb (75 kg) and is 1.8 m (5 feet, 9 inches) tall has a BMI of 23.15 ($75 \div 1.8^2 = 23.15$). The website for the National Heart, Lung,

and Blood Institute

(https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmicalc.htm) provides an easy way to calculate BMI. A patient is overweight if his or her BMI is 25 to 30. Obesity, defined by a BMI of greater than 30, places a patient at higher medical risk of coronary heart disease, some cancers, DM, and hypertension.

Laboratory and Biochemical Tests

No single laboratory or biochemical test is diagnostic for malnutrition. Factors that frequently alter test results include fluid balance, liver function, kidney function, and the presence of disease. Common laboratory tests used to study nutritional status include measures of plasma proteins such as albumin, transferrin, prealbumin, retinol-binding protein, total iron-binding capacity, and hemoglobin. After feeding, the response time for changes in these proteins ranges from hours to weeks. The metabolic half-life of albumin is 21 days, transferrin is 8 days, prealbumin is 2 days, and retinol-binding protein is 12 hours. Use this information to determine the most effective measure of plasma proteins for your patients. Factors that affect serum albumin levels include hydration; hemorrhage; renal or hepatic disease; large amounts of drainage from wounds, drains, burns, or the GI tract; steroid administration; exogenous albumin infusions; age; and trauma, burns, stress, or surgery. Albumin level is a better indicator for chronic illnesses, whereas prealbumin level is preferred for acute conditions (Bharadwaj et al., 2016).

Nitrogen balance is important in determining serum protein status (see discussion of protein in this chapter). Calculate nitrogen balance by dividing 6.25 into the total grams of protein ingested in a day (24 hours). Use laboratory analysis of a 24-hour urine urea nitrogen (UUN) to determine nitrogen output. For patients with diarrhea or fistula drainage, estimate a further addition of 2 to 4 g of nitrogen output. Calculate nitrogen balance by subtracting the nitrogen output from the nitrogen intake. A positive 2- to 3-g nitrogen balance is necessary for anabolism. By contrast, negative nitrogen balance is present when catabolic states exist.

Diet History and Health History

In addition to the general nursing history, use data from a more specific diet history to assess a patient's actual or potential nutritional needs. Box 45.6 lists some specific assessment questions to ask in the diet history. The

diet history focuses on a patient's habitual intake of foods and liquids and includes information about preferences, allergies, and other relevant areas such as the patient's ability to obtain food. Gather information about the patient's illness/activity level to determine energy needs and compare food intake. Your nursing assessment of nutrition includes health status; age; cultural background (see [Box 45.5](#)); religious food patterns (see [Table 45.3](#)); socioeconomic status; personal food preferences; psychological factors; use of alcohol or illegal drugs; use of vitamin, mineral, or herbal supplements; prescription or over-the-counter (OTC) drugs (see [Table 45.2](#)); and the patient's general nutrition knowledge.

Box 45.6 Nursing Assessment Questions

Dietary Intake and Food Preferences

- What type of food do you like?
- How many meals a day do you eat?
- What times do you normally eat meals and snacks?
- What portion sizes do you eat at each meal?
- Are you on a special diet because of a medical problem?
- Tell me about your dietary religious or cultural food preferences.
- Who prepares the food at home?
- Who purchases the food?
- How do you cook your food (e.g., fried, broiled, baked, grilled)?

Unpleasant Symptoms

- Which foods cause indigestion, gas, or heartburn?
- How often does this occur?
- What relieves the symptoms?

Allergies

- Are you allergic to any foods?
- Which types of problems do you have with these foods?

- How are these food allergies treated (e.g., EpiPen, oral antihistamines)?

Taste, Chewing, and Swallowing

- Have you noticed any changes in taste?
- Did these changes occur with medications or following an illness?
- Do you wear dentures? Are the dentures comfortable?
- Do you have any mouth pain or sores (e.g., cold sore, canker sores)?
- Do you have difficulty swallowing?
- Do you cough or gag when you swallow?

Appetite and Weight

- Tell me about any recent change in appetite.
- Tell me about any recent change in your weight.
- Was this change anticipated (e.g., were you on a weight-reduction diet)?

Use of Medications

- Which medications do you take?
- Do you take any over-the-counter medications that your doctor does not prescribe?
- Do you take any nutritional or herbal supplements?

In an outpatient setting, have a patient keep a 3- to 7-day food diary. This allows you to calculate nutritional intake and to compare it with DRI to see whether the patient's dietary habits are adequate. Use food questionnaires to establish patterns over time. In a health care setting nurses collaborate with RDs to complete calorie counts for patients.

Physical Examination

The physical examination is one of the most important aspects of a nutritional assessment. Because improper nutrition affects all body

systems, observe for malnutrition during physical assessment (see [Chapter 30](#)). Complete the general physical assessment of body systems and recheck relevant areas to evaluate a patient's nutritional status. The clinical signs of nutritional status ([Table 45.4](#)) serve as guidelines for observation during physical assessment.

TABLE 45.4**Physical Signs of Nutritional Status**

Body Area	Indicators of Malnutrition
General appearance	Easily fatigued, no energy, falls asleep easily; looks tired, apathetic, cachectic
Weight	Overweight, obese, or underweight (special concern for underweight); unplanned weight loss over period of time
Posture	Poor posture, sagging shoulders, sunken chest, humped back
Muscles	Flaccid, weak, poor tone, tender; "wasted" appearance; impaired mobility
Mental status	Inattentive, irritable, confused
Neurological function	Burning and tingling of hands and feet (paresthesia), loss of position and vibratory sense, decrease or loss of ankle and knee reflexes
Gastrointestinal function	Anorexia, indigestion, constipation or diarrhea, symptoms of malabsorption, liver or spleen enlargement, abdominal distention
Cardiovascular function	Tachycardia, abnormal rhythm, elevated blood pressure
Hair	Stringy, dull, brittle, dry, thin and sparse, depigmented
Skin (general)	Rough, dry, scaly, pale, pigmented, irritated, bruises, petechiae
Face and neck	Swollen, skin dark over cheeks and under eyes
Lips	Dry, scaly, swollen; redness and swelling at the corners of the mouth (cheilosis); angular lesions at corners of mouth, fissures, or scars (stomatitis)
Mouth, oral mucous membranes	Swollen, deep red oral mucous membranes; oral lesions
Gums	Spongy, bleed easily, inflamed, receding
Tongue	Swelling, scarlet and raw, magenta color, beefy (glossitis)
Teeth	Missing teeth, broken teeth
Eyes	Eye membranes pale (pale conjunctivae), redness of membrane (conjunctival injection), dryness or infection
Nails	Spoon-shaped (koilonychia), brittle, ridged
Legs and feet	Edema, tender calf, tingling, weakness, lesions
Skeleton	Bowlegs, knock-knees, chest deformity at diaphragm, beaded ribs, prominent scapulas

Data from Jelliffe DB: The assessment of the nutritional status of the community, WHO Monograph No. 53, Geneva, 1966; Clinical assessment of nutritional status, *Am J Public Health* 63(11 Suppl):18, 1973, http://ajph.aphapublications.org/doi/pdf/10.2105/AJPH.63.11_Suppl.18; and Williams SR: Nutritional assessment and guidance in prenatal care. In Worthington-Roberts BS, Williams SR: *Nutrition in pregnancy and lactation*, ed 5, New York, 1993, McGraw-Hill.

Dysphagia

Dysphagia refers to difficulty swallowing. There are a variety of causes and complications of dysphagia ([Box 45.7](#)). Complications include aspiration pneumonia, dehydration, decreased nutritional status, and weight loss. Dysphagia leads to disability or decreased functional status, increased length of stay and health care costs, increased likelihood of discharge to institutionalized care, and increased mortality ([Yang et al., 2017](#)).

Box 45.7 Causes of Dysphagia

Myogenic

- Myasthenia gravis
- Aging
- Muscular dystrophy
- Polymyositis

Neurogenic

- Stroke
- Cerebral palsy
- Guillain-Barré syndrome
- Multiple sclerosis
- Amyotrophic lateral sclerosis (Lou Gehrig disease)
- Diabetic neuropathy
- Parkinson's disease

Obstructive

- Benign peptic stricture
- Lower esophageal ring
- Candidiasis

- Head and neck cancer
- Inflammatory masses
- Trauma/surgical resection
- Anterior mediastinal masses
- Cervical spondylosis

Other

- Gastrointestinal or esophageal resection
- Rheumatological disorders
- Connective tissue disorders
- Vagotomy

Be aware of warning signs for dysphagia. They include cough during eating; change in voice tone or quality after swallowing; abnormal movements of the mouth, tongue, or lips; and slow, weak, imprecise, or uncoordinated speech. Abnormal gag, delayed swallowing, incomplete oral clearance or pocketing, regurgitation, pharyngeal pooling, delayed or absent trigger of swallow, and inability to speak consistently are other signs of dysphagia. Patients with dysphagia often do not show overt signs such as coughing when food enters the airway. *Silent aspiration* is aspiration that occurs in patients with neurological problems that leads to decreased sensation. It often occurs without a cough, and symptoms (for example, adventitious breath sounds, slight fever) usually do not appear for 24 hours. Silent aspiration is common in patients with dysphagia following stroke (Yang et al., 2017).

Dysphagia often leads to an inadequate amount of food intake, which results in malnutrition. Frequently patients with dysphagia become frustrated with eating and show changes in skinfold thickness and albumin. During the rehabilitation period patients experience longer adjustment periods regarding new dietary restrictions. Furthermore, malnutrition significantly slows swallowing recovery and may increase mortality (Bharadwaj et al., 2016).

Dysphagia screening quickly identifies problems with swallowing and helps you initiate referrals for more in-depth assessment by an RD or a speech-language pathologist (SLP) (see Skill 45.1). Early and ongoing assessment of patients with dysphagia using a valid dysphagia-screening tool increases quality of care and decreases incidence of aspiration

pneumonia. Dysphagia screening includes medical record review; observation of a patient at a meal for change in voice quality, posture, and head control; percentage of meal consumed; eating time; drooling or leakage of liquids and solids; cough during/after a swallow; facial or tongue weakness; palatal movement; difficulty with secretions; pocketing; choking; and a spontaneous dry cough. Several validated screening tools are available such as the Bedside Swallowing Assessment, Burke Dysphagia Screening Test, Acute Stroke Dysphagia Screen, and Standardized Swallowing Assessment (Dong et al., 2016). The Acute Stroke Dysphagia Screen is an easily administered and reliable tool for health care professionals who are not speech-language pathologists (SLPs). Screening for and treatment of dysphagia requires an interprofessional team approach of nurses, RDs, health care providers, and SLPs (ASHA 019).

REFLECT NOW

Consider a patient you recently cared for during a clinical experience and who had risks for nutritional alterations. What assessments did you make of his or her nutritional status? What are some risk factors that potentially put your patient at risk for malnutrition?

• Nursing Diagnosis

Cluster all assessment data to identify appropriate nursing diagnoses (Box 45.8). A nutritional problem occurs when overall intake is significantly decreased or increased or when one or more nutrients are not ingested, completely digested, or completely absorbed. When identifying a negative or problem-focused nursing diagnosis, you select the appropriate related factors (e.g., inability to digest food or reduced daily activity). Related

factors need to be accurate, so you select the right interventions. For example, *Impaired Low Nutritional Intake* related to economic disadvantage will require very different interventions than *Impaired Low Nutritional Intake* related to an inability to ingest food.

Box 45.8 Nursing Diagnostic Process Impaired Low Nutrition Intake

Assessment Activities	Assessment Findings
Body mass index (BMI)	Body mass index (BMI) = 17
Obtain weight	68-year-old woman 24-lb (10.8-kg) weight loss Weight is 20% below her ideal body weight
Obtain 24-hour food and fluid history	Lack of satiety Lack of interest in food Fluid intake is juice and coffee Eats sandwich in afternoon
Physical assessment	Poor muscle tone Fatigue Hair loss Dry, scaly skin Pale conjunctiva and mucous membranes
Medication	Takes sertraline for depression
Social	Husband died 6 months ago Has quit attending monthly quilting club Started counseling 3 months ago

A patient will have a risk nursing diagnosis when assessment reveals risk factors. For example, *Risk for Nutritional Excess* can be identified by the presence of risk factors such as excessive alcohol consumption or high frequency of eating restaurant food and adult BMI approaching 25 kg/m². Be specific so that you can direct interventions toward risk factors.

Assessment findings may also point to a health promotion diagnosis such as *Health Seeking Behavior*. The following are examples of nursing diagnoses applicable to nutritional problems:

- *Risk for Aspiration*
- *Overweight*
- *Impaired Low Nutritional Intake*
- *Impaired Self Feeding*
- *Impaired Swallowing*

In addition, there are clinical situations in which patients have multiple related nursing diagnoses. The concept map in Fig. 45.5 shows the relationship of nursing diagnoses for Mrs. Cooper.

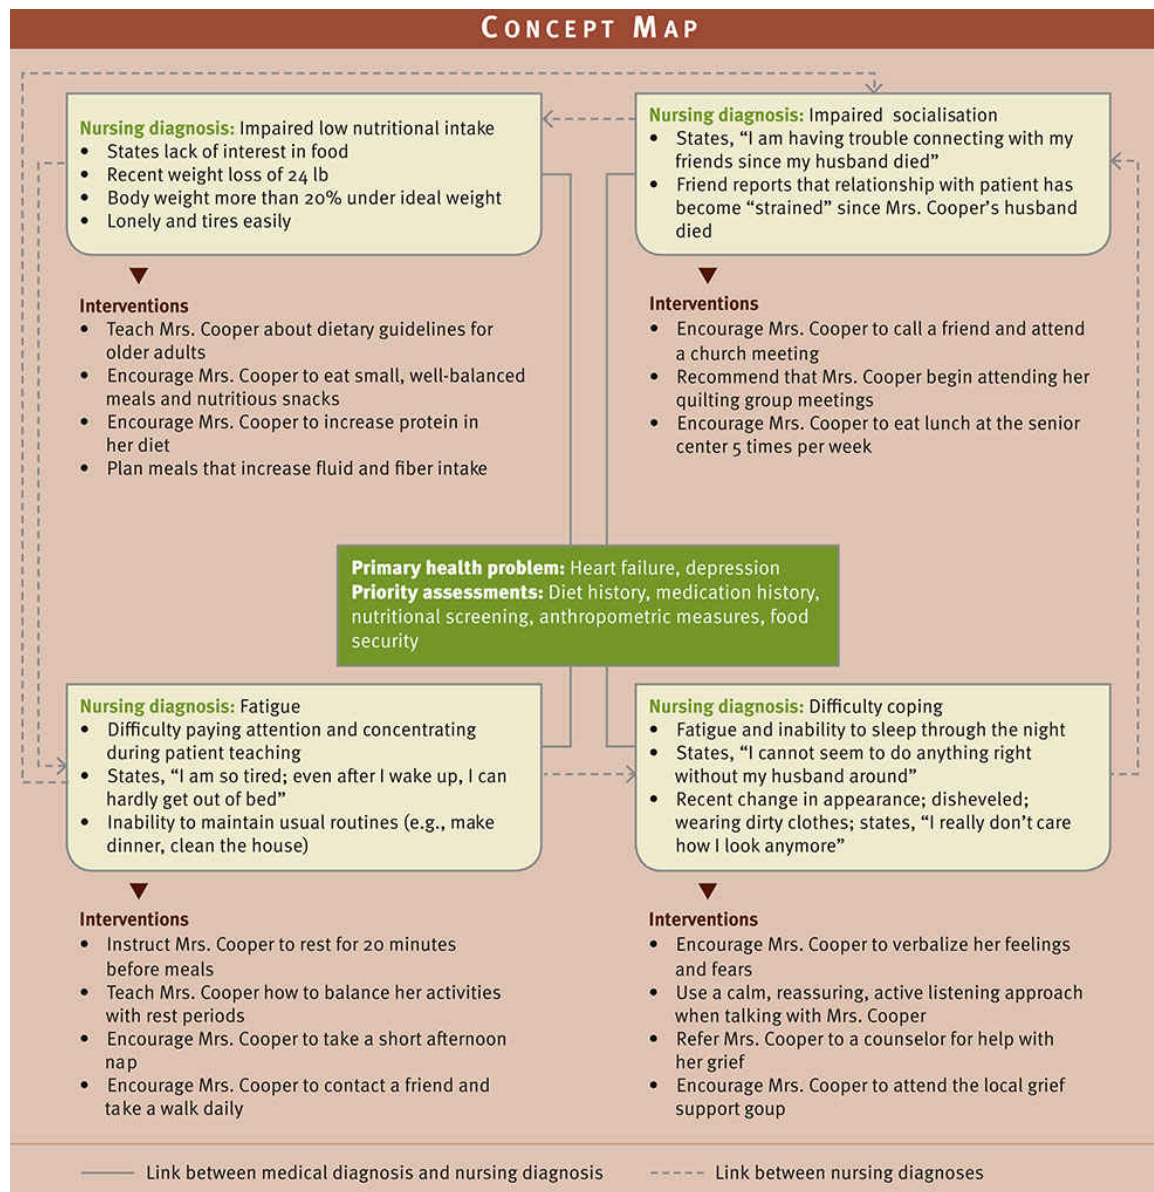

FIG. 45.5 Concept map for Mrs. Cooper.

• Planning

Planning to maintain patients' optimal nutritional status requires a higher level of care than simply correcting nutritional problems. Often there is a

need for patients to make long-term changes for nutrition to improve. Synthesis of patient information from multiple sources is necessary to create an individualized approach of care that is relevant to a patient's needs and situation ([Fig. 45.6](#)). Apply critical thinking to ensure that you consider all data sources in developing a patient's plan of care. The accurate identification of nursing diagnoses related to patients' nutritional problems results in a care plan that is relevant and appropriate (see the [Nursing Care Plan](#)). Referring to professional standards for nutrition is especially important during this step, because scientific findings support current published standards.

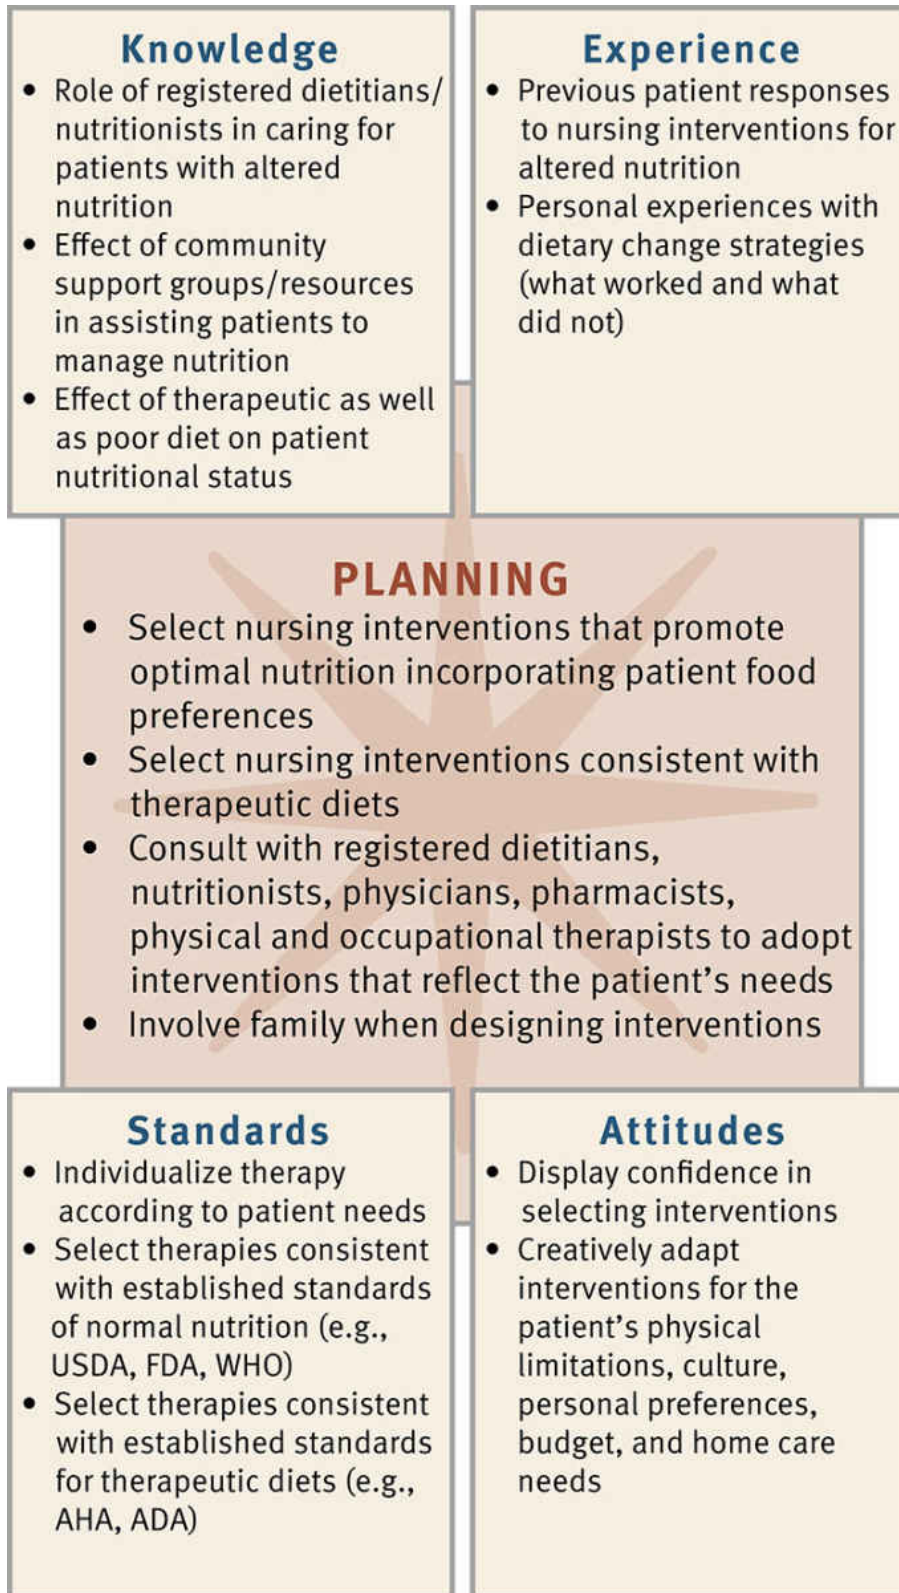

FIG. 45.6 Critical thinking model for nutrition planning. *ADA*, American Diabetes Association; *AHA*, American Heart Association; *FDA*, Food and

Goals and Outcomes

Goals and outcomes of care reflect a patient's physiological, therapeutic, and individualized needs. Nutritional education and counseling are important to prevent disease and promote health. Plan to educate your patients about any therapeutic

Nursing Care Plan

Impaired Low Nutrition Intake

Assessment

A nurse practitioner (NP) at a senior center is seeing Mrs. Cooper, who is 68 years old and has a history of heart failure. Recently Mrs. Cooper experienced an unexpected 15% weight loss. Three months ago, she started taking sertraline (Zoloft) for depression related to the loss of her husband earlier in the year. She no longer participates in her monthly quilting club. Mrs. Cooper started counseling 3 months ago for help with her grief and depression. When the NP inquires about her financial situation, Mrs. Cooper responds by saying that it is tight living on a small pension and Social Security but that she is able to manage.

Assessment Activities	Assessment Findings ^a
Ask Mrs. Cooper about her food intake during the past 2 days.	She responds that she drinks some juice in the morning and two or three cups of coffee. In addition, she often has a sandwich in the late afternoon. She often skips dinner . “I’m just not interested in food. It has no taste.”
Ask Mrs. Cooper about social interaction.	Mrs. Cooper complains of loneliness and says that she does not get out much. Her friends at church call her to come back to meetings, but she is just not ready. She says that she tires easily and no longer attends the monthly meetings of her quilt club.
Weigh patient and assess posture.	Her weight is 20% below her ideal body weight (IBW) and her body mass index (BMI) is 17. This weight loss has happened over the past 6 months, and she has lost 24 lb . Stooped posture
Observe Mrs. Cooper for signs of poor nutrition.	Hair loss Sore oral mucous membranes Pale mucous membranes

^a Assessment findings are shown in bold type.

Nursing Diagnosis:

Impaired Low Nutrition Intake related to a decreased ability to ingest food as a result of depression and insufficient intake

Planning

Goals	Expected Outcomes (NOC) ^b
	Weight Gain Behavior
Mrs. Cooper will progressively gain weight.	Mrs. Cooper gains 1 to 2 lb per month until reaching a goal of 130 lb.
	Physical assessment findings are within normal limits.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Nutritional Counseling	
Coordinate plan of care with health care provider, psychologist, Mrs. Cooper, and registered dietitian.	Successful nutrition care planning is a multidisciplinary approach throughout the continuum of care (Phelps et al., 2017).
Individualize menu plans according to Mrs. Cooper's preferences.	Incorporating her food preferences into the meal plans encourages the patient to eat (Phelps et al., 2017).
Teach Mrs. Cooper about MyPlate for Older Adults.	MyPlate for Older Adults is adapted to meet the nutritional requirements for older adults (USDA, 2017a).
Nutritional Management	
Encourage Mrs. Cooper to eat small nutritious meals and snacks and to increase dietary intake to help offset anorexia secondary to sertraline.	Sertraline is a selective serotonin reuptake inhibitor (SSRI) antidepressant medication that causes diminished taste and anorexia. Frequent small nutritious meals and snacks help to reduce anorexia-associated weight loss.
Encourage fluid intake to eight 8-oz glasses daily.	Older adults need eight 8-oz (240 mL) glasses per day of fluid from beverage and food sources. Concentrating intake in the morning and early afternoon is acceptable to prevent nocturia (Meiner and Yeager, 2019).
Encourage fiber intake.	Prevents constipation and enhances appetite.
Encourage Mrs. Cooper to eat lunch at the senior center 5 times per week.	Eating with others encourages good nutrition and promotes socialization with peers (American Dietetic Association, 2019; Nix, 2017).

^c Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Monitor Mrs. Cooper monthly for weight gain, anemia, serum albumin level, and transferrin levels.	After 2 weeks Mrs. Cooper has gained 3 lb, and her hemoglobin B level is 12.	Mrs. Cooper is making progress with weight gain; her hemoglobin level still reflects mild anemia.
Observe Mrs. Cooper's physical appearance.	At 2 weeks her mucous membranes are less pale, and her hair appears to be in better condition and styled.	Mrs. Cooper has improved physical parameters of nutrition; still needs follow-up.
Ask Mrs. Cooper about appetite and energy level.	Mrs. Cooper responds that on days that she eats at the senior center her appetite seems better and she "wants to do more things." She notes that weekends are very lonely.	Weekday support for nutritional status appears effective; need to increase patient's activity status and nutritional intake during weekends.

diets prescribed, specifically how diets control their illnesses and whether there are any implications. When planning care, be aware of all factors that influence a patient's food intake. For example, patients with heart failure often experience decreased hunger, dietary restrictions, fatigue, shortness of breath, and sadness, which influence their food intake.

Individualized planning is essential. Incorporate what you learned about a patients' feelings about food, their weight, diet, and medical condition to set realistic and achievable goals. Mutually planned goals negotiated among the patient, RD, health care provider, and nurse ensure

success. For the patient with heart failure described previously, an overall goal is “Patient will achieve appropriate BMI height-weight range or be within 10% of IBW.” The following outcomes help to achieve this goal:

- Patient’s daily nutritional intake meets the minimal DRIs.
- Patient will eat well-balanced meals and healthy snacks every day.
- Patient will increase daily protein intake.

Meeting nutritional goals requires input from the patient and the interprofessional team. Knowledge of the role of each discipline in providing nutritional support is necessary to maximize nutritional outcomes. For example, collaboration with an RD helps develop appropriate nutritional treatment plans. Calorie counts are frequently ordered, and help is necessary to obtain accurate data. An effective plan of care requires accurate exchange of information among disciplines.

Setting Priorities

After identifying and prioritizing patients’ nursing diagnoses, use the priorities to plan timely and successful interventions. For example, managing a patient’s oral pain will be a priority over the intervention of diet education to improve nutrition if the patient’s pain makes it difficult to swallow and maintain adequate food intake. *Lack of Knowledge* regarding diet therapy will become a priority if it is necessary to promote long-term and effective weight loss for a patient being discharged from a hospital.

During acute illness and surgery, food intake varies in the perioperative period. The priority of care is to provide optimal preoperative nutritional support in patients with malnutrition. The priority for the resumption of food intake after surgery depends on the return of bowel function, the extent of the surgical procedure, and the presence of any complications (see [Chapter 50](#)). For example, when patients have oral and throat surgery, they chew and swallow food in the presence of excision sites, sutures, or tissue manipulated during surgery. The priority of care is to first provide comfort and pain control. Then address nutritional priorities and plan care to maintain nutrition that does not cause pain or injury to the healing tissues.

The patient and family must collaborate with you in planning care and setting priorities. This is important because food preferences, food purchases, and preparation involve the entire family. The plan of care

cannot succeed without their commitment to, involvement in, and understanding of the nutritional priorities.

Teamwork and Collaboration

The care of a patient often extends beyond the acute hospital setting, requiring continued collaboration among members of the health care team. It is important that discharge planning include nutritional interventions as patients return to their homes or extended-care settings. Communication of patient goals and planned interventions to all team members helps to achieve expected patient outcomes. In addition, consult with an SLP, RD, pharmacist, and/or occupational therapist about patients with dysphagia and those who need ongoing nutritional assessment and interventions to meet their nutritional needs.

When patients have difficulty in feeding themselves, occupational therapists work with patients and their families to identify assistive devices. Devices such as utensils with large handles and plates with elevated sides help a patient with self-feeding. An SLP helps a patient with swallowing exercises and techniques to reduce the risk of aspiration. Occupational therapists also help patients maintain function in the home setting by rearranging food preparation areas in an effort to maximize a patient's functional capacity.

REFLECT NOW

Identify nursing interventions that you would use on clinical to assist a patient with dysphagia to improve his or her nutritional status.

Implementation

Diet therapies are numerous and chosen on the basis of a patient's overall health status, ability to eat and digest normally, and long-term nutritional

needs. The focus of health promotion is to educate patients and family caregivers about balanced nutrition and to help them obtain resources to eat high-quality meals. In acute care your role as a nurse is to manage acute conditions that alter patients' nutritional status and to help in ways that promote their appetite and ability to take in nutrients. Patients who are ill or debilitated often have poor appetites (anorexia). Anorexia has many causes (e.g., pain, fatigue, and the effects of medications). Help patients understand the factors that cause anorexia and use creative approaches to stimulate appetite. In the restorative care setting you help patients learn how to follow the therapeutic diets necessary for recovery and treatment of chronic health conditions.

Health Promotion

As a nurse you are in a key position to educate patients about healthful diet choices and good nutrition. Incorporating knowledge of nutrition into patients' lifestyles serves to prevent the development of many diseases. Outpatient and community-based settings are optimal locations for nursing assessment of nutritional practices and status. Early identification of potential or actual problems is the best way to avoid serious problems. Similarly, in other health care settings patients with nutritional problems such as obesity often require help in menu planning and adherence strategies. Your role as educator includes reassessing a patient's and family's health literacy (i.e., how much do they understand regarding their nutritional need) and providing nutritional education and information about community resources. Telephone numbers of an RD or nurse for follow-up questions are always a part of counseling.

Meal planning considers a family's budget and different preferences of family members. Choose specific foods on the basis of the dietary prescription and recommended food groups. For families on limited budgets, use substitutes. For example, bean or cheese dishes often replace meat in a meal, and the use of evaporated milk or dry skim milk when cooking is a low-cost nutritional supplement. Have patients modify the method of preparation when it is necessary to minimize certain substances. For example, baking rather than frying reduces fat intake, and patients can use lemon juice or spices to add flavor to low-sodium diets.

Planning menus a week in advance has several benefits. It helps ensure good nutrition or adherence to a specific diet and helps families stay within their allotted budgets. Nurses or RDs need to check menus for content. Often a simple tip is helpful in meal planning, such as avoiding grocery shopping when hungry, which can lead to impulsive purchases of

more expensive or less nutritious foods that are not included in meal plans. The US Department of Agriculture ([USDA, 2017b](#)) provides sample weekly meal-planning services for a range of budgets on its website.

Support individuals who are interested in losing weight. A high percentage of those who attempt to lose weight are unsuccessful, regaining lost weight over time. Adherence to diet and exercise affect success with weight loss. Information on weight loss is available from multiple sources. Help patients develop a successful weight-loss plan that considers their preferences and resources and includes awareness of portion sizes and knowledge of energy content of food ([AHA, 2018](#)).

Food safety is an important public health issue. Foodborne bacteria can occur from improper food cleaning, preparation, or poor hygiene practices of food workers. Health care professionals not only need to be aware of the factors related to food safety but also should provide patient education to reduce the risks for foodborne illnesses ([Table 45.5](#); [Box 45.9](#)).

TABLE 45.5

Food Safety

Foodborne Disease	Organism	Food Source	Symptoms ^a
Botulism	<i>Clostridium botulinum</i>	Improperly home-canned foods, smoked and salted fish, ham, sausage, shellfish	Symptoms vary from mild discomfort to death in 24 hours; initially nausea, vomiting, dizziness, and weakness progressing to motor (respiratory) paralysis
<i>Escherichia coli</i>	<i>E. coli</i>	Undercooked meat (ground beef)	Severe cramps, nausea, vomiting, diarrhea (may be bloody), renal failure; appears 1-8 days after eating; lasts 1-7 days
Listeriosis	<i>Listeria</i> <i>L. monocytogenes</i>	Soft cheese, meat (hot dogs, pâté, lunch meats), unpasteurized milk, poultry, seafood	Severe diarrhea, fever, headache, pneumonia, meningitis, endocarditis; appears 3-21 days after infection
Perfringens enteritis	<i>Clostridium</i> <i>C. perfringens</i>	Cooked meats, meat dishes held at room or warm temperature	Mild diarrhea, vomiting; appears 8-24 hours after eating; lasts 1-2 days
Salmonellosis	<i>Salmonella</i> <i>S. typhi</i> <i>S. paratyphi</i>	Milk, custards, egg dishes, salad dressings, sandwich fillings, polluted shellfish	Mild-to-severe diarrhea, cramps, vomiting; appears up to 72 hours after ingestion; lasts 4-7 days
Shigellosis	<i>Shigella</i> <i>S. dysenteriae</i>	Milk, milk products, seafood, salads	Cramps, diarrhea to fatal dysentery; appears 12-50 hours after ingestion; lasts 3-14 days
Staphylococcus	<i>Staphylococcus</i> <i>S. aureus</i>	Custards, cream fillings, processed meats, ham, cheese, ice cream, potato salad, sauces, casseroles	Severe abdominal cramps, pain, vomiting, diarrhea, perspiration, headache, fever, prostration; appears 1-6 hours after ingestion; lasts 1-2 days

^a Symptoms are generally most severe for youngest and oldest age-groups.

Box 45.9 Patient Teaching Food Safety

Objective

- Patient is able to verbalize measures to protect from foodborne illness.

Teaching Strategies

- Explain that food safety is an important public health issue. Populations particularly at risk are older and younger people and immunosuppressed individuals.
- Instruct patients using the following four principles:
 1. CLEAN
 - Wash hands with warm, soapy water before touching or eating food.
 - Wash fresh fruits and vegetables thoroughly.
 - Clean the inside of refrigerator and microwave regularly to prevent microbial growth.
 - Clean cutting surfaces after each use.
 - When possible, use separate surfaces for fruit, meat, poultry, fish
 2. SEPARATE
 - Wash cooking utensils and cutting boards with hot, soapy water.
 - Wash hands after handling foods, especially meats, poultry, and eggs.
 - Clean vegetables and lettuce used in salads thoroughly.
 - Wash dishrags, towels, and sponges regularly or use paper towels.
 3. COOK
 - Use a food thermometer to verify that meat, poultry, and fish are cooked properly.
 - Do not eat raw meats or unpasteurized milk.
 4. CHILL
 - Keep foods properly refrigerated at 40° F (4.4° C) and frozen at 0° F (-17.8° C).
 - Do not save leftovers for more than 2 days in refrigerator.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Tell me what you do to prevent foodborne illnesses while you are preparing meals.
- Please show me what you do while cooking to ensure safe food-preparation practices.

Data from US Department of Agriculture: 10 tips: be food safe, n.d., <https://www.choosemyplate.gov/ten-tips-be-food-safe>.

Building Competency in Teamwork and Collaboration

You are the nurse in charge of developing an interprofessional team to help patients with Crohn's disease, an inflammatory bowel disease, manage their diets at home. Knowing that patients with Crohn's disease must adhere to a diet that is low in fiber and high in calories and protein, you bring your nursing knowledge to the team. What strengths and limitations do you bring to the team? What other members of the team would you need to help prepare the plan of care for patients with Crohn's disease? How would you promote effective teamwork?

Acute Care

The nutritional care of patients who are acutely ill requires you to consider a variety of factors that influence nutritional intake. Diagnostic testing and procedures in the acute care setting disrupt food intake. Often a patient must refrain from eating or drinking anything by mouth (NPO) as he or she prepares for or recovers from a diagnostic test. Frequent interruptions during mealtimes occur in the health care setting, or patients have poor appetites. Patients often are too tired or uncomfortable to eat. It is important to assess a patient's nutritional status continuously and to adopt interventions that promote normal intake, digestion, and metabolism of nutrients. Patients who are NPO and receive only standard IV fluids for more than 5 to 7 days are at high nutritional risk.

Advancing Diets

Acute and chronic conditions affect a patient’s immune system and nutritional status. Patients with decreased immune function (e.g., from cancer, chemotherapy, human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS], or organ transplants) require special diets that decrease exposure to microorganisms and are higher in selected nutrients. [Table 45.6](#) provides an overview of the immune system, the impact of malnutrition, and beneficial nutrients. In addition, patients who are ill, who have had surgical procedures, or who were NPO for an extended time have specialized dietary needs. Health care providers order a gradual progression of dietary intake or therapeutic diet to manage patients’ illness ([Box 45.10](#)).

TABLE 45.6

Nutrition and the Immune System

Immune/Physiological Component	Malnutrition Effect	Vital Nutrient
Antibodies	Decreased amount	Protein, vitamins A, B ₆ , B ₁₂ , C, folic acid, thiamin, biotin, riboflavin, niacin
GI tract	Systemic movement of bacteria	Arginine, glutamine, omega-3 fatty acids
Granulocytes and macrocytes	Longer time for phagocytosis kill time and lymphocyte activation	Protein, vitamins A, B ₆ , B ₁₂ , C, folic acid, thiamin, riboflavin, niacin, zinc, iron
Mucus	Flat microvilli in GI tract, decreased antibody secretion	Vitamins B ₆ , B ₁₂ , C, biotin
Skin	Integrity compromised, density reduced, wound healing slowed	Protein, vitamins A, B ₁₂ , C, niacin, copper, zinc
T-lymphocytes	Depressed T-cell distribution	Protein, arginine, iron, zinc, omega-3 fatty acids, vitamins A, B ₆ , B ₁₂ , folic acid, thiamin, riboflavin, niacin, pantothenic acid

GI, Gastrointestinal.

Modified from Grodner M, et al: *Foundations and clinical applications of nutrition: a nursing approach*, ed 7, St Louis, 2020, Elsevier.

Box 45.10 Diet Progression and Therapeutic Diets

Clear Liquid

Clear fat-free broth, bouillon, coffee, tea, carbonated beverages, clear fruit juices, gelatin, fruit ices, popsicles

Full Liquid

As for clear liquid, with addition of smooth-textured dairy products (e.g., ice cream), strained or blended cream soups, custards, refined cooked cereals, vegetable juice, pureed vegetables, all fruit juices, sherbets, puddings, frozen yogurt

Dysphagia Stages, Thickened Liquids, Pureed

As for clear and full liquid, with addition of scrambled eggs; pureed meats, vegetables, and fruits; mashed potatoes and gravy

Mechanical Soft

As for clear and full liquid and pureed, with addition of all cream soups, ground or finely diced meats, flaked fish, cottage cheese, cheese, rice, potatoes, pancakes, light breads, cooked vegetables, cooked or canned fruits, bananas, soups, peanut butter, eggs (not fried)

Soft/Low Residue

Addition of low-fiber, easily digested foods such as pastas, casseroles, moist tender meats, and canned cooked fruits and vegetables; desserts, cakes, and cookies without nuts or coconut

High Fiber

Addition of fresh uncooked fruits, steamed vegetables, bran, oatmeal, and dried fruits

Low Sodium

4-g (no added salt), 2-g, 1-g, or 500-mg sodium diets; vary from no-added-salt to severe sodium restriction (500-mg sodium diet), which requires selective food purchases

Low Cholesterol

300 mg/day cholesterol, in keeping with American Heart Association guidelines for serum lipid reduction

Diabetic

Nutrition recommendations by the American Diabetes Association: focus on total energy, nutrient and food distribution; include a balanced intake of carbohydrates, fats, and proteins; varied caloric recommendations to accommodate patient's metabolic demands

Gluten Free

Eliminates wheat, oats, rye, barley, and their derivatives

Regular

No restrictions unless specified

Promoting Appetite

Providing an environment that promotes nutritional intake includes keeping a patient's environment free of odors, providing oral hygiene as needed to remove unpleasant tastes, and maintaining patient comfort. Offering smaller, more frequent meals often helps. In addition, certain medications affect dietary intake and nutrient use. For example, medications such as insulin, glucocorticoids, and thyroid hormones affect metabolism. Other medications such as antifungal agents frequently affect taste. Some of the psychotropic medications affect appetite, cause nausea, and alter taste. You and the RD help patients select foods that reduce the altered taste sensations or nausea. Consult with an RD regarding using seasonings that improve food taste. In other situations, medications need to be changed. Assessing patients for the need for pharmacological agents to stimulate appetite such as cyproheptadine, megestrol, or dronabinol or to manage symptoms that interfere with nutrition requires health care provider consultation.

Mealtime is usually a social activity. If appropriate, encourage visitors to eat with a patient. When patients experience anorexia, encourage other nurses or care providers to converse and engage them in conversation. Mealtime is also an excellent opportunity for any patient education topic. Instruct a patient about any therapeutic diets, medications, energy conservation measures, or adaptive devices to help with independent feeding.

Assisting Patients With Oral Feeding

When a patient needs help, it is important to protect his or her safety, independence, and dignity. Clear the table or over-bed tray of clutter. Assess his or her risk of aspiration (see Skill 45.1). Patients at high risk for aspiration have decreased level of alertness, decreased gag and/or cough reflexes, and difficulty managing saliva (see Assessment section of this chapter).

Patients with dysphagia are at risk for aspiration and need more help with feeding and swallowing. An SLP identifies patients at risk and provides recommendations for therapy (Pietsch et al., 2018). Provide a 30-minute rest period before eating and position the patient in an upright,

seated position in a chair or raise the head of the bed to 90 degrees. Have the patient flex the head slightly to a chin-down position to help prevent aspiration. If the patient has unilateral weakness, teach him or her and the caregiver to place food in the stronger side of the mouth. With the help of an SLP, determine the viscosity of foods that the patient tolerates best using trials of different consistencies of foods and fluids. Thicker fluids are generally easier to swallow. According to the American Speech-Language-Hearing Association (ASHA, 2019), there are four levels of diet: dysphagia puree, dysphagia mechanically altered, dysphagia advanced, and regular. The four levels of liquid include thin liquids (low viscosity), nectarlike liquids (medium viscosity), honeylike liquids (viscosity of honey), and spoon-thick liquids (viscosity of pudding).

Feed a patient with dysphagia slowly, providing smaller-size bites. Allow him or her to chew thoroughly and swallow the bite before taking another. More frequent chewing and swallowing assessments throughout the meal are necessary. Allow the patient time to empty the mouth after each spoonful, matching the speed of feeding to the patient's readiness (see Skill 45.1). If he or she begins to cough or choke, remove the food immediately. Sometimes it is necessary to have oral suction equipment available at the patient's bedside.

Provide opportunities for patients to direct the order in which they want to eat the food items and how fast they wish to eat. Determine a patient's food preferences and, unless contraindicated, try to have these items included on his or her dietary tray. Ask the patient whether the food is the right temperature. These seem like small acts, but they go a long way in maintaining the patient's sense of independence.

Patients with visual deficits also need special assistance. Patients with decreased vision are able to feed themselves when given adequate information. For example, identify the food location on a meal plate as if it were a clock (e.g., meat at 9 o'clock and vegetable at 3 o'clock). Tell the patient where the beverages are located in relation to the plate. Be sure that other care providers set the meal tray and plate in the same manner. Patients with impaired vision and those with decreased motor skills are more independent during mealtimes with the use of large-handled adaptive utensils (Fig. 45.7). These are easier to grip and manipulate.

FIG. 45.7 Adaptive equipment. Clockwise from upper left: Two-handed cup with lid, plate with plate guard, utensils with splints, and utensils with enlarged handles.

Enteral Tube Feeding

Enteral nutrition (EN) provides nutrients into the GI tract. It is the preferred method of meeting nutritional needs if a patient is unable to swallow or take in nutrients orally yet has a functioning GI tract. EN provides physiological, safe, and economical nutritional support. Patients with enteral feedings receive formula via nasogastric, jejunal, or gastric tubes. Patients with a low risk of gastric reflux receive gastric feedings; however, if there is a risk of gastric reflux, which leads to aspiration, jejunal feeding is preferred. [Box 45.11](#) lists indications for tube feeding. Either a nurse or a family caregiver can easily give enteral tube feedings in the home setting. After insertion of an enteral tube, it is initially necessary to verify tube placement by x-ray film examination. Confirmation of placement is needed before a patient receives the first enteral feeding (see Skill 45.2).

Box 45.11 Indications for Enteral and Parenteral Nutrition

GI, Gastrointestinal.

Enteral Nutrition

(Used with patients who have a functional gastrointestinal tract)

- Cancer
 - Head and neck
 - Upper GI
- Critical illness/trauma
- Neurological and muscular disorders
 - Brain neoplasm
 - Cerebrovascular accident
 - Dementia
 - Myopathy
- Parkinson's disease
- GI disorders
 - Enterocutaneous fistula
 - Inflammatory bowel disease
 - Mild pancreatitis
- Respiratory failure with prolonged intubation
- Inadequate oral intake
 - Anorexia nervosa
 - Difficulty chewing, swallowing
 - Severe depression

Parenteral Nutrition

- Nonfunctional GI tract
 - Massive small bowel resection/GI surgery/massive GI bleed
 - Paralytic ileus
 - Intestinal obstruction
 - Trauma to abdomen, head, or neck
 - Severe malabsorption
 - Intolerance to enteral feeding (established by trial)

- Chemotherapy, radiation therapy, bone marrow transplantation
- Extended bowel rest
 - Enterocutaneous fistula
 - Inflammatory bowel disease exacerbation
 - Severe diarrhea
 - Moderate-to-severe pancreatitis
- Preoperative total parenteral nutrition
 - Preoperative bowel rest
 - Treatment for co-morbid severe malnutrition in patients with nonfunctional GI tracts
- Severely catabolic patients when GI tract not usable for more than 4 to 5 days

An enteral formula is usually one of four types. Polymeric (1 to 2 kcal/mL) includes milk-based blenderized foods prepared by hospital dietary staff or in a patient's home. The polymeric classification also includes commercially prepared whole-nutrient formulas. For this type of formula to be effective, a patient's GI tract needs to be able to absorb whole nutrients. The second type, modular formulas (3.8 to 4 kcal/mL), consists of single macronutrient (e.g., protein, glucose, polymers, or lipids) preparations and is not nutritionally complete. You can add this type of formula to other foods to meet your patient's individual nutritional needs. The third type, elemental formulas (1 to 3 kcal/mL), contains predigested nutrients that are easier for a partially dysfunctional GI tract to absorb. Finally, specialty formulas (1 to 2 kcal/mL) are designed to meet specific nutritional needs in certain illnesses (e.g., liver failure, pulmonary disease, or HIV infection).

Typically tube feedings start at full strength at slow rates (see Skill 45.3; [Box 45.12](#)). Increase the hourly rate every 8 to 12 hours per health care provider's order if no signs of intolerance appear (high gastric residuals, nausea, cramping, vomiting, or diarrhea). Implement evidence-based guidelines when caring for patients receiving tube feedings ([Box 45.13](#)). Studies have demonstrated a beneficial effect of enteral feedings compared with PN. Feeding by the enteral route reduces sepsis, minimizes the hypermetabolic response to trauma, decreases hospital mortality, and maintains intestinal structure and function ([Lewis et al., 2017](#)). EN is successful within 24 to 48 hours after surgery or trauma to provide fluids, electrolytes, and nutritional support. If the patient develops a gastric ileus,

it prevents instituting nasogastric feedings. Nasointestinal or jejunal tubes allow successful postpyloric feeding because the formula instills directly into the small intestine or jejunum or beyond the pyloric sphincter of the stomach (Lewis et al., 2017).

Box 45.12 Advancing the Rate of Tube Feeding

Protocols for advancing tube feedings are commonly institution specific. There does not appear to be a benefit to slow initiation of enteral nutrition over days. Most patients are able to tolerate feeding 24 to 48 hours after initiation. Do not dilute formulas with water; this increases the risk of bacterial contamination (Lewis, 2017). The common delivery options for enteral feedings are continuous, intermittent via a pump or gravity, and cyclical. Usually patients who are more critically ill receive continuous feedings (Lewis, 2017). Patients who are stable or are getting feedings in the home frequently receive intermittent feedings (Lewis, 2017). Cyclical feedings are used when patients begin to eat a normal diet but still need additional nutritional support (Lewis, 2017).

Intermittent

1. Start formula at full strength for isotonic formulas (300 to 400 mOsm) or at ordered concentration.
2. Infuse bolus of formula over at least 20 to 30 minutes via syringe or feeding container.
3. Begin feedings with a volume of 2.5 to 5 mL/kg 5 to 8 times per day. Increase by 60 to 120 mL per feeding every 8 to 12 hours to achieve needed volume and calories in four to six feedings (Stewart, 2014).

Continuous

1. Start formula at full strength for isotonic formulas (300 to 400 mOsm) or at ordered concentration.
2. Begin infusion rate at designated rate typically at 10 to 40 mL/hr (Stewart, 2014).
3. Advance rate slowly (e.g., 10 to 20 mL/hr every 8 to 12 hours) to target rate if tolerated (tolerance indicated by absence of nausea and diarrhea and low gastric residuals) (Stewart, 2014).

Box 45.13 Evidence-Based Practice Reducing Malnutrition and Risk of Aspiration with Enteral Feedings

PICOT Question: In adult patients who are receiving tube feedings, does regular nutritional assessment reduce malnutrition and the risk of aspiration?

Evidence Summary

Enteral feedings provide calories, preserve the client's immune system, preserve the integrity of the gut, and reduce the severity of disease (VanBlarcom and McCoy, 2018). It is essential to perform a nutritional assessment regularly in adult patients who are receiving tube feedings. According to ASPEN (2019), clients are considered malnourished if they exhibit two of the following six characteristics: insufficient protein intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation, and diminished functional status measured by handgrip strength.

In collaboration with the dietitian, the nurse will work to prevent undernutrition and aspiration, two common complications associated with tube feedings that can lead to pneumonia. According to VanBlarcom and McCoy (2018), one cause of undernutrition in patients in critical care units is interrupted enteral feedings. Each time the head of the bed is lowered below 30 degrees (e.g., for hygiene care, dressing changes, moving the patient), the nurse pauses a patient's feeding to prevent aspiration. However, this interruption in tube feedings can contribute to poor nutrition.

To reduce the risk for aspiration, nurses follow several practices, such as keeping the head of bed elevated at 30 to 45 degrees, reducing the use of sedatives, assessing placement of the enteral access device and tolerance to the enteral feeding every 4 hours, and ensuring adequate bowel function (VanBlarcom and McCoy, 2018). Patients diagnosed with pancreatitis, gastric outlet obstruction, gastroparesis, and a history of aspiration are at an increased risk for aspiration with an enteral feeding and may benefit from a small-bore feeding tube placed into the duodenum (VanBlarcomm and McCoy, 2018).

In addition to reducing the risk of aspiration, the nurse needs to assess a patient's tolerance to enteral feedings. New guidelines from ASPEN (2019) limit the use of measuring gastric residual volumes as an

assessment tool to determine the patient's tolerance to enteral feeding. The current literature indicates that there is no correlation between gastric residual volumes and gastric emptying and that these are poor indicators of intolerance to enteral feedings (VanBlarcom and McCoy, 2018). Additionally, measuring gastric residual volumes may lead to a clogged enteral access device and inappropriate cessation of the enteral feeding, which also places the client at an increased risk for undernutrition. Implementing an evidence-based nutrition bundle is effective in reducing malnutrition and the risk of aspiration (VanBlarcom and McCoy, 2018).

Application to Nursing Practice

- Implement an evidence-based nutrition bundle to reduce malnutrition and reduce the risk of aspiration, such as the one created by ASPEN in conjunction with the Society of Critical Care Medicine (VanBlarcom and McCoy, 2018).
- Assess patients for malnutrition by using the gold standard of indirect calorimetry to estimate protein/energy needs (ASPEN, 2019).
- Initiate and maintain enteral feedings appropriately.
- Implement enteral feeding institution-specific protocols.
- Initiate parenteral feeding when enteral nutrition cannot be initiated.
- Administer a prokinetic agent, especially in patients with high gastric residual volumes, as ordered to reduce the risk of aspiration (VanBlarcom and McCoy, 2018).

A serious complication associated with enteral feedings is aspiration of formula into the tracheobronchial tree. Aspiration of enteral formula into the lungs irritates the bronchial mucosa, resulting in decreased blood supply to affected pulmonary tissue (McCance, 2019). This leads to necrotizing infection, pneumonia, and potential abscess formation. The high glucose content of a feeding serves as a bacterial medium for growth, promoting infection. Acute respiratory distress syndrome (ARDS) is also an outcome frequently associated with pulmonary aspiration. Some of the common conditions that increase the risk of aspiration include coughing, gastroesophageal reflux disease (GERD), cerebral vascular accident (CVA), Parkinson's disease, nasotracheal suctioning, an artificial airway, decreased level of consciousness, and lying flat. Prokinetic medications such as metoclopramide, erythromycin, or cisapride promote gastric emptying and decrease the risk of aspiration (McCuston et al., 2018). Keep

the head of the bed elevated a minimum of 30 degrees, preferably 45 degrees, unless medically contraindicated, during feedings and for 30 to 60 minutes after feeding (Lewis et al., 2017). You need to measure gastric residual volumes (GRVs) every 4 to 6 hours in patients receiving continuous feedings and immediately before the feeding in patients receiving intermittent feedings (Lewis et al., 2017). Delayed gastric emptying is a concern if 250 mL or more remains in a patient's stomach on two consecutive assessments (1 hour apart) or if a single GRV measurement exceeds 500 mL (Stewart, 2014). A gastric residual volume of between 250 and 500 mL should lead to implementation of measures to reduce the risk of aspiration (Boullata et al., 2017). The North American Summit on Aspiration in the Critically Ill Patient recommends the following: (1) stop feedings immediately if aspiration occurs; (2) withhold feedings and reassess patient tolerance to feedings if GRV is over 500 mL; (3) routinely evaluate the patient for aspiration; and (4) use nursing measures to reduce the risk of aspiration if GRV is between 250 and 500 mL (Boullata et al., 2017).

Enteral Access Tubes

Enteral tube feedings are used with patients who are unable to ingest food but maintain the ability to digest and absorb nutrients. Feeding tubes are inserted through the nose (nasogastric or nasointestinal), surgically (gastrostomy or jejunostomy), or endoscopically (percutaneous endoscopic gastrostomy or jejunostomy [PEG or PEJ]). Nasogastric or nasojejunal feeding tubes may be used if a patient is expected to need EN therapy for less than 4 weeks. Surgically or endoscopically placed tubes are preferred for long-term feeding (more than 6 weeks) to reduce the discomfort of a nasal tube and provide a more secure, reliable access (Lewis et al., 2017). Some patients such as those with gastroparesis (decreased or absent innervation to the stomach that results in delayed gastric emptying), esophageal reflux, or a history of aspiration pneumonia require placement of tubes beyond the stomach into the intestine (Lewis et al., 2017).

Most health care settings use small-bore feeding tubes because they create less discomfort for a patient (Fig. 45.8, A). Adult patients typically have an 8- to 12-Fr tube that is 36 to 44 inches (90 to 110 cm) long. These flexible tubes come with a stylet, which makes the tube stiffer and is used when the tube is inserted. The stylet is removed after correct tube location is confirmed and before feedings are started. **Never reinsert the stylet in the tube.** It is now standard to use an enteral-only connector (ENFit) designed for the specific enteral tube. Standardization of connector tubing

improves patient safety (Fig. 45.8, B). Tubing standards are designed to reduce tubing misconnections that result in patient injury (TJC, 2018). Skill 45.3 describes the procedure for initiating nasogastric, gastrostomy, and jejunostomy enteral feedings.

FIG. 45.8 A, Enteral tubes, small-bore. B, Enteral-only connector (ENFit) designed to fit the specific enteral tube.

Historically nurses confirmed placement of feeding tubes by injecting air into the tube while auscultating the stomach for a bubbling or gurgling sound or by asking the patient to speak. Current evidence shows these methods are ineffective in verifying tube placement. Currently, the most accurate method for verification of tube placement is x-ray film examination. At the bedside, nurses test the pH of secretions withdrawn from the feeding tube to confirm tube location on an ongoing basis (Box 45.14).

Box 45.14 Procedural Guidelines Obtaining Gastrointestinal Aspirate for pH Measurement, Large-Bore, and Small-Bore Feeding Tubes: Intermittent and Continuous Feeding Delegation and Collaboration

The skill of verifying tube placement and irrigating a feeding tube is the responsibility of the nurse and cannot be delegated to assistive personnel (AP). The nurse directs the AP to:

- Immediately inform the nurse if patient's respirations change or patient complains of shortness of breath, coughing, or choking.
- Immediately inform the nurse if the patient vomits or the AP notices vomitus in patient's mouth during oral hygiene.
- Immediately inform the nurse if nasal skin irritation or excoriation is present.
- Immediately inform the nurse if a change in the external length of the tube occurs, which could indicate displacement of the tube.
- Report when a continuous tube feeding stops infusing.

Equipment

60-mL ENFit syringe; water (tap water or sterile [see agency policy], dated and initialed container at patient's bedside); towel; stethoscope; clean gloves; pH indicator strip (scale of 1.0 to 11.0); small medication cup; measuring tape/device; pulse oximeter

Steps

1. Review agency policy and procedures for frequency of irrigation and frequency and method of checking tube placement. **Do not insufflate air into tube to check placement.**
2. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy (TJC, 2020).
3. Review patient's medication record for orders for enteral feeding, a gastric acid inhibitor (e.g., ranitidine, famotidine, nizatidine), or a proton pump inhibitor (e.g., omeprazole).
4. Review patient's medical record for history of prior tube displacement.
5. Observe for signs and symptoms of respiratory distress during feeding: coughing, choking, or reduced oxygen saturation.
6. Identify conditions that increase risk for spontaneous tube migration or dislocation: altered level of consciousness, agitation; retching, vomiting; nasotracheal suction.
7. Perform hand hygiene. Assess bowel sounds and perform abdominal exam.
8. Obtain pulse oximetry reading.
9. Note ease with which previous tube feedings infuse through tubing. Monitor volume of continuous enteral formula administered during

shift and compare with ordered amount.

10. Assess patient's or family caregiver's knowledge, experience, and health literacy level. Perform hand hygiene and apply clean gloves. Be sure pulse oximeter is in place.
11. Verify tube placement.

CLINICAL DECISION: Listening for insufflated air instilled through tube to check tube tip position is unreliable (Boullata et al., 2017; Fan et al., 2017).

- a. Check tube placement at following times
 - (1) For patients receiving intermittent tube feedings, test placement immediately before each feeding (usually a period of at least 4 hours will have elapsed since previous feeding) and before medications.
 - (2) Follow agency policy regarding when to test pH for patients receiving continuous tube feedings. AACN (2016) recommends stopping continuous feedings for several hours to obtain reliable pH readings. However this is not always appropriate for a patient's therapeutic plan of care.
 - (3) Wait to verify placement at least 1 hour after medication administration by tube or mouth.
 - (4) Measure length of tube extending from nare.
 - b. If tube feeding is infusing, turn off or place tube feeding on hold. Clamp or kink feeding tube and disconnect from end of infusion bag tubing. For intermittent feedings, remove plug at end of feeding tube. Draw up 30 mL of air into a 60-mL ENFit syringe. Place tip of syringe into end of gastric or small bowel feeding tube. Flush with air before attempting to aspirate fluid. Repositioning patient from side to side is helpful. In some cases more than one bolus of air is necessary.
- c. Draw back on syringe slowly and obtain 5 to 10 mL of gastric aspirate (see illustration). Observe appearance of aspirate. Aspirates from gastric tubes of patients receiving

continuous tube feedings often look like curdled enteral formula. Gastric aspirates from patients receiving intermittent feedings typically are not bile stained (unless intestinal fluid has refluxed into stomach) (AACN, 2016).

STEP 11C Obtain gastric aspirate.

- d. Gently mix aspirate in syringe. Expel few drops into clean medicine cup. Note color of aspirate. Measure pH of aspirated GI contents by dipping pH strip into fluid or applying few drops of fluid to strip. Compare color of strip with color on chart (see illustration) provided by manufacturer.

STEP 11D Compare color on test strip with color on pH chart.

- (1) Gastric fluid from patient who has fasted for at least 4 hours usually has pH range of 5.0 or less.
 - (2) Fluid from tube in small intestine of patient who is fasting usually has pH greater than 6.0 (Bourgault et al., 2015).
 - (3) The pH of pleural fluid from the tracheobronchial tree is generally greater than 6.0.
12. If after repeated attempts it is not possible to aspirate fluid from tube that was confirmed by x-ray film to be in desired position and if (1) there are no risk factors for tube dislocation, (2) tube has remained in original taped position, (3) patient is not in respiratory distress, assume that tube is correctly placed. Continue with irrigation (AACN, 2016; Bourgault et al., 2015; Fan et al., 2017).
13. Irrigate tube.
- a. Irrigate routinely before, between, and after final medication (before feedings are reinstated), and before an intermittent feeding is administered.
 - b. Draw up 30 mL of water in ENFit syringe. Do not use irrigation fluids from bottles that are used on other patients. Patient should have individual bottle of solution.

CLINICAL DECISION: Do not use cola or fruit juices for flushing tubing as these liquids can clog tube.

- c. Change irrigation bottle every 24 hours. Irrigation trays, which hold both irrigation fluid and syringe, are considered open systems and may be more easily contaminated than sterile water bottles. **Note:** Be sure that syringe in tray has ENFit adapter.
 - d. Kink feeding tube while disconnecting it from infusion tubing (continuous feeding) or while removing plug at end of tube (intermittent feeding).
 - e. Insert tip of ENFit syringe into end of feeding tube. Release kink and slowly instill irrigation solution.
 - f. If unable to instill fluid, reposition patient on left side and try again.
 - g. When water or sterile saline has been instilled, remove syringe. Reinstigate tube feeding or administer medication as ordered. Then flush each medication completely through tube (see Chapter 31).
14. Help patient assume comfortable position. Raise side rails as appropriate and lower bed to lowest position. Remove and discard gloves; dispose of supplies in appropriate receptacle and perform hand hygiene.
 15. Place nurse call system in an accessible location within patient's reach. Instruct patient in its use.
 16. Observe patient for respiratory distress: persistent gagging, paroxysms of coughing, drop in oxygen (O₂) saturation, or respiratory patterns (e.g., rate and depth) that are inconsistent with baseline measures.
 17. Verify that external length of tube, pH, and appearance of aspirate are consistent with initial tube placement.
 18. Observe ease with which tube feeding instills through tubing.
 19. Monitor patient's caloric intake.
 20. **Use Teach-Back:** "I want to go over what I explained earlier. Tell me why it is important for me to test the gastric pH and the color of the gastric secretions in your stomach before feedings." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.

Table 45.7 outlines major complications of EN. Of special note, patients who are severely malnourished are at risk for electrolyte disturbances from refeeding syndrome during EN or PN therapy. In refeeding syndrome, potassium, magnesium, and phosphate move intracellularly, resulting in low serum (extracellular) levels and edema. These changes may cause cardiac dysrhythmias, heart failure, respiratory distress, convulsions, coma, or death.

TABLE 45.7

Enteral Tube-Feeding Complications

Problem	Possible Cause	Intervention ^a
Pulmonary aspiration	Regurgitation of formula	Verify tube placement. Place patient in high-Fowler's position or elevate head of bed a minimum of 30 (preferably 45) degrees during feedings and for 2 hours afterward.
	Feeding tube displaced	Reposition tube and verify tube placement by ordered x-ray.
	Deficient gag reflex	Reassess for return of normal gag reflex; until then place patient on aspiration precautions and in semi-Fowler's position.
	Delayed gastric emptying	See delayed gastric emptying below.
Diarrhea	Hyperosmolar formula or medications	Deliver formula continuously, lower rate, dilute, or change to isotonic enteral nutrition.
	Antibiotic therapy	Antibiotics destroy normal intestinal flora; consult with health care provider to consider changing medication; treat symptoms with antidiarrheal agents; culture stool for <i>Clostridium difficile</i> .
	Bacterial contamination	Do not hang formula longer than 4-8 hours in bag, wash bag out well when refilling, change tube-feeding bags and tubing q24h, and use aseptic practices. Check expiration dates.
	Malabsorption	Check for pancreatic insufficiency; use low-fat, lactose-free formula and continuous feedings.
Constipation	Lack of fiber	Consult with a dietitian to select a formula containing fiber.
	Lack of free water	Add water during tube flushes. ^a
	Inactivity	Monitor patient's ability to ambulate; collaborate with health care provider and/or physical therapist for activity order.
Tube occlusion	Pulverized medications given per tube	Irrigate with 30 mL of water before and after each medication per tube. ^a Use liquid medications when available. Completely dissolve crushed medications in liquid if liquid medication is unavailable.
	Sedimentation of formula	Shake cans well before administering (read label).
	Reaction of incompatible medications or formula	Read pharmacological information on compatibility of drugs and formula.
Tube displacement	Coughing, vomiting	Replace tube and confirm placement before restarting tube feeding.
	Not taped securely	With placement verification check that tape is secure (nasoenteric).
Abdominal cramping, nausea/vomiting	High osmolality of formula	Suggest an isotonic formula or dilution of current formula to health care provider.
	Rapid increase in rate/volume	Lower rate of delivery to increase tolerance. Maintain head of bed at least 45 degrees.
	Lactose intolerance	Suggest use of lactose-free formula.
	Intestinal obstruction	Stop feeding with GI obstruction.
	High-fat formula used	Use greater proportion of carbohydrate.
	Cold formula used	Warm formula to room temperature.
Delayed gastric emptying	Diabetic gastroparesis	Consult with health care provider regarding prokinetic medication for increasing gastric motility.
	Serious illnesses	Consult health care provider regarding advancing tube to intestinal placement.
	Inactivity	Monitor medications and pathological conditions that affect GI motility.
Serum electrolyte imbalance	Excess GI losses Dehydration Presence of disease states such as cirrhosis, renal insufficiency, heart failure, or diabetes mellitus	Monitor serum electrolyte levels daily. Provide free water per registered dietitian recommendation.
Fluid overload	Refeeding syndrome in malnutrition	Restrict fluids if necessary and use either a specialized formula or a diluted enteral formula at first.
	Excess free water or diluted (hypotonic) formula	Monitor levels of serum proteins and electrolytes. Use more concentrated formula with fluid volume excess without risk of refeeding syndrome.
Hyperosmolar dehydration	Hypertonic formula with insufficient free water	Slow rate of delivery, dilute, or change to isotonic formula.

GI, Gastrointestinal.

^a First, check for fluid-restricted conditions that affect how much water can be given safely.

Parenteral Nutrition

Parenteral nutrition (PN) is a form of specialized nutritional support provided intravenously. Patients who are unable to digest or absorb EN benefit from PN. Patients in highly stressed physiological states such as sepsis, head injury, or burns are candidates for PN therapy (see [Box 45.11](#)). A basic PN formula is a combination of crystalline amino acids, hypertonic dextrose, electrolytes, vitamins, and trace elements. Total PN (TPN), administered through a central line, is a 2-in-1 formula in which administration of fat emulsions occurs separately from the protein and dextrose solution ([Lewis et al., 2017](#)). Safe administration depends on appropriate assessment of nutritional needs, meticulous management of the central venous catheter (CVC), and careful monitoring to prevent or treat metabolic complications. Administration of PN happens in a variety of settings, including a patient's home. Regardless of the setting, adhere to principles of asepsis and infusion management to ensure safe nutritional support.

PN therapy requires clinical and laboratory monitoring by an interprofessional team. Consistent reevaluation for the continuation of PN is required. The goal to move toward use of the GI tract is constant ([Lewis et al., 2017](#)). Disuse of the GI tract has been associated with villus atrophy and generalized cell shrinkage. Furthermore, the disuse of the GI tract may cause bacteria to move from the unused gut into the bloodstream, resulting in gram-negative septicemia.

Sometimes adding **intravenous fat emulsions** to PN supports the patient's need for supplemental kilocalories to prevent essential fatty-acid deficiencies and help control hyperglycemia during periods of stress ([Phillips, 2018](#)). Administer these emulsions through a separate peripheral line, through the central line by using Y-connector tubing (see [Chapter 42](#)), or as an admixture to the PN solution. The addition of fat emulsion to a PN solution is called a *3-in-1 admixture* or *total nutrient admixture*. The patient receives it over a 24-hour period. Do not use the admixture if you observe oil droplets or an oily or creamy layer on the surface of the admixture. This observation indicates that the emulsion has broken into large lipid droplets that cause fat emboli if administered. IV fat emulsions are white and opaque. Take care to avoid confusing enteral formula with parenteral lipids.

Initiating Parenteral Nutrition

Patients with short-term nutritional needs often receive IV solutions of less than 10% dextrose via a peripheral vein in combination with amino acids and lipids. TPN is more calorically dense than peripheral solutions;

therefore, peripheral solutions are usually temporary. PN with greater than 10% dextrose requires a CVC that a health care provider places into a high-flow central vein such as the superior vena cava under sterile conditions (see [Chapter 42](#)). If you are using a CVC that has multiple lumens, use a port exclusively dedicated for the TPN. Label the port for TPN and do not infuse other solutions or medications through it (Lewis et al., 2018). Nurses with special training insert peripherally inserted central catheters (PICCs) that start in a vein of the arm and then thread into the subclavian or superior vena cava vein.

After catheter placement wait to flush and use the catheter until position confirmation by radiology. The health care provider secures the CVC with a securement device and covers the site with a sterile bio-occlusive dressing. Before applying the sterile dressing, stabilize the PICC with sterile strips of tape, and follow the institution's central line infection prevention protocol ([Lewis et al., 2017](#)).

Before beginning any PN infusion, verify the health care provider's order and inspect the solution for particulate matter or a break in the fat emulsion. Always use an infusion pump to deliver a constant rate. The initial rate delivers no more than 50% of estimated needs for the first 24 to 48 hours and gradually increases the rate until a patient's complete nutritional needs are supplied. Patients receiving PN at home frequently administer the entire daily solution over 12 hours at night. This allows the patient to disconnect from the infusion each morning, flush the central line, and have independent mobility during the day.

Preventing Complications

Complications of PN include catheter-related problems and metabolic alterations ([Table 45.8](#)). Pneumothorax results from an initial puncture during catheter insertion, resulting in the accumulation of air in the pleural cavity with subsequent collapse of the lung and impaired breathing. The clinical symptoms of a pneumothorax include sudden sharp chest pain, dyspnea, and coughing. In relation to PN, pneumothorax most often occurs during CVC placement. Monitor a patient with a CVC for the first 24 hours for signs and symptoms of pulmonary distress.

TABLE 45.8**Metabolic Complications of Parenteral Nutrition**

Problem	Signs/Symptoms	Intervention
Electrolyte imbalance	See Chapter 42 for signs of deficiency/toxicity	Check TPN for supplemental electrolyte levels. Notify health care provider of imbalances. Maintain steady rate of infusion. Monitor intake and output.
Hypercapnia	Increased oxygen consumption, CO ₂ , respiratory quotient (>1), and minute ventilation	Patients who are dependent on a ventilator are at risk; provide 30% to 60% of energy requirements per health care provider's order.
Hypoglycemia	Diaphoresis, shakiness, confusion, loss of consciousness	To prevent hypoglycemia, do not abruptly discontinue TPN but taper rate down to within 10% of infusion rate 1 to 2 hours before stopping. If you suspect hypoglycemia, test blood glucose and administer IV bolus of 50% dextrose or glucagon per order or protocol if necessary.
Hyperglycemia	Thirst, headache, lethargy, increased urination	Monitor blood glucose level every 6 hours. Initiate TPN slowly and taper up to maximal infusion rate to prevent hyperglycemia. Additional insulin may be required during therapy if problem persists or patient has diabetes mellitus.
Hyperglycemic hyperosmolar nonketotic coma (HHNKC) or hyperosmolar hyperglycemic nonketotic syndrome (HHNS)	Hyperglycemia (>500 mg/dL), glycosuria, serum osmolarity >350 mOsm/L, confusion, azotemia, headache, severe signs of dehydration (see Chapter 42), hypernatremia, metabolic acidosis, convulsions, coma	Monitor blood glucose, BUN, serum osmolarity, glucose in urine, and fluid losses; administer insulin as ordered; replace fluids as ordered; maintain constant infusion rate; and provide 30% of daily energy needs as fat. Patients at risk are those receiving steroids; older adults diagnosed with diabetes who have impaired renal or pancreatic function or increased metabolism or who are septic.

BUN, Blood urea nitrogen; *IV*, intravenous; *TPN*, total parenteral nutrition.

An air embolus possibly occurs during insertion of the catheter or when changing the tubing or cap. Turn the patient into a left lateral decubitus position and have him or her perform a Valsalva maneuver (holding the breath and “bearing down”) during catheter insertion to help prevent air embolus. The increased venous pressure created by the maneuver prevents air from entering the bloodstream. Maintaining integrity of the closed IV system also helps prevent air embolus.

Catheter occlusion is present when there is sluggish or no flow through the catheter. Temporarily stop the infusion and flush with saline or per protocol orders. If this is unsuccessful, attempt to aspirate a clot. If still unsuccessful, follow institution protocol for use of a thrombolytic agent (e.g., urokinase).

Suspect catheter sepsis if a patient develops fever, chills, or glucose intolerance and has a positive blood culture. To prevent infection, change

the TPN infusion tubing every 24 hours. Do not hang a single container of PN for more than 24 hours or lipids more than 12 hours. Change the administration system every 72 hours when infusing a 2-in-1 solution and every 24 hours for a 3-in-1 solution (Lewis et al., 2017). During CVC dressing changes always use a sterile mask and gloves and assess insertion sites for signs and symptoms of infection (see Chapter 42). Change the CVC dressing per institution policy and any time it becomes wet or contaminated. Use either alcohol or an alcoholic solution of chlorhexidine gluconate to clean the injection port or catheter hub 15 seconds before and after each time it is used. Use a 1.2-micron filter for 3-in-1 formulas and an inline 0.22-micron filter for PN solutions that do not include IV fat emulsions.

PN solutions contain most of the major electrolytes, vitamins, and minerals. Patients also need supplemental vitamin K as ordered throughout therapy. Synthesis of vitamin K occurs by the microflora found in the jejunum and ileum with normal use of the GI tract; however, because PN circumvents GI use, patients need to receive exogenous vitamin K.

Electrolyte and mineral imbalances often occur. Administration of concentrated glucose accompanies an increase in endogenous insulin production, which causes cations (potassium, magnesium, and phosphorus) to move intracellularly. Monitor blood glucose levels every 6 hours to assess for hyperglycemia, and administer supplemental insulin as ordered (Lewis et al., 2017) (see Skill 45.4).

Too-rapid administration of hypertonic dextrose can result in an osmotic diuresis and dehydration (see Chapter 42). If an infusion falls behind schedule, do not increase the rate in an attempt to catch up. Sudden discontinuation of a solution can cause hypoglycemia. Usually it is recommended to infuse 10% dextrose when discontinuing PN solution suddenly. Patients with diabetes are more at risk.

The goal is to move patients from PN to EN and/or oral feeding. Once patients are meeting one-third to one-half of their kilocalorie needs per day, health care providers usually decrease PN by half the original volume and increase EN feedings to meet the patient's nutritional needs. Patients who make the transition from PN to oral feedings typically have early satiety and decreased appetite. Consult with RD about decreasing PN in response to increased oral intake. If oral intake is inadequate, small frequent meals are helpful. Recommend calorie/protein counts when patients begin taking soft foods. When meeting 75% of nutritional needs by enteral feedings or reliable dietary intake, it is usually safe to

discontinue PN therapy. Discontinuation of PN may also happen if complications occur or the health care provider determines that it is not benefiting the patient ([Lewis et al., 2017](#)).

Restorative and Continuing Care

Patients discharged from a hospital with diet prescriptions often need dietary education to plan meals that meet specific therapeutic requirements. Restorative care includes both immediate postsurgical care and routine medical care and therefore includes patients in the hospital and at home. The following sections address nutritional interventions for some common disease states.

Medical Nutrition Therapy

Optimal nutrition is just as important in illness as it is in health. As a result, dietary modifications and intake are often needed to maintain the nutritional requirements of patients with certain illnesses. **Medical nutrition therapy (MNT)** is the use of specific nutritional therapies to treat an illness, injury, or condition. It is necessary to help the body metabolize certain nutrients, correct nutritional deficiencies related to a disease, and eliminate foods that may exacerbate disease symptoms. It is most effective using a team approach that promotes collaboration between the health care team and an RD ([American Dietetic Association, 2019](#)).

Gastrointestinal Diseases

Control peptic ulcers with regular meals and ordered medications such as histamine receptor antagonists that block secretion of HCl or proton pump inhibitors. *Helicobacter pylori* was indentified in 1984. *H. pylori*, a bacterium that causes up to 85% of peptic ulcers, is confirmed by laboratory tests or a biopsy during endoscopy ([Nix, 2017](#)). Antibiotics treat and control the bacterial infection. Stress and overproduction of gastric HCl also irritate a preexisting ulcer. Encourage patients to avoid foods that increase stomach acidity and pain such as caffeine, decaffeinated coffee, frequent milk intake, citric acid juices, and certain seasonings (hot chili peppers, chili powder, black pepper). Discourage smoking, alcohol, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs). Teach patients to eat a well-balanced, healthy diet; avoid eating large meals; and eat three regular meals (or several small meals) without snacks, especially at bedtime ([Nix, 2017](#)). Family members of the patient with *H. pylori* infection also need to be tested and, if indicated, treated.

Inflammatory bowel disease includes Crohn's disease and idiopathic ulcerative colitis. Treatment of acute inflammatory bowel disease includes elemental diets (formula with the nutrients in their simplest form ready for absorption) or PN when symptoms such as diarrhea and weight loss are prevalent. In the chronic stage of the disease, a regular highly nourishing diet is appropriate. Vitamins and iron supplements are often required to correct or prevent anemia. Patients manage inflammatory bowel syndrome by decreasing fiber, reducing fat, avoiding large meals, and avoiding lactose or sorbitol-containing foods for susceptible individuals.

The treatment of **malabsorption** syndromes such as celiac disease includes a gluten-free diet. Gluten is present in wheat, rye, and barley. Short-bowel syndrome results from extensive resection of the bowel, after which patients suffer from malabsorption caused by lack of intestinal surface area. These patients require lifetime feeding with either elemental enteral formulas or PN.

Diverticulitis is a condition that results from an inflammation of diverticula, which are abnormal but common pouchlike herniations that occur in the bowel lining. Nutritional treatment for diverticulitis includes a moderate- or low-residue diet until the infection subsides. Afterward, prescribing a high-fiber diet for chronic diverticula problems ensues.

Diabetes Mellitus

Type 1 DM requires both insulin and dietary management for optimal control, with treatment beginning at diagnosis ([ADA, 2019](#)). By contrast, patients often control type 2 DM initially with exercise and diet therapy. If these measures prove ineffective, it is common to add oral medications. Insulin injections often follow if type 2 DM worsens or fails to respond to these initial interventions.

Individualize the diet according to a patient's age, build, weight, and activity level. Maintaining a prescribed carbohydrate intake is the key in diabetes management. The ADA recommends a diet that includes carbohydrates from fruits, vegetables, whole grains, legumes, and low-fat milk ([American Dietetic Association, 2019](#)). Monitoring carbohydrate consumption is a key strategy in achieving glycemic control ([ADA, 2019](#)). Limit saturated fat to less than 7% of the total calories and cholesterol intake to less than 200 mg/day. In addition, varieties of foods containing fiber are recommended. Patients are able to substitute sucrose-containing foods for carbohydrates but need to make sure to avoid excess energy intake. Patients with diabetes can eat sugar alcohols and nonnutritive sweeteners as long as they follow the recommended daily intake level

([ADA, 2019](#)). Patients with diabetes and normal renal function should continue to consume usual amounts of protein (15% to 20% of energy) ([ADA, 2019](#)).

The goal of MNT treatment is to have glycemic levels that are normal or as close to normal as safely possible; lipid and lipoprotein profiles that decrease the risk of microvascular (e.g., renal and eye disease), cardiovascular, neurological, and peripheral vascular complications; and blood pressure in the normal or near-normal range ([ADA, 2019](#)). Be aware of signs and symptoms of hypoglycemia and hyperglycemia.

Cardiovascular Diseases

The goal of the American Heart Association (AHA) dietary guidelines ([AHA, 2018](#)) is to reduce risk factors for the development of hypertension and coronary artery disease. Diet therapy for reducing the risk of cardiovascular disease includes balancing calorie intake with exercise to maintain a healthy body weight; eating a diet high in fruits, vegetables, and whole-grain high-fiber foods; eating fish at least 2 times per week; and limiting food and beverages that are high in added sugar and salt. The AHA guidelines also recommend limiting saturated fat to less than 7%, trans fat to less than 1%, and cholesterol to less than 300 mg/day. To accomplish this goal, patients choose lean meats and vegetables, use fat-free dairy products, and limit intake of fats and sodium ([Nix, 2017](#)).

Cancer and Cancer Treatment

Malignant cells compete with normal cells for nutrients, increasing a patient's metabolic needs. Most cancer treatments cause nutritional problems. Patients with cancer often experience anorexia, nausea, vomiting, and taste distortions. The goal of nutritional therapy is to meet the increased metabolic needs of a patient ([Nix, 2017](#)). Malnutrition in cancer is associated with increased morbidity and mortality. Enhanced nutritional status often improves a patient's quality of life.

Radiation therapy destroys rapidly dividing malignant cells; however, normal rapidly dividing cells such as the epithelial lining of the GI tract are often affected. Radiation therapy causes anorexia, stomatitis, severe diarrhea, strictures of the intestine, and pain. Radiation treatment of the head and neck region causes taste and smell disturbances, decreased salivation, and dysphagia. Nutritional management of a patient with cancer focuses on maximizing intake of nutrients and fluids. Individualize diet choices to a patient's needs, symptoms, and situation ([Nix, 2017](#)). Use creative approaches to manage alterations in taste and smell. For example,

patients with altered taste often prefer chilled foods or foods that are spicy. Encourage patients to eat small frequent meals and snacks that are nutritious and easy to digest.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

Patients with HIV/AIDS typically experience body wasting and severe weight loss related to anorexia, stomatitis, oral thrush infection, nausea, or recurrent vomiting, all resulting in inadequate intake. Factors associated with weight loss and malnutrition include severe diarrhea, GI malabsorption, and altered metabolism of nutrients. Systemic infection results in hypermetabolism from cytokine elevation. The medications that treat HIV infection often cause side effects that alter patients' nutritional status.

Restorative care of malnutrition resulting from AIDS focuses on maximizing kilocalories and nutrients. Address each cause of nutritional depletion in the care plan. The progression of individually tailored nutritional support begins with administering oral, to enteral, and finally to parenteral nutrition. Good hand hygiene and food safety are essential because of a patient's reduced resistance to infection. For example, minimization of exposure to *Cryptosporidium* in drinking water, lakes, or swimming pools is important. Small, frequent, nutrient-dense meals that limit fatty and overly sweet foods are easier to tolerate. Patients benefit from eating cold foods and drier or saltier foods with fluid in between (Nix, 2017).

. Evaluation

Through the Patient's Eyes

Patients expect competent, timely, and accurate care. Patients also expect nurses to determine when nutritional therapies do not result in successful outcomes and alter the plan of care accordingly. Expectations and health care values held by nurses frequently differ from those held by patients. Successful interventions and outcomes require nurses to know what patients expect in addition to nursing knowledge and skill. Work closely with patients to confirm their expectations and talk with them about their concerns if their expectations are not realistic. Consider the limits of your patients' conditions and treatment, their dietary preferences, and their cultural beliefs when evaluating outcomes.

Patient Outcomes

Care plans need to reflect achievable goals and outcomes. Evaluate the actual outcomes of nursing actions and compare them with expected outcomes to determine whether the goals were met (Fig. 45.9).

Interprofessional collaboration remains essential in providing nutritional support. Nutritional therapy does not always produce rapid results. You need to evaluate a patient's current weight in comparison with his or her baseline weight, serum albumin or prealbumin, and protein and kilocalorie intake routinely. If your patient does not gain weight gradually or continues to lose weight, evaluate the dietary EN prescription and determine whether the patient is experiencing any adverse effects from medications that are affecting his or her nutritional status. Changes in condition also indicate a need to change the nutritional plan of care. Consult with all members of the health care team in an effort to better individualize this plan. The patient is an active participant whenever possible. In the end a patient's ability to incorporate dietary changes into his or her lifestyle with the least amount of stress or disruption facilitates attainment of outcome measures. Failing to meet expected outcomes requires revising the nursing interventions or expected outcomes on the basis of the patient's most current nursing diagnoses. When outcomes are unmet, ask questions such as "How has your appetite been?" "Have you noticed a change in your weight?" "How much would you like to weigh?" or "Have you changed your exercise pattern?"

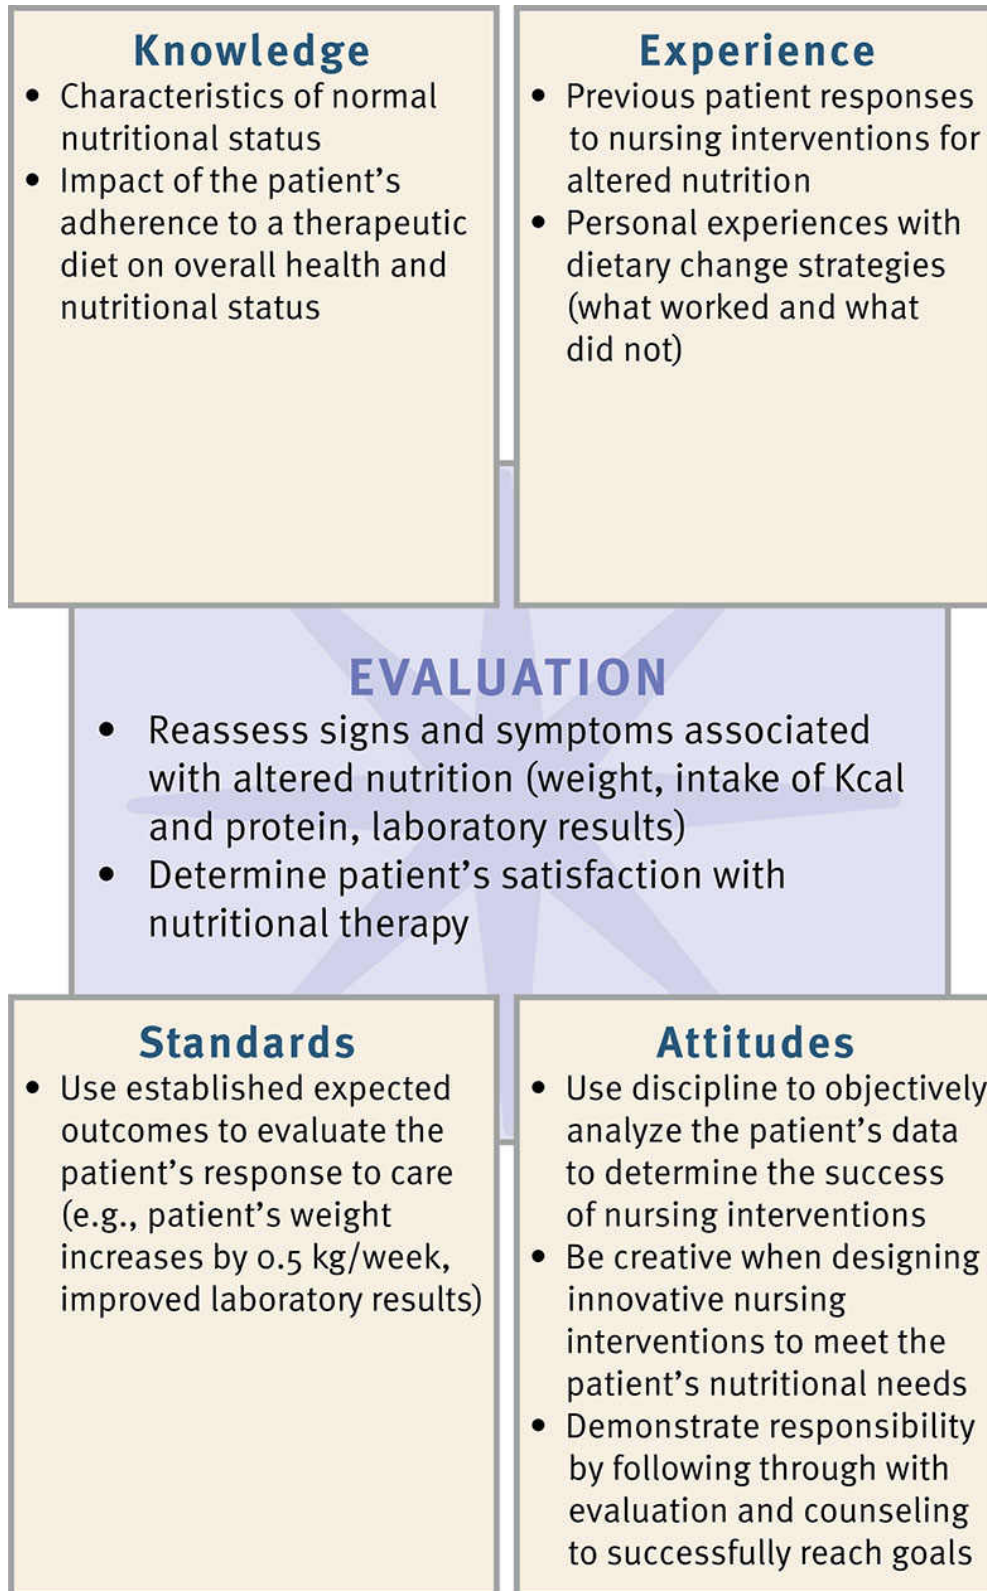

FIG. 45.9 Critical thinking model for nutrition evaluation.

Safety Guidelines For Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate a patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care.

- Verify that the appropriate ENFit connector is attached to the enteral tube when administering tube feedings (TJC, 2018).
- Use aseptic technique when preparing and delivering enteral feedings. Check agency policy for wearing gloves when handling feedings (Lewis et al., 2017).
- Label enteral equipment with patient name and room number; formula name, rate, and date and time of initiation; and nurse initials (Lewis et al., 2017).
- Practice “right patient, right formula, right tube, right ENFit adapter” by matching formula and rate to feeding order and verifying that enteral tubing set connects formula to a feeding tube (Lewis et al., 2017).
- Position the patient upright or elevate the head of the bed a minimum of 30 (preferably 45) degrees unless medically contraindicated for patients receiving enteral feedings (Lewis et al., 2017).
- Trace all lines and tubing back to the patient to ensure only enteral-to-enteral connections (Lewis et al., 2017).
- Do not add food coloring or dye to EN because the use of dye has been linked to hypotension, metabolic acidosis, and death (Lewis et al., 2017).
- Refer to manufacturer guidelines to determine hang time for enteral feedings. Maximum hang time for formula is 8 hours in an open system and 24 to 48 hours in a closed, ready-to-hang system (if it remains closed). There is increased risk of bacterial growth in feedings that exceed the recommended hang time.
- Always use an infusion pump for continuous enteral feedings and PN.
- Be alert for signs of aspiration during oral feedings as well as when EN is administered.

Skill 45.1. • Aspiration Precautions

Delegation and Collaboration

The skill of following aspiration precautions while feeding a patient can be delegated to assistive personnel (AP). However, the nurse is responsible for the ongoing assessment of a patient's risk for aspiration and determination of positioning and any special feeding techniques. The nurse directs the AP to:

- Position patient upright (45 to 90 degrees preferred) or according to medical restrictions during and after feeding.
- Use aspiration precautions while feeding patients who need help and explain feeding techniques that are successful for specific patients.
- Immediately report any onset of coughing, gagging, or a wet voice or pocketing of food to the nurse.

Equipment

- Chair or bed that allows patient to sit upright
- Thickening agents as ordered by SLP (rice, cereal, yogurt, gelatin, commercial thickener)
- Tongue blade
- Penlight
- Oral hygiene supplies (see Chapter 40)
- Suction equipment (see Chapter 41)
- Clean gloves
- *Option:* Pulse oximeter

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC,2020).
2. Review patient's medical history, nutritional risks and results of nutritional screening in medical record. Assess for presence of conditions that cause dysphagia (see Box 45.7). Note patient's weight. Consult with SLP and/or RD.	Reveals patient risk patterns for altered nutrition and dysphagia. Weight provides baseline for determining change in nutritional status.
3. Assess patient's current medications for use of sedatives, hypnotics, or other agents that may impair cough or swallowing reflex and for any medications that dry oral secretions (e.g., calcium channel blockers, diuretics) (Tan et al., 2018).	Medication side effects may increase risk of developing dysphagia.
4. Perform hand hygiene. Assess patient for signs and symptoms of dysphagia. Consult with SLP.	Patient symptoms aid in determining whether further swallow evaluation is needed and approach to feeding.
5. Assess patient's or family caregiver's knowledge of dysphagia risk and diet options, experience, and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2016).
Table Continued	

Step	Rationale
6. Assess patient's mental status: alertness, orientation, and ability to follow simple commands (e.g., open your mouth; stick out your tongue).	Disorientation and inability to follow commands present higher risk for dysphagia.
7. Apply gloves. Assess patient's oral cavity, level of dental hygiene, missing teeth, or poorly fitting dentures. Remove and dispose of gloves.	Poorly fitting dentures and absence of teeth can cause chewing and swallowing difficulties, increasing aspiration risk. Poor oral hygiene and periodontal disease can result in growth of bacteria in oropharynx, which if aspirated, can lead to pneumonia (Liantonio et al., 2014). Findings indicate level of oral hygiene needed and diet selection needed.
8. <i>Option:</i> Obtain baseline assessment oxygen saturation. A decline in SpO ₂ ≥ 2% has been regarded as a possible marker of aspiration (Marian et al., 2017). Perform hand hygiene.	Despite its clinical use, research findings question whether oximetry can reliably detect aspiration (American Speech-Language-Hearing Association [ASHA], 2016; Lancaster, 2015; Marian et al., 2017).
9. Prepare to observe patient during mealtime for signs of dysphagia. Observe patient attempt to feed self; note type of food consistencies and liquids able to swallow. Note during and at end of meal if patient tires.	Detects abnormal eating patterns such as frequent clearing of throat or prolonged eating time. Chewing and sitting up for feeding bring on onset of fatigue (Meiner and Yeager, 2019). Provides data for future planning of meal assistance.
10. Indicate in patient's health record that dysphagia/aspiration risk is present. <i>Option:</i> Some agencies use different-colored meal trays to signify patients at risk for aspiration.	Identifying patients with dysphagia reduces risk that they will receive improperly prepared oral nutrition without supervision.
Planning	
1. Provide patient rest time before meals.	Some practitioners recommend rest time before meals (Metheny, 2012). Muscle weakness and fatigue may increase risk of aspiration.
2. Explain to patient why you are observing him or her while eating.	Signs or symptoms associated with aspiration indicate need for further swallowing evaluation such as fluoroscopic examination.
3. Explain to patient and family caregiver about the aspiration precautions you are implementing.	Increases patient cooperation and prepares family caregiver for being able to assist.
Implementation	
1. Perform hand hygiene and have patient or family caregiver (if going to help with feeding) perform hand hygiene.	Prevents transmission of microorganisms. Educates patient and family caregiver about need to maintain infection control practices.
2. Apply clean gloves. Use penlight and tongue blade to gently inspect mouth for pockets of food.	Pockets of food found inside cheeks occur when patient has difficulty moving food from mouth into pharynx; may lead to aspiration (Zupek-Kania and O'Flaherty, 2017). Patient is usually unaware of pocketing.
3. Provide thorough oral hygiene, including brushing tongue, before meal (see Chapter 40). Remove and dispose of gloves, perform hand hygiene.	Risk for aspiration pneumonia has been associated with poor oral hygiene (Liantonio et al., 2014).
4. Position patient upright (90 degrees) in chair or elevate head of patient's bed to a 90-degree angle or highest position allowed by medical condition during meal.	Position facilitates safe swallowing and enhances esophageal motility (Liantonio et al., 2014; Metheny and Frantz, 2013). Side-lying position is an option if patient cannot have head elevated.
5. <i>Option:</i> Apply pulse oximeter to patient's finger; monitor during feeding.	Pulse oximetry continues to be used in many agencies in an effort to predict aspiration, but recent research questions its efficacy (ASHA, 2016; Marian et al., 2017)
6. Provide appropriate thickness of liquids per SLP and RD assessment (International Dysphagia Diet Standardisation Initiative, 2016). Encourage patient to feed self.	Thin liquids are difficult to control in mouth and pharynx and are more easily aspirated.
7. Have patient assume chin-down position. Remind patient to not tilt head backward when eating or while drinking.	Chin-down position may help reduce aspiration (Kagaya et al., 2011; Liantonio et al., 2014). One study suggests a head-turn-plus-chin-down maneuver may be more successful (Nagy et al., 2016).
8. Adjust the rate of feeding and size of bites to match the patient's tolerance. If patient unable to feed self, place ½ to 1 teaspoon of food on unaffected side of mouth, allowing utensil to touch mouth or tongue (Liantonio et al., 2014).	Small bites help patient swallow (Liantonio et al., 2014). Provides tactile cue to food being eaten; avoids pocketing of food on weaker side.
9. Provide verbal coaching; remind patient to chew and think about swallowing with comments such as the ones that follow. Open your mouth. Feel the food in your mouth. Chew and taste the food. Raise your tongue to the roof of your mouth. Think about swallowing. Close your mouth and swallow. Swallow again. Cough to clear your airway.	Verbal cueing keeps patient focused on normal swallowing (Metheny, 2012). Positive reinforcement enhances patient's confidence in ability to swallow.
10. Avoid mixing food of different textures in same mouthful. Alternate liquids and bites of food (Liantonio et al., 2014). Refer to RD for next meal if patient has difficulty with particular consistency.	Gradual increase in types and textures combined with constant monitoring helps patient to eat more safely. Single textures are easier to swallow than multiple textures. Alternating solids with liquids removes food residue in mouth.
Step	Rationale

Table Continued

Step	Rationale
11. During the meal explain to patient and family caregiver the techniques being used to promote swallowing.	Enhances patient and family caregiver's ability to use techniques in the home.
12. Monitor swallowing and observe for any respiratory difficulty. Observe for throat clearing, coughing, choking, gagging, and drooling of food; suction airway as needed (see Chapter 41).	These are indications that suggest dysphagia and thus pose risk for aspiration (National Stroke Association, 2017).
13. Minimize distractions, do not talk, and do not rush patient (Liantonio et al., 2014). Allow time for adequate chewing and swallowing. Provide rest periods as needed during meal.	Environmental distractions and conversations during mealtime increase risk for aspiration. Avoiding fatigue reduces aspiration risk.
CLINICAL DECISION: <i>If patient remains stable without difficulty, this is good time to delegate continued feeding to AP so that you can attend to other patients and assigned priorities.</i>	
14. Use sauces, condiments, and gravies (if part of dysphagia diet) to facilitate cohesive food bolus formation.	Cohesive food bolus helps to prevent pocketing or small food particles from entering the airway.
15. Ask patient to remain sitting upright for at least 30 to 60 minutes after a meal. Provide nurse call system to patient and instruct patient to utilize if needed	Remaining upright after meals or snack reduces chance of aspiration by allowing food particles remaining in pharynx to clear (Metheny, 2012). Promotes patient safety.
16. Apply gloves. Provide thorough oral hygiene after meal (see Chapter 40).	Rigorous oral hygiene reduces plaque and secretions containing bacteria, with studies showing reduction in incidence of pneumonia (Liantonio et al., 2014).
17. Return patient's tray to appropriate place. Remove and dispose of gloves.	Reduces spread of microorganisms.
18. Raise side rails (as appropriate) and lower bed to lowest position. Perform hand hygiene	Promotes patient safety. Reduces transmission of microorganisms.
Evaluation	
1. Observe patient's ability to swallow food and fluids of various textures and thickness without choking.	Indicates whether there is ease with swallowing and absence of signs related to aspiration.
2. Monitor pulse oximetry readings (if ordered) for high-risk patients during eating.	Deteriorating oxygen saturation levels may indicate aspiration, but current research questions predictive accuracy of oximetry.
3. Monitor patient's intake and output (I&O), calorie count, and food intake.	Helps to detect malnutrition and dehydration resulting from dysphagia.
4. Weigh patient daily or weekly.	Determines whether weight is stable and reflects nutritional status.
5. Observe patient's oral cavity after meal.	Determines presence of food pockets after meal that has included foods of various textures.
6. Use Teach-Back: "We talked about why your husband is at risk to aspirate his food. Tell me the things to observe for that will tell you if he is having trouble swallowing. What should you do if these things happen during a meal?" Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
1. Patient coughs, gags, complains of food "stuck in throat," and has wet quality to voice when eating. • Stop feeding immediately and place patient on NPO. • Notify health care provider and suction as needed (see Chapter 41). • Anticipate consultation with SLP for swallowing exercises and techniques to improve swallowing.	
2. Patient experiences weight loss over next several days/weeks. • Discuss findings with health care provider and RD. Determine whether increasing frequency or quality of foods is needed. • Nutritional supplements may be needed.	
Recording and Reporting	
<ul style="list-style-type: none"> Record patient's diet, tolerance of liquids and food textures, amount of assistance required, response to instruction, position during meal, absence or presence of any symptoms of dysphagia, fluid intake, and amount of food eaten. Document your evaluation of patient learning. Report patient's tolerance to diet and degree of assistance required during hand-off report. Report any coughing, gagging, choking, or swallowing difficulties to nurse in charge or health care provider immediately. 	
Home Care Considerations	
<ul style="list-style-type: none"> Teach the patient and family the importance of frequent small meals with small bites and balancing with MNT. Teach patient and family how to recognize problems in swallowing. Teach patient and family about when to seek medical attention and what to report to the health care provider. 	

Skill 45.2. Inserting and Removing a Small-Bore Nasoenteric Tube for Enteral Feedings

Delegation and Collaboration

The skill of feeding tube insertion cannot be delegated to assistive personnel (AP). However, AP may help with patient positioning and comfort measures during tube insertion.

Equipment (Insertion)

- Small-bore feeding tube with or without stylet (select the smallest diameter possible to enhance patient comfort)
- 60-mL ENFit syringe
- Stethoscope, pulse oximeter, capnography (*optional*)
- Hypoallergenic tape, semipermeable (transparent) dressing, or tube fixation device
- Tincture of benzoin or other skin barrier protectant
- pH indicator strip (scale 1.0 to 11.0)
- Cup of water and straw or ice chips (for patients able to swallow)
- Water-soluble lubricant
- Emesis basin
- Towel or disposable pad
- Facial tissues
- Clean gloves
- Suction equipment in case of aspiration
- Penlight to check placement in nasopharynx
- Tongue blade
- Oral hygiene supplies
- Measuring tape

Equipment (Removal)

- Disposable pad
- Tissues
- Clean gloves
- Disposable plastic bag
- Towel

Step	Rationale
Assessment	
1. Verify health care provider's order for type of tube and EN feeding schedule. Also check order to determine whether health care provider wants prokinetic agent (e.g., metoclopramide) given before tube placement.	Health care provider's order is needed to insert feeding tube. Prokinetic agent given before tube placement may help advance tube (if it is to be advanced into intestine).
2. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
3. Review patient's medical history (e.g., for basilar skull fracture, nasal problems, nosebleeds, facial trauma, nasal-facial surgery, deviated septum, anticoagulant therapy, coagulopathy).	History of these problems may require you to consult with health care provider to change route of nutritional support. Passage of tube intracranially can cause neurological injury.
CLINICAL DECISION: <i>If a patient is at risk for intracranial passage of the tube, avoid the nasal route. Oral placement or placement under medical supervision using fluoroscopic direct visualization is preferable. Insertion of a gastrostomy or jejunostomy tube is another alternative.</i>	
4. Assess patient's height, weight, hydration status, electrolyte balance, caloric needs and intake and output (I&O).	Provides baseline information to measure nutritional improvement after enteral feedings.
5. Perform hand hygiene. Have patient close each nostril alternately and breathe. Examine each naris for patency and skin breakdown (apply clean gloves if drainage present). If patient previously had NG tube, check for medical device related pressure injury (see illustration).	Reduces transmission of microorganisms. Nares can sometimes be obstructed or irritated, or septal defect or facial fractures are present. Place tube in most patent naris.
6. Perform physical assessment of abdomen (see Chapter 30). Remove and dispose of gloves (if worn). Perform hand hygiene.	Absent bowel sounds, abdominal pain, tenderness, or distention may indicate medical problem contraindicating feedings. Reduces transmission of microorganisms.

STEP 5 Medical device-related pressure injury under nose.

Table Continued

Step	Rationale
7. Assess patient's knowledge and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
8. Assess patient's mental status (ability to cooperate with procedure, level of sedation), presence of cough and gag reflex, ability to swallow, critical illness, and presence of artificial airway.	These are risk factors for inadvertent tube placement into tracheobronchial tree (Metheny, 2012). Sedation impairs the ability of the patient to clear contents in the pharynx, thus increasing the risk of aspiration (Boullata et al., 2017).
9. Assess patient's experience with procedure and expectations.	Provides data to determine level of instruction needed.
CLINICAL DECISION: Recognize situations in which blind placement of a feeding tube poses an unacceptable risk for placement. Devices designed to detect pulmonary intubation such as CO ₂ sensors or electromagnetic tracking devices enhance patient safety. Alternatively, to avoid insertion complications from blind placement in high-risk situations, clinicians trained in the use of visualization or imaging techniques should place tubes (Metheny and Meert, 2017; Milsom et al., 2015).	
PLANNING	
1. Provide privacy and prepare bedside environment for patient safety.	Promotes patient comfort and safety.
2. Prepare and organize equipment needed for insertion of NG feeding tube.	Ensures an organized approach for insertion of NG feeding tube.
3. Explain procedure to patient, including sensations anticipated during insertion (burning in nasal passages) and to raise index finger to indicate gagging or discomfort during insertion	Reduces anxiety and helps patient assist in insertion.
Implementation	
1. Perform hand hygiene. Stand on same side of bed as naris chosen for insertion and position patient upright in high-Fowler's position (unless contraindicated). If patient is comatose, raise head of bed as tolerated in semi-Fowler's position with head tipped forward, using a pillow chin to chest. If necessary have an AP help with positioning of confused or comatose patients. If patient is forced to lie supine, place in reverse Trendelenburg's position.	Reduces transmission of microorganisms. Allows for easier manipulation of tube. Fowler's position reduces risk of aspiration and promotes effective swallowing. Forward head position helps with closure of airway and passage of tube into esophagus.
2. Apply pulse oximeter/capnograph and measure vital signs. Maintain oximetry or capnography continuously.	Provides baseline for objective assessment of respiratory status during tube insertion and throughout time a tube is in place. Lowered oxygen saturation or increased end-tidal CO ₂ can indicate tube being misplaced into the lungs or moving out of the stomach into lungs (Holland et al., 2013).
CLINICAL DECISION: If patient has increase in end-tidal carbon dioxide or decrease in oxygen saturation, tube should not be inserted until you determine patient stability.	
3. Place bath towel over patient's chest. Keep facial tissues within reach.	Prevents soiling of gown. Insertion of tube frequently produces tearing.
4. Determine length of tube to be inserted and mark location with tape or indelible ink. Some tubes have centimeter markings.	Ensures organized procedure and estimation of the proper length of tube to insert into patient.
a. <i>Option, Adult:</i> Measure distance from tip of nose to earlobe to xyphoid process (NEX) of sternum (see illustration). Mark this distance on tube with tape.	Most traditional method. Length approximates distance from nose to stomach. Research has shown this method may be least effective compared with others, though more research is needed (Santos et al., 2016).

Step	Rationale
	

STEP 4A Measure to determine length of tube to insert.
Copyright © Mosby's Clinical Skills: Essentials Collection.

Step	Rationale
b. <i>Option, Adult:</i> A nose to earlobe to mid-umbilicus (NEMU) method to estimate appropriate nasogastric tube placement has been recommended.	Promotes placement of the tube end holes in or closer to the gastric fluid pool (Boullata et al., 2017).
c. <i>Option, Adult:</i> Measure distance from xyphoid process to earlobe to nose (XEN) + 10 cm (Taylor et al., 2014).	Shown to be more accurate than NEX (Taylor et al., 2014).
d. <i>Option, Children:</i> Use NEMU option.	Estimates proper length of tube insertion for pediatric patient.
e. Add 20 to 30 cm (8 to 12 inches) for post-pyloric tubes.	Length approximates distance from nose to jejunum.
CLINICAL DECISION: <i>Tip of pre-pyloric tubes must reach stomach to avoid the risk for pulmonary aspiration, which occurs when tubes end instead in the esophagus. Research has mixed findings regarding the best technique for estimating tube length (Santos et al., 2016). Confirmation of placement via x-ray immediately after completed insertion is still needed.</i>	
5. Prepare tube for intubation. Note: Do not ice tubes.	Iced tube becomes stiff and inflexible, causing trauma to nasal mucosa.
a. Obtain order for stylet tube and check agency policy for trained clinician to insert tube.	The practice of inserting a tube requires great care and attention to practice guidelines.
b. If tube has guidewire or stylet, inject 10 mL of water from ENFit syringe into tube.	Aids in guidewire or stylet removal. Activates lubrication of tube for easier passage and ensures that tube is patent. ENFit devices are not compatible with Luer connection or any other type of small-bore medical connector, thus preventing misadministration of an enteral feeding (ISMP, 2015).
c. If using stylet, make certain that it is positioned securely within tube. Inject 10 mL of water from ENFit syringe into tube.	Promotes smooth passage of tube into gastrointestinal (GI) tract. Improperly positioned stylet can cause tube to kink or injure patient. Ensures that tube is patent and aids in stylet removal. Once tube insertion is confirmed, have trained clinician remove stylet.
6. Prepare tube fixation materials. Cut hypoallergenic tape 10 cm (4 inches) long or prepare membrane dressing or other tube fixation device (e.g., bridle).	Used to secure tubing after insertion. Fixation devices allow tube to float free of nares, thus reducing pressure on nares, preventing device-related pressure injury (DRPI).
7. Apply clean gloves.	Reduces transmission of microorganisms.
8. <i>Option:</i> Dip tube with surface lubricant into glass of room-temperature water or apply water-soluble lubricant (see manufacturer directions).	Activates lubricant to facilitate passage of tube into nares and GI tract.
9. Offer an patient a cup of water with straw (if alert and able to swallow).	Patient is asked to swallow water to facilitate tube passage.
10. Explain next steps and gently insert tube through nostril to back of throat (posterior nasopharynx). This may cause patient to gag. Aim back and down toward ear (see illustration).	Natural contours facilitate passage of tube into GI tract.
11. Have patient take deep breath, relax, and flex head toward chest after tube has passed through nasopharynx.	Closes off glottis and reduces risk for tube entering trachea.
12. Encourage patient to swallow small sips of water. Advance tube as patient swallows. Rotate tube gently 180 degrees while inserting.	Swallowing water lubricates and facilitates passage of tube into esophagus. Distinct tug may be felt as patient swallows, indicating that tube is following expected path. Tube rotation redirects the tip of tube away from glottis.
13. Emphasize need to mouth breathe and swallow during insertion.	Helps facilitate passage of tube and alleviates patient's fears during procedure.

Step	Rationale
	

STEP 10 Insert tube through nostril to back of throat.

STEP 15 NG tube inserted through nasopharynx and esophagus into stomach.

Step	Rationale
14. Do not advance tube during inspiration or coughing because it is more likely to enter respiratory tract. Monitor oximetry and capnography at this time.	Can cause tube to inadvertently enter patient's airway, which will be reflected in changes in oxygen saturation and/or capnography.
15. Advance tube each time patient swallows until desired length has been reached (see illustration).	Reduces discomfort and trauma to patient. Helps facilitate tube passage.
CLINICAL DECISION: Do not force the tube or push against resistance. If patient starts to cough, experiences a drop in oxygen saturation, rise in end-tidal CO ₂ , or shows other signs of respiratory distress, withdraw the tube into the posterior nasopharynx until normal breathing resumes.	
16. Check for position of tube in back of throat using penlight and tongue blade.	Tube may be coiled, kinked, or entering trachea.
17. Temporarily anchor tube to nose with small piece of tape.	Movement of tube stimulates gagging. Assesses general position before anchoring tube more securely.
18. Keep tube secure and check its placement by aspirating stomach contents to measure gastric pH (see Box 45.14). Also measure amount, color, and quality of return.	Provides baseline for appearance and pH of aspirate at initial location before x-ray confirmation.
CLINICAL DECISION: insufflation of air into tube while auscultating abdomen is not a reliable means to determine position of feeding tube tip (Bourgault et al., 2015).	
19. Anchor tube to patient's nose, avoiding pressure on nares. Mark exit site on tube with indelible ink. Select one of the following options for anchoring:	Marking tube can alert nurses to possible displacement of tube. Properly secured tube allows patient more mobility and prevents trauma to nasal mucosa (Matheny, 2016).
a. Apply membrane dressing or tube fixation device:	Permits longer securement without need to change dressing.
(1) Membrane dressing:	Allows membrane to adhere to skin.
(a) Apply tincture of benzoin or other skin protector to patient's cheek and area of tube to be secured.	Used to protect the skin from irritation and infection.
(b) Place tube against patient's cheek and secure tube with membrane dressing, out of patient's line of vision.	Eliminates application of tape around nares. Decreases risk for patient's inadvertent extubation.
(2) Tube fixation device:	Secures tube and reduces friction on nares.
(a) Apply wide end of patch to bridge of nose (see illustration).	
(b) Slip connector around feeding tube as it exits nose (see illustration).	
b. Apply tape:	Prevents pulling of tube. May require frequent change if tape becomes soiled.
(1) Apply tincture of benzoin or other skin adhesive on tip of patient's nose and allow it to become "tacky."	Helps tape adhere better. Protects skin from breakdown.
(2) Remove gloves and tear two horizontal slits on each side of tape at 1/3 and 2/3 length. Do not split tape. Fold middle sections forward.	Creates a gap in tape that once secured will allow tube to float and exert less pressure on nares.
(3) Tear vertical strip at bottom of tape. Print date and time on nasal part of tape.	Secures tube firmly and provides date of insertion.
	
STEP 18A(2)(A) Apply tube fixation device to bridge of nose.	STEP 18A(2)(B) Slip connector around feeding tube.

Table Continued

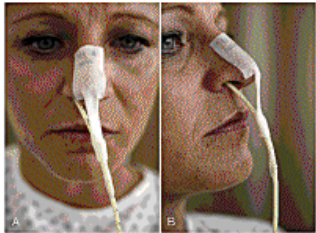

Step	Rationale
(4) Place intact end of tape over bridge of patient's nose. Wrap each strip around tube as it exits (see illustration).	Tube is free floating in the naris with this taping method, resulting in movement of tube in pharynx. Securing tape to naris in this method reduces pressure on naris and risk for medical device-related pressure injury (Markowitz et al., 2013).
20. Fasten end of tube to patient's gown using clip (see illustration) or piece of tape. Do not use safety pins to secure tube to gown.	Reduces traction on naris if tube moves, which can cause medical device-related pressure injury. Safety pins become unfastened and cause injury to patients.
21. Help patient to comfortable position but keep head of the bed elevated at least 30 degrees (preferably 45 degrees) unless contraindicated (Schallom et al., 2015).	Promotes patient comfort and lowers risk of aspiration should patient receive tube feeding.
22. Remove gloves and perform hand hygiene.	Reduces transmission of microorganisms.
CLINICAL DECISION: Leave stylet in place until correct position is verified by x-ray film. Never reinsert a partially or fully removed stylet while feeding tube is in place. This can cause perforation of tube and injure patient. Contact the health care provider if problems arise with feeding tube.	
23. Contact radiology to obtain x-ray film of chest/abdomen.	Radiographic examination is most accurate method to determine feeding-tube placement (Milsom et al., 2015).
24. Perform hand hygiene. Apply clean gloves and administer oral hygiene (see Chapter 40). Clean tubing at nostril with washcloth dampened in mild soap and water.	Promotes patient comfort and integrity of oral mucous membranes. Reduces transmission of microorganisms.
25. Remove and dispose of equipment, remove and dispose of gloves, and perform hand hygiene.	Reduces transmission of microorganisms.
26. Place nurse call system in an accessible location within patient's reach. Instruct patient in its use.	Promotes patient safety.
27. Raise side rails as appropriate and lower bed to lowest position.	Promotes patient safety.
28. Tube Removal	
a. Verify health care provider's order for tube removal.	Health care provider's order is needed to remove feeding tube.
b. Gather equipment.	Ensures organized procedure.
c. Explain procedure to patient.	Encourages cooperation, reduces anxiety, and minimizes risks. Identifies teaching needs.
d. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms.
e. Position patient in high-Fowler's position unless contraindicated.	Reduces risk for pulmonary aspiration in event patient should vomit.
f. Place disposable pad or towel over patient's chest.	Prevents mucus and gastric secretions from soiling patient's clothing.
g. Disconnect tube from feeding administration set (if present), and clamp or cap end.	Prevents formula from spilling from tube as it is removed.
 <p data-bbox="354 1396 667 1428">STEP 192(4) A, Applying tape to anchor nasogastric tube. B, Naris is free of pressure from tape and tube.</p>	 <p data-bbox="834 1455 1281 1476">STEP 20 Fasten feeding tube to patient's gown.</p>

Table Continued

Step	Rationale
h. Remove tape or tube fixation device from patient's nose. Unclip tube from patient's gown.	Allows tube to be removed easily.
i. Instruct patient to take deep breath and hold it. Then as you kink end of tube securely (folding it over on itself), completely withdraw tube by pulling it out steadily and smoothly onto towel or disposable bag. Dispose of it into appropriate receptacle.	Prevents inadvertent aspiration of gastric contents while tube is removed. Kinking prevents leakage of fluid from tube. Promotes patient comfort. Reduces transmission of microorganisms.
j. Offer tissues to patient to blow nose.	Clears nasal passages of remaining secretions.
k. Offer mouth care.	Promotes patient's comfort.
l. Remove and dispose of gloves; perform hand hygiene.	Reduces transmission of microorganisms.
Evaluation	
1. Observe patient's response to tube placement. Assess lung sounds; have patient speak; check vital signs; note any coughing, dyspnea, cyanosis, or decrease in oxygen saturation or increase in end-tidal CO ₂ .	Symptoms may indicate placement in respiratory tract. Auscultation of crackles, wheezes, dyspnea, or fever may be delayed response to aspiration. Lowered oxygen saturation or increased end-tidal CO ₂ may detect tip of tube is in trachea or lung.
2. Confirm radiographic film results with health care provider.	Verifies position of tube before initiating enteral feeding.
3. Remove stylet after x-ray film verification of correct placement. Review agency policy regarding requirement of trained clinician for insertion.	If placement needs adjustment, stylet is still in place and contact health care provider.
4. Check condition of nares, location of external exit site marking on tube, and color and pH of fluid aspirated from tube per agency policy.	Routine evaluation ensures no formation of medical device-related pressure injury and correct placement of tube.
5. Assess patient's level of comfort after removal.	Provides for continued comfort of patient.
6. Use Teach-Back: "I want to be sure that I explained to you what you can do during insertion of the nasogastric tube so that you can communicate with me. Tell me how you are going to communicate with me during tube insertion." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Aspiration of stomach contents into respiratory tract (delayed response or small-volume aspiration), evidenced by auscultation of crackles or wheezes, dyspnea, or fever</p> <ul style="list-style-type: none"> • Report change in patient condition to health care provider immediately; if there has not been a recent chest x-ray film, suggest ordering one. • Position patient on side to protect airway. • Suction nasotracheally and orotracheally (Chapter 41). • Prepare for possible initiation of antibiotics. <p>2. Displacement of feeding tube to another site (e.g., from duodenum to stomach) possibly occurs when patient coughs or vomits.</p> <ul style="list-style-type: none"> • Aspirate GI contents and measure pH. • Remove displaced tube and insert and verify placement of new tube. • If there is question of aspiration, obtain chest x-ray film. 	
Recording and Reporting	
<ul style="list-style-type: none"> • Tube insertion: Record procedure and report type and size of tube placed; location of distal tip of tube; patient's tolerance of procedure; confirmation of tube position by x-ray film examination; length of tube that extends from nostril; color, pH, and amount of aspirate; securing device. • Tube removal: Record procedure and patient's level of comfort and condition of nares. • Report any type of unexpected outcome and the interventions performed to health care provider. • Report during hand-off tube placement, when confirmation of placement was received, condition of patient's nares. 	

Skill 45.3. Administering Enteral Feedings via Nasoenteric, Gastrostomy, or Jejunostomy Tubes Delegation and Collaboration

The skill of administration of nasoenteric tube feeding can be delegated to assistive personnel (AP) (refer to agency policy). A registered nurse (RN) or licensed practical nurse (LPN) must first verify tube placement and patency. The nurse directs the AP to:

- Elevate head of bed to 30 to 45 degrees or sit patient up in bed or a chair unless contraindicated.
- Not adjust feeding rate; infuse the feeding as ordered.

- Report any difficulty in infusing the feeding or any discomfort voiced by the patient.
- Report any gagging, vomiting, paroxysms of coughing, or choking.
- Provide frequent oral hygiene.

Equipment

- Disposable feeding bag, tubing, or ready-to-hang system
- 60-mL or larger ENFit syringe
- Stethoscope
- Enteral infusion pump for continuous feedings
- pH indicator strip (scale 1.0 to 11.0)
- Water for flushing tube; sterile or purified water as indicated
- Prescribed enteral formula (standard polymeric or high protein) (McClave et al., 2016)
- Clean gloves
- ENFit connector

Step	Rationale
Assessment	
1. Verify health care provider's order for type of tube feeding formula, rate, route, and frequency.	Ensures that correct formula will be administered in appropriate volume. Enteral formulas are not interchangeable.
2. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC,2020).
3. Review medical record for risk factors of malnutrition and current clinical characteristics of malnutrition (see Table 45.4). Consult with nutritional support team and health care provider.	Determines patient's risk for malnutrition and potential need for early initiation of EN (McClave et al., 2016; Meehan et al., 2016; White et al., 2012).
4. Assess patient for factors that increase risk for aspiration: sedation, mechanical ventilation, nasotracheal suctioning, neurological compromise, lying flat, and sepsis (Eglsner et al., 2018).	Identifies patients at high risk for aspiration so that decision may be made based on safety of gastric versus intestinal feeding (McClave et al., 2016).
5. Perform hand hygiene. Perform physical assessment of abdomen, including auscultation for bowel sounds, before feeding (see Chapter 30).	Objective measures for assessing tolerance include changes in bowel sounds, expanding girth, tenderness and firmness on palpation, increasing nasogastric (NG) output, and vomiting (McCarthy and Martindale, 2015). Report findings to health care provider to determine whether tube feeding can proceed safely.
6. Obtain baseline weight and review serum electrolytes and blood glucose measurement (see Skill 45.4). Assess patient for fluid volume excess or deficit, electrolyte abnormalities, and metabolic abnormalities (e.g., hyperglycemia).	Enteral feedings should restore or maintain patient's nutritional status. Measures provide objective data and baseline to determine selection of formula and measure effectiveness of feedings.
7. Collaborate with RD for determination of patient's caloric and protein requirements. Then set goal for delivery of EN (McClave et al., 2016).	Sets objective measure for determining percent of prescribed calories and protein delivered.
8. Assess patient's or family caregiver's knowledge, experience and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
Planning	
1. Provide privacy and prepare bedside environment for patient safety.	Promotes patient's comfort and safety.
2. Prepare and organize equipment for enteral feeding administration.	Ensures organized approach for administration of feedings.
3. Explain enteral feeding administration procedure to patient and/or caregiver.	Decreases patient anxiety. Promotes patient cooperation and increases adherence.
Implementation	
1. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms and potential contamination of enteral formula.
2. Reverify correct formula and check expiration date; note integrity of container and appearance of formula.	Ensures that correct therapy is to be administered and checks integrity of formula.
a. Prepare formula for administration, following manufacturer guidelines.	
<i>CLINICAL DECISION: Discard unused reconstituted and refrigerated formulas within 24 hours of preparation (Boullata et al., 2017).</i>	
b. Have formula at room temperature.	Cold formula causes gastric cramping and discomfort because liquid is not warmed by mouth and esophagus.
c. Use aseptic technique to connect administration set tubing to container as needed. Use proper ENFit connector and avoid handling feeding system or touching can tops, container openings, spike, and spike port.	Bag, connections, and tubing must be free of contamination to prevent bacterial growth. The use of a closed system lowers the risk of infections due to bacterial contamination (Boullata et al., 2017).
d. Shake formula container well. Clean top of canned formula with alcohol swab before opening it.	Ensures integrity of formula; prevents transmission of microorganisms.

Table Continued

Step	Rationale
<p>e. For closed systems connect administration tubing to container. If using open system, pour formula from brick pack or can into administration bag (see illustration).</p>	<p>Formulas are available in closed-system containers that contain a 24- to 48-hour supply of formula or in an open system, in which formula must be transferred from brick packs or cans to a bag before administration.</p>
<p>4. Open roller clamp and allow administration tubing to fill. Clamp off tubing with roller clamp. Hang container on intravenous (IV) pole.</p>	<p>Prevents introduction of air into stomach once feeding begins.</p>
<p>5. Keep patient in high-Fowler's position or elevate head of bed at least 30 degrees (45 degrees recommended). For patient forced to remain supine, place in reverse Trendelenburg's position, which raises head.</p>	<p>Elevation of head of bed helps prevent pulmonary aspiration (Boullata et al., 2017). Researchers recommend HOB elevation of 45 degrees for patients receiving EN who require mechanical ventilation or are heavily sedated, but lowering the head to 30 degrees might be done periodically for patient comfort and in patients at risk of developing pressure injury (Schallom et al., 2015).</p>
<p>6. Verify tube placement (see Skill 45.2). Observe appearance of aspirate, measure the length of the tube extending from the nares and compare to the insertion length, and note pH.</p>	<p>Verifies whether tip of tube is in stomach, intestine, or lung based on pH value (<5.0) (Fan et al., 2017; Ni et al., 2017).</p>
<p>a. <i>Nasoenteric and gastrostomy tube:</i> Attach ENFit syringe to end of enteral feeding tube and aspirate gastric or intestinal contents.</p>	<p>Gastric fluid for patient who has fasted for at least 4 hours usually has pH of 1.0 to 4.0 (if not receiving gastric acid inhibitor, then pH of <5.0) (Fan et al., 2017). If continuous feedings into stomach or intestine, check pH if feedings held for at least 1 hour for diagnostic reason (stomach pH <5.0; intestinal pH >6.0) (Fan et al., 2017).</p>
<p>b. <i>Jejunostomy tube:</i> Attach ENFit syringe to end of tube and aspirate intestinal secretions. Observe appearance; if significant amounts are returned or resemble gastric secretions, check pH.</p>	<p>Presence of intestinal fluid at pH greater than 6.0 indicates that end of tube is in small intestine. If fluid tests acidic on pH test or looks like gastric fluid, tube may be displaced into stomach.</p>
<p>7. Check gastric residual volume (GRV) per agency policy. Routine use is no longer recommended (Boullata et al., 2017) and should not be used as a single measure of tolerance.</p>	<p>GRV has poor correlation with pneumonia, regurgitation and aspiration. Frequent checking may delay feeding. However, if other signs of intolerance (e.g., abdominal distention, vomiting, or pain) are present, GRV of 250 to 500 mL may indicate the need to take measures to prevent aspiration or hold feeding completely (Boullata et al., 2017). Intestinal residual is usually very small. If residual volume is greater than 10 mL, displacement of intestinal tube into stomach may have occurred.</p>
<p>CLINICAL DECISION: Limit gastric residual checks to recommended standard intervals as acidic gastric contents may cause protein in enteral formulas to precipitate within the lumen of the tube, creating risk for obstruction (Boullata et al., 2017). Use of GRVs leads to increased EAD clogging, inappropriate cessation of EN, consumption of nursing time, and allocation of health care resources and may adversely affect outcome through reduced volume of EN delivered (Boullata et al., 2017).</p>	
Step	Rationale

STEP 3E Pour formula into open feeding container.
Kangaroo™ ePump © 2018 Courtesy of Cardinal Health UK Ltd.

Table Continued

Step	Rationale
a. Draw up 10 to 30 mL air into ENFit syringe and connect to end of feeding tube. Inject air slowly into tube. Pull back slowly and aspirate total amount of gastric contents you can aspirate.	GRV may not be easy to obtain from small-bore feeding tube. A 60-mL syringe prevents gastric tube collapse.
b. Return aspirated contents to stomach slowly. Refer to agency policy for any cutoff to hold aspirated contents instead (McCarthy and Martindale, 2015).	Prevents loss of nutrients and electrolytes in discarded fluid. Some questions exist regarding safety of returning high volumes of fluid into stomach.
c. GRVs in range of 200 to 500 mL may raise concern and lead to implementation of measures to reduce risk of aspiration. Automatic cessation of feeding shouldn't occur for GRV less than 500 mL in absence of other signs of intolerance (Boullata et al., 2017, McClave et al., 2016).	Raising cutoff value for GRV from lower number to higher number doesn't increase risk for regurgitation, aspiration, or pneumonia (Boullata et al., 2017).
d. Flush feeding tube with 30 mL water.	Prevents clogging of tubing and ensures that complete feeding is administered.
CLINICAL DECISION: Minimize the use of sedatives in patients receiving continuous feeding because airway clearance is reduced in sedated patients (Boullata et al., 2017).	
8. Intermittent feeding (administered at certain times during the day):	
a. Pinch proximal end of feeding tube and remove cap. Connect distal end of administration set tubing to ENFit device on feeding tube and release tubing.	Prevents excessive air from entering patient's stomach and leakage of gastric contents. Ensures that feeding will be administered into correct tubing (Boullata et al., 2017).
b. Set rate by adjusting roller clamp on tubing or attach tubing to feeding pump (see illustration). Allow bag to empty gradually over 30 to 45 minutes (length of time of a comfortable meal). Bag label should include: patient identifiers, formula type, enteral delivery site (route and access), administration method and type, and volume and frequency of water flushes (Boullata et al., 2017). Also include a label with date, time, and initials when hanging a feeding.	Gradual emptying of tube feeding reduces risk for abdominal discomfort, vomiting, or diarrhea induced by bolus or too-rapid infusion of tube feedings. Critical elements for an EN order should be on EN label (Boullata et al., 2017). Labeling indicates when to change administration set and confirms that right patient is receiving feeding.
CLINICAL DECISION: Use pumps designated for tube feeding, not IV fluids.	
c. Immediately follow feeding with prescribed amount of water (per health care provider's orders or agency policy). Cover end of feeding tube with cap when not in use. Keep bag as clean as possible. Change administration set every 24 hours.	Prevents tube from clogging. Prevents air from entering stomach between feedings and limits microbial contamination of system.
9. Continuous infusion method:	
a. Remove cap on tubing and connect distal end of administration set tubing to feeding tube using ENFit connector as in Step 8a.	Method delivers prescribed hourly rate of feeding and reduces risk for abdominal discomfort.

Step	Rationale
	

STEP 08 Administer intermittent feeding.

Table Continued

Step	Rationale
b. Thread tubing through feeding pump; set rate on pump and turn on (see illustration).	Delivers continuous feeding at steady rate and pressure. Feeding pump alarms for increased resistance.
c. Advance rate of tube feeding (and concentration of feeding) gradually, as ordered.	Tube feeding can usually begin with full-strength formula. Conservative initiation and advancement of EN nutrition depend on patient's age, medical condition, nutritional status, and expected patient tolerance (Kozeniecki and Fritzsche, 2015).
CLINICAL DECISION: Limit infusion time for open EN feeding systems to 4 to 8 hours maximum (12 hours in the home setting) (Boullata et al., 2017). Follow the manufacturer's recommendations for duration of infusion through an intact closed delivery device (Boullata et al., 2017).	
10. After feeding, flush tubing with 30 mL water every 4 hours during continuous feeding (see agency policy) or before and after an intermittent feeding. Have RD recommend total free-water requirement per day and obtain health care provider's order.	Provides patient with source of water to help maintain fluid and electrolyte balance. Clears tubing of formula and helps maintain tube patency.
11. Rinse bag and tubing with warm water whenever feedings are interrupted. Use new administration set every 24 hours.	Rinsing bag and tubing with warm water clears old tube feedings and reduces bacterial growth.
12. Dispose of supplies and perform hand hygiene.	Reduces transmission of microorganisms.
13. Be sure patient is comfortable and remains in position with head of elevated 30 to 45 degrees. Provide nurse call bell system to patient, and instruct patient to use if needed.	Reduces risk of aspiration. Call system summons nurse to patient bedside if assistance required.
14. Raise side rails (as appropriate) and lower bed to lowest position.	Promotes patient safety.
Evaluation	
1. Monitor patient's tolerance to feeding by assessing for abdominal distention, firmness, feeling of fullness, or nausea (Boullata et al., 2017). GRV checks should be limited and done per policy.	Symptoms are warnings that patient may have gastric reflux, leading to aspiration. Bowel sounds indicate whether peristalsis is present.
2. Monitor intake and output at least every 8 hours, and calculate daily totals every 24 hours.	Intake and output are indications of fluid balance, which can indicate fluid volume excess or deficit.
3. Weigh patient daily until maximum administration rate is reached and maintained for 24 hours; then weigh patient 3 times per week.	Slow weight gain is indicator of improved nutritional status; however, sudden gain of more than 2 lb (0.9 kg) in 24 hours usually indicates fluid retention.

STEP 00 Connect tubing through infusion pump.

Table Continued

Step	Rationale
4. Monitor patient for appropriate feeding tube placement at least every 4 hours or per agency protocol. Monitor visible length of tubing or marking at tube exit site (naris or stoma); check placement when a deviation is noted (Boullata et al., 2017).	Accidental displacement of tip of tube could lead to aspiration.
5. Monitor laboratory values as ordered by health care provider.	Determines correct administration of formula rate and strength.
6. Observe patient's respiratory status for coughing, dyspnea, tachypnea, change in oxygen saturation, hoarseness, crackles in lungs.	Change in respiratory status may indicate aspiration of tube feeding into respiratory tract.
7. Inspect site of gastrostomy or jejunostomy tube for signs of impaired skin integrity and symptoms of infection, injury, or tightness of tube.	Enteral tubes often cause pressure and excoriation at insertion site.
8. Observe nasoenteral tube insertion site at least daily (see agency policy). Note skin integrity and look for edema under device, excoriation, or presence of injury.	Allows for early detection of excoriation that can progress to a medical device-related pressure injury.
9. Use Teach-Back: "I want to be sure that I explained to you what you need to look for that may tell us you're not tolerating your tube feeding. Tell me two things that may tell us that you are not tolerating your tube feedings." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Feeding tube becomes clogged.</p> <ul style="list-style-type: none"> • Attempt to flush tube with water. • Special products are available for unclogging feeding tubes; do not use carbonated beverages and juices. • Hold feeding and notify health care provider. • Maintain patient in semi-Fowler's position. • Contact pharmacist to change medications to liquid form and flush before and after intermittent feedings and medications (Kozeniecki and Fritzhall, 2015). <p>2. Patient develops large amount of diarrhea (more than three loose stools in 24 hours).</p> <ul style="list-style-type: none"> • Notify health care provider. • Consult dietician about need to change formula to prevent malabsorption. • Identify and treat underlying medical/surgical issues and infections (Kozeniecki and Fritzhall, 2015). • Provide perianal skin care after each stool. • Determine other causes of diarrhea (e.g., <i>Clostridium difficile</i> infection, contaminated tube feeding, medication containing sorbitol). <p>3. Patient has an enteral tube misconnection (e.g., connecting an enteral tube to an intravenous [IV] site or ventilator in-line suction catheter).</p> <ul style="list-style-type: none"> • Infusion of enteral feeding into vein or directly into lung is a medical emergency. • Call health care provider and rapid response team immediately. <p>4. Patient aspirates formula indicated by sudden appearance of respiratory symptoms (such as severe coughing, dyspnea, and cyanosis) associated with eating, drinking, or regurgitation of gastric contents. Auscultation of lungs reveals crackles or wheezes.</p> <ul style="list-style-type: none"> • Immediately position patient on side with head of bed elevated. • Report change in condition to health care provider. • Suction nasotracheally or orotracheally. 	
<p>CLINICAL DECISION: Small-volume aspirations that produce no overt symptoms are common and are often not discovered until the condition progresses to aspiration pneumonia (Egiseer et al., 2018).</p>	
Recording and Reporting	
<ul style="list-style-type: none"> • Record placement checks (length of tube, GRV type, pH, and amount), findings on abdominal assessment, amount and type of feeding, infusion rate (continuous feeding) or time for infusion (bolus method), patient's response to tube feeding, patency of tube, and condition of skin at tube site. • Document your evaluation of patient learning. • Record volume of formula and any additional water on I&O form. • Report adverse outcomes to health care provider. • During a hand-off report note the type of feeding, infusion rate and volume infused during shift, status of feeding tube placement, and patient's tolerance, and trace the administration set tubing to the enteral tube connection point to ensure the feeding is being infused enterally (Boullata et al., 2017). 	
Home Care Considerations	
<ul style="list-style-type: none"> • Teach patient or family caregiver how to determine correct placement of feeding tube. • Inform patient or family caregiver of signs associated with pulmonary aspiration, delayed gastric emptying. • Reinforce signs and symptoms associated with feeding tube complications and when to call health care provider. • Explain and demonstrate how to do skin care around gastrostomy or jejunostomy tube, and explain signs and symptoms of infection at the insertion site. 	

Skill 45.4. Blood Glucose Monitoring Delegation and Collaboration

During an acute illness assessment of a patient's blood glucose cannot be delegated to assistive personnel (AP). When the patient's condition is

stable, the skill of obtaining and testing for blood glucose level can be delegated to AP. The nurse informs the AP by:

- Explaining appropriate sites to use for puncture and when to obtain glucose levels.
- Instructing AP to report all glucose levels to RN.

Equipment

- Antiseptic swab
- Cotton ball
- Lancet device, either self-activating or button activated
- Blood glucose meter (e.g., Accucheck III, OneTouch) (Fig. 45.10)

FIG. 45.10 Blood glucose monitor.
Courtesy LifeScan, Inc., Milpitas, CA.

- Blood glucose test strips appropriate for meter brand used
- Clean gloves
- Paper towel

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review health care provider's order for time or frequency of measurement.	Health care provider determines test schedule on basis of patient's physiological status and risk for glucose imbalance.
CLINICAL DECISION: <i>For some critically ill patients, handheld point-of-care glucometers yield inconsistent results when the patient has low hematocrit levels or is hypotensive; in the presence of vasopressors, ascorbic acid, or other medications; or in the use of capillary blood specimens as opposed to arterial or venous blood samples. These factors can potentially lead to incorrect insulin dosing (Isbell, 2017).</i>	
3. Determine whether specific conditions need to be met before or after sample collection (e.g., fasting, postprandial, after certain medications, before insulin doses).	Dietary intake of carbohydrates and ingestion of concentrated glucose preparations alter blood glucose levels.
4. Determine whether risks exist for performing skin puncture (e.g., low platelet count, anticoagulant therapy, bleeding disorders).	Abnormal clotting mechanisms increase risk for local ecchymosis and bleeding.
5. Perform hand hygiene. Assess area of skin to be used as puncture site. Inspect fingers or forearms for edema, inflammation, cuts, or sores. Avoid areas of bruising, recently punctured areas, and open lesions. Avoid using hand on side of mastectomy. Sides of fingers are commonly selected because they have fewer nerve endings.	Recently punctured sites are avoided because these factors cause increased interstitial fluid and blood to mix and increase risk for infection.
6. Assess patient's or family caregiver's health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).

Table Continued

Step	Rationale
7. Assess patient's understanding of procedure, purpose of blood glucose monitoring, ability to perform test, and its importance in glucose control.	Provides baseline for developing teaching plan. Patient's physical health may change (e.g., vision disturbance, fatigue, pain, disease process) and affect him or her when performing test.
Planning	
1. Provide privacy and prepare bedside environment for patient safety.	Promotes patient comfort and safety.
2. Prepare and organize equipment needed for blood glucose monitoring.	Ensures an organized approach for the procedure.
3. Explain procedure and purpose to patient and family. Offer patient and family opportunity to practice testing procedure. Provide resources and teaching aids for patient and family.	Promotes understanding of the procedure and cooperation.
Implementation	
1. Perform hand hygiene. Instruct adult to perform hand hygiene, including forearm (if applicable), with soap and warm water. Rinse and dry.	Promotes skin cleansing and vasodilation at selected puncture site. Reduces transmission of microorganisms.
2. Remove reagent strip from vial and tightly seal cap. Check code on test strip vial. Use only test strips recommended for glucose meter. Some newer meters do not require code and/or have disk or drum with 10 or more test strips.	Protects strips from accidental discoloration caused by exposure to air or light. Code on test strip vial must match code entered into glucose meter.
3. Insert strip into meter (refer to manufacturer directions (see illustration). Do not bend strip. Meter turns on automatically.	Some machines must be calibrated; others require zeroing of timer. Each meter is adjusted differently.
4. Remove unused reagent strip from meter and place on paper towel or clean, dry surface with test pad facing up (see manufacturer directions).	Moisture on strip can alter accuracy of final test results.
5. Meter displays code on screen that must match code from test strip vial. Press proper button on meter to confirm matching codes. Meter is ready for use.	Codes must match for meter to operate. Meters have different messages that confirm that meter is ready for testing and blood can be applied.
6. Perform hand hygiene and apply clean gloves. Prepare single-use lancet or multiple-use lancet device. Note: Some meters recommend that this step be completed before preparing test strip. Remove cap from lancet device; insert new lancet. Some lancet devices have disk or cylinder that rotates to new lancet.	Reduces transmission of microorganisms. Never reuse a lancet because of risk of infection.
a. Twist off protective cover on tip of lancet. Replace cap of lancet device.	
b. Cock lancet device, adjusting for proper puncture depth.	Each patient varies as to depth of insertion needed for lancet to produce blood drop.
7. Obtain blood sample.	
a. Wipe patient's finger or forearm lightly with antiseptic swab and allow to dry. Choose vascular area for puncture site. In stable adults select lateral side of finger. Avoid central tip of finger, which has denser nerve supply (Pagana et al., 2019).	Removes microorganisms from skin surface. Side of finger is less sensitive to pain.
b. Hold area to be punctured in dependent position. Do not milk or massage finger site.	Increases blood flow to area before puncture. Milking may hemolyze specimen and introduce excess tissue fluid (Pagana et al., 2019).
c. Hold tip of lancet device against area of skin chosen for test site (see illustration). Press release button on device. Some devices allow you to see blood sample forming. Remove device.	Placement ensures that lancet enters skin properly.
d. With some devices, a blood sample begins to appear. Otherwise gently squeeze or massage fingertip until round drop of blood forms (see illustration).	Adequate-size blood sample is needed to test glucose.

STEP 3 Load test strip into meter.
Courtesy Accu-Chek Glucometer.

Step

Rationale

STEP 7C Prick side of finger with lancet.
Courtesy Ascuscheck Glucometer.

Step

Rationale

STEP 7D Gently squeeze puncture site until drop of blood forms.

Table Continued

Step	Rationale
8. Obtain test results.	Exposure of blood to test strip for prescribed time ensures proper results.
a. Be sure that meter is still on. Bring test strip in meter to drop of blood. Blood will be wicked onto test strip (see illustration). Follow specific meter instructions to be sure that you obtain adequate sample.	Blood enters strip, and glucose device shows message on screen to signal that enough blood is obtained.
CLINICAL DECISION: Do not scrape blood onto the test strips or apply it to wrong side of test strip. This results in an inaccurate glucose measurement.	
b. Blood glucose test result will appear on screen (see illustration). Some devices "beep" when completed.	
9. Turn meter off. Some meters turn off automatically. Dispose of test strip, lancet, and gloves in proper receptacles.	Meter is battery powered. Proper disposal reduces risk for needlestick injury and spread of infection.
CLINICAL DECISION: Point-of-care (POC) blood glucose testing meters must be cleaned and disinfected after each patient use .	
10. Remove and dispose of gloves and perform hand hygiene.	Reduces transmission of microorganisms.
11. Discuss test results with patient and encourage questions and eventual participation in care if this is a new diabetes mellitus diagnosis.	Promotes participation and adherence to therapy.
Evaluation	
1. Inspect puncture site for bleeding or tissue injury.	Site can be source of discomfort and infection.
2. Compare glucose meter reading with normal blood glucose levels and previous test results.	Determines whether glucose level is normal.
3. Use Teach-Back: "I want to be sure I explained the way to obtain a blood glucose reading. Show me the steps you will use to obtain your blood glucose measurement." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<ol style="list-style-type: none"> Puncture site is bruised or continues to bleed. <ul style="list-style-type: none"> Apply pressure. Notify health care provider if bleeding continues. Blood glucose level is above or below target range. <ul style="list-style-type: none"> Continue to monitor patient. Check for any medication orders for deviations in glucose level. Notify health care provider. Administer insulin or carbohydrate source as ordered, depending on glucose level. Glucose meter malfunctions. <ul style="list-style-type: none"> Review instructions for troubleshooting glucose meter. Repeat test. 	
Recording and Reporting	
<ul style="list-style-type: none"> Record glucose results on appropriate flow sheet and describe response, including presence or absence of pain or excessive oozing of blood at puncture site. Document your evaluation of patient learning Report blood glucose levels out of target range and the action taken for hypoglycemia or hyperglycemia. Report patient response to treatment for out-of-range blood glucose levels. 	

Step	Rationale
	

STEP 8A Touch test strip to blood drop. Blood wicks into test strip.
Courtesy Accucheck Glucometer.

STEP 8B Results appear on meter screen.
Courtesy Accucheck Glucometer.

Key Points

- Ingestion of a diet balanced with carbohydrates, fats, proteins, and vitamins and minerals provides the essential nutrients to carry out the normal physiological functioning of the body across the life span.
- Through digestion food is broken down into its simplest form for absorption. Digestion and absorption occur mainly in the small intestine.
- The ChooseMyPlate program provides guidelines for a heart-healthy lifestyle.
- Guidelines for dietary change recommend reduced fat, saturated fats, sodium, refined sugar, and cholesterol and increased intake of complex carbohydrates and fiber.
- Patients with alterations in chewing and swallowing are at risk for aspiration.
- Improper nutrition impacts all body systems; nutritional assessment includes a review of physical assessment.
- Enteral feedings are for patients who are unable to ingest food but who have a functioning GI tract.
- One of the most important responsibilities of a nurse administering enteral feedings is to take precautions to prevent patients from aspirating the feeding.
- The most important responsibility of the nurse monitoring parenteral nutrition is to take precautions to prevent patients from developing a catheter-related infection, hyperglycemia, or fluid overload.

- MNT is a recognized treatment modality for both acute and chronic disease states.
- Special diets alter the composition, texture, digestibility, and residue of foods to suit the patient's needs.

Reflective Learning

- You are providing nursing care to a patient with cardiovascular disease. What assessment data would you need to gather to help you develop an MNT plan for the patient? What points would you include in your teaching plan?
- Consider a patient that you cared for on the clinical unit who was having nutritional problems. What strategies did you find most effective to help this patient? Why were the strategies effective?
- Using your knowledge of enteral feedings, develop a discharge teaching plan for a patient who will be going home with enteral feedings.

Review Questions

1. The nurse is caring for a client with pneumonia, who has severe malnutrition. The nurse should assess the patient for which of the following assessment findings? (Select all that apply.)
 1. Heart disease
 2. Sepsis
 3. Hemorrhage

4. Skin breakdown
 5. Diarrhea
2. The nurse is evaluating the recent lab results for a patient. Which labs are the best indicators for malnutrition? (Select all that apply.)
1. Serum total protein
 2. Potassium
 3. Lipids
 4. Albumin
 - 5 Serum BUN
3. The nurse is caring for a client with dysphagia and is feeding her a pureed chicken diet when she begins to choke. What is the priority nursing intervention?
1. Suction her mouth and throat.
 2. Turn her on her side.
 3. Put on oxygen at 2 L nasal cannula.
 4. Stop feeding her.
4. A client who is receiving parenteral nutrition (PN) through a central venous catheter (CVC) has an air embolus. What should be the nurse's priority action?
1. Have the patient turn on the left side and perform a Valsalva maneuver.
 2. Clamp the intravenous (IV) tubing to prevent more air from entering the line.
 3. Have the patient take a deep breath and hold it.
 4. Notify the health care provider immediately.

5. A patient is receiving both parenteral (PN) and enteral nutrition (EN). When would the nurse collaborate with the health care provider and request a discontinuation of parenteral nutrition?
 1. When 25% of the patient's nutritional needs are met by the tube feedings
 2. When bowel sounds return
 3. When the central line has been in for 10 days
 4. When 75% of the patient's nutritional needs are met by the tube feedings
6. A client is receiving an enteral feeding at 65 mL/hr. The gastric residual volume in 4 hours was 125 mL. What is the priority nursing intervention?
 1. Assess bowel sounds.
 2. Raise the head of the bed to at least 45 degrees.
 3. Continue the feedings; this is normal gastric residual for this feeding.
 4. Hold the feeding until you talk to the primary care provider.
7. Which action can a nurse delegate to assistive personnel (AP)?
 1. Performing glucose monitoring every 6 hours on a patient
 2. Teaching the client about the need for enteral feeding
 3. Administering enteral feeding bolus after tube placement has been verified
 4. Evaluating the client's tolerance of the enteral feeding

8. Which statement made by the parents of a 2-month-old infant requires further education by the nurse?
1. "I'll continue to use formula for the baby until he is at least a year old."
 2. "I'll make sure that I purchase iron-fortified formula."
 3. "I'll start feeding the baby cereal at 4 months."
 4. "I'm going to alternate formula with whole milk, starting next month."
9. A nurse sees an assistive personnel (AP) perform the following intervention for a patient receiving continuous enteral feedings. Which action would require immediate attention by the nurse?
1. Fastening tube to the gown with new tape
 2. Placing client supine while giving a bath
 3. Monitoring the client's weight as ordered
 4. Ambulating patient with enteral feedings still infusing
10. A patient is receiving total parenteral nutrition (TPN). What are the primary interventions the nurse should follow to prevent a central line infection? (Select all that apply.)
1. Change the dressing using sterile technique.
 2. Change TPN containers every 48 hours.
 3. Change the TPN tubing every 24 hours.
 4. Monitor glucose levels to watch and assess for glucose intolerance.
 5. Elevate head of the bed 45 degrees to prevent aspiration.

Answers: 1. 2, 3, 4; 2. 1, 5; 3. 4; 4. 1; 5. 4; 6. 3; 7. 1; 8. 4; 9. 2; 10. 1, 3.

Urinary Elimination

OBJECTIVES

- Explain the function and role of urinary system structures in urine formation and elimination.
- Identify factors that commonly impact urinary elimination.
- Compare and contrast common alterations associated with urinary elimination.
- Obtain a nursing history from a patient with an alteration in urinary elimination.
- Perform a physical assessment focused on urinary elimination.
- Interpret features of normal and abnormal urine.
- Appraise nursing implications of common diagnostic tests of the urinary system.
- Select nursing diagnoses associated with alterations in urinary elimination.
- Discuss nursing interventions to promote normal urinary elimination.
- Discuss nursing interventions to reduce risk for urinary tract infections.
- Perform safely skills associated with assessment and promotion of urinary elimination.

Urinary retention, p. 1152

Ureterostomy, p. 1155

A basic human function is urinary elimination. This function can be compromised by a variety of illnesses and conditions. Nurses are key members of the health care team when treating patients with urinary problems. It is your role to assess patients' urinary tract functions and provide support for bladder emptying. During acute illness a patient may require urinary catheterization for close monitoring of urine output or to facilitate bladder emptying when bladder function is compromised. Some patients require long-term indwelling urethral or suprapubic catheters, when the bladder fails to empty effectively. You also implement measures to minimize risk for infection when bladder function is impaired or urinary drainage tubes are required. Nurses in all health care settings play an important role in teaching patients about bladder health and in supporting them to improve or obtain continence.

Scientific Knowledge Base

Urinary elimination is the last step in the removal and elimination of excess water and by-products of body metabolism. Adequate elimination depends on the coordinated function of the kidneys, ureters, bladder, and urethra (Fig. 46.1). The kidneys filter waste products of metabolism from the blood. The ureters transport urine from the kidneys to the bladder. The bladder holds urine until the volume in the bladder triggers a sensation of urge, indicating the need to pass urine. **Micturition** occurs when the brain gives the bladder permission to empty, the bladder contracts, the urinary sphincter relaxes, and urine leaves the body through the urethra.

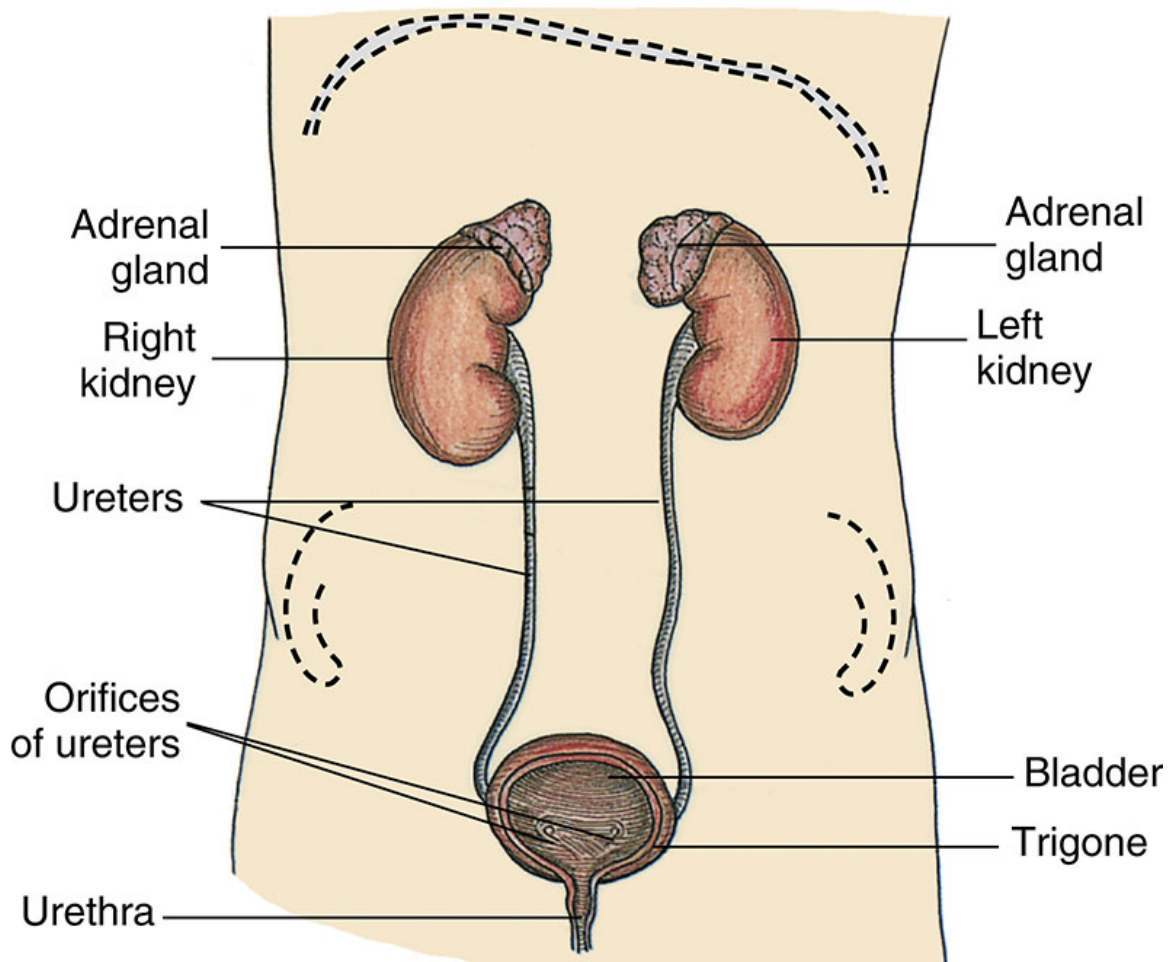

FIG. 46.1 Organs of urinary system.

Kidneys

The kidneys lie retroperitoneal on either side of the vertebral column behind the peritoneum and against the deep muscles of the back. Normally the left kidney is higher than the right because of the anatomical position of the liver.

Nephrons, the functional unit of the kidneys, remove waste products from the blood and play a major role in the regulation of fluid and electrolyte balance. Each nephron contains a cluster of capillaries called the *glomerulus*. The glomerulus filters water, glucose, amino acids, urea, uric acid, creatinine, and major electrolytes. Large proteins and blood cells do not normally filter through the glomerulus. When protein (**proteinuria**) or blood (**hematuria**) is found in the urine, glomerular injury is suspected.

Not all glomerular filtrate is excreted as urine. Approximately 99% is resorbed into the plasma by the proximal convoluted tubule of the nephron, the loop of Henle, and the distal tubule. The remaining 1% is excreted as urine. It is in the resorption process that the delicate balance of fluid and electrolytes is maintained. The normal range of urine production is 1 to 2 L/day (Huether and McCance, 2017). Many factors can influence the production of urine such as fluid intake and body temperature (Box 46.1).

Box 46.1 Factors Influencing Urinary Elimination

Growth and Development

- Children cannot voluntarily control voiding until 18 to 24 months.
- Readiness for toilet training includes the ability to recognize the feeling of bladder fullness, hold urine for 1 to 2 hours, and communicate the sense of urgency.
- Older adults may experience a decrease in bladder capacity, increased bladder irritability, and an increased frequency of bladder contractions during bladder filling.
- In older adults the ability to hold urine between the initial desire to void and an urgent need to void decreases.
- Older adults are at increased risk for urinary incontinence because of chronic illnesses and factors that interfere with mobility, cognition, and manual dexterity.

Sociocultural Factors

- Cultural and gender norms vary. Some cultures expect toilet facilities to be private, whereas some cultures accept communal toilet facilities.
- Religious or cultural norms may dictate who is acceptable to help with elimination practices.
- Social expectations (e.g., school recesses, work breaks) can interfere with timely voiding.

Psychological Factors

- Anxiety and stress sometimes affect a sense of urgency and increase the frequency of voiding.
- Anxiety can impact bladder emptying because of inadequate relaxation of the pelvic floor muscles and urinary sphincter.
- Depression can decrease the desire for urinary continence.

Personal Habits

- The need for privacy and adequate time to void can influence the ability to empty the bladder adequately.

Fluid Intake

- If fluids, electrolytes, and solutes are balanced, increased fluid intake increases urine production.
- Alcohol decreases the release of antidiuretic hormones, thus increasing urine production.
- Fluids containing caffeine and other bladder irritants can prompt unsolicited bladder contractions, resulting in frequency, urgency, and incontinence.

Pathological Conditions

- Diabetes mellitus, multiple sclerosis, and stroke can alter bladder contractility and the ability to sense bladder filling. Patients experience either bladder overactivity or deficient bladder emptying.
- Arthritis, Parkinson's disease, dementia, and chronic pain syndromes can interfere with timely access to a toilet.
- Spinal cord injury or intervertebral disk disease (above S1) can cause the loss of urine control because of bladder overactivity and impaired coordination between the contracting bladder and urinary sphincter.
- Prostatic enlargement (e.g., benign prostatic hyperplasia [BPH]) can cause obstruction of the bladder outlet, causing urinary retention.

Surgical Procedures

- Local trauma during lower abdominal and pelvic surgery sometimes obstructs urine flow, requiring temporary use of an indwelling urinary catheter.
- Urinary retention in the postoperative period has two main causes—one is mechanical obstruction of the lower urinary tract; the other is altered neural control of the bladder and detrusor mechanism, most commonly due to analgesic drugs (Akkoc et al., 2016).

Medications

- Diuretics increase urinary output by preventing resorption of water and certain electrolytes.
- Some drugs change the color of urine (e.g., phenazopyridine-orange, riboflavin—intense yellow).
- Anticholinergics (e.g., atropine, overactive agents) may increase the risk for urinary retention by inhibiting bladder contractility (Burchum and Rosenthal, 2019).
- Hypnotics and sedatives (e.g., analgesics, antianxiety agents) may reduce the ability to recognize and act on the urge to void.

Diagnostic Examinations

- Cystoscopy may cause localized trauma of the urethra, resulting in transient (1 to 2 days) dysuria and hematuria.
- Whenever the sterile urinary tract is catheterized, there is a risk for infection.

The kidneys have essential functions other than elimination of body wastes. Erythropoietin, produced by the kidneys, stimulates red blood cell production and maturation in bone marrow. Patients with chronic kidney conditions cannot produce sufficient quantities of this hormone; therefore, they are prone to anemia. The kidneys play a major role in blood pressure control via the renin-angiotensin system (i.e., release of aldosterone and prostacyclin) (Huether and McCance, 2017). In times of renal ischemia (decreased blood supply), renin is released from juxtaglomerular cells. Renin functions as an enzyme to convert angiotensinogen (a substance synthesized by the liver) into angiotensin I. Angiotensin I is converted to angiotensin II in the lungs. Angiotensin II causes vasoconstriction and stimulates aldosterone release from the adrenal cortex. Aldosterone causes retention of water, which increases blood volume. The kidneys also produce prostaglandin E₂ and prostacyclin, which help maintain renal blood flow through vasodilation. These mechanisms increase arterial blood pressure and renal blood flow (Huether and McCance, 2017).

The kidneys affect calcium and phosphate regulation by producing a substance that converts vitamin D into its active form. Patients with kidney impairment can have problems such as anemia, hypertension, and electrolyte imbalances.

Ureters

A ureter is attached to each kidney pelvis and carries urinary waste to the bladder. Urine draining from the ureters to the bladder is sterile. Peristaltic waves cause the urine to enter the bladder in spurts rather than steadily. Contractions of the bladder during micturition compress the lower part of the ureters to prevent urine from backflowing into the ureters (Huether and McCance, 2017). Obstruction of urine flow through the ureters such as by a kidney stone can cause a backflow of urine (urinary reflux) into the ureters and pelvis of the kidney, causing distention (hydroureter/hydronephrosis) and in some cases permanent damage to sensitive kidney structures and function.

Bladder

The urinary bladder is a hollow, distensible, muscular organ that holds urine. When empty, the bladder lies in the pelvic cavity behind the symphysis pubis. In males the bladder rests against the rectum, and in females it rests against the anterior wall of the uterus and vagina. The bladder has two parts, a fixed base called the *trigone* and a distensible body called the *detrusor*. The bladder expands as it fills with urine. Normally the pressure in the bladder during filling remains low, and this prevents the dangerous backward flow of urine into the ureters and kidneys. Backflow can cause infection. In a pregnant woman the developing fetus pushes against the bladder, reducing capacity and causing a feeling of fullness.

Urethra

Urine travels from the bladder through the urethra and passes to the outside of the body through the urethral meatus. The urethra passes through a thick layer of skeletal muscles called the *pelvic floor muscles*. These muscles stabilize the urethra and contribute to urinary continence. The external urethral sphincter, made up of striated muscles, contributes to voluntary control over the flow of urine. The female urethra is approximately 3 to 4 cm (1 to 1.5 inches) long, and the male urethra is about 18 to 20 cm (7 to 8 inches) long. The shorter length of the female urethra increases risk for urinary tract infection (UTI) because of close access to the bacteria-contaminated perineal area ([Huether and McCance, 2017](#)).

Act of Urination

Urination, micturition, and voiding are all terms that describe the process of bladder emptying. Micturition is a complex interaction among the bladder, urinary sphincter, and central nervous system. Several areas in the brain are involved in bladder control: cerebral cortex, thalamus, hypothalamus, and brainstem. There are two micturition centers in the spinal cord: one coordinates inhibition of bladder contraction; the other coordinates bladder contractility. As the bladder fills and stretches, bladder contractions are inhibited by sympathetic stimulation from the thoracic micturition center. When the bladder fills to approximately 400 to 600 mL, most people experience a strong sensation of urgency. When in the appropriate place to void, the central nervous system sends a message

to the micturition centers, stopping sympathetic stimulation and starting parasympathetic stimulation from the sacral micturition center. The urinary sphincter relaxes, and the bladder contracts. When the time and place are inappropriate, the brain sends messages to the micturition centers to contract the urinary sphincter and relax the bladder muscle.

Factors Influencing Urination

Physiological factors, psychosocial conditions, and diagnostic or treatment-induced factors can all affect normal urinary elimination (see [Box 46.1](#)). Knowledge of these factors enables you to anticipate possible elimination problems and intervene when problems develop.

Common Urinary Elimination Problems

The most common urinary elimination problems involve the inability to store urine or fully empty urine from the bladder. Problems can result from infection; irritable or overactive bladder; obstruction of urine flow; impaired bladder contractility; or issues that impair innervation to the bladder, resulting in sensory or motor dysfunction.

Urinary Retention

Urinary retention is the inability to partially or completely empty the bladder. Acute or rapid-onset urinary retention stretches the bladder, causing feelings of pressure, discomfort/pain, tenderness over the symphysis pubis, restlessness, and sometimes diaphoresis. Patients may have no urine output over several hours and in some cases experience frequency, urgency, small-volume voiding, or incontinence of small volumes of urine. Chronic urinary retention has a slow, gradual onset during which patients may experience a decrease in voiding volumes, straining to void, frequency, urgency, incontinence, and sensations of incomplete emptying. **Postvoid residual (PVR)** is the amount of urine left in the bladder after voiding and is measured either by ultrasound or straight catheterization. Incontinence caused by urinary retention is called *overflow incontinence* or *incontinence associated with chronic retention of urine*. The pressure in the bladder exceeds the ability of the sphincter to prevent the passage of urine, and the patient will dribble urine ([Table 46.1](#)).

TABLE 46.1**Urinary Incontinence**

Definition	Characteristics	Selected Nursing Interventions
Transient Incontinence		
Incontinence caused by medical conditions that in many cases are treatable and reversible	Common reversible causes include: <ul style="list-style-type: none"> • Delirium and/or acute confusion • Inflammation (e.g., urinary tract infection [UTI], urethritis) • Medications (e.g., diuretics) (Burchum and Rosenthal, 2019) • Excessive urine output (e.g., hyperglycemia, congestive heart failure) • Mobility impairment from any cause • Fecal impaction • Depression • Acute urinary retention 	With new-onset or increased incontinence, look for reversible causes. Notify health care provider of any suspected reversible causes.
Functional Incontinence		
Loss of continence because of causes outside the urinary tract Usually related to functional deficits such as altered mobility and manual dexterity, cognitive impairment, poor motivation, or environmental barriers Direct result of caregivers not responding in a timely manner to requests for help with toileting	Toilet access restricted by: <ul style="list-style-type: none"> • Sensory impairments (e.g., vision) • Cognitive impairments (e.g., delirium, dementia, severe retardation) • Altered mobility (e.g., hip fracture, arthritis, chronic pain, spastic paralysis associated with multiple sclerosis, slow movements associated with Parkinson's disease, hemiparesis) • Altered manual dexterity (e.g., arthritis, upper extremity fracture) • Environmental barriers (e.g., caregiver not available to help with transfers, pathway to bathroom not maneuverable with a walker, tight clothing that is difficult to remove, incontinence briefs) 	Adequate lighting in the bathroom Individualized toileting program designed for the degree of cognitive impairment: habit training program, scheduled toileting program, prompted voiding program Mobility aides (e.g., raised toilet seats, toilet grab bars) Toilet area cleared to allow access for a walker or wheelchair Elastic-waist pants without buttons or zippers Nurse call system always within reach Use of incontinence containment product patient can easily remove such as a pull-up-type pant or a pad that can be moved aside easily for voiding
Urinary Incontinence Associated with Chronic Retention of Urine (Overflow Urinary Incontinence)		
Involuntary loss of urine caused by an overdistended bladder often related to bladder outlet obstruction or poor bladder emptying because of weak or absent bladder contractions	Distended bladder on palpation High postvoid residual Frequency Involuntary leakage of small volumes of urine Nocturia	Interventions are individualized related to the severity of the urinary retention, ability of bladder to contract, existing kidney damage. Mild retention with some bladder function: <ul style="list-style-type: none"> • Timed voiding • Double voiding • Monitor postvoid residual per health care provider's direction • Intermittent catheterization Severe retention, no bladder function: <ul style="list-style-type: none"> • Intermittent catheterization • Indwelling catheterization
Stress Urinary Incontinence		
Involuntary leakage of small volumes of urine associated with increased intraabdominal pressure related to either urethral hypermobility or an incompetent urinary sphincter (e.g., weak pelvic floor muscles, trauma after childbirth, radical prostatectomy) Result of weakness or injury to the urinary sphincter or pelvic floor muscles Underlying result: urethra cannot stay closed as pressure increases in the bladder as a result of increased abdominal pressure (e.g., a sneeze or cough)	Small-volume loss of urine with coughing, laughing, exercise, walking, getting up from a chair Usually does not leak urine at night when sleeping	As directed by the health care provider, instruct patient in pelvic muscle exercises.
Urge or Urgency Urinary Incontinence		
Definition	Characteristics	Selected Nursing Interventions
Involuntary passage of urine often associated with strong sense of urgency related to an overactive bladder caused by neurological problems, bladder inflammation, or bladder outlet obstruction In many cases bladder overactivity is idiopathic; cause is not	May experience one or all of the following symptoms: <ul style="list-style-type: none"> • Urgency • Frequency • Nocturia 	Ask patient about symptoms of a UTI. Avoid bladder irritants (e.g., caffeine, artificial sweeteners, alcohol). As directed by the health care provider, instruct patient in pelvic muscle

<p>known Caused by involuntary contractions of the bladder associated with an urge to void that causes leakage of urine</p>	<ul style="list-style-type: none"> • Difficulty or inability to hold urine once the urge to void occurs • Leaks on the way to the bathroom • Leaks larger volumes of urine, sometimes enough to wet outer clothing • Dribbles small amounts on the way to the bathroom • Strong urge/leaks when one hears water running, washes hands, drinks fluids 	<p>exercises, in urge-inhibition exercises, and/or in bladder training. If ordered by the health care provider, monitor patient symptoms and for the presence of side effects of antimuscarinic medications.</p>
Reflex Urinary Incontinence		
<p>Involuntary loss of urine occurring at somewhat predictable intervals when patient reaches specific bladder volume related to spinal cord damage between C1 and S2</p>	<p>Diminished or absent awareness of bladder filling and the urge to void Leakage of urine without awareness May not completely empty the bladder because of dyssynergia of the urinary sphincter— inappropriate contraction of the sphincter when the bladder contracts, causing obstruction to urine flow Caution: At risk for developing autonomic dysreflexia, a life-threatening condition that causes severe elevation of blood pressure and pulse rate and diaphoresis</p>	<p>Follow the prescribed schedule for emptying the bladder either through voiding or by intermittent catheterization. Supply urine-containment products: condom catheter, undergarments, pads, briefs. Monitor for signs and symptoms of urinary retention and UTI. Monitor for autonomic dysreflexia; this is a medical emergency requiring immediate intervention. Notify the health care provider immediately.</p>

Urinary Tract Infections (UTIs)

UTIs are the fourth most common type of health care–associated infection, virtually all caused by instrumentation of the urinary tract (CDC, 2019). *Escherichia coli*, a bacterium commonly found in the colon, is the most common causative pathogen (Nicolle, 2014). The risk for a UTI increases in the presence of an indwelling catheter, any instrumentation of the urinary tract, urinary retention, urinary and fecal incontinence, and poor perineal hygiene practices.

UTIs are characterized by location (i.e., upper urinary tract [kidney] or lower urinary tract [bladder, urethra]) and have signs and symptoms of infection. **Bacteriuria**, or bacteria in the urine, does not always mean that there is a UTI. In the absence of symptoms, the presence of bacteria in the urine as found on a urine culture is called *asymptomatic bacteriuria* and is not considered an infection and should not be treated with antibiotics (Duncan, 2019). Symptomatic infection of the bladder can lead to a serious upper UTI (**pyelonephritis**) and life-threatening bloodstream infection (**bacteremia** or urosepsis) and should be treated with antibiotics. Symptoms of a lower UTI (bladder) can include burning or pain with urination (**dysuria**); irritation of the bladder (**cystitis**) characterized by urgency, frequency, incontinence, or suprapubic tenderness; and foul-smelling cloudy urine. Elderly people with infections, including UTIs, often have nonspecific symptoms such as delirium, confusion, fatigue, loss of appetite, decline in function, mental status changes, incontinence, falls, or subnormal temperature. (Touhy and Jett, 2018).

Urinary tract infections are the most common hospital-acquired infection, accounting for up to 40% of infections reported by acute care hospitals. The major risk factors for **catheter-associated urinary tract infection (CAUTI)** are the presence of an indwelling urinary catheter and the length of its use. Because a CAUTI is common, costly, and believed to be reasonably preventable, as of October 1, 2008, the Centers for Medicare and Medicaid Services (CMS) chose it as one of the complications for which hospitals no longer receive additional payment to compensate for the extra cost of treatment. Consequently there has been a shift in clinical care practices from the traditional focus on early recognition and prompt treatment to one of prevention. Effective prevention strategies that must be implemented to reduce the risk of CAUTIs include training and education of health care providers and increasing their awareness regarding basic infection control knowledge of optimal hand hygiene practices and methods for handling indwelling catheter and urine collecting systems appropriately, securing catheters properly, and maintaining unobstructed urine flow and closed sterile drainage system using sterile technique properly (CDC, 2015; Assadi, 2018).

Urinary Incontinence

Urinary incontinence (UI) is defined as the “complaint of any involuntary loss of urine” (Wilson, 2016; Vethanayagam et al., 2017) (see Table 46.1). UI is a common problem, affecting 27% of men and 43% women over the age of 40, 20% to 40% of older adults, and over 70% of elderly nursing home patients (Testa, 2015; Coyne and Wein, 2014). Common forms of UI are urge or urgency UI (involuntary leakage associated with urgency) and stress UI (involuntary loss of urine associated with effort or exertion on sneezing or coughing (Bardsley, 2016). Mixed UI is when stress- and urgency-type symptoms are both present. Overactive bladder is defined as urinary urgency, often accompanied by increased urinary frequency and nocturia that may or may not be associated with urgency incontinence and is present without obvious bladder pathology or infection. UI associated with chronic retention of urine (formally called *overflow UI*) is urine leakage caused by an overfull bladder. Functional UI is caused by factors that prohibit or interfere with a patient’s access to the toilet or other acceptable receptacle for urine. In most cases there is no bladder pathology. It is a significant problem for older adults who experience problems with mobility or the dexterity to manage their clothing and toileting behaviors. Patients with other types of incontinence can also have a functional aspect to their incontinence (Seshan et al., 2016). A recently

added category of incontinence is identified as multifactorial incontinence. This describes incontinence that has multiple interacting risk factors, some within the urinary tract and others not, such as multiple chronic illnesses, medications, age-related factors, and environmental factors (Saito et al., 2017).

Urinary Diversions

Patients who have had the bladder removed (cystectomy) because of cancer or significant bladder dysfunction related to radiation injury or neurogenic dysfunction with frequent UTI require surgical procedures that divert urine to the outside of the body through an opening in the abdominal wall called a *stoma*. Urinary diversions are constructed from a section of intestine to create a storage reservoir or conduit for urine. Diversions can be temporary or permanent, continent or incontinent.

There are two types of continent urinary diversions. The first is called a *continent urinary reservoir* (Fig. 46.2, A), which is created from a distal part of the ileum and proximal part of the colon. The ureters are embedded into the reservoir. This reservoir is situated under the abdominal wall and has a narrow ileal segment brought out through the abdominal wall to form a small stoma. The ileocecal valve creates a one-way valve in the pouch through which a catheter is inserted through the stoma to empty the urine from the pouch. Patients must be willing and able to catheterize the pouch 4 to 6 times a day for the rest of their lives.

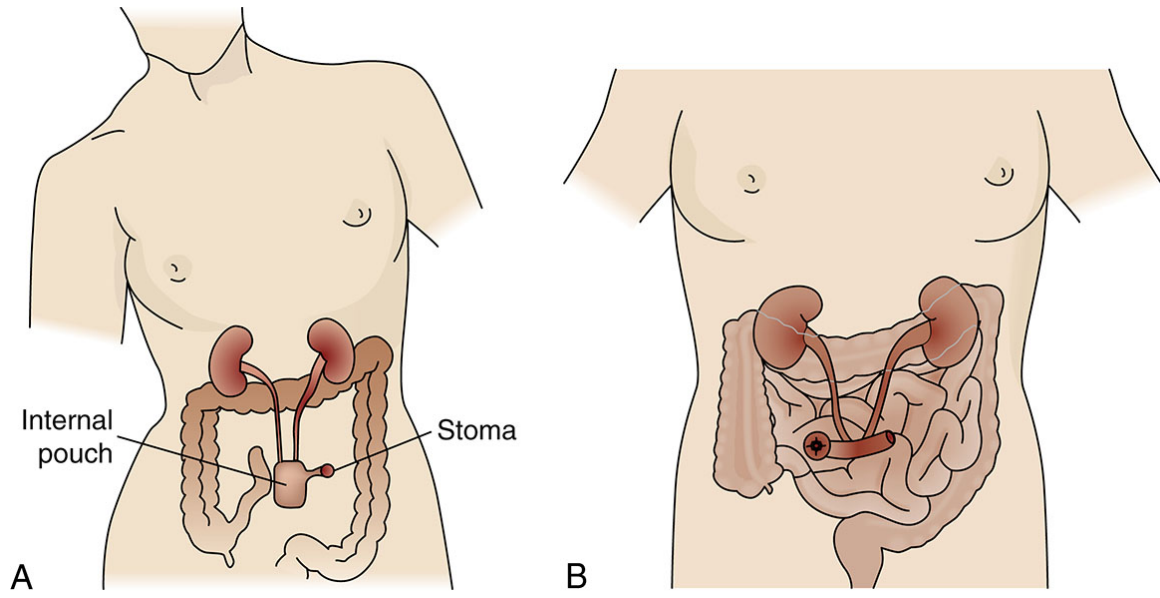

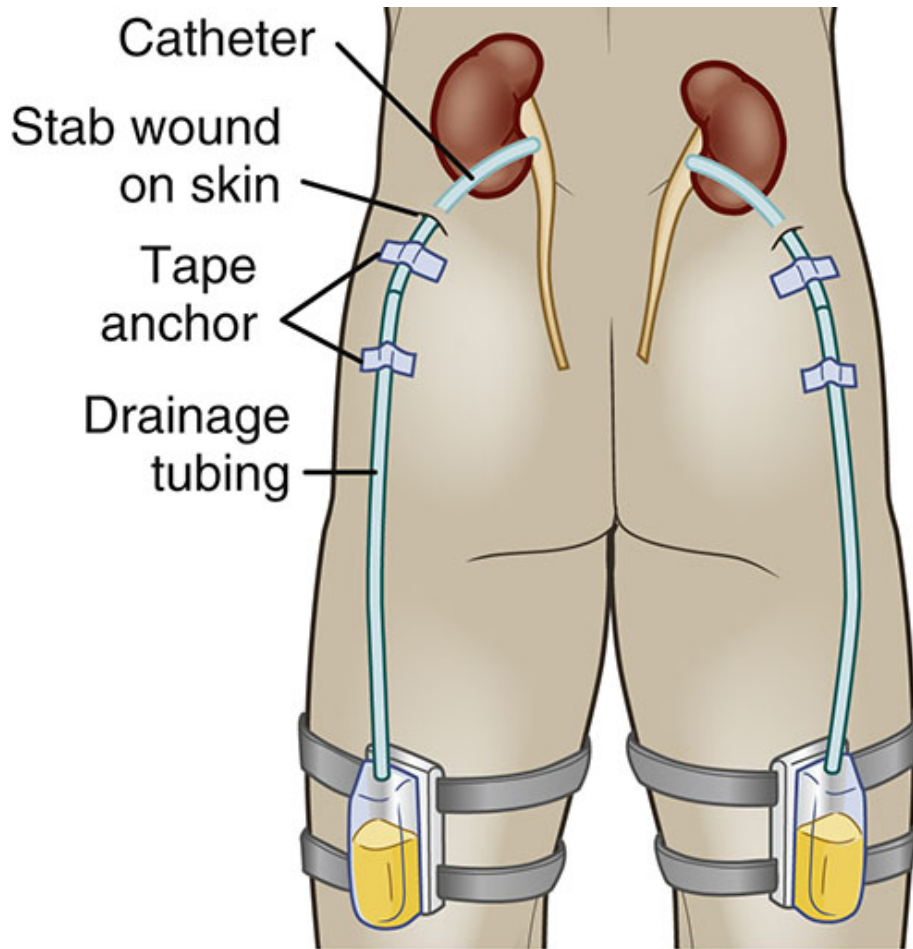

FIG. 46.2 Types of urinary diversions. **A**, Continent urinary reservoir. **B**, Ureterostomy (ileal conduit).

The second type of continent urinary diversion is called an *orthotopic neobladder*, which uses an ileal pouch to replace the bladder. Anatomically the pouch is in the same position as the bladder was before removal, allowing a patient to void through the urethra using a Valsalva technique.

A **ureterostomy** or ileal conduit is a permanent incontinent urinary diversion created by transplanting the ureters into a closed-off part of the intestinal ileum and bringing the other end out onto the abdominal wall, forming a stoma (Fig. 46.2, B). The patient has no sensation or control over the continuous flow of urine through the ileal conduit, requiring the effluent (drainage) to be collected in a pouch.

Nephrostomy tubes are small tubes that are tunneled through the skin into the renal pelvis. These tubes are placed to drain the renal pelvis when the ureter is obstructed. Patients do go home with these tubes and need careful teaching about site care and signs of infection (Fig. 46.3).

Bilateral nephrostomy tubes inserted into renal pelvis; catheters exit through an incision on each flank, or there may be just one kidney

FIG. 46.3 Nephrostomy tubes.

From Lewis SL, et al: *Medical-surgical nursing*, ed 10, St Louis, 2017, Elsevier.

REFLECT NOW

You recently cared for a young woman with recurrent urinary tract infections (UTIs). Think about how these affect her lifestyle.

Nursing Knowledge Base

Urinary elimination is a basic body function and carries with it a variety of psychological and physiological needs. When illness or disability interferes with meeting these needs, nursing care that addresses both the physiological and the psychological needs is essential. You need an understanding beyond anatomy and physiology of the urinary system to give appropriate care.

Infection Control and Hygiene

The urinary tract is sterile. Use infection control principles to help prevent the development and spread of UTIs. You need to follow the principles of medical and surgical asepsis when carrying out procedures involving the urinary tract or external genitalia. Perineal hygiene is an essential component of care (see [Chapter 40](#)) when there is an alteration in the usual pattern of urinary elimination. Perineal care or examination of the genitalia requires medical asepsis, including proper hand hygiene. Any invasive procedure such as catheterization requires sterile aseptic technique.

Growth and Development

It is important to apply knowledge of normal growth and development when caring for the patient with urinary problems. A patient's ability to control micturition changes during the life span. The neurological system is not well developed until 2 to 3 years of age. Until this stage of development, the small child is unable to associate the sensation of filling and urge with urination. When the child recognizes feelings of urge, can hold urine for 1 to 2 hours, and is able to communicate his or her needs, toilet training becomes successful. Continence starts during daytime hours. Children who wet the bed at night without waking from sleep have what is called *nocturnal enuresis*. In some cases they can experience this nighttime incontinence until late in childhood. Infants and young children cannot effectively concentrate urine. Their urine appears light yellow or clear. In relation to their small body size, infants and children

excrete large volumes of urine. For example, a 6-month-old infant who weighs 13 to 18 lb (6 to 8 kg) excretes 400 to 500 mL of urine daily.

Pregnancy causes many changes in the body, including the urinary tract. In early and late pregnancy urinary frequency is common. Hormonal changes and the pressure of the growing fetus on the bladder cause increased urine production and shrinking bladder capacity.

Normal aging causes changes in the urinary tract and the rest of the body. These changes are not the cause of bladder dysfunction, but age does increase risk and incidence (Box 46.2).

Box 46.2 Focus on Older Adults Urinary

Incontinence

Urinary incontinence is due to anatomical and functional deficits, including inappropriately functioning lower urinary tract, physical problems, cognitive decline, functional impairment co-morbidities, and medications. The most common type of urinary incontinence is urgency urinary incontinence in both elderly men and women. The most common reasons for urgency urinary incontinence in men and women are prostate hypertrophy and atrophic urethral mucosa, respectively. Age-related urinary incontinence often remains untreated in the elderly because the condition is considered a part of normal aging (Eshkoo et al., 2017). Older adults have a decreased ability to delay voiding, an increased incidence of overactive bladder, and potentially a loss of bladder contractility, increasing the risk for urinary retention. Older women have a decrease in estrogenization of perineal tissue, which increases the risk of urinary tract infection (Seshan et al., 2016). The use of multiple medications, called *polypharmacy*, is more common in older adults (Touhy and Jett, 2018). Many of these medications have the potential to impact normal elimination by affecting the ability of the bladder to hold urine or adequately empty (antihypertensives, cholinesterase inhibitors, antidepressants, sedatives) (Burchum and Rosenthal, 2019).

Implications for Practice

- Older adults with cognitive impairment may need to be reminded to void more frequently to improve continence.
- Evaluate all possible causes of new-onset incontinence, which should include taking note of any new medications that might impact cognition, alertness, mobility, or voiding.
- Older adults newly started on an antimuscarinic medication should be assessed carefully for mental status changes. This class of medications has the potential to cause cognitive impairment in older adults (American Geriatrics Society, 2018).
- Older adults with impaired mobility and incontinence should have interventions put in place to maximize self-care and continence (e.g., toileting program, mobility aids, help with hygiene).
- Teach older women with stress incontinence about pelvic muscle exercises. There is no age limit on their effectiveness.
- The sensation of thirst decreases with aging. Adequate hydration promotes bladder health. Older adults may need to be reminded to drink adequate amounts of water (Touhy and Jett, 2018).
- To decrease nocturia, instruct patients to restrict fluid intake for the 2 hours before bedtime.
- Older men with voiding pattern changes (e.g., urgency, frequency, slow stream, decreased output, dribbling) should be assessed for urinary retention because of age-related prostate enlargement.

Psychosocial Implications

Self-concept, culture, and sexuality are all closely related concepts that are affected when patients have elimination problems. Self-concept changes over one's life span and includes body image, self-esteem, roles, and identity (see [Chapters 33](#) and [34](#)). When children begin to achieve bladder control and learn the appropriate toileting

skills, they sometimes resist urinating on the toilet and associate their urine and feces as extensions of self and thus do not want to flush them away. The process of micturition is often a culturally private event and requires you to be sensitive to a need for privacy. Incontinence can be devastating to self-image and self-esteem. When your patient asks for help for such a private and personal activity, it can be perceived as embarrassing or as being treated like a child, or it may threaten the patient's sense of self-determination. When a patient has a urinary diversion, it will influence his or her sense of body image, resulting in a perceived threat in being able to maintain a healthy sexual relationship with a partner. As a nurse, be aware of how elimination disorders affect patients psychosocially so that you can understand the full impact of the patient's elimination problem.

Critical Thinking

Successful critical thinking requires synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate and collect necessary information, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis (Fig. 46.4).

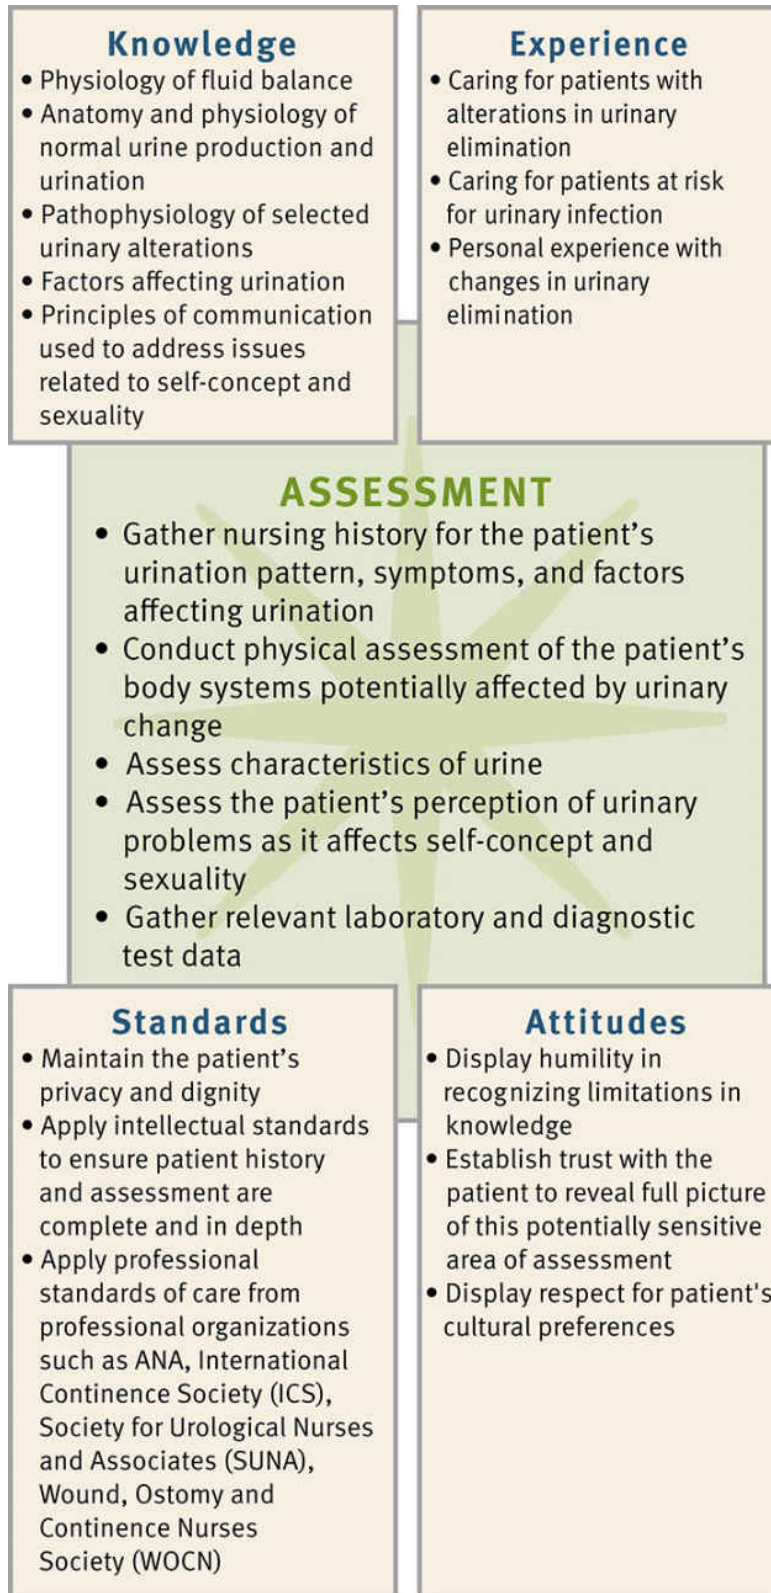

FIG. 46.4 Critical thinking model for urinary elimination assessment. ANA, American Nurses Association.

When applying the nursing process, take into consideration the knowledge you have learned about the urinary system. Integrate the knowledge from nursing and other disciplines, previous experiences, and patients to understand the process of urinary elimination and the impact on a patient and family. The urinary system is affected by many factors, both as part of and outside the urinary tract. As a result you are able to identify the unique impact of these problems on patients and families. For example, men after prostate cancer surgery may experience stress UI because of trauma to the urinary sphincter, people with high caffeine intake or those who take a diuretic may experience increased urinary urgency and frequency, and patients who are normally continent and become immobile may become incontinent.

Urinary elimination problems are common in all health care settings. Reflect on previous and personal experiences to help you determine a patient's elimination needs. If you have personally had a UTI, the experience helps you to understand a patient's frustration and embarrassment as a result of frequency, urgency, and dysuria. Caring for other older adults with functional disabilities helps you to anticipate patient needs related to toileting.

In addition, use critical thinking attitudes such as perseverance to find a plan of care to provide successful management of urinary elimination problems. Professional standards also provide valuable directions. You are in a key position to serve as a patient advocate by suggesting noninvasive alternatives to catheterization use (e.g., the use of a bladder scanner to evaluate urine volume without invasive instrumentation or implementation of a voiding schedule for the incontinent patient).

Practice standards and guidelines prepared by nursing specialty organizations and those developed by national and international professional organizations are valuable tools to use when critically assessing patient problems and developing a plan of care. [Box 46.3](#) lists some of these resources. The professional nurse incorporates such evidence-based guidelines into the plan of care.

REFLECT NOW

You have received shift report and your patient assignment includes a 65-year-old male with an indwelling catheter. How can you reduce the risk for a CAUTI?

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in the care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze assessment findings to ensure that you make patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes

Throughout the nursing assessment it is important for you to consider a patient's frame of reference related to his or her illness or urinary problem. Assess the patient's understanding of the urinary problem and expectations of treatment. Because urination is a private matter, some patients find it difficult to talk about urinary incontinence or their voiding habits. Approach patients in a professional manner and assure them that their problems will be kept confidential. Postoperative patients or patients receiving medications that affect bladder function may become concerned that something is wrong when you assess voiding amount and frequency. Patients receiving intravenous (IV) fluids do not always realize that they have an increased need for urination. Sensitivity to patient misconceptions will allow you to quickly identify areas for patient education. Always ask what he or she expects from care. For example, does the patient expect that the UTI will be resolved? Does the patient expect the ureterostomy to be only temporary?

Self-Care Ability

It is very important to thoroughly assess patients' ability to perform necessary behaviors associated with voiding. Investigate their expectations of how nurses will assist them and what they can do independently. Do not assume that because a patient has a diagnosis of cognitive impairment that he or she cannot understand or participate in care. Balancing patient safety and supporting self-care are sometimes challenges and should be discussed with the patient. For example, a patient with poor balance will need assistance with transfers to a toilet and may need continued

supervision while on the toilet, something the patient may find embarrassing or demeaning.

Cultural Considerations

Assess cultural and gender differences related to the very private act of voiding and how they affect nursing assessment and care. Be sensitive and ask questions in a straightforward manner. Be aware of gender preferences in positioning for urination: most men stand to void, whereas women sit. This makes a difference in how you will assist patients unable to use a bathroom. There are gender-linked urinary alterations such as prostate enlargement in men and pelvic organ prolapse in women. Culture often dictates gender-specific roles when it comes to care of elimination issues. It may be inappropriate for a male to touch or even talk about elimination matters with a woman (Box 46.4).

Box 46.4 Cultural Aspects of Care Urinary

Elimination

Urinary elimination is private. It is important when caring for patients from diverse cultures and religions to incorporate into the plan of care sensitivity and awareness of factors that may impact care when dealing with urinary elimination problems. Some cultures may have specific beliefs and practices related to elimination, privacy, and gender-specific care. Because of the personal nature and cultural practices surrounding elimination, urinary problems such as incontinence often are not discussed with medical professionals (Wang et al., 2014; Lai et al., 2017). Variations within a cultural group are common; thus each patient must be assessed and cared for as an individual.

Implications for Patient-Centered Care

- Each patient is unique. As a professional nurse you must determine the extent to which a patient's cultural background, such as age-group, geographic location, ethnicity, or race, affects individual elimination problems.
- Whenever possible, provide for a same-gender caregiver for individuals whose cultural preferences emphasize female modesty and prohibit nonrelated males and females from touching (Jarvis, 2016).

- Privacy is important in many cultures; thus careful attention to closing doors, bedside curtains, and draping is important (Lai et al., 2017).
- Pay special attention that the patient understands instructions and patient education when English is not the primary language. If available, provide written materials in patient's primary language. Provide a professional interpreter as needed.
- Certain cultures may observe meticulous hygiene practices that designate the left hand to perform unclean procedures, such as genitourinary hygiene. Ask patient or family caregivers their practice preferences.
- Some cultures may continue to practice female genital circumcision, leaving only a small opening for urine and menses (Clarke, 2016; Malik et al., 2018). Long-term consequences include recurrent urinary tract infections, incontinence, pelvic infections, fistulas, scarring, and sexual dysfunction (Malik et al., 2018).
- Cultural practices dictate the level of involvement of family in a patient's care. This source of strength is important to the health of the patient, and family must be included in the plan of care.

Nursing History

Before gathering a history, assess your patient's health literacy to be sure you communicate clearly and can understand patient's problems. The nursing history includes a review of the patient's elimination patterns, symptoms of urinary alterations, and assessment of factors that are affecting the ability to urinate normally. [Box 46.5](#) lists nursing history questions that will help direct the patient to focus on urinary problems.

Box 46.5 Nursing Assessment Questions

Nature of the Problem

- Which problems are you having with passing urine?

Signs and Symptoms

- Does it hurt or burn when you pass your urine?
- Are you having abdominal pain/flank pain/fevers/chills?
- Has there been a change in the color or odor of your urine? Please describe that change.
- Do you feel like you are emptying your bladder completely?
- Are you passing urine more frequently than normal during the day?
- Do you need to strain and/or wait before your urine stream starts?
- Do you need to get up at night to pass urine?
- Do you leak urine when feeling a strong desire to void?
- Do you ever leak urine when you cough, sneeze, and/or exercise?
- Are you ever wet with urine and do not know when it happened?
- Do you dribble urine before you void, after you void, or at other times?

Onset and Duration

- When did you first notice a problem?
- How long has this problem lasted?

Severity

- How many times a day do you pass urine?
- How many times a day and how many times at night do you leak urine?
- How many times are you wet/need to change a pad in a day and at night?
- How often are you awakened with the urge to void and get up to use the bathroom?
- How does this pattern compare with the pattern you last remember?

Predisposing Factors

- Have you noticed any patterns to your urinary problem?
- Tell me what you usually eat/drink in a day. Does it include such things as caffeinated beverages, chocolate, citrus, or alcohol?

- Which medicines do you take routinely, and have any recently changed?
- Have you been hospitalized or diagnosed with a new medical problem recently?

Effect on Patient

- How have these symptoms affected your life?
- Tell me how your urinary problem affects any of your usual activities.
- Have you ever tried any treatment for this problem (self-help, complementary therapies, over-the-counter remedies, medical professional, or specialist)?

Pattern of Urination

Ask the patient about daily voiding patterns, including frequency and times of day, normal volume at each voiding, and history of recent changes. Frequency of voiding varies among individuals depending on fluid intake, medications such as diuretics, and the intake of bladder irritants such as caffeine or other caffeinated beverages. The common times for urination are on awakening, after meals, and before bedtime. Most people void an average of 5 or more times a day. Be sure to ask whether the patient is awakened from sleep with an urge to void and how many times this occurs. It is normal for patients who wake at night because of noise, pain, or nighttime treatments to experience an urge to void. Information about the pattern of urination is necessary to establish a baseline for comparison.

Symptoms of Urinary Alterations

Certain symptoms specific to urinary alterations may occur in more than one type of disorder. During assessment ask the patient about the presence of symptoms related to urination ([Table 46.2](#)). Also determine whether the patient is aware of conditions or factors that precipitate or aggravate the symptoms and determine what he or she does if any of these symptoms occur.

TABLE 46.2**Common Symptoms of Urinary Alterations**

Description	Common Causes
Urgency	
An immediate and strong desire to void that is not easily deferred	Full bladder Urinary tract infection Inflammation or irritation of the bladder Overactive bladder
Dysuria	
Pain or discomfort associated with voiding	Urinary tract infection Inflammation of the prostate Urethritis Trauma to the lower urinary tract Urinary tract tumors
Frequency	
Voiding more than 8 times during waking hours and/or at decreased intervals, such as less than every 2 hours	High volumes of fluid intake Bladder irritants (e.g., caffeine) Urinary tract infection Increased pressure on bladder (e.g., pregnancy) Bladder outlet obstruction (e.g., prostate enlargement, pelvic organ prolapse) Overactive bladder
Hesitancy	
Delay in start of urinary stream when voiding	Anxiety (e.g., voiding in public restroom) Bladder outlet obstruction (e.g., prostate enlargement, urethral stricture)
Polyuria	
Voiding excessive amounts of urine	High volumes of fluid intake Uncontrolled diabetes mellitus Diabetes insipidus Diuretic therapy
Oliguria	
Diminished urinary output in relation to fluid intake	Fluid and electrolyte imbalance (e.g., dehydration) Kidney dysfunction or failure Increased secretion of antidiuretic hormone (ADH) Urinary tract obstruction
Nocturia	
Awakened from sleep because of the urge to void	Excess intake of fluids (especially coffee or alcohol before bedtime) Bladder outlet obstruction (e.g., prostate enlargement) Overactive bladder Medications (e.g., diuretic taken in the evening) Cardiovascular disease (e.g., hypertension) Urinary tract infection
Dribbling	
Leakage of small amounts of urine despite voluntary control of micturition	Bladder outlet obstruction (e.g., prostatic enlargement) Incomplete bladder emptying Stress incontinence
Hematuria	
Presence of blood in urine Gross hematuria (blood is easily seen in urine) Microscopic hematuria (blood not visualized but measured on urinalysis)	Tumors (e.g., kidney, bladder) Infection (e.g., glomerular nephritis, cystitis) Urinary tract calculi Trauma to the urinary tract
Retention	
Acute retention: Suddenly unable to void when bladder is adequately full or overfull Chronic retention: Bladder does not empty completely during voiding, and urine is retained in the bladder	Bladder outlet obstruction (e.g., prostatic enlargement, urethral obstruction) Absent or weak bladder contractility (e.g., neurological dysfunction such as caused by diabetes, multiple sclerosis, lower spinal cord injury) Side effects of certain medications (e.g., anesthesia, anticholinergics, antispasmodics, antidepressants)

Physical Assessment

A physical examination (see [Chapter 30](#)) provides you with data to determine the presence and severity of urinary elimination problems. The primary areas to assess include the kidneys, bladder, external genitalia, urethral meatus, and perineal skin. Fluid intake, voiding pattern, and amounts provide additional objective data.

Kidneys

When the kidneys become infected or inflamed, they can become tender, resulting in flank pain. You assess for tenderness by gently percussing the costovertebral angle (the angle formed by the spine and twelfth rib). Auscultation with the bell of the stethoscope is sometimes performed to detect the presence of a renal artery bruit (sound resulting from turbulent blood flow through a narrowed artery), but this skill is usually performed by an advanced practice nurse.

Bladder

In adults the bladder rests below the symphysis pubis. When distended with urine, the bladder will rise above the symphysis pubis along the midline of the abdomen. A very full bladder can extend as far as the umbilicus. On inspection you may observe a swelling or convex curvature of the lower abdomen. On gentle palpation of the lower abdomen, a full bladder may be felt as a smooth and rounded mass. When a full bladder is palpated, patients report a sensation of urinary urge tenderness or even pain. If an overfull bladder is suspected, further assessment with an ultrasound device or a bladder scanner is recommended if available.

External Genitalia and Urethral Meatus

Careful and sensitive inspection of the external genitalia and urethral meatus yields important data that may indicate inflammation and infection. Normally there should be no drainage or inflammation. To best examine the female patient, position her in the dorsal recumbent position to provide full exposure of the genitalia. Observe the labia majora for swelling, redness, tenderness, rashes, lesions, or evidence of scratching. Using a gloved hand, retract the labial folds. The labia minora is normally pink and moist. The urethral meatus will appear as an irregular or slitlike opening below the clitoris and above the vaginal opening. Look for drainage and lesions, and ask the patient whether there is discomfort. If there is drainage, note the color and consistency and any odor. The vaginal

tissue of a postmenopausal woman may be drier and less pink than that of younger women.

For the male patient, examine the penis. Look for any redness or irritation. If the man is uncircumcised, retract the foreskin or ask the patient to do so. The foreskin should move back easily to expose the glans penis. In some cases the foreskin will become tight and cannot be retracted (phimosis), increasing risk for inflammation and infection. The urethral meatus is a slitlike opening just below the tip of the penis. Inspect the glans penis and meatus for discharge, lesions, and inflammation. Following inspection, return the foreskin to the unretracted position. Retracted foreskins can cause dangerous swelling (paraphimosis) of the penis (Ball et al., 2019).

All patients with an indwelling catheter should have the urinary meatus assessed for catheter-related damage and for the presence of inflammation and discharge that can indicate infection. Pulling and traction on catheters can damage the urinary meatus by creating pressure on the urethra and meatus. In some severe cases the catheter will erode through the meatus to the vagina or in men through the glans and shaft of the penis. Early detection of trauma means that a plan for prevention for further damage can be implemented.

Perineal Skin

Assessment of skin exposed to moisture, especially urine, needs to occur at least daily (and more often if incontinence is ongoing) to pick up early signs of skin damage related to the moisture. Observe for erythema in areas exposed to moisture, skin erosion, and patient complaints of a burning, itching pain.

Assessment of Urine

The assessment of urine includes measuring the patient's fluid intake and urinary output (I&O) and observing the characteristics of the urine.

Intake and Output

Assessment of I&O is a way to evaluate bladder emptying, renal function, and fluid and electrolyte balance. Although often written as part of a health care provider's order, placing a patient on I&O is also a nursing judgment. Obtaining accurate I&O measurement often requires cooperation and assistance from the patient and family. Intake measurements need to include all oral liquids and semiliquids, enteral

feedings, and any parenteral fluids (see [Chapter 42](#)). Output measurement includes not only urine but any fluid that leaves the body that can be measured such as vomitus, gastric drainage tubes, and wound drains.

Urinary output is a key indicator of kidney and bladder function. A change in urine volume can be a significant indicator of fluid imbalance, kidney dysfunction, or decreased blood volume. For example, a postoperative catheterized patient's hourly urinary output provides an indirect measure of circulating blood volume. If the urinary output falls below 30 mL/hr, the nurse should immediately assess for signs of blood loss and notify the health care provider. Urinary output is also an indicator of bladder function. Patients who have not voided for longer than 3 to 6 hours and have had fluid intake recorded should be evaluated for urinary retention. Just helping some patients to a normal position to void prompts voiding. Assess for any extreme increase or decrease in urine volume. Urine output of less than 30 mL per hour for more than 2 consecutive hours or excessive urine output (polyuria) is a cause for concern and should prompt further assessment and notification of the health care provider.

Urine volume is measured using receptacles with volume-measurement markings. After a patient voids in a bedside commode, bedpan, or urinal, or when urine is emptied from a catheter drainage bag, urine can be measured using a graduated measuring container. For patients who void in a toilet, a urine hat ([Fig. 46.5](#)) collects urine, allowing for patient privacy in the bathroom. Catheterized patients may have a specialized drainage bag with a urometer ([Fig. 46.6](#)) attached between the drainage tubing and drainage bag that allows for accurate hourly urine measurement. When emptying catheter drainage bags, follow Standard Precautions ([Chapter 28](#)), and make sure that the drainage tube is reclamped and secured. Each patient needs to have a graduated receptacle for individual use to prevent potential cross-contamination. Label each container with the patient's name or other identifiers according to agency policy. The container needs to be rinsed after each use to minimize odor and bacterial growth.

FIG. 46.5 Urine hat.

FIG. 46.6 Urometer. (Courtesy Michael Gallagher, RN, BSN, OSF Saint Francis Medical Center, Peoria, IL.)

Characteristics of Urine

Inspect the patient's urine for color, clarity, and odor. Monitor and document any changes.

Color

Normal urine ranges in color from a pale straw to amber, depending on its concentration. Urine is usually more concentrated in the morning or with fluid volume deficits. As the patient drinks more fluids, urine becomes less concentrated, and the color lightens. Patients taking diuretics commonly void dilute urine while the medication is active.

Blood in the urine (hematuria) is never a normal finding. Bleeding from the kidneys or ureters usually causes urine to become dark red; bleeding from the bladder or urethra usually causes bright red urine. Hematuria and blood clots are a common cause of urinary catheter blockage.

Various medications and foods change the color of the urine. For example, patients taking phenazopyridine, a urinary analgesic, void urine that is bright orange. Eating beets, rhubarb, and blackberries causes red urine. The kidneys excrete special dyes used in IV diagnostic studies, and this discolors the urine. Dark amber urine is the result of high concentrations of bilirubin (urobilinogen) in patients with liver disease. Report unexpected color changes to the health care provider.

Clarity

Normal urine appears transparent at the time of voiding. Urine that stands several minutes in a container becomes cloudy. In patients with renal disease, freshly voided urine appears cloudy because of protein concentration. Urine may also appear thick and cloudy as a result of bacteria and white blood cells. Early-morning voided urine may be cloudy because of urine held in the bladder overnight but will be clear on the next voiding.

Odor

Urine has a characteristic ammonia odor. The more concentrated the urine, the stronger the odor. As urine remains standing (e.g., in a collection device), more ammonia breakdown occurs, and the odor becomes stronger. A foul odor may indicate a UTI. Some foods such as asparagus and garlic can change the odor of urine.

Laboratory and Diagnostic Testing

You are often responsible for collecting urine specimens for laboratory testing. The type of test determines the method of collection. Label all specimens with the patient's name, date, time, and type of collection. Most urine specimens need to reach the laboratory within 2 hours of collection or must be preserved according to the laboratory protocol ([Pagana et al., 2019](#)). Urine that stands in a container at room temperature without the

required preservative will grow bacteria resulting in changes that will affect the accuracy of the test. Agency infection control policies require adherence to Standard Precautions during the handling of urine specimens (see [Chapter 28](#)). To obtain urine that is fresh or new, you need to ask the patient to double void. The second voided specimen is the one sent to the laboratory. To obtain urine as free of bacterial contamination as possible, a midstream clean-catch urine specimen may be required. [Table 46.3](#) describes nursing considerations for a variety of common tests. [Table 46.4](#) describes the components of the most common of the urinary tests, urinalysis.

TABLE 46.3**Urine Testing**

Collection Type/Use of Specimen	Nursing Considerations
<p>Random (routine urinalysis) Includes a number of tests that are used for screening and are diagnostic for fluid and electrolyte disturbances, urinary tract infection, presence of blood and other metabolic problems</p>	<p>Collect during normal voiding or from an indwelling catheter or urinary diversion collection bag. Do not collect from an indwelling catheter drainage bag (urine is not freshly voided). Use a clean specimen cup. In some health care settings you may be responsible for testing urine with reagent strips. Follow manufacturer instructions when performing and reading the strips. Dip the reagent strip into fresh urine, then observe color changes on the strip. Compare the color on the strip with the color chart on the reagent strip container. Each color is examined at the exact time indicated on the container.</p>
<p>Clean-voided or midstream (culture and sensitivity)</p>	<p>Urine may be collected by the patient after detailed instruction on proper cleansing and collection technique (see Skill 46.1). Always use a sterile specimen cup.</p>
<p>Sterile specimen for culture and sensitivity Determines the presence of bacteria and to which antibiotic the bacteria are sensitive</p>	<p>If the patient has an indwelling catheter, collect a specimen by using sterile aseptic technique through the special sampling port (see Fig. 46.12) found on the side of the catheter. Never collect the specimen from the drainage bag. Clamp the tubing below the port, allowing fresh, uncontaminated urine to collect in the tube. After wiping the port with an antimicrobial swab, insert a sterile syringe hub and withdraw at least 3 to 5 mL of urine (check agency policy). Using sterile aseptic technique, transfer the urine to a sterile container (see Chapter 28). Patients with a urinary diversion need to have the stoma catheterized to obtain an accurate specimen. A preliminary report will be available in 24 hours, but usually 48 to 72 hours is needed for bacterial growth and sensitivity testing.</p>
<p>Timed urine specimens Measure bodily substances that may be excreted at higher levels at specific times of the day or over a specific time period</p>	<p>Requires urine collection and testing either at specific time of day or urine collected over a specific time period (e.g., 2-, 12-, or 24-hour collections). The timed period begins after the patient urinates and ends with a final voiding at the end of the time period. In most 24-hour specimen collections discard the first voided specimen and then start collecting urine. Patient voids into a clean receptacle, and the urine is transferred to the special collection container, which often contains special preservatives. Depending on the test, the urine container may need to be kept cool by setting it in a container of ice. Each specimen must be free of feces and toilet tissue. Missed specimens make the whole collection inaccurate. Check with agency policy and the laboratory for specific instructions. Patients' education should include an explanation of the test, an emphasis on the need to collect all urine voided during the prescribed time period, and urine collection procedure.</p>

TABLE 46.4**Routine Urinalysis**

Measurement (Normal Value)	Interpretation
pH (4.6 to 8.0)	pH level indicates acid-base balance. Acid pH helps protect against bacterial growth. Urine that stands for several hours becomes alkaline from bacterial growth.
Protein (up to 8 mg/100 mL)	Protein is normally not present in urine. The presence of protein is a very sensitive indicator of kidney function. Damage to the glomerular membrane (such as in glomerulonephritis) allows for the filtration of larger molecules such as protein to seep through.
Glucose (not normally present)	Patients with poorly controlled diabetes have glucose in the urine because of inability of tubules to resorb high serum glucose concentrations (>180 mg/100 mL). Ingestion of high concentrations of glucose causes some to appear in urine of healthy people.
Ketones (not normally present)	With poor control of diabetes, patients experience breakdown of fatty acids. End products of fatty acid metabolism are ketones. Patients with dehydration, starvation, or excessive aspirin ingestion also have ketonuria.
Specific gravity (1.005 to 1.030)	Specific gravity tests measure concentration of particles in urine. High specific gravity reflects concentrated urine, and low specific gravity reflects diluted urine. Dehydration, reduced renal blood flow, and increase in ADH secretion elevate specific gravity. Overhydration, early renal disease, and inadequate ADH secretion reduce specific gravity.
Microscopic examination RBC (up to 2)	Damage to glomeruli or tubules allows RBCs to enter the urine. Trauma, disease, presence of urethral catheters, or surgery of the lower urinary tract also causes RBCs to be present.
WBCs (0-4 per low-power field)	Elevated numbers indicate inflammation or infection.
Bacteria (not normally present)	Bacteria in the urine can mean infection or colonization (if the patient shows no symptoms).
Casts (cylindrical bodies not normally present, the shapes of which take on the likeness of objects within the renal tubule)	Types include hyaline, WBCs, RBCs, granular cells, and epithelial cells. Their presence indicates renal disease.
Crystals (not normally present)	Crystals indicate increased risk for the development of renal calculi (stone). Patients with high uric acid levels (gout) may develop uric acid crystals.

ADH, Antidiuretic hormone; RBC, red blood cell; WBC, white blood cell.

Data from Pagana KD, et al: *Mosby's diagnostic and laboratory test reference*, ed 14, St Louis, 2019, Elsevier.

Diagnostic Examinations

The urinary system is one of the few organ systems accessible to accurate diagnostic study by radiographic techniques. Studies can be simple and

noninvasive or complex and invasive. See [Table 46.5](#) for a review of some common diagnostic testing of the urinary tract.

TABLE 46.5

Common Diagnostic Tests of Urinary Tract

Procedure	Description	Special Nursing Considerations
Noninvasive Procedures		
Abdominal roentgenogram (plain film; kidney, ureter, bladder [KUB] or flat plate)	X-ray film of the abdomen to determine the size, shape, symmetry, and location of the structures of the lower urinary tract. Common uses: Detect and measure the size of urinary calculi	No special preparation
Computed tomography of abdomen and pelvis (CT)	Detailed imagery of the abdominal structures provided by computerized reconstruction of cross-sectional images. Common uses: Identify anatomical abnormalities, renal tumors and cysts, calculi, and obstruction of the ureters	Preparation: Explain procedure to patient Assess for presence of any allergies and previous reaction to contrast iodinated dye. All patients with allergies are at increased risk for anaphylactoid reactions to radiocontrast. NPO: Restrict food and fluid up to 4 hours before test (see agency or health care provider protocol). After procedure: Encourage fluids to promote dye excretion. Assess for delayed hypersensitivity reaction to the contrast media. Patient teaching: Explain that he or she will be placed on a special bed that will move through a tunnel-like imaging chamber. He or she will need to lie still when instructed by the technician; some patients may feel claustrophobic.
Intravenous pyelogram (IVP)	Imaging of the urinary tract that views the collecting ducts and renal pelvis and outlines the ureters, bladder, and urethra. (After intravenous injection of contrast media [iodine based that converts to a dye], a series of x-ray films are taken to observe the passage of urine from the renal pelvis to the bladder.) Common uses: Detect and measure urinary calculi, tumors, hematuria, obstruction of the urinary tract	Preparation: Assess for allergies to iodinated dyes. Assess for dehydration. Follow agency bowel cleansing protocol. Follow agency food and fluid restriction protocol. After procedure: Assess for delayed hypersensitivity to the contrast media. Encourage fluids after the test to dilute and flush dye from the patient. Assess urine output. Less than 30 mL/hr increases risk for contrast-induced nephropathy. Patient teaching: Facial flushing is a normal response during dye injection, and patients may feel dizzy or warm or feel some nausea.
Ultrasound: Renal bladder	Imaging of the kidneys, ureters, and bladder using sound waves. Identifies gross structural abnormalities and estimates the volume of urine in the bladder. Common uses: Detect masses, obstruction, presence of hydronephrosis or hydroureter, abnormalities of the bladder wall, and calculi; measure postvoid residual	Patients may be instructed to void before scan or come with a full bladder; verify preprocedure order for patient. Do not schedule within 24 hours after intravenous pyelogram.
Invasive Procedures		
Cystoscopy	Introduction of a cystoscope through the urethra into the bladder to provide direct visualization, specimen collection, and/or treatment of the bladder and urethra. (In most cases the procedure is performed using local anesthesia, but under certain circumstances general anesthesia or conscious sedation may be used.) Common uses: Microscopic hematuria, detect bladder tumors and obstruction of the bladder outlet and urethra	Follow agency bowel cleansing protocol. Patients may be requested to drink fluids before procedure. Patient teaching: Urine may be pink tinged after the test; signs and symptoms of urinary tract infection.

Data from Pagana KD, et al: *Mosby's diagnostic and laboratory test reference*, ed 14, St Louis, 2019, Elsevier.

Many of the nursing responsibilities related to diagnostic testing of the urinary tract are common to most studies. Those responsibilities before testing include the following:

- Ensure that a signed consent is completed (check agency policy).
- Assess the patient for any iodinated dye allergies and whether he or she has experienced a previous reaction to a contrast agent (Pagana et al., 2019).
- Administer agency bowel-cleansing protocol to ensure kidneys can be visualized (check agency policy).
- Ensure that the patient adheres to the appropriate pretest diet (clear liquids) or nothing by mouth (NPO).
- Responsibilities after testing include:
 - Assessing I&O.
 - Assessing voiding and urine (color, clarity, presence of blood, dysuria, problems with emptying).
 - Encouraging fluid intake, especially if using radiopaque dye.

REFLECT NOW

In providing care for a patient with urinary incontinence, what are some physical assessment findings to expect?

• Nursing Diagnosis

A thorough assessment of a patient's urinary elimination function reveals patterns of data that allow a nurse to make relevant and accurate nursing diagnoses. Use critical thinking to reflect on knowledge of previous patients, apply knowledge of urinary function and the effects of disorders, review assessment findings, and make a specific nursing diagnosis. Data from questions about the urinary system are important in identifying nursing diagnoses. The diagnosis focuses on a specific urinary elimination alteration or an associated problem such as *Impaired Tissue Integrity related*

to urinary incontinence. Identification of assessment findings leads to selection of an appropriate negative or problem-focused diagnosis. Identification of risk factors leads to selection of a risk diagnosis (see Chapter 17).

An important part of formulating negative or problem-focused nursing diagnoses lies in identifying the relevant causative or related factor. In the case of risk diagnoses, you select correct risk factors. You will choose interventions that treat or modify the related factor or risk factor for the diagnosis to be resolved. Specifying related factors for a diagnosis allows selection of individualized nursing interventions. For example, *Impaired Self Toileting related to an impaired ability to transfer* status guides the selection of nursing interventions that remove barriers to toilet access. *Impaired Self Toileting related to cognitive impairment* guides the selection of nursing interventions such as a prompted voiding program or habit training program. Box 46.6 provides an example of diagnostic reasoning. Some nursing diagnoses common to patients with urinary elimination problems include the following:

Box 46.6 Nursing Diagnostic Process Urge Urinary Incontinence Related to Bladder Infection

Assessment Activities	Assessment Findings
Ask patient to describe voiding problems/incontinence.	Patient complains of urine leakage associated with a strong urge to void.
Assess patient's voiding pattern.	Bladder record shows episodes of urinary incontinence. Patient describes or is observed to leak urine on the way to or at the toilet. Patient describes or is observed to rush or hurry to the toilet.

- *Urinary Incontinence: Functional; Overflow; Reflex; Stress; Urge*
- *Infection*
- *Impaired Self Toileting*
- *Impaired Skin Integrity*
- *Urinary Retention*

Planning

During planning integrate the knowledge from assessment and information about available resources and therapies to develop an individualized plan of care (see the [Nursing Care Plan](#)). Match the patient's needs with clinical and professional standards recommended in the literature ([Fig. 46.7](#)). Building a relationship of trust with patients is important because the implementation of care involves interaction of a very personal nature.

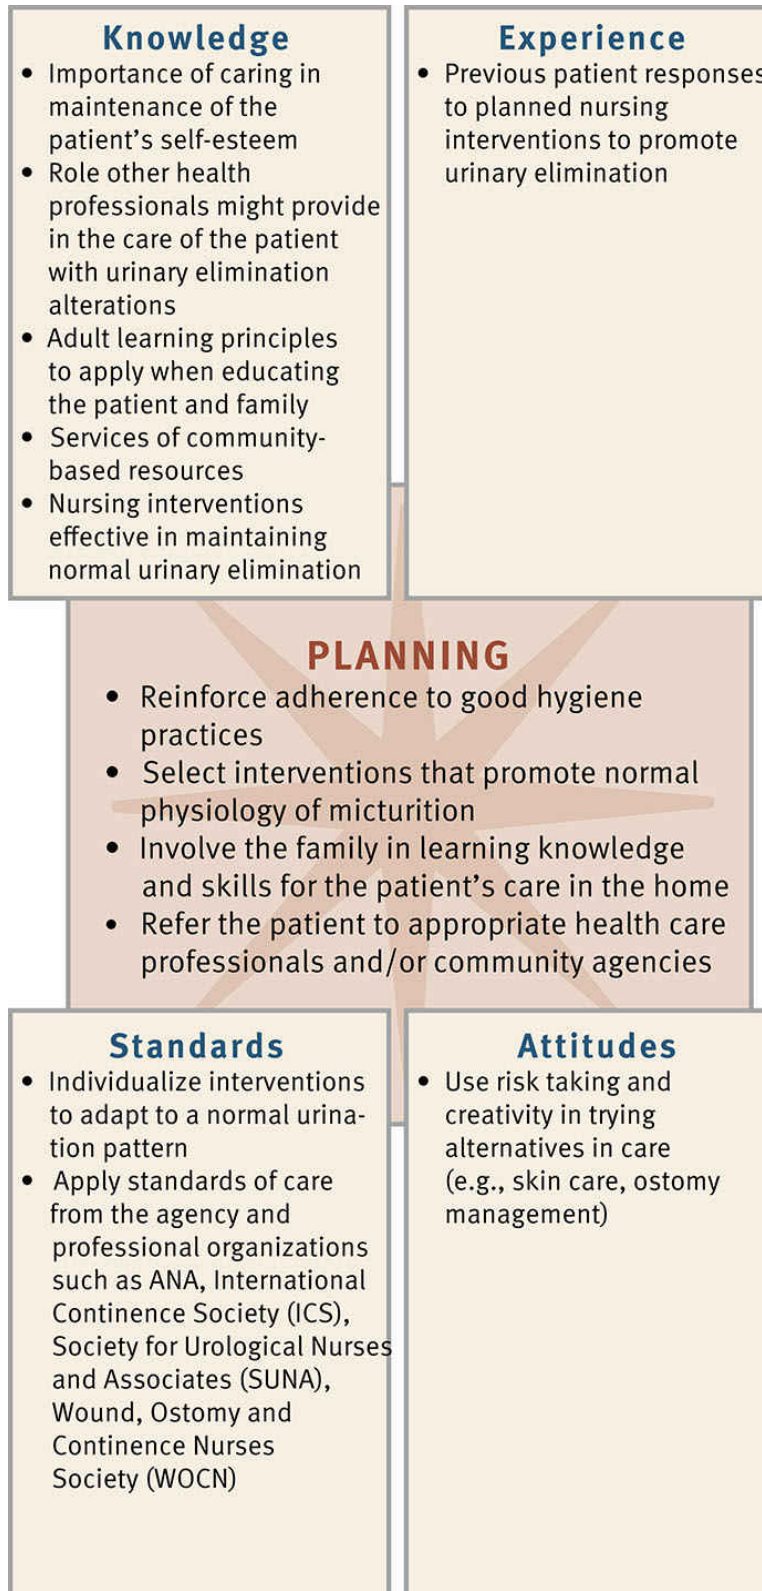

FIG. 46.7 Critical thinking model for urinary elimination planning. ANA, American Nurses Association.

Goals and Outcomes

The plan of care for urinary elimination alterations must include realistic and individualized goals along with relevant outcomes. The nurse and the patient need to collaborate in setting goals and outcomes and ultimately in choosing nursing interventions. A general goal is often normal urinary elimination, but sometimes the individual goal differs, depending on the problem. The goals are short term or long term.

For example, a realistic short-term goal for a patient with *Impaired Self Toileting related to impaired mobility status* would be that the patient will be able to independently use the toilet. An appropriate outcome would be that the “patient is observed to safely transfer to the toilet.” To achieve this outcome you identify a number of interventions, such as ensuring that the nurse call system is within reach, providing assistive devices such as a raised toilet seat, and providing easy access to the urinal when in bed. Conversely, the patient with stress incontinence often has a long-term goal that depends on weeks of pelvic floor muscle exercise to improve urinary control: Patient will experience normal continence. An outcome for this goal would be to “decrease the number of incontinence pads by 1 to 2 within 8 weeks.” Interventions will include daily Kegel exercises. Make sure that goals and outcomes are reasonably achievable and relevant to the patient’s situation (see [Box 46.8](#)).

Box 46.7 Health Promotion/Restoration: Patient Education for a Healthy Bladder

1. Maintain adequate hydration.
 - Drink six to eight glasses of water a day. Spread it out evenly throughout the day.
 - Avoid or limit drinking beverages that contain caffeine (coffee, tea, chocolate drinks, soft drinks).
 - To decrease nocturia, avoid drinking fluids 2 hours before bedtime.
 - Do not limit fluids if you experience incontinence. Concentrated urine may irritate the bladder and increase bladder symptoms.
2. Keep good voiding habits.

- Women: Sit well back on the toilet seat, avoid “hovering over the toilet,” and make sure that the feet are flat on the floor.
 - Void at regular intervals, usually every 3 to 4 hours, depending on fluid intake.
 - Avoid straining when voiding or moving the bowels.
 - Take enough time to empty the bladder completely.
3. Keep the bowels regular. A rectum full of stool may irritate the bladder, causing urgency and frequency.
 4. Prevent urinary tract infections.
 - Women: Cleanse the perineum from front to back after each voiding and bowel movement; wear cotton undergarments.
 - Drink enough water to pass pale yellow urine.
 - Shower or bathe regularly.
 5. Stop smoking to reduce your risk for bladder cancer and reduce the risk of developing a cough, which can contribute to stress urinary incontinence.
 6. Report to your health care provider any changes in bladder habits, frequency, urgency, pain when voiding, or blood in the urine.

Box 46.8 Patient Teaching Teaching Patients About Pelvic Muscle Exercises (Kegel Exercises)

Objective

- Patient will verbalize and/or demonstrate how to perform pelvic muscle exercises (Kegel exercises).

Teaching Strategies

- Use pictures and plain language to teach the patient pelvic anatomy and the location of the pelvic muscles (see Fig. 46.16).
- Teach patient how to identify and contract the correct muscle.
 - Women: Instruct the patient to squeeze the anus as if to hold in gas or to insert a finger into the vagina and feel the muscle

squeeze around her finger. The woman can also observe the perineum pulling in by using a mirror.

- Men: Instruct the patient to stand in front of a mirror, squeeze the anus as if to hold in gas, and watch to see if the penis moves up and down as he contracts the pelvic floor muscles.
- Instruct to not contract the abdomen, buttocks, or thighs when contracting the pelvic muscles.
- Teach patients pelvic muscle contraction exercises.
 - Quick flicks: Squeeze the muscle for 2 to 3 seconds and relax.
 - Sustained contractions: Squeeze the muscle for 10 seconds and relax after each contraction for 10 seconds.
 - Counting out loud prevents breath holding during exercises.
- Teach patient to maintain a daily exercise schedule.
 - Perform three to five quick flicks followed by 10 sustained contractions.
 - Do these exercises 3 to 4 times a day.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Describe how you would correctly identify the pelvic floor muscles.
- Explain how you would perform pelvic muscle exercises.

Setting Priorities

It is important to establish priorities of care on the basis of a patient's immediate physical and safety needs, patient expectations, and readiness to perform some self-care activities. Establish a relationship with the patient that allows discussion and intervention. While you are collaborating with the patient, priorities become apparent, enhancing patient understanding of all the goals. When a patient has multiple nursing diagnoses (Fig. 46.8), it is important to recognize the primary health problem and its influence on other problems. For example, a patient with a long-term indwelling catheter is admitted to acute care with a severe UTI. The patient expects to resume self-care of the catheter. However, because of the severity of the infection and the patient's condition, the nurse needs to perform all care for the patient's catheter. In

this case the priorities are to treat the infection, prevent reinfection, and teach the patient how to resume care of the catheter using techniques to prevent infection.

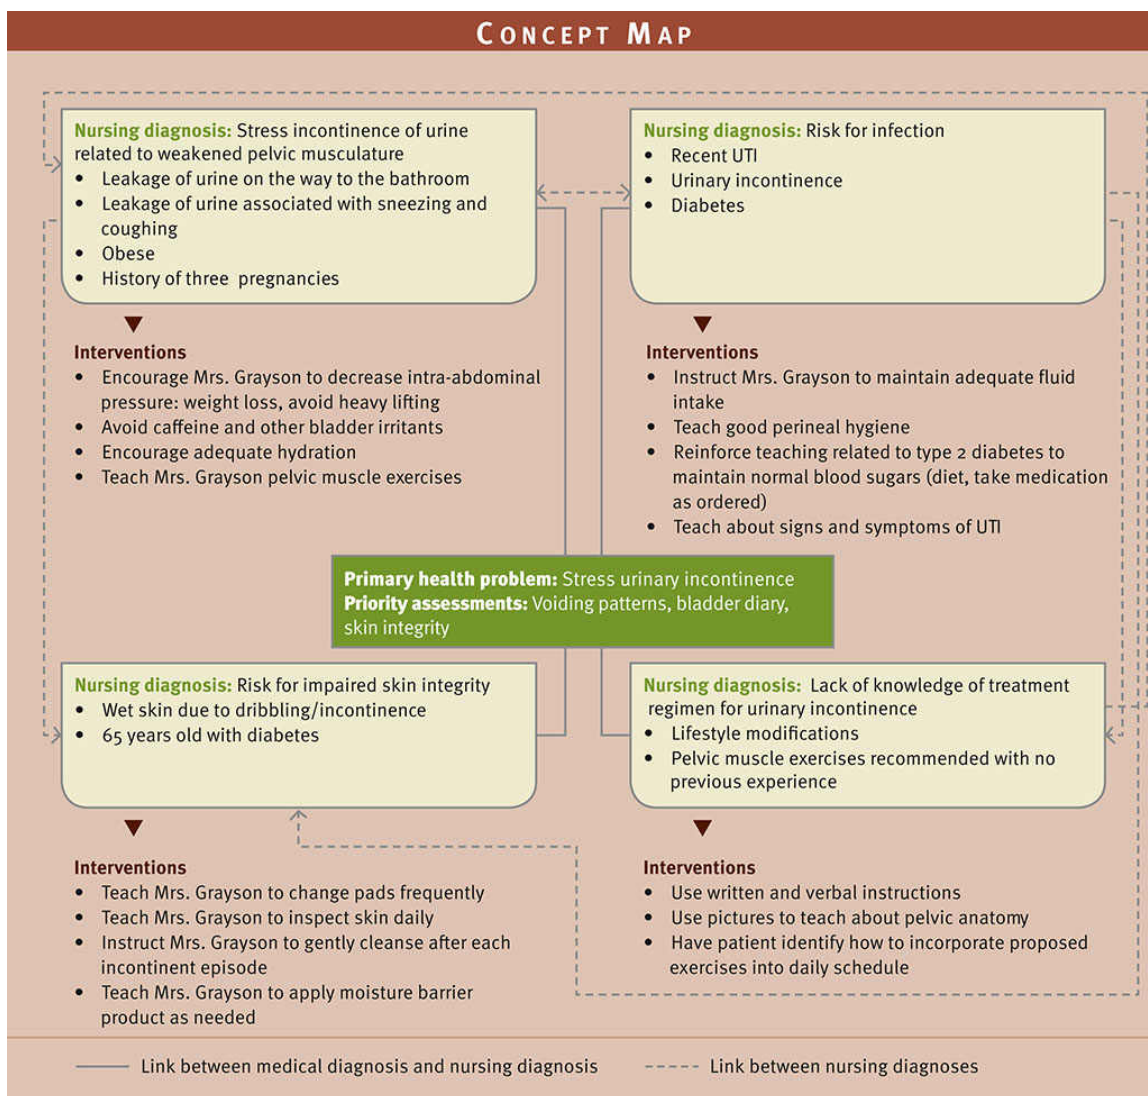

FIG. 46.8 Concept map for Mrs. Grayson.

Teamwork and Collaboration

When planning individualized care, it is essential to use the expertise of the health care team and incorporate them into the plan. For example, when planning care for a patient with urge UI, incorporate the expertise of a continence nurse specialist to help the patient learn techniques to inhibit the urinary urge, strengthen pelvic floor muscles, and learn fluid and food

modifications. Have the occupational therapist help the patient learn efficient and safe toilet transfers; the physical therapist help with strengthening exercises of the lower extremities; and the social worker facilitate obtaining assistive devices in the home that are covered by insurance. The family caregiver is included in planning when applicable. When a patient requires an indwelling urinary catheter because of acute illness and a need to measure accurate urinary output, the nurse is a key member of the team by monitoring patient progress and ensuring that the catheter is removed in a timely manner. Your active and thoughtful role in planning these interventions will result in the patient's progress toward improved urinary elimination.

Implementation

Complete independent and collaborative interventions to help the patient achieve the desired outcomes and goals. The independent activities are those in which nurses use their own judgment. An example of this is teaching self-care activities to the patient. Collaborative activities are those prescribed by the health care provider and carried out by the nurse, such as medication administration.

Health Promotion

Health promotion helps the patient understand and participate in self-care practices to preserve and protect healthy urinary system function ([Box 46.7](#)). You can achieve this focus using several means.

Patient Education

Success of therapies aimed at eliminating or minimizing urinary elimination problems depends in part on successful patient education (see [Box 46.7](#)). Although many patients need to learn about all aspects of healthy urinary elimination, it is best to focus on a specific elimination problem first. For example, a patient who presents with a UTI would greatly benefit from learning about symptoms of UTI and preventive measures in order to potentially prevent recurring UTIs. You can easily incorporate teaching when giving nursing care. For example, teach about common bladder irritants such as caffeine when preparing a clinic patient for discharge. Include in any teaching an awareness of the patient's health literacy. Pictures are helpful when teaching about urinary tract anatomy

and the relationship with UTI. If a patient speaks a different language, involve a professional interpreter.

Promoting Normal Micturition

Maintaining normal urinary micturition helps to prevent many problems. Many measures that promote normal voiding are independent nursing interventions.

Maintaining Elimination Habits

Many patients follow routines to promote normal voiding. When in a hospital or long-term care setting, institutional routines often conflict with those of the patient. Integrating the patient's habits into the care plan fosters a more normal voiding pattern. Elimination is a very private act. Create as much privacy as possible by closing the door and bedside curtain; asking visitors to leave a room when a bedside commode, bedpan, or urinal is used; and masking the sounds of voiding with running water. Respond to requests for help with toileting as quickly as possible. Embarrassing accidents are easily avoided when help comes in time. Avoid the use of incontinence-containment products unless needed for uncontrolled urine leakage. Some containment products may be difficult to remove and interfere with prompt toilet access.

Maintaining Adequate Fluid Intake

A simple method to promote normal micturition is to maintain optimal fluid intake. A patient with normal renal function who does not have heart disease or alterations requiring fluid restriction should have approximately 2300 mL of fluid in a 24-hour period. Adequate fluid intake will help flush out solutes or particles that collect in the urinary system and decrease bladder irritability. Help patients change their fluid intake by teaching the importance of adequate hydration. If a patient needs to increase fluid intake, set a schedule for drinking extra fluids, identify fluid preferences, increase high fluid foods such as fruits, and encourage fluid intake in small volumes frequently. Excessive fluid intake should be avoided. To prevent nocturia, suggest that the patient avoid drinking fluids 2 hours before bedtime.

Promoting Complete Bladder Emptying

It is normal for a small volume of urine to remain in the bladder after micturition. When the bladder does not empty completely and residual

urine volumes are high, there is risk for incontinence and dangerous urinary retention. Urinary retention increases the risk for UTI and damage to the kidneys. Adequate bladder emptying depends on feeling an urge to urinate, contraction of the bladder, and the ability to relax the urethral sphincter. A strategy to promote relaxation and stimulate bladder contractions is to help patients assume the normal position for voiding. The normal anatomical position for female voiding is in the squatting position. Women empty the bladder better when sitting on the toilet or bedside commode with the feet on the floor. If the patient cannot use a toilet, position her on a bedpan (see [Chapter 47](#)). After bedpan use help the patient perform perineal hygiene (see [Chapter 40](#)). A man voids more easily in the standing position. If the patient is unable to reach a toilet, have him stand at the bedside and void into a urinal (a plastic or metal receptacle for urine) ([Fig. 46.9, A](#)). Always assess mobility status

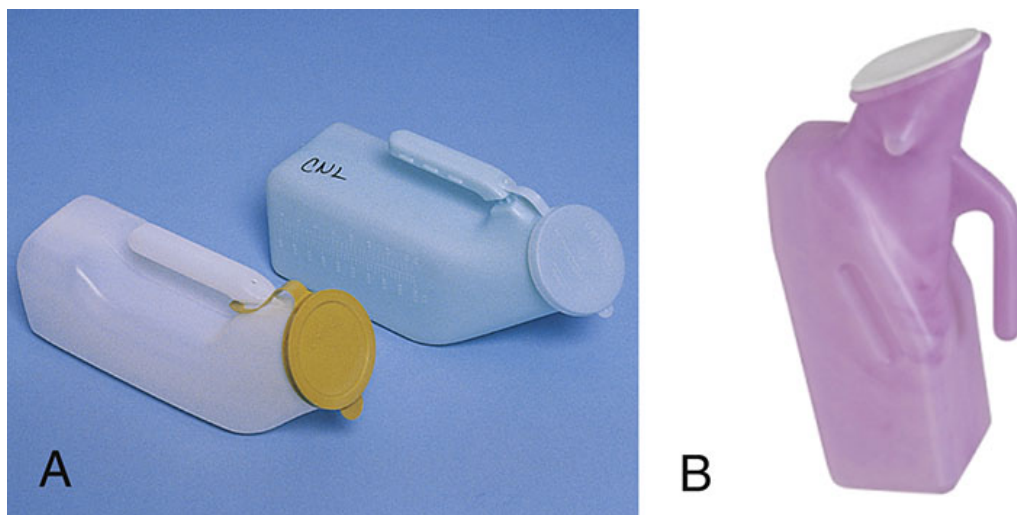

FIG. 46.9 Types of male (**A**) and female (**B**) urinals. (**B** courtesy Briggs Medical Service Co.)

Nursing Care Plan

Stress Incontinence of Urine

Assessment

Mrs. Grayson is 65 years old and the mother of five adult children. She was widowed 6 months ago; before her husband's death she was his primary caregiver for 4 years. She is preparing for retirement and would like to travel. For the past 2 years she noticed an increase in urine incontinence when she sneezes, laughs, or coughs. She recently noted incontinence when exercising. She feels the weight she gained while caring for her husband made the incontinence worse.

Assessment Activities	Assessment Findings ^a
Ask Mrs. Grayson about the effects of her urinary symptoms on her daily life.	She responds, "I find myself being embarrassed and frustrated for losing control . I dribble when I'm on the way to the bathroom. I'm afraid to cough, sneeze, or laugh because I leak urine . I don't go places and try to avoid being close to other people because I'm afraid I might have an odor."
Ask her about any interventions she has tried to help with the incontinence.	She states, "I've been wearing a pad and will go to the bathroom every hour just in case. I try to limit the amount of water I drink, so I will not have to go to the bathroom."
Ask Mrs. Grayson about any other effects caused by her leakage.	She begins to cry and states, "I don't even like to go to the movies or visit my grandchildren. It's safer to stay home."
Observe Mrs. Grayson's behavior.	She appears anxious and sad .
Conduct a focused nursing history addressing urinary leakage and other lower urinary tract symptoms.	Mrs. Grayson's report of urine leakage on physical exertion, sneezing, coughing, and laughing and leakage on the way to the bathroom increases the likelihood of a diagnosis of mixed incontinence. Her risk factors for this condition include five pregnancies , being postmenopausal , and being overweight . The history helps to define the proper interventions.

^a **Assessment findings** are shown in bold type.

Nursing diagnosis

Stress incontinence of urine related to weakened pelvic musculature

Goals	Expected Outcomes (NOC)
Urinary Continence	
Mrs. Grayson will have reduced episodes of urine leakage (incontinence) between voiding within 6 to 8 weeks.	Patient reports fewer than two episodes of daily incontinence.
	Patient reports less incontinence during coughing or sneezing.
	Patient states decreased anxiety about her incontinence.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Urinary Incontinence Care	
Teach Mrs. Grayson measures to reduce intraabdominal pressure by: <ul style="list-style-type: none"> • Losing weight. • Avoiding heavy lifting. 	These measures reduce intraabdominal and bladder pressure, which increase leakage.
Teach Mrs. Grayson about how to keep her bladder healthy (see Box 46.7): <ul style="list-style-type: none"> • Avoid bladder irritants (e.g., caffeine) • Drink adequate amounts of water; avoid drinking large amounts at one time. 	Fluids that contain caffeine and other irritants can prompt unwanted bladder contractions, resulting in frequency, urgency, and incontinence.
Pelvic Muscle Exercise	
Teach Mrs. Grayson how to perform pelvic muscle exercises (see Box 46.8): <ul style="list-style-type: none"> • Instruct her how to identify and contract the muscle. • Help her set up a daily schedule for performing the exercises. 	Pelvic muscle training is effective in treating stress urinary incontinence (Shivkumar et al., 2015).
Bladder retraining (behavioral therapy) <ul style="list-style-type: none"> • Instruct her how to inhibit strong sensations of urinary urgency by taking slow and deep breaths to relax and performing 5 to 6 quick, strong pelvic muscle exercises (flicks) in quick succession, followed by focusing the attention away from the bladder sensations. • Once successful with inhibiting the urge to void and avoiding incontinence, instruct her to gradually increase the time period between trips to the bathroom. 	Bladder training and pelvic floor muscle exercises progressively re-establish voluntary control over micturition (Shivkumar et al., 2015).

^c Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classifications (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Ask Mrs. Grayson about frequency of incontinence.	She responds, "I'm dry most of the time now. I'm now babysitting my grandchildren and have returned to my volunteer job."	Mrs. Grayson is experiencing reduced episodes of urine leakage (incontinence).
Ask Mrs. Grayson to keep a 3-day bladder diary.	Bladder diary revealed one small-volume loss of urine with a strong cough and voiding every 3 to 4 hours.	Mrs. Grayson is experiencing reduced episodes of urine leakage during stressful event.

and determine whether he can stand safely. At times it is necessary for one or more nurses to help a male patient stand. If the patient is unable to stand at the bedside, you will need to help him use the urinal in bed. Some patients need the nurse to position the penis completely within the urinal and hold the urinal in place or help them hold the urinal. Once the patient

has finished voiding, carefully remove the urinal and perform perineal hygiene (see [Chapter 40](#)).

There are specially designed urinals for women (see [Fig. 46.9, B](#)). The female urinal has a larger opening at the top with a defined rim, which helps position the urinal closely against the genitalia.

There are other measures that improve bladder emptying. To promote relaxation and stimulate bladder contractions, use sensory stimuli (e.g., turning on running water, putting a patient's hand in a pan of warm water) and provide privacy. In addition, bladder exercises help to improve pelvic muscles, which reduces stress incontinence and improves bladder emptying ([Box 46.8](#)).

To improve bladder emptying, encourage patients to wait until the urine flow completely stops when voiding and encourage them to attempt a second void (double voiding). Timed voiding is voiding according to the clock, not the urge to void, and is a helpful strategy when the bladder does not fully empty. The Credé method or manual compression of the bladder (i.e., placing the hands over the bladder and compressing it to help in emptying) should not be implemented until consultation with the health care provider. In the presence of high PVRs or a complete inability of the bladder to empty, urinary catheterization, either intermittent or indwelling, is needed.

Preventing Infection

UTIs are the fourth most common type of health care–associated infection ([CDC, 2019](#)). It is important to implement evidence-based practices to avoid this common and potentially dangerous infection. Some key interventions include promoting adequate fluid intake, promoting perineal hygiene, and having patients void at regular intervals. Encourage women to wipe front to back after voiding and defecation and teach them to avoid perfumed perineal washes and sprays, bubble baths, and tight clothing. If a patient has a problem with urine leakage, hygiene should be especially stressed. Patients should use containment products that are designed for urine and wick wetness away from the body. Prolonged periods of urine wetness should be avoided.

REFLECT NOW

Think about health promotion for your next assigned patient. What strategies would improve this patient's elimination?

Acute Care

Patients with acute illness, surgery, or impaired function of the urinary tract may require more invasive interventions that support urinary elimination.

Catheterization

Urinary **catheterization** is the placement of a tube through the urethra into the bladder to drain urine (see Skill 46.2). There is a risk for catheter-associated urinary tract infections (CAUTIs), which are the fourth leading cause of health care–associated infections in acute care hospitals (Ferguson, 2018). The ANA developed an evidenced-based tool, the *ANA CAUTI Prevention Tool*, to guide the decision making of the health care team regarding indwelling catheter insertion and care, maintenance of sterile technique, and best practices for timely catheter removal (Panchisin, 2016).

Urinary catheterization can be intermittent (one-time catheterization for bladder emptying) or indwelling (remains in place over a period of time). Indwelling catheterization may be short term (2 weeks or less) or long term (more than 1 month) (Taylor, 2018; Yates, 2016). Conditions requiring the use of a short- or long-term urinary catheter include the need for accurate monitoring of urine output either perioperative or postoperative after urological or gynecological procedures, or when the bladder inadequately empties because of obstruction or a neurological condition. Excessive accumulation of urine in the bladder is painful for a patient, increases the risk for UTI, and can cause backward flow of urine up the ureters, increasing risk for kidney damage. For some patients, the only method of managing their bladder dysfunction is through a catheter (Davey, 2015). Intermittent catheterization is used to measure PVR when ultrasound or a bladder scanner is unavailable or as a way to manage chronic urinary retention.

Types of Catheters

The difference among urinary catheters is related to the number of catheter lumens, the presence of a balloon to keep the indwelling catheter in place, the shape of the catheter, and a closed drainage system. Urinary catheters are made with one to three lumens. Single-lumen catheters (see [Fig. 46.10A](#)) are used for intermittent/straight catheterization. Double-lumen catheters, designed for indwelling catheters, provide one lumen for urinary drainage while a second lumen is used to inflate a balloon that keeps the catheter in place (see [Fig. 46.10B](#)). Triple-lumen catheters (see [Fig. 46.10C](#)) are used for continuous bladder irrigation (CBI) or when it becomes necessary to instill medications into the bladder. One lumen drains the bladder, a second lumen is used to inflate the balloon, and a third lumen delivers irrigation fluid into the bladder.

FIG. 46.10 **A**, Straight catheter (cross-section). **B**, Indwelling (Foley) retention catheter (cross-section). **C**, Triple-lumen catheter (cross-section).

A health care provider chooses a catheter on the basis of factors such as latex allergy, history of catheter encrustation, anatomical factors, and susceptibility to infection. Indwelling catheters are made of latex or silicone. Latex catheters with special coatings reduce urethral irritation (Yates, 2016). All silicone catheters have a larger internal diameter and may be helpful in patients who require frequent catheter changes as a result of encrustation. Intermittent/straight catheters are made of rubber (softer and more flexible) or polyvinyl chloride (PVC). Patients who self-catheterize have a large selection of catheters, some with special coatings that do not require lubrication and others that are self-contained systems consisting of a prelubricated catheter and packaged with a preconnected drainage bag. Catheter shape can differ; shape chosen is based on anatomical differences

in patients. One such catheter is a Coudé-tip catheter. This catheter has a curvature at the end that helps it maneuver through the prostatic urethra in the presence of a large prostate. Nurses need special training to use this type of catheter.

Catheter Sizes

The size of a urinary catheter is based on the French (Fr) scale, which reflects the internal diameter of the catheter. Most adults with an indwelling catheter should use a size 10 to 12 Fr for women and 12 to 14 Fr for men to minimize trauma and risk for infection (Bardsley, 2015). Larger catheter diameters increase the risk for urethral trauma (Yates, 2016). However, larger sizes are used in special circumstances, such as after urological surgery or in the presence of gross hematuria. Smaller sizes are needed for children, such as a 5 to 6 Fr for infants, 8 to 10 Fr for children, and 12 Fr for young girls.

Indwelling catheters come in a variety of balloon sizes—from 3 mL (for a child) to 30 mL for CBI. The size of the balloon is usually printed on the catheter port (Fig. 46.11). The recommended balloon size for an adult is a 10-mL balloon (the balloon is 5 mL and requires 10 mL to fill completely) (Yates, 2016). Long-term use of larger balloons (30 mL) has been associated with increased patient discomfort, irritation and trauma to the urethra, increased risk of catheter expulsion, and incomplete emptying of the bladder resulting from urine that pools below the level of the catheter drainage eyes.

FIG. 46.11 Size of catheter and balloon printed on catheter.

Catheter Changes

Use clinical indicators, such as obstruction, prior treatment of a symptomatic infection, malfunction of the catheter, or compromise of the closed system to determine when to change long-term indwelling catheters and drainage bags ([Gesmundo, 2016a,b](#)). When long-term catheterization is required, the catheter will need to be changed every 4 to 6 weeks. Whenever possible, avoid the use of long-term catheterization due to the increased risk for CAUTI.

Closed Drainage Systems

An indwelling catheter is attached to a urinary drainage bag to collect the continuous flow of urine. This is a closed drainage system and tubing connections should not be separated to avoid introducing pathogens. In patients with indwelling catheters specimens are collected without opening the drainage system by using a special port in the tubing ([Fig. 46.12](#)). Always hang the drainage bag below the level of the bladder on the bedframe or a chair so that urine will drain down out of the bladder. The

bag should never touch the floor to prevent accidental contamination during emptying. When a patient ambulates, carry the bag below the level of the patient's bladder. Ambulatory patients may use a leg bag. This is a bag that attaches to the leg with straps. Leg bags are usually worn during the day and replaced at night with a standard drainage bag. The only drainage bag that does not need to be kept dependent to the bladder is a specially designed drainage bag (belly bag) that is worn across the abdomen. A one-way valve prevents the back flow of urine into the bladder. To keep the drainage system patent, check for kinks or bends in the tubing, avoid positioning the patient on drainage tubing, prevent tubing from becoming dependent, and observe for clots or sediment that may block the catheter or tubing.

FIG. 46.12 Urine specimen collection: aspiration from a collection port in drainage tubing of indwelling catheter (needleless technique).
Courtesy and © Becton, Dickinson and Company.

Routine Catheter Care

Patients with indwelling catheters require regular perineal hygiene, especially after a bowel movement, to reduce the risk for CAUTI ([CDC](#),

2019; Lo et al., 2014). In many institutions patients receive catheter care every 8 hours as the minimal standard of care. See [Chapter 40](#) for routine perineal care and Skill 46.3 for catheter care. Empty drainage bags when they are half full ([Fig. 46.13](#)). An overfull drainage bag can create tension and pull on the catheter, resulting in trauma to the urethra and/or urinary meatus and increasing risk for CAUTI ([CDC, 2019](#)). Expect continuous drainage of urine into the drainage bag. In the presence of no urine drainage, first check to make sure that there are no kinks or obvious occlusion of the drainage tubing or catheter.

FIG. 46.13 Urine drainage bag.

Preventing Catheter-Associated Infection

A critical part of routine catheter care is reducing the risk for CAUTI (Box 46.9). In addition, there are specific CDC (2019) guidelines and interventions (Box 46.10). A key intervention to prevent infection is to maintain a closed urinary drainage system. Portals for entry of bacteria into the system are illustrated in Fig. 46.14. Another key intervention is prevention of urine backflow from the tubing and bag into the bladder. Many urine drainage systems are equipped with an antireflux valve, but you should monitor the system to prevent pooling of urine within the tubing and to keep the drainage bag below the level of the bladder.

Box 46.9 Evidence-Based Practice Factors to Decrease Catheter-Associated Urinary Tract Infection (CAUTI)

PICOT Question: Does the use of evidence-based nursing protocols reduce the occurrence of catheter-associated urinary tract infection (CAUTI) in hospitalized patients with an indwelling catheter?

Evidence Summary

Approximately 12% to 16% of adult hospital inpatients will have an indwelling urinary catheter at some time during their hospitalization, and each day the indwelling urinary catheter remains, a patient has a 3% to 7% increased risk of acquiring a catheter-associated urinary tract infection (CAUTI) (CDC, 2019). A systematic review and meta-analysis of studies regarding measures to use to reduce catheter use and decrease CAUTI showed that CAUTI rates can be reduced when reminders to evaluate catheter need and stop orders are in place (Meddings et al., 2014). Measures to reduce CAUTI are organized into five areas: appropriate catheter use, proper insertion and maintenance techniques, quality improvement programs, ongoing surveillance for CAUTI, and related causative factors (CDC, 2019). Nurse-led interventions reduced the duration of indwelling catheter use and incidence of CAUTI (Scanlon et al., 2017; Dy et al., 2016). In addition, a hospital-wide strategy that included reeducation of nurses about CAUTI prevention and infusing best practice into current-practice nursing care also decreased CAUTI rates (McNeil, 2017; Cartwright, 2018). Best practices, staff education, data reporting, and the use of an icon in the electronic health record as a catheter reminder decreased the CAUTI rates (Ferguson, 2018; Purvis et al., 2014).

Application to Nursing Practice

- Become familiar with guidelines related to CAUTI prevention and care (see Box 46.10). (Galiczweski, 2016).
- Be aware of indications for catheter insertion and be prepared to advocate for the patient if the indications do not meet accepted guidelines (Ferguson, 2018; Bardsley, 2015).
- Collaborate with health care providers to remove catheters early when medical indications no longer exist (Dy et al., 2016).
- Develop or use evidence-based nurse-driven protocols for CAUTI prevention (Ferguson, 2018; Dy et al., 2016).

Box 46.10 Preventing Catheter-Associated Urinary Tract Infection (CAUTI)

- Prevention of CAUTI often requires use of an evidence based “bundle” to perform all elements of care at one time along with completion of a checklist to ensure that each element is included in that care. Know the policies of your institution to determine which components are in a care bundle (AACN Practice Alert, 2018; Dy et al., 2016).
- Patients in acute care hospital should have urinary catheters inserted using aseptic technique with sterile equipment (Galiczweski and Shurpin, 2017).
- Secure indwelling catheters to prevent movement and pulling on the catheter.
- Maintain a closed urinary drainage system.
- Maintain an unobstructed flow of urine through the catheter, drainage tubing, and drainage bag.
- Keep the urinary drainage bag below the level of the bladder at all times.
- Avoid dependent loops in urinary drainage tubing.
- Prevent the urinary drainage bag from touching or dragging on the floor.

- When emptying the urinary drainage bag, use a separate measuring receptacle for each patient. Do not let the drainage spigot touch the receptacle.
- Before transfers or activity, drain all urine from the tubing into bag and empty the drainage bag.
- Empty the drainage bag when half full.
- Perform routine perineal hygiene daily and after soiling using antiseptic wipes. Be sure to use a wipe to clean the length of the exposed catheter.
- Obtain urine samples using the sampling port. Cleanse the port with disinfectant. Use a sterile syringe/cannula.
- Quality improvement programs should be in place that alert providers that a catheter is in place and that include regular educational programming about catheter care.

Data from Centers for Disease Control and Prevention (CDC): Urinary tract infection (catheter-associated urinary tract infection [CAUTI] and non-catheter-associated urinary tract infection [UTI]) and other urinary system infection [USI] events, 2019.

<http://www.cdc.gov/nhsn/PDFs/pscManual/7pscCAUTIcurrent.pdf>.

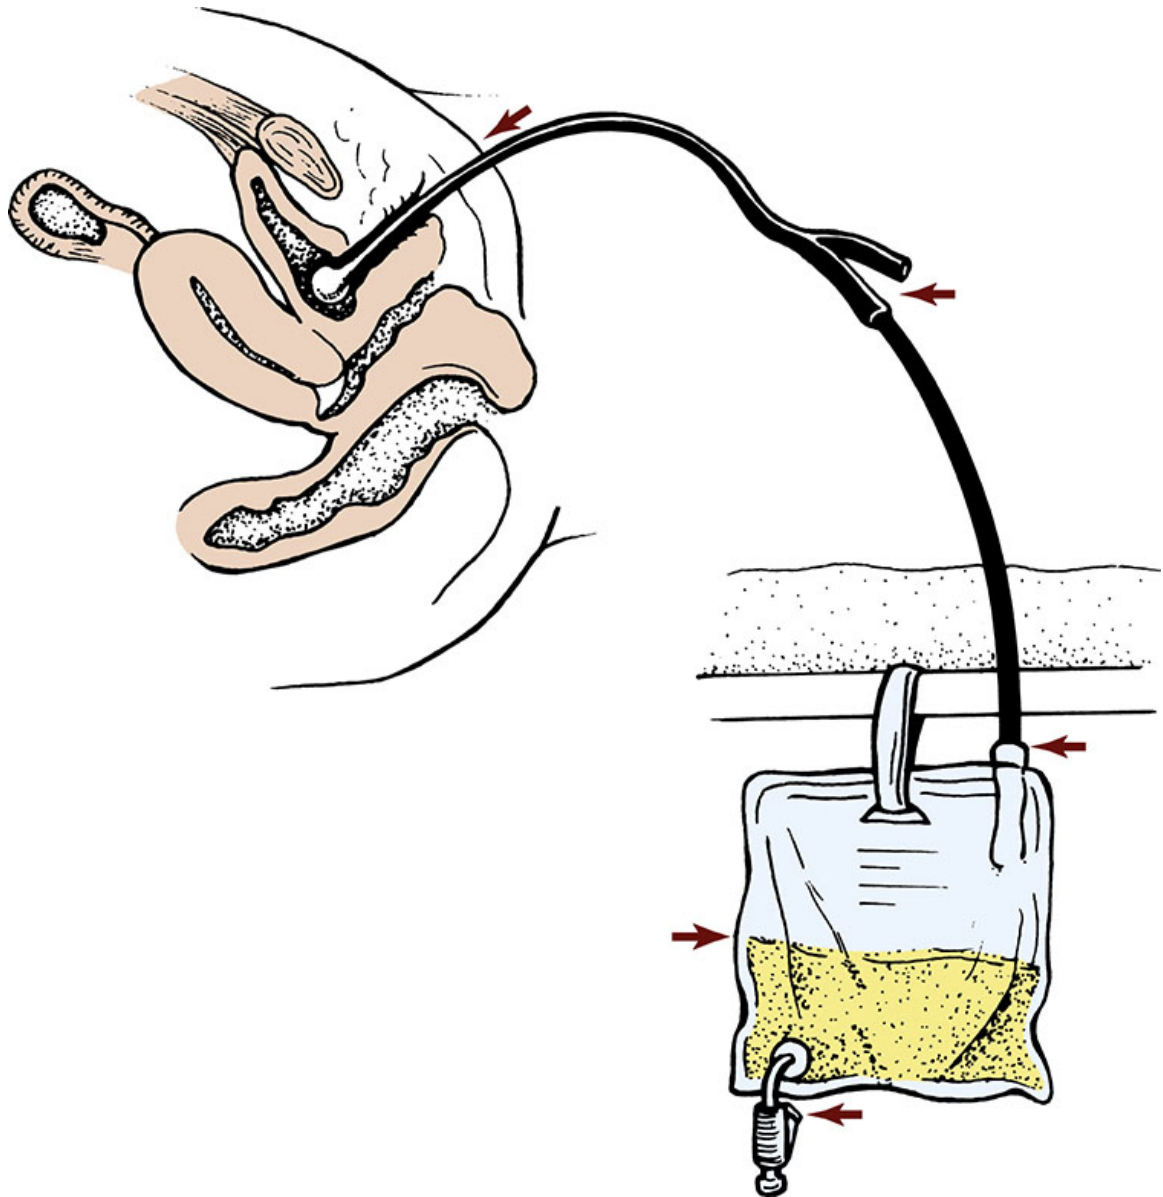

FIG. 46.14 Potential sites for introduction of infectious organisms into urinary drainage system.

Building Competency in Evidence-Based Practice

A nursing unit is experiencing an increase in catheter-associated urinary tract infections (CAUTIs). A team of staff nurses is investigating this problem and discovers that some nurses are resistant to implementing

new evidence-based practice (EBP) guidelines in CAUTI prevention. What can you do to decrease resistance and enhance EBP care on this unit?

Catheter Irrigations and Instillations

To maintain the patency of indwelling urinary catheters, it is sometimes necessary to irrigate or flush a catheter with sterile solution. However, irrigation poses the risk of causing a UTI and thus must be done maintaining a closed urinary drainage system. Generally, if a catheter becomes occluded, it is best to change it rather than risk flushing debris into the bladder. In some instances the health care provider will determine that irrigations are needed to keep a catheter patent such as after genitourinary surgery when there is high risk for catheter occlusion from blood clots. Bladder instillations are used to instill medication into the bladder. Refer to specific instructions for these medications in terms of how long the medication needs to stay in the bladder.

Closed catheter irrigation provides intermittent or continuous irrigation of a urinary catheter without disrupting the sterile connection between the catheter and the drainage system (see Skill 46.4). CBI is an example of a continuous infusion of a sterile solution into the bladder, usually using a three-way irrigation closed system with a triple-lumen catheter. CBI is frequently used following genitourinary surgery to keep the bladder clear and free of blood clots or sediment.

Removal of Indwelling Catheter

The Centers for Medicare and Medicaid Services (CMS) identified CAUTI as a never event ([Galiczewski, 2016](#); [CDC, 2019](#)). Prompt removal of an indwelling catheter after it is no longer needed is a key intervention that has proven to decrease the incidence and prevalence of hospital-acquired UTIs (HAUTIs) (see Skill 46.2). Monitor patient's voiding after catheter removal for at least 24 to 48 hours by using a voiding record or bladder diary. The bladder diary should record the time and amount of each voiding, including any incontinence. The use of ultrasound or a bladder scanner can monitor bladder function by measuring postvoid residual (PVR) volume ([Box 46.11](#)). The first few times a patient voids after catheter removal may be accompanied by some discomfort, but continued complaints of painful urination indicate possible infection. Abdominal pain and distention, a sensation of incomplete emptying, incontinence, constant dribbling of urine, and voiding in very small amounts can indicate inadequate bladder emptying requiring intervention.

Box 46.11 Procedural Guidelines Using a Bladder Scanner to Measure Postvoid Residual

Delegation and Collaboration

The skill of measuring bladder volume by bladder scan can be delegated to assistive personnel (AP). The nurse must first determine the timing and frequency of the bladder scan measurement and interpret the measurements obtained. The nurse also assesses the patient's ability to toilet before measuring postvoid residual (PVR) and the abdomen for distention if urinary retention is suspected. The nurse directs the AP to:

- Follow manufacturer recommendations for the use of the device.
- Measure PVR volumes within 5 to 15 minutes after helping the patient to void.
- Report and record bladder scan volumes.

Equipment

Bladder scanner, ultrasound gel, cleansing agent (e.g. alcohol pad) for scanner head, urethral catheterization tray for single-use catheter/intermittent (see Skill 46.2), paper towel or washcloth

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy (TJC, 2020).
2. Assess intake and output (I&O) record to determine urine output trends and whether patient has voided since surgery; check the plan of care to verify correct timing of the bladder scan measurement.
3. Assess patient's health literacy to determine approach for teaching about procedure.
4. Provide privacy by closing room door and bedside curtain.
5. Help patient to supine position with head slightly elevated. Raise bed to appropriate working height. If side rails are raised, lower side rail on working side.
6. Perform hand hygiene and apply clean gloves.
7. Discuss procedure with patient. If measurement is for PVR, ask patient to void and measure volume retained in bladder with

scanner within 5 to 15 minutes of voiding:

- a. Pull back sheet to expose patient's lower abdomen.
- b. Turn on scanner per manufacturer guidelines.
- c. Set gender designation per manufacturer guidelines.
Women who have had a hysterectomy should be designated as male.
- d. Wipe scanner head with alcohol pad or other cleaner and allow to air-dry.
- e. Palpate patient's symphysis pubis (pubic bone). Apply generous amount of ultrasound gel (or if available a bladder scan gel pad) to midline abdomen 2.5 to 4 cm (1 to 1.5 inches) above symphysis pubis.
- f. Place scanner head on gel, ensuring that scanner head is oriented per manufacturer guidelines.
- g. Apply light pressure, keep scanner head steady, and point it slightly downward toward bladder. Press and release the scan button (see illustration).
- h. Verify accurate aim (refer to manufacturer guidelines). Complete scan and print image (if needed).

STEP 7G Placement of bladder scan head.

8. Remove ultrasound gel from patient's abdomen with paper towel or moist cloth.
9. Remove ultrasound gel from scanner head and wipe with alcohol pad or other cleaner; allow to air-dry.
10. Help patient to comfortable position. Raise side rails (as appropriate) and lower bed to lowest position. Be sure nurse call system is in an accessible location within patient's reach.
11. Remove and dispose of gloves and perform hand hygiene.
12. Compare PVR results with prevoiding scan (if available); urine volume should be less. Or if first-time scan, PVR should be <100 mL urine.
13. Review health care provider's order to determine how often to assess residual urine or if catheterization is ordered.
14. Review I&O record to determine urine output trends.
15. Record findings of scan, PVR, and patient tolerance of procedure.

Alternative to Urethral Catheterization

To avoid the risks associated with urethral catheters, two alternatives are available for urinary drainage.

Suprapubic Catheterization

A **suprapubic catheter** is a urinary drainage tube inserted surgically into the bladder through the abdominal wall above the symphysis pubis (Fig. 46.15). The catheter may be sutured to the skin, secured with an adhesive material, or retained in the bladder with a fluid-filled balloon similar to an indwelling catheter. Suprapubic catheters are placed when there is blockage of the urethra (e.g., enlarged prostate, urethral stricture, after urological surgery) and in situations in which a long-term urethral catheter causes irritation or discomfort or interferes with sexual functioning.

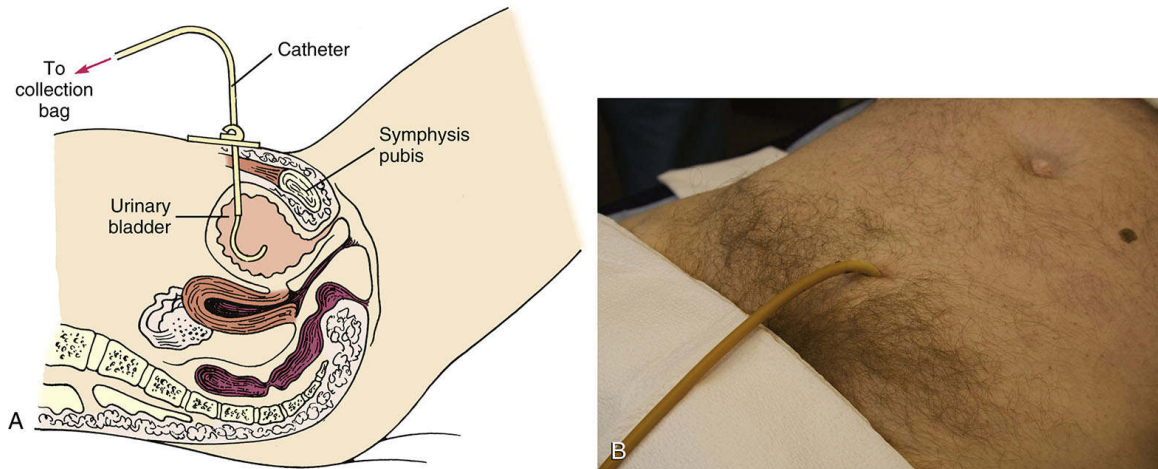

FIG. 46.15 **A**, Placement of suprapubic catheter above symphysis pubis. **B**, Suprapubic catheter without a dressing.

Care of a suprapubic catheter involves daily cleansing of the insertion site and catheter. The same care for the tubing and drainage bag for a urethral catheter applies to a suprapubic catheter. The insertion site should be assessed for signs of inflammation and the growth of overgranulation tissue. If insertion is new, slight inflammation may be expected as part of normal wound healing, but it can also indicate infection. Overgranulation tissue can develop at the insertion site as a reaction to the catheter. In some instances intervention may be needed. Site care applies the principles of applying a dry dressing; institutional policy will indicate whether aseptic or sterile technique is required (see [Chapter 48](#)).

External Catheter

The external catheter, also called a *condom catheter* or *penile sheath*, is a soft, pliable condom-like sheath that fits over the penis, providing a safe and noninvasive way to contain urine. Most external catheters are made of soft silicone that aids in reducing friction and are clear to allow for easy visualization of skin under the catheter. Latex catheters are still available and used by some patients. It is important to verify that a patient does not have a latex allergy before applying this type of catheter. Condom-type external catheters are held in place by an adhesive coating of the internal lining of the sheath, a double-sided self-adhesive strip, brush-on adhesive applied to the penile shaft, or in rare cases an external strap or tape. They may be attached to a small-volume (leg) drainage bag or a large-volume (bedside) urinary drainage bag, both of which need to be kept lower than the level of the bladder. The condom-type external catheter is suitable for incontinent patients who have complete and spontaneous bladder

emptying. Condom-type external catheters come in a variety of styles and sizes. For the best fit and correct application it is important to refer to manufacturer guidelines. See [Box 46.12](#) for the steps in applying a condom catheter. Condom-type external catheters are associated with less risk for UTI than indwelling catheters; thus they are an excellent option for the male with UI. For men who cannot be fitted for a condom-type external catheter, there are other externally applied catheters.

Box 46.12 Procedural Guidelines Applying a Male Incontinence Device

Delegation and Collaboration

Assessment of the skin of a patient's penile shaft and determination of a latex allergy are done by a nurse before catheter application. The skill of applying a condom catheter can be delegated to assistive personnel (AP), depending on agency policy. The nurse directs the AP to:

- Follow manufacturer directions for applying the condom catheter and securing device.
- Monitor intake and output (I&O) and record if applicable.
- Immediately report any redness, swelling, or skin irritation or breakdown of glans penis or penile shaft.

Equipment

- Condom catheter kit—condom sheath of appropriate size, securing device (internal adhesive, strap), skin preparation solution (per manufacturer's recommendations); *Option:* hydrocolloid incontinence device; urinary collection bag with drainage tubing or leg bag and straps; basin with warm water and soap; towels, washcloth, bath blanket; clean gloves; scissors, hair guard, or paper towel

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency

- policy (TJC, 2020).
2. Review electronic health record (EHR), and assess urinary pattern, ability to empty bladder effectively, and degree of urinary continence.
 3. Assess patient's or family caregiver's knowledge, experience, and health literacy.
 4. Review EHR for history of allergy to rubber or latex. Confirm with patient if possible. Check patient's allergy wristband.
 5. Assess patient's or family caregiver's mental status, knowledge of and experience with condom-type catheter, and ability to apply device.
 6. Perform hand hygiene. Assess integrity of penile tissue. Verify patient's size and type of condom catheter from plan of care, or use manufacturer measuring guide to measure length and diameter of penis in flaccid state (apply gloves for measurement). Perform hand hygiene.

CLINICAL DECISION: Apply condom catheters only when the skin on the penile surface is intact.

7. Provide privacy by closing room door or curtain. Organize and set up equipment needed.
8. Raise bed to appropriate working height. Lower side rail on working side.
9. Explain procedure to patient.
10. Perform hand hygiene.
11. Prepare urinary drainage collection bag and tubing (large-volume drainage bag or leg bag). Clamp off drainage bag port. Place nearby ready to attach to condom after applied.
12. Help patient to supine or sitting position.
13. Place bath blanket over upper torso. Fold sheets so that only penis is exposed.
14. Apply clean gloves. Provide perineal care (see Chapter 40). Dry thoroughly before applying device. In uncircumcised male, ensure that foreskin has been replaced to normal position before applying condom catheter. Do not apply barrier cream.
15. Remove and dispose of gloves. Perform hand hygiene.
16. Apply clean gloves. Assess skin of penis for rashes, erythema, and/or open areas.

17. Clip hair at base of penis as necessary before application of condom sheath. Some manufacturers provide hair guard that is placed over penis before applying device. Remove hair guard after applying catheter. An alternative to hair guard is to tear a hole in a paper towel, place it over penis, and remove after application of device.

CLINICAL DECISION: The pubic area should not be shaved because any microabrasions in skin increase risk for skin irritation and infection.

18. Apply incontinence device

- a. **Condom catheter.** With nondominant hand, grasp penis along shaft. With dominant hand, hold rolled condom sheath at tip of penis with head of penis in cone. Smoothly roll sheath onto penis. Allow 2.5 to 5 cm (1 to 2 inches) of space between tip of glans penis and end of condom catheter (see illustration).
- b. **Hydrocolloid device.** One size fits all. Place the device onto the tip of the penis, not the shaft (see manufacturer's directions, see Step 19c):

STEP 18A Condom catheter.

19. Apply appropriate securement device as indicated in manufacturer guidelines.
 - a. Self-adhesive condom catheters: After application apply gentle pressure on penile shaft for 10 to 15 seconds.
 - b. Outer securing strip-type condom catheters: Spiral wrap penile shaft with strip of supplied elastic adhesive. Strip should not overlap itself. Elastic strip should be snug, not tight (see illustration).

STEP 19B Spiral application of adhesive strip.

- c. Hydrocolloid incontinence device: Remove release papers from adhesive on faceplate of device. Center faceplate over opening of urinary meatus. Smooth hydrocolloid adhesive backing strips onto tip of penis. Then cover with hydrocolloid seal (see illustration).

STEP 19C Men's Liberty acute male incontinence device.
Courtesy BioDerm, Inc. Largo, Florida.

CLINICAL DECISION: Never use regular adhesive tape to secure a condom catheter. Constriction from tape can reduce blood flow to tissues.

20. Remove hair guard or paper towel (if used). Connect drainage tubing to end of incontinence device. Be sure that a condom catheter is not twisted. If using large drainage bag, place excess tubing on bed and secure to bottom sheet.
21. Help patient to safe, comfortable position. Raise side rails (as appropriate) and lower bed to lowest position.
22. Be sure nurse call system is in an accessible location within patient's reach.
23. Dispose of contaminated supplies, remove and dispose of gloves, and perform hand hygiene.
24. Remove and reapply daily following the previous steps unless an extended-wear device is used. To remove condom, wash penis with

warm, soapy water and gently roll sheath and adhesive off penile shaft

25. Observe urinary drainage.
26. Inspect penis with condom catheter in place within 15 to 30 minutes after application. Assess for swelling and discoloration, and ask patient whether there is any discomfort.
27. Inspect skin on penile shaft for signs of breakdown or irritation at least daily, when performing hygiene, and before reapplying condom or incontinence device.
28. Record condition of penis, type of external device applied, patient's response to procedure, and patient's level of understanding of purpose of device.

Urinary Diversions

Immediately after surgery the patient with an incontinent urinary diversion must wear a pouch to collect the effluent (drainage). The pouch will keep the patient clean and dry, protect the skin from damage, and provide a barrier against odor. Urinary pouches with an antireflux flap can be opaque or clear, drainable one-piece or two-piece pouches, with cut-to-fit or precut wafers. The pouch should be changed every 4 to 6 days. Each pouch may be connected to a bedside drainage bag for use at night.

When changing a pouch, gently cleanse the skin surrounding the stoma with warm tap water using a washcloth and pat dry. Do not use soap because it can leave a residue on the skin. Measure the stoma and cut the opening in the pouch. Then apply the pouch after removing the protective backing from the adhesive surface. Press firmly into place over the stoma. Observe the appearance of the stoma and surrounding skin. The stoma is normally red and moist and is located in the right lower quadrant of the abdomen. It is important for the patient to have the correct type and fit of an ostomy pouch. A specialty ostomy nurse is an essential resource when selecting the right appliance so that the pouch fits snugly against the surface of the skin around the stoma, preventing damaging leakage of urine (see [Chapter 47](#)).

Patients with continent urinary diversions do not have to wear an external pouch. However, if the patient has a continent urinary reservoir, he or she must be taught how to intermittently catheterize the pouch. Patients need to be able and willing to do this 4 to 6 times a day for the rest of their lives. After creation of an orthotopic neobladder, patients will have frequent episodes of incontinence until the neobladder slowly stretches and the urinary sphincter is strong enough to contain the urine. To achieve

continence the patient will need to follow a bladder-training schedule and perform pelvic muscle exercises (Shivkumar et al., 2015). The postoperative care of patients having continent urinary diversions varies widely with the surgical techniques used; it is important to learn the surgeon's preferred routine or health care agency procedures before caring for these patients.

Medications

A small number of medications, antimuscarinics (e.g., oxybutynin and trospium), are used to treat urinary urgency. Another medication, mirabegron, is in a class of medications called beta-3 adrenergic agonists. It relaxes the bladder muscles to prevent urgent, or uncontrolled, urination. The most common adverse effects of antimuscarinics are dry mouth, constipation, and blurred vision. In some cases these medications can cause a change in mental status in older adults (Burchum and Rosenthal, 2019). Patients taking mirabegron should have their blood pressure monitored because of possible increases. There are no medications, other than off-label use of vaginal estrogen in postmenopausal women, to treat stress urinary incontinence (Lukacz et al., 2017). Urinary retention is sometimes treated with bethanechol, and men with outlet obstruction caused by an enlarged prostate are treated with agents that relax the smooth muscle of the prostatic urethra, such as tamsulosin and silodosin and agents that shrink the prostate, such as finasteride and dutasteride. Know the medications and indications for all medications your patient is taking.

When a patient is newly started on an antimuscarinic, monitor for effectiveness, including a decrease in urgency, frequency, and incontinence episodes. A bladder diary is one of the best ways to do this. In addition, regularly assess the patient for side effects such as constipation by monitoring the bowel movement record. Watch for a decrease in bowel movement frequency, straining at bowel movements, and changes in stool consistency.

UTIs are treated with antibiotics. Patients with painful urination are sometimes prescribed urinary analgesics that act on the urethral and bladder mucosa (e.g., phenazopyridine). Patients taking drugs with phenazopyridine need to be aware that their urine will be orange. They must drink large amounts of fluids to prevent toxicity from the sulfonamides and maintain optimal flow through the urinary system (Burchum and Rosenthal, 2019).

Continuing and Restorative Care

There are techniques that can improve control over bladder emptying and restore some degree of urinary continence. These techniques are commonly referred to as behavioral therapy and are considered first-line treatment for stress, urge, and mixed incontinence (Lukacz et al., 2017). They include lifestyle changes, **pelvic floor muscle training** (PFMT), bladder retraining, and a variety of toileting schedules (see Table 46.1). In some cases, when the bladder does not empty, patients or caregivers learn to intermittently catheterize. Whenever there is a risk for urine leakage, skin care is an essential component of the plan of care. Adequate urine containment and skin protection promote patient comfort and dignity.

Lifestyle Changes

A number of lifestyle modifications can improve bladder function and decrease incontinence. In addition to interventions listed earlier in this chapter under health promotion and in Box 46.7, you can teach patients about foods and fluids that cause bladder irritation and increase symptoms, such as frequency, urgency, and incontinence. Teach patients to avoid common irritants such as artificial sweeteners, spicy foods, citrus products, and especially caffeine (Bykoviene et al., 2018). Discourage patients from drinking large volumes of fluid at one time. Constipation can also impact bladder symptoms, and measures to promote bowel regularity should be implemented (see Chapter 47). Encourage patients with edema to elevate the feet for a minimum of a few hours in the afternoon to help diminish nighttime voiding frequency.

Pelvic Floor Muscle Training

Evidence has shown that patients with urgency, stress, and mixed UI experience improvement and can eventually achieve continence when treated with pelvic floor muscle training (Lukacz et al., 2017; Bykoviene et al., 2018). Pelvic floor muscle training involves teaching patients how to identify and contract the pelvic floor muscles in a structured exercise program. This exercise program is commonly called *Kegel exercises* and is based on therapy first developed by obstetrician gynecologist Dr. Arnold Kegel in the 1940s. The exercises work by increasing the pressure within the urethra by strengthening the pelvic floor muscles and inhibiting unwanted bladder contractions (Fig. 46.16). Many patients benefit from verbal instructions on how to do the exercises (see Box 46.8). Patients who have difficulty correctly identifying and contracting the pelvic floor

muscles can be sent to a continence specialist for biofeedback. Biofeedback involves intensive instruction augmented by computerized measurement of muscle activity that is displayed on a monitor. The visual feedback helps the patient learn to contract the muscles correctly.

FIG. 46.16 Pelvic floor muscles.

From Lewis S, et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 10, St Louis, 2017, Elsevier.

Bladder Retraining

Bladder retraining is a behavioral therapy designed to help patients control bothersome urinary urgency and frequency. Patients are taught about their bladder and techniques to suppress urgency. They are given a schedule of toileting on the basis of their diary of voiding and leaking; the schedule is designed to slowly increase the interval between voiding. Successful bladder retraining requires that patients get regular support and positive reinforcement. Patients are taught to inhibit the urge to void by taking slow, deep breaths to relax, performing five to six quick, strong pelvic muscle exercises (flicks) in quick succession, followed by distracting attention from bladder sensations. When the urge to void becomes less severe or subsides, only then should the patient start his or her trip to the bathroom. Only highly motivated and cognitively intact patients are

candidates for this therapy. If a patient is in such a program, you can support him or her by reinforcing the schedule and providing emotional encouragement.

Toileting Schedules

A key component to any treatment plan for urinary incontinence is regular toilet access. Toileting schedules should be individualized based on the type of incontinence and functional disability (e.g., cognitive impairment). Toileting can be implemented in any care setting and should be the first plan of action when you assess a patient to be incontinent. Timed voiding or scheduled toileting is toileting based on a fixed schedule, not the patient's urge to void. The schedule may be set by a time interval, such as every 2 to 3 hours, or at times of day, such as before and after meals. It is very successful with moderate-to-severe cognitively and mobility-impaired adults. Habit training is a toileting schedule based on the patient's usual voiding pattern. Using a bladder diary, the usual times a patient voids are identified. It is at these times that the patient is then toileted. Prompted voiding is a program of toileting designed for patients with mild or moderate cognitive impairment. Patients are toileted based on their usual voiding pattern. Caregivers ask the patient if he or she is wet or dry, give positive feedback for dryness, prompt the patient to toilet, and reward the patient for desired behavior. This is a very successful toileting program; but it does require a consistent and motivated caregiver, a cooperative patient, and evidence that the patient will void when toileted at least 50% of the time or more.

Intermittent Catheterization

Some patients experience chronic inability to completely empty the bladder as a result of neuromuscular damage related to multiple sclerosis, diabetes, spinal cord injury, and urinary retention caused by outlet obstruction. To minimize the risk of UTI, patients or family caregivers are taught to catheterize the bladder. It is important they follow the principles of asepsis as discussed earlier in the chapter. Teach patients and caregivers about the importance of adequate fluid intake, signs of infection, and their individualized catheterization schedule. The goal for intermittent catheterization is drainage of 400 mL of urine with the schedule individualized to meet this goal.

Skin Care

Incontinence-associated dermatitis (IAD) presents as inflammation of the skin and can also cause blistering and swelling to the affected area (Paulin and Dowling-Castronovo, 2017). IAD is a multifaceted condition and should be treated as such. However, the main cause is moisture from incontinence, so preventing incontinence or having a good management plan when a patient is incontinent is imperative. The *do's* for effective management include identification and treatment, use of skin risk assessment tools, use of appropriate barrier products, and ensuring adequate hydration. The *don'ts* include only using traditional soap and water for cleaning, double padding the bed, leaving soiled pads in contact with the skin, and assuming incontinence is inevitable (Yates, 2018).

REFLECT NOW

Complementary approaches to care can often resolve incontinency. What are interventions that you would choose for an older adult to promote urinary continence and comfort?

• Evaluation

Through the Patient's Eyes

The patient is the best source of evaluation of outcomes and responses to nursing care. Include patients in the revision of the care plan based on their perception of its success. It is important to remember that urinary problems impact the patient not only physically but emotionally, psychologically, spiritually, and socially. Carefully assess the patient's self-image, social interactions, sexuality, and emotional status as impacted by the urinary problem (Fig. 46.17).

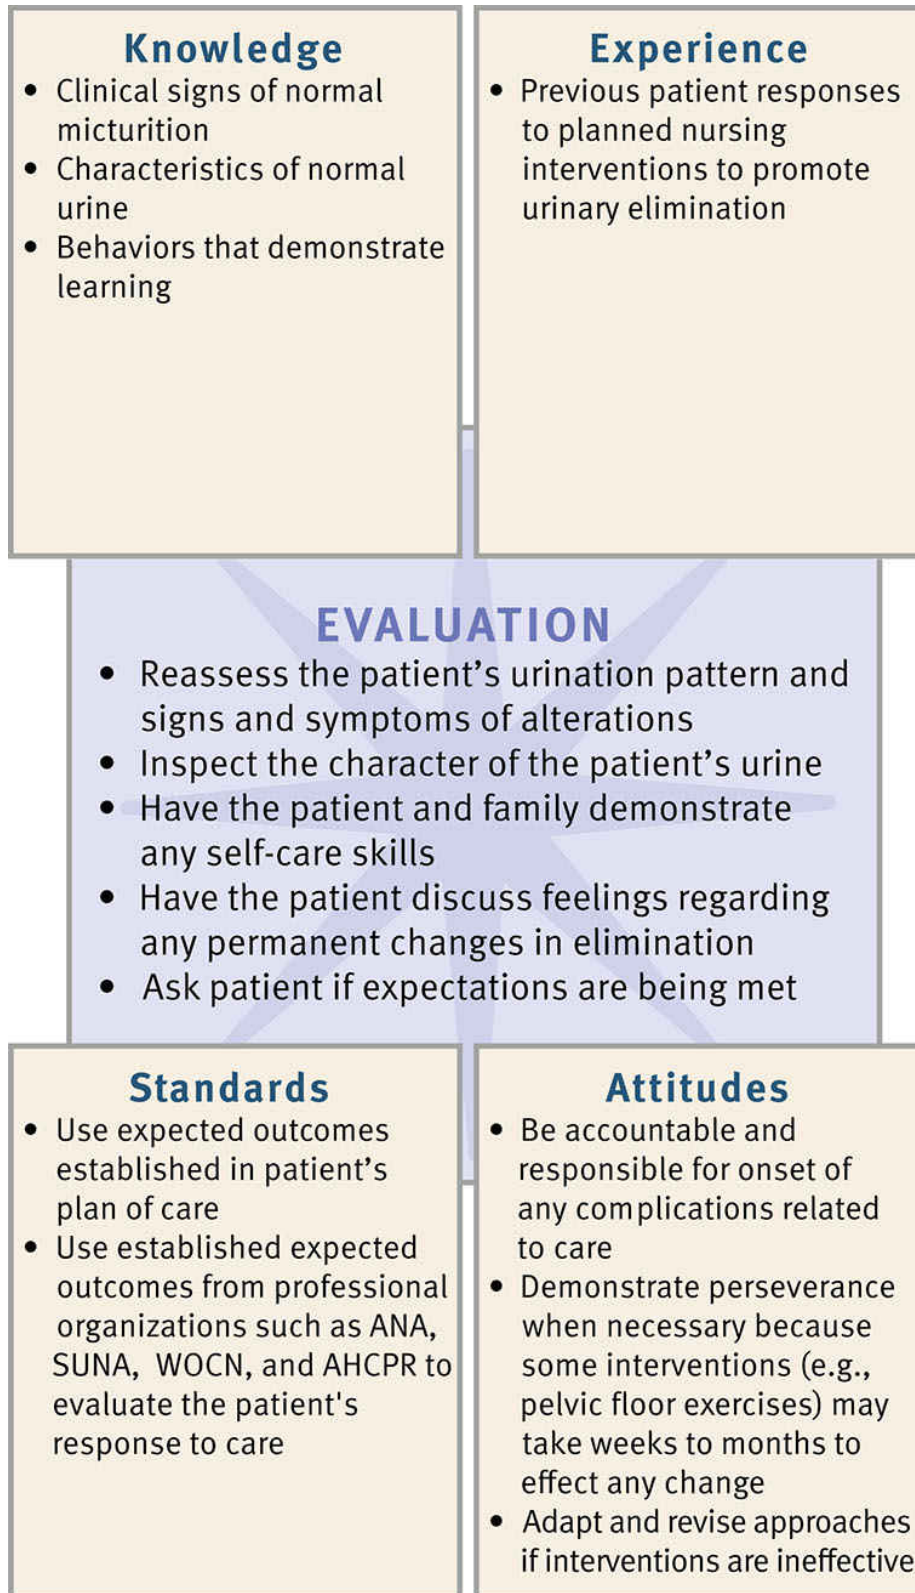

FIG. 46.17 Critical thinking model for urinary elimination evaluation. AHCPR, Agency for Health Care Policy and Research; ANA, American

Patient Outcomes

To evaluate the care plan use the expected outcomes developed during planning to determine whether interventions were effective. This evaluation process is dynamic. Information gathered is used to modify the plan of care to meet expected outcomes. Evaluate for changes in the patient's voiding pattern and/or presence of symptoms such as dysuria, urinary retention, and UI. If a behavioral plan is in effect, evaluate patient/caregiver adherence to the plan, such as toileting according to the schedule, or determine the number of incontinent episodes. Actual outcomes are compared with expected outcomes to determine success or partial success in achieving these outcomes. Examples of questions to ask for evaluation include:

- "Tell me, how frequently are you voiding now?" "How many times are you awakened from sleep with a strong urge to void?"
- "Do you continue to experience that sensation of urgency or need to rush to the toilet?"
- "How many episodes of urine leakage have you experienced over the past week?"
- "Do you have pain or burning when you pass urine?"

The effectiveness of an intervention may take place within a day or two, or it may take weeks or months to fully evaluate effectiveness. Evaluate initial adherence to dietary changes, understanding of instructions for pelvic muscle exercise, or effectiveness of antibiotic treatment for UTI in 1 to 2 days. Evaluation of the effectiveness of pelvic muscle exercises in decreasing urgency and incontinence will need to be weeks or months after therapy is started. Continuous evaluation, when possible, allows you to determine progress toward goals, encourage adherence, and revise the diagnosis and/or plan as needed.

Safety Guidelines for Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health

care team, assess and incorporate a patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember to follow points to ensure safe, individualized care:

- Follow principles of surgical and medical asepsis as indicated when performing catheterizations, handling urine specimens, or helping patients with their toileting needs.
- Identify patients at risk for latex allergies (i.e., patient history of hay fever; asthma; and allergies to certain foods such as bananas, grapes, apricots, kiwifruit, and hazelnuts).
- Identify patients with allergies to povidone-iodine. Provide alternatives such as chlorhexidine.

Skill 46.1. Collecting Midstream (Clean-Voided) Urine Specimen

Delegation and Collaboration

The skill of collecting urine specimens can be delegated to assistive personnel (AP). The nurse instructs the AP to:

- Obtain the specimens at a specified time when appropriate.
- Position patient as necessary when mobility restrictions are present.
- Report to the nurse if the urine is not clear (e.g., contains blood, cloudiness, or excess sediment).
- Report to the nurse when a patient is unable to initiate a stream or has pain or burning on urination.

Equipment

- Completed identification labels with appropriate patient identifiers
- Completed laboratory requisition, including patient identification, date, time, name of test, and source of culture
- Biohazard bag or container for delivery of specimen to laboratory (as specified by agency)

Clean-Voided Urine Specimen

- Commercial kit (Fig. 46.18) for clean-voided urine, containing:

FIG. 46.18 Commercial midstream urine collection kit.

- Sterile cotton balls or antiseptic towelettes
- Antiseptic solution (chlorhexidine or povidone-iodine solution)
- Sterile water or normal saline
- Sterile specimen container
- Urine cup
- Clean gloves
- Soap, water, washcloth, and towel
- Bedpan (for nonambulatory patient), specimen hat (for ambulatory patient)

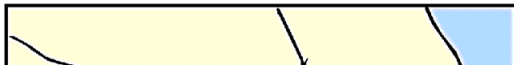

Sterile Urine Specimen From Urinary Catheter

- 20-mL Luer-Lok for routine urinalysis or 3-mL safety Luer-Lok syringe for culture
- Alcohol, chlorhexidine, or other disinfectant swab
- Clamp or rubber band

- Specimen container (nonsterile for routine urinalysis; sterile for culture)
- Clean gloves

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review health care provider's order.	Ensures accurate testing of specimen; order is needed to perform test.
3. Refer to agency procedures for specimen collection methods.	Agency policies may vary regarding collection and/or handling of specimens.
4. Assess patient's or family caregiver's knowledge, experience, and health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
5. Assess patient's ability to help with urine specimen collection; able to position self and hold container.	Determines degree of help patient requires.
6. Assess for signs and symptoms of UTI (frequency, urgency, dysuria, hematuria, flank pain, fever; cloudy malodorous urine).	May indicate need for health care provider intervention.
7. Assess patient's or family caregiver's understanding of purpose of test and method of collection.	Allows you to clarify misunderstanding; promotes patient cooperation.
Planning	
1. Perform hand hygiene. Close room door or bedside curtains around bed.	Reduces transmission of microorganisms. Provides privacy.
2. Organize equipment needed for procedure (see Fig. 46.18).	Facilitates organized completion of procedure.
3. Explain the procedure and what is required of the patient. Note: Mobile patients may be able to collect a clean-voided specimen in the bathroom.	Patients often prefer to obtain their own clean voided specimen but need appropriate education to correctly collect the sample.
Implementation	
1. Check labels and verify complete laboratory requisition for specimen container.	Organizes procedure.
2. Collect clean-voided urine specimen.	
a. Perform hand hygiene and apply clean gloves. Give patient cleaning towelette or towel, washcloth, and soap to clean perineum or help with cleaning perineum. Help bedridden patient onto bedpan to facilitate access to perineum. Remove and dispose of gloves and perform hand hygiene.	Reduces transfer of microorganisms. Patients prefer to wash their own perineal areas when possible. Cleaning prevents contamination of specimen from skin and surface bacteria after urine passes from urethra.
b. Using aseptic technique, open outer package of commercial specimen kit.	Maintains sterility of equipment.
c. Apply clean gloves.	Prevents contact of microorganisms on your hands.
d. Pour antiseptic solution over cotton balls (unless kit contains prepared antiseptic towelettes).	Cotton ball or towelette is used to clean perineum.
e. Open specimen container, maintaining sterility of inside specimen container, and place cap with sterile inside up. Do not touch inside of cap or container.	Contaminated specimen is most frequent reason for inaccurate reporting of urine C&S.
f. Use aseptic technique to help patient or allow patient to independently clean perineum and collect specimen. Amount of help needed varies with each patient. Inform patient that antiseptic solution will feel cold.	Maintains patient's dignity and comfort.
(1) Male:	
(a) Hold penis with one hand; using circular motion and antiseptic towelette, clean meatus, moving from center to outside 3 times with 3 different towelettes (see illustration). Have uncircumcised male patient retract foreskin for effective cleaning of urinary meatus and keep retracted during voiding. Return foreskin when done.	Reduces number of microorganisms at urethral meatus and moves from areas of least to most contamination. Return of foreskin prevents stricture of penis.
(b) If agency procedure indicates, rinse area with sterile water and dry with cotton balls or gauze pad.	Prevents contamination of specimen with antiseptic solution.
(c) After patient initiates urine stream into toilet, urinal, or bedpan, have him pass urine specimen container into stream and collect 90 to 120 ml. of urine (Pagana et al., 2019) (see illustration).	Initial urine flushes out microorganisms that normally accumulate at urinary meatus and prevents transfer into specimen.
(2) Female:	
(a) Either nurse or patient spreads labia minora with fingers of nondominant hand.	Provides access to urethral meatus.

Step	Rationale
	

STEP 2F(1)(A) Cleaning technique (male).

STEP 2F(1)(C) Collecting midstream urine specimen (male).

Table Continued

Step	Rationale
(b) With dominant hand clean urethral area with antiseptic swab (cotton ball or gauze). Move from front (above urethral orifice) to back (toward anus). Use fresh swab each time; clean 3 times; begin with labial fold farthest from you, then labial fold closest, and then down center (see illustration).	Prevents contamination of urinary meatus with fecal material. Cleaning down center last decreases contamination from labia.
(c) If agency procedure indicates, rinse area with sterile water and dry with cotton ball.	Prevents contamination of specimen with antiseptic solution.
(d) While continuing to hold labia apart, patient initiates urine stream into toilet or bedpan; after stream is achieved, pass specimen container into stream and collect 90 to 120 mL of urine (Pagana et al., 2019) (see illustration).	Initial stream flushes out resident microorganisms that accumulate at urethral meatus and prevents transfer into specimen.
g. Remove specimen container before flow of urine stops and before releasing labia or penis. Patient finishes voiding into bedpan or toilet. Offer to help with personal hygiene as appropriate.	Prevents contamination of specimen with skin flora. Prevents sediment from bladder getting into specimen.
h. Replace cap securely on specimen container, touching only outside.	Retains sterility of inside of container and prevents spillage of urine.
i. Clean urine from exterior surface of container.	Prevents transfer of microorganisms to others.
3. Collect urine from indwelling urinary catheter.	
a. Explain that you will use syringe without needle to remove urine through catheter port and that patient will not experience any discomfort.	Minimizes anxiety when you manipulate catheter and aspirate urine with syringe from catheter port.
b. Explain that you will need to clamp catheter for 10 to 15 minutes before obtaining urine specimen and that urine cannot be obtained from drainage bag.	Allows urine to accumulate in catheter. Urine in drainage bag is not considered sterile.
c. Perform hand hygiene and apply clean gloves. Clamp drainage tubing with clamp or rubber band for as long as 15 minutes below site chosen for withdrawal (see illustration).	Permits collection of fresh sterile urine in catheter tubing rather than draining into bag.
d. After 15 minutes, position patient so that catheter sampling port is easily accessible. Location of port is where catheter attaches to drainage bag tube (see Fig. 46-12). Clean port for 15 seconds with disinfectant swab and allow to dry.	Prevents entry of microorganisms into catheter.
e. Attach needleless Luer-Lok syringe to built-in catheter sampling port (see illustration). Some needleless ports use blunt plastic valve or slip-tip syringe inserted into port diaphragm.	Guideline recommends use of Luer-Lok needleless system. Needleless system prevents injury by needlestick.
f. Withdraw 3 mL for culture or 20 mL for routine urinalysis.	Allows collection of urine without contamination. Proper volume is needed to perform test.
g. Transfer urine from syringe into clean urine container for routine urinalysis or into sterile urine container for culture.	Prevents contamination of urine during transfer procedure.
h. Place lid tightly on container.	Prevents contamination of specimen by air and loss by spillage.
i. Unclamp catheter and allow urine to flow into drainage bag. Ensure that urine flows freely.	Allows urine to drain by gravity and prevents stasis of urine in bladder.
4. Securely attach label to container (not lid). If patient is female, indicate if she is menstruating. In presence of patient, complete label (two identifiers, specimen source, collection date and time) and attach to container. Attach completed laboratory requisition to container. Enclose specimen in a biohazard bag and send immediately to laboratory.	Incorrect patient identification could lead to diagnostic or therapeutic error (TJC, 2020). Bacteria multiply quickly. Specimen should be analyzed promptly for accurate results.
5. Dispose of soiled supplies. Remove and dispose of gloves and perform hand hygiene.	Prevents transmission of microorganisms.
6. Offer patient hand hygiene or provide time to wash hands.	Reduces transmission of microorganisms
7. Assist patient to comfortable position.	

Step	Rationale
	

STEP 2F(2)(B) Clean from front to back, holding labia apart.

STEP 2F(2)(D) Collecting midstream urine specimen (female).

Table Continued

Step	Rationale
8. Ensure that the nurse call system is in an accessible location and within patient's reach, and instruct patient in its use.	Provides for patient safety.
9. Send specimen and completed requisition to laboratory within 20 minutes. Refrigerate specimen if delay cannot be avoided.	Delay of analysis may significantly alter test results (Pagana et al., 2019).
Evaluation	
1. Inspect clean-voided specimen for contamination with toilet paper or stool.	Contaminants prevent specimen from being used.
2. Evaluate patient's urine C&S report for bacterial growth.	Routine cultures identify organism(s), and sensitivity study identifies antimicrobial medications that may be effective against pathogen.
3. Observe urinary drainage system in catheterized patient to ensure that it is intact and patent.	System must remain closed to remain sterile.
4. Use Teach-Back: "I want to be sure I explained the way to obtain a clean-voided specimen. Please repeat the steps back to me." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<ol style="list-style-type: none"> Urine specimen is contaminated with stool or toilet paper. <ul style="list-style-type: none"> Repeat patient instruction and specimen collection. If unable to obtain specimen through clean voiding, patient may need catheterization (see Skill 46.2). Urine culture reveals bacterial growth (determined by colony count of more than 10,000 organisms per milliliter). <ul style="list-style-type: none"> Report findings to health care provider. Administer medications as ordered. Monitor patient for fever and dysuria. Lumen leading to balloon that holds catheter in place is punctured. <ul style="list-style-type: none"> Notify health care provider. Prepare for removal of existing catheter and insertion of new catheter. 	
Recording and Reporting	
<ul style="list-style-type: none"> Record method used to obtain specimen, date and time collected, type of test ordered, laboratory receiving specimen, characteristics of specimen, and patient's tolerance to procedure of specimen collection. Document your evaluation of patient learning. Report any abnormal findings to health care provider, the type of urinalysis, and when specimen was sent to laboratory. 	
Home Care Considerations	
<ul style="list-style-type: none"> If patient is to collect specimen as outpatient, a clean technique may be used. Provide instruction for collection and appropriate equipment. Provide information about storing specimen until time for delivery to health care provider's office or hospital laboratory. 	
 <p>STEP 3C Rubber band used to clamp drainage tube.</p>	 <p>STEP 3E Access urinary catheter port with Luer-Lok syringe or syringe with blunt plastic valve.</p>

Skill 46.2. Inserting and Removing a Straight (Intermittent) or Indwelling Catheter

Delegation and Collaboration

The skill of inserting a straight or indwelling urinary catheter cannot be delegated to assistive personnel (AP). The nurse directs the AP to:

- Assist the nurse with patient positioning, focus lighting for the procedure, maintain privacy, empty urine from collection bag, and help with perineal care.
- Report postprocedure patient discomfort or fever to the nurse.
- Report abnormal color, odor, or amount of urine in drainage bag and whether the catheter is leaking or causes pain.

Equipment

- Catheter kit containing sterile items (**Note:** Catheter kits vary.)
 - Straight catheterization kit: single-lumen catheter (12 to 14 Fr), drapes (one fenestrated—has an opening in the center), sterile gloves, lubricant, cleansing solution incorporated in an applicator or to be added to cotton balls, and specimen container and label.
 - Indwelling catheterization kit (see Fig. 46.11: double-lumen catheter, drapes (one fenestrated—has an opening in the center), sterile gloves, lubricant, antiseptic cleansing solution incorporated in an applicator or to be added to cotton balls, specimen container and label, and a prefilled syringe with sterile water or normal saline (to inflate balloon). **Note:** Some kits contain a catheter with attached drainage bag; others contain only a catheter; others have no catheter.
- Sterile drainage tubing and bag (if not included in indwelling catheter insertion kit)
- Device to secure catheter (catheter strap or other device)
- Extra sterile gloves and catheter (*optional*)
- Clean gloves
- Basin with warm water, washcloth, towel, and soap for perineal care
- Flashlight or other additional light source
- Bath blanket, waterproof absorbent pad
- Measuring container for urine

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review patient's EHR, including health care provider's order and nurses' notes. Note previous catheterization, including catheter size, response of patient, and time of catheterization.	Identifies purpose of inserting catheter (such as for measurement of PVR, preparation for surgery, or specimen collection) and potential difficulty with catheter insertion.
3. Review EHR for any pathological conditions that may impair passage of catheter (e.g., enlarged prostate gland in men, urethral strictures).	Obstruction of urethra may prevent passage of catheter into bladder.
4. Assess patient's gender and age.	Assists with selection of catheter size.
5. Assess patient's or family caregiver's knowledge, experience, and health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
6. Ask patient and check EHR for history of allergies. Check allergy bracelet.	Catheter made of different material is needed if patient has latex allergy.
7. Perform hand hygiene. Assess patient's weight, level of consciousness, developmental level, ability to cooperate, and mobility.	Determines positioning to use for catheterization; indicates how much help is needed to properly position patient, ability of patient to cooperate during procedure, and level of explanation needed.
8. Assess for pain and bladder fullness. Palpate bladder over symphysis pubis or use bladder scanner (if available) (see Box 46.11).	Palpation of full bladder causes pain and/or urge to void, indicating full or overfull bladder.
9. Apply clean gloves. Inspect perineal region, observing for perineal anatomical landmarks, erythema, drainage or discharge, and odor. Remove and dispose of gloves and perform hand hygiene.	Assessment of perineum (especially female perineal landmarks) improves accuracy and speed of catheter insertion. Reduces transmission of microorganisms.
10. Assess patient's knowledge, prior experience with catheterization, and feelings about procedure.	Reveals need for patient instruction and/or support.
Planning	
1. Close room door or curtains around bed.	Provides privacy.
2. Organize and set up any equipment needed to perform the procedure.	Organization ensures efficiency in completing the skill.
CLINICAL DECISION: Some patients may be unable to assume positioning independently. Arrange for extra assistance before initiating the procedure.	
3. Explain procedure to patient.	Reduces patient anxiety and promotes cooperation.

Table Continued

Step	Rationale
Implementation	
<p>1. Check patient's plan of care for size and type of catheter (if this is a reinsertion). Use smallest-size catheter possible. Size 14 to 16 Fr most common for adults; older adults (12 to 14 Fr); larger sizes (20 to 22 Fr) are needed in special circumstances, such as after urological surgery or in the presence of gross hematuria.</p>	<p>Ensures that patient receives correct size and type of catheter. Larger catheter diameters increase the risk for urethral trauma. Small catheter allows for adequate drainage of periurethral glands.</p>
<p>2. Perform hand hygiene.</p>	<p>Reduces transmission of microorganisms.</p>
<p>3. Raise bed to appropriate working height. If side rails in use, raise side rail on opposite side of bed and lower side rail on working side.</p>	<p>Promotes good body mechanics. Use of side rails in this manner promotes patient safety.</p>
<p>4. Place waterproof pad under patient.</p>	<p>Prevents soiling bed linen.</p>
CLINICAL DECISION: Obtain help to position and support patients who are weak, frail, obese, or confused.	
5. Position patient:	
a. Female patient:	
<p>(1) Help to dorsal recumbent position (on back with knees flexed). Ask patient to relax thighs so that you can rotate hips.</p>	<p>Exposes perineum and allows hip joints to be externally rotated.</p>
<p>(2) Alternate female position: Position side-lying (Sims') position with upper leg flexed at knee and hip. Support patient with pillows if necessary to maintain position.</p>	<p>Alternate position is more comfortable if patient cannot abduct leg at hip joint (e.g., patient has arthritic joints or contractures).</p>
b. Male patient:	
<p>(1) Position supine with legs extended and thighs slightly abducted.</p>	<p>Comfortable position for patient and aids in visualization of penis.</p>
6. Drape patient	
a. Female	
<p>(1) Drape with bath blanket. Place blanket diamond fashion over patient, with one corner at patient's midsections, side corners over each thigh and abdomen, and last corner over perineum (see illustration).</p>	
b. Male	
<p>(1) Drape patient by covering upper part of body with small sheet or towel; drape with separate sheet or bath blanket so that only perineum is exposed (see illustration).</p>	
 <p data-bbox="354 1724 678 1738">STEP 6A(1) Female patient draped and in dorsal recumbent position.</p>	 <p data-bbox="1052 1184 1260 1199">STEP 6B(1) Drape male patient with blankets.</p>

Step	Rationale
Table Continued	

Step	Rationale
7. Apply clean gloves. Clean perineal area with soap and water, rinse, and dry (see Chapter 40). Use gloves to examine patient and identify urinary meatus. Remove and discard gloves. Perform hand hygiene.	Hygiene before initiating aseptic catheter insertion removes secretions, urine, and feces that could contaminate sterile field and increase risk for catheter-associated urinary tract infection (CAUTI). Perform hand hygiene immediately before catheter insertion (Gould et al., 2017).
8. Position portable light to illuminate genitals or have assistant available to hold light.	Adequate visualization of urinary meatus assists with accuracy of catheter insertion.
9. Open outer wrapping of catheterization kit. Place inner wrapped catheter kit tray on clean, accessible surface such as bedside table or, if possible, between patient's open legs. Patient size and positioning dictate exact placement.	Provides easy access to supplies during catheter insertion.
10. Open inner sterile wrap covering tray containing catheterization supplies using sterile technique (see Chapter 28). Fold back each flap of sterile covering with first flap opened away from you, next two flaps open to each side one at a time, and last flap opened toward patient.	Sterile wrap serves as sterile field. Sequence prevents you from reaching over sterile field.
a. Indwelling catheterization open system: Open separate package containing drainage bag, check to make sure that clamp on drainage port is closed, and place drainage bag and tubing in easily accessible location. Open outer package of sterile catheter, maintaining sterility of inner wrapper (see Chapter 28).	Open drainage bag systems have separate sterile packaging for sterile catheter, drainage bag and tubing, and insertion kit.
b. Indwelling catheterization closed system: All supplies are in sterile tray and arranged in sequence of use.	Closed drainage bag systems have catheter preattached to drainage tubing and bag.
c. Straight catheterization: All needed supplies are in sterile tray that contains supplies and can be used for urine collection.	
11. Apply sterile gloves.	Maintains surgical asepsis.
12. <i>Option:</i> Apply sterile drape with ungloved hands when drape is packed as first item. Touch only 1-inch edges of drape. Then apply sterile gloves.	Maintains surgical asepsis.
13. Drape perineum, keeping gloves and working surface of drape sterile.	Sterile drapes provide sterile field over which you will work during catheterization.
a. Drape female:	
(1) Pick up square sterile drape touching only edges (2.5 cm [1 inch]).	
(2) Allow drape to unfold without touching unsterile surfaces. Allow top edge of drape (2.5 to 5 cm [1 to 2 inches]) to form cuff over both hands.	When creating cuff over sterile gloved hands, sterility of gloves and workspace is maintained.
(3) Place drape with shiny side down on bed between patient's thighs. Slip cuffed edge just under buttocks as you ask patient to lift hips. Take care not to touch contaminated surfaces or patient's thighs with sterile gloves. If gloves are contaminated, remove and apply new pair.	
(4) Pick up fenestrated sterile drape out of tray. Allow drape to unfold without touching unsterile surfaces. Allow top edge of drape to form cuff over both hands. Apply drape over perineum so that opening is over exposed labia (see illustration).	Opening in drape creates sterile field around labia.

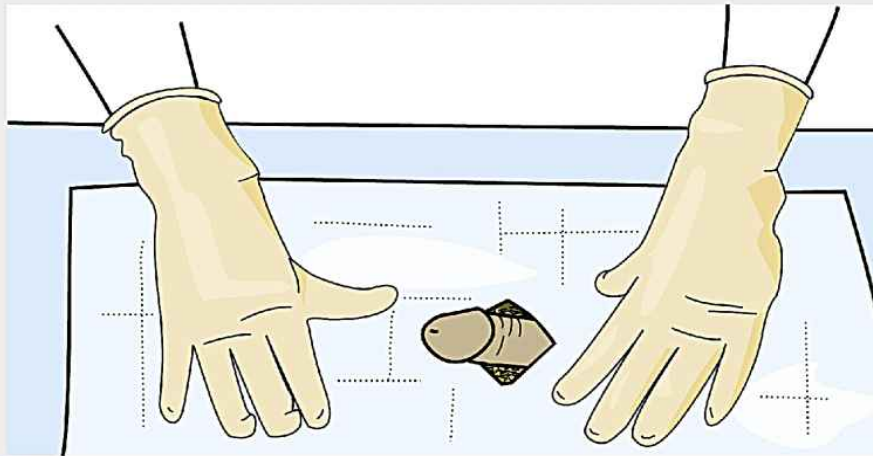

Step	Rationale
	

STEP 13A(4) Place sterile fenestrated drape (with opening in center) over female's perineum.

Table Continued

Step	Rationale
b. Drape Male:	
(1) Use of square drape is optional; you may apply fenestrated drape instead.	
(2) Pick up edges of square drape and allow to unfold without touching unsterile surfaces. Place over thighs, with shiny side down, just below penis. Take care not to touch contaminated surfaces with sterile gloves.	
(3) Place fenestrated drape with opening centered over penis (see illustration).	
14. Move tray closer to patient. Arrange remaining supplies on sterile field, maintaining sterility of gloves. Place sterile tray with cleaning solution (premoistened swab sticks or cotton balls, forceps, and solution), lubricant, catheter, and prefilled syringe for inflating balloon (indwelling catheterization only) on sterile drape.	Provides easy access to supplies during catheter insertion and helps to maintain aseptic technique. Appropriate placement is determined by size of patient and position during catheterization.
a. If kit contains sterile cotton balls, open package of sterile antiseptic solution and pour over cotton balls. Some kits contain package of premoistened swab sticks. Open end of package for easy access (see illustration).	Use of sterile supplies and antiseptic solution reduces risk of CAUTI (Gould et al., 2017)
b. Open sterile specimen container if specimen is to be obtained (see Skill 46.1).	Makes container accessible to receive urine from catheter if specimen is needed.
c. For indwelling catheterization, open sterile inner wrapper of catheter and leave catheter on sterile field. If part of closed system kit, remove tray with catheter and preattached drainage bag and place on sterile drape. Make sure that clamp on drainage port of bag is closed. If needed and if part of sterile tray, attach catheter to drainage tubing.	Indwelling catheterization trays vary. Some have preattached catheters; others need to be attached but are part of the sterile tray; others do not have catheter or drainage system as part of tray.
d. Open packet of lubricant and squeeze out on sterile field. Lubricate catheter tip by dipping it into water-soluble gel 2.5 to 5 cm (1 to 2 inches) for women and 12.5 to 17.5 cm (5 to 7 inches) for men (see illustration).	Lubrication minimizes trauma to urethra and discomfort during catheter insertion. Male catheter needs enough lubricant to cover length of catheter inserted.

STEP 13B(2) Drape male with fenestrated drape.

Step	Rationale
	

STEP 14A Sterile kit includes antiseptic swabs.

STEP 14D Lubricate catheter.

Table Continued

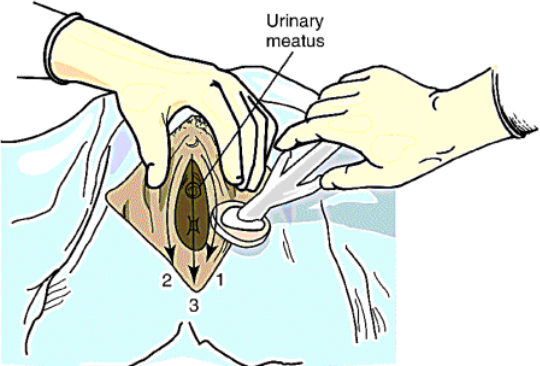

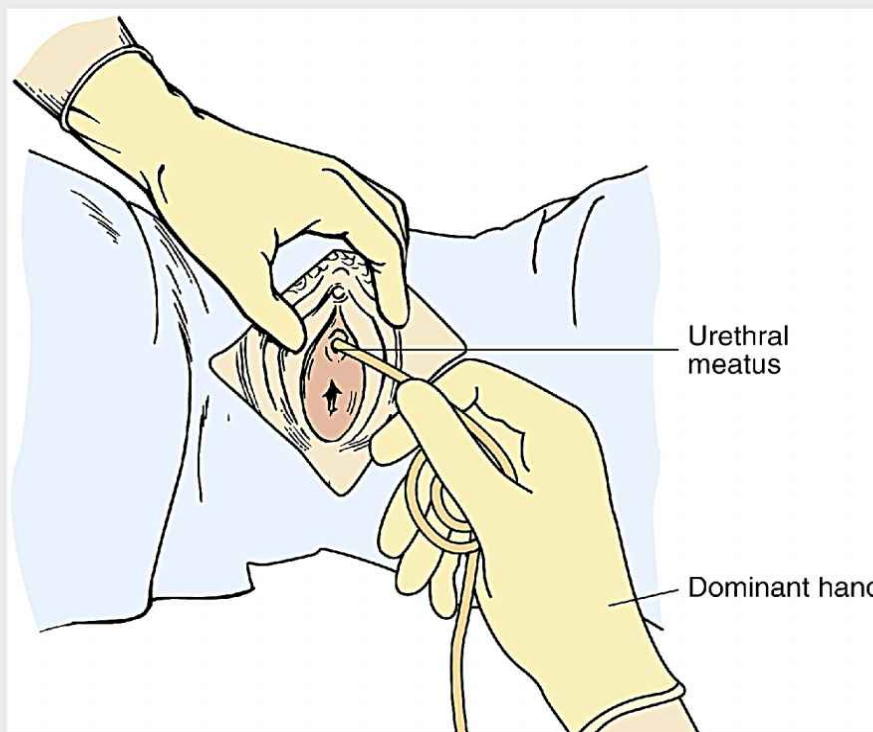

Step	Rationale
CLINICAL DECISION: Pretesting a balloon on an indwelling catheter by injecting fluid from the prefilled sterile normal saline syringe into the balloon port is no longer recommended . Testing the balloon may distort and stretch it and lead to damage, causing increased trauma on insertion.	
15. Clean urethral meatus:	
a. Female patient:	
(1) Separate labia with fingers of nondominant hand (now contaminated) to fully expose urethral meatus.	Optimal visualization of urethral meatus is possible.
(2) Maintain position of nondominant hand throughout procedure.	Closure of labia during cleaning means that area is contaminated and requires cleaning procedure to be repeated.
(3) Holding forceps in dominant hand, pick up one moistened cotton ball or pick up one swab stick at a time. Clean labia and urinary meatus from clitoris toward anus. Use new cotton ball or swab for each area that you clean. Clean by wiping far labial fold, near labial fold, and last, directly over center of urethral meatus (see illustration).	Front-to-back cleaning moves from area of least contamination toward highly contaminated area. Follows principles of medical asepsis (see Chapter 28). Dominant gloved hand remains sterile.
b. Male patient:	
(1) With nondominant hand (now contaminated) retract foreskin (if uncircumcised) and gently grasp penis at shaft just below glans. Hold shaft of penis at right angle to body. This hand remains in this position for remainder of procedure.	When grasping shaft of penis, avoid pressure on dorsal surface to prevent compression of urethra. Losing grasp during cleaning means that area is contaminated and requires cleaning procedure to be repeated.
(2) Using uncontaminated dominant hand, clean meatus with cotton balls/swab sticks, using circular strokes, beginning at meatus and working outward in spiral motion.	Circular cleaning pattern follows principles of medical asepsis (see Chapter 28).
(3) Repeat cleaning 3 times using clean cotton ball/swab stick each time (see illustration).	
16. Pick up and hold catheter 7.5 to 10 cm (3 to 4 inches) from catheter tip with catheter loosely coiled in palm of hand. If catheter is not attached to drainage bag, make sure to position urine tray so that end of catheter can be placed there once insertion begins.	Holding catheter near tip allows for its easier manipulation during insertion. Coiling catheter in palm prevents distal end from striking nonsterile surface.
 <p data-bbox="370 1318 532 1335">STEP 15A(3) Clean female perineum.</p>	 <p data-bbox="1073 1146 1263 1163">STEP 15B(3) Clean male urinary meatus.</p>

Table Continued

Step	Rationale
17. Insert catheter. Explain to patient that feeling of discomfort or pressure may be experienced as catheter is inserted into urethra. This sensation is normal and will go away quickly.	Helps to minimize patient anxiety.
a. Female patient:	
(1) Ask patient to bear down gently and slowly insert catheter through urethral meatus (see illustration).	Bearing down may help visualize urinary meatus and promotes relaxation of external urinary sphincter, aiding in catheter insertion.
(2) Advance catheter total of 5 to 7.5 cm (2 to 3 inches) or until urine flows out of catheter. When urine appears, advance catheter another 2.5 to 5 cm (1 to 2 inches). Do not use force to insert catheter.	Urine flow indicates that catheter tip is in bladder or lower urethra.
(3) Release labia and hold catheter securely with nondominant hand.	Prevents accidental expulsion of catheter from the patient's bladder.
b. Male patient	
(1) Lift penis to position perpendicular (90 degrees) to patient's body and apply gentle upward traction.	Straightens urethra to ease catheter insertion.
(2) Ask patient to bear down as if to void, and slowly insert catheter through urethral meatus (see illustration).	Relaxation of external sphincter aids in insertion of catheter.

STEP 17A(1) Insert catheter into female urinary meatus.

Step	Rationale

Apply slight
upward traction
of penis

STEP 17B(2) Insert catheter into male urinary meatus.

Step

Rationale

Bladder

Catheter tip

Bifurcation

STEP 17B(4) Male anatomy with correct catheter insertion to bifurcation.

Table Continued

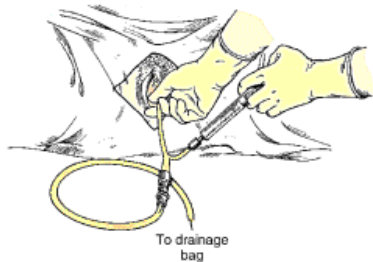

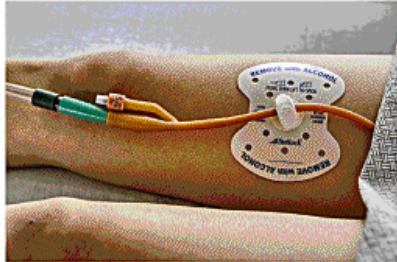

Step	Rationale
(3) Advance catheter 17 to 22.5 cm (7 to 9 inches) or until urine flows out end of catheter.	Length of male urethra varies. Flow of urine indicates that tip of catheter is in bladder or urethra but not necessarily that balloon part of indwelling catheter is in bladder.
(4) Stop advancing with straight catheter. When urine appears in indwelling catheter, advance it to bifurcation (inflation and deflation ports exposed) (see illustration).	Further advancement of catheter to bifurcation of drainage and balloon inflation port ensures that balloon part of catheter is not still in prostatic urethra.
(5) Lower penis and hold catheter securely in nondominant hand.	Prevents accidental expulsion of catheter from the patient's bladder.
18. Allow bladder to empty fully unless agency policy restricts maximum volume of urine drained (see agency policy).	There is no definitive evidence regarding whether there is benefit in limiting maximal volume drained.
19. Collect urine specimen as needed (see Skill 46.1). Fill specimen container to 20 to 30 ml. by holding end of catheter over cup. Set aside. Keep end of catheter sterile.	Sterile specimen for culture analysis can be obtained.
20. <i>Option for straight catheterization:</i> When urine stops flowing, withdraw catheter slowly and smoothly until removed.	Minimizes trauma to urethra.
21. Inflate indwelling catheter balloon with amount of fluid designated by manufacturer.	Indwelling catheter balloon should not be underinflated. Underinflation causes balloon distortion and potential bladder damage.
a. Continue to hold catheter with nondominant hand.	Holding on to catheter before inflating balloon prevents expulsion of catheter from urethra.
b. With free dominant hand, connect prefilled syringe to injection port at end of catheter.	
c. Slowly inject total amount of solution (see illustration).	Full amount of solution needed to inflate balloon properly.
CLINICAL DECISION: <i>If patient reports sudden pain during inflation of a catheter balloon or when resistance is felt when inflating the balloon, stop inflation, allow the fluid from the balloon to flow back into the syringe, advance catheter farther, and reinflate balloon. The balloon may have been inflating in the urethra. If pain continues, remove catheter and notify the health care provider.</i>	
d. After inflating catheter balloon, release catheter from nondominant hand. Gently pull catheter until resistance is felt. Then advance catheter slightly.	By moving catheter slightly back into bladder, pressure on bladder neck is avoided.
e. Connect drainage tubing to catheter if it is not already preconnected.	
22. Secure indwelling catheter with catheter strap or other securement device. Leave enough slack to allow leg movement. Attach securement device at tubing just above catheter bifurcation.	Securing catheter reduces risk of movement, urethral erosion, CAUTI, or accidental catheter removal (Gould et al., 2017; McNeill, 2017). Attachment of securement device at catheter bifurcation prevents occlusion of catheter.
a. Female patient	
(1) Secure catheter tubing to inner thigh, allowing enough slack to prevent tension (see illustration).	
b. Male patient	
(1) Secure catheter tubing to upper thigh (see illustration) or lower abdomen (with penis directed toward chest). Allow slack in catheter so that movement does not create tension on catheter.	Anchoring catheter reduces traction on urethra and minimizes urethral injury (Gould et al., 2017; McNeill, 2017).
(2) If retracted, replace foreskin over glans penis.	Leaving foreskin retracted can cause discomfort and dangerous edema.
 <p>STEP 21C Inflate balloon (indwelling catheter).</p>	 <p>STEP 22A(1) Secure indwelling catheter on female with adhesive securement device.</p>

Table Continued

Step	Rationale
23. Clip drainage tubing to edge of mattress. Position drainage bag below level of bladder by attaching to bedframe (Gould et al., 2017). Do not attach to side rails of bed, and do not rest on floor (see illustration).	Keeping the collection bag below the level of the bladder at all times prevents backflow into bladder, which can cause risk for CAUTI (Gould et al., 2017). Bags attached to movable objects such as side rail increase risk for urethral trauma because of pulling or accidental dislodgment.
24. Check to ensure that there is no obstruction to urine flow. Coil excess tubing on bed and fasten to bottom sheet with clip or other securement device.	Keeping the catheter and collecting tube free from kinking may reduce risk of CAUTI (Gould et al., 2017).
25. Provide perineal hygiene as needed. Help patient to comfortable position.	Promotes patient comfort
26. Dispose of supplies in appropriate receptacles.	Reduces transmission of microorganisms.
27. If ordered, label and bag specimen according to agency policy. Label specimen in front of patient. Send to laboratory as soon as possible.	Fresh urine specimen ensures more accurate findings. Labeling ensures that diagnostic results will be connected to correct patient (TJC, 2020).
28. Measure urine and record.	Provides baseline for urine output.
29. Remove and dispose of gloves and perform hand hygiene.	Reduces transmission of infection.
30. Raise side rails (as appropriate) and lower bed to lowest position. Be sure nurse call system is in an accessible location within patient's reach.	Promotes patient comfort and safety. Ensures patient can call for assistance if needed.
Evaluation	
1. Palpate bladder for distention or use bladder scan (see Box 46.11) as per agency protocol.	Determines whether distention is relieved.
2. Ask patient to describe level of comfort.	Determines whether patient's sensation of discomfort or fullness has been relieved.
3. Indwelling catheter: Observe character and amount of urine in drainage system.	Determines whether urine is flowing adequately.
4. Indwelling catheter: Determine that there is no urine leaking from catheter or tubing connections.	Prevents injury to patient's skin and ensures closed sterile system.
5. Use Teach-Back: "I want to be sure I explained clearly about your urinary catheter and some things you can do to ensure the urine flows out of the catheter. Tell me what you can do to keep the urine flowing." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
 <p data-bbox="363 1304 586 1318">STEP 22B(1) Secure indwelling catheter on male.</p>	 <p data-bbox="992 1472 1203 1486">STEP 23 Drainage Bag below level of bladder.</p>

Table Continued

Step	Rationale
<p>Unexpected Outcomes and Related Interventions</p> <ol style="list-style-type: none"> Catheter goes into vagina. <ul style="list-style-type: none"> Leave first catheter in vagina so that you can correctly identify the urinary meatus. Clean urinary meatus again. Using another catheter kit, reinsert sterile catheter into meatus (check agency policy). Note: If gloves become contaminated, start procedure again. Remove first catheter that was left in vagina after successful insertion of second catheter. Sterility is broken during catheterization by nurse or patient. <ul style="list-style-type: none"> Replace gloves if contaminated and start over. If patient touches sterile field but equipment and supplies remain sterile, avoid touching that part of sterile field. If equipment and/or supplies become contaminated, replace with sterile items or start over with new sterile kit. Patient reports bladder discomfort, and catheter is patent as evidenced by adequate urine flow. <ul style="list-style-type: none"> Check catheter to ensure that there is no traction on it. Notify health care provider. Patient may be experiencing bladder spasms or symptoms of UTI. Monitor catheter output for color, clarity, odor, and amount. 	
<p>Recording and Recording</p> <ul style="list-style-type: none"> Record reason for catheterization, type and size of catheter inserted, amount of fluid used to inflate balloon, specimen collection (if applicable), characteristics and amount of urine, patient's response to procedure, and evaluation of patient learning. Record I&O on flow sheet record. Report at change of shift reason for catheterization, type and size of catheter inserted, amount of fluid used to inflate balloon, specimen collection (if applicable), characteristics and amount of urine, patient's response to procedure, and any education. Report to health care provider persistent catheter-related pain and discomfort. <p>Home Care Considerations</p> <ul style="list-style-type: none"> Patients who are at home may use a leg bag during the day and switch to a larger-volume bag at night. If a patient changes from a large-volume bag to a leg bag, instruct in the importance of handwashing and cleansing the connection ports with alcohol before changing bags. Teach patients and family caregivers how to properly position the drainage bag, empty a urinary drainage bag, and observe urine color, clarity, odor, and amount. Educate patients and/or caregivers about the signs of UTI and troubleshooting techniques for a leaking catheter. Arrange for home delivery of catheter supplies, always ensuring that there is at least one extra catheter, insertion kit, and drainage bag in the home. 	

Skill 46.3. Care and Removal of an Indwelling Catheter

Delegation and Collaboration

The skill of performing routine catheter care can be delegated to assistive personnel (AP). Depending on agency policy, the skill of removing an indwelling catheter may be delegated to AP; however, a nurse must first assess a patient's status and verify the order. The nurse directs the AP to:

- Report characteristics of the urine (color, clarity, odor, and amount) before and after removal.
- Report the condition of the patient's genital area (e.g., color, rashes, open areas, odor, soiling from fecal incontinence, trauma to tissues around urinary meatus).
- If allowed to remove catheter per agency policy, check size of balloon and syringe needed to deflate balloon; report if balloon does not deflate and if there is bleeding after removal.
- Report time and amount of first voiding after catheter is removed.
- Report if patient experiences fever, chills, change in mental status, burning, flank or back pain, and/or hematuria (signs of UTI); dysuria after catheter removal.

Equipment

Catheter Care

- Clean gloves
- Waterproof pad
- Bath blanket
- Basin with warm water, washcloth, towel, and soap for perineal care

Catheter Removal

- Clean gloves
- 10-mL syringe or larger without a needle (size depends on volume of solution used to inflate the balloon)
- Graduated cylinder to measure urine
- Waterproof pad
- Toilet, bedside commode, urine “hat,” urinal, or bedpan
- Bladder scanner (as indicated)

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Perform hand hygiene. Apply clean gloves.	Reduces transmission of microorganisms.
3. Assess need for catheter care:	
a. Observe urinary output and urine characteristics.	Sudden decrease in urine output may indicate occlusion of catheter. Cloudy, foul-smelling urine associated with other systemic symptoms may indicate CAUTI.
b. Assess for history or presence of bowel incontinence.	Most common bacteria to cause CAUTI are <i>Escherichia coli</i> , a major colonizer of the bowel; thus, fecal incontinence increases risk for CAUTI (Fekete, 2018).
c. Position patient, retract labia or foreskin to observe for any discharge, redness, bleeding, or presence of tissue trauma around urethral meatus (this may be deferred until catheter care).	Indicates inflammatory process, possible infection, or erosion of catheter through urethra.
d. Remove and dispose of gloves; perform hand hygiene.	Reduces transmission of microorganisms.
4. Assess need for catheter removal:	
a. Review patient's electronic health record (EHR), including health care provider's order and nurses' notes. Note length of time catheter has been in place.	Catheters in place for more than a few days cause higher risk for catheter encrustation and UTI.
b. Perform hand hygiene and apply clean gloves. Assess urine color, clarity, odor, and amount. Note any urethral discharge, irritation of genital region, or trauma to urinary meatus (this may be deferred until just before removal). Remove and dispose of gloves. Perform hand hygiene.	May be indicator of inflammation or UTI and source of discomfort during catheter removal. Reduces transmission of microorganisms.
c. Determine size of catheter inflation balloon by looking at balloon inflation valve.	Determines size of syringe needed to deflate balloon and amount of fluid expected in syringe after deflation.
5. Assess patient's or family caregiver's knowledge, health literacy, and prior experience with catheter care and/or catheter removal.	Ensures patient has the capacity to obtain, communicate, process and understand basic health information (CDC, 2019).
Planning	
1. Close room door and bedside curtain	Provides privacy.
2. Obtain and organize equipment for perineal care/catheter removal at bedside.	Ensures more efficient procedure.
3. Explain procedure to patient. Discuss signs and symptoms of UTI. If applicable, teach patient or family caregiver how to perform catheter hygiene.	Reduces anxiety and promotes cooperation. Self-care supports patient's sense of autonomy.
Implementation	
1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Raise bed to appropriate working height. If side rails are raised, lower side rail on working side.	Promotes use of proper body mechanics.
3. Position patient with waterproof pad under buttocks and cover with bath blanket, exposing only genital area and catheter (see Skill 46.2).	Shows respect for patient dignity by exposing only genital area and catheter.
a. Female in dorsal recumbent position.	
b. Male in supine position.	
4. Apply clean gloves.	Reduces transmission of microorganisms.
5. Remove catheter securement device while maintaining connection with drainage tubing.	Provides ability to easily clean around catheter and to remove it.
6. Catheter care:	
a. Female: Use nondominant hand to gently separate labia to fully expose urethral meatus and catheter. Maintain position of hand throughout procedure.	Provides full visualization of urethral meatus. Full separation of labia prevents contamination of meatus during cleaning.
b. Male: Use nondominant hand to retract foreskin if not circumcised and hold penis at shaft just below glans. Maintain hand position throughout procedure.	Retraction of foreskin provides full visualization of urethral meatus.
c. Grasp catheter with two fingers of nondominant hand to stabilize it.	Prevents unnecessary traction on catheter. Pulling on catheter is cause of discomfort for patient and can damage urethra and bladder neck.

Table Continued

Step	Rationale
d. If not performed earlier, assess urethral meatus and surrounding tissues for inflammation, swelling, discharge, or tissue trauma, and ask patient if burning or discomfort is present.	Determines frequency and type of ongoing care required. Indicates possibility of CAUTI or catheter erosion through urethra.
e. Provide perineal hygiene using mild soap and warm water (see Chapter 40). <i>Option:</i> Use chlorhexidine gluconate (CHG) 2% cloth.	Antiseptic cleaners have not been shown to definitively decrease CAUTI; mild soap and water are appropriate (McNeill, 2017). Although chlorhexidine 2% cloth can be used, there is no clear scientific evidence for use of antiseptics versus nonantiseptics to reduce rates of CAUTI (Fasugba et al., 2017).
f. Using clean washcloth or CHG cloth, clean catheter.	
(1) Starting close to urinary meatus, clean catheter in circular motion along its length for about 10 cm (4 inches), moving away from body (see illustration). Remove all traces of soap. <i>For male patients:</i> Reduce or reposition foreskin after care.	Reduces presence of secretions or drainage on outside catheter surface.
g. Reapply catheter securement device. Allow slack in catheter so that movement does not create tension on it.	Securing indwelling catheter reduces risk of urethral trauma, urethral erosion, CAUTI, or accidental removal (Gould et al., 2017; McNeill, 2017).
7. Routinely check drainage tubing and bag.	
a. Catheter is secured to upper thigh.	Maintains unobstructed flow of urine out of bladder (Gould et al., 2017; McNeill, 2017).
b. Tubing is coiled and secured onto bed linen.	
c. Tubing is not looped or positioned above level of bladder.	
d. Tubing is not kinked or clamped.	
e. Drainage bag is positioned below level of bladder with urine flowing freely into bag.	
f. Drainage bag is not overfull. Empty drainage bag when ½ full.	Overfull drainage bag creates tension and pulls on catheter, resulting in trauma to urethra and/or urinary meatus. Facilitates unobstructed flow of urine (Gould et al., 2017).

Step	Rationale
	

STEP 06(1) Clean Catheter starting at meatus and moving downward while holding it securely.

Table Continued

Step	Rationale
8. Catheter removal: (Perform catheter care; see Step 6 before catheter removal.)	
a. With clean gloves still on, move syringe plunger up and down to loosen and then pull it back to 0.5 mL. Insert hub of syringe into inflation valve (balloon port). Allow balloon fluid to drain into syringe automatically by itself. Syringe should fill. Make sure that entire amount of fluid is removed by comparing removed amount to volume needed for inflation.	Partially inflated balloon can traumatize urethral wall during removal. Passive drainage of catheter balloon prevents formation of ridges in balloon. These ridges can cause discomfort or trauma during removal.
b. Pull catheter out smoothly and slowly. Examine it to ensure that it is whole. Catheter should slide out easily. Do not use force. If you note any resistance, repeat Step 8a to remove remaining inflation fluid.	A nonwhole catheter means that pieces of catheter may still be in bladder. Notify health care provider immediately.
c. Wrap contaminated catheter in waterproof pad. Unhook collection bag and drainage tubing from bed.	Promotes safety and reduces the risk for transmission of microorganisms.
d. Empty, measure, and record urine present in drainage bag.	Documents urinary output.
e. Encourage patient to maintain or increase fluid intake (unless contraindicated by restrictions).	Maintains normal urine output.
f. Initiate voiding record or bladder diary. Instruct patient to tell you when need to empty bladder occurs, and that all urine needs to be measured. Make sure that patient understands how to use collection container.	Evaluates bladder function.
g. Explain that many patients experience mild burning, discomfort, or small-volume voiding with first voiding, which soon subsides.	Burning results from urethral irritation.
h. Measure PVR volume (if ordered) (see Box 46.11) within 5 to 15 minutes after helping the patient to void.	Provides the most reliable PVR reading (Huetber and McCance, 2017).
i. Inform patient to report any signs of UTI.	Promotes patient safety.
j. Ensure easy access to toilet, commode, bedpan, or urinal. Place urine "hat" on toilet seat if patient is using toilet. Place nurse call system within easy reach.	Reduces incidence of falls during toileting. Urine hat collects first voided urine.
9. Provide patient personal hygiene as needed. Dispose of all contaminated supplies in appropriate receptacle, remove and dispose of gloves, and perform hand hygiene.	Promotes patient comfort and safety. Reduces transmission of microorganisms.
10. Help patient to comfortable position. Raise side rails (as appropriate) and lower bed to lowest position. Be sure nurse call system is in an accessible location within patient's reach.	Promotes patient comfort and safety. Ensures patient can call for assistance if needed.
Evaluation	
1. Inspect catheter and genital area for soiling, irritation, and skin breakdown. Ask patient about discomfort.	Determines whether area is cleaned properly and/or if patient has any irritation.
2. Observe time and measure amount of first voiding after catheter removal.	Indicates return of bladder function after catheter removal.
3. Evaluate patient for signs and symptoms of UTI.	Any patient who has a catheter or has had a catheter removed recently is at risk for UTI.
4. Use Teach-Back: "I want to be sure I explained clearly the signs of a urinary tract infection and some things you should do to prevent infection. Tell me some ways in which you can prevent a urinary tract infection." Revise your instruction now or develop plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Normal saline from inflation balloon does not return into syringe.</p> <ul style="list-style-type: none"> • Reposition patient; ensure that catheter is not pinched or kinked. • Remove syringe. Attach new syringe and allow enough time for passive emptying. • Attempt to empty balloon by gently pulling back on syringe plunger. • If catheter balloon does not deflate, do not cut balloon inflation valve to drain fluid. Notify health care provider. <p>2. Patient has cloudy foul-smelling urine, fever, chills, dysuria, flank pain, back pain, hematuria, urgency, frequency, lower abdominal pain, change in mental status, and lethargy.</p> <ul style="list-style-type: none"> • Assess for bladder distention and tenderness. • Monitor vital signs and urine output. • Report findings to health care provider; signs and symptoms may indicate UTI. • Consult with health care provider for order to remove catheter. <p>3. Patient is unable to void within 6 to 8 hours after catheter removal, has sensation of not emptying, strains to void, or experiences small voiding amounts with increasing frequency.</p> <ul style="list-style-type: none"> • Assess for bladder distention. Perform bladder scan (see Box 46.11) • Help to normal position for voiding and provide privacy. • If patient is unable to void within 6 to 8 hours of catheter removal and/or experiences abdominal pain, notify health care provider. 	
Recording and Reporting	
<ul style="list-style-type: none"> • Record time catheter was removed; teaching related to increasing fluid intake and signs and symptoms of UTI; and time, amount, and characteristics of first voiding. • Record intake and voiding times and amounts on voiding record or bladder diary as indicated. • Record patient symptoms experienced upon and after catheter removal. • Document your evaluation of patient learning. • Report hematuria, dysuria, inability or difficulty voiding, and any new incontinence after a catheter is removed to health care provider. 	
Home Care Considerations	
<ul style="list-style-type: none"> • If patient is discharged with indwelling catheter, teach patient and family catheter care and signs and symptoms to report to nurse or health care provider. 	

Skill 46.4. Closed Catheter Irrigation

Delegation and Collaboration

The skill of catheter irrigation cannot be delegated to assistive personnel (AP). The nurse directs the AP to:

- Report if the patient has concerns of pain, discomfort, or leakage of fluid around the catheter.
- Monitor and record intake and output (I&O) and to report immediately any decrease in urine output to the nurse.
- Report any change in the color of the urine, especially if blood clots are noted.

Equipment

- Clean gloves
- Antiseptic swabs
- Container of sterile irrigation solution at room temperature as prescribed
- Intravenous (IV) pole (closed continuous or intermittent)

Closed Intermittent Irrigation

- Sterile 50-mL syringe to access system: Luer-Lok syringe for needleless access port (per manufacturer's instructions)
- Screw clamp or rubber band (used to occlude catheter temporarily as irrigant is instilled)

Closed Continuous Irrigation

- Sterile irrigation tubing with clamp to regulate irrigation flow rate
- Y connector (*optional*) to connect irrigation tubing to triple-lumen catheter

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number), according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Verify in electronic health record (EHR):	
a. Order for irrigation method (continuous or intermittent), solution type (sterile saline or medicated solution), and amount of irrigant.	Health care provider's order is required to initiate therapy. Frequency and volume of solution used for irrigation may be in the order or standardized as part of agency policy.
b. Type of catheter in place (see Fig. 46.10).	Triple-lumen catheters are used for intermittent and continuous closed irrigation.
3. Perform hand hygiene. Palpate bladder for distention and tenderness or use bladder scan (see Box 46.11).	Reduces transmission of microorganisms. Bladder distention indicates that flow of urine may be blocked from draining.
4. Assess patient for abdominal pain or spasms, sensation of bladder fullness, or catheter bypassing (leaking). (Wear clean gloves if risk of contacting urine).	May indicate overdistention of bladder caused by catheter blockage. Offers baseline to determine whether therapy is successful.
5. Observe urine for color, amount, clarity, and presence of mucus, clots, or sediment. Remove and dispose of gloves (if worn), perform hand hygiene.	Indicates if patient is bleeding or sloughing tissue, which would require increased irrigation rate or frequency of catheter irrigation.
6. Monitor I&O. If continuous bladder irrigation (CBI) is being used, amount of fluid draining from bladder should exceed amount of fluid infused into bladder.	If output does not exceed irrigant infused, catheter obstruction (i.e., blood clots, kinked tubing) should be suspected, irrigation stopped, and prescriber notified (Ignatavicius et al., 2018).
7. Assess patient's or family caregiver's knowledge, experience, and health literacy.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
Planning	
1. Close room door and bedside curtains.	Provides privacy.
2. Obtain supplies and set up at bedside.	Ensures efficient procedure.
3. Raise bed to an appropriate working height. If side rails are raised, lower side rail on working side.	Promotes good body mechanics. Position provides access to catheter.
4. Explain procedure to patient.	Reduces anxiety and promotes cooperation.
Implementation	
1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Position patient supine and expose catheter junctions (catheter and drainage tubing).	Position provides access to catheter and promotes patient dignity as much as possible.
Table Continued	

Step	Rationale
3. Remove catheter securement device.	Eases access to catheter parts.
4. Organize supplies according to type of irrigation prescribed. Apply clean gloves.	Ensures an efficient procedure.
5. Closed continuous irrigation:	
a. Close clamp on new irrigation tubing and hang bag of irrigating solution on IV pole. Insert (spike) tip of sterile irrigation tubing into designated port of irrigation solution bag using aseptic technique (see illustration).	Prevents air from entering tubing. Air can cause bladder spasms. Technique prevents transmission of microorganisms.
b. Fill drip chamber half full by squeezing chamber. Remove cap at end of tubing, and then open clamp and allow solution to flow (prime) through tubing, keeping end of tubing sterile. Once fluid has completely filled tubing, close clamp and recap end of tubing.	Priming tubing with fluid prevents introduction of air into bladder.
c. Using aseptic technique, remove cap and connect end of tubing securely to port for infusing irrigation fluid into double/triple-lumen catheter.	Reduces transmission of microorganisms.
d. Adjust clamp on irrigation tubing to begin flow of solution into bladder. If set volume rate is ordered, calculate drip rate and adjust rate at roller clamp (see Chapter 42). If urine is bright red or has clots, increase irrigation rate until drainage appears pink (according to ordered rate or agency protocol).	Continuous drainage is expected. It helps to prevent clotting in presence of active bleeding in bladder and flushes clots out of bladder.
e. Observe for outflow of fluid into drainage bag. Empty catheter drainage bag as needed.	Discomfort, bladder distention, and possible injury can occur from overdistention of bladder when bladder irrigant cannot adequately flow from bladder. Bag will fill rapidly and may need to be emptied every 1 to 2 hours.
6. Closed intermittent irrigation:	
a. Pour prescribed sterile irrigation solution into sterile container.	
b. Draw prescribed volume of irrigant (usually 30 to 50 mL) into sterile syringe, using aseptic technique. Place sterile cap on tip of needleless syringe.	Ensures sterility of irrigating fluid.
c. Clamp catheter tubing below soft injection port with screw clamp (or fold catheter tubing onto itself and secure with rubber band).	Occluding catheter tubing below point of injection allows irrigating solution to enter catheter and flow into bladder.

Step	Rationale
	

STEP 5A Spiking bag of sterile irrigation solution for continuous bladder irrigation.

Table Continued

Step	Rationale
d. Using circular motion, clean catheter port (specimen port) with antiseptic swab. Allow to dry.	Reduces transmission of microorganisms.
e. Insert tip of needleless syringe using twisting motion into port.	Ensures that catheter tip enters lumen of catheter.
f. Inject solution using slow, even pressure.	Gentle instillation of solution minimizes trauma to bladder mucosa.
g. Remove syringe and clamp (or rubber band), allowing solution to drain into urinary drainage bag. (Notes: Some medicated irrigants may need to dwell in bladder for prescribed period, requiring catheter to be clamped temporarily before being allowed to drain.)	Allows drainage to flow out by gravity. Medications must be instilled long enough to be absorbed by lining of bladder. Clamped drainage tubing and bag should not be left unattended.
7. Anchor catheter with catheter securement device (see Skill 46.2).	Prevents trauma to urethral tissue caused by pulling catheter.
8. Help patient to safe and comfortable position. Lower bed and place side rails accordingly. Place nurse call light in reach and instruct patient in its use.	Promotes patient comfort and safety.
9. Dispose of all contaminated supplies in appropriate receptacle, remove and dispose of gloves, and perform hand hygiene.	Reduces transmission of microorganisms.
Evaluation	
1. Measure actual urine output by subtracting total amount of irrigation fluid infused from total volume drained into collection bag or basin.	Determines accurate urinary output.
2. Review I&O flow sheet to verify that hourly output into drainage bag is in appropriate proportion to irrigating solution entering bladder. Expect more output than fluid instilled because of urine production.	Determines urinary output in relation to irrigation.
3. Inspect urine for blood clots and sediment, and be sure that tubing is not kinked or occluded.	Decrease in blood clots means that therapy is successful in maintaining catheter patency. System is patent.
4. Evaluate patient's comfort level.	Indicates catheter patency by absence of symptoms of bladder distention.
5. Monitor for signs and symptoms of infection.	Patients with indwelling catheters remain at risk for infection.
6. Use Teach-Back: "I want to be sure I explained clearly about why we are irrigating your catheter. Tell me in your own words the reason we are doing the irrigation." Revise your instruction now or develop plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Drainage output is less than amount of irrigation solution infused.</p> <ul style="list-style-type: none"> Examine drainage tubing for clots, sediment, or kinks. Inspect urine for presence of or increase in blood clots and sediment. Evaluate patient for pain and distended bladder. Notify health care provider. 	
<p>2. Bright-red bleeding with the irrigation (CBI) infusion wide open.</p> <ul style="list-style-type: none"> Assess for hypovolemic shock (vital signs, skin color and moisture, anxiety level). Leave irrigation infusion wide open and notify health care provider. 	
<p>3. Patient experiences pain with irrigation.</p> <ul style="list-style-type: none"> Examine drainage tubing for clots, sediment, or kinks. Evaluate urine for presence of or increase in blood clots and sediment. Evaluate for distended bladder. Notify health care provider. 	
<p>Recording and Reporting</p> <ul style="list-style-type: none"> Record irrigation method, amount of and type of irrigation solution, amount returned as drainage, characteristics of output, and urine output. Record I&O. Document your evaluation of patient learning. Report catheter occlusion, sudden bleeding, infection, or increased pain. <p>Home Care Considerations</p> <ul style="list-style-type: none"> Patients and/or family caregivers can be taught to perform catheter irrigations with adequate support, demonstration/return demonstration, and written instructions. Teach patients and/or family caregivers to observe urine color, clarity, odor, and amount and to observe for signs of catheter obstruction and UTI. Arrange for home delivery and storage of catheter/irrigation supplies. 	

Key Points

- Micturition involves complex interactions between the central nervous system, bladder, and urinary sphincter.
- Common urinary tract symptoms include urgency, dysuria, frequency, hesitancy, polyuria, oliguria, nocturia, dribbling, hematuria, and urinary retention.
- Nursing care for patients with urinary dysfunction needs to take into account multiple factors that affect urinary function such as fluid intake, medications, functional ability, environment, medical problems outside the urinary tract, and dysfunction within the urinary tract.
- The presence or recent history of an indwelling catheter increases risk for a UTI.
- Prevention of catheter-associated urinary tract infection (CAUTI) requires use of an evidence-based “bundle” to perform all elements of care at one time.
- To minimize the risk for infection when caring for a patient with a closed bladder drainage system, nursing care must include careful attention to aseptic technique.
- Planning care for an incontinent patient requires selecting interventions specific to the type of incontinence.
- A key intervention when caring for an incontinent patient is to ensure regular toilet access.

Reflective Learning

- At the end of your clinical practice day, your instructor asks how you promoted urinary elimination for a confused older adult. What would be your answer?
- Consider a moment in which you actively prevented infection during the shift. What did you do that was successful in preventing infection?
- Think of some ways to best promote comfort when assessing the urinary system. What would be the biggest barriers to these care components?

Review Questions

1. A patient is scheduled to have an intravenous pyelogram (IVP) the next morning. Which nursing measures should be implemented before the test? (Select all that apply.)
 1. Ask the patient about any allergies and reactions.
 2. Instruct the patient that a full bladder is required for the test.
 3. Instruct the patient to save all urine in a special container.
 4. Ensure that informed consent has been obtained.
 5. Instruct the patient that facial flushing can occur when the contrast media is given.
2. What is a critical step when inserting an indwelling catheter into a male patient?
 1. Slowly inflate the catheter balloon with sterile saline.
 2. Secure the catheter drainage tubing to the bedsheets.

3. Advance the catheter to the bifurcation of the drainage and balloon ports.
 4. Advance the catheter until urine flows, then insert $\frac{1}{4}$ inch more.
3. Which instruction should the nurse give the assistive personnel (AP) concerning a patient who has had an indwelling urinary catheter removed that day?
 1. Limit oral fluid intake to avoid possible urinary incontinence.
 2. Expect patient complaints of suprapubic fullness and discomfort.
 3. Report the time and amount of first voiding.
 4. Instruct patient to stay in bed and use a urinal or bedpan.
 4. A postoperative patient with a three-way indwelling urinary catheter and continuous bladder irrigation (CBI) complains of lower abdominal pain and distention. What should be the nurse's *initial* intervention(s)? (Select all that apply.)
 1. Increase the rate of the CBI.
 2. Assess the patency of the drainage system.
 3. Measure urine output.
 4. Assess vital signs.
 5. Administer ordered pain medication.
 5. An ambulatory elderly woman with dementia is incontinent of urine. She has poor short-term memory and has not been seen toileting independently. What is the *best* nursing intervention for this patient?

1. Recommend that she be evaluated for an overactive bladder (OAB) medication.
 2. Establish a toileting schedule.
 3. Recommend that she be evaluated for an indwelling catheter.
 4. Start a bladder-retraining program.
6. What should the nurse teach a young woman with a history of urinary tract infections (UTIs) about UTI prevention? (Select all that apply.)
1. Maintain regular bowel elimination.
 2. Limit water intake to 1 to 2 glasses a day.
 3. Wear cotton underwear.
 4. Cleanse the perineum from front to back.
 5. Practice pelvic muscle exercise (Kegel) daily.
7. Place the following steps for insertion of an indwelling catheter in a female patient in appropriate order.
1. Insert and advance catheter.
 2. Lubricate catheter.
 3. Inflate catheter balloon.
 4. Cleanse urethral meatus with antiseptic solution.
 5. Drape patient with the sterile square and fenestrated drapes.
 6. When urine appears, advance another 2.5 to 5 cm.
 7. Prepare sterile field and supplies.
 8. Gently pull catheter until resistance is felt.
 9. Attach drainage tubing.

8. Which nursing interventions should a nurse implement when removing an indwelling urinary catheter in an adult patient? (Select all that apply.)
1. Attach a 3-mL syringe to the inflation port.
 2. Allow the balloon to drain into the syringe by gravity.
 3. Initiate a voiding record/bladder diary.
 4. Pull the catheter quickly.
 5. Clamp the catheter before removal.
9. Which nursing intervention decreases the risk for catheter-associated urinary tract infection (CAUTI)?
1. Cleansing the urinary meatus 3 to 4 times daily with antiseptic solution
 2. Hanging the urinary drainage bag below the level of the bladder
 - 3 Emptying the urinary drainage bag daily
 4. Irrigating the urinary catheter with sterile water
10. There is no urine when a catheter is inserted 3 inches into a female's urethra. What should the nurse do next?
1. Remove the catheter and start all over with a new kit and catheter.
 2. Leave the catheter there and start over with a new catheter.
 3. Pull the catheter back and reinsert at a different angle.
 4. Ask the patient to bear down and insert the catheter farther.

Bowel Elimination

OBJECTIVES

- Discuss the role of gastrointestinal organs and their physiological function in digestion and elimination.
- Discuss how psychological and physiological factors may alter the elimination process.
- Assess a patient's elimination pattern.
- Describe nursing implications for common diagnostic examinations of the gastrointestinal tract.
- List nursing interventions that promote normal elimination.
- Discuss nursing care measures required for patients with an intestinal diversion.
- Describe nursing procedures related to bowel elimination.
- Explain how critical thinking is important in providing care to patients with alterations in bowel elimination.

Regular elimination of bowel waste products is essential for normal body functioning. Alterations in bowel elimination are often early signs or symptoms of problems within either the gastrointestinal (GI) tract or other body systems. Because bowel function depends on the balance of several factors, elimination patterns and habits vary among individuals.

Understanding normal bowel elimination and factors that promote, impede, or cause alterations in elimination help a nurse manage patients' elimination problems. Supportive nursing care respects a patient's privacy and emotional needs. Measures designed to promote normal elimination also need to minimize a patient's discomfort and embarrassment.

Scientific Knowledge Base

The GI tract consists of the alimentary canal and its accessory organs. The alimentary canal is a single tube that extends from the mouth to the anus and includes the mouth, esophagus, stomach, and intestines. The accessory organs are the teeth, tongue, salivary glands, liver, pancreas, and gallbladder. These organs absorb fluid and nutrients, prepare food for absorption and use by body cells, and provide for temporary storage of feces (Fig. 47.1). The GI tract absorbs high volumes of fluids, making fluid and electrolyte balance a key function of the GI system. In addition to ingested fluids and foods, the GI tract also receives secretions from the gallbladder and pancreas.

FIG. 47.1 Organs of gastrointestinal tract.

From Monahan FD, Neighbors M: *Medical-surgical nursing*, ed 2, Philadelphia, 1998, Saunders.

Mouth

The mouth mechanically and chemically breaks down nutrients into usable size and form. The teeth chew food, breaking it down into a size suitable for swallowing. Saliva, produced by the salivary glands in the mouth, dilutes and softens the food in the mouth for easier swallowing.

Esophagus

As food enters the upper esophagus, it passes through the upper esophageal sphincter, a circular muscle that prevents air from entering the esophagus and food from refluxing into the throat. The bolus of food travels down the esophagus with the aid of *peristalsis*, which is a contraction that propels food through the length of the GI tract. The food moves down the esophagus and reaches the cardiac sphincter, which lies between the esophagus and the upper end of the stomach. The sphincter prevents reflux of stomach contents back into the esophagus.

Stomach

The stomach performs three tasks: storage of swallowed food and liquid, mixing of food with digestive juices into a substance called *chyme*, and regulated emptying of its contents into the small intestine. The stomach produces and secretes hydrochloric acid (HCl), mucus, the enzyme pepsin, and intrinsic factor. Pepsin and HCl help to digest protein. Mucus protects the stomach mucosa from acidity and enzyme activity. Intrinsic factor is essential in the absorption of vitamin B₁₂.

Small Intestine

Movement within the small intestine, occurring by peristalsis, facilitates both digestion and absorption. Chyme comes into the small intestine as a liquid material and mixes with digestive enzymes. Resorption in the small intestine is so efficient that, by the time the fluid reaches the end of the small intestine, it is a thick liquid with some semisolid particles. The small intestine is divided into three sections: the duodenum, the jejunum, and the ileum.

The duodenum is approximately 20 to 28 cm (8 to 11 inches) long and continues to process fluid from the stomach. The second section, the jejunum, is approximately 2.5 m (8 feet) long and absorbs carbohydrates and proteins. The ileum is approximately 3.7 m (12 feet) long and absorbs water, fats, and bile salts. The duodenum and jejunum absorb most

nutrients and electrolytes in the small intestine. The ileum absorbs certain vitamins, iron, and bile salts. Digestive enzymes and bile enter the small intestine from the pancreas and the liver to further break down nutrients into a form usable by the body.

The digestive process is greatly altered when small intestine function is impaired. Conditions such as inflammation, infection, surgical resection, or obstruction disrupt peristalsis, reduce absorption, or block the passage of fluid, resulting in electrolyte and nutrient deficiencies.

Large Intestine

The lower GI tract is called the *large intestine* or *colon* because it is larger in diameter than the small intestine. However, its length, 1.5 to 1.8 m (5 to 6 feet), is much shorter. The large intestine is divided into the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. The large intestine is the primary organ of bowel elimination.

Digestive fluid enters the large intestine by waves of peristalsis through the ileocecal valve (i.e., a circular muscle layer that prevents regurgitation back into the small intestine). The muscular tissue of the colon allows it to accommodate and eliminate large quantities of waste and gas (flatus). The colon has three functions: absorption, secretion, and elimination. The colon resorbs a large volume of water (up to 1.5 L) and significant amounts of sodium and chloride daily. The amount of water absorbed depends on the speed at which colonic contents move. Normally the fecal matter becomes a soft, formed solid or semisolid mass. If peristalsis is abnormally fast, there is less time for water to be absorbed, and the stool will be watery. If peristaltic contractions slow down, water continues to be absorbed, and a hard mass of stool forms, resulting in *constipation*.

Peristaltic contractions move contents through the colon. Mass peristalsis pushes undigested food toward the rectum. These mass movements occur only 3 or 4 times daily, with the strongest during the hour after mealtime.

The rectum is the final part of the large intestine. Normally the rectum is empty of fecal matter until just before defecation. It contains vertical and transverse folds of tissue that help to control expulsion of fecal contents during defecation. Each fold contains veins that can become distended from pressure during straining. This distention results in *hemorrhoid* formation.

Anus

The body expels feces and flatus from the rectum through the anus. Contraction and relaxation of the internal and external sphincters, which are innervated by sympathetic and parasympathetic nerves, aid in the control of defecation. The anal canal contains a rich supply of sensory nerves that allow people to tell when there is solid, liquid, or gas that needs to be expelled and aids in maintaining continence.

Defecation

The physiological factors essential to bowel function and defecation include normal GI tract function, sensory awareness of rectal distention and rectal contents, voluntary sphincter control, and adequate rectal capacity and compliance. Normal defecation begins with movement in the left colon, moving stool toward the anus. When stool reaches the rectum, the distention causes relaxation of the internal sphincter and an awareness of the need to defecate. At the time of defecation, the external sphincter relaxes, and abdominal muscles contract, increasing intrarectal pressure and forcing the stool out. Normally defecation is painless, resulting in passage of soft, formed stool. Straining while having a bowel movement indicates that the patient may need changes in diet or fluid intake or that there is an underlying disorder in GI function.

REFLECT NOW

The digestive system is a complex group of organs that allow the body to transport and digest food and fluids and eliminate waste products. Each part of the system plays an important role, yet illness or surgery can cause significant changes in digestive function. Consider symptoms patients may experience as a result of these changes and how their quality of life may be affected.

Nursing Knowledge Base

Factors Influencing Bowel Elimination

Many factors influence the process of bowel elimination. Knowledge of these factors helps to anticipate measures required to maintain a normal elimination pattern.

Age

Infants have a smaller stomach capacity, less secretion of digestive enzymes, and more rapid intestinal peristalsis. The ability to control defecation does not occur until 2 to 3 years of age. Adolescents experience rapid growth and increased metabolic rate. There is also rapid growth of the large intestine and increased secretion of gastric acids to digest food fibers and act as a bactericide against swallowed organisms. Older adults may have decreased chewing ability. Partially chewed food is not digested as easily. Peristalsis declines, and esophageal emptying slows. This impairs absorption by the intestinal mucosa. Muscle tone in the perineal floor and anal sphincter weakens, which sometimes causes difficulty in controlling defecation ([NIH, 2018a](#)).

Diet

Regular daily food intake helps maintain a regular pattern of peristalsis in the colon. Fiber in the diet provides the bulk in the fecal material. Bulk-forming foods such as whole grains, fresh fruits, and vegetables help remove the fats and waste products from the body with more efficiency. Some of these foods such as cabbage, broccoli, or beans may also produce gas, which distends the intestinal walls and increases colonic motility. The bowel walls stretch, creating peristalsis and initiating the defecation reflex.

Fluid Intake

Although individual fluid needs vary with the person, a fluid intake of 3.7 L per day for men and 2.7 L per day for women is recommended ([Mayo Clinic, 2017](#)). Some fluid needs are met by drinking fluids, but there is also fluid in foods that are ingested such as fruits. An inadequate fluid intake or disturbances resulting in fluid loss (such as vomiting) affect the character of feces. Fluid liquefies intestinal contents by absorbing into the fiber from the diet and creating a larger, softer stool mass. This increases peristalsis and promotes movement of stool through the colon. Reduced

fluid and fiber intake slows the passage of food through the intestine and results in hardening of stool contents, causing constipation.

Physical Activity

Physical activity promotes peristalsis, whereas immobilization depresses it. Encourage early ambulation as illness begins to resolve or as soon as possible after surgery to promote maintenance of peristalsis and normal elimination. Maintaining tone of skeletal muscles used during defecation is important. Weakened abdominal and pelvic floor muscles impair the ability to increase intraabdominal pressure and control the external sphincter. Muscle tone is sometimes weakened or lost as a result of long-term illness, spinal cord injury, or neurological diseases that impair nerve transmission. As a result of these changes in the abdominal and pelvic floor muscles, there is an increased risk for constipation.

Psychological Factors

Prolonged emotional stress impairs the function of almost all body systems (see [Chapter 37](#)). During emotional stress the digestive process is accelerated, and peristalsis is increased. Side effects of increased peristalsis include diarrhea and gaseous distention. Several diseases of the GI tract are exacerbated by stress, including ulcerative colitis, irritable bowel syndrome, certain gastric and duodenal ulcers, and Crohn's disease. If a person becomes depressed, the autonomic nervous system may slow impulses that decrease peristalsis, resulting in constipation.

Personal Habits

Personal elimination habits influence bowel function. Most people benefit from being able to use their own toilet facilities at a time that is most effective and convenient for them. A busy work schedule sometimes prevents the individual from responding appropriately to the urge to defecate, disrupting regular habits and causing possible alterations such as constipation. Individuals need to recognize the best time for elimination.

Position During Defecation

Squatting is the normal position during defecation. Modern toilets facilitate this posture, allowing a person to lean forward, exert intraabdominal pressure, and contract the gluteal muscles. For a patient immobilized in bed, defecation is often difficult. In a supine position it is hard to effectively contract the muscles used during defecation. If a

patient's condition permits, raise the head of the bed to help him or her to a more normal sitting position on a bedpan, enhancing the ability to defecate.

Pain

Normally the act of defecation is painless. However, several conditions such as hemorrhoids; rectal surgery; anal fissures, which are painful linear splits in the perianal area; and abdominal surgery result in discomfort. In these instances, the patient often suppresses the urge to defecate to avoid pain, contributing to the development of constipation.

Pregnancy

As pregnancy advances, the size of the fetus increases, and pressure is exerted on the rectum. A temporary obstruction created by the fetus impairs passage of feces. Slowing of peristalsis during the third trimester often leads to constipation. A pregnant woman's frequent straining during defecation or delivery may result in formation of hemorrhoids.

Surgery and Anesthesia

General anesthetic agents used during surgery cause temporary cessation of peristalsis (see [Chapter 50](#)). Inhaled anesthetic agents block parasympathetic impulses to the intestinal musculature. The action of the anesthetic slows or stops peristaltic waves. A patient who receives a local or regional anesthetic is less at risk for elimination alterations because this type of anesthesia generally affects bowel activity minimally or not at all.

Any surgery that involves direct manipulation of the bowel temporarily stops peristalsis. This condition, called an **ileus**, usually lasts about 24 to 48 hours. If a patient remains inactive or is unable to eat after surgery, return of normal bowel elimination is further delayed.

Medications

Many medications prescribed for acute and chronic conditions have secondary effects on a patient's bowel elimination patterns. For example, opioid analgesics slow peristalsis and contractions, often resulting in constipation; and antibiotics decrease intestinal bacterial flora, often resulting in diarrhea ([Burchum and Rosenthal, 2019](#)). It is important for the nurse and patient to be aware of these possible side effects and use appropriate measures to promote healthy bowel elimination. Some medications are used primarily for their action on the bowel and will

promote defecation, such as **laxatives** or **cathartics**, or control diarrhea. If laxatives are needed for regular evacuation of the rectum, a fiber laxative is the first type used. If this is not enough to relieve constipation, the next one tried should be an osmotic laxative. Patients need to avoid regular use of a stimulant laxative because the intestine often becomes dependent on it.

Diagnostic Tests

Diagnostic examinations involving visualization of GI structures often require a prescribed bowel preparation (e.g., laxatives and/or **enemas**) to ensure that the bowel is empty. Usually patients cannot eat or drink several hours before examinations such as an endoscopy, colonoscopy, or other testing that requires visualization of the GI tract. Following the diagnostic procedure, changes in elimination such as increased gas or loose stools often occur until the patient resumes a normal eating pattern.

Common Bowel Elimination Problems

You will frequently care for patients who have or are at risk for elimination problems because of physiological changes in the GI tract, such as abdominal surgery, inflammatory diseases, medications, emotional stress, environmental factors, or disorders impairing defecation.

Constipation

Constipation is a symptom, not a disease, and there are many possible causes ([Box 47.1](#)). Improper diet, reduced fluid intake, lack of exercise, and certain medications can cause constipation. For example, patients receiving opioids for pain after surgery often require a stool softener or laxative to prevent constipation. A research study of the bowel function of men and women revealed that female gender and older age were the highest risk factors for constipation ([Uduak et al., 2016](#)). Signs of constipation include infrequent bowel movements (less than three per week) and hard, dry stools that are difficult to pass ([NIH, 2018a](#)). When intestinal motility slows, the fecal mass becomes exposed to the intestinal walls over time, and most of the fecal water content is absorbed. Little water is left to soften and lubricate the stool. Passage of a dry, hard stool often causes rectal pain. Constipation is a significant source of discomfort. Assess the need for intervention before defecation becomes painful or the stool is impacted.

Box 47.1 Common Causes of Constipation

- Irregular bowel habits and ignoring the urge to defecate
- Chronic illnesses (e.g., Parkinson's disease, multiple sclerosis, rheumatoid arthritis, chronic bowel diseases, depression, eating disorders)
- Low-fiber diet high in animal fats (e.g., meats and carbohydrates); low fluid intake
- Stress (e.g., illness of a family member, death of a loved one, divorce)
- Physical inactivity
- Medications, especially use of opiates
- Changes in life or routine, such as pregnancy, aging, and travel
- Neurological conditions that block nerve impulses to the colon (e.g., stroke, spinal cord injury, tumor)
- Chronic bowel dysfunction (e.g., colonic inertia, irritable bowel)

Impaction

Fecal *impaction* results when a patient has unrelieved constipation and is unable to expel the hardened feces retained in the rectum. In cases of severe impaction, the mass extends up into the sigmoid colon. If not resolved or removed, severe impaction results in intestinal obstruction. Patients who are debilitated, confused, or unconscious are most at risk for impaction. They are dehydrated or too weak or unaware of the need to defecate, and the stool becomes too hard and dry to pass.

An obvious sign of impaction is the inability to pass a stool for several days, despite the repeated urge to defecate. Suspect an impaction when a continuous oozing of liquid stool occurs. The liquid part of feces located higher in the colon seeps around the impacted mass. Loss of appetite (anorexia), nausea and/or vomiting, abdominal distention and cramping, and rectal pain may accompany the condition. If you suspect an impaction, gently perform a digital examination of the rectum and palpate for the impacted mass ([Hussain et al., 2014](#)).

Diarrhea

Diarrhea is an increase in the number of stools and the passage of liquid, unformed feces. It is associated with disorders affecting digestion,

absorption, and secretion in the GI tract. Intestinal contents pass through the small and large intestine too quickly to allow for the usual absorption of fluid and nutrients. Irritation within the colon results in increased mucus secretion. As a result, feces become watery, and the patient often has difficulty controlling the urge to defecate.

Excess loss of colonic fluid results in dehydration (Box 47.2) with fluid and electrolyte or acid-base imbalances if the fluid is not replaced. Infants and older adults are particularly susceptible to associated complications (see Chapter 42). Because repeated passage of diarrhea stools exposes the skin of the perineum and buttocks to irritating intestinal contents, meticulous skin care and containment of fecal drainage is necessary to prevent skin breakdown (see Chapter 48).

Box 47.2 Signs of Dehydration

- Signs of dehydration in adults include:
 - Thirst
 - Less frequent urination than usual
 - Dark-colored urine
 - Dry skin
 - Fatigue
 - Dizziness
 - Light-headedness
- Signs of dehydration in infants and young children include:
 - Dry mouth and tongue
 - No tears when crying
 - No wet diapers for 3 hours or more
 - Sunken eyes or cheeks or soft spot in the skull
 - High fever
 - Listlessness or irritability

Incontinence

Fecal *incontinence* is the inability to control passage of feces and gas from the anus. Incontinence harms a patient's body image (see Chapter 33). The embarrassment of soiling clothes often leads to social isolation. Physical conditions that impair anal sphincter function or large-volume liquid

stools cause incontinence. Impaired cognitive function often leads to incontinence of both urine and stool.

Many conditions cause fecal incontinence or diarrhea. You need to identify precipitating conditions and refer patients to health care providers for medication management. Antibiotic use alters the normal flora in the GI tract. A common causative agent of diarrhea is *Clostridium difficile* (*C. difficile*), which produces symptoms ranging from mild diarrhea to severe colitis. The Infectious Diseases Society of America (IDSA) has identified *C. difficile* as the most common health care–related infection in America. Patients acquire *C. difficile* infection in one of two ways: by antibiotic therapy that causes an overgrowth of *C. difficile* and by contact with the *C. difficile* organism. Patients are exposed to the organism from a health care worker’s hands or direct contact with environmental surfaces contaminated with it. Only hand hygiene with soap and water is effective to physically remove *C. difficile* spores from the hands. New tests have been developed for detecting the infection in the stool, and the 2017 IDSA guidelines recommend an NAAT (nucleic acid amplification test). Research is ongoing to determine the most sensitive and accurate diagnostic test and the most effective treatment regimen (McDonald et al., 2018). Elderly patients are especially vulnerable to *C. difficile* infection when exposed to antibiotics, and higher mortality and morbidity are observed in this age-group (McDonald et al., 2018). To decrease the spread of infection, patients with *C. difficile* are placed on contact/enteric isolation precautions.

Communicable foodborne pathogens also cause diarrhea. Hand hygiene following the use of the bathroom, before and after preparing foods, and when cleaning and storing fresh produce and meats greatly reduces the risk of foodborne illnesses. When diarrhea results from a foodborne pathogen, the goal usually is to rid the GI system of the pathogen rather than slow peristalsis.

Surgeries or diagnostic testing of the lower GI tract may also cause diarrhea. Patients receiving enteral nutrition are also at risk for diarrhea and need a dietary consult to find the right formula for the feeding (see Chapter 45). Food intolerances can increase peristalsis and cause diarrhea. Food intolerance is not an allergy; rather, a particular food causes the body distress within a few hours of ingestion. The result is diarrhea, cramps, or flatulence. For example, people who drink cow’s milk and have these symptoms are not allergic to milk but lack the enzyme needed to digest the milk sugar lactase and therefore are lactose intolerant. Another condition called *celiac disease* is a syndrome in which a patient has a

hypersensitivity to protein in certain cereal grains and gluten. Food allergies are less common but do occur, and people with these allergies need to know how to read labels on foods carefully. True food allergies may be life threatening and lead to anaphylaxis ([USFDA, 2018](#)).

Flatulence

As gas accumulates in the lumen of the intestines, the bowel wall stretches and distends. *Flatulence* is a common cause of abdominal fullness, pain, and cramping. Normally intestinal gas escapes through the mouth (belching) or the anus (passing of flatus). However, flatulence causes abdominal distention and severe, sharp pain if intestinal motility is reduced because of opiates, general anesthetics, abdominal surgery, or immobilization.

Hemorrhoids

Hemorrhoids are dilated, engorged veins in the lining of the rectum. They are either external or internal. External hemorrhoids are clearly visible as protrusions of skin. There is usually a purplish discoloration (thrombosis) if the underlying vein is hardened. This causes increased pain and sometimes requires excision. Internal hemorrhoids occur in the anal canal and may be inflamed and distended. Increased venous pressure from straining at defecation, pregnancy, heart failure, and chronic liver disease causes hemorrhoids.

Bowel Diversions

Certain diseases or surgical alterations make the normal passage of intestinal contents throughout the small and large intestine difficult or inadvisable. When these conditions are present, a temporary or permanent opening (*stoma*) is created surgically by bringing part of the intestine out through the abdominal wall. These surgical openings are called an *ileostomy* or *colostomy*, depending on which part of the intestinal tract is used to create the stoma (Figs. [47.2](#) and [47.3](#)). Newer surgical techniques allow more patients to have parts of their small and large intestine removed and the remaining parts reconnected, so they will continue to defecate through the anal canal.

FIG. 47.2 Sigmoid colostomy.

FIG. 47.3 Ileostomy.

Ostomies

The location of an ostomy determines stool consistency. A person with a sigmoid colostomy will have a more formed stool. The output from a transverse colostomy will be thick liquid to soft consistency. These ostomies are the easiest to perform surgically and are done as a temporary means to divert stool from an area of trauma or perianal wounds. They may also be a palliative diversion if obstruction from a tumor is present. With an ileostomy the fecal effluent leaves the body before it enters the colon, creating frequent, liquid stools.

Loop colostomies are reversible stomas that a surgeon constructs in the ileum or the colon. The surgeon pulls a loop of intestine onto the abdomen and often places a plastic rod, bridge, or rubber catheter temporarily under the bowel loop to keep it from slipping back. The surgeon then opens the bowel and sutures it to the skin of the abdomen. The loop ostomy has two

openings through the stoma. The proximal end drains fecal *effluent*, and the distal part drains mucus.

The end colostomy consists of a stoma formed by bringing a piece of intestine out through a surgically created opening in the abdominal wall, turning it down like a turtleneck and suturing it to the abdominal wall. The intestine distal to the stoma is either removed or sewn closed (called *Hartmann's pouch*; see [Fig. 47.2](#)) and left in the abdominal cavity. End ostomies are permanent or reversible. The rectum is either left intact or removed.

Other Procedures

Ileoanal Pouch Anastomosis

The ileoanal pouch anastomosis is a surgical procedure for patients who need to have a colectomy for treatment of ulcerative colitis or familial adenopolyposis (FAP) ([Goldberg et al., 2017](#)). In this procedure the surgeon removes the colon, creates a pouch from the end of the small intestine, and attaches the pouch to the patient's anus ([Fig. 47.4](#)). This pouch provides for the collection of fecal material, which simulates the function of the rectum. The patient is continent of stool because stool is evacuated via the anus. When the ileal pouch is created, the patient has a temporary ileostomy to divert the effluent and allow the suture lines in the pouch to heal.

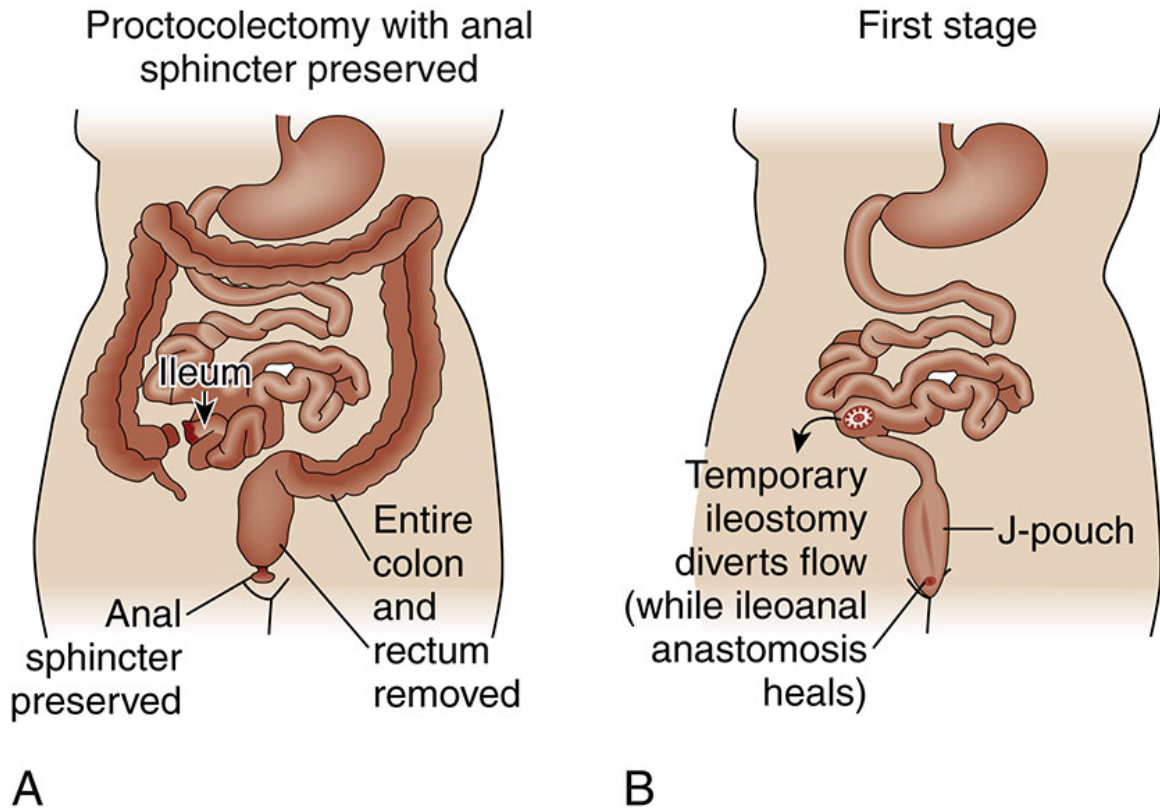

FIG. 47.4 Ileoanal pouch anastomosis.

A continent ileostomy involves creating a pouch from the small intestine. The pouch has a continent stoma on the abdomen created with a valve that can be drained only when the patient places a large catheter into the stoma. The patient empties the pouch several times a day. This procedure is rarely performed now.

Children with fecal soiling associated with neuropathic or structural abnormalities of the anal sphincter sometimes have an antegrade continence enema (ACE) procedure. The surgeon creates a continence valve with an opening on to the abdomen in the intestine, so the patient or caregiver can insert a tube and give himself or herself an enema that comes out through the anus. Colonic evacuation begins about 10 to 20 minutes after a patient receives the enema fluid.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary, analyze the data, and make decisions regarding your patient's care. During assessment consider all elements that build toward making an appropriate nursing diagnosis (Fig. 47.5).

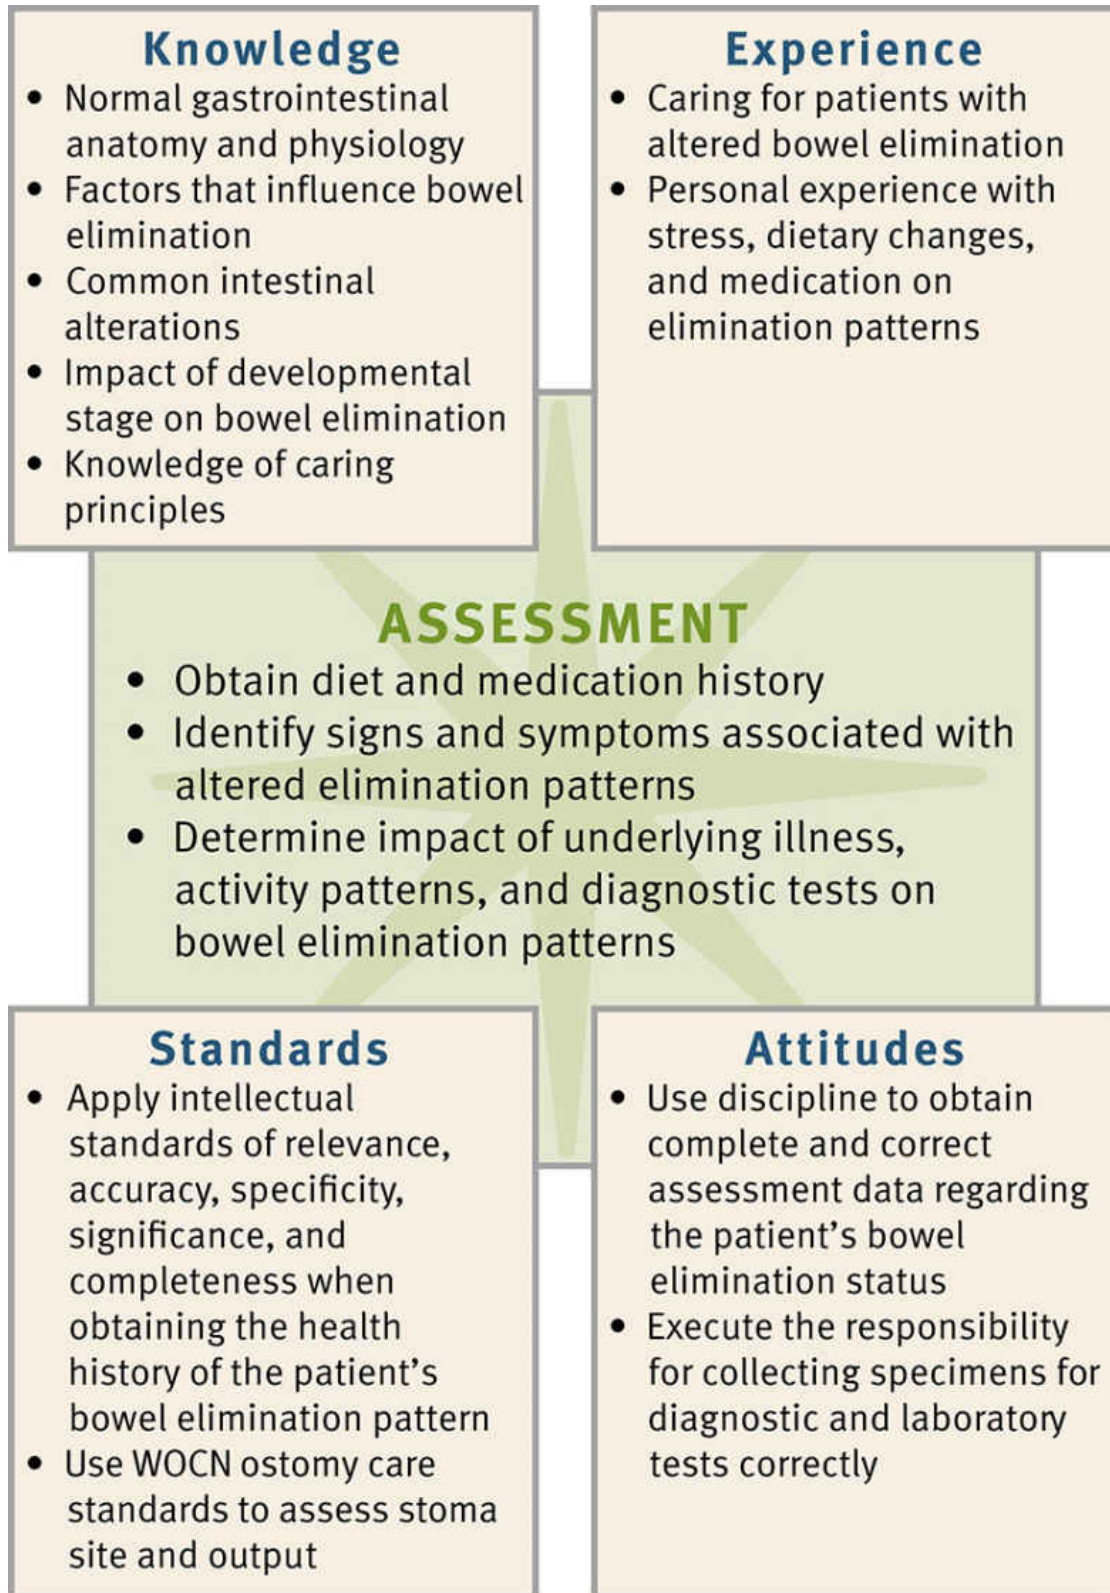

FIG. 47.5 Critical thinking model for elimination assessment. WOCN, Wound, Ostomy and Continence Nurses Society.

In the case of bowel elimination, integrate knowledge from nursing and other disciplines to understand a patient's response to bowel elimination alterations. Experience in caring for patients with elimination alterations helps you provide an appropriate plan of care. Use critical thinking attitudes such as fairness, confidence, and discipline when listening to and exploring a patient's nursing history. Apply relevant standards of practice when selecting nursing measures.

REFLECT NOW

Consider the social stigma of impaired bowel function and try to understand your personal attitudes toward caring for a patient who may suffer from odor, soiling, and embarrassment when he or she loses control of this important bodily function.

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

Assessment for bowel elimination patterns and abnormalities includes a nursing history, physical assessment of the abdomen, inspection of fecal characteristics, and review of relevant test results. In addition, determine the patient's medical history, pattern and types of fluid and food intake, mobility, chewing ability, medications, recent illnesses and/or stressors, and environmental situation.

Through the Patient's Eyes

Patients expect nurses to answer all of their questions regarding diagnostic tests and the preparation for these tests. They are concerned about discomfort and exposure of their perineal area. Bowel problems are often a source of discomfort and embarrassment for patients and their families. Fecal and urinary incontinence in older people is often a reason for admission to a long-term care agency, and the rate of development of both fecal and urinary incontinence after admission to a long-term care facility is 28% at 6 months, 42% at 1 year, and 61% 2 years after admission (Bliss, 2017). Some older patients who fail to recognize their elimination needs require monitoring for elimination patterns so that negative consequences do not occur. Remember that each patient has a unique situation and a perception of what is "right" for him or her. Patients expect a knowledgeable nurse with the ability to teach methods of promoting and maintaining normal bowel elimination patterns or means of managing altered elimination. Encourage the patient and/or caregiver to describe cultural practices and use this information when providing care to enhance the patient's comfort.

Nursing History

The nursing history provides information about a patient's usual bowel pattern and habits. What a patient describes as normal or abnormal is often different from factors and conditions that tend to promote normal elimination. Identifying normal and abnormal patterns, habits, and the patient's perception of normal and abnormal bowel elimination allows you to better determine a patient's problems. Organize the nursing history around factors that affect elimination.

- *Determination of the usual elimination pattern:* Include frequency and time of day. Having a patient or caregiver complete a bowel elimination diary provides an accurate assessment of a patient's current bowel elimination pattern.
- *Patient's description of usual stool characteristics:* Determine whether the stool is normally watery or formed, soft or hard, and the typical color. Ask the patient to describe the shape of a normal stool and the number of stools per day. Use a scale such as the Bristol Stool Form Scale to get an objective measure of stool characteristics (Fig. 47.6).

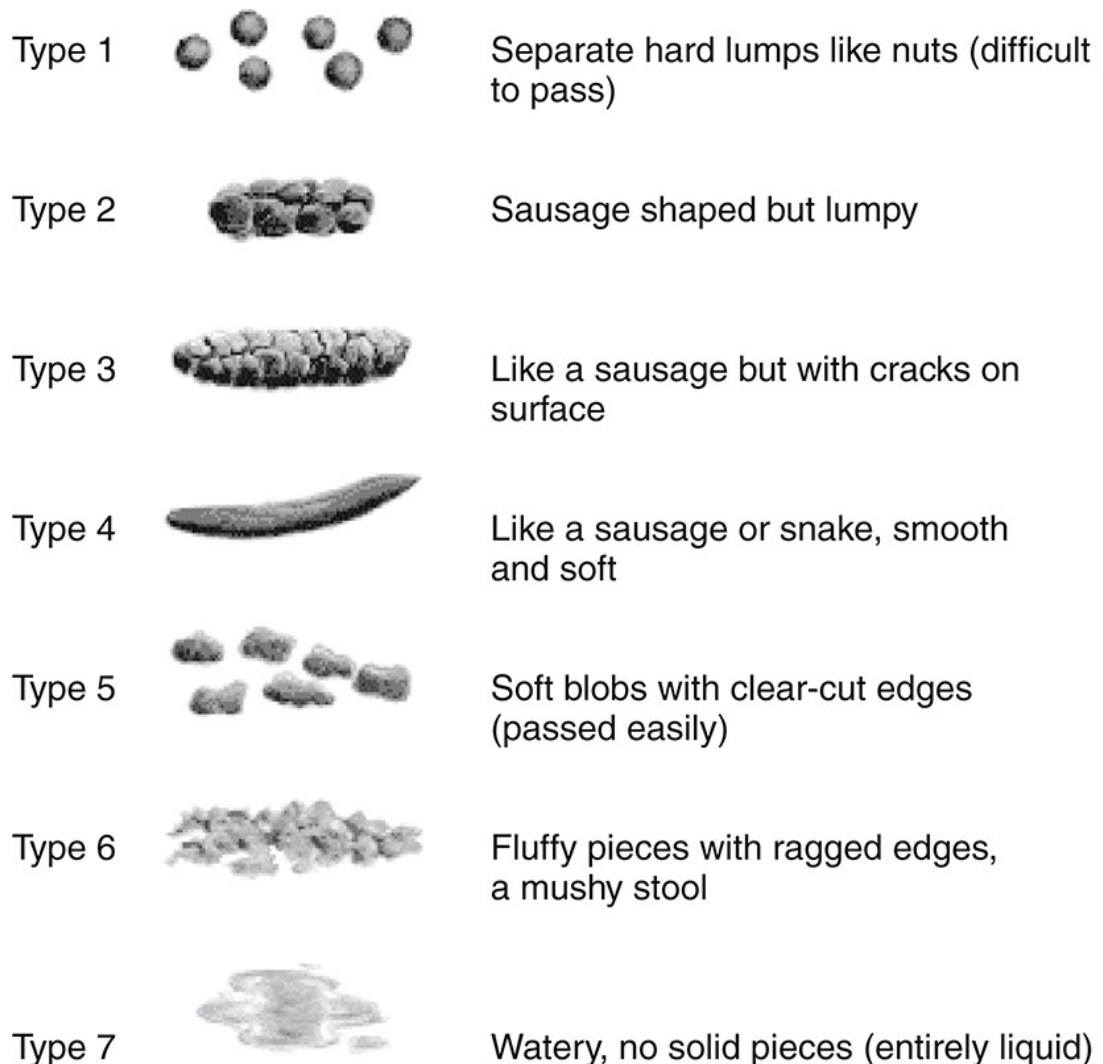

FIG. 47.6 Bristol Stool Form Scale.

Used with permission. Bristol Stool Form Guideline.

<https://www.webmd.com/digestive-disorders/poop-chart-bristol-stool-scale>.

- *Identification of routines followed to promote bowel elimination:* Examples are drinking hot liquids, eating specific foods, or taking time to defecate during a certain part of the day or use of laxatives, enemas, or bulk-forming fiber additives.
- *Presence and status of bowel diversions:* If a patient has an ostomy, assess frequency of emptying the ostomy pouch, character of feces, appearance and condition of the stoma (color, height at or above skin level), condition of peristomal skin, type of pouching system device used, and methods used to maintain the function of the ostomy.
- *Changes in appetite:* Include changes in eating patterns and a change in weight (amount of loss or gain). If a loss of weight is present, ask whether the patient intended to lose weight (e.g., a diet or exercise routine) or whether it happened unexpectedly.
- *Diet history:* Determine the patient's dietary preferences. Determine the intake of fruits, vegetables, and whole grains and whether mealtimes are regular or irregular.
- *Description of daily fluid intake:* This includes the type and amount of fluid. Patients often estimate the amount using common household measurements.
- *History of surgery or illnesses affecting the GI tract:* This information helps explain symptoms, the potential for maintaining or restoring normal bowel elimination pattern, and whether there is a family history of GI cancer.
- *Medication history:* Ask patients for a list of all the medications they take, and assess whether they take medications such as laxatives, antacids, iron supplements, and analgesics that alter defecation or fecal characteristics.
- *Emotional state:* A patient's emotional status may alter frequency of defecation. Ask the patient whether he or she has experienced unusual stress and if so, whether he or she thinks that this may have caused a change in bowel movements.
- *History of exercise:* Ask the patient to specifically describe the type and amount of daily exercise.
- *History of pain or discomfort:* Ask the patient whether there is a history of abdominal or anal pain. The type, frequency, and location of pain help identify the source of the problem. For instance, cramping pain, nausea, and the absence of bowel movements sometimes indicate there is an intestinal obstruction.
- *Social history:* Patients have many different living arrangements. Where patients live affects their toileting habits. If the patient lives with other people, ask how many bathrooms there are. Find out whether the patient must share a bathroom, creating a need to adjust the time that he or she uses the bathroom to accommodate others. If the patient lives

alone, can he or she ambulate to the toilet safely? When patients are not independent in bowel management, determine who helps them and how.

- *Mobility and dexterity*: Evaluate patients' mobility and dexterity to determine whether they need assistive devices or help from personnel

See [Box 47.3](#) for a summary of the types of assessment questions to use for gathering a detailed nursing history.

Box 47.3 Nursing Assessment Questions

Signs and Symptoms

Nausea or Vomiting: Onset, Duration, Associated Symptoms, Character, Exposures

- When did the nausea/vomiting start?
- Is it related to particular stimuli (odors, after eating specific food)?
- How does the emesis look (mucus, blood, coffee-ground appearance, undigested food), and what is the color?
- Do you have other symptoms such as fever, dizziness, headaches, abdominal pain, or weight loss?
- Do you have family members who are experiencing the same symptoms?

Indigestion: Onset, Character, Location, Associated Symptoms, Alleviating Factors

- Is the indigestion related to meals, types or quantity of food, time of day or night?
- Does the discomfort from indigestion radiate to the shoulders or arms?
- Do you feel bloated after eating?
- Do you have any other symptoms (vomiting, headaches, diarrhea, belching, flatulence, heartburn, or pain)?
- Does the indigestion respond to antacids or other self-care measures?

Diarrhea: Onset, Duration, Character, Associated Symptoms, Alleviating Factors, Exposure

- When did the diarrhea start? Was it gradual or sudden?
- How many stools do you have per day? Is it watery or explosive? What is the color and consistency?
- Have you had fever, chills, weight loss, or abdominal pain?
- Have you taken antibiotics recently?
- Have you been under stress?
- What have you used to try to alleviate the diarrhea? Was it successful?
- Have you been out of the country recently?

Constipation: Onset, Character, Symptoms, Alleviating Factors

- When was your last bowel movement? How many bowel movements do you have in a typical week?
- Is this a recent occurrence or a long-standing problem?
- Describe your bowel movements.
- Do you have to strain to have a bowel movement?
- Do you have abdominal or rectal pain when you have a bowel movement?
- Do you feel as though your bowel movements are incomplete?
- Have you recently changed your diet or fluid intake?
- Do you use stool softeners, laxatives, or enemas?
- Has it ever been necessary to manually remove the bowel movements?

Medical History

- Do you have a previous history of gastrointestinal problems or disease? If yes, explain.
- Have you had abdominal surgery or trauma?
- Do you have a history of major illnesses such as cancer; arthritis; or respiratory, kidney, or cardiac disease?
- Which medications do you take?

Effect on the Patient

- How do these symptoms affect you?
- Have you missed work or social engagements because of these symptoms?

Physical Assessment

Conduct a physical assessment of body systems and functions likely to be influenced by the presence of elimination problems (see [Chapter 30](#)).

Mouth

Inspect the patient's teeth, tongue, and gums. Poor dentition or poorly fitting dentures influence the ability to chew. Sores in the mouth make eating not only difficult but also painful.

Abdomen

Inspect all four abdominal quadrants for contour, shape, symmetry, and skin color. Note masses, peristaltic waves, scars, venous patterns, stomas, and lesions. Normally you do not see peristaltic waves. Observable peristalsis is often a sign of intestinal obstruction

Abdominal distention appears as an overall outward protuberance of the abdomen. Intestinal gas, large tumors, or fluid in the peritoneal cavity causes distention. A distended abdomen feels tight like a drum; the skin is taut and appears stretched.

Normal bowel sounds occur every 5 to 15 seconds and last a second to several seconds. Absent (no auscultated bowel sounds) or hypoactive sounds occur with an ileus such as after abdominal surgery but may also mean that you did not capture the bowel sounds when you were assessing them. High-pitched and hyperactive bowel sounds occur with small intestine obstruction and inflammatory disorders. Although auscultating bowel sounds during assessment is standard nursing practice, some current research questions its validity.

Auscultation of the abdomen is done with a stethoscope, but the validity and reliability of this practice has come into question. A 2018 systematic review of the literature on bowel sound auscultation in ICU patients concluded that there is a low sensitivity, low positive predictive value, and poor inter- and intra-observer agreement in auscultating bowel sounds. The authors stated that bowel sounds were not sufficiently accurate for clinical decision making and questioned the usefulness of the practice ([Van Bree et al., 2018](#)).

Percussion identifies underlying abdominal structures and detects lesions, fluid, or gas within the abdomen. Gas or flatulence creates a tympanic note. Masses, tumors, and fluid are dull to percussion.

Gently palpate the abdomen for masses or areas of tenderness. It is important for your patient to relax. Tensing abdominal muscles interferes with palpating underlying organs or masses.

Rectum

Inspect the area around the anus for lesions, discoloration, inflammation, and hemorrhoids. Pain results when hemorrhoid tissues are irritated. The primary goal for a patient with hemorrhoids is to have soft-formed, painless bowel movements. Proper diet, fluids, and regular exercise improve the likelihood of stools being soft. If the patient becomes constipated, passage of hard stools causes bleeding and irritation. An ice pack or a warm sitz bath (see [Chapter 48](#)) provides temporary relief of swollen hemorrhoids. A health care provider sometimes prescribes topical medication to relieve the swelling and pain.

Laboratory Tests

There are no blood tests to specifically diagnose most GI disorders, but hemoglobin and hematocrit help determine whether anemia from GI bleeding is present. Other laboratory tests often ordered by the health care provider include liver function tests, serum amylase, and serum lipase, which are used to assess for hepatobiliary diseases and pancreatitis.

Fecal Specimens

You need to ensure that specimens are obtained accurately, labeled properly in appropriate containers, and transported to the laboratory on time. Laboratories provide special containers for fecal specimens. Some tests require that specimens are placed in chemical preservatives, and some require that they are refrigerated or placed on ice after collection and before delivery to the laboratory. Use medical aseptic technique during collection of stool specimens (see [Chapter 28](#)).

Hand hygiene is necessary for anyone who comes in contact with the specimen. Often the patient is able to obtain the specimen if properly instructed. Teach the patient to avoid mixing feces with urine or water. He or she defecates into a clean, dry bedpan or a special container under the toilet seat. Observe the stool characteristics when collecting a specimen ([Table 47.1](#)).

TABLE 47.1**Fecal Characteristics**

Characteristic	Normal	Abnormal	Abnormal Cause
Color	Infant: yellow; adult: brown	White or clay	Absence of bile
		Black or tarry (melena)	Iron ingestion or gastrointestinal (GI) bleeding
		Red	GI bleeding, hemorrhoids, ingestion of beets
		Pale and oily	Malabsorption of fat
Odor	Malodorous; may be affected by certain foods	Noxious change	Blood in feces or infection
Consistency	Soft, formed	Liquid	Diarrhea, reduced absorption
		Hard	Constipation
Frequency	Varies: infant 4 to 6 times daily (breastfed) or 1 to 3 times daily (bottle-fed); adult twice daily to 3 times a week	Infant more than 6 times daily or less than once every 1 to 2 days; adult more than 3 times a day or less than once a week	Hypermotility or hypomotility
Shape	Resembles diameter of rectum	Narrow, pencil shaped	Obstruction, increased peristalsis
Constituents	Undigested food, dead bacteria, fat, bile pigment, cells lining intestinal mucosa, water	Blood, pus, foreign bodies, mucus, worms	Internal bleeding, infection, swallowed objects, irritation, inflammation, infestation of parasites
		Oily stool	Malabsorption syndrome, enteritis, pancreatic disease, surgical resection of intestine
		Mucus	Intestinal irritation, inflammation, infection, or injury

Tests performed by the laboratory for occult (microscopic) blood in the stool and stool cultures require only a small sample. Collect about a 3-cm (1-inch) mass of formed stool or 15 to 30 mL of liquid stool. Tests for measuring the output of fecal fat require a 3- to 5-day collection of stool. You need to save all fecal material throughout the test period.

After obtaining a specimen, label and tightly seal the container and complete all laboratory requisition forms. Record specimen collections in the patient's medical record. It is important to avoid delays in sending specimens to the laboratory. Some tests such as measurement for ova and parasites require the stool to be warm. When stool specimens remain at room temperature, bacteriological changes that alter test results occur.

A common stool test is the *fecal occult blood test (FOBT)*, which measures microscopic amounts of blood in the feces. It is a useful screening test for colon cancer as recommended by the American Cancer Society. There are two types of tests, the guaiac fecal occult blood test (gFOBT) and the *fecal immunochemical test (FIT)*. The FIT test requires no preparation or dietary restrictions and is a more sensitive test, but it is more expensive; thus, the gFOBT is more commonly used. The nurse or the patient needs to repeat the test at least 3 times on three separate bowel movements. The FOBT is done in a patient's home or health care provider's office (Box 47.4). All positive tests are followed up with flexible sigmoidoscopy or *colonoscopy* (ACS, 2018).

Box 47.4 Procedural Guidelines Performing a Guaiac

Fecal Occult Blood Test

Delegation and Collaboration

The skill of fecal occult blood test (FOBT) can be delegated to assistive personnel (AP). However, the nurse is responsible for assessing the significance of the findings. You may need to send the specimen to the laboratory. Refer to your agency policies. The nurse instructs the AP to:

- Notify the nurse if frank bleeding occurs after obtaining the sample.

Equipment

Hemoccult test paper, Hemoccult developer, wooden applicator, and clean gloves (Check the expiration dates on the developer and the test paper before using.)

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy.
2. Explain purpose of test and ways patient can help. Patient can collect own specimen if possible.
3. Perform hand hygiene and apply clean gloves.
4. Use tip of wooden applicator (see illustration) to obtain a small part of stool specimen. Be sure that specimen is free of toilet paper and not contaminated with urine.

STEP 4 Equipment needed for fecal occult blood testing.

5. Perform Hemocult slide test:

- a. Open flap of slide and, using a wooden applicator, thinly smear stool in first box of the guaiac paper. Apply a second fecal specimen from a different part of the stool to second box of slide (see illustration).

STEP 5a Application of fecal specimen on guaiac paper.

- b. Close slide cover and turn the packet over to reverse side (see illustration). After waiting 3 to 5 minutes, open cardboard flap and apply 2 drops of developing solution on each box of guaiac paper. A blue color indicates a positive guaiac or presence of fecal occult blood.

STEP 5b Application of Hemocult developing solution on guaiac paper on reverse side of test kit.

- c. Interpret the color of the guaiac paper after 30 to 60 seconds.
d. After determining whether the patient's specimen is positive or negative, apply 1 drop of developer to the quality control section and interpret within 10 seconds.
e. Dispose of test slide in proper receptacle.
6. Wrap wooden applicator in paper towel, remove gloves, and discard in proper receptacle.
 7. Perform hand hygiene.
 8. Record results of test; note any unusual fecal characteristics. (Submit only one sample per day.)

When your patients are going to have a gFOBT, it is important to instruct them to avoid eating red meat for 3 days before testing. If there are no contraindications and it is approved by the health care provider, instruct your patient to stop taking aspirin, ibuprofen, naproxen, or other nonsteroidal antiinflammatory drugs for 7 days because these could cause a false-positive test result. Patients also need to avoid vitamin C supplements and citrus fruits and juices for 3 days before the test because they can cause a false-negative result ([ACS, 2018](#)).

Diagnostic Examinations

For patients experiencing alterations in the GI system, various radiological and diagnostic examinations such as a colonoscopy require bowel preparation (bowel prep) for the test to be completed successfully. A bowel-cleansing program is sometimes difficult or unpleasant for patients. You provide education and support to ensure an optimal test result (Box 47.5).

Box 47.5 Radiological and Diagnostic Tests

Direct Visualization

Endoscopy

- Examinations such as a gastroscopy or colonoscopy use a lighted fiberoptic tube to gain direct visualization of the upper gastrointestinal (GI) tract (upper endoscopy) or large intestine (colonoscopy). The fiberoptic tube contains a lens, forceps, and brushes for biopsy. If an endoscopy identifies a lesion such as a polyp, the polyp can be removed, and a biopsy will be done.
- These tests are done under sedation, usually in outpatient centers.
- Patients receive instruction about the preparation needed for the tests at the time they are scheduled for the procedure. Patients are usually on a clear liquid diet the day before the test. Bowel preparation is necessary before a colonoscopy can be performed successfully.

Indirect Visualization

Anorectal Manometry

- Measures the pressure activity of internal and external anal sphincters and reflexes during rectal distention, relaxation during straining, and rectal sensation.

Plain Film of Abdomen/Kidneys, Ureter, Bladder (KUB)

- A simple x-ray film of the abdomen requiring no preparation.

Barium Swallow/Enema

- An x-ray film examination using an opaque contrast medium (barium, which is swallowed) to examine the structure and motility of the upper GI tract, including pharynx, esophagus, and stomach. Barium instilled through the anal opening via an enema provides visualization of the structures of the lower GI tract.
- Preparation required varies by physician and agency doing the procedure but usually includes a clear liquid diet, laxatives the day before the procedure, and in some instances enemas to empty out any remaining stool particles.

Ultrasound Imaging

- A technique that uses high-frequency sound waves to echo off body organs, creating a picture of the GI tract

Computed Tomography Scan (Virtual Colonoscopy)

- An x-ray examination of the body from many angles using a scanner analyzed by a computer. An oral contrast solution for the patient to drink may be ordered before the test. Intravenous contrast solution may be injected during the test to improve visualization. If contrast is used, patient should not have food or fluids for 4 to 6 hours before the examination.
- Virtual colonoscopy or computerized tomography (CT) colonography requires bowel preparation before the test. This does not replace the colonoscopy because it does not allow for removal of *polyps* and for biopsies to be obtained.

Colonic Transit Study

- The patient swallows a capsule containing radiopaque markers.
- The patient maintains his or her normal diet and fluid intake for 5 days and refrains from medications that affect bowel function. On the fifth day x-ray film examination is performed.

Magnetic Resonance Imaging

- A noninvasive examination that uses magnet and radio waves to produce a picture of the inside of the body.
- Preparation is NPO 4 to 6 hours before examination.
- The patient needs to lie very still. If claustrophobia is a problem, light sedation may be ordered.
- No metallic objects, including metal objects on clothes, are allowed in the room. If the patient has a pacemaker or a metal implanted in his or her body, he or she may not be able to have magnetic resonance imaging (MRI).

REFLECT NOW

The assessment of the body and fecal matter related to bowel elimination requires questions and procedures that are very private to many patients. What actions can you take while conducting this assessment that promote patients' comfort and decrease their embarrassment?

• Nursing Diagnosis

Nursing assessment of a patient's bowel function sometimes reveals data that indicate an actual or potential elimination problem or a problem resulting from elimination alterations. In the examples discussed in the Nursing Care Plan, a patient has constipation as a result of pain medications and decreased fiber intake. Examples of diagnoses that apply to patients with elimination problems include the following:

- *Bowel Incontinence*
- *Constipation*
- *Risk for Constipation*
- *Lack of Knowledge of Dietary Regime*

Associated problems such as age, body-image changes, or skin breakdown require interventions unrelated to bowel function impairment. It is important to establish the correct "related to" factor for a diagnosis. This depends on the thoroughness of your assessment and your recognition of the assessment findings and factors that impair elimination ([Box 47.6](#)). For example, with the

diagnosis of *Constipation* you distinguish between related factors of *nutritional imbalance, exercise, medications, and emotional problems*. Selection of the correct related factors for each diagnosis ensures that you will implement the appropriate nursing interventions.

Box 47.6 Nursing Diagnostic Process: Constipation

Assessment Activities	Assessment Findings
Ask patient about bowel elimination patterns.	Patient reports no bowel movement for 4 days.
Ask patient about other gastrointestinal symptoms.	Patient denies any feeling of nausea, abdominal cramping, or loss of appetite.
Ask patient to describe recent food and fluid intake.	Patient reports drinking two cups of coffee and one glass of iced tea each day; eating one serving of cooked vegetables and a banana every other day; having peanut butter and jelly sandwiches, meat, potatoes, and white bread every day.
Palpate abdomen.	Patient reports feeling of fullness. Left lower quadrant is firm.

• Planning

When planning care, synthesize information from multiple resources (Fig. 47.7). Critical thinking ensures that the plan of care integrates everything known about a patient and current clinical problem. Rely on professional standards when possible—for example, the *American College of Gastroenterology Rome IV Criteria for Colorectal Disorders* (Simren et al., 2017). For the patient with a fecal diversion, referring to *Clinical Guideline: Management of the Adult with a Fecal or Urinary Ostomy* (WOCN, 2017), may be helpful.

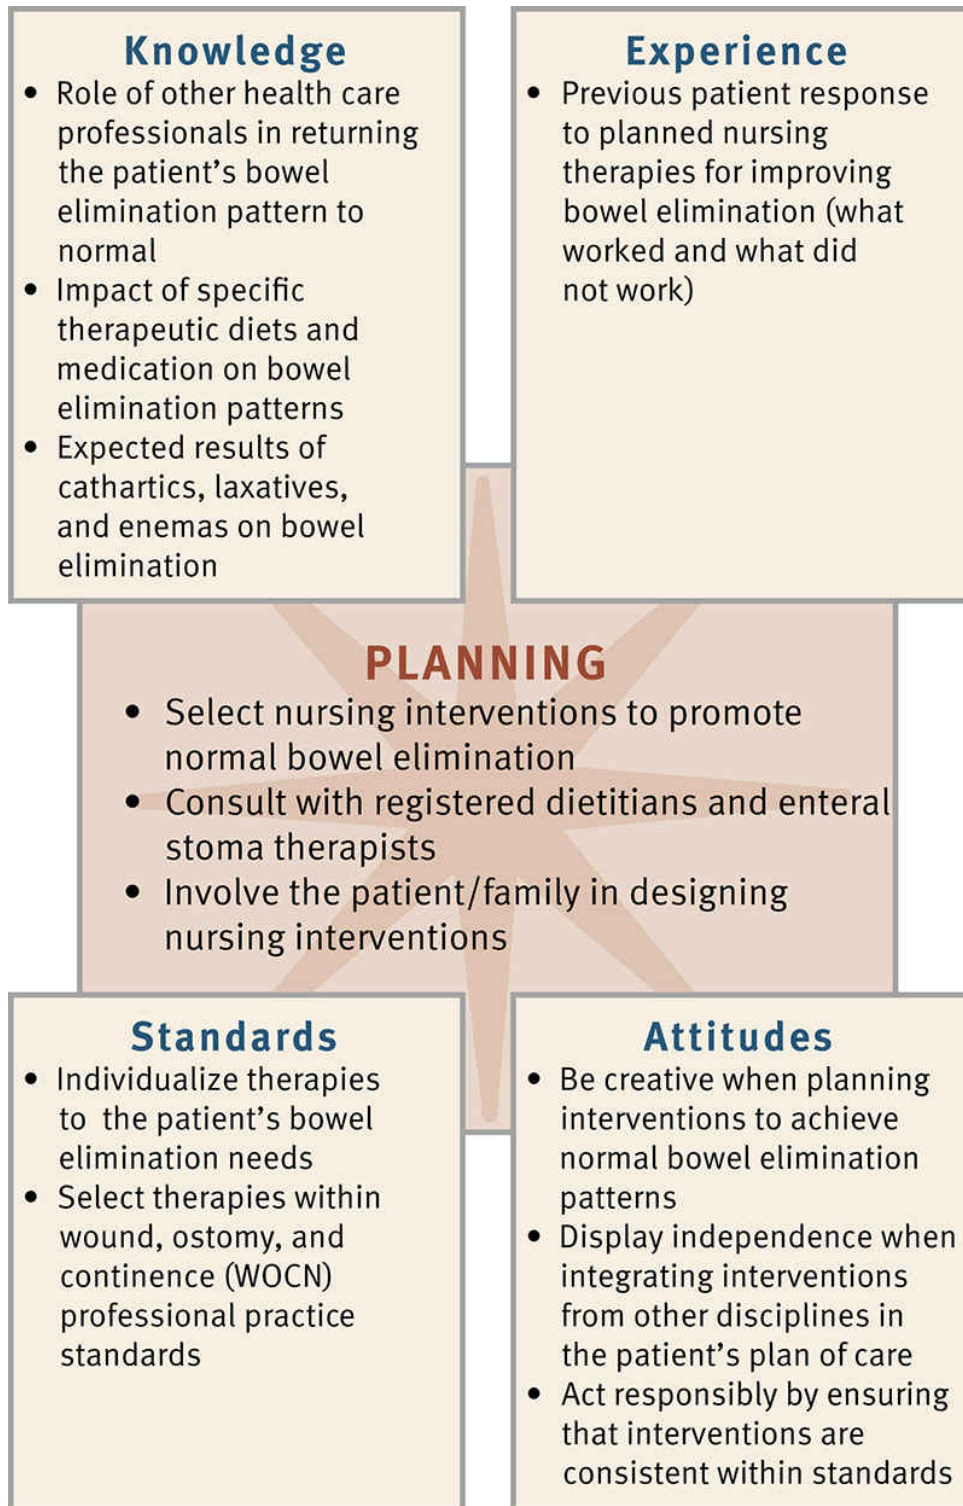

FIG. 47.7 Critical thinking model for elimination planning.

Goals and Outcomes

Help patients establish goals and outcomes by incorporating their elimination habits or routines as much as possible and reinforcing the routines that promote health (see the [Nursing Care Plan](#)). In addition, consider preexisting health concerns. For example, if a patient's diet, activity, and irregular bowel habits caused the elimination problem, help him or her learn to make lifestyle changes to improve bowel function. The overall goal of returning a patient to a normal bowel elimination pattern includes the following outcomes:

- Patient establishes a regular defecation schedule
- Patient lists proper fluid and food intake needed to soften stool and promote regular bowel elimination
- Patient implements a regular exercise program
- Patient reports daily passage of soft, formed brown stool
- Patient does not report straining or discomfort associated with defecation

🌀 Nursing Care Plan

Constipation

Assessment

The home health nurse is visiting Mr. Johnson, age 76, at his home, where he lives alone. Mr. Johnson has two grown children who live in another state. They came to visit him and help him get settled back in his home after being hospitalized. Mr. Johnson had surgery 10 days ago for a total knee replacement after suffering from osteoarthritis for many years. He tells the nurse that he is trying to follow the exercise program that the physical therapist has recommended but is having difficulty because of pain. He is taking the prescribed pain medication because of the continued pain. His history includes hypertension, which has been controlled with medication for the past 10 years. He had some edema of both feet in the hospital and took a mild diuretic for 5 days for relief. The nurse knows that immobility from the surgery, recent use of a diuretic, and opioid pain medication are factors that can cause constipation.

Assessment Activities	Assessment Findings ^a
Ask Mr. Johnson about his bowel elimination patterns since his surgery.	Mr. Johnson tells the nurse that he had one small, hard bowel movement in the hospital but has not had one in the 7 days since he has been home.
Review patient's medication.	Mr. Johnson says he is taking his blood pressure medication, a daily multivitamin with iron , a stool softener once a day, and 1 or 2 oxycodone 4 times a day (Burchum and Rosenthal, 2019).
Review dietary and fluid intake over last day.	Diet included whole-grain cereal , a banana, and toast for breakfast; a sandwich for lunch; and a frozen dinner in the evening, which has a small serving of meat, potatoes or rice, and corn or green beans. He says he is trying to drink fluids but has started feeling a little nauseated when he drinks very much. He also isn't sure if too much fluid would make his feet swell again. He has a cup of coffee and a small glass of orange juice in the morning. He drinks a small glass of iced tea with lunch and dinner.
Assess which foods and fluids Mr. Johnson likes, can obtain, and will prepare.	He reports that a friend will shop for him for groceries. Occasionally a friend brings him dinner, but he relies on frozen dinners because they are easy to get and to heat. He hates prune juice but will drink apple or orange juice. He agrees that he can drink more water but prefers iced tea with sugar. He likes lettuce and tomato salads; most fruits; and frozen peas, corn, or green beans. He'll try whole-grain bread but prefers white bread.
Ask about any nausea or vomiting.	Complains of mild nausea when he eats and a constant feeling of fullness but no vomiting.
Palpate abdomen.	While the nurse is palpating Mr. Johnson's abdomen, Mr. Johnson says, "It really feels full," and he winces with very little pressure applied. Abdomen feels taut and mildly distended.

^a **Assessment findings** are shown in bold type.

Nursing Diagnosis:

Constipation related to opiate-containing pain medication, decreased mobility, and decreased food and fluid intake

Planning

Goals	Expected Outcomes (NOC) ^b
	Bowel Elimination
Mr. Johnson will establish normal defecation.	Mr. Johnson reports passage of soft, formed stool without straining in next 24 hours.
	Nutritional Status: Food and Fluid Intake
Mr. Johnson will make changes to his diet to prevent constipation.	Mr. Johnson drinks at least 1500 mL of fluid over the next 24 hours.
	Mr. Johnson increases the fiber content of his diet by eating an apple with his breakfast, lettuce and tomato on his sandwich, and some carrots with his dinner.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Constipation/Impaction Management	
Encourage fluid intake of appropriate fluids, fruit juice, and water.	At least 1500 mL fluid intake daily will help to soften the stool (Mayo Clinic, 2017).
Encourage activity within patient's mobility regimen.	Minimal activity (such as leg lifts) increases peristalsis (Harding et al, 2020).
Instruct Mr. Johnson to eat more fruits and vegetables and have a bran cereal for breakfast.	Added fiber in food relieves constipation (NIH, 2018a).
Provide stimulant laxative and stool softeners as ordered.	Stimulant laxatives increase peristalsis and are an effective way to relieve constipation and promote normal bowel function when used on a short-term basis (Burchum and Rosenthal, 2019).
Encourage Mr. Johnson to try to have a bowel movement at the same time each day.	A regular time for bowel movements encourages normal bowel function (Harding et al, 2020).

^c Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Ask Mr. Johnson to identify foods high in fiber and fluid intake.	Able to state appropriate foods and fluids but still has little appetite and feels full soon after eating.	Mr. Johnson verbalizes understanding of teaching.
Get medication history for past 2 days.	Patient has taken a stimulant laxative and stool softener twice a day for last 2 days.	Patient has not had a bowel movement.
Ask Mr. Johnson about physical activity.	Mr. Johnson states that he has not changed his activity pattern because of the pain from surgery.	Mr. Johnson did not increase activity pattern and needs to continue to work on this intervention. Revise care plan.
Inquire about bowel movements.	Mr. Johnson still has not had a bowel movement.	Mr. Johnson did not achieve passage of regular, formed stool. Revise care plan.

Building Competency in Patient-Centered Care

Mr. Johnson started taking a stimulant laxative every day to avoid constipation after he had a fecal impaction removed. He drank more fluids, especially water, and began to add more fruits and vegetables to his diet. On the day after the impaction was removed, he had a formed, firm bowel movement with some straining required. Then he began to have daily bowel movements with soft, formed stool. Now it is 1 month later, and he is still taking laxatives but not continuing with the fluid and dietary modifications that were recommended for him. The physical therapist is ready to discharge him from home care but asks the nurse to make another visit when Mr. Johnson states he is having trouble moving his bowels. Which assessment questions and teaching strategies, approaches, and tools does the nurse use to enhance Mr. Johnson's learning and ability to prevent constipation?

Setting Priorities

Defecation patterns vary among individuals. For this reason, a nurse and patient work together closely to plan effective interventions. Patients often have multiple diagnoses. The concept map (Fig. 47.8) shows an example of how the nursing diagnosis of constipation is related to three other diagnoses and their respective interventions. A realistic time frame to establish a normal defecation pattern for one patient is sometimes very different for another. In a

patient with recent abdominal surgery, the priorities of pain management and the avoidance of constipation through increasing fluids in the diet and encouraging early ambulation help in the recovery process.

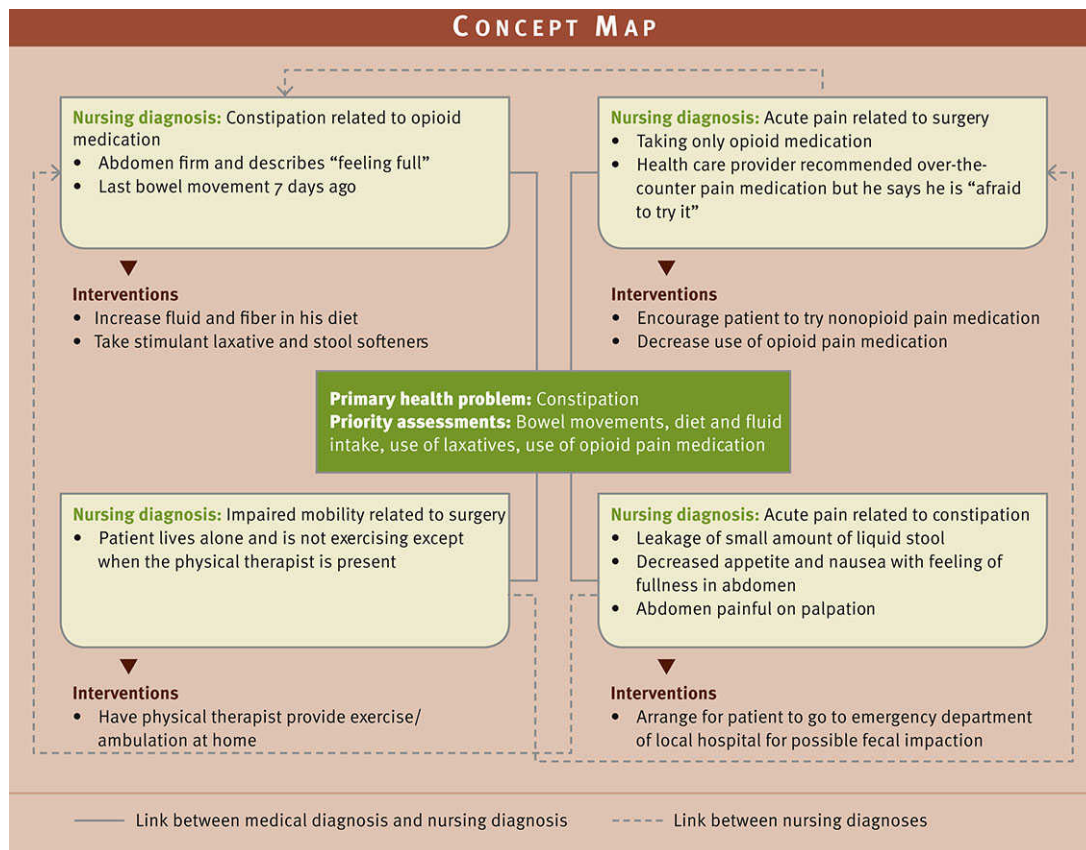

FIG. 47.8 Concept map for Mr. Johnson.

Teamwork and Collaboration

When patients are disabled or debilitated by illness, you need to include the family in the plan of care. In some situations, family members have the same ineffective elimination habits as the patient. Thus, patient and family teaching is an important part of the care plan. Other health team members such as registered dietitians and WOCNs are often valuable resources. You coordinate activities of the interprofessional health care team.

A patient with alterations in bowel elimination sometimes requires intervention from several members of the health care team. Certain tasks such as assisting patients onto the bedpan or bedside commode are appropriate to delegate to assistive personnel (AP). It is important to remind the AP to report any abnormal findings or difficulties encountered during the elimination process. Many of the diagnostic tests for evaluation of the GI system are

performed by nonnursing personnel. Maintaining ongoing communication with these caregivers will ensure that you provide safe and effective patient-centered care and address a patient's needs, wants, and concerns.

Implementation

Successful nursing interventions improve patients' and family members' understanding of bowel elimination. Teach them about proper diet, adequate fluid intake, and factors that stimulate or slow peristalsis such as emotional stress. This is often best done during a patient's mealtime. Patients also need to learn the importance of establishing regular bowel routines, exercising regularly, and taking appropriate measures when elimination problems develop.

Health Promotion

One of the most important habits to teach regarding bowel habits is to take time for defecation. To establish regular bowel habits, a patient needs to know when the urge to defecate normally occurs. Advise the patient to begin to establish a routine during a time when defecation is most likely to occur, usually an hour after a meal. When patients are restricted to bed or need help to ambulate, offer a bedpan or help them reach the bathroom in a timely manner.

Colorectal cancer is the third most common cancer in the United States and the second most common cause of cancer death (ACS, 2018). When diagnosed early, it can be treated and eliminated. Following the guidelines for prevention, knowing the early symptoms, and seeking medical help if these symptoms occur are the most effective ways to prevent death from this disease (Box 47.7).

Box 47.7 Screening for Colorectal Cancer

Risk Factors

- Age: Over 50
- Family history: Colorectal cancer, familial adenomatous polyposis, hereditary nonpolyposis colon cancer (Lynch syndrome)
- Personal history: Colorectal cancer or colorectal polyps, inflammatory bowel disease (IBD)
- Race: African Americans have highest colon cancer rates
- Diet: High intake of red meat and processed meats such as lunch meats or hot dogs

- Obesity and physical inactivity
- Smoking and heavy alcohol consumption

Warning Signs

- Change in bowel habits (e.g., diarrhea, constipation, narrowing of stool lasting more than few days)
- Rectal bleeding or blood in stool
- Sensation of incomplete evacuation
- Unexplained abdominal or back pain

American Cancer Society Screening Guidelines for the Early Detection of Colorectal Cancer in Average-Risk Asymptomatic People

Test	Frequency
Guaiac fecal occult blood test (gFOBT) done on multiple samples at home	Annual, starting at age 45
Fecal immunochemical test (FIT) done on multiple samples at home	Annual, starting at age 45
Flexible sigmoidoscopy	Every 5 years, starting at age 45
DNA stool test	Every 3 years starting at age 45
Computed tomography, colonography	Every 5 years, starting at age 45
Colonoscopy	Every 10 years, starting at age 45

These procedures will be ordered by a health care provider, depending on availability of resources and patient needs. If positive findings result from the flexible sigmoidoscopy or colonography, follow-up with a colonoscopy should be done. Those with higher risk of colorectal cancer due to personal or family history may be advised to have earlier or more frequent screening.

Data from American Cancer Society, 2018, www.cancer.gov.

African Americans have the highest rates of cancer and highest death rates from cancer of any cultural group in the United States. However, for the first time, one study showed that the death rates from lung, colorectal, and prostate cancer are dropping faster in African Americans than in whites (ACS, 2019). There still is a lower rate of colorectal cancer screening among African Americans, but this disparity is decreasing (Box 47.8).

Box 47.8 Cultural Aspects of Care Variables

Influencing Colorectal Cancer Screening in African Americans

There has been a decline in the incidence and mortality rates for colorectal cancer in the United States over the past 10 years. African Americans have a higher incidence of colorectal cancer and have a higher rate of death from the cancer. However, in 2019 the American Cancer Society reported that the death rate from colorectal cancer is dropping faster in the African-American population than in whites (ACS, 2019). Patient factors that contribute to disparities include poor knowledge of benefits of colorectal cancer screening, limited access to health care, and insurance status, along with fear and anxiety. A study of this disparity in 2005 by the American College of Gastroenterology included the recommendation that African Americans begin cancer screening at the age of 45. However, most insurances and providers followed the American Cancer Society recommendation for screening to start at age 50 (Williams et al., 2016). With the recent change to age 45 for all groups for screening to begin, it is hoped that this will lead to earlier detection across all racial and ethnic groups in the United States (ACS, 2018).

Implications for Patient-Centered Care

- Lack of routine visits to a primary care provider is one of the strongest predictors for inadequate colorectal cancer (CRC) screening and advanced stage at presentation (Williams et al., 2016).
- Patients who do not have health insurance frequently do not seek CRC screening (Williams et al., 2016).
- Patients who participate in preventive health practices (e.g., regular physical activity) often seek regular screening for CRC because these patients are often interested in promoting their own health (Williams et al., 2016).
- Identification of additional social system predictors such as family support, church affiliation, and geographical access also help in receiving timely CRC screening (Williams et al., 2016).
- Removing barriers of safety, quality, and cost-effectiveness improves the involvement of patients in CRC screening (ACS, 2018).

Promotion of Normal Defecation

A number of interventions stimulate the defecation reflex, affect the character of feces, or increase peristalsis to help patients evacuate bowel contents normally and without discomfort.

Sitting Position

Help patients who have difficulty sitting because of muscular weakness and mobility problems. Place an elevated seat on the toilet or a bedside commode when patients are unable to lower themselves to a sitting position because of pain or weakness. These seats require patients to use less effort to sit or stand.

Positioning on Bedpan

Patients restricted to bed use bedpans for defecation. Women use bedpans to pass both urine and feces, whereas men use bedpans only for defecation. Sitting on a bedpan is often uncomfortable. Help position patients comfortably. Two types of bedpans are available (Fig. 47.9). The regular bedpan, made of plastic, has a curved smooth upper end and a sharper-edged lower end and is about 5 cm (2 inches) deep. The smaller fracture pan, designed for patients with lower-extremity fractures, has a shallow upper end about 2.5 cm (1 inch) deep. The shallow end of the pan fits under the buttocks toward the sacrum; the deeper end, which has a handle, goes just under the upper thighs. The pan needs to be high enough that feces enter it.

FIG. 47.9 Types of bedpans. From left, regular bedpan and fracture bedpan.

When positioning a patient, it is important to prevent muscle strain and discomfort. Never try to lift a patient onto a bedpan. Never place a patient on a bedpan and then leave with the bed flat unless activity restrictions demand it because it forces the patient to hyperextend the back to lift the hips on the pan. The proper position for the patient on a bedpan is with the head of the bed elevated 30 to 45 degrees (Figs. 47.10 and 47.11). When patients are immobile or it is unsafe to allow them to raise their hips, it is safest for both caregivers and

patients to roll them on to the bedpan (Box 47.9). Always wear gloves when handling a bedpan.

FIG. 47.10 Improper positioning of patient on bedpan.

FIG. 47.11 Proper position reduces patient's back strain.

Box 47.9 Procedural Guidelines **Assisting Patient On and Off a Bedpan**

Delegation and Collaboration

The skill of providing a bedpan can be delegated to assistive personnel (AP). The nurse instructs the AP to:

- Correctly position patients with mobility restrictions or those who have therapeutic equipment such as wound drains, intravenous (IV) catheters, or traction.
- Provide perineal and hand hygiene for patient as necessary after using a bedpan.

Equipment

Clean gloves; bedpan (regular or fracture) (Fig. 47.9); bedpan cover; toilet tissue or premoisturized perineal wipes; specimen container (if necessary); plastic bag clearly labeled with date, patient's name, and identification number; basin; washcloths; towels; soap; waterproof, absorbent pads (if necessary); clean drawsheet (if necessary); stethoscope.

Steps

1. Assess patient's normal bowel elimination habits: routine pattern, character of stool, effect of certain foods/fluids and eating habits on bowel elimination, effect of stress and level of activity on normal bowel elimination patterns, current medications, and normal fluid intake.
2. Determine need for stool specimen before bedpan use
3. Perform hand hygiene

Clinical Decision: If patient is postoperative or has a gastrointestinal illness, auscultate for bowel sounds and palpate abdomen for distention.

4. Assess patient to determine level of mobility, including ability to sit upright and lift hips or turn.
5. Assess patient's level of comfort. Ask about presence of rectal or abdominal pain, presence of hemorrhoids, or irritation of skin surrounding anus.
6. Apply clean gloves. Inspect condition of perianal and perineal skin. Remove and dispose of gloves and perform hand hygiene.
7. For patient comfort prepare metal bedpan by running warm water over it for a few minutes.

Clinical Decision: *Use a fracture pan if the patient had a total hip replacement. An abduction pillow must be placed between the legs when turning patient to prevent dislocation of new joint.*

8. Provide privacy by closing curtains around bed or door of room.
9. Raise side rail on opposite side of bed.

10. Raise bed horizontally according to your height.
11. Assist patient to the supine position.
12. Place patient who can assist on bedpan.
 - a. Perform hand hygiene and apply clean gloves. Raise head of patient's bed 30 to 60 degrees.
 - b. Remove upper bed linens so that they are out of the way but do not expose patient.
 - c. Have patient flex knees and lift hips upward.
 - d. Place hand closest to patient's head palm up under patient's sacrum to help lift. Ask patient to bend knees and raise hips. As patient raises hips, use other hand to slip bedpan under him or her (see illustration). Be sure that open rim of bedpan is facing toward foot of bed. Do not force pan under patient's hips (see Fig. 47.11). (*Optional:* Have patient use overhead trapeze frame to raise hips.)

STEP 12d Placing bedpan under patient's hips.

- e. *Optional:* If using fracture pan, slip it under patient as hips are raised (see illustration). Be sure that deep, open, lower end of bedpan is facing toward foot of bed.

STEP 12e Patient lifts hips as fracture pan is positioned.

13. Place patient who is immobile or has mobility restrictions on bedpan.
 - a. Perform hand hygiene and apply clean gloves. Lower head of bed flat or raise head slightly (if tolerated by medical condition).
 - b. Remove top linens as necessary to turn patient while minimizing exposure.
 - c. Assist patient to roll onto side with back toward you. Place bedpan firmly against patient's buttocks and down into mattress. Be sure that open rim of bedpan is facing toward foot of bed (see illustrations).
 - d. Keep one hand against bedpan; place other around far hip of patient. Assist patient to roll back onto bedpan, flat in bed. Do not force pan under patient.
 - e. Raise patient's head 30 degrees or to a comfortable level (unless contraindicated).
 - f. Have patient bend knees (unless contraindicated).

14. Maintain patient's comfort, privacy, and safety. Cover patient for warmth. Place small pillow or rolled towel under lumbar curve of back. Leave room but stay close by.
15. Place nurse call system and toilet tissue within reach for patient.
16. Ensure that bed is in lowest position and raise upper side rails.
17. Remove and discard gloves and perform hand hygiene.
18. Allow patient to be alone, but monitor status and respond promptly.
19. Perform hand hygiene and apply clean gloves.
20. Remove bedpan:
 - a. Perform hand hygiene and apply clean gloves. Place patient's bedside chair close to working side of bed.
 - b. Maintain privacy; determine if patient is able to wipe own perineal area. If you clean perineal area, apply clean gloves and use several layers of toilet tissue or disposable washcloths. For female patients clean from mons pubis toward rectal area.
 - c. Deposit contaminated tissue in bedpan if no specimen or intake and output (I&O) is needed. Remove and dispose of gloves and perform hand hygiene.
 - d. **For mobile patient:** Ask patient to flex knees, placing body weight on lower legs, feet, and upper torso; lift buttocks up from bedpan. At same time place hand farthest from patient on side of bedpan to support it (prevent spillage) and place other hand (closest to patient) under sacrum to help lift. Have patient lift and remove bedpan. Place bedpan on draped bedside chair and cover.
 - e. **For immobile patient:** Apply clean gloves. Lower head of bed. Help patient roll onto side away from you and off bedpan. Hold bedpan flat and steady while patient is rolling off; otherwise spillage will occur. Place bedpan on draped bedside chair and cover.
 - f. Assist patient with hand and perineal hygiene as needed.
21. Change soiled linens, remove and dispose of gloves, and return patient to comfortable position.
22. Place bed in its lowest position. Ensure that nurse call system, drinking water, and desired personal items (e.g., books) are within easy access
Option: Obtain stool specimen as ordered. Wear clean gloves when emptying contents of bedpan into toilet or in special receptacle in utility room. Use spray faucet attached to most institution toilets to rinse bedpan thoroughly. Use disinfectant if required by agency; store pan. Remove and dispose of gloves.
23. Perform hand hygiene and apply clean gloves. Assess characteristics of stool. Note color, odor, consistency, frequency, amount, shape, and constituents. Assess characteristics of urine if patient voided in bedpan.

24. Evaluate patient's ability to use bedpan.
25. Inspect patient's perianal area and surrounding skin while removing bedpan.
26. **Use Teach-Back:** "Since your leg is immobilized, I want to make sure you're comfortable getting off and on the bedpan by using the trapeze to pull your torso off the bed. Show me how you use the trapeze to move your torso." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.

STEP 13c A, Position patient on one side and place bedpan firmly against buttocks. B, Push down on bedpan and toward patient. C, Nurse places bedpan in position. (A and B from Sorrentino SA, Remmert LA: *Mosby's textbook for nursing assistants*, ed 9, St Louis, 2017, Elsevier.)

Acute Care

With some acute illnesses the GI system becomes affected. Changes in a patient's fluid status, mobility patterns, nutrition, and sleep cycle affect regular bowel habits. Surgical interventions on the GI tract obviously affect bowel elimination. However, surgery on other systems (e.g., the musculoskeletal and cardiovascular systems) sometimes also affects it.

Chronically ill and hospitalized patients are not always able to maintain privacy during defecation. In a hospital or extended-care setting, patients sometimes share bathroom facilities with a roommate. In addition, chronic illness may limit a patient's mobility and activity tolerance and require the use of a bedpan or bedside commode. The sights, sounds, and odors associated with sharing toilet facilities or using bedpans are often embarrassing. This embarrassment often causes patients to ignore the urge to defecate, which leads to constipation and discomfort. Remain sensitive to patients' elimination needs, and intervene to help them maintain bowel elimination habits that are as normal as possible.

Cathartics and Laxatives

Some medications initiate and facilitate stool passage. Laxatives and cathartics have the short-term action of emptying the bowel. These agents are also used to cleanse the bowel for patients undergoing GI tests and abdominal surgery. Although the terms *laxative* and *cathartic* are often used interchangeably, cathartics generally have a stronger and more rapid effect on the intestines. Teach patients about the potential harmful effects of overuse of laxatives such as impaired bowel motility and decreased response to sensory stimulus. Make sure patients understand that laxatives are not to be used long term for maintenance of bowel function.

Although patients usually take medications orally, laxatives prepared as suppositories may act more quickly because of their stimulant effect on the rectal mucosa. Suppositories such as bisacodyl act within 30 minutes. Give the suppository shortly before a patient's usual time to defecate or immediately after a meal.

Laxatives are classified by the method by which the agent promotes defecation ([Table 47.2](#)). Some newer drugs are being used now for chronic constipation or motility disorders. It is too soon to tell whether these medications will be effective and safe for long-term treatment, but they are not used for the relief of occasional constipation.

TABLE 47.2

Common Types of Laxatives and Cathartics

Agent/Brand Name	Action	Indications	Risks
Bulk Forming			
Methylcellulose (Citrucel) Psyllium (Metamucil, Naturacil) Polycarbophil (Fibercon)	High-fiber content absorbs water and increases solid intestinal bulk, which will stretch intestinal wall to stimulate peristalsis. Passage of stool will occur in 12 to 24 hours. These agents must be taken with water and should be used with patients who have an adequate food and fluid intake. Patients may note increased gas formation and flatus when they first start taking these laxatives, but this will abate after 4-5 days.	Agents are least irritating, most natural, and safest type of laxatives. Agents are drugs of choice for chronic constipation (e.g., pregnancy, low-residue diet). They also relieve mild diarrhea. If treating diarrhea, administer less water.	Agents that are in powder form could cause constipation if not mixed with at least 240 mL of water or juice and swallowed quickly. Caution is necessary with bulk-forming laxatives that also contain stimulants. Agents are not for patients for whom large fluid intake is contraindicated.
Emollient or Wetting			
Docusate sodium (Colace) Docusate calcium (Surfak) Docusate potassium (Dialose)	Stool softeners are detergents that lower surface tension of feces, allowing water and fat to penetrate. They increase secretion of water by intestine.	Agents are for short-term therapy to relieve straining on defecation (e.g., hemorrhoids, perianal surgery, pregnancy, recovery from myocardial infarction).	Agents are of little value for treatment of chronic constipation.
Osmotic			
Saline-based Magnesium citrate or citrate of magnesia Magnesium hydroxide (Milk of Magnesia) Sodium phosphate (Fleet Phospho-Soda) Polyethylene glycol, lactulose, sorbitol based, Lactulose, Miralax	Osmotic effect increases pressure in bowel to act as stimulant for peristalsis. Osmotic laxatives are any agents that pull fluid into the bowel to soften the stool and distend the bowel to stimulate peristalsis.	Saline-based agents are only for acute emptying of bowel (e.g., endoscopic examination, suspected poisoning, acute constipation). Agents may be used to treat chronic constipation.	Saline-based agents are not for long-term management of constipation or for patients with kidney dysfunction. They may cause toxic buildup of magnesium. Phosphate salts are not recommended for patients on fluid restriction.
Stimulant Cathartics			
Bisacodyl (Dulcolax) Castor oil Casanthranol (Peri-Colace) Correctol Senna (Ex-Lax, Senokot)	Agents cause local irritation to the intestinal mucosa, increase intestinal motility, and inhibit resorption of water in the large intestine. The rapid movement of feces causes retention of water in the stool. The drugs cause formation of a soft-to-liquid stool in 6 to 8 hours and usually contain bisacodyl or senna. These laxatives should be used occasionally because regular use of a stimulant laxative can lead to dependence on the stimulus for defecation.	Agents prepare bowel for diagnostic procedures or may be needed for those with constipation from frequent opioid use	Agents cause severe cramping. Agents are not for long-term use. Chronic use could cause fluid and electrolyte imbalances.

Antidiarrheal Agents

Antidiarrheal agents decrease intestinal muscle tone to slow the passage of feces. As a result, the body absorbs more water through the intestinal walls. However, the cause of diarrhea must be determined before effective treatment

can be ordered by a health care provider. For example, if an infection is the causative factor, an antibiotic may be used for treatment; if inflammation is the cause, steroids may be given. The most commonly used antidiarrheal agents are loperamide or diphenoxylate with atropine. Codeine or tincture of opium may be used for management of chronic severe diarrhea in patients with diseases such as Crohn's disease, ulcerative colitis, and acquired immunodeficiency syndrome (AIDS). Patients need to use antidiarrheal agents that contain opiates with caution because opiates are habit forming.

Enemas

An enema is the instillation of a solution into the rectum and sigmoid colon. The primary reason for an enema is to promote defecation by stimulating peristalsis. The volume of fluid instilled breaks up the fecal mass, stretches the rectal wall, and initiates the defecation reflex. Enemas are also a vehicle for medications that exert a local effect on rectal mucosa. They are used most commonly for the immediate relief of constipation, emptying the bowel before diagnostic tests or surgery, and beginning a program of bowel training.

Cleansing Enemas

Cleansing enemas promote the complete evacuation of feces from the colon. They act by stimulating peristalsis through the infusion of a large volume of solution or through local irritation of the mucosa of the colon. They include tap water, normal saline, soapsuds solution, and low-volume hypertonic saline. Each solution has a different osmotic effect, influencing the movement of fluids between the colon and interstitial spaces beyond the intestinal wall. Infants and children receive only normal saline because they are at greater risk for fluid imbalance.

Tap Water

Tap water is hypotonic and exerts an osmotic pressure lower than fluid in interstitial spaces. After infusion into the colon, tap water escapes from the bowel lumen into interstitial spaces. The net movement of water is low. The infused volume stimulates defecation before large amounts of water leave the bowel. Use caution if ordered to repeat tap-water enemas because water toxicity or circulatory overload develops if the body absorbs large amounts of water.

Normal Saline

Physiologically normal saline is the safest solution to use because it exerts the same osmotic pressure as fluids in interstitial spaces surrounding the bowel. The volume of infused saline stimulates peristalsis. Giving saline enemas lessens the danger of excess fluid absorption.

Hypertonic Solutions

Hypertonic solutions infused into the bowel exert osmotic pressure that pulls fluids out of interstitial spaces. The colon fills with fluid, and the resultant distention promotes defecation. Patients unable to tolerate large volumes of fluid benefit most from this type of enema, which is by design low volume. This type of enema is contraindicated for patients who are dehydrated and young infants. A hypertonic solution of 120 to 180 mL (4 to 6 ounces) is usually effective. The commercially prepared Fleet enema is the most common.

Soapsuds

You add soapsuds to tap water or saline to create the effect of intestinal irritation to stimulate peristalsis. Use only pure castile soap that comes in a liquid form, included in most soapsuds enema kits. Use soapsuds enemas with caution in pregnant women and older adults because they could cause electrolyte imbalance or damage to the intestinal mucosa.

A health care provider sometimes orders a high- or low-cleansing enema. The terms *high* and *low* refer to the height from which, and hence the pressure with which, the fluid is delivered. High enemas cleanse more of the colon. After the enema is infused, ask the patient to turn from the left lateral to the dorsal recumbent, over to the right lateral position. The position change ensures that fluid reaches the large intestine. A low enema cleanses only the rectum and sigmoid colon.

Oil Retention

Oil-retention enemas lubricate the feces in the rectum and colon. The feces absorb the oil and become softer and easier to pass. To enhance action of the oil, the patient retains the enema for several hours if possible.

Other Types of Enemas

Carminative enemas provide relief from gaseous distention. They improve the ability to pass flatus. An example of a carminative enema is MGW solution, which contains 30 mL of magnesium, 60 mL of glycerin, and 90 mL of water.

Medicated enemas contain drugs. An example is sodium polystyrene sulfonate (Kayexalate), used to treat patients with dangerously high serum potassium levels. This drug contains a resin that exchanges sodium ions for potassium ions in the large intestine. Another medicated enema is neomycin solution, an antibiotic used to reduce bacteria in the colon before bowel surgery. An enema containing steroid medication may be used for acute inflammation in the lower colon.

Enema Administration

Enemas are available in commercially packaged, disposable units or with reusable equipment prepared before use. Sterile technique is unnecessary because the colon normally contains bacteria. However, wear gloves to prevent the transmission of fecal microorganisms.

Explain the procedure, including the position to assume, precautions to take to avoid discomfort, and length of time necessary to retain the solution before defecation. If a patient needs to take the enema at home, explain the procedure to a family member.

Giving an enema to a patient who is unable to contract the external sphincter poses difficulties. Give the enema with the patient positioned on the bedpan. Giving the enema with a patient sitting on the toilet is unsafe because the position of the rectal tubing could injure the rectal wall. Skill 47.1 outlines the steps for an enema administration.

Digital Removal of Stool

For a patient with an impaction, the fecal mass is sometimes too large to pass voluntarily. If a digital rectal examination reveals a hard stool mass in the rectum, it may be necessary to manually remove it by breaking it up and bringing out a section at a time. Digital removal is the last resort in the management of severe constipation, but it may be necessary if the fecal mass is too large to pass through the anal canal. The procedure ([Box 47.10](#)) is very uncomfortable for the patient. Excess rectal manipulation causes irritation to the mucosa, bleeding, and stimulation of the vagus nerve, which sometimes results in a reflex slowing of the heart rate ([Hussain et al., 2014](#)).

Box 47.10 PROCEDURAL GUIDELINES Digital Removal of Stool

Delegation and Collaboration

The skill of digitally removing stool cannot be delegated to assistive personnel (AP). In some institutions only health care providers perform this procedure. The nurse instructs the AP:

- To provide perineal care and other necessary hygiene following each bowel movement.
- To observe any evacuated stool for color and consistency.

Equipment

Bedpan, waterproof pad, water-soluble lubricant, washcloths, towels, soap, and clean gloves

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Perform hand hygiene, pull curtains around bed, obtain patient's baseline vital signs and assess level of comfort, auscultate bowel sounds, and palpate for abdominal distention before the procedure.
3. Explain the procedure and help patient lie on left side in Sims' position with knees flexed and back toward you.
4. Drape trunk and lower extremities with a bath blanket and place a waterproof pad under buttocks. Keep a bedpan next to patient.
5. Perform hand hygiene and apply clean gloves; lubricate index finger of dominant hand with water-soluble lubricant.
6. Instruct patient to take slow, deep breaths. Gradually and gently insert index finger into the rectum and advance the finger slowly along the rectal wall.
7. Gently loosen the fecal mass by massaging around it. Work the finger into the hardened mass.
8. Work the feces downward toward the end of the rectum. Remove small pieces one at a time and discard into bedpan.
9. Periodically reassess patient's pulse and level of comfort and look for signs of fatigue. Stop the procedure if pulse rate drops significantly (check agency policy) or rhythm changes.
10. Continue to clear rectum of feces and allow patient to rest at intervals.
11. After completion, wash and dry buttocks and anal area.
12. Remove bedpan; inspect feces for color and consistency. Dispose of feces. Remove gloves by turning them inside out and then discard.
13. Help patient to toilet or on a bedpan if urge to defecate develops.
14. Perform hand hygiene. Record results of procedure by describing fecal characteristics and amount.
15. Follow procedure with enemas or cathartics as ordered by health care provider.
16. Reassess patient's vital signs and level of comfort, auscultate bowel sounds, and observe status of abdominal distention.

Inserting and Maintaining a Nasogastric Tube

A patient's condition or situation sometimes requires special interventions to decompress the GI tract. Such conditions include surgery (see [Chapter 50](#)),

obstruction of the GI tract often caused by tumors, trauma to the GI tract, and conditions in which peristalsis is absent.

A nasogastric (NG) tube is a pliable hollow tube that is inserted through the patient’s nasopharynx into the stomach. NG intubation has several purposes (Table 47.3). There are two main categories of NG tubes: fine- or small-bore tubes and large-bore tubes. Small-bore tubes are frequently used for medication administration and enteral feedings (see Chapter 45 for enteral feedings). Large-bore tubes, 12-Fr and above, are usually used for gastric decompression or removal of gastric secretions. The Levin and Salem sump tubes are the most common for stomach decompression. The Levin tube is a single-lumen tube with holes near the tip. It is connected to a drainage bag or an intermittent suction device to drain stomach secretions.

TABLE 47.3

Purposes of Nasogastric Intubation

Purpose	Description	Type of Tube
Decompression	Removal of secretions and gaseous substances from gastrointestinal (GI) tract; prevention or relief of abdominal distention (Harding et al., 2017)	Salem sump, Levin, Miller-Abbott
Enteral feeding (see Chapter 45)	Instillation of liquid nutritional supplements or feedings into stomach or small intestine for patients with impaired swallowing (Harding et al., 2017)	Duo, Dobhoff, Levin
Compression	Internal application of pressure by means of inflated balloon to prevent internal esophageal or GI hemorrhage (Harding et al., 2017)	Sengstaken-Blakemore
Lavage	Irrigation of stomach in cases of active bleeding, poisoning, or gastric dilation (Harding et al., 2017)	Levin, Ewald, Salem sump

The Salem sump tube is preferable for stomach decompression. The tube has two lumina: one for removal of gastric contents and one to provide an air vent. A blue “pigtail” is the air vent that connects with the second lumen. When the main lumen of the sump tube is connected to suction, the air vent permits free, continuous drainage of secretions. Do not clamp off the air vent if the tube is connected to suction.

NG tube insertion does not require sterile technique. Instead you use clean technique. The procedure is uncomfortable. Patients experience a burning sensation as the tube passes through the sensitive nasal mucosa. When it reaches the back of the pharynx, patients sometimes begin to gag. Help them relax to make tube insertion easier. Some institutions allow the use of Xylocaine jelly or atomized lidocaine when inserting the tube because it decreases patient discomfort during the procedure. The procedure for inserting an NG tube is described in Skill 47.2.

One of the greatest problems in caring for a patient with a NG tube is to maintain comfort. Because the tube irritates the nasal and pharyngeal mucosa, you assess the condition of the patient’s nares and throat for inflammation. The

tape or fixation device used to anchor the tube often becomes soiled or loosened. Change it as needed to prevent migration of the tube. Frequent lubrication of the nares may minimize discomfort. With one nostril occluded, the patient breathes through the mouth. Frequent mouth care helps minimize discomfort from a dry mouth. Water-moistened swabs or lozenges for the patient to suck may provide some relief of mouth and throat dryness. Often patients complain of a sore throat. A health care provider may order gargles with topical Xylocaine jelly to minimize the irritation.

After you insert the tube, you need to maintain its patency. Sometimes the tip of the tubing rests against the stomach wall, or the tube becomes blocked with thick secretions. Flushing the tube regularly with a catheter-tipped syringe filled with normal saline or warm water helps to prevent blockage of the tube. If an NG tube does not drain properly after flushing, reposition it by advancing or withdrawing it slightly. A change in tube position could require physician-ordered imaging to verify correct placement in the patient's GI tract. Consult agency policy and/or provider preferences as necessary.

Continuing and Restorative Care

Regular elimination patterns should begin before a patient goes home or to an extended-care setting. With a new ostomy, a patient or a caregiver needs to learn to manage the care that is required (Box 47.11). Other patients require bowel retraining. It is important to remember that you initiate ostomy care and bowel retraining in acute care settings. However, because these are long-term care needs, teaching usually continues in restorative care or home settings.

Box 47.11 Patient Teaching **Teaching Patients How to Provide Ostomy Care**

Objective

- Patient/caregiver will demonstrate how to empty and change an ostomy pouch.

Teaching Strategies

- Provide a comprehensive list of the products needed to care for the ostomy (Prinz et al., 2015)
- Provide patient/caregiver with supplies to last 1 to 2 weeks and the contact number information for a medical supply company (Prinz et al., 2015).

- Show patient/caregiver the step-by-step approach for changing an ostomy pouch.
- Provide at least one opportunity for patient/caregiver to empty and change the ostomy pouch while patient is in the hospital (Prinz et al., 2015).
- Provide detailed instructions for diet and fluids; peristomal skin care; restrictions on lifting; resuming exercise and intimacy; and when to contact the health care provider (Prinz et al., 2015).
- Arrange follow-up with an ostomy nurse if possible.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Show me how you change your ostomy pouch.
- Tell me three important points about your diet and fluid intake that you need to follow now that you have an ostomy.

Care of Ostomies

Patients with temporary or permanent bowel diversions have unique elimination needs. An individual with an ostomy wears a pouch to collect effluent or output from the stoma. The pouches are odor-proof and have a protective skin barrier surrounding the stoma. Empty the pouch when it is one-third to one-half full. Change the pouching system approximately every 3 to 7 days, depending on a patient's individual needs (Goldberg et al., 2017). Assess the stoma color. It should be pink or red. You observe the skin at each pouch change for signs of irritation or skin breakdown. Skin protection is important because the effluent has digestive enzymes that cause irritant dermatitis if there is leakage on the peristomal skin. Other peristomal skin problems are fungal rashes, folliculitis, or ulcerations. Refer patients with these problems to an ostomy care nurse (Goldberg et al., 2017) (Box 47.12).

Box 47.12 Evidence-Based Practice Recognition of

Peristomal Skin Problems

PICOT Question: In patients with ostomies, what is the effect of patient education and knowledge on the prevention of peristomal skin breakdown?

Evidence Summary

Patients with an ostomy are at risk for development of peristomal skin problems. Studies show that 23% to 45% of persons with ileostomies and 7% to

20% of persons with colostomies will develop peristomal skin complications (Steinhagen et al., 2017). Maintenance of healthy peristomal skin, with the skin around the stoma being clean, dry, and intact, is a priority following ostomy surgery (Goldberg et al., 2017). The most common cause of peristomal skin disorders is effluent, which causes skin irritation, ulceration, or erosion. Reasons for effluent leakage include poor-fitting stoma pouches, poor adhesive adherence, peristomal hernia, and surgical complications (Burch, 2017). With shorter postoperative hospital stays, it is challenging for nurses to provide the extensive patient education on pouching systems, ostomy care, and problem-solving techniques needed to prevent peristomal skin problems (Goldberg et al., 2017). Patients often failed to recognize early signs of skin irritation and did not report a skin problem (Steinhagen et al., 2017). This lack of knowledge resulted in delays in patients seeking health care to treat the skin problem. Patient education is an important factor in preventing complications following ostomy surgery. Nurses need to provide education to patients before discharge and follow up with them after discharge to prevent peristomal skin problems (Prinz et al., 2015).

Application to Nursing Practice

- Evaluate patients' knowledge and ability to assess their peristomal skin changes for early recognition and treatment of skin disorders.
- Provide patient education about signs and symptoms of skin disorders to ensure early identification of skin problems.
- Refer patients to an ostomy nurse if assistance is needed to manage the ostomy (Goldberg et al., 2017).

Irrigating a Colostomy

Although this practice is not as common because of improved odor-proof pouches, some patients irrigate their sigmoid colostomies to regulate colon emptying. This process takes about an hour a day to complete but usually means that a patient wears only a mini-pouch afterward to absorb mucus from the stoma and contain gas. Specific equipment designed for ostomies is used. The equipment has a silicone cone attached by plastic tubing to a bag that will hold the irrigation fluid, which is usually warm water. Follow the routine that the patient has established for this care. Occasionally a patient with a colostomy who has constipation will have an irrigation or enema ordered. Use equipment that is designed specifically for the irrigation rather than an enema administration set used by patients without a stoma.

Pouching Ostomies

An ostomy requires a pouch to collect fecal material. An effective pouching system protects the skin, contains fecal material, remains odor free, and is comfortable and inconspicuous. A person wearing a pouch needs to feel secure enough to participate in any activity (Goldberg et al., 2017).

Many pouching systems are available. To ensure that a pouch fits well and meets a patient's needs, consider the location of the ostomy, type and size of the stoma, type and amount of ostomy drainage, size and contour of the abdomen, condition of the skin around the stoma, physical activities of the patient, patient's personal preference, age and dexterity, and cost of equipment. A **wound, ostomy, and continence nurse (WOCN)** is a nurse specially educated to care for ostomy patients. A WOCN collaborates with staff nurses and patients to be sure that the patients have the best pouching system for their individual needs. A pouching system consists of a pouch and skin barrier (Fig. 47.12). Pouches come in one- and two-piece systems and are flat or convex. Some pouches have the opening precut by the manufacturer; others require the stoma opening to be custom cut to a patient's specific stoma size. Newer pouches have an integrated closure; older ones use a clip to close the pouch. One of the first skills to teach a patient with a new ostomy is how to open and close the pouch. Skill 47.3 describes steps for applying an ostomy pouch.

FIG. 47.12 Ostomy pouches and skin barriers. **A**, One-piece pouch with Velcro closure. **B**, Two-piece pouching system with separate skin barrier and attachable pouch. **Note:** Skin barriers need to be custom cut according to stoma size.
 Courtesy Coloplast, Minneapolis, MN.

Nutritional Considerations

After surgery it usually takes a few days for patients with new ostomies to feel that their appetite has returned to normal. Small servings of soft foods are typically more appetizing, as they would be for any patient who has had an abdominal surgery.

Patients with colostomies have no diet restrictions other than the diet discussed for normal healthy bowel function, with adequate fiber and fluid to keep the stool softly formed. Patients with ileostomies digest their food completely but lose both fluid and salt through their stoma and need to be sure to replace this to avoid dehydration. A good reminder for patients is to encourage drinking an 8-ounce glass of fluid when they empty their pouch. This helps them remember that they have greater fluid needs than they did before having an ileostomy. A condition that occurs infrequently with people with ileostomies is called a *food blockage*. Foods with indigestible fiber such as sweet corn, popcorn, raw mushrooms, fresh pineapple, and Chinese cabbage can cause this problem. However, if patients eat these foods in small quantities, drink fluids with the food, and chew it well, they are unlikely to experience any difficulty.

Psychological Considerations

After ostomy surgery patients face a variety of anxieties and concerns, from learning how to manage their stoma to coping with conflicts of self-esteem, body image, and sexuality. Provide emotional support before and after surgery (Goldberg et al., 2017). Adjustment to a stoma takes time and is a very individual matter. A study of patients with colorectal cancer and a colostomy showed that the lowest quality of life after ostomy surgery occurred at 2 months, with improvement at 6 months and return to almost preoperative levels at 12 months (Goldberg et al., 2017). Important factors affecting adjustment to the stoma include the ability to successfully assume care of the ostomy, including emptying the pouch and changing the pouching system so that unexpected odor and leakage of stool does not occur. Inability to resume self-care sometimes causes a loss of self-esteem. The aging process often affects the ability to manage stomas, even in people who have had them for years. You need to recognize and intervene when problems resulting from advanced age such as skin changes, weight loss or gain, visual impairments, or changes in diet occur. If possible, consult with an ostomy nurse. The Wound, Ostomy and Continence Nurses Society (<http://www.wocn.org>) provides information and helps patients locate a WOCN. Consider referral to local ostomy groups such as those affiliated with the United Ostomy Associations of America at <http://www.ostomy.org>.

REFLECT NOW

When a patient has a new ostomy, he or she is experiencing a significant change in body image. Consider how you can help him or her, the family members, and other nurses to demonstrate acceptance of this change so that the patient feels less isolated and ashamed of his or her ostomy.

Bowel Training

A patient with chronic constipation or fecal incontinence secondary to cognitive impairment may benefit from **bowel training**, also called *habit training*. (NIH, 2018b) The training program involves setting up a daily routine. By attempting to defecate at the same time each day and using measures that promote defecation, a patient may establish a normal defecation pattern. The

program requires time, patience, and consistency. A patient with cognitive impairment needs to have a caregiver able to devote the time to the training program. A successful program includes the following:

- Assessing the normal elimination pattern and recording times when a patient is incontinent
- Incorporating principles of gerontological nursing when providing bowel retraining programs for an older adult (Box 47.13)

Box 47.13 Focus on Older Adults **Bowel Retraining**

- Older age is a risk factor for having constipation. Constipation affects people living in nursing homes, and between 50% and 74% of residents use laxatives (Blekken et al, 2016).
 - Increase fiber in diet with whole grains, legumes, fruits, and vegetables.
 - A minimum of 1500 mL of fluid per day reduces the risk of constipation, with increased fluid needs during summer months and for those on diuretics with stable cardiovascular status.
 - If holding a drinking cup is a problem, consider using a lighter plastic cup and filling half full, refilling frequently.
 - Encourage regular exercise within the limitations imposed by other conditions.
 - Patients need to feel at ease during elimination. Lack of privacy leads a patient to ignore the urge to defecate.
 - Review all medications with a patient's health care provider to substitute medications that are less likely to cause constipation whenever possible.
 - Behavioral interventions such as timed toileting help establish a scheduled time for bowel elimination. Try to maintain the same schedule each day for toileting.
-
- Choosing a time based on the patient's pattern to initiate defecation-control measures
 - Offering a hot drink (hot tea) or fruit juice (prune juice) (or whatever fluids normally stimulate peristalsis for the patient) before the defecation time
 - Helping the patient to the toilet at the designated time
 - Providing privacy
 - Instructing the patient to lean forward at the hips while sitting on the toilet, apply manual pressure with the hands over the abdomen, and bear down but not strain to stimulate colon emptying

- An unhurried environment and a nonjudgmental caregiver
- Maintaining normal exercise within the patient's physical ability

Maintenance of Proper Fluid and Food Intake

In choosing a diet for promoting normal elimination, consider the frequency of defecation, characteristics of feces, and types of foods that impair or promote defecation. A well-balanced diet with whole grains, legumes, fresh fruits, and vegetables eaten regularly promotes normal elimination. Fiber adds bulk to the stool, eliminates excess fluids, and promotes more frequent and regular movements. With increasing fiber, it is important to drink enough fluids. If fluid intake is inadequate, the stool becomes hard because less water is retained in the large intestine to soften it. The amount of fiber and fluids necessary for optimal bowel function varies among individuals. Consulting a registered dietitian may be helpful if a patient has chronic problems with constipation.

When a patient has diarrhea, low-residue foods such as white rice, potatoes, bread, bananas, and cooked cereals are recommended until the diarrhea is controlled. Discourage foods that typically cause gastric upset or abdominal cramping. Diarrhea caused by illness is sometimes debilitating. If the patient cannot tolerate foods or liquids orally, intravenous therapy with electrolyte replacement is necessary. The patient returns to a normal diet slowly, often beginning with fluids.

Promotion of Regular Exercise

A daily exercise program helps prevent elimination problems. Walking, riding a stationary bicycle, or swimming stimulates peristalsis. It is recommended by the American Heart Association and the Centers for Disease Control and Prevention that adults get at least 150 minutes of exercise each week.

For a patient temporarily immobilized, attempt ambulation as soon as possible. If the condition permits, help the patient walk to a chair on the evening of the day of surgery and encourage him or her to walk a little more each day.

Management of the Patient With Fecal Incontinence or Diarrhea

You may apply a fecal collector around the anal opening if the skin is intact. These can be difficult to apply when there is a deep fold between the buttocks and there is hair in the area, but it may be considered if a patient is having very frequent liquid stools. There are also fecal-management systems available for short-term use with high-volume diarrhea. They are intended for use primarily in acute care settings. The devices have an intra-anal soft silicone catheter with a retention balloon much like a Foley catheter for insertion into the rectal vault to divert liquid stool away from the skin in immobilized patients. The catheter

is connected to a drainage bag for collection of the liquid fecal effluent. Refer to package insertion instructions and agency policies for appropriate use.

Maintenance of Skin Integrity

A patient with diarrhea, fecal incontinence, or an ileostomy is at risk for skin breakdown when fecal contents remain on the skin. Liquid stool usually contains digestive enzymes, which causes rapid skin breakdown. Irritation from repeated wiping with toilet tissue or frequent ostomy pouch changes further irritate the skin. Meticulous perianal skin care and frequent removal of fecal drainage is necessary to prevent skin breakdown (see [Chapter 48](#)). Clean the skin with a no-rinse cleanser and apply a barrier ointment after each episode of diarrhea. If a patient is incontinent, check on the patient frequently and change absorbent products immediately after providing thorough but gentle skin cleansing. Patients with ostomies are often unaware of the skin irritation under their ostomy wafer or think that this is a normal part of having an ostomy. Education about skin breakdown and its management are important roles for the ostomy nurse (see [Box 47.12](#)).

Evaluation

Through the Patient's Eyes

The effectiveness of care depends on success in meeting the expected outcomes of self-care. Optimally a patient will be able to have regular, pain-free defecation of soft-formed stools. The patient or caregiver is the only one able to determine whether the bowel elimination problems have been relieved and which therapies were the most effective ([Fig. 47.13](#)).

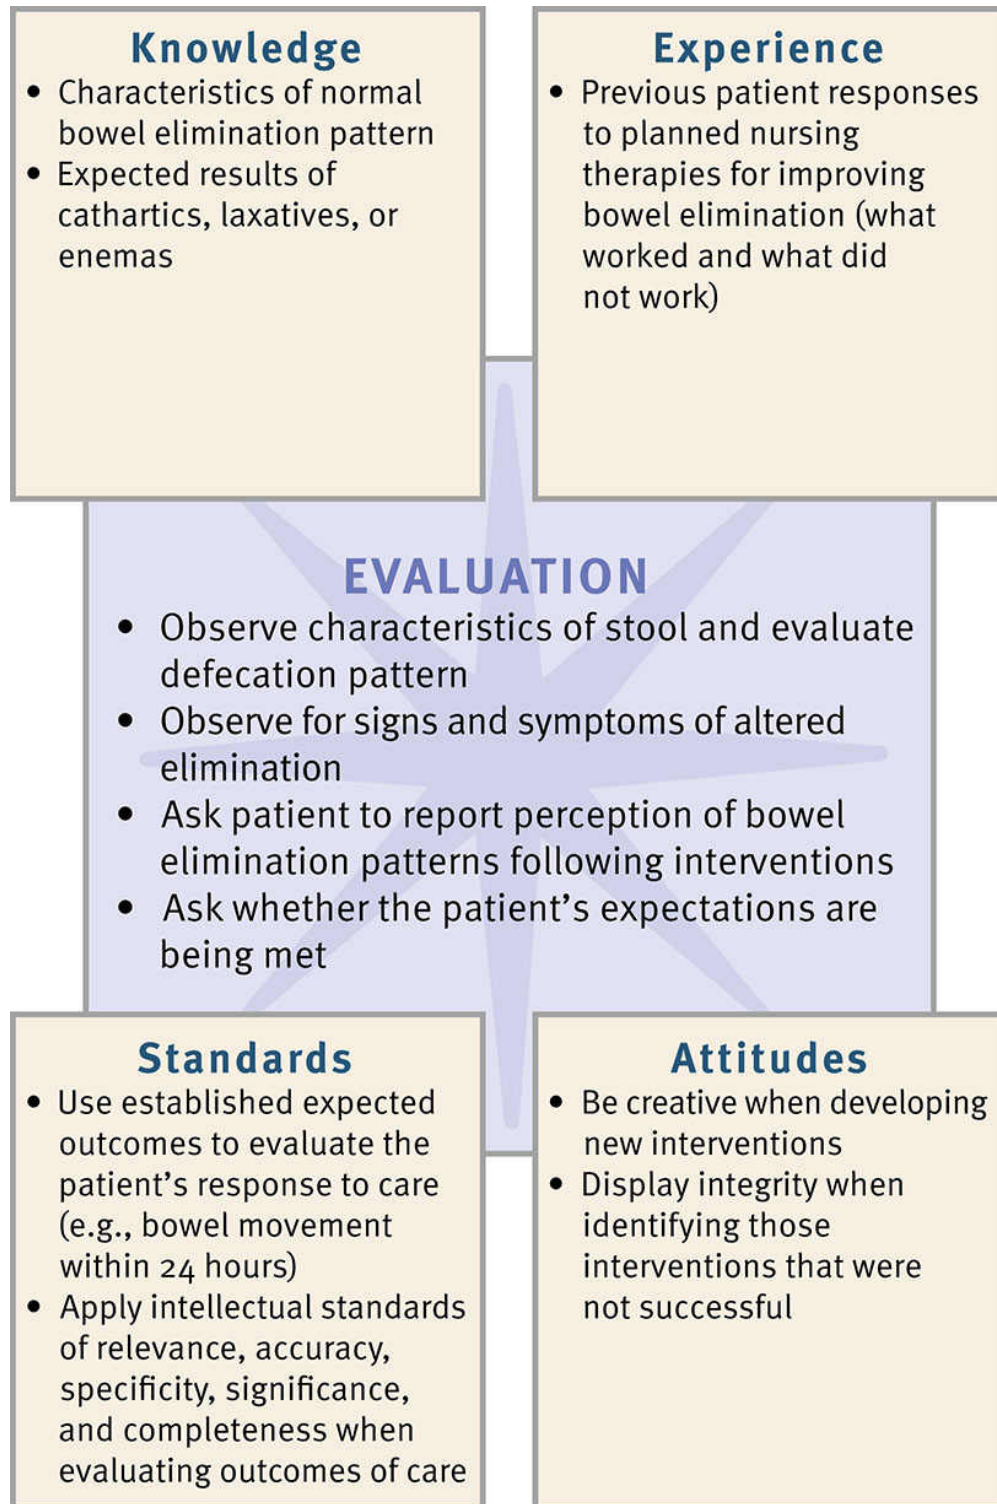

FIG. 47.13 Critical thinking model for elimination evaluation.

Patient Outcomes

When you establish a therapeutic relationship with a patient, the patient feels comfortable to discuss the intimate details often associated with bowel elimination. Patients are less embarrassed as you help them with elimination needs. Patients relate feelings of comfort and freedom from pain as elimination needs are met within the limits of their condition and treatment. Evaluate a patient's level of knowledge regarding establishing a normal elimination pattern, caring for an ostomy, and promoting skin integrity. Also determine the extent to which the patient accomplishes normal defecation. Ask the patient to describe changes in diet, fluid intake, and activity to promote bowel health. Ask the following questions when the patient's expected outcome has not been achieved:

- Do you use medications such as laxatives or enemas to help you defecate? How often?
- Which barriers prevent you from eating a diet high in fiber and participating in regular exercise?
- How much fluid do you drink in a typical day? Which types of fluids do you normally drink?
- What challenges do you encounter when you change your ostomy pouch?

Safety Guidelines for Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized, patient care:

- Instruct patients who self-administer enemas to use the side-lying position. Tell them not to self-administer an enema while sitting on the toilet because this position results in the rectal tubing causing friction that could injure the rectal wall
- If a patient has cardiac disease or is taking cardiac or hypertensive medication, obtain a pulse rate, because manipulation of rectal tissue stimulates the vagus nerve and sometimes causes a sudden decline in pulse rate, which increases the patient's risk of fainting while on the bedpan, bedside commode, or toilet

Skill 47.1. • Administering a Cleansing Enema

Delegation and Collaboration

The skill of administering an enema can be delegated to assistive personnel (AP). **Note:** If a medicated enema is ordered, then it must be administered by a nurse. The nurse instructs the AP about:

- How to properly position patients who have mobility restrictions or therapeutic equipment such as drains, intravenous (IV) catheters, or traction.
- Informing the nurse immediately about patient's new abdominal pain (*exception:* a patient reports cramping) or rectal bleeding.
- Informing the nurse immediately about the presence of blood in the stool or around the rectal area or any change in vital signs.

Equipment

- Clean gloves
- Water-soluble local anesthetic lubricant (**Note:** Some facilities require use of water-soluble lubricant without anesthetic when nurse performs procedure.)
- Waterproof, absorbent pads
- Bedpan
- Bedpan cover (*optional if available*)
- Bath blanket
- Washbasin, washcloths, towels, and soap
- Stethoscope

Enema Bag Administration

- Enema container
- IV pole
- Tubing and clamp (if not already attached to container)
- Appropriate-size rectal tube (adult, 22 to 30 Fr; child, 12 to 18 Fr)
- Correct volume of warmed (tepid) solution (adult, 750 to 1000 mL; adolescent, 500 to 700 mL; school-age child, 300 to 500 mL; toddler, 250 to 350 mL; infant, 150 to 250 mL)

Prepackaged Enema

- Prepackaged enema container with lubricated rectal tip (Fig. 47.14)

FIG. 47.14 Prepackaged enema container with rectal tip.

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review health care provider's order for enema and clarify reason for administration.	Order by health care provider is usually required for hospitalized patient. Order states which type of enema patient will receive.
3. Review medical record and assess last bowel movement, normal versus most recent bowel pattern, presence of hemorrhoids, and presence of abdominal pain or cramping.	Determines need for enema and type of enema used. Also establishes baseline for bowel function. Hemorrhoids may obscure rectal opening and cause discomfort or bleeding during evacuation.
4. Assess patient's mobility and ability to turn and position on side.	Determines whether assistance is needed for positioning patient.
5. Assess patient for allergy to any active ingredients of Fleet enema.	Reduces risk for allergic reaction.
6. Perform hand hygiene.	Reduces transmission of microorganisms.
7. Inspect and palpate abdomen for presence of distention, and auscultate for bowel sounds.	Establishes assessment baseline before enema administration.
8. Assess patient's or family caregiver's knowledge, experience, and health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
Clinical Decision: When "enemas until clear" is ordered, the water expelled may be tinted but should not contain solid fecal material. It is essential to observe contents of solution passed. Check agency policy, but a patient should receive only three consecutive enemas to prevent fluid and electrolyte imbalance.	
Planning	
1. Provide privacy by closing curtains around bed or closing door, and prepare bedside environment for patient safety.	Respects patient right to privacy. Preparing the environment helps the nurse think about the steps needed; removing clutter from over-bed table removes barriers to completing procedure.
2. Prepare and organize enema equipment at bedside.	Ensures organized approach to enema administration.
3. Place bedpan or bedside commode in easily accessible position. If patient will be expelling contents in toilet, ensure that the toilet is available and place patient's nonskid slippers and bathrobe in easily accessible position.	Bedpan is used if patient is unable to get out of bed. Nonskid slippers help to prevent falls when moving from bed to bathroom.
4. Explain enema administration procedure to patient and/or caregiver.	Decreases patient anxiety and promotes patient cooperation.
Implementation	
1. Check accuracy and completeness of each medication administration record (MAR) with health care provider's written order. Check patient's name, type of enema, and time for administration. Compare MAR with label of enema solution. <i>Note: If enema is medicated, the skill may not be delegated to AP (see agency policy).</i>	The health care provider's order is the most reliable source and only legal record of drugs or procedure that patient is to receive. Ensures that patient receives correct enema.
2. Perform hand hygiene.	Reduces transmission of microorganisms.
3. With side rail raised on patient's right side and bed raised to appropriate working height, help patient turn onto left side-lying (Sims') position with right knee flexed. Determine that patient is comfortable and encourage patient to remain in position until procedure is complete. <i>Note: Place a child in the dorsal recumbent position.</i>	Allows enema solution to flow downward by gravity along natural curve of sigmoid colon and rectum, thus improving retention of solution.
Clinical Decision: Patients with poor sphincter control require placement of a bedpan under the buttocks. Administering enema with patient sitting on toilet is unsafe because curved rectal tubing can abrade rectal wall.	
4. Apply clean gloves and place waterproof pad, absorbent side up, under hips and buttocks. Cover patient with bath blanket, exposing only rectal area, clearly visualizing anus.	Pad prevents soiling of linen. Blanket provides warmth, reduces exposure of body parts, and allows patient to feel more relaxed and comfortable.
5. Separate buttocks and examine perianal region for abnormalities, including hemorrhoids, anal fissure, and rectal prolapse.	Findings influence approach for inserting enema tip. Prolapse contraindicates enema.
6. Administer enema.	
a. Administer prepackaged disposable enema:	
(1) Remove plastic cap from tip of container. Tip may already be lubricated. Apply more water-soluble lubricant as needed. (see Fig. 47.14).	Lubrication provides for smooth insertion of rectal tube without causing rectal irritation or trauma. With presence of hemorrhoids, extra lubricant provides added comfort.
(2) Gently separate buttocks and locate anus. Instruct patient to relax by breathing out slowly through mouth.	Breathing out promotes relaxation of external rectal sphincter.
(3) Hold container upright and expel any air from enema container.	Introducing air into colon causes further distention and discomfort.
Step	
(4) Insert lubricated tip of container gently into anal canal toward umbilicus (see illustration).	Gentle insertion prevents trauma to rectal mucosa.
Adult: 7.5–10 cm (3–4 inches)	
Adolescent: 7.5 cm–10 cm (3–4 inches)	
Child: 5–7.5 cm (2–3 inches)	
Infant: 2.5–3.75 cm (1–1½ inches)	
Clinical Decision: If pain occurs or you feel resistance at any time during procedure, stop and discuss with health care provider. Do not force insertion.	
(5) Squeeze and roll plastic bottle from bottom to tip until all of solution has entered rectum and	Prevents instillation of air into colon and ensures

colon. Instruct patient to retain solution until urge to defecate occurs, usually 2 to 5 minutes.	that all content enters rectum. Hypertonic solutions require only small volumes to stimulate defecation.
b. Administer enema in standard enema bag:	
(1) Add warmed prescribed type of solution and amount to enema bag. Warm tap water as it flows from faucet. Place saline container in basin of warm water before adding saline to enema bag. Check temperature of solution by pouring small amount of solution over inner wrist.	Hot water burns intestinal mucosa. Cold water causes abdominal cramping and is difficult to retain.
(2) If soapsuds enema (SSE) is ordered, add castile soap after water.	Reduces suds in enema bag.
(3) Raise container, release clamp, and allow solution to flow long enough to fill tubing.	Removes air from tubing.
(4) Reclamp tubing.	Prevents further loss of solution.
(5) Lubricate 6–8 cm (2½–3 inches) of tip of rectal tube with lubricant.	Allows smooth insertion of rectal tube without risk for irritation or trauma to mucosa.
(6) Gently separate buttocks and locate anus. Instruct patient to relax by breathing out slowly through mouth. Touch patient's skin next to anus with tip of rectal tube.	Breathing out and touching skin with tube promotes relaxation of external anal sphincter.
(7) Insert tip of rectal tube slowly by pointing it in direction of patient's umbilicus. Length of insertion varies (see Step 6a [4]).	Careful insertion prevents trauma to rectal mucosa from accidental lodging of tube against rectal wall. Insertion beyond proper limit can cause bowel perforation.
<i>Clinical Decision: If tube does not pass easily, do not force. Consider allowing a small amount of fluid to infuse and then try to reinsert the tube slowly. The instillation of fluid relaxes the sphincter and provides additional lubrication. If fecal impaction is present, remove it before administering the enema.</i>	
(8) Hold tubing in rectum constantly until end of fluid instillation.	Prevents expulsion of rectal tube during bowel contractions.
(9) Open regulating clamp and allow solution to enter slowly with container at patient's hip level.	Rapid infusion stimulates evacuation of tubing and can cause cramping.
(10) Raise height of enema container slowly to appropriate level: 12 inches above anus and 18 inches above mattress. (see illustration). Instillation time varies with volume of solution administered (e.g., 1 L may take 10 minutes). You may use an IV pole to hold an enema bag once you establish a slow flow of fluid.	Allows for continuous, slow instillation of solution. Raising container too high causes rapid instillation and possible painful distention of colon. High pressure can result in bowel rupture.
<i>Clinical Decision: Temporary cessation of infusion minimizes cramping and promotes ability to retain solution. Lower container or clamp tubing if patient complains of cramping or if fluid escapes around rectal tube.</i>	
(11) Instill all solution and clamp tubing. Tell patient that procedure is completed and that you will remove tubing.	Prevents entrance of air into rectum. Patients may misinterpret sensation of removing tube as loss of control.

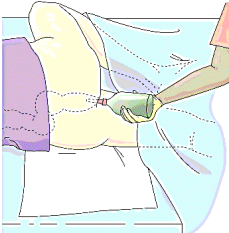

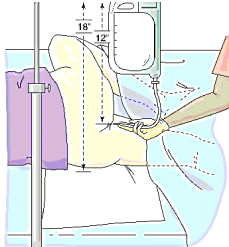

Step	Rationale
<p>7. Place layers of toilet tissue around tube at anus and gently withdraw rectal tube and tip.</p>	<p>Provides for patient's comfort and cleanliness.</p>  <ul style="list-style-type: none"> <p>Step 6a(4) With patient in left lateral Sims' position, insert tip of commercial enema into rectum. (From Sorrentino SA, Remmert LA: <i>Mosby's textbook for nursing assistants</i>, ed 9, St Louis, 2017, Elsevier.)</p>  <ul style="list-style-type: none"> <p>Step 6b(10) IV pole is positioned so that the enema bag is 12 inches above the anus and 18 inches above the mattress. (From Sorrentino SA, Remmert LA: <i>Mosby's textbook for nursing assistants</i>, ed 9, St Louis, 2017, Elsevier.)</p>

Table Continued

Step	Rationale
8. Explain to patient that some distention and abdominal cramping are normal. Ask the patient to retain solution as long as possible until urge to defecate occurs. This usually takes a few minutes. Stay at bedside. Have patient lie quietly in bed if possible. (For infant or young child gently hold buttocks together for few minutes.)	Solution distends bowel. Length of retention varies with type of enema and patient's ability to contract rectal sphincter. Longer retention promotes stimulation of peristalsis and defecation.
9. Discard enema container or disposable bag and tubing in proper receptacle. Remove and dispose of gloves and perform hand hygiene.	Reduces transmission and growth of microorganisms.
10. Help patient to bathroom or commode if possible. If using bedpan, apply clean gloves and help patient to as near a normal position for evacuation as possible (see Box 47.9).	Normal squatting position promotes defecation.
11. Observe character of stool and solution (instruct patient not to flush toilet before inspection).	Determines whether enema was effective.
12. Help patient as needed to wash anal area with warm soap and water (use gloves for perineal care).	Fecal contents irritate skin. Hygiene promotes patient's comfort.
13. Remove and discard gloves and perform hand hygiene.	Reduces transmission of microorganisms.
Evaluation	
1. Inspect color, consistency, and amount of stool; odor; and fluid passed.	Determines whether stool is evacuated or fluid is retained. Note abnormalities such as presence of blood or mucus.
2. Palpate for abdominal distention.	Determines whether distention is relieved.
3. Use Teach-Back: "I want to be sure I explained clearly how to position yourself in bed if you need to self-administer a Fleet enema. Show me how you would position yourself." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Severe abdominal cramping, bleeding, or sudden abdominal pain develops and is unrelieved by temporarily stopping or slowing flow of solution.</p> <ul style="list-style-type: none"> • Stop enema. • Notify health care provider. • Obtain vital signs. <p>2. Patient is unable to hold enema solution.</p> <ul style="list-style-type: none"> • If this occurs during installation, slow rate of infusion. 	
Recording and Reporting	
<ul style="list-style-type: none"> • Record the time, type, and volume of enema administered; patient's signs and symptoms; response to enema; and results, including color, amount, and appearance of stool. • Report failure of patient to defecate or any adverse reactions to health care provider. 	
Home Care Considerations	
<ul style="list-style-type: none"> • For patients who require enemas at home, instruct family not to exceed recommended fluid volume levels or number of enemas. Instruct family about need for slow administration of warmed fluid. • Place waterproof padding on the bed. • Instruct family members not to give the enema on the toilet. 	

Skill 47.2. Inserting and Maintaining a Nasogastric Tube for Gastric Decompression

Delegation and Collaboration

The skill of inserting and maintaining an NG tube cannot be delegated to assistive personnel (AP). The nurse instructs the AP to:

- Measure and record the drainage from an NG tube.
- Provide oral and nasal hygiene measures.
- Perform selected comfort measures such as positioning or offering ice chips if allowed.
- Anchor the tube to patient's gown during routine care to prevent accidental displacement.
- Immediately report to the nurse any patient complaints of burning or signs of redness or irritation to nares.

Equipment

- 14 Fr or 16 Fr NG tube (smaller-lumen catheters are not used for decompression in adults because they must be able to remove thick secretions)
- Water-soluble lubricating jelly
- pH test strips 1.0 to 11.0 or higher (measure gastric aspirate acidity)
- Tongue blade
- Clean gloves
- Flashlight
- Emesis basin
- Asepto bulb or catheter-tipped syringe
- Commercial fixation device or 2.5 cm (1 inch)–wide hypoallergenic tape (*option*: Bridle nasal tube system)
- Rubber band and plastic clip to attach tube to gown
- Clamp, drainage bag, or suction machine or pressure gauge if wall suction is to be used
- Towel
- Glass of water with straw
- Facial tissues
- Normal saline
- Tincture of benzoin (*optional*)
- Gastric suction equipment
- Stethoscope
- Pulse oximeter

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Verify health care provider order for type of NG tube to be placed and whether tube is to be attached to suction or drainage bag.	Requires order from health care provider. Adequate decompression depends on NG suction.
3. Perform hand hygiene (apply clean gloves if risk of body fluid exposure). Inspect condition of skin integrity around patient's nares and nasal and oral cavity.	Provides baseline data on the condition of the patient's skin before NG tube insertion. All patients with any medical device are at risk for pressure injury (Delmore and Ayello, 2017).
4. Assess patient's or caregiver's knowledge, experience, and health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
5. Ask whether patient has history of nasal surgery or congestion and allergies, and note whether deviated nasal septum is present.	Alerts nurse to potential obstruction. Insert tube into uninvolved nasal passage. Procedure may be contraindicated if surgery is recent.
6. Auscultate for bowel sounds. Palpate patient's abdomen for distention, pain, and rigidity. Remove and discard gloves if applied and perform hand hygiene.	In presence of diminished or absent bowel sounds, auscultate abdomen in all four quadrants (Ball et al., 2019). Documents baseline for any abdominal distention, gastrointestinal (GI) ileus, and general GI function, which later serves as comparison once tube is inserted.
7. Assess patient's level of consciousness and ability to follow instructions.	Determines patient's ability to help in procedure.
Clinical Decision: <i>If patient is confused, disoriented, or unable to follow commands, get help from another staff member to insert the tube.</i>	
8. Determine whether patient had previous NG tube, and if so, which naris was used.	Patient's previous experience complements any explanations and prepares patient for NG tube placement.
Planning	
1. Provide privacy by closing curtains around bed or closing door, and prepare bedside environment for patient safety.	Respects patient's right to privacy. Preparing the environment helps the nurse think about the steps needed; removing clutter from over-bed table removes barriers to completing procedure.
2. Prepare and organize NG tube equipment at bedside.	Ensures organized approach to NG tube insertion.
3. Explain NG tube insertion procedure to patient and/or caregiver. Inform patient that procedure may cause gagging and that there may be a burning sensation in nasopharynx as tube is passed. Develop hand signal with patient if too much discomfort occurs.	Decreases patient anxiety and promotes patient cooperation. If patient is too uncomfortable or unable to tolerate procedure, the use of a hand signal will alert the nurse.
Implementation	
1. Raise the bed to working height. Position patient upright in high-Fowler's position unless contraindicated. If patient is comatose, raise head of bed as tolerated in semi-Fowler's position with head tipped forward, chin to chest.	Promotes patient's ability to swallow during procedure. Good body mechanics prevent injury to you or patient.
2. Perform hand hygiene and place bath towel over patient's chest; give facial tissues to patient. Allow to blow nose if necessary. Place emesis basin within reach.	Prevents soiling of patient's gown. Tube insertion through nasal passages may cause tearing and coughing with increased salivation.
3. Wash bridge of nose with soap and water or alcohol swab. Dry thoroughly.	Removes oils from nose to allow fixation devices to adhere completely.

Table Continued

Step	Rationale
4. Stand on patient's right side if right-handed, left side if left-handed. Lower side rail.	Allows easiest manipulation of tubing.
5. Instruct patient to relax and breathe normally while occluding one naris. Then repeat this action for other naris. Select nostril with greater airflow.	Tube passes more easily through naris that is more patent.
Clinical Decision: Insertion of a nasogastric tube is a painful procedure. Research provides evidence that in some instances, topical lidocaine, either as a gel or spray, significantly reduces pain (Solomon and Jurica, 2017).	
6. Determine length of tube to be inserted, and mark location with tape or indelible ink.	Ensures organized procedure and estimation of the proper length of tube to insert into patient.
a. <i>Option for adults:</i> Measure distance from tip of nose to earlobe to xyphoid process (NEX) of sternum (see illustration). Mark this distance on tube with tape.	Most traditional method. Length approximates distance from nose to stomach. Research has shown this method may be least effective compared with others, though more research is needed (Santos et al., 2016).
b. <i>Option for adults:</i> Measure distance from tip of nose to earlobe to mid-umbilicus (NEMU); also used for pediatric patients.	Promotes placement of the tube end holes in or closer to the gastric fluid pool (Boullata et al., 2017).
c. <i>Option for adults:</i> Measure distance from xyphoid process to earlobe to nose (XEN) + 10 cm (Taylor et al., 2014).	Shown to be more accurate than NEX (Taylor et al., 2014).
d. <i>Option for children:</i> Use the NEMU method (Hockenberry et al., 2019).	Estimates proper length of tube insertion for the pediatric patient.
Clinical Decision: Tip of NG tube must reach stomach to avoid the risk for pulmonary aspiration, which occurs when tubes terminate in the esophagus. Research has mixed findings in regard to the best technique for estimating tube length (Santos et al., 2016). Confirmation of placement via x-ray immediately after completed insertion is still needed.	
7. With small piece of tape placed around tube, mark length that will be inserted.	Indicates length of tube you will insert.
8. Prepare materials for tube fixation. Tear off a 7.5- to 10-cm (3- to 4-inch) length of hypoallergenic tape or open membrane dressing or another fixation device (see Step 22a[2]).	Fixation devices allow tube to float free of nares, thus reducing pressure on nares and preventing medical device-related pressure injuries (MDRPI) (Pittman et al., 2015).
9. Perform hand hygiene and apply clean gloves.	Reduces transmission of infection.
10. Apply pulse oximetry/capnography device and measure vital signs. Monitor oximetry/capnography during insertion.	Provides objective assessment of respiratory status before and during tube insertion.
11. <i>Option:</i> Dip tube with surface lubricant into glass of room temperature water or lubricate 7.5 to 10 cm (3-4 inches) of end of tube with water-soluble lubricant (see manufacturer directions).	Water activates lubricant, minimizes friction against nasal mucosa, and aids in insertion of tube. Water-soluble lubricant is less toxic than oil-based lubricant if aspirated.
12. Hand an alert patient a cup of water if able to hold cup and swallow. Explain that you are about to insert tube.	Swallowing water facilitates tube passage. Explanation decreases patient anxiety and increases patient cooperation.
13. Explain next steps. Insert tube gently and slowly through naris to back of throat (posterior nasopharynx). Aim back and down toward patient's ear.	Natural contour facilitates passage of tube into GI tract and reduces gagging.
14. Have patient relax and flex head toward chest after tube is passed through nasopharynx.	Closes off glottis and reduces risk of tube entering trachea.
15. Encourage patient to swallow by taking small sips of water when possible. Advance tube as patient swallows. Rotate tube gently 180 degrees while inserting.	Swallowing facilitates passage of tube past oropharynx. A tug may be felt as patient swallows, indicating that tube is following desired path.

Step	Rationale
16. Emphasize need to mouth breathe during procedure.	Helps facilitate passage of tube and alleviates patient's anxiety and fear during procedure.
	

Step 6a Determine length of tube to be inserted.

Table Continued

Step	Rationale
17. Do not advance tube during inspiration or coughing because it is likely to enter respiratory tract. Monitor oximetry/capnography.	When tube inadvertently enters airway, changes in oxygen saturation or end-tidal CO ₂ (capnography) occur.
18. Advance tube each time patient swallows until you reach desired length.	Reduces discomfort and trauma to patient.
Clinical Decision: Do not force NG tube. If patient starts to cough or has a drop in O ₂ saturation or an increased CO ₂ , withdraw tube into the posterior nasopharynx until normal breathing resumes.	
19. Using penlight and tongue blade, check to be sure that tube is not positioned or coiled in back of throat.	Tube could become coiled, kinked, or enter trachea.
20. Temporarily anchor tube to nose with small piece of tape.	Securing tube prevents movement of tube and subsequent gagging. Allows for verification of tube placement.
21. Verify tube placement. Check agency policy for recommended methods of checking tube placement.	
a. Follow order for bedside x-ray film and notify radiology for examination of chest and abdomen.	Radiography remains the gold standard for verification of initial placement of tube (McFarland, 2017; Mordiffi et al., 2016). This must be done before any medication or liquid is administered (ENA, 2015).
b. While waiting for x-ray film to be performed, follow these procedures: Attach Asepto or catheter-tipped syringe to end of tube. Aspirate gently back on syringe to obtain gastric contents, observing amount, color, and quality of return.	Observation of gastric contents is useful to determine initial tube placement. Gastric contents are usually green but are sometimes off-white, tan, bloody, or brown in color. Other common aspirate colors include yellow or bile stained (duodenal placement) or possibly saliva-appearing (esophagus) (Mordiffi et al., 2016).
c. Use pH test paper to measure aspirate for pH with color-coded pH paper. Be sure that paper range of pH is at least from 1.0 to 11.0 (see illustration).	Evidence supports pH test to be used as indicator for placement (McFarland, 2017; Tho et al., 2011). A pH of 1.0 to 4.0 is a good indicator of gastric placement.
22. After tube is properly inserted and positioned, either clamp end or connect it to drainage bag or suction source. Anchor tube with a fixation device, avoiding pressure on the nares. Select one of the following fixation methods.	Drainage bag is used for gravity drainage. Intermittent low suction is most effective for decompression. Proper anchoring and marking of tube helps prevent migration of tube and pressure injury formation.
a. Apply tape.	
(1) Apply tincture of benzoin or other skin adhesive on bridge of patient's nose and allow it to become "tacky."	Helps tape adhere better. Protects underlying skin.
(2) Tear small horizontal slits at one-third and two-thirds length of tape without splitting tape (see illustration). Fold middle sections toward one another to form a closed strip.	The strip holds tubing to lessen rubbing against soft palate and nares.
(3) Print date and time on tape and place top end of tape over bridge of patient's nose.	
(4) Wrap bottom end of tape around tube as it exits nose (see illustration).	

Step	Rationale
b. Apply tube fixation device using shaped adhesive patch (see manufacturer directions).	<p>Secures tube and reduces friction on nares, and decreases risk for MDRPI (Delmore and Ayello, 2017).</p> 

Step 21c Checking pH of gastric aspirate.

Step 22a(2) Taping method. A, Start with piece of tape. B, Make two slits on both sides of tape. C, Fold middle section inward. D, Tear a new slit in bottom of tape. Top part (A) should attach to patient's nose; bottom part (B) should be wrapped around tube.

Table Continued

Step	Rationale
(1) Apply wide end of patch to bridge of nose (see illustration).	
(2) Slip connector around tube as it exits nose (see illustration).	
CLINICAL DECISION: Assess at least twice daily the condition of the nares and mucosa for inflammation, blistering, excoriation, or any type of skin or tissue injury. Injury can develop for many reasons: rigidity of device rubbing against mucosa, difficulty in securing or adjusting the device to the body, increased moisture surrounding the tubing, tight securement of the device, and poor positioning or fixation of the device (Delmore and Ayello, 2017).	
23. Fasten end of nasogastric tube to patient's gown with piece of tape (see illustration). Do not use safety pins to fasten tube to gown.	Anchors tubing to prevent pulling on nose.
24. Keep head of bed elevated 30 to 45 degrees (preferably 45 degrees) unless contraindicated (AACN, 2017).	Patients receiving nasogastric tube feedings have an increased risk for aspiration (AACN, 2017). Head-of-bed elevation reduces risk for aspiration of stomach contents (Metheny, 2016).
CLINICAL DECISION: If inserting a Salem sump tube, keep the blue "pigtail" of the tube above level of the stomach. This prevents a siphoning action that clogs the tube. The blue "pigtail" is the air vent that connects with the second lumen. When the main lumen of the sump tube is connected to suction, the air vent permits free, continuous drainage of secretions. Never clamp off the air vent, connect to suction, or use for irrigation.	

Step	Rationale
25. Assist radiology as needed in obtaining ordered x-ray film of chest and abdomen.	<p>X-ray verification is the gold standard for NG tube verification (ENA, 2018; McFarland, 2017; Mordiffi et al., 2016).</p> 

Step 22a(4) **A**, Tape applied to anchor nasogastric tube. **B**, Nares are free of pressure from tape and tube.

Step 22b(1) Apply patch to bridge of nose.

Step 22b(2) Slip connector around nasogastric tube.

Step 23 Fasten nasogastric tube to patient gown.

Table Continued

Step	Rationale
26. Remove and dispose of gloves, perform hand hygiene, and help patient to comfortable position.	Reduces transmission of microorganisms.
27. Once placement is confirmed, measure amount of tube that is external and mark exit of tube at nares with indelible marker as guide for any tube displacement. Record this information in nurses' notes in electronic health record (EHR) or chart.	The mark alerts nurses and other health care providers to possible tube displacement, which will require confirmation of tube placement.
Clinical Decision: <i>Never reposition an NG tube of a gastric surgical patient since positioning can rupture the suture line.</i>	
28. Attach NG tube to suction as ordered.	Suction setting is usually ordered low intermittent, which decreases gastric irritation from NG tube.
Clinical Decision: <i>If lumen of tube is narrow and secretions are thick, NG will not drain as desired. Irrigate tube (see Step 29). Consult with health care provider for higher suction setting if unable to irrigate tube because of thick secretions.</i>	
29. NG tube irrigation:	
a. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
b. Verify tube placement in stomach by disconnecting NG tube, connecting irrigating syringe, and aspirating contents (see Step 21b). Temporarily clamp NG tube or reconnect to connecting tube and remove syringe.	pH of gastric aspirate must measure between 1.0 and 4.0 to ensure that NG tube is in the stomach (McFarland, 2017). Prevents accidental entrance of irrigating solution into lungs.
c. Empty syringe of aspirate and use it to draw up 30 mL of normal saline.	Use of saline minimizes loss of electrolytes from stomach fluids.
d. Disconnect NG from connecting tubing and lay end of connection tubing on towel.	Reduces soiling of patient's gown and bed linen.
e. Insert tip of irrigating syringe into end of NG tube. Remove clamp. Hold syringe with tip pointed at floor, and inject saline slowly and evenly. Do not force solution.	Position of syringe prevents introduction of air into vent tubing, which causes gastric distention. Solution introduced under pressure causes gastric trauma.
Clinical Decision: <i>Do not introduce saline through blue "pigtail" air vent of Salem sump tube.</i>	
f. If resistance occurs, check for kinks in tubing. Turn patient onto left side. Repeated resistance should be reported to health care provider.	Tip of tube may lie against stomach lining. Repositioning on left side may dislodge tube away from stomach lining. Buildup of secretions causes distention.
g. After instilling saline, immediately aspirate or pull back slowly on syringe to withdraw fluid. If amount aspirated is greater than amount instilled, record difference as output. If amount aspirated is less than amount instilled, record difference as intake.	Irrigation clears tubing, so stomach should remain empty. Measure and document amount of irrigant fluid inserted in tube as intake.
h. Use an Asepto syringe to place 10 mL of air into blue pigtail.	Ensures patency of air vent.
i. Reconnect NG tube to drainage or suction. (Repeat irrigation if solution does not return.)	Reestablishes drainage collection; may repeat irrigation or repositioning of tube until NG tube drains properly.
30. Removal of NG tube:	
a. Verify order to remove NG tube.	A health care provider order is required for procedure.
b. Per agency policy, auscultate abdomen for presence of bowel sounds or clamp the tube for a short period of time, assessing for nausea or discomfort.	Verifies return of peristalsis. Early removal of the NG tube helps to restore normal anatomy and physiology of the GI system (Goudar et al., 2017).
c. Explain procedure to patient and reassure that removal is less distressing than insertion.	Minimizes anxiety and increases cooperation. Tube passes out smoothly.
d. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
e. Turn off suction and disconnect NG tube from drainage bag or suction. With irrigating syringe, insert 20 mL of air into lumen of NG tube. Remove tape or fixation device from bridge of nose and patient's gown.	Have tube free of connections before removal. Clears gastric fluids from tube to prevent aspiration of contents or soiling of clothing and bedding.
f. Hand patient facial tissue; place clean towel across chest. Instruct patient to take and hold breath as tube is removed.	Some patients wish to blow nose after tube is removed. Towel keeps gown from soiling. Temporary airway obstruction occurs during tube removal.

Table Continued

Step	Rationale
g. Clamp or kink tubing securely and pull tube out steadily and smoothly into towel held in other hand while patient holds breath.	Clamping prevents tube contents from draining into oropharynx. Reduces trauma to mucosa and minimizes patient's discomfort. Towel covers tube, which is an unpleasant sight. Holding breath helps to prevent aspiration.
h. Inspect intactness of tube.	
i. Measure amount of drainage and note character of content. Dispose of tube and drainage equipment into proper container.	Provides accurate measure of fluid output. Reduces transfer of microorganisms.
j. Clean nares and provide mouth care.	Promotes comfort.
k. Position patient comfortably and explain procedure for drinking fluids if not contraindicated. Instruct patient to notify you if nausea occurs.	Sometimes patients are not allowed anything by mouth (NPO) for up to 24 hours. When fluids are allowed, orders usually begin with small amount of ice chips each hour and increase as patient is able to tolerate more.
31. For all procedures, clean equipment and return to proper place. Place soiled linen in utility room or proper receptacle.	Proper disposal of equipment prevents spread of microorganisms and ensures proper exchange procedures.
32. Remove and discard gloves and perform hand hygiene.	Reduces transmission of microorganisms.
Evaluation	
1. Observe amount and character of contents draining from NG tube. Ask if patient feels nauseated.	Determines if tube is decompressing stomach of contents.
2. Auscultate for presence of bowel sounds. Turn off suction while auscultating. Assess for nausea and patient discomfort if tube is clamped for short trial period.	Sound of suction apparatus is sometimes misinterpreted as bowel sounds. Nausea and discomfort will occur if peristalsis is not returned.
3. Palpate patient's abdomen periodically. Note any distention, pain, and rigidity.	Determines success of abdominal decompression and return of peristalsis.
4. Inspect condition of nares, nose, and all skin and tissue around NG tubing.	Evaluates onset of skin and tissue irritation.
5. Observe position of tubing.	Prevents tension applied to nasal structures.
6. Explain that it is normal if patient feels sore throat or irritation in pharynx.	Result of tube irritation.
7. Use Teach-Back: "I need to be sure I explained the importance of letting me know if you are nauseated. Tell me why it is important for me to know if you feel nauseated." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<ol style="list-style-type: none"> Patient complains of nausea, or patient's abdomen is distended and painful. <ul style="list-style-type: none"> Assess patency of tube. NG tube may be occluded or no longer in stomach. Irrigate tube. Verify that suction is on as ordered. Notify health care provider if distention is unrelieved. Patient develops irritation or erosion of skin around nares. <ul style="list-style-type: none"> Provide frequent skin care to area. Use taping method designed to reduce MDRPI (see taping methods, Step 22). Consider switching tube to other nares. Patient develops signs and symptoms of pulmonary aspiration: fever, shortness of breath, or pulmonary congestion. <ul style="list-style-type: none"> Perform complete respiratory assessment. Notify health care provider. Obtain chest x-ray film examination as ordered. 	
Recording and Reporting	
<ul style="list-style-type: none"> Record length, size, type of gastric tube inserted, and nares in which tube was introduced. Also record patient's tolerance of procedure, confirmation of tube placement, character and pH of gastric contents, results of x-ray film, whether the tube is clamped or connected to drainage bag or to suction, and amount of suction supplied. Document your evaluation of patient learning. When irrigating NG tube, record difference between amount of normal saline instilled and amount of gastric aspirate removed on I&O sheet. Record amount and character of contents draining from NG tube every shift in nurses' notes or flow sheet. Record removal of tube "intact," patient's tolerance to procedure, and final amount and character of drainage. Report occurrence of abdominal distention, unexpected increase or sudden stoppage in gastric drainage, and patient complaining of gastric distress to health care provider. 	

Skill 47.3. Pouching an Ostomy Delegation and Collaboration

The skill of pouching a new ostomy should not be delegated to assistive personnel (AP). In some agencies care of an established ostomy (4 to 6 weeks or more after surgery) can be delegated to AP. The nurse directs the AP about:

- The expected amount, color, and consistency of drainage from an ostomy
- The expected appearance of the stoma
- Special equipment needed to complete a particular patient's pouching
- The changes in a patient's stoma and surrounding skin integrity that should be reported

Equipment

- Pouch: drainable one-piece or two-piece, cut-to-fit, precut size, or moldable
- Pouch closure device, such as a clip, if needed
- Measuring guide
- Adhesive releaser (*optional*)
- Clean gloves
- Washcloth
- Towel or disposable waterproof barrier
- Basin with warm tap water
- Scissors
- Waterproof bag for disposal of pouch
- Gown and goggles (if there is a risk of splashing when emptying the pouch)

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
3. Observe existing skin barrier and pouch for leakage and length of time in place. Pouch should be changed every 3 to 7 days, not daily (Carmel et al., 2016). If an opaque pouch is being used, remove it to fully observe stoma. Dispose of such a pouch in proper receptacle.	Assesses effectiveness of pouching system and detects potential for problems. To minimize skin irritation, avoid unnecessary changing of entire pouching system. When pouch leaks, skin damage from effluent causes more skin trauma than early removal of wafer.
Clinical Decision: Repeated leaking may indicate need for different type of pouch or addition of accessory products such as rings, seals, or paste. If the pouch is leaking, change it. Taping or patching it to contain effluent leaves the skin exposed to chemical or enzymatic irritation.	
4. Remove used pouch and skin barrier gently, and observe amount of effluent. Empty the effluent if it is more than one-third to one-half full by opening the pouch and draining it into a container for measurement of output. Note consistency of effluent, and record intake and output.	Weight of pouch may disrupt seal of adhesive on skin. Monitors fluid balance and bowel function after surgery. Normal colostomy effluent is soft or formed stool, whereas normal ileostomy effluent is liquid.
5. Observe stoma for type, location, color, swelling, presence of sutures, trauma, and healing or irritation of peristomal skin (see illustrations).	Stoma characteristics influence selection of an appropriate pouching system. Convexity in skin barrier is often necessary with a flush or retracted stoma.
6. Observe placement of stoma in relation to abdominal contours and presence of scars or incisions. Remove and dispose of gloves; perform hand hygiene.	Determines whether current pouching system is effective or new selection is needed. Abdominal contours, scars, or incisions affect type of system and adhesion to skin surface. Reduces transmission of microorganisms.
7. Assess patient's or family caregiver's knowledge, experience, and health literacy.	Ensures patient or family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
8. Explore patient's attitudes, perceptions, knowledge, and acceptance of stoma; discuss interest in learning self-care. Identify others who will be helping patient after leaving hospital.	<p>Determines patient's willingness to learn. Facilitates teaching plan and timing of care to coincide with availability of family caregivers.</p> <div data-bbox="943 890 1281 1012" style="text-align: center;"> </div> <p>Step 6 A, Budded stoma. B, Retracted stoma. Courtesy Jane Fellows.</p>

Table Continued

Step	Rationale
Planning	
1. Provide privacy by closing curtains around bed or closing door, and prepare bedside environment for patient safety.	Respects patient right to privacy. Preparing the environment helps the nurse think about the steps needed; removing clutter from over-bed table removes barriers to completing procedure.
2. Prepare and organize ostomy pouching equipment at bedside.	Ensures organized approach to changing the ostomy pouch.
3. Explain ostomy pouching procedure to patient and/or caregiver.	Decreases patient anxiety and promotes patient cooperation.
Implementation	
1. Have patient assume semi-reclining or supine position (same position assumed during assessment and pouching). (Note: Some patients with established ostomies prefer to stand.) If possible, provide patient with mirror for observation.	When patient is semi-reclining, there are fewer skinfolds, which allows for ease of application of pouching system.
2. Perform hand hygiene and apply clean gloves.	Reduces transmission of microorganisms.
3. Place towel or disposable waterproof barrier under patient and across patient's lower abdomen.	Protects bed linen; maintains patient's dignity.
4. If not done during assessment, remove used pouch and skin barrier gently by pushing skin away from barrier. Use adhesive releaser to facilitate removal of skin barrier. Empty pouch and dispose of it in an appropriate receptacle. Measure output if needed. Note: There may be no output at time of first pouch change.	Reduces skin trauma. Improper removal of pouch and barrier can cause peristomal skin irritation or breakdown.
5. Clean peristomal skin gently with warm tap water using washcloth; do not scrub skin. If you touch stoma, minor bleeding is normal. Pat skin dry. Have washcloth handy for additional cleaning if there is output from the stoma while preparing pouch.	Soap leaves residue on skin, which may irritate skin. Pouch does not adhere to wet skin. Ileostomies have frequent output, especially after eating.
6. Measure stoma (see illustration). Expect size of stoma to change for first 4 to 6 weeks after surgery.	Allows for proper fit of pouch that will protect peristomal skin.
7. Trace pattern of stoma measurement on pouch backing or skin barrier (see illustration).	Prepares for cutting opening in pouch.
8. Cut opening on backing or skin barrier wafer (see illustration). If using moldable or shape to fit barrier, use fingers to mold shape to fit stoma.	Customizes pouch to provide appropriate fit over stoma.
9. Remove protective backing from adhesive backing or wafer (see illustration).	Prepares skin barrier for placement.
10. Apply pouch over stoma (see illustration). Press firmly into place around stoma and outside edges. Have patient hold hand over pouch to apply heat to secure seal.	Pouch adhesives are heat and pressure sensitive and hold more securely at body temperature.
11. Close end of pouch with clip or integrated closure. Remove drape from patient. Help patient to assume comfortable position.	Ensures that pouch is secure. Contains effluent. Gives patient sense of well-being.
12. Be sure nurse call system is in an accessible location within patient's reach.	Ensures patient can call for assistance if needed.
13. Raise side rails (as appropriate) and lower bed to lowest position.	Ensures patient safety.
14. Remove and dispose of gloves and other disposables. Perform hand hygiene.	Reduces transmission of microorganisms.
Evaluation	
1. Observe condition of skin barrier and adherence of pouch to abdominal surface	Determines presence of leaks.
2. Observe appearance of stoma, peristomal skin, abdominal contours, suture line, and presence of any flatus during pouch change.	Determines condition of stoma and peristomal skin and progress of wound healing.
3. Note whether there is presence of any flatus during pouch change.	Determines whether peristalsis is returning.

Step	Rationale
4. Observe patient's and family caregiver's willingness to view stoma and ask questions about procedure.	Determines level of adjustment and understanding of stoma care and pouch application. Allows planning for future education needs and progress toward acceptance of altered body image.

Step 6 Measure stoma.

Table Continued

Step	Rationale
<p>5. Use Teach-Back: "I want to be sure you understand what is involved in changing your ostomy pouch. Tell me what you should do to prevent your skin from becoming irritated and the frequency with which you should empty your pouch." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.</p>	<p>Determines patient's/family caregiver's level of understanding of instructional topic.</p>
<p>Unexpected Outcomes and Related Interventions</p>	
<ol style="list-style-type: none"> 1. Skin around stoma is irritated, blistered, or bleeding or a rash is noted. May be caused by undermining of pouch seal by fecal contents, causing irritant dermatitis, or by adhesive removal causing skin stripping or fungal or other skin eruption. <ul style="list-style-type: none"> • Remove pouch more carefully. • Change pouch more frequently or use different type of pouching system. • Consult ostomy care nurse. 2. Necrotic stoma is manifested by purple or black color, dry instead of moist texture, failure to bleed when washed gently, or tissue sloughing. <ul style="list-style-type: none"> • Report to nurse in charge or health care provider. • Document appearance. 3. Patient refuses to view stoma or participate in care. <ul style="list-style-type: none"> • Obtain referral for ostomy care nurse. • Allow patient to express feelings. • Encourage family support. 	
<p>Recording and Reporting</p> <ul style="list-style-type: none"> • Record type of pouch and skin barrier applied, amount and appearance of effluent in pouch, size and appearance of stoma, and condition of peristomal skin. Record what patient and family caregivers are able to demonstrate and level of participation. • Document your evaluation of patient learning. • Record abnormal appearance of stoma, suture line, or peristomal skin or change in volume, consistency, or color of output. • Record whether pouch change was done. • Record patient's response to pouch change and participation in process. 	
<p>Home Care Considerations</p> <ul style="list-style-type: none"> • Evaluate patient's home toileting facilities and help patient develop an ostomy care routine that is compatible with available facilities. Ostomy pouches are not flushable. • Encourage patient to stand in front of a mirror when changing pouch to increase visibility and avoid abdominal creases that might be present in the sitting position.

Key Points

- To effectively manage symptoms of altered or impaired digestive function, a knowledge of how the various organs work together to transport and utilize nutrients and eliminate waste is essential.
- There are many factors both simple and complex to consider when a patient presents with symptoms related to digestion and elimination.
- Listening carefully to patient or caregiver reporting and thorough physical assessment are necessary steps to determine the appropriate plan of care for a patient with alterations in his or her usual pattern of elimination.
- Knowledge of diagnostic and screening testing for gastrointestinal evaluation is important for the nurse to know so that appropriate patient education can be provided.
- Nursing interventions to promote normal bowel elimination include lifestyle changes, medications, and procedures that patients need to learn to improve bodily function and quality of life.
- A patient with a new ostomy needs both physical and emotional support from the nurse and should be referred to a nurse with specialized ostomy training whenever available.
- Nurses need to be proficient in the skills needed to relieve physical and psychological discomfort from altered bowel elimination.

- Every patient has bowel elimination needs regardless of age, care setting, diagnosis and co-morbid conditions. Critical thinking is essential in promoting normal bowel elimination and in providing care to patients with altered bowel elimination.

Reflective Learning

- A single young person with Crohn's disease is facing life with an ileostomy. The patient is relieved not to have the chronic pain he or she has been experiencing for years, but now the patient must navigate dating and intimacy issues with an ostomy. Think about how you would feel in the same situation and what would be helpful in discussing this patient's concerns.
- Most people with bowel elimination problems that require the assistance of health care personnel experience embarrassment. How can you treat them in a way that increases their comfort in both discussion of their bowel function and the performance of procedures related to bowel function?
- Often solutions to chronic constipation require lifestyle changes. What are some ways to motivate people to make these changes?

Review Questions

1. Which nursing actions do you take when placing a bedpan under an immobilized patient? (Select all that apply.)

1. Lift the patient's hips off the bed and slide the bedpan under the patient.
 2. After positioning the patient on the bedpan, elevate the head of the bed to a 45-degree angle.
 3. Adjust the head of the bed so that it is lower than the feet, and use gentle but firm pressure to push the bedpan under the patient.
 4. Have the patient stand beside the bed, and then have him or her sit on the bedpan on the edge of the bed.
 5. Make sure the patient has a nurse call system in reach to notify the nurse when he or she is ready to have the bedpan removed.
2. During the administration of a warm tap-water enema, a patient complains of cramping abdominal pain that he rates 6 out of 10. What nursing intervention should the nurse do first?
1. Stop the instillation.
 2. Ask the patient to take deep breaths to decrease the pain.
 3. Tell the patient to bear down as he would when having a bowel movement.
 4. Continue the instillation; then administer a pain medication.
3. Which instructions do you include when educating a person with chronic constipation? (Select all that apply.)
1. Increase fiber and fluids in the diet.
 2. Use a low-volume enema daily.
 3. Avoid gluten in the diet.
 4. Take laxatives twice a day.

5. Exercise for 30 minutes every day.
 6. Schedule time to use the toilet at the same time every day.
 7. Take probiotics 5 times a week.
4. Which skills does the nurse teach a patient with a new colostomy before discharge from the hospital? (Select all that apply.)
1. How to change the pouch
 2. How to empty the pouch
 3. How to open and close the pouch
 4. How to irrigate the colostomy
 5. How to determine whether the ostomy is healing appropriately
5. Place the steps for an ileostomy pouch change in the correct order.
1. Close the end of the pouch.
 2. Measure the stoma.
 3. Cut the hole in the wafer to fit around the stoma and not leave skin exposed to the effluent.
 4. Press the pouch in place over the stoma.
 5. Remove the old pouch.
 6. Trace the correct measurement onto the back of the wafer.
 7. Assess the stoma and the skin around it.
 8. Cleanse and dry the peristomal skin.
6. Which symptoms are warning signs of possible colorectal cancer according to the American Cancer Society

guidelines? (Select all that apply.)

1. Change in bowel habits
 2. Blood in the stool
 3. A larger-than-normal bowel movement
 4. Fecal impaction
 5. Muscle aches
 6. Incomplete emptying of the colon
 7. Food particles in the stool
 8. Unexplained abdominal or back pain
7. A nurse is teaching a patient to obtain a specimen for fecal occult blood testing using fecal immunochemical testing (FIT) at home. How does the nurse instruct the patient to collect the specimen?
1. Get three fecal smears from one bowel movement.
 2. Obtain one fecal smear from an early-morning bowel movement.
 3. Collect one fecal smear from three separate bowel movements.
 4. Get three fecal smears when you see blood in your bowel movement.
8. What should the nurse teach family caregivers when a patient has fecal incontinence because of cognitive impairment?
1. Cleanse the skin with antibacterial soap, and apply talcum powder to the buttocks.
 2. Initiate bowel or habit training program to promote continence.
 3. Help the patient to toilet once every hour.

4. Use sanitary pads in the patient's underwear.
9. The patient states, "I have diarrhea and cramping every time I have ice cream. I am sure this is because the food is cold." Based on this assessment data, which health problem does the nurse suspect?
 1. A food allergy
 2. Irritable bowel syndrome
 3. Increased peristalsis
 4. Lactose intolerance
10. A nurse is taking a health history of a newly admitted patient with a diagnosis of possible fecal impaction. Which question is the priority to ask the patient or caregiver?
 1. Have you eaten more high-fiber foods lately?
 2. Have you taken antibiotics recently?
 3. Do you have gluten intolerance?
 4. Have you experienced frequent, small liquid stools recently?

Skin Integrity and Wound Care

OBJECTIVES

- Discuss the risk factors that contribute to pressure injury formation.
- Describe the pressure injury staging system.
- Discuss the normal process of wound healing.
- Describe the differences in wound healing by primary and secondary intention.
- Explain the factors that impede or promote wound healing.
- Describe the differences in nursing care with acute and chronic wounds.
- Complete an assessment for a patient with impaired skin integrity.
- Develop a nursing care plan for a patient with impaired skin integrity.
- Apply critical thinking when providing care to patients at risk for or with actual impaired skin integrity.

Skin, the largest organ in the body, is a protective barrier against disease-causing organisms and a sensory organ for pain, temperature, and touch; it also synthesizes vitamin D (Wysocki, 2016). Injury to the skin poses risks to an individual's safety and triggers a complex healing response. Your most important responsibilities include assessing and monitoring skin integrity, identifying patient risks for skin problems, identifying actual problems, and planning, implementing, and evaluating interventions to maintain skin integrity. Once a wound occurs, it is critical to know the process of normal wound healing to identify and implement the appropriate nursing interventions.

Scientific Knowledge Base

Skin

The skin has two layers: the epidermis and the dermis (Fig. 48.1). They are separated by a membrane, often referred to as the *dermal-epidermal junction*. The epidermis, or the top layer, has several layers. The stratum corneum is the thin outermost layer of the epidermis. It consists of flattened, dead, keratinized cells. The cells originate from the innermost epidermal layer, commonly called the *basal layer*. Cells in the basal layer divide, proliferate, and migrate toward the epidermal surface. After they reach the stratum corneum, they flatten and die. This constant movement ensures replacement of surface cells sloughed during normal desquamation or shedding. The thin stratum corneum protects underlying cells and tissues from dehydration and prevents entrance of certain chemical agents. The stratum corneum allows evaporation of water from the skin and permits absorption of certain topical medications.

FIG. 48.1 Layers of skin.

From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.

The dermis, the inner layer of the skin, provides tensile strength; mechanical support; and protection for the underlying muscles, bones, and organs. It differs from the epidermis in that it contains mostly connective tissue and few skin cells. Collagen (a tough, fibrous protein), blood vessels, and nerves are found in the

dermal layer. Fibroblasts, which are responsible for collagen formation, are the only distinctive cell type within the dermis.

Understanding skin structure helps you understand the risks for impaired skin integrity and promote wound healing. Intact skin protects the patient from chemical and mechanical injury. When the skin is injured, the epidermis functions to resurface the wound and restore the barrier against invading organisms, and the dermis responds to restore the structural integrity (collagen) and the physical properties of the skin. The normal aging process alters skin characteristics and makes skin more vulnerable to damage (see [Box 48.1](#)).

Box 48.1 Focus on Older Adults Skin-Associated Issues

When caring for the older adult there are several skin-related issues to consider when assessing skin and risk for skin breakdown. Age-related changes such as reduced skin elasticity, decreased collagen, and thinning of underlying muscle and tissues cause the older adult's skin to be easily torn in response to mechanical trauma, especially shearing forces (Wysocki, 2016). The attachment between the epidermis and dermis becomes flattened in older adults, allowing the skin to be easily torn in response to mechanical trauma (e.g., tape removal). Existing medical conditions and polypharmacy are factors that interfere with wound healing. Aging causes a diminished inflammatory response, resulting in slow epithelialization and wound healing (Doughty and Sparks, 2016).

Implications for Practice

- There is a decreased barrier function and less protection from excessive moisture, shear, friction, and pressure.
- Aging skin has decreased epidermal turnover, and healing requires more time.
- When removing any adhesive dressings or tapes, gently release the skin from the tape; do not pull the tape away from the skin. Release the skin from the adhesive by gently pushing the skin from the adhesive.
- Decreased subcutaneous tissue reduces padding protection over bony prominences.
- There is a decrease in subcutaneous padding over bony prominences, where impaired skin integrity and injury to other tissues are most likely to occur (Wysocki, 2016).

Pressure Injuries

Pressure injury, *pressure ulcer*, *decubitus ulcer*, and *bedsore* are terms used to describe impaired skin integrity related to unrelieved, prolonged pressure. The most current terminology is **pressure injury** ([Fig. 48.2](#)), which is consistent with the recommendations of the National Pressure Ulcer Advisory Panel ([Edsberg et al., 2016](#)). A pressure injury is localized damage to the skin and underlying soft tissue,

usually over a bony prominence or related to a medical device or other device. The injury can present as intact skin, a blister, or an open ulcer and may be painful. The injury occurs as a result of intense and/or prolonged pressure or pressure in combination with shear (Edsberg et al., 2016). The tolerance of soft tissue for pressure and shear may also be affected by microclimate, nutrition, perfusion, comorbidities, and condition of the soft tissue.

FIG. 48.2 Pressure injury with tissue necrosis.

A number of contributing factors are associated with pressure injuries; the significance of these factors is not yet clear (EPUAP, NPIAP, PPPIA, 2019a). Any patient experiencing decreased mobility, decreased sensory perception, fecal or urinary incontinence, and/or poor nutrition is at risk for pressure injury development. Examples of patients who are at risk for the development of pressure injuries include the following:

- Older adults, those who have experienced trauma
- Those with spinal-cord injuries (SCI)
- Those who have sustained a fractured hip
- Those in long-term homes or community care, the acutely ill, or those in a hospice setting
- Individuals with diabetes
- Patients in critical care settings (EPUAP, NPIAP, PPPIA, 2019a)

Pressure is a major cause of injury. Tissue receives oxygen and nutrients and eliminates metabolic wastes via the blood. Pressure or other factors that interfere

with blood flow in turn interfere with cellular metabolism and the function or life of the cells. Prolonged, intense pressure affects cellular metabolism by decreasing or obliterating blood flow, resulting in tissue ischemia and ultimately tissue death.

Pathogenesis of Pressure Injuries

Pressure is the major element in the cause of pressure injuries. Current theory suggests that skin and soft tissue damage can begin at the surface and progress inward or begin at the muscle and progress outward, depending on causation (WOCN, 2016). Top-down damage (superficial) is thought to be caused by superficial shear or friction, presenting as red skin (stage 1 pressure injury). Bottom-up (deep) damage is believed to be caused by several pressure-related factors: (1) pressure intensity, (2) pressure duration, and (3) tissue tolerance.

Pressure Intensity

A classic research study identified capillary closing pressure as the minimal amount of pressure required to collapse a capillary (e.g., when the pressure exceeds the normal capillary pressure range of 15 to 32 mm Hg) (Burton and Yamada, 1951). Therefore, when the pressure applied over a capillary exceeds the normal capillary pressure and the vessel is occluded for a prolonged period of time, **tissue ischemia** can occur. If the patient has reduced sensation and cannot respond to the discomfort of the ischemia, tissue ischemia and tissue death result.

The clinical presentation of obstructed blood flow occurs when evaluating areas of pressure. After a period of tissue ischemia, if the pressure is relieved and the blood flow returns, the skin turns red. The effect of this redness is vasodilation (blood vessel expansion), called *hyperemia* (redness). You assess an area of hyperemia by pressing a finger over the affected area. If it blanches (turns lighter in color) and the erythema returns when you remove your finger, the hyperemia is transient and is an attempt to overcome the ischemic episode, thus called **blanchable hyperemia**. However, if the erythematous area does not blanch (**nonblanchable erythema**) when you apply pressure, deep tissue damage is probable.

Blanching occurs when the normal red tones of the light-skinned patient are absent. When checking for pressure injuries in patients with darkly pigmented skin, dark skin may not show the blanch response. Inspect suspected pressure-related skin alterations with an adjacent or opposite area of the body for comparison (Box 48.2). Skin inspection should include assessment of changes in skin tissue, consistency (firm vs. boggy [less than normal stiffness or mushy] when palpated), sensation (pain), edema, and warmer or cooler temperature (EPUAP, NPIAP, PPIA, 2019a,b; Bryant and Nix, 2016a).

Box 48.2 Cultural Aspects of Care Impact of Skin Color

Detecting cyanosis and other changes in skin color in patients is an important clinical skill. However, this detection becomes a challenge in patients with darkly pigmented skin (EPUAP, NPIAP, PPIA, 2019a; Henderson et al., 1997). Color

differentiation of cyanosis varies according to skin pigmentation. In patients with darkly pigmented skin, you need to know the individual's baseline skin tone. For example, do not confuse the normal hyperpigmentation of Mongolian spots that are seen on the sacrum of African, Native American, and Asian patients with cyanosis.

Implications for Patient-Centered Care

- Patients with darkly pigmented skin cannot be assessed for pressure injury risk by examining only skin color (EPUAP, NPIAP, PPIA, 2019a).
- Use natural lighting but note that visual inspection techniques to identify pressure injuries are ineffective in darkly pigmented skin. Assess for changes in sensation, temperature, or tissue consistency, which may precede visual skin changes (Ratliff et al., 2017; WOCN, 2016).
- Examine body sites with the least melanin such as under the arm for underlying color identification (Nix, 2016).
- Assess pressure areas and localized skin color changes. Any of the following may appear (WOCN, 2016):
 - Color remains unchanged when pressure is applied.
 - Color changes occur at site of pressure, which differ from patient's usual skin color.
 - If patient previously had a pressure injury, that area of skin may be lighter than original color.
 - Localized area of skin may be purple/blue or violet instead of red. Purple or maroon discoloration may indicate deep tissue injury.
- Palpate surrounding tissues to identify any changes in temperature, edema, or tissue consistency between area of injury or suspected injury and normal tissue (EPUAP, NPIAP, PPIA, 2019a; Nix, 2016).
- Circumscribed area of intact skin may be warm to touch. As tissue changes color, intact skin will feel cool to touch. **Note:** Gloves may decrease sensitivity to changes in skin temperature.
- Localized heat (inflammation) is detected by making comparisons to surrounding skin. Localized area of warmth eventually will be replaced by area of coolness, which is a sign of tissue devitalization.
- Edema may occur with induration of more than 15 mm in diameter, and skin may appear taut and shiny (Nix, 2016).

Pressure Duration

Low pressure over a prolonged period and high-intensity pressure over a short period are two concerns related to duration of pressure. Both types of pressure cause tissue damage. Extended pressure occludes blood flow and nutrients and contributes to cell death (Pieper, 2016). Clinical implications of pressure duration include evaluating the amount of pressure (checking skin for nonblanching hyperemia) and determining the amount of time that a patient tolerates pressure (checking to be sure after relieving pressure that the affected area blanches).

Tissue Tolerance

The ability of tissue to endure pressure depends on the integrity of the tissue and the supporting structures. The extrinsic factors of shear, friction, and moisture affect the ability of the skin to tolerate pressure: the greater the degree to which the factors of shear, friction, and moisture are present, the more susceptible the skin will be to damage from pressure. The second factor related to tissue tolerance is the ability of the underlying skin structures (blood vessels, collagen) to help redistribute pressure. Systemic factors such as poor nutrition, aging, hydration status, and low blood pressure affect the tolerance of the tissue to externally applied pressure.

Risk Factors for Pressure Injury Development

A variety of factors predispose a patient to pressure injury formation. These factors may be related to a disease (e.g., reduced peripheral circulation from diabetes), or they may be secondary to an illness (e.g., decreased sensation following a cerebrovascular accident).

Impaired Sensory Perception

Patients with altered sensory perception for pain and pressure are more at risk for impaired skin integrity. They are unable to feel when a part of their body undergoes increased, prolonged pressure or pain. Thus a patient who can't feel or sense that there is pain or pressure is at risk for the development of pressure injuries.

Impaired Mobility

Patients who are unable to independently change positions are at risk for pressure injury. For example, a patient who is seriously ill will be weakened and less likely to turn independently. Patients with spinal cord injuries have decreased or absent motor and sensory function and are unable to reposition off bony prominences.

Alteration in Level of Consciousness

Patients who are comatose, confused or disoriented; those who have expressive aphasia or the inability to verbalize; and those with changing levels of consciousness are unable to protect themselves from pressure injury. Also patients who are confused or disoriented may be able to feel pressure but are not always able to understand how to relieve it or communicate their discomfort. A patient in a coma cannot perceive pressure and is unable to move voluntarily to relieve pressure.

Shear

Shear force is the sliding movement of skin and subcutaneous tissue while the underlying muscle and bone are stationary (Bryant, 2016). Shear force occurs when the head of the bed is elevated and the sliding of the skeleton starts but the skin is fixed because of friction with the bed (Fig. 48.3). It also occurs when transferring a patient from bed to stretcher when a patient's skin is pulled across the bed. (This can be avoided using safe patient handling techniques.) When shear is present, the skin

and subcutaneous layers adhere to the surface of the bed, and the layers of muscle and the bones slide in the direction of body movement. The damage that shear causes occurs at the deeper fascial level of the tissues over the bony prominence (Pieper, 2016). The underlying tissue capillaries are stretched and angulated by the shear force. As a result, necrosis occurs deep within the tissue layers. The tissue damage is deep in the tissues and causes undermining of the dermis and is a cause of pressure injury development.

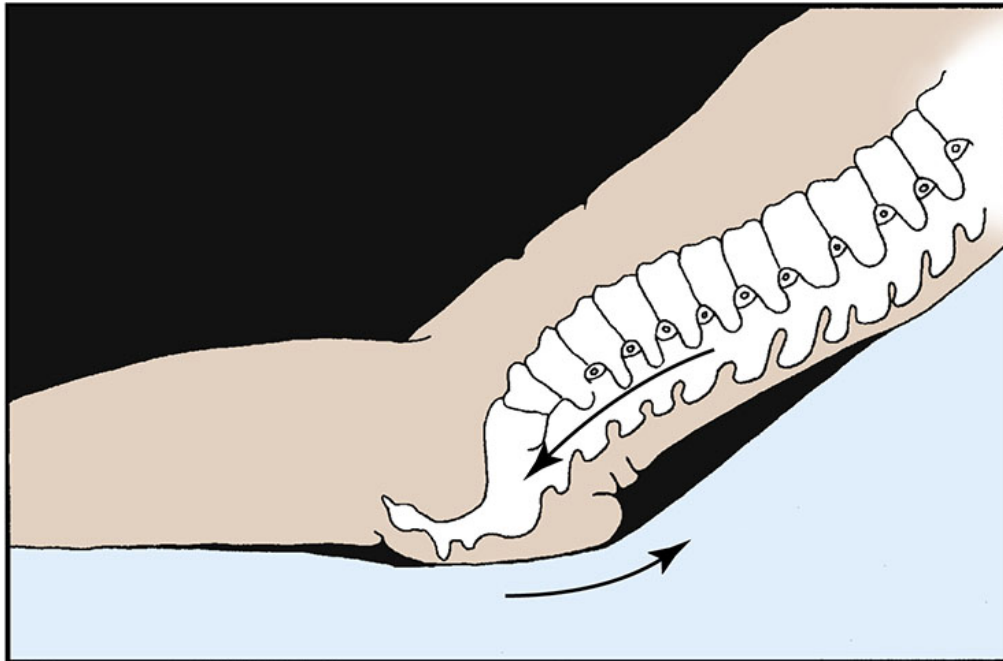

FIG. 48.3 Shear exerted in sacral area.

Friction

The force of two surfaces moving across one another such as the mechanical force exerted when skin is dragged across a coarse surface such as bed linens is called **friction** (WOCN, 2016). Unlike shear injuries, friction injuries affect the epidermis or top layer of the skin (superficial skin loss). The denuded skin appears red and painful and is sometimes referred to as a *sheet burn*. A friction injury occurs in patients who are restless, in those who have uncontrollable movements such as spastic conditions, and in those whose skin is dragged rather than lifted from the bed surface during position changes or transfer to a stretcher. This type of injury should not be classified as a pressure injury (EPUAP, NPIAP, PPIA, 2019b). Friction leads to pressure injury formation only when it causes harmful shear stress and strain (Brienza et al., 2015).

Moisture

The presence and duration of moisture on the skin increases the risk of pressure injury. Moisture reduces the resistance of the skin to other physical factors such as pressure, friction, or shear. Prolonged moisture softens skin, making it more susceptible to damage. The term moisture-associated skin damage (MASD) is defined as inflammation and erosion to the skin caused by prolonged exposure to various sources of moisture, including wound drainage, urine or stool, perspiration, wound exudate, mucus or saliva (Colwell et al., 2011).

Classification of Pressure Injuries

A staging system classifies pressure injuries. Accurate staging requires knowledge of the skin layers. A major drawback of a staging system is that you cannot stage an injury when it is covered with necrotic tissue because the necrotic tissue is covering the depth of the injury. In serious wounds with necrotic tissue, the wound must be debrided or removed (if appropriate to the overall treatment plan) to expose the wound base to allow for assessment.

Pressure injury staging describes the pressure injury depth at the point of assessment. Thus, once you have staged the pressure injury, this stage endures even as it heals. Pressure injuries do not progress from a stage 3 to a stage 1; rather, a stage 3 injury demonstrating signs of healing is described as a healing stage 3 pressure injury (Pieper, 2016). In 2016, the National Pressure Advisory Panel developed the following classification/staging system (EPUAP, NPIAP, PPPIA, 2019b; Edsberg et al., 2016):

- **Stage 1 Pressure Injury:** Nonblanchable erythema of intact skin
Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin (Fig. 48.4A). Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.

FIG. 48.4 Diagram of Pressure Injury Stages. **A**, Stage 1 pressure injury. **B**, Stage 2 pressure injury. **C**, Stage 3 pressure injury. **D**, Stage 4 pressure injury. **E**, Deep tissue injury. **F**, Unstageable pressure injury. Used with permission of the European Pressure Ulcer Advisory Panel [EPUAP] and National Pressure Injury Advisory Panel [NPIAP], and Pan Pacific Pressure Injury Alliance: Treatment of pressure ulcers/injuries: Quick Reference Guide, Emily Haesler (Ed.). EPUAP/NPIAP/PPPIA, 2019.

- Stage 2 Pressure Injury:** Partial-thickness skin loss with exposed dermis
 Partial-thickness loss of skin with exposed dermis (see Fig. 48.4B). The wound bed is viable, pink or red, and moist and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible, and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage (MASD), including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).
- Stage 3 Pressure Injury:** Full-thickness skin loss

Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present (see [Fig. 48.4C](#)). Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop in deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.

- **Stage 4 Pressure Injury:** Full-thickness skin and tissue loss

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer (see [Fig. 48.4D](#)). Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss this is an Unstageable Pressure Injury.

- **Deep-Tissue Pressure Injury:** Persistent nonblanchable deep red, maroon, or purple discoloration

Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, purple discoloration or epidermal separation revealing a dark wound bed or blood-filled blister (see [Fig. 48.4E](#)). Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle or other underlying structures are visible, this indicates a full-thickness pressure injury (Unstageable, Stage 3, or Stage 4). Do not use Deep-Tissue Pressure Injury to describe vascular, traumatic, neuropathic, or dermatologic conditions.

- **Unstageable Pressure Injury:** Obscured full-thickness skin and tissue loss

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar (see [Fig. 48.4F](#)). If slough or eschar is removed, a Stage 3 or Stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema or **fluctuance**) on the heel or ischemic limb should not be softened or removed.

The [EPUAP,NPIAP, PPPIA \(2019 a, b\)](#) guidelines suggest that when conducting a skin assessment on an individual with darkly pigmented skin, carefully inspect any discoloration over pressure areas, and surrounding skin should be assessed more

closely for temperature changes, edema, and changes in tissue consistency and pain . For additional aspects of assessing darkly pigmented skin, see [Box 48.2](#).

Wound Classifications

A **wound** is a disruption of the integrity and function of tissues in the body ([Baranoski et al., 2016](#)).

All wounds require careful evaluation and treatment based on a thorough assessment, the patient’s overall condition, and the goal of treatment. Understanding the etiology of a wound is important because the treatment will vary depending on the underlying disease process.

There are many ways to classify surgical and traumatic wounds. Wound classification systems describe onset and duration of healing process (e.g., the status of skin integrity, cause of the wound, or severity or extent of tissue injury or damage) ([Table 48.1](#)) and descriptive qualities of the pressure injury or wound tissue such as color ([Fig. 48.5](#)). Wound classification enables a nurse to understand the risks associated with a wound and implications for healing.

TABLE 48.1

Wound Classification

Description	Causes	Implications for Healing
Onset and Duration		
Acute		
Wound that proceeds through an orderly and timely reparative process that results in sustained restoration of anatomical and functional integrity	Trauma Surgical incision	Wound edges are clean and intact.
Chronic		
Wound that fails to proceed through an orderly and timely process to produce anatomical and functional integrity	Vascular compromise, chronic inflammation, or repetitive insults to tissue (Doughty and Sparks, 2016)	Continued exposure to insult impedes wound healing.
Healing Process		
Primary Intention		
Wound that is closed	Surgical incision Wound that is sutured or stapled	Healing occurs by epithelialization; heals quickly with minimal scar formation.
Secondary Intention		
Wound edges not approximated	Surgical wounds that have tissue loss or contamination	Wound heals by granulation tissue formation, wound contraction, and epithelialization.
Tertiary Intention		
Wound that is left open for several days; then wound edges are approximated (see Fig. 48.4,C)	Wounds that are contaminated and require observation for signs of inflammation	Closure of wound is delayed until risk of infection is resolved (Doughty and Sparks, 2016).

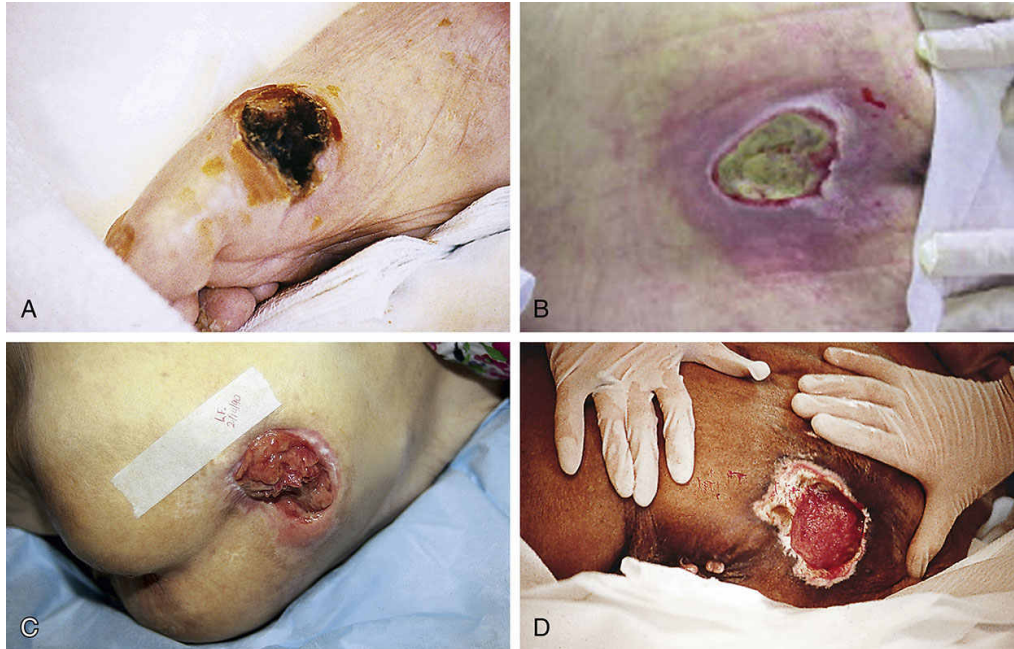

FIG. 48.5 Wounds classified by color assessment. **A**, Black wound. **B**, Yellow wound. **C**, Red wound. **D**, Mixed-color wound.

Process of Wound Healing

Wound healing involves integrated physiological processes. The tissue layers involved and their capacity for regeneration determine the mechanism for repair for any wound (Doughty and Sparks, 2016). Table 48.1 reviews the classification of wounds by onset and duration and healing process. Wounds can also be classified by the extent of tissue loss: partial-thickness wounds that involve only a partial loss of skin layers (the epidermis and superficial dermal layers) and full-thickness wounds that involve total loss of the skin layers (epidermis and dermis) (Doughty and Sparks, 2016). Partial-thickness wounds are shallow in depth, moist, and painful, and the wound base generally appears red. A full-thickness wound extends into the subcutaneous layer, can be painful, and the depth and tissue type varies, depending on body location. The significance of determining whether an injury is a partial- or full-thickness wound lies in the mechanism of healing. A partial-thickness wound heals by regeneration, and a full-thickness wound heals by forming new tissue, a process that can take longer than the healing of a partial-thickness wound.

A clean surgical incision is an example of a wound with little tissue loss. The surgical incision heals by **primary intention** (Fig. 48.6A). The skin edges are **approximated**, or closed, and the risk of infection is low. Healing occurs quickly, with minimal scar formation, as long as infection and secondary breakdown are prevented (Doughty and Sparks, 2016). In contrast, a wound involving loss of tissue such as a burn, stage II pressure injury, or severe laceration heals by **secondary intention**. The wound is left open until it becomes filled by scar tissue. It takes

longer for a wound to heal by secondary intention; thus the chance of infection is greater. If scarring from secondary intention is severe, loss of tissue function is often permanent (see Fig. 48.6B).

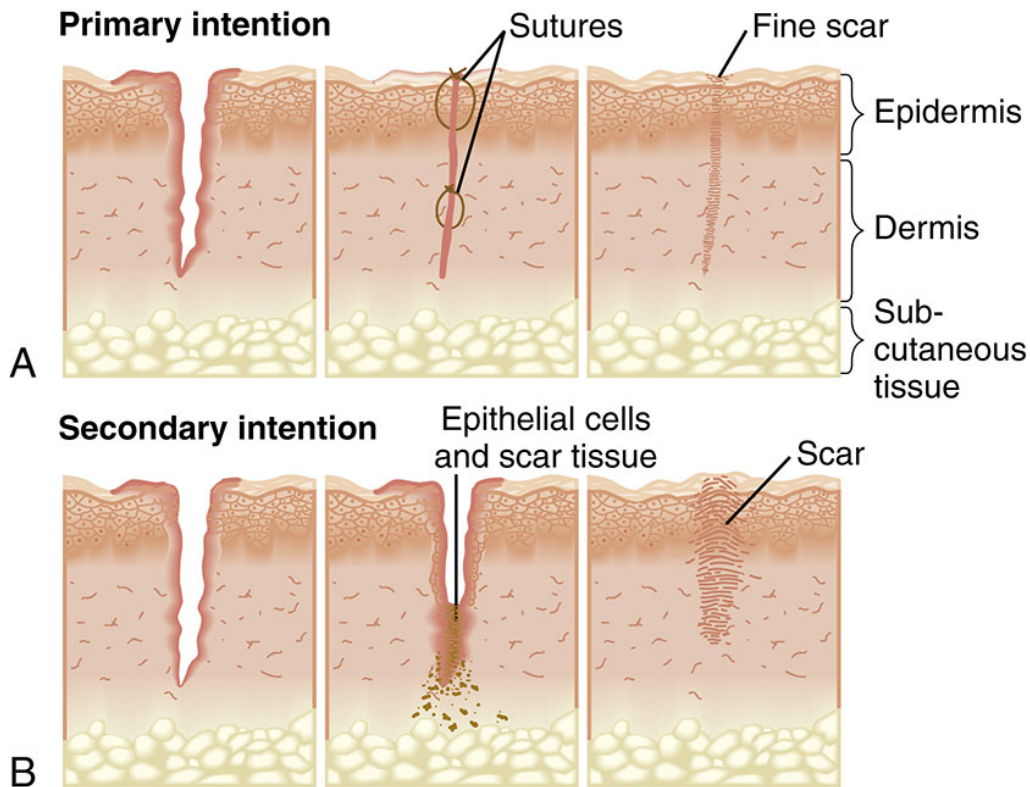

FIG. 48.6 **A**, Wound healing by primary intention such as a surgical incision. Wound healing edges are pulled together and approximated with sutures or staples, and healing occurs by connective tissue deposition. **B**, Wound healing by secondary intention. Wound edges are not approximated, and healing occurs by granulation tissue formation and contraction of the wound edges.

Wound Repair

Partial-thickness wounds are shallow, involving loss of epidermis and possible loss of dermis. These wounds heal by regeneration because epidermis regenerates. An example of a partial-thickness wound is a scrape or an abrasion. Full-thickness wounds extend into the dermis and heal by scar formation because deeper structures do not regenerate. Stage III and IV pressure injuries are examples of full-thickness wounds.

Partial-Thickness Wound Repair

Three components are involved in the healing process of a partial-thickness wound: inflammatory response, epithelial proliferation (reproduction) and migration, and

reestablishment of the epidermal layers.

Tissue trauma causes the *inflammatory response*, which in turn causes redness and swelling to the area with a moderate amount of **serous** exudate. This response generally is limited to the first 24 hours after wounding. The epithelial cells begin to regenerate, providing new cells to replace the lost cells. The *epithelial proliferation and migration* start at both the wound edges and the epidermal cells lining the epidermal appendages, allowing for quick resurfacing. Epithelial cells begin to migrate across a wound bed soon after the wound occurs. A wound that is kept moist can resurface in 4 days, whereas one left open to air can resurface within 6 to 7 days. The difference in the healing rate is related to the fact that epidermal cells only migrate across a moist surface. In a dry wound the cells migrate down into a moist level before migration can occur (Doughty and Sparks, 2016). New epithelium is only a few cells thick and must undergo *reestablishment of the epidermal layers*. The cells slowly reestablish normal thickness and appear as dry pink tissue.

Full-Thickness Wound Repair

The four phases involved in the healing process of a full-thickness wound are hemostasis, inflammatory, proliferative, and maturation.

Hemostasis

A series of physiological events designed to control blood loss, establish bacterial control, and seal the defect occurs when there is an injury. During **hemostasis** injured blood vessels constrict, and platelets gather to stop bleeding. Clots form a fibrin matrix that later provides a framework for cellular repair.

Inflammatory Phase

In the inflammatory stage damaged tissue and mast cells secrete histamine, resulting in vasodilation of surrounding capillaries and movement/migration of serum and white blood cells into the damaged tissues. This results in localized redness, edema, warmth, and throbbing. The inflammatory response is beneficial, and there is no value in attempting to cool the area or reduce the swelling unless the swelling occurs within a closed compartment (e.g., spinal cord injury, ankle, or neck) (Kelechi et al., 2017).

Leukocytes (white blood cells) reach a wound within a few hours. The primary-acting white blood cell is the neutrophil, which begins to ingest bacteria and small debris. The second important leukocyte is the monocyte, which transforms into macrophages. The macrophages are the “garbage cells” that clean a wound of bacteria, dead cells, and debris by phagocytosis. Macrophages continue the process of clearing a wound of debris and release growth factors that attract fibroblasts, the cells that synthesize collagen (connective tissue). Collagen appears as early as the second day and is the main component of scar tissue.

In a clean wound the inflammatory phase establishes a clean wound bed. The inflammatory phase is prolonged if too little inflammation occurs, as in a debilitating disease such as cancer or after administration of steroids. Too much inflammation

also prolongs healing because arriving cells compete for available nutrients. An example is a wound infection in which the increased metabolic energy requirements present in an infected wound compete for the available calorie intake.

Proliferative Phase

With the appearance of new blood vessels as reconstruction progresses, the proliferative phase begins and lasts from 3 to 24 days. The main activities during this phase are the filling of a wound with granulation tissue, wound contraction, and wound resurfacing by **epithelialization**. Fibroblasts are present in this phase and are the cells that synthesize collagen, providing the matrix for granulation. Collagen mixes with the granulation tissue to form a matrix that supports the reepithelialization. Collagen provides strength and structural integrity to a wound. During this period a wound contracts to reduce the area that requires healing. Finally the epithelial cells migrate from the wound edges to resurface. In a clean wound the proliferative phase accomplishes the following: the vascular bed is reestablished (granulation tissue), the area is filled with replacement tissue (collagen, contraction, and granulation tissue), and the surface is repaired (epithelialization). Impairment of healing during this stage usually results from systemic factors such as age, anemia, hypoproteinemia, and zinc deficiency.

Maturation

Maturation, the final stage of healing, sometimes takes place for more than a year, depending on the depth and extent of the wound. The collagen scar continues to reorganize and gain strength for several months. However, a healed wound usually does not have the tensile strength of the tissue it replaces. Collagen fibers undergo remodeling or reorganization before assuming their normal appearance. Usually scar tissue contains fewer pigmented cells (melanocytes) and has a lighter color than normal skin. In individuals with darkly pigmented skin, the scar tissue may be more highly pigmented than surrounding skin.

Complications of Wound Healing

Hemorrhage

Hemorrhage, or bleeding from a wound site, is normal during and immediately after initial trauma. However hemostasis occurs within several minutes unless large blood vessels are involved or a patient has poor clotting function. Hemorrhage occurring after hemostasis indicates a dislodged surgical suture, a clot, infection, or erosion of a blood vessel by a foreign object (e.g., a drain). Hemorrhage may occur externally or internally. For example, if a surgical suture is dislodged from a blood vessel, bleeding occurs internally within the tissues, and there may not be visible signs of blood unless a surgical drain is present. A surgical drain may be inserted into tissues beneath a wound to remove fluid that collects in underlying tissues.

You detect internal hemorrhaging by looking for distention or swelling of the affected body part, a change in the type and amount of drainage from a surgical

drain, or signs of hypovolemic shock. A hematoma is a localized collection of blood underneath the tissues. It appears as swelling, change in color, sensation, or warmth that often takes on a bluish discoloration. A hematoma near a major artery or vein is dangerous because pressure from the expanding hematoma obstructs blood flow.

External hemorrhaging is obvious. You observe dressings covering a wound for bloody drainage, and you observe for blood underneath the body. If bleeding is extensive, the dressing soon becomes saturated, and frequently blood drains from under the dressing and pools beneath the patient. Observe all wounds closely, particularly surgical wounds, in which the risk of hemorrhage is great during the first 24 to 48 hours after surgery or injury.

Infection

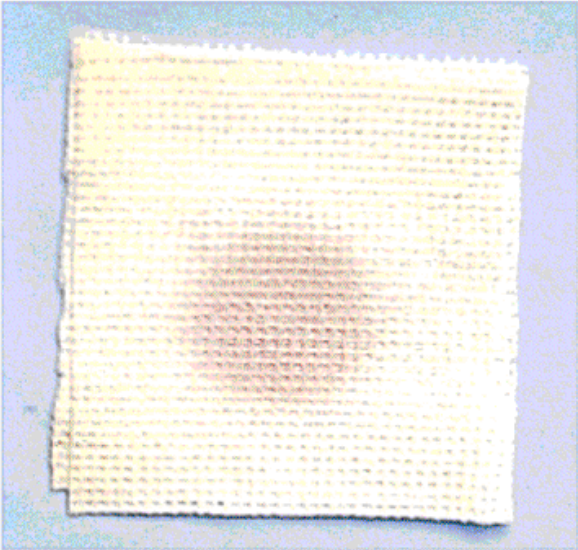

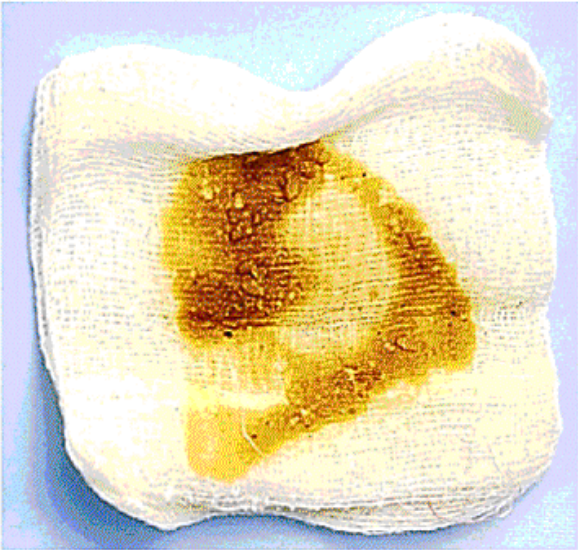

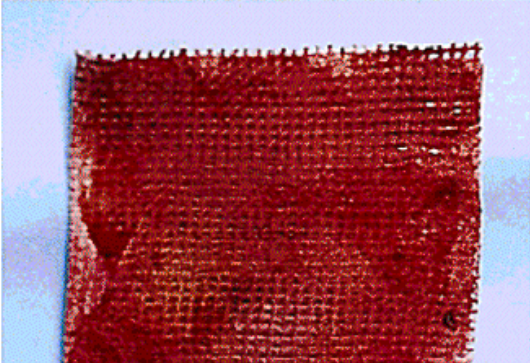

Wound infection is the second most common health care–associated infection (see [Chapter 28](#)). All wounds have some level of bacterial burden; few wounds are infected ([Stotts, 2016b](#)). Wound infection is present when the microorganisms invade the wound tissues. The local clinical signs of wound infection can include erythema; increased amount of wound drainage; change in appearance of the wound drainage (thick, color change, presence of odor); and periwound warmth, pain, or edema. A patient may have a fever and an increase in white blood cell count. Laboratory tests such as a wound culture or tissue biopsy can be done to evaluate the wound for infection.

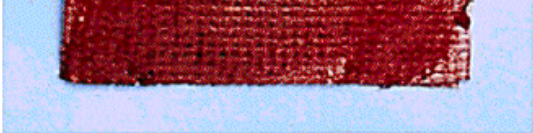

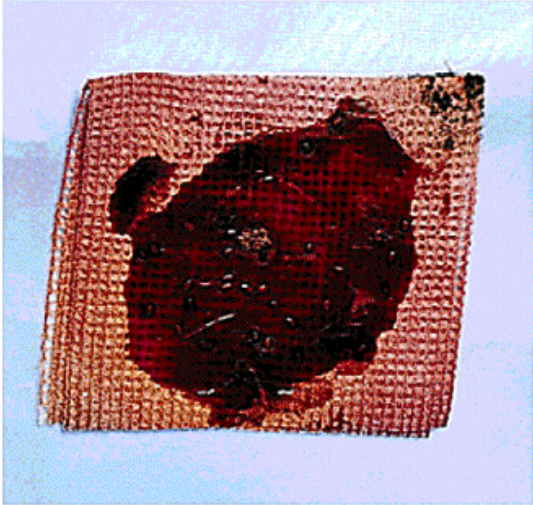

Some contaminated or traumatic wounds show signs of infection early, within 2 to 3 days. Surgical site infections occur within 30 days of surgery; risk factors include hyperglycemia, smoking, untreated peripheral vascular disease, obesity, age, and emergency surgery ([Burden and Thornton, 2018](#)). If a surgical site infection occurs, the patient will have a fever, tenderness, and pain at the wound site and an elevated white blood cell count ([Stryja, 2018](#)). The edges of the wound will appear inflamed. If drainage is present, it is odorous and **purulent**, which causes a yellow, green, or brown color, depending on the causative organism ([Table 48.2](#)).

Chart shows four types of wound drainage as follows: Serous: Clear, watery plasma. Purulent: Thick, yellow, green, tan, or brown. Serosanguineous: Pale, pink watery; mixture of clear and red fluid. Sanguineous: Bright red; indicates active bleeding.

TABLE 48.2

Types of Wound Drainage

Type	Appearance
Serous	<p data-bbox="451 220 576 241">Clear, watery plasma</p> 
Purulent	<p data-bbox="451 846 657 867">Thick, yellow, green, tan, or brown</p> 
Serosanguineous	<p data-bbox="451 1476 738 1497">Pale, pink, watery; mixture of clear and red fluid</p> 

	
Sanguineous	Bright red; indicates active bleeding 

Dehiscence

When an incision fails to heal properly, the layers of skin and tissue separate. This most commonly occurs before collagen formation (3 to 11 days after injury).

Dehiscence is the partial or total separation of wound layers. A patient who is at risk for poor wound healing (e.g., poor nutritional status, infection, or underlying diseases such as diabetes mellitus or peripheral vascular disease) is at risk for dehiscence. Obese patients have a higher risk of wound dehiscence because of the constant strain placed on their wounds and the poor healing qualities of fat tissue (Pierpont et al., 2014). Dehiscence can happen in abdominal surgical wounds and occurs after a sudden strain such as coughing, vomiting, or sitting up in bed. Patients often report feeling as though something has given way. When there is an increase in serosanguineous drainage from a wound in the first few days after surgery, be alert for the potential for dehiscence.

Evisceration

With total separation of wound layers, **evisceration** (protrusion of visceral organs through a wound opening) occurs. The condition is an emergency that requires surgical repair. When evisceration occurs, place sterile gauze soaked in sterile saline

over the extruding tissues to reduce chances of bacterial invasion and drying of the tissues. If the organs protrude through the wound, blood supply to the tissues can be compromised. Then contact the surgical team, do not allow the patient anything by mouth (NPO), observe for signs and symptoms of shock, and prepare the patient for emergency surgery.

REFLECT NOW

Consider a patient you recently cared for. What were the patient's risk factors for pressure injuries and in what way did those risk factors affect the condition of the skin?

Nursing Knowledge Base

Prediction and Prevention of Pressure Injuries

Preventing pressure injuries is a priority and is not limited to patients with restrictions in mobility. Impaired skin integrity usually is not a problem in healthy individuals but is a serious and potentially devastating problem in ill or debilitated patients (WOCN, 2016). Consistent, planned skin-care interventions are critical to ensuring high-quality care. Whenever you are in direct contact with a patient, observe the skin for impaired skin integrity and/or pressure injury.

Risk Assessment

Several tools are available for assessing patients who are at risk for developing a pressure injury. By identifying at-risk patients, you are able to put preventive interventions into place and also spare those low-risk patients unnecessary and sometimes costly preventive treatments.

The incidence of pressure injuries in a health care agency is an important indicator of quality of care. Evidence exists that a program of prevention guided by risk assessment simultaneously reduces the institutional incidence of pressure injuries by as much as 60% and brings down the costs of prevention at the same time (Martin et al., 2017). Several risk-assessment scales developed by nurses enable systematic risk assessment of patients. The Braden Scale is the most widely used risk-assessment tool for pressure injuries and is in the WOCN guidelines (2016) as being a valid tool to use for pressure injury risk assessment. The Braden Scale (Table 48.3) was developed on the basis of risk factors in a nursing home population (Braden and Bergstrom, 1994) and is widely used on general patient care units in hospitals. However, the Braden Scale has shown insufficient predictive validity and poor accuracy in discriminating intensive care patients at risk for developing pressure injuries (Han et al., 2018; Hyun et al., 2013). Research involving critical care patients continues. The Braden Scale contains six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction/shear. The total

score ranges from 6 to 23; a lower total score indicates a higher risk for pressure injury development ([Braden and Bergstrom, 1989](#)). The cutoff score for patients not at risk for pressure injury in the general adult population is 18 ([Ayello et al., 2016](#)). Research has shown that the cutoff score for onset of risk in intensive care patients is 13 ([Hyun et al., 2013](#)).

TABLE 48.3

Braden Scale for Predicting Pressure Ulcer Risk

Sensory Perception				
Ability to respond appropriately to pressure-related discomfort	1. Completely limited: Unresponsive (does not moan, flinch, or grasp) to painful stimuli caused by diminished level of consciousness or sedation or Limited ability to feel pain over most of body surface	2. Very limited: Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness or Has sensory impairment that limits ability to feel pain or discomfort over half of body	3. Slightly limited: Responds to verbal commands but cannot always communicate discomfort or need to be turned or Has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	4. No impairment: Responds to verbal commands Has no sensory deficit that would limit ability to feel or voice pain or discomfort
Moisture				
Degree to which skin is exposed to moisture	1. Constantly moist: Skin kept moist almost constantly by bodily elimination such as perspiration or urine Dampness detected every time patient is moved or turned	2. Very moist: Skin often, but not always, moist Necessary to change linen at least once a shift	3. Occasionally moist: Skin occasionally moist, requiring an extra linen change approximately once a day	4. Rarely moist: Skin usually dry Required linen changing only at routine intervals
Activity				
Degree of physical activity	1. Bedfast: Confined to bed	2. Chairfast: Ability to walk severely limited or nonexistent Cannot bear own weight and/or must be helped into chair or wheelchair	3. Walks occasionally: Walks occasionally during day but for very short distances, with or without assistance Spends majority of each shift in bed or chair	4. Walks frequently: Walks outside room at least twice a day and inside room at least once every 2 hours during waking hours
Mobility				
Ability to change and control body position	1. Completely immobile: Does not make even slight changes in body or extremity position without assistance	2. Very limited: Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	3. Slightly limited: Makes frequent, though slight, changes in body or extremity position independently	4. No limitations: Makes major and frequent changes in position without assistance
Nutrition				
Usual food intake pattern	1. Very poor: Never eats a complete meal; rarely eats more than one-third of any food offered; eats two servings or less of protein (meat or dairy products) per day Takes fluids poorly Does not take a liquid dietary supplement or Is NPO and/or maintained on clear liquids or IV for more than 5 days	2. Probably inadequate: Rarely eats a complete meal and generally eats only about ½ of any food offered Protein intake includes only 3 servings of meat or dairy products per day Occasionally takes a dietary supplement or Receives less than optimum amount of liquid diet or tube feeding	3. Adequate: Eats over half of most meals Eats a total of four servings of protein (meat, dairy products) each day Occasionally refuses a meal but usually takes a supplement if offered or Is on tube feeding or TPN regimen that probably meets most of nutritional needs	4. Excellent: Eats most of every meal; never refuses a meal; usually eats a total of four or more servings of meat and dairy products Occasionally eats between meals Does not require supplementation
Friction and Shear				
	1. Problem: Requires moderate-to-maximum help to move; complete lifting without sliding against sheets impossible Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance Spasticity, contractures, or agitation leads to almost constant friction	2. Potential problem: Moves feebly or requires minimum assistance; during a move skin probably slides to some extent against sheets, chair, restraints, or other devices Maintains relatively good position in chair or bed most of the time but occasionally slides down	3. No apparent problem: Moves in bed and in chair independently and has sufficient muscle strength to sit up completely during move Maintains good position in bed or chair at all times	TOTAL SCORE

NPO, nothing by mouth.; *TPN*, total parenteral nutrition.

Instructions: Score patient in each of the six subscales for overall score. Level of risk: *Not at risk*, greater than 18; *mild risk*, 15-18; *moderate risk*, 13-14; *high risk*, 10-12; and *very high risk*, less than 9.

Economic Consequences of Pressure Injuries

Pressure injuries are a continual problem in acute and restorative care settings, especially in patients 65 years and older ([WOCN, 2016](#)). Paralysis and spinal cord injury are common preexisting conditions among younger adults with primary diagnosis of pressure injuries. Older adults admitted to acute and long-term facilities are a vulnerable population. Although the cost to provide pressure injury prevention to patients at risk can impact health care services' budgets, the costs to treat a severe pressure injury are substantially higher ([Demarré et al., 2015](#)).

When a pressure injury occurs, the length of stay in a hospital and the overall cost of health care increase. These injuries are also costly to patients in terms of disability, pain, and suffering. About 1.6 million patients each year in acute care settings develop pressure injuries, representing a cost of \$11 billion to \$17.2 billion to the US health care system ([Pieper, 2016](#)). The Centers for Medicare and Medicaid Services (CMS) implemented a policy effective October 1, 2008, whereby hospitals no longer receive reimbursement for care related to stage 3 and 4 pressure injuries that occur during a hospitalization. Guidelines such as the WOCN Guidelines ([WOCN, 2016](#)) help reduce or eliminate the occurrence of pressure injuries and prevent the expenses that will not be reimbursed.

Factors Influencing Pressure Injury Formation and Wound Healing

In addition to previously discussed risk factors of impaired sensation, impaired mobility, shear, friction, and moisture, a patient's nutrition, tissue perfusion, infection, or age may increase the risk for pressure injury and poor wound healing.

Nutrition

Normal wound healing requires proper nutrition ([Table 48.4](#)). Deficiencies in any of the nutrients result in impaired or delayed healing ([Stotts, 2016a](#)). Physiological processes of wound healing depend on the availability of protein, vitamins (especially A and C), and the trace minerals zinc and copper. Collagen is a protein formed from amino acids acquired by fibroblasts from protein ingested in food. Vitamin C is necessary for synthesis of collagen. Vitamin A reduces the negative effects of steroids on wound healing. Trace elements are also necessary (i.e., zinc for epithelialization and collagen synthesis and copper for collagen fiber linking).

TABLE 48.4**Role of Selected Nutrients in Wound Healing**

Nutrient	Role in Healing	Recommendations	Sources
Calories	Fuel for cell energy "Protein protection"	30-35 kcal/kg/day (Individuals who are underweight or have significant unintentional weight loss may need additional calories.)	Protein smoothies, whole milk, nuts, beans, salmon
Protein	Fibroplasia, angiogenesis, collagen formation and wound remodeling, immune function	1.25-1.5 g protein/kg body weight	Poultry, fish, eggs, beef, milk
Vitamin C (ascorbic acid)	Collagen synthesis, capillary wall integrity, fibroblast function, immunological function, antioxidant	1000 mg/day	Citrus fruits, tomatoes, potatoes, fortified fruit juices
Vitamin A	Epithelialization, wound closure, inflammatory response, angiogenesis, collagen formation	1600-2000 retinol equivalents per day	Green leafy vegetables (spinach), broccoli, carrots, sweet potatoes, liver
	Can reverse steroid effects on skin and delayed healing		
Zinc	Collagen formation, protein synthesis, cell membrane and host defenses	15-30 mg Correct deficiencies No improvement in wound healing with supplementation unless zinc deficient Use with caution—large doses can be toxic May inhibit copper metabolism and impair immune function	Vegetables, meats, legumes
Fluid	Essential fluid environment for all cell function	30-35 mL/kg/day	Use noncaffeinated, nonalcoholic fluids without sugar Water is best—6-8 glasses/day

Adapted from Stotts NA: Nutritional assessment and support. In Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts*, ed 5, St Louis, 2016a, Elsevier.

Calories provide the energy source needed to support the cellular activity of wound healing. Protein needs especially are increased and are essential for tissue repair and growth. A balanced intake of various nutrients (i.e., protein, fat, carbohydrates, vitamins, and minerals) is critical to support wound healing. Consult with a nutritional team for dietary prescriptions individualized for the caloric needs of patients who are assessed as being at risk of malnutrition ([EPUAP, NPIAP, PPPIA, 2019a](#)).

Serum proteins are biochemical indicators of malnutrition ([Stotts, 2016a](#)). Serum albumin is probably the most frequently measured of these laboratory parameters. Albumin alone is not sensitive to rapid changes in nutritional status. The best measure of nutritional status is prealbumin because it reflects not only what the patient has recently

ingested but also what the body has absorbed, digested, and metabolized (Stotts, 2016a).

Tissue Perfusion

Oxygen fuels the cellular functions essential to the healing process; therefore the ability to perfuse the tissues with adequate amounts of oxygenated blood is critical to wound healing (Doughty and Sparks, 2016). Patients with diabetes and peripheral vascular disease are at risk for poor tissue perfusion because of poor circulation. Oxygen requirements depend on the phase of wound healing (e.g., chronic tissue hypoxia is associated with impaired collagen synthesis and reduced tissue resistance to infection).

Infection

Wound infection prolongs the inflammatory phase; delays collagen synthesis; prevents epithelialization; and increases the production of proinflammatory cytokines, which leads to additional tissue destruction (Stotts, 2016b). Indications that a wound infection is present include the presence of purulent drainage; change in odor, volume, or character of wound drainage; redness in the surrounding tissue; fever; or pain.

Age

The physiological changes associated with aging affect all phases of wound healing. A decrease in the functioning of macrophages leads to a delayed inflammatory response, delayed collagen synthesis, and slower epithelialization.

Psychosocial Impact of Wounds

The psychosocial impact of wounds on the physiological process of healing is unknown. Body image changes often impose a great stress on a patient's adaptive mechanisms. They also influence self-concept (see Chapter 33) and sexuality (see Chapter 34). Factors that affect a patient's perception of a wound include: location, the presence of scars, stitches, drains (often needed for weeks or months), odor from drainage, and temporary or permanent prosthetic devices.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require a nurse to anticipate the information necessary, analyze the data, and make decisions regarding patient care. Critical thinking is always changing. During assessment ([Fig. 48.7](#)) consider all elements that build toward making appropriate nursing diagnoses.

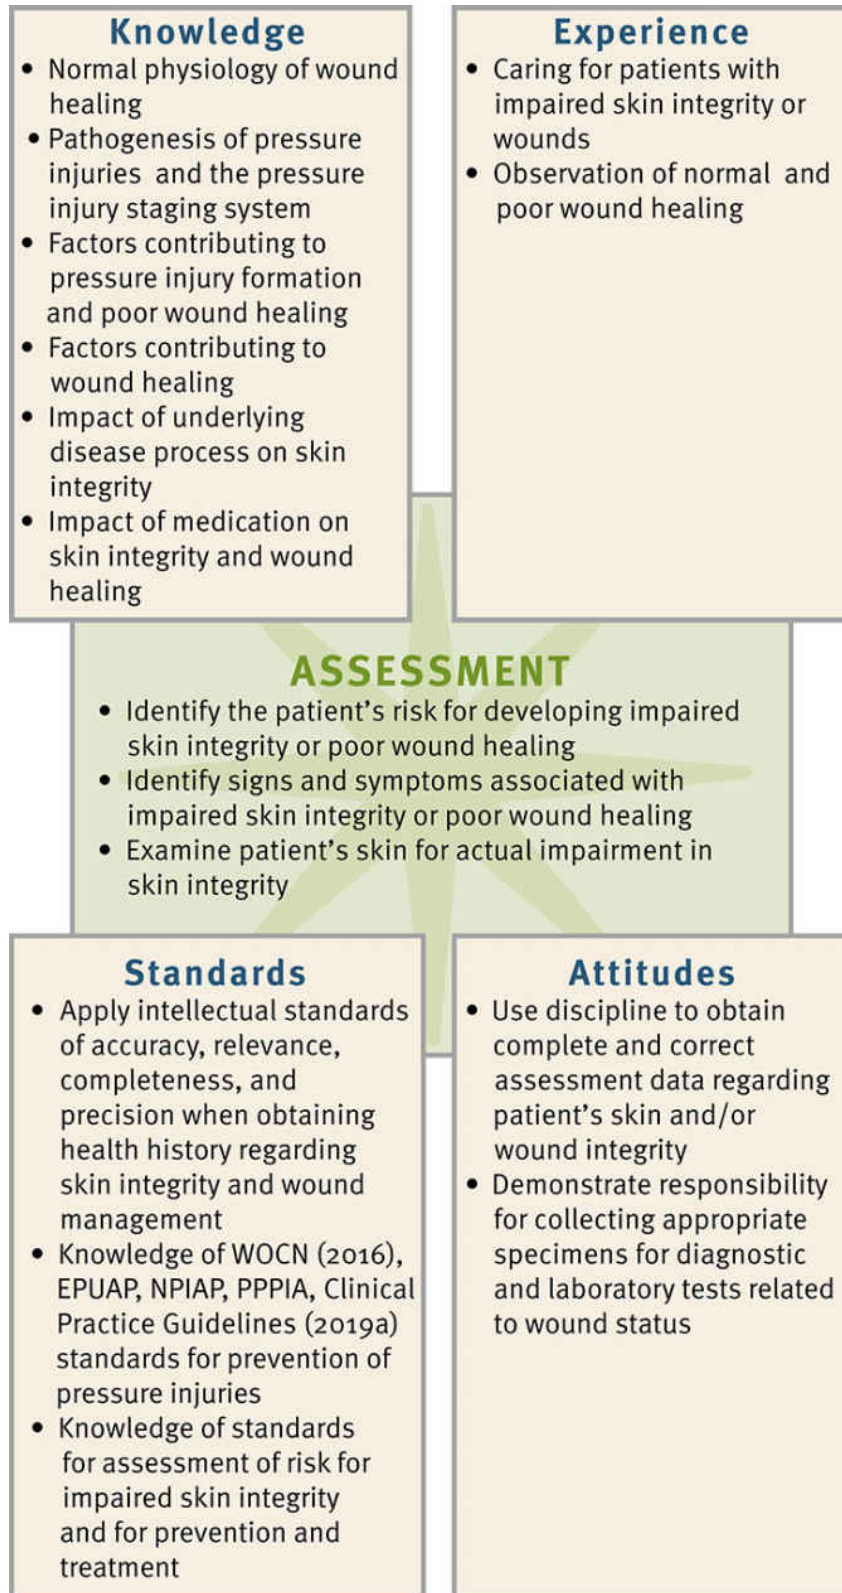

FIG. 48.7 Critical thinking model for skin integrity and wound-care assessment. WOCN, Wound, Ostomy and Continence Nurses Society.

When caring for patients who have impaired skin integrity and chronic wounds, integrate knowledge from nursing and other disciplines, previous experiences, practice standards, and information gathered from patients to understand the risk to skin integrity and wound healing. Knowledge of normal musculoskeletal physiology, the pathogenesis of pressure injuries, pressure injury stages, normal wound healing, and the pathophysiology of underlying diseases enables you to have a scientific basis for care. The [WOCN \(2016\)](#) has guidelines for assessment of risk for impaired skin integrity, prevention measures, interventions to promote wound healing, and other standards of practice, which you should use in planning care. Past experience with patients at risk for impaired skin integrity or patients with wounds increases the experiential knowledge base, helping you to identify interventions. Finally you need to be disciplined during assessment to obtain comprehensive and correct data. You also need to be creative. Because chronic wounds are difficult to heal, be diligent in evaluating nursing interventions and in determining which interventions are effective and which need modification.

REFLECT NOW

Think about the information in the Braden Scale. How will this impact your knowledge about identifying risks for pressure injuries and potential interventions?

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. Baseline and continual assessment data provide critical information about a patient's skin integrity and the increased risk for pressure injury development. Focusing on specific elements such as a patient's level of sensation, movement, and continence status helps guide the skin assessment (Box 48.3).

Box 48.3 Nursing Assessment Questions

Sensation

- Do you have tingling, decreased feeling, or absent feeling in your extremities?
- Can you feel pressure when sitting or lying down?
- When preparing a bath is your skin sensitive to heat or cold?

Mobility

- Do you have any physical limitations, injury, or paralysis that limits your ability to move on your own?
- Can you change your position easily?
- Tell me about any pain you have when you walk, sit down, or move about your home.

Continence

- Do you have any problems or accidents leaking urine or stool?
- What help do you need when using the toilet? In what way?
- How often do you need to use the toilet? During the day? At night?

Presence of Wound

- What do you believe caused your wound?
- When did the wound occur? Where is it located?
- When did you receive a tetanus shot?
- What has happened to this wound since it occurred? What were the changes and what caused them?
- What have you done to treat the wound? Which treatments, activities, or care have slowed or helped the wound to heal?
- Do you have any pain, itching, or other symptoms with the wound? How are you managing the itching, and what works best for you?
- Who helps you care for your wound?

Through the Patient's Eyes

When patients have acute surgical or traumatic wounds, the wounds sometimes heal promptly and without complications. However, when pressure injuries or chronic wounds develop, the course of treatments can be lengthy and costly. Because a patient and family need to be involved with wound-care management, it is important to know a patient's expectations. Does the patient expect to have home care? Is there the expectation the patient will heal to allow a quick return to work? A patient who has realistic goals and is informed about the length of time for wound healing is more likely to adhere to the specific therapies designed to promote healing and prevent further skin breakdown. Therefore assess each patient's perception of proposed wound treatment and what is occurring once wound-healing interventions begin. For example, why are certain dressings being used and how do they work? You want to determine a patient's and family's understanding of wound assessment; wound interventions; and supportive interventions such as positioning, nutrition, and ambulation.

Skin

Perform skin assessment of a patient when you initiate care and then at a minimum of once a shift (see agency policies). Inspect the skin for signs of skin breakdown and/or injury development (see Skill 48.1). High-risk patients—including those who are neurologically impaired, chronically ill in long-term care, or have altered mental status; those in the intensive care unit (ICU), oncology units, hospice, or orthopedic units; and patients with medical devices—need more frequent skin assessments, such as every 4 hours.

Assessment for tissue pressure damage includes visual and tactile inspection of the skin. Perform a baseline assessment to determine a patient's normal skin

characteristics and any actual or potential areas of breakdown (Nix, 2016). Individualize assessment characteristics of a patient's skin, depending on his or her skin tone (EPUAP, NPIAP, PPPIA, 2019a,b). Accurate assessment of patients with darker skin pigmentation is an essential skill for all health care providers (see Boxes 48.2 and 48.3).

Medical device–related pressure injuries (MDRPIs) are injuries that result from the use of devices designed and applied for diagnostic or therapeutic purposes (Kayser et al., 2018). Upon assessment, the resultant pressure injury generally closely conforms to the pattern or shape of the device (EPUAP, NPIAP, PPPIA, 2019b; Pittman et al., 2015). Pay particular attention to areas located over bony prominences; next to and around medical devices; and under casts, traction, splints, braces, collars, or other orthopedic devices (Table 48.5). The frequency of pressure checks depends on the response of the skin to the external pressure (Fig. 48.8). Consider adults with medical devices (e.g., tubes, drainage systems, and oxygen devices) to be at risk for pressure injuries (Black et al., 2010; Black and Kalowes, 2016).

Table 48.5**Strategies to Prevent Medical and Immobilization Device–Related Pressure Injuries**

Device	Pressure Areas	Prevention Strategies ^a
Feeding tubes and nasogastric tubes	Nares Skin on nasal bridge	Secure tube using pressure-relieving techniques, which direct the pressure from the tube away from the nares (see Chapters 45 and 47). Reposition tube.
Endotracheal tubes	Lips Tongue	Remove securing device daily and inspect for pressure injury (Branson et al., 2014) (see Chapter 41). Rotate tube every shift or more often.
Nasotracheal tube	Nose/nasal bridge Nares	Remove securing device daily and inspect for pressure injury (Branson et al., 2014) (see Chapter 41). Reposition.
Tracheostomy tubes	Front of neck and stoma site	Remove securing device daily. Increase stoma care (Chapter 41).
Oxygen cannula and tubing	Ears Nose	Apply dressing to external ear. Periodically remove cannula to relieve pressure and inspect for pressure injury (Schallom et al., 2015) (Chapter 41).
Noninvasive positive-pressure ventilation (NIPPV)/bi-level positive airway pressure (BiPAP)	Forehead Nose/nasal bridge	Apply protective dressing or liquid skin barrier to bridge of nose or forehead before application of device. If appropriate, remove mask periodically for a few minutes.
Drainage tubing	Area immediately next to drainage tube Adjacent area during patient position changes	Apply appropriate dressing around drainage tube insertion site. Check tubing placement with each position change. Instruct patient not to lie on the tubing (Pittman et al., 2015).
Indwelling urinary catheter	Thighs Female: urethra, labia Male: tip of penis	Provide meticulous perineal care (see Chapter 40). Anchor and secure catheter to reduce pressure (see Chapter 46).
Orthopedic devices	All areas where device (e.g., cast or brace) comes in contact with patient's skin and tissues	When possible and not contraindicated, inspect under the device.
Neck collar	Neck and occipital region Scalp	Remove hard collars as soon as possible and replace with softer collar (Black et al., 2015). Inspect scalp daily.
Compression stockings	Calf Behind knee Heel Toes	Verify proper fit. To reduce pressure and risk of injury to skin and underlying tissue, remove stockings twice daily for at least 1 hour (Black et al., 2015) (Chapter 39).
Immobilization devices	Wrists Ankles	Apply dressing between immobilizer and patient's skin (Black et al., 2015). Verify that there is some space between immobilizer and patient's skin. With assistive personnel present, remove restraints one at a time to inspect skin (see Chapter 27).

^a In addition to routine inspection and cleaning of skin under and around medical device.

FIG. 48.8 Formation of pressure injury on heel resulting from external pressure from bed mattress.

Courtesy Janice Colwell, RN, MS, CWOCN, FAAN, Clinical Nurse Specialist, University of Chicago Medicine.

Medical adhesive–related pressure injury is an occurrence in which erythema and/or other manifestation of cutaneous abnormality (including but not limited to vesicle, bulla, erosion, or skin tear) persists 30 minutes or more after removal of the adhesive. Skin stripping, or tape burns, from adhesives is the most commonly reported injury; thus a careful assessment of skin exposed to adhesive tape or other adhesive devices should be routinely done (McNichol et al., 2013).

When you note hyperemia of the skin, gently palpate the reddened tissue; differentiate whether the skin redness is blanchable or nonblanchable. Blanchable erythema is visible skin redness that becomes pale or white when pressure is applied and reddens when pressure is relieved. It may result from normal reactive hyperemia that should disappear within several hours or from inflammatory erythema with an intact capillary bed. Nonblanchable erythema is visible skin redness that persists with the application of pressure. It indicates structural damage to the capillary bed/microcirculation. This is an indication for a stage 1 pressure injury (EPUAP, NPIAP, PPIA, 2019a).

Use visual and tactile inspection over the body areas most frequently at risk for pressure injury development (Fig. 48.9). For example, when a patient lies in

bed or sits in a chair, he or she places body weight heavily on certain bony prominences. Turn the patient in bed to inspect the skin and, once you return a patient to bed from a chair, look at all areas exposed to pressure. Body surfaces subjected to the greatest weight or pressure are at greatest risk for pressure injury formation.

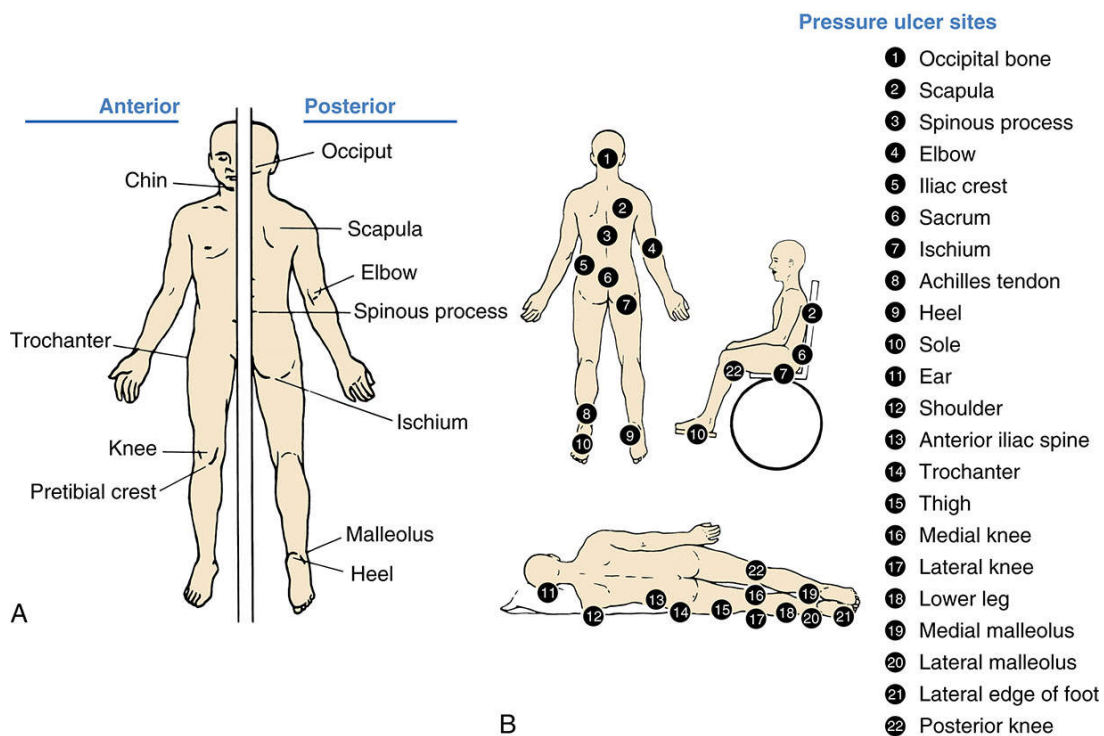

FIG. 48.9 A, Bony prominences most frequently underlying pressure injury. B, Pressure injury sites.

Modified from Trelease CC: Developing standards for wound care, *Ostomy Wound Manage* 20:46, 1988.

Wounds and Pressure Injuries

When you identify the presence of a skin wound or pressure injury, closer assessment is required. Assess the type of tissue in the wound base so that you can plan appropriate interventions. The assessment includes the amount (percentage) and appearance (color) of viable and nonviable tissue.

Granulation tissue is red, moist tissue composed of new blood vessels, the presence of which indicates progression toward healing. Soft yellow or white tissue is characteristic of **slough** (stringy substance attached to wound bed), and it must eventually be removed by a qualified clinician or by an appropriate wound dressing before the wound is able to heal. Black, brown, tan or necrotic tissue is **eschar**, which also needs to be removed before healing can occur.

Measurement of the wound size provides information on overall changes in dimensions, which is an indicator for wound healing progress (Nix, 2016). This includes measuring the length and width of a wound, as well as determining its depth (see Skill 48.2). Use a disposable wound-measuring device to measure wound width and length. This approach offers a uniform, consistent method for measuring meaningful comparisons of wound status across time (EPUAP, NPIAP, PPIA, 2019b). Measure depth by using a cotton-tipped applicator in the wound bed (see Skill 48.2). Note that if a deep laceration exists it will likely require suturing by a qualified clinician.

Assessment of wound **exudate** should describe the amount, color, consistency, and odor of wound drainage. Excessive exudate indicates the presence of infection. Wound pain, including the location, distribution, type, quality and intensity, and any aggravating or relieving factors, also should be assessed (Krasner, 2016). Examine the skin around the wound (periwound) for redness, warmth, and signs of maceration, and palpate the area for signs of pain or **induration**. The presence of any of these factors on the periwound skin indicates wound deterioration.

Predictive Measures

On admission to acute care, rehabilitation hospitals, nursing homes, home care, and other health care facilities, patients are assessed for risk of pressure injury development (WOCN, 2016). Assessment for pressure injury risk includes using an appropriate predictive measure and assessing a patient's mobility, nutrition, presence of body fluids, and comfort level (see Skill 48.1). Perform pressure injury risk assessment systematically (WOCN, 2016) using an assessment tool such as the Braden Scale (see Table 48.3) or a tool preferred by your agency. The interpretation of the meaning of the total numerical scores differs with each risk-assessment scale relevant to the population being assessed by the agency. Lower numerical scores on the Braden Scale indicate that the patient is at high risk for skin breakdown. A benefit of the predictive instruments is to increase a nurse's early detection of patients at greater risk for injury development (WOCN, 2016). Perform reassessment for pressure injury risk on a scheduled basis (see agency policy).

Mobility

Assessment includes documenting the baseline level of mobility and the potential effects of impaired mobility on skin integrity. Documenting assessment of mobility includes obtaining data regarding the quality of muscle tone and strength. For example, determine whether the patient is able to lift his or her weight off the sacral area and roll the body to a side-lying position. Some patients have inadequate range of motion to move independently into a more protective position. Finally, assess a patient's activity tolerance to

determine whether the patient can be transferred to a chair or ambulated more often to relieve pressure from lying down (see [Chapter 39](#)).

Nutritional Status

An assessment of a patient's nutritional status is an integral part of the initial assessment data for any patient, especially one at risk for impaired skin integrity ([Stotts, 2016a](#)). [The Joint Commission \(2019\)](#) recommends nutritional assessment within 24 hours of admission. Weigh the patient and perform this measure more often for at-risk patients. A loss of 5% of usual weight, weight less than 90% of ideal body weight, and a decrease of 10 lb in a brief period are all signs of actual or potential nutritional problems ([Stotts, 2016a](#)). Assess the patient's mouth and teeth for oral sores and ill-fitting dentures that impact nutritional intake (see [Chapter 45](#)).

Body Fluids

It is important to prevent and reduce the patient's exposure to body fluids; when exposure occurs, provide meticulous hygiene and skin care. Continual exposure of the skin to body fluids increases a patient's risk for skin breakdown and pressure injury formation. Some body fluids such as saliva and serosanguineous drainage are not as caustic, and the risk of skin breakdown from exposure to these fluids is low. However, exposure to urine, bile, stool, ascitic fluid, and purulent wound exudate carries a moderate risk for skin breakdown, especially in patients who have other risk factors such as chronic illness or poor nutrition. Frequent exposure to urine and fecal contents increases patients' risk for incontinence-associated dermatitis (IAD) ([McNichol et al., 2018](#)). Additionally, exposure to gastric and pancreatic drainage has the highest risk for skin breakdown. These fluids have digestive qualities that can irritate and break down the skin quickly.

Pain

Significant research has been conducted in the study of pain in surgical patients with wounds. The routine assessment of pain in surgical patients is critical to selecting appropriate pain management therapies and to determine a patient's ability to progress toward recovery. The [WOCN \(2016\)](#) has recommended that assessment and management of pain also be included in the care of patients with pressure injuries ([EPUAP, NPIAP, PPIA, 2019b](#)). Use standard pain assessment tools to measure pain acuity, and be thorough in assessing the character of a patient's pain (see [Chapter 44](#)). Maintaining adequate pain control and patient comfort increases the patient's willingness and ability to increase mobility, which in turn reduces pressure injury risk.

Surgical and Traumatic Wounds

Assess wounds at the time of injury, during wound care, when a patient's overall condition changes, and on a regularly scheduled basis. Regardless of the setting, it is important that you initially obtain information regarding the cause and history of the wound, treatment of the wound, wound description (location, dimensions, quality of the wound base tissue, and presence of odor, warmth, or redness on the periwound skin), and response to therapy.

Emergency Setting

You see wounds in any setting, including clinics, emergency departments, youth camps, or your own backyard. The type of wound determines the criteria for inspection. For example, you do not need to inspect for signs of internal bleeding after an abrasion, but you should inspect in the event of a puncture wound.

After a traumatic wound, when you judge a patient's condition to be stable because of the presence of spontaneous breathing, a clear airway, and a strong carotid pulse (see [Chapters 30](#) and [41](#)), inspect the wound for bleeding. An **abrasion** is superficial with little bleeding and is considered a partial-thickness wound. The wound often appears "weepy" because of plasma leakage from damaged capillaries. A **laceration** sometimes may bleed more profusely (especially if the patient is taking anticoagulants or other blood thinners), depending on the depth and location of the wound. For example, minor scalp lacerations tend to bleed profusely because of the rich blood supply to the scalp. Lacerations greater than 5 cm (2 inches) long or 2.5 cm (1 inch) deep cause serious bleeding. **Puncture wounds** bleed in relation to the depth, size, and location of the wound (e.g., a nail puncture does not cause as much bleeding as a knife wound). A puncture wound is usually a small, circular wound with the edges coming together toward the center. The primary dangers of puncture wounds are internal bleeding and infection.

Inspect traumatic wounds for foreign bodies or contaminant material. Most traumatic wounds are dirty. Soil, broken glass, shreds of cloth, and foreign substances clinging to penetrating objects sometimes become embedded in a wound. Next, assess the size and depth of a wound (see Skill 48.2).

When an injury is a result of trauma from a dirty penetrating object, determine when the patient last received a tetanus toxoid injection. Tetanus bacteria reside in soil and in the gut of humans and animals.

Stable Setting

When a patient's condition is stabilized (e.g., after surgery or treatment), assess the wound to determine progress toward healing. If the wound is covered by a dressing and the health care provider has not ordered it changed, do not

inspect it directly unless you suspect serious complications such as a large volume of bright red bleeding, excessive odor, or severe pain under the dressing. In such a situation inspect only the dressing and any external drains. If the health care provider prefers to change the dressing, he or she should assess the wound at least daily. When removing dressings, remove one dressing layer at a time to avoid accidental removal or displacement of underlying drains. Because removal of dressings can be painful, consider giving an analgesic at least 30 minutes before exposing a wound.

Wound Appearance

A surgical incision healing by primary intention should have clean, well-approximated edges. There may be some redness at the edges of the incision that can be present for the first few days after surgery. Crusts often form along wound edges from exudate. If a wound is open, the edges are separated, and you inspect the condition of tissue at the wound base. The outer edges of a wound normally appear inflamed for the first 2 to 3 days, but this slowly disappears. Within 7 to 10 days a normally healing wound resurfaces with epithelial cells, and edges close. [Table 48.6](#) lists assessment characteristics for abnormal wound healing in primary and secondary wounds. If infection develops, the area directly surrounding the wound becomes brightly inflamed and swollen.

TABLE 48.6

Assessment of Abnormal Healing in Primary- and Secondary-Intention Wounds

Primary Intention Wounds	Secondary Intention Wounds
Incision line poorly approximated	Pale or fragile granulation tissue, hypergranulation tissue present
Drainage present more than 3 days after closure	Wound exudate is purulent
Inflammation increased in first 3-5 days after injury	Nonviable tissues such as necrotic or slough in wound base
No healing ridge by day 9	Fruity, earthy, or putrid odor present after wound base is cleansed Presence of fistula(s), tunneling, undermining

Modified from Nix D: Skin and wound inspection and assessment. In Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts*, ed 5, St Louis, 2016, Elsevier.

Skin discoloration usually results from bruising of interstitial tissues or hematoma formation. Blood collecting beneath the skin first takes on a bluish

or purplish appearance. Gradually, as the clotted blood is broken down, shades of brown and yellow appear.

Character of Wound Drainage

Note the amount, color, odor, and consistency of wound drainage (see [Table 48.2](#)). The amount of drainage depends on the type of wound. For example, drainage is minimal after a simple appendectomy. In contrast, it is moderate for 1 to 2 days after drainage of a large abscess. When you need an accurate measurement of the amount of drainage within a dressing, weigh the dressing and compare it with the weight of the same dressing that is clean and dry. The general rule is that 1 g of drainage equals 1 mL of volume of drainage. Another method of quantifying wound drainage is to chart the number of dressings used and the frequency of change. An increase or decrease in the number or frequency of dressings indicates a relative increase or decrease in wound drainage. If the drainage has a pungent or strong odor, you should suspect an infection. Describe the appearance of the wound according to characteristics observed, the type of closures used, and the dressing changes performed.

Drains

Drains provide a means for fluid or blood that accumulates within a wound bed to drain out of the body. A surgeon inserts a drain into or near a surgical wound if there is a large amount of drainage. A drain can also be placed by the interventional radiologist to drain an area found after or before surgery. Some drains are sutured in place. Exercise caution when changing a dressing around drains that are not sutured in place to prevent accidental removal. A Penrose drain lies under a dressing; at the time of placement a pin or clip is placed through the drain to prevent it from slipping farther into a wound ([Fig. 48.10](#)). One dressing is split and placed around the drain and another over the drain to collect drainage. When removing the dressings remove one dressing at a time to prevent accidental dislodgement of the drain. It is usually the health care provider's responsibility to pull or advance the drain as drainage decreases to permit healing deep within the drain site. The wound will heal from the inside out.

FIG. 48.10 Penrose drain with dressing.

Assess the number and type of drains, drain placement, character of drainage, and condition of collecting equipment. Observe the security of the drain and its location with respect to the wound. Next note the character of drainage. If there is a collecting device, measure the drainage volume. Because a drainage system needs to be patent, look for drainage flow through and around the tubing. A sudden decrease in drainage through the tubing may indicate a blocked drain, and you need to notify the health care provider. When a drain is connected to suction, assess the system to be sure that the pressure ordered is being exerted. Evacuator units such as a Hemovac or Jackson-Pratt (Fig. 48.11) exert a constant low pressure as long as the suction device (bladder or container) is fully compressed. When the evacuator device is unable to maintain a vacuum on its own, notify the surgeon, who then orders a secondary vacuum system (such as wall suction). If fluid accumulates within the tissues, wound healing does not progress at an optimal rate, and this increases the risk of infection.

FIG. 48.11 Jackson-Pratt drainage device. Drainage tube and reservoir.

Wound Closures

Surgical wounds are closed with staples, sutures, or wound adhesives. A frequent skin closure is the stainless-steel staple. The staple provides more strength than nylon or silk sutures and tends to cause less irritation to tissue. Look for irritation with redness around staple or suture sites and note whether closures are intact. Normally for the first 2 to 3 days after surgery the skin around sutures or staples is edematous because of the normal inflammatory response.

Dermabond is a liquid tissue adhesive that forms a strong bond across approximated wound edges, allowing normal healing to occur below. It can be used to replace small sutures for incisional repair. A vial containing the Dermabond solution is used to apply the product to approximated tissue. The wound edges are held together until the solution dries, providing an adhesive closure. Tissue adhesives take less time to apply, have lower risk of infection, have tensile strength comparable to sutures, and also provide less pain and anxiety (Januchowski and Ferguson, 2014).

Palpation of Wound

When inspecting a wound, observe for swelling or separation of wound edges. While wearing clean gloves, lightly press the wound edges, detecting localized areas of tenderness or drainage collection. If pressure causes fluid to be expressed, note the characteristics of the drainage. The patient is normally sensitive to palpation of wound edges. Extreme tenderness indicates infection.

Wound Cultures

If you detect purulent or suspicious-looking drainage, report to the health care provider because a specimen of the drainage may need to be obtained for culture. Never collect a wound culture sample from old drainage. Resident colonies of bacteria flora from the skin grow within exudate and are not always the true causative organisms of a wound infection. Clean a wound first with normal saline to remove skin flora. Aerobic organisms grow in superficial wounds exposed to the air, and anaerobic organisms tend to grow within body cavities. Use a different method of specimen collection for each type of organism per agency policy (Box 48.4).

Box 48.4 Recommendations for Standardized Techniques for Wound Cultures^a

Needle Aspiration Procedure (Anaerobic Organisms)

- Clean intact skin with povidone iodine and allow to dry for 60 seconds to remove skin flora. Then wipe the skin with alcohol and allow to dry, which reduces the possibility that the specimen will be altered by the iodine on the skin surface.
- Use a sterile 10-mL disposable syringe with a 22-gauge needle, pulling 0.5 mL of air into the syringe.

- Insert the needle through intact skin next to the wound; withdraw plunger and apply suction to the 10-mL mark.
- Move the needle back and forward at different angles for two to four explorations. The plunger is then released back to the 0.5 mL mark, the needle is withdrawn, and the syringe is capped and sent to the lab (Weir and Schultz, 2016).

Quantitative Swab Procedure (Aerobic Organisms)

- Clean the wound surface with an antiseptic solution. Allow to dry.
- Use a sterile swab from a culturette tube (Fig. 48.12).
- Identify a 1-cm area of the wound that is free from necrotic tissue. Rotate the swab while applying pressure sufficient to express fluid from the wound tissue (Weir and Schultz, 2016).
- Insert the tip of the swab into the appropriate sterile container, label, and transport to the laboratory.

Gram stains of drainage are often performed as well. This test allows the health care provider to order appropriate treatment earlier than when only cultures are done. No additional specimens are usually required. The microbiology laboratory needs only to be notified to perform the additional test.

The gold standard of wound culture is tissue biopsy. A health care provider or wound-care specialist with special training obtains the biopsy (Stotts, 2016b).

Psychosocial

Assess how a wound is influencing a patient's self-perception and socialization. Ask the patient to describe how the wound affects his or her view of self. Does the patient have unwarranted fears that the wound will not heal? Does a chronic wound interfere with the patient's willingness to participate in social activities at home? Does it affect the patient's ability to continue working? Make sure that the patient's personal and social resources for adaptation are a part of your assessment. Is there a family caregiver who is able to assist with wound care in the home?

REFLECT NOW

Think about a patient you have recently cared for and who had a medical device, such as a urinary catheter, oxygen mask, or feeding tube. What were the patient's risks for skin breakdown? How did you assess the patient for medical device pressure injury?

Nursing Diagnosis

Assessment reveals clusters of data to indicate whether a problem-focused or negative diagnosis of *Impaired Skin Integrity* or a risk diagnosis of *Risk for Impaired Skin Integrity* exists. In addition, the assessment data provide information about the related factor. For example, a postoperative patient has purulent drainage from a surgical wound and reports tenderness around the area of the wound. These data support a nursing diagnosis of *Impaired Skin Integrity* related to infection (Box 48.5). After completing an assessment of a patient's wound, the nurse identifies nursing diagnoses that direct the interventions that will be needed to support wound healing and prevent complications. Additional nursing diagnoses associated with impaired skin integrity and wounds:

Box 48.5 Nursing Diagnostic Process Impaired Skin Integrity Related to Infection

Assessment Activities	Assessment Findings
Inspect surface of wound and periwound skin.	Break in skin integrity Yellow, foul-smelling drainage from wound Edges of wound red and warm, not approximated Macerated periwound area
Inspect wound for signs of healing.	Brown-red or beige drainage 5 days after surgery Edges of wound not approximated
Palpate wound and ask patient if there is tenderness.	Patient expresses pain on palpation; rates pain as a 5 on scale of 0 to 10 Periwound edema
Obtain patient's temperature, heart rate, white blood cell count.	Patient febrile, heart rate 125 beats/min, leukocyte (white blood cell) count 12,000/mm ³

- *Risk for Infection*
- *Acute or Chronic Pain*
- *Impaired Mobility*
- *Impaired Peripheral Tissue Perfusion*

Some patients are at risk for poor wound healing because of the presence of previously defined conditions that impair healing. Thus, even though a patient's wound appears normal, the nurse identifies nursing diagnoses such as *Impaired Nutritional Intake* or *Ineffective Tissue Perfusion* that direct nursing care toward support of wound repair.

The nature of a wound can cause problems unrelated to wound healing. An alteration in comfort with the diagnosis of *Acute Pain* and *Impaired Mobility* have implications for a patient's eventual recovery. For example, a large abdominal incision causes enough pain to interfere with the patient's ability to turn in bed effectively, making him or her at risk for impaired skin integrity.

• Planning

After identifying nursing diagnoses, develop a plan of care for a patient so that interventions promote wound healing and prevent complications of any existing wounds. During planning synthesize information from multiple resources (Fig. 48.13). Critical thinking ensures that a patient's plan of care integrates all that you know about the individual and key critical thinking elements. Professional standards are especially important to consider when you develop a plan of care. Practice standards will ensure your use of appropriate wound therapies.

FIG. 48.12 Wound culturette tube.

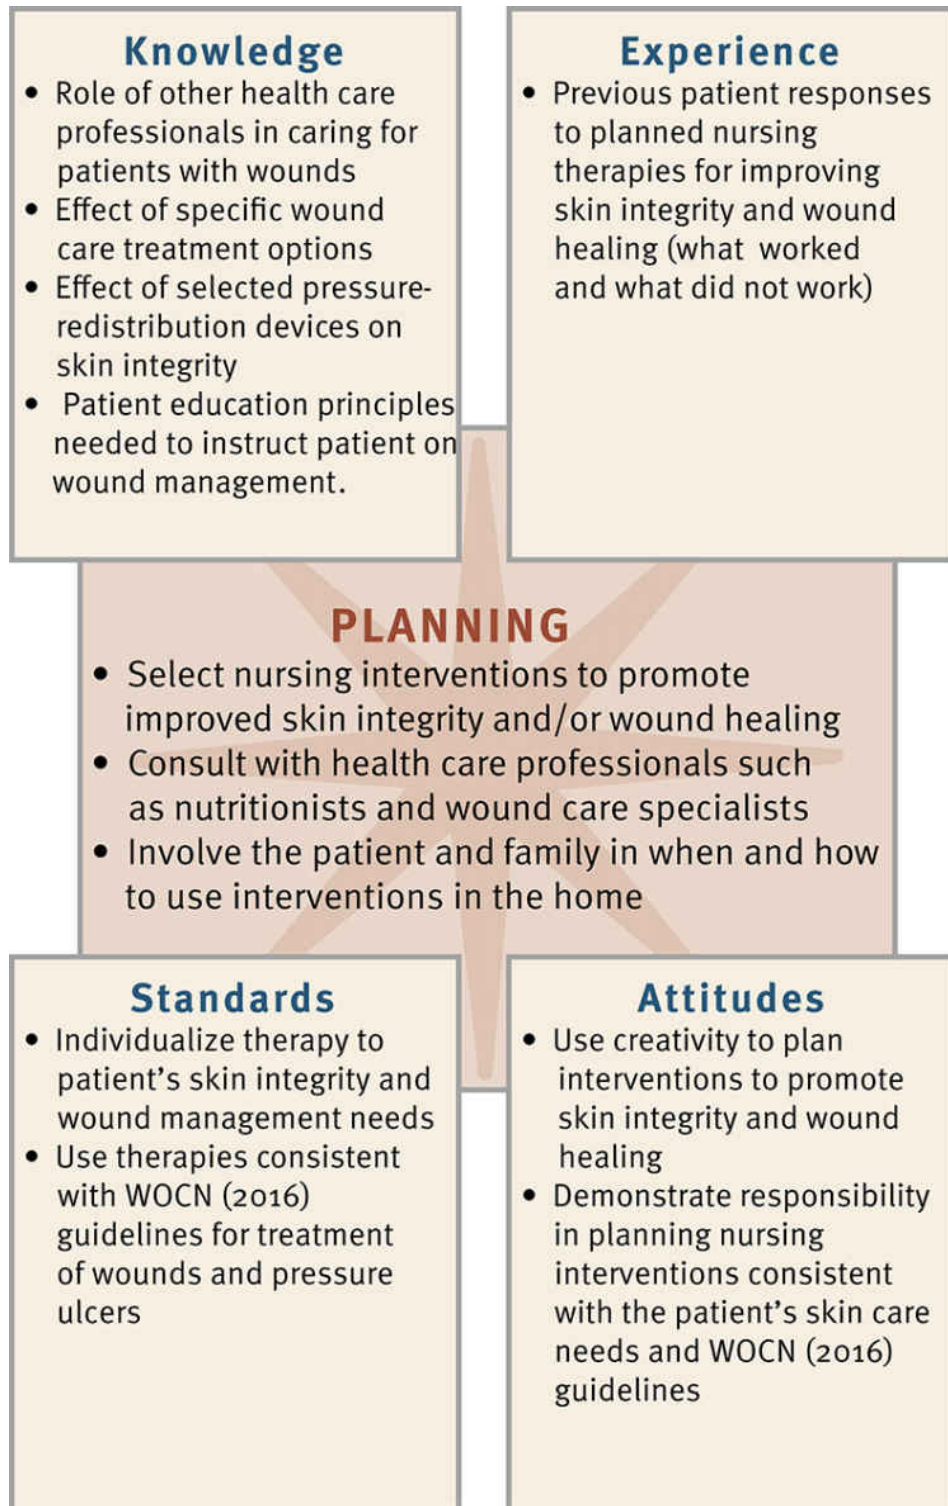

FIG. 48.13 Critical thinking model for skin integrity and wound-care planning. WOCN, Wound, Ostomy and Continence Nurses Society.

Patients who have large chronic wounds or infected wounds have multiple nursing care needs. A concept map helps to individualize care for a patient

who has multiple health problems and related nursing diagnoses (Fig. 48.14). This map helps you use critical thinking skills to organize complex patient assessment data into related nursing diagnoses with the patient’s chief medical diagnosis. As you identify links between the nursing diagnoses and the chief medical diagnosis, the concept map also links potential interventions that apply to the patient’s multiple health care needs.

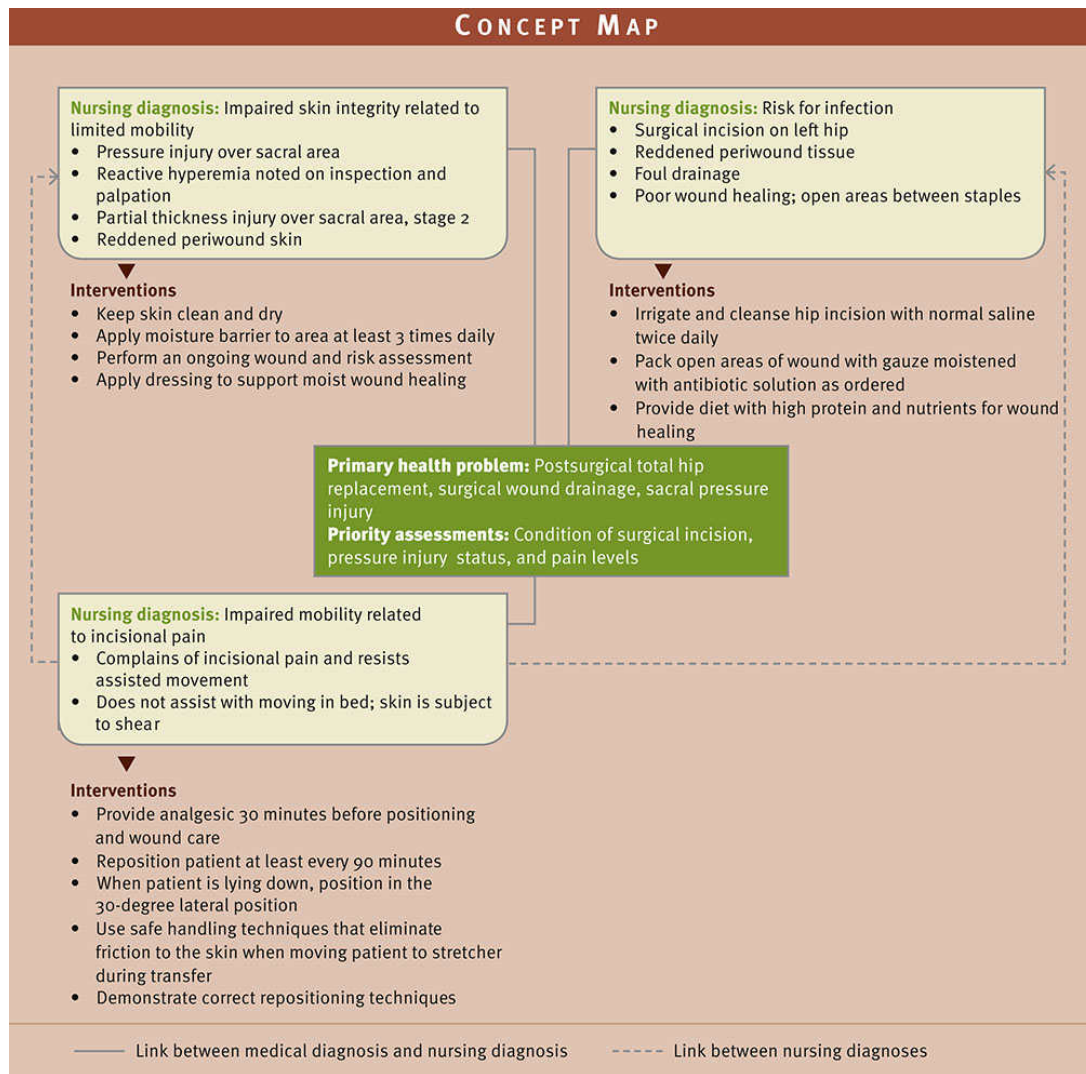

FIG. 48.14 Concept map for Mrs. Stein.

Goals and Outcomes

Nursing care is based on a patient’s identified needs and priorities. You establish goals and expected outcomes, and from the goals you plan interventions according to the risk for pressure injuries or the type and severity

of the wound and the presence of any complications such as infection, poor nutrition, peripheral vascular diseases, or immunosuppression that can affect wound healing (see the [Nursing Care Plan](#)). A goal frequently identified when working with a patient with a wound is to see the wound progressing toward healing within a 2-week period. The outcomes of this goal can include the following:

- Increase in the percentage of granulation tissue in the wound base
- No further skin breakdown
- Increase in caloric intake by 10%

These outcomes are reasonable if the overall goal for the patient is to heal the wound. Plan therapies according to the severity and type of wound and the presence of any complicating conditions (e.g., infection, poor nutrition, immunosuppression, and diabetes) that affect wound healing. Other goals of care for patients with wounds include the following: promoting wound hemostasis, preventing infection, promoting wound healing, maintaining skin integrity, gaining comfort, and promoting health.

Setting Priorities

Establish nursing care priorities in wound care on the basis of the comprehensive patient assessment and goals and established outcomes. These priorities also depend on whether the patient's condition is stable or emergent. When there is a risk for pressure injury development, preventive interventions such as skin-care practices, elimination of risks, and positioning are high priorities. An acute wound needs immediate intervention, whereas in the presence of a chronic, stable wound, the patient's hygiene and education on wound care are more important. Promotion of wound healing and the type of wound care administered depend on the type, size, and location of the wound and overall treatment goals.

Other patient factors to consider when establishing priorities include patient preferences, daily activities, and family factors. These factors are important, regardless of the setting for health care. The priorities of care may not vary from outpatient, home, acute care, or restorative care settings.

Teamwork and Collaboration

With early discharge from health care settings, it is important to consider a patient's plan for discharge as soon as a patient is admitted to a facility. Anticipating the patient's discharge wound-care needs and related equipment and health care resources such as referral to a home care agency or outpatient wound-care clinic helps to improve not only wound healing but also the

patient's level of independence. Patients and their family caregivers often need to continue the objectives of wound management after discharge. Carefully consider the ability of a family caregiver and the amount of time needed to change a particular dressing when selecting a dressing for the patient to use after discharge. For example, in the home setting a patient's spouse may choose more expensive dressing materials to reduce the frequency of dressing changes (Box 48.6).

Box 48.6 Home Care Recommendations

Injury/Wound Assessment

Assessment and documentation of a pressure injury/wound needs to occur at least weekly unless there is evidence of deterioration, in which case the nurse needs to reassess both the pressure injury and the patient's overall management immediately. In the home setting this requires the help of the patient and family because weekly assessment is not always feasible. Wound assessment in the home is the same as in a health care agency; see Skills 48.1 and 48.2 for specific assessment parameters.

Injury Care Dressings

- Consider family caregiver time and ability when selecting a dressing.
- In the home setting some family caregivers choose dressing materials manufactured to reduce the frequency of dressing changes.

Infection Control

- Clean dressings, as opposed to sterile ones, are recommended for home use until research demonstrates otherwise. This recommendation is in keeping with principles regarding nosocomial infections and with past success of clean urinary catheterization in the home setting, and it takes into account the expense of sterile dressings and the dexterity required for application. The family caregiver can use the "no-touch" technique for dressing changes. This technique is a method of changing surface dressings without touching the wound or the surface of any dressing that might be in contact with the wound. Adherent dressings should be grasped by the corner and removed slowly, whereas gauze dressings can be pinched in the center and lifted off.
- Contaminated dressings in the home should be disposed of in a manner consistent with local regulations. The Environmental Protection Agency

recommends placing soiled dressings in securely fastened plastic bags before adding them to other household trash. However, local regulations vary, and home care agencies and patients need to follow procedures that are consistent with local laws.

Modified from Agency for Health Care Policy and Research, Panel for the Treatment of Pressure Ulcers in Adults: *Treatment of pressure ulcers*, Clinical Practice Guideline No. 15, AHCPR Pub No. 95-0653, Rockville, MD, 1994, Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services.

Implementation

Health Promotion

Prompt identification of patients at high risk for pressure injuries or for impaired wound healing require timely and appropriate preventive measures.

Nutrition

Patients with existing wounds or those at risk for pressure injury will need extra protein, calories, and nutrients. The [Cleveland Clinic \(2017\)](#) recommends these daily nutrients to improve and promote wound healing:

- Protein (5 to 8 servings daily). Eat the protein portion of your meals first in case you become too full.
- Whole grains for higher protein content (5 servings daily)
- Vegetables (2 servings daily). Add to fruit smoothies for an extra boost without a bitter taste.
- Fruit (3 servings daily). Use as toppings for cooked cereals, yogurt, and ice cream. Choose fruit for dessert.
- Dairy (3 servings daily). Substitute milk for water in recipes; add powdered milk or yogurt to shakes, smoothies, and cooked cereals. Top soups with cheese or Greek yogurt.

Prevention of Pressure Injuries

Nursing interventions for patients who are immobile or have other risk factors for pressure injuries focus on prevention ([Table 48.7](#)). Prevention minimizes the impact that risk

TABLE 48.7**Quick Guide to Pressure Injury Prevention**

Risk Factor	Nursing Interventions
Decreased sensory perception	Provide pressure-redistribution surface (Gruccio and Ashton, 2018).
Medical device	Protect pressure points from medical devices such as oxygen tubing, feeding tubes, and casts (Kayser et al., 2018; Black et al., 2015).
Moisture	Following each incontinent episode, clean area with no-rinse perineal cleaner and protect skin with moisture-barrier ointment (Bryant and Nix, 2016a). Keep skin dry and free of maceration (Collier, 2016; Colwell et al., 2011).
Friction and shear	Reposition patient using drawsheet or a transfer board surface. Provide trapeze to facilitate movement in bed. Position patient at a 30-degree lateral turn and limit head elevation to 30 degrees (see Fig. 48.15).
Decreased activity/mobility	Establish and post individualized turning schedule. Turn patient off at-risk areas often.
Poor nutrition	Provide adequate nutritional and fluid intake; help with intake as necessary (Stotts, 2016a). Consult dietitian for nutritional assessment and recommended nutrients.

Nursing Care Plan

Impaired Skin Integrity

Assessment

Mrs. Stein, an 86-year-old patient, fell at home and fractured her left hip. She had a hip replacement 2 days ago and has been hesitant to move due to pain and fear of falling. When asked to participate in repositioning, she slides her body up and down in bed while protecting her hip. She does not like the staff to use a lift sheet to reposition her in bed. She becomes slightly diaphoretic when moving, causing her to sweat upon movement. You note drainage on her gown over the area of the hip.

Assessment Activities	Assessment Findings ^a
Ask Mrs. Stein about her mobility.	She relates that her hip always aches, limiting movement , and that her lower leg is sore and the pain increases on movement. She tells you that she prefers to keep the hip and leg immobile to keep the pain level down. Position of comfort is supine, and Mrs. Stein resists position changes.
Assess sacral area.	There is a partial-thickness injury directly over the sacral area. Patient has nonblanchable erythema around the open sacral area. Incontinent of urine.
Assess left hip, surgical incision.	Small openings between staples oozing tan, foul-smelling fluid. Periwound area red and warm.

^a **Assessment Findings** are shown in bold type.

Nursing diagnosis

Impaired Skin Integrity related to pressure, friction, and shearing forces over sacral bony prominence and infectious drainage from surgical site

Planning

Goals	Expected Outcomes (NOC) ^b
	Tissue Integrity: Skin and Mucous Membranes
Injury to Mrs. Stein's skin and underlying tissue resulting from pressure, friction, and shear over the bony prominence will be reduced within 2 to 4 weeks.	Intact skin integrity in the area of nonblanching erythema. Sacral injury shows signs of healing. Intact skin over other pressure points.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Skin Surveillance	
Place an order for a pressure reduction mattress per agency's protocol and place on bed.	Reduces the duration and magnitude of pressure over vulnerable areas of the body and contributes to comfort, hygiene, dignity, and functional ability (Bryant and Nix, 2016a).
Assist with repositioning every 90 minutes as her condition allows. Use a drawsheet when helping to reposition.	Repositioning is still required for pressure redistribution and comfort when a support surface is in use. A lift or transfer sheet minimizes friction and/or shear (EPUAP, NPIAP, PPIA, 2019a).
Elevate head of bed no more than 30 degrees (EPUAP, NPIAP, PPIA, 2019a,b). Note: Some hip replacement patients may not be allowed to turn in to 30-degree lateral position.	A slouched position places pressure and shear on the sacrum and coccyx (EPUAP, NPIAP, PPIA, 2019a).
Keep skin dry and clean; avoid rubbing or massaging around the open area (McNichol et al., 2018).	The presence of skin damage from moisture/maceration contributes to the development of pressure injuries (Colwell et al., 2011; EPUAP, NPIAP, PPIA, 2019a). Rubbing or massaging areas of nonblanching erythema can cause further tissue damage (WOCN, 2016).
Use moisture barrier ointment over the injury at least 3 times a day to decrease friction and provide moisture to the open tissue.	An ointment covers the area, providing base of ulcer with moisture, which encourages healing. Ointment prevents sheets from rubbing on area, thus decreasing the friction (Bryant and Nix, 2016a).
Wound Care	
Irrigate wound with saline solution twice a day per wound-care provider's order.	Cleanse wound and surrounding area of wound debris and exudate.
Apply dressing (i.e., gauze moistened with solution twice a day after irrigation) according to wound-care provider's order.	Provides appropriate topical therapy to wound, placing wound in best environment for healing (Bryant and Nix, 2016b).
Evaluate patient's pain level at least every 2 hours and offer pain medication as indicated by assessment.	Provides patient with pain reduction/relief, allowing for greater mobility and comfort (Krasner, 2016).

^c Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Findings	Outcome Status
Perform daily total body skin and wound assessments.	Skin intact in area of nonblanching erythema.	Intact skin integrity in the area of nonblanching erythema. Intact skin over other pressure points.
	Decreased redness at the sacral area. Presence of reepithelialization in sacral area.	Injury in sacral region improving.
Palpate reddened area around sacrum.	Sacral area begins to show signs of reactive hyperemia and blanching following palpation; no new break in epidermis.	Intact skin over other pressure points. Sacral area improving. Reactive hyperemia with blanching occurring.

factors or contributing factors have on pressure injury development. Three major areas of nursing interventions for prevention of pressure injuries are (1) skin care and management of incontinence; (2) mechanical loading and support devices, which include proper positioning and the use of therapeutic surfaces; and (3) education (WOCN, 2016).

Topical Skin Care and Incontinence Management

When you clean the skin, avoid soap and hot water. Use cleaners with nonionic surfactants that are gentle to the skin (WOCN, 2016). Many types of products are available for skin care, and you need to match their use to the specific needs

of the patient. After you clean the skin and make sure that it is completely dry, apply moisturizer to keep the epidermis well lubricated but not oversaturated.

Make an effort to control, contain, or correct incontinence, perspiration, or wound drainage (see [Chapters 46 and 47](#)). Patients who have fecal incontinence and who are also receiving enteral tube feeding provide a management challenge. Often the feedings can result in diarrhea. When patients have an incontinent episode, gently clean the area, dry, and apply a thick layer of moisture barrier to the exposed areas. A moisture barrier protects the skin from excessive moisture and from bacteria found in the urine or stool ([McNichol et al., 2018](#)).

It is helpful to use the expertise of an advanced practice nurse with a focus on wound care or management of incontinence while caring for at-risk patients. Methods for controlling or containing incontinence vary. Bowel incontinence can sometimes be better managed with proper diet and medications. Urinary incontinence is treated with behavioral techniques, medication, and surgery. Behavioral techniques help patients learn ways to control their bladder and sphincter muscles.

Consider using absorbent pads and garments only after trying these measures. Although controversial, absorbent products such as absorptive underpads and garments are sometimes part of the treatment plan for an incontinent patient. Use only products that wick moisture away from the patient's skin ([WOCN, 2016](#)).

Positioning

Repositioning (turning) patients is a consistent element of evidence-based pressure injury prevention ([EPUAP, NPIAP, PPPIA, 2019a](#)). The twofold aim of repositioning should be to reduce or relieve pressure at the interface between bony prominence and support surface (bed or chair) and to limit the amount of time the tissue is exposed to pressure ([Maklebust and Magnan, 2016](#)). Elevating the head of the bed to 30 degrees or less decreases the chance of pressure injury development from **shearing forces** ([WOCN, 2016](#)). Change the immobilized patient's position according to tissue tolerance, level of activity and mobility, general medical condition, overall treatment objectives, skin condition, and comfort ([EPUAP, NPIAP, PPPIA, 2019a](#)). A standard turning interval of 1.5 to 2 hours does not always prevent pressure injury development; repositioning intervals are based on patient assessment. Some patients may need more frequent position changes, while other patients can tolerate every-2-hour position changes without tissue injury. When repositioning, use positioning devices to protect bony prominences ([WOCN, 2016](#)). The WOCN guidelines (2016) recommend a 30-degree lateral position ([Fig. 48.15](#)), which should prevent positioning directly over the bony prominence. To prevent shear and friction injuries, use a transfer device to lift rather than drag the patient when changing positions (see [Chapter 39](#)).

FIG. 48.15 Thirty-degree lateral position at which pressure points are avoided. Adapted from Bryant RA, Nix DP, editors: *Acute and chronic wounds: current management concepts*, ed 5, St Louis, 2016, Elsevier.

Building Competency in Evidence-Based Practice

The nurses on a neurology unit are concerned about patients who develop skin breakdown after recovery from a stroke. The nurses would like to implement a new evidence-based positioning protocol using safe patient handling with the goal of preventing pressure injury development. What is the nurses' PICOT question, and what topics should the nurses include in the evidence-based literature review?

For patients at risk for skin breakdown who are able to sit in a chair, limit the amount of time they sit to 2 hours or less at any given time. In the sitting position the pressure on the ischial tuberosities is greater than in the supine position. In addition, teach the patient to shift weight every 15 minutes while sitting (WOCN, 2016). Shifting weight provides short-term relief on the ischial tuberosities. Also have him or her sit on foam, gel, or an air cushion to redistribute weight away from the ischial areas. Rigid and donut-shaped cushions are contraindicated because they reduce blood supply to the area, resulting in wider areas of ischemia (WOCN, 2016).

After repositioning the patient, reassess the skin. Remember to use caution when evaluating early signs of tissue ischemia in darkly pigmented skin. For

patients with light-toned skin, observe for **reactive hyperemia** and blanching. Never massage reddened areas. Massaging reddened areas increases the breakdown of the capillaries in the underlying tissues and leads to the risk of tissue injury and pressure injury formation ([WOCN, 2016](#)).

Support Surfaces (Therapeutic Beds and Mattresses)

Support surfaces are “specialized devices for pressure redistribution designed for management of tissue loads, microclimate, and/or other therapeutic functions (i.e., any mattress, integrated bed system, mattress replacement, overlay, seat cushion, or seat cushion overlay)” ([EPUAP, NPIAP, PPIA, 2019a](#)). Support surfaces redistribute tissue loads by immersion (depth of penetration or sinking into the support surface by the patient’s body) and envelopment (deform around the body), thus evenly distributing pressure across the entire body surface ([Jordan and Phipps, 2019](#); [Maklebust and Magnan, 2016](#)). Support surfaces reduce the hazards of immobility to the skin and musculoskeletal system. However, none eliminates the need for meticulous skin assessment and skin care. No single device completely eliminates the effects of pressure on the skin.

When selecting support surfaces, consider a patient’s unique needs. Knowledge about support-surface characteristics ([Table 48.8](#)) helps you in clinical decision making. In selecting a support surface, know the patient’s risks and the purpose for the support surface; a flow chart is often helpful. If your agency has a wound care clinical nurse specialist, consult with him or her on choice of support surface. Teach patients and families the reason for and proper use of the devices ([Box 48.7](#)). Some common errors with support surfaces are placing the wrong side of the support surface toward the patient, not plugging powered support surfaces into the electrical source, not turning on the power source for powered support surfaces, failing to place a hand between the metal bedframe and the mattress to determine whether the patient sinks to the point of touching the bedframe for some support surfaces, using several layers of sheets and pads between the patient and the surface, and improperly inflating some support surfaces. When used correctly, these support surfaces help redistribute pressure to the skin of patients who are at risk for or have skin breakdown.

TABLE 48.8**Support Surfaces**

Category and Mechanism of Action	Indications for Use	Advantages	Disadvantages
Support Surfaces and Overlays			
Foam Overlay (Available as an Overlay or in a Full Mattress)			
Reduces pressure; the cover (top) can reduce friction and shear. Base height of 7.5-10 cm (3-4 inches); see manufacturer guidelines regarding amount of body weight supported	Use for moderate- to high-risk patients	Onetime charge No setup fee Cannot be punctured Available in various sizes (e.g., bed, chair, operating room table) Little maintenance Does not need electricity	Elevated body temperature Hot and may trap moisture Limited life span Plastic protective sheet needed for incontinent patients or patients with draining wounds Not indicated for those with existing stage 3 or 4 pressure injuries
Water Overlay (Available as an Overlay or in a Full Mattress)			
Redistributes pressure and pressure points because surface provides flotation by redistributing patient's weight evenly over entire support surface	Use for high-risk patients	Readily available Some control over motion sensations Easy to clean	Easily punctured Heavy Fluid motion may make procedures (e.g., dressing changes, CPR) difficult Maintenance needed to prevent microorganism growth Patient transfers out of bed are difficult. Difficult to raise and lower head of bed
Gel Overlay			
Redistributes pressure because surface provides flotation by redistributing patient's weight evenly over entire support surface	Use for moderate- to high-risk patients Use for patients who are wheelchair dependent	Low maintenance Easy to clean Multiple-patient use Impermeable to needle punctures	Heavy Expensive Lacks airflow for moisture control Variable friction control
Nonpowered Air-Filled Overlay			
Redistributes pressure by lowering mean interface pressure between patient's tissue and overlay	Use for moderate- to high-risk patients Use for patients who can reposition themselves	Easy to clean Multiple-patient use Low maintenance Potential repair of some air-filled products Durable	Damaged by punctures from needles and sharps Requires routine monitoring to determine adequate inflation pressure Patient transfers out of bed can be difficult
Low-Air-Loss Overlay (Available as an Overlay or in a Full Mattress)			
Maintains constant and slight air movement against patient's skin; redistributes pressure, assists in managing the heat and humidity (microclimate) of the skin	Use for moderate- to high-risk patients	Easy to clean Maintains constant inflation Deflates to facilitate transfer and CPR Moisture control Fabric covering overlay is air permeable, bacteria impermeable, and waterproof Reduces shear and friction Setup provided by manufacturer	Damaged by needles and sharps Can be noisy Requires electricity, some are available with short backup battery In home may need to purchase backup generator in case of loss of electrical power
Specialty Beds			

Category and Mechanism of Action	Indications for Use	Advantages	Disadvantages
Air-Fluidized Bed			
Bedframe contains silicone-coated beads and provides pressure redistribution by the fluidlike medium that is created by forcing air through beads, resulting in immersion and envelopment of the patient.	Use for high-risk patients Use for patients with stage 3 or 4 pressure injuries or burns	Less frequent turning or repositioning Improved patient comfort Becomes firm for CPR or other	Continuous circulation of warm, dry air may increase patient risk for dehydration Possible increase in room temperature Patient may experience

		treatments when device is turned "off" Reduces shear, friction, and edema to site May facilitate management of copious wound drainage or incontinence Setup provided by manufacturer	disorientation Patient transfer difficult Heavy Expensive May not be wide enough for use with obese patients or patients with contractures Patient cannot lie prone because of risk of suffocation
Low-Air-Loss Bed			
Bedframe with series of connected air-filled pillows. The flow of air controls the amount of pressure in each pillow and assists in managing the heat and humidity (microclimate) of the patient's skin. Redistributes pressure.	Use for patients who need pressure redistribution, those who cannot be repositioned frequently, or those who have skin breakdown on more than one surface Contraindicated in patients with unstable spinal column	Can raise and lower head and foot of bed Easy transfer in and out of bed Setup provided by manufacturer	Portable motor can be noisy Bed surface material slippery; patients can easily slide down mattress or out of bed when being transferred
Kinetic Therapy			
Provides continuous passive motion to promote mobilization of pulmonary secretions and low air loss and provides pressure redistribution	Used primarily to facilitate pulmonary hygiene in patients with acute respiratory conditions Should not be used when the patient is hemodynamically unstable	Reduces pulmonary complications associated with restricted mobility	Does not reduce shear or moisture Cannot be used with cervical or skeletal traction Possible motion sickness initially

CPR, Cardiopulmonary resuscitation.

Laurel, NJ, 2016, Author.

Box 48.7 PATIENT TEACHING Pressure-Redistribution

Surfaces

Objective

- Patient and family caregiver will describe understanding of the purposes and basic operations of the pressure-redistribution surface.

Teaching Strategies

- Explain the reasons for the pressure-redistribution surface.

- Explain the need to maintain proper body mechanics while using the pressure-redistribution surface. Demonstrate technique.
- Discuss possible patient sensations associated with the device.
- Instruct that minimal layers of linens should be placed over the pressure-redistribution surface.
- Educate in the use and care of the pressure-redistribution surface (based on manufacturer guidelines).
- Explain common errors in the use of support surfaces.
- Explain additional pressure-redistribution measures (e.g., safe patient handling during turning, avoidance of friction, 30-degree lateral position (WOCN, 2016)).

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Now that we have discussed the use of the pressure-redistribution surface, explain to me the purpose for using the device.
- Describe to me the possible sensations that you might experience while using the support surface.
- Show me how you will correctly position yourself on the pressure-redistribution surface.

Acute Care

Management of Pressure Injuries

Treatment of patients with pressure injuries requires a holistic approach that uses interprofessional expertise (WOCN, 2016). In addition to the nurse, the health care provider, wound-care nurse specialist, physical therapist, occupational therapist, nutritionist, and pharmacist are involved. Aspects of pressure injury treatment include local care of the wound and supportive measures such as adequate nutrients and redistribution of pressure (see Skill 48.2).

Before treating a pressure injury, reassess the wound for location, stage, size, tissue type and amount, exudate, and surrounding skin condition (see Skill 48.1) (Nix, 2016). Acute wounds require close monitoring (every 4-8 hours; check agency policy). Chronic wound assessment occurs less frequently. Depending on the topical management system, evaluate the wound with every dressing change, usually not more than once a day.

The use and documentation of a systematic approach to monitor progress of an actual pressure injury leads to better decision making and optimal outcomes

(Nix, 2016). Several healing and documentation tools are available to document wound assessments over time. Using a tool helps link assessment to outcomes so that an evaluation of the plan of care follows objective criteria (Nix, 2016). For example, the Bates-Jensen Wound Assessment Tool (BWAT) (Bates-Jensen, 2016) addresses 15 wound characteristics. You score individual items and calculate the sum total, providing an overall indication of wound status. The scoring helps to evaluate whether the goals of the wound management are effective.

Wound Management

Maintenance of a physiological local wound environment is the goal of effective wound management (Bryant and Nix, 2016b). To maintain a healthy wound environment, you need to address the following objectives: prevent and manage infection, clean the wound, remove nonviable tissue, maintain the wound in a moist environment, eliminate dead space, control odor, eliminate or minimize pain, and protect the wound and periwound skin (Ramundo, 2016).

A wound does not move through the phases of healing if infected. Preventing wound infection includes cleaning and removing nonviable tissue. Clean pressure injuries *only with noncytotoxic wound cleaners* such as normal saline or commercial wound cleaners. Noncytotoxic cleaners do not damage or kill fibroblasts and healing tissue (Bryant and Nix, 2016b). Some commonly used cytotoxic solutions are Dakin's solution (sodium hypochlorite solution), acetic acid, and povidone-iodine. These are not to be used in clean, granulating wounds.

Irrigation is a common method of delivering a wound-cleansing solution to the wound. Wound irrigation cleans and debrides necrotic tissue with pressure that can remove debris from the wound bed without damaging healthy tissue (Ramundo, 2016). One method to ensure an irrigation pressure within the correct range is to use a 19-gauge angiocatheter and a 35-mL syringe, which delivers saline to a pressure injury at 8 psi (Fig. 48.16).

FIG. 48.16 Wound irrigation.

Debridement is the removal of nonviable, necrotic tissue. Removal of necrotic tissue is necessary to rid the wound of a source of infection, enable visualization of the wound bed, and provide a clean base necessary for healing.

The method of debridement depends on which is most appropriate for a patient's condition and goals of care (WOCN, 2016). It is important to remember that during the debridement process some normal wound observations include an increase in wound exudate, odor, and size. You need to assess and prevent or effectively manage pain that occurs with debridement (WOCN, 2016). Plan to administer an ordered analgesic 30 minutes before debridement.

Methods of debridement include mechanical, autolytic, chemical, and sharp/surgical. Autolytic debridement is the removal of dead tissue via lysis of necrotic tissue by the white blood cells and natural enzymes of the body (Ramundo, 2016). You accomplish this by using dressings that support moisture at the wound surface. If the wound base is dry, use a dressing that adds moisture; if there is excessive exudate, use a dressing that absorbs the excessive moisture while maintaining moisture at the wound bed. Some examples of these dressings are transparent film and hydrocolloid dressings.

You can accomplish chemical debridement with the use of a topical enzyme preparation, Dakin's solution, or sterile maggots. Topical enzymes induce changes in the substrate, resulting in the breakdown of necrotic tissue (Ramundo, 2016). Depending on the type of enzyme used, the preparation

either digests or dissolves the tissue. These preparations require a health care provider's order. Dakin's solution breaks down and loosens dead tissue in a wound. Apply the solution to gauze and apply to the wound. Sterile maggots are used in a wound because it is thought that they ingest the dead tissue.

Surgical debridement is the removal of devitalized tissue with a scalpel, scissors, or other sharp instrument. Physicians and, in some states, trained advanced practice nurses perform surgical debridement of an injury or wound. Nurses should check the Nurse Practice Act for their state to see whether surgical debridement is a nursing function. It is the quickest method of debridement. It is usually indicated when the patient has signs of cellulitis or sepsis. Other methods of mechanical debridement are wound irrigation (high-pressure irrigation and pulsatile high-pressure lavage) and whirlpool treatments (Ramundo, 2016).

A moist environment supports the movement of epithelial cells and facilitates wound closure. A wound that has excessive exudate (drainage) provides an environment that supports bacterial growth, macerates the periwound skin, and slows the healing process. If excessive wound exudate is present, evaluate the volume, consistency, and odor of the drainage to determine whether an infection is present.

Remember, the wound will not heal unless the contributory factors are controlled or eliminated. Therefore it is critically important for you to address the causative factors (e.g., shear, friction, pressure, and moisture), or it is unlikely that the wound will heal despite topical therapy (Bryant and Nix, 2016b).

The treatment plan needs to be altered as a wound heals. For example, a transparent film dressing is used initially to autolytically debride (liquefy the tissue using body moisture) a necrotic wound. Once the wound is cleaned of necrotic tissue, discontinue the transparent film dressing; and, on the basis of the wound base characteristics, choose a new dressing. A wound with excessive drainage requires a dressing with a high absorptive capacity. Continued reassessment is key to supporting the wound as it moves through the phases of wound healing.

Protection

Protecting a wound from further injury is a priority. A strategy to prevent surgical wound dehiscence is to place a folded thin blanket or pillow over an abdominal wound so that a patient can splint the area during coughing (see Chapter 50). Because coughing increases the intraabdominal pressure, the patient applies light but firm pressure over the wound when coughing to support the healing tissue. A patient may also wear an abdominal binder to make movement less uncomfortable and to provide support for the abdomen and surgical site. Teach the patient this technique and keep the splint within hand's reach.

Education

Education of the patient and family caregivers is an important nursing function (Bryant and Nix, 2016a). A variety of educational tools, including videos and written materials, are available for you to use when teaching patients and family caregivers how to prevent and treat pressure injuries and care for wounds. The US National Library of Medicine (2019) has an excellent website with information on the prevention of pressure injuries (<https://www.nlm.nih.gov/medlineplus/ency/patientinstructions/000147.htm>).

Understanding and assessing the experience of the patient and support person are also important dimensions in the treatment of people with wounds and pressure injuries (WOCN, 2016). Clinicians are only just now exploring through research the caregiver's perspective of the concerns and issues faced by frail older spouses caring for their loved ones with pressure injuries. Plan interventions to meet the identified psychosocial needs of patients and their support people (WOCN, 2016).

Nutritional Status

Nutritional support of a patient with a wound is based on the appreciation that nutrition is fundamental to normal cellular integrity and tissue repair (Stotts, 2016a). Early intervention is necessary to correct inadequate nutrition and support healing. Refer patients with pressure injuries to a registered dietitian for early intervention involving therapeutic diets or enteral or parenteral nutrition (see Chapter 45). Your patient will need 30 to 35 calories/kg of body weight if a pressure injury is present and he or she is assessed to be at risk for malnutrition. Increased caloric intake helps replace subcutaneous tissue. Patients will also receive vitamin and mineral supplements if suspected or known deficiencies exist. Vitamin C promotes collagen synthesis, capillary wall integrity, fibroblast function, and immunological function.

Patients with pressure injuries who are underweight or losing weight need enhanced protein supplementation (WOCN, 2016). A patient can lose as much as 50 g of protein per day from an open, high exudative pressure injury. Although the recommended intake of protein for adults is 0.8 g/kg/day, a higher intake up to 1.8 g/kg/day is necessary for healing. Increased protein intake helps rebuild epidermal tissue (EPUAP, NPIAP, PPIA, 2019a). Evaluation of weight, laboratory values, and skin parameters reflect changes in status and effects of nutritional interventions (Stotts, 2016a).

First Aid for Wounds

Use first-aid measures for wound protection and management in an emergency situation. Under stable conditions a variety of interventions ensure wound healing. When a patient suffers a traumatic wound, first-aid interventions

include stabilizing cardiopulmonary function (see [Chapter 41](#)), promoting hemostasis, cleaning the wound, and protecting it from further injury.

Hemostasis

After assessing the type and extent of a wound, control bleeding by applying direct pressure with a sterile or clean dressing such as a washcloth. After bleeding subsides, an adhesive bandage or gauze dressing taped over the laceration allows skin edges to close and a blood clot to form. If a dressing becomes saturated with blood, add another layer of dressing, continue to apply pressure, and elevate the affected part. Avoid further disruption of skin layers. Serious lacerations need to be sutured by a health care provider. Pressure dressings used during the first 24 to 48 hours after trauma help maintain hemostasis.

Normally allow a puncture wound to bleed to remove dirt and other contaminants such as saliva from a dog bite. When a penetrating object such as a knife blade is present, *do not remove the object*. The presence of the object provides pressure and controls some bleeding. Removal causes massive, uncontrolled bleeding. Except for skull injuries, apply pressure around the penetrating object but not on it, and transport the patient to an emergency department.

Cleaning

The process of cleaning a wound involves selecting an appropriate cleaning solution and using a mechanical means of delivering that solution without causing injury to the healing wound tissue ([WOCN, 2016](#)). Gently cleaning a wound removes contaminants that serve as sources of infection. However, vigorous cleaning using a method with too much mechanical force causes bleeding or further injury. For abrasions, minor lacerations, and small puncture wounds, first rinse the wound with normal saline and lightly cover the area with a dressing. When a laceration is bleeding profusely, only brush away surface contaminants and concentrate on hemostasis until the patient can be cared for in a clinic or hospital.

According to the [WOCN guidelines \(2016\)](#), normal saline is the preferred cleaning agent. It is physiologically neutral and does not harm tissue. Normal saline keeps the wound surface moist to promote the development and migration of epithelial tissue. Gentle cleansing with normal saline and application of moist saline dressings are commonly used for healing wounds.

Protection

Regardless of whether bleeding has stopped, protect a traumatic wound from further injury by applying sterile or clean dressings and immobilizing the body

part. A light dressing applied over minor wounds prevents entrance of microorganisms.

Dressings

The use of dressings requires an understanding of wound healing. A variety of dressing materials are available commercially. The correct dressing selection facilitates wound healing (Bryant and Nix, 2016b). The dressing type depends on the assessment of the wound and the phase of wound healing. When you identify the objectives for the wound care, the dressing choice becomes clear. A wound that requires infection management requires a different set of dressings than one requiring the removal of nonviable tissue.

The more extensive a wound, the larger the dressing required. For example, a bulky dressing applied with pressure minimizes movement of underlying tissues and helps immobilize the entire body part. A bandage or cloth wrapped around a penetrating object should immobilize it adequately.

Alternative dressings are available to cover and protect certain types of wounds such as large wounds, wounds with drainage tubes or suction catheters in the wound, and wounds that need frequent changing because of excessive drainage. In the home setting a clean towel or diaper is often the best secondary dressing. Pouches or special wound collection systems cover wounds with excessive drainage and collect the drainage. Some of the collection systems have a plastic window on the front of the wound pouch, allowing you to change the packing without removing the pouch from the skin.

Many surgical wounds no longer have dressings (see Chapter 50). However, when a surgical wound has a dressing, its purpose is to promote wound healing by primary intention. Thus it is common to remove surgical dressings as soon as drainage stops. In contrast, when dressing a wound healing by secondary intention, the dressing material becomes a means for providing moisture to the wound or helping in debridement.

Purposes of Dressings

A dressing serves several purposes:

- Protects a wound from microorganism contamination
- Aids in hemostasis
- Promotes healing by absorbing drainage and debriding a wound
- Supports or splints a wound site
- Promotes thermal insulation of a wound surface
- Provides a moist environment

When the skin is broken, a dressing helps reduce exposure to microorganisms. However, when drainage is minimal, the healing process

forms a natural fibrin seal that eliminates the need for a dressing. Wounds with extensive tissue loss always need a dressing.

Pressure dressings promote hemostasis. Applied with elastic bandages, a pressure dressing exerts localized downward pressure over an actual or potential bleeding site. It eliminates dead space in underlying tissues so that wound healing progresses normally. Check pressure dressings to be sure that they do not interfere with circulation to a body part. Assess skin color, pulses in distal extremities, the patient's comfort, and changes in sensation. Pressure dressings are not removed routinely.

The functions of a dressing on a healing wound are to provide protection, deliver medication, and absorb drainage. Gauze dressings come in various types, including gauze sponges, used to pack wounds with depth and drainage; gauze placed over a shallow healing wound as a topper dressing; or gauze placed over a wound to wick the wound drainage. Gauze dressings are available in several sizes, frequently 2 × 2-inch or 4 × 4-inch squares. A problem occurs if wound drainage dries, causing the dressing to stick to the suture line. Improperly removing a dressing disrupts the healing epidermal surface. If a gauze dressing sticks to a surgical incision, lightly moisten it with saline solution before removal. This saturates the dressing and loosens it from the incisional area, thus preventing trauma to the incisional area during removal.

The dressing technique varies, depending on the goal of the treatment plan for a wound. For example, if the goal is to maintain a moist environment to promote wound healing, it is important to not let the saline-moistened gauze dressing become dry and stick to the wound. This is in direct contrast to the dressing technique that you use if the goal of care is to mechanically debride the wound using a saline moist-to-dry dressing. When wounds such as a necrotic wound require debriding, a moist-to-dry dressing technique can be considered. You place the moist dressing (contact dressing) over the wound bed, cover with a clean gauze, and allow the contact layer to dry. In this case the contact dressing is allowed to dry so that it sticks to underlying tissue and debrides the wound during removal. This type of debridement is nonselective and can remove viable tissue; it is recommended for debridement in a necrotic wound (Ramundo, 2016).

Dressings applied to a draining wound require frequent changing to prevent microorganism growth and skin breakdown. Bacteria grow readily in the dark, warm, moist environment under a dressing. The periwound area can become macerated and irritated. Minimize periwound skin breakdown by keeping the skin clean and dry and reducing the use of tape. The absorbent dressing inner layer serves as a reservoir for secretions. The wicking action of woven gauze dressings pulls excess drainage into the dressing and away from the wound. The final outer layer of the dressing (usually an ABD pad that has an outer layer that prevents strike-through) helps prevent bacteria and other external

contaminants from reaching the wound surface. Apply adhesives to this layer to secure the dressings.

A dressing needs to support a moist wound environment if the wound is healing by secondary intention. A moist wound base facilitates the movement of epithelialization, thus allowing the wound to resurface as quickly as possible.

Types of Dressings

Dressings vary by type of material and mode of application (moist or dry) (see Skill 48.3). They need to be easy to apply, comfortable, and made of materials that promote wound healing. The [WOCN guidelines \(2016\)](#) are helpful when selecting dressings based on the goal of wound treatment ([Box 48.8](#)). To avoid causing damage to the periwound skin, it is important that the dressing technique that you use to treat pressure injuries and other wounds is not excessively moist ([Box 48.9](#)).

Box 48.8 Dressing Considerations

- Clean the wound and periwound area at each dressing change, minimizing trauma to the wound (WOCN, 2016).
- Use a dressing that continuously provides a moist environment.
- Perform wound care using topical dressings as determined by a thorough assessment.
- No specific studies have proven an optimal dressing type for pressure injuries (WOCN, 2016).
- Choose a dressing that keeps the periwound skin dry while keeping the injury bed moist.
- Choose a dressing that controls exudate but does not desiccate the injury bed.
- The type of dressing may change over time as the pressure injury heals or deteriorates. The wound should be monitored at every dressing change and regularly assessed to determine whether modifications in the dressing type are needed (WOCN, 2016).
- Consider caregiver time, ease of use, availability, and cost when selecting a dressing.

Box 48.9 Evidence-Based Practice Moisture-Associated Skin Damage

PICOT Question: In hospitalized patients, which interventions prevent or reduce the risk of medical device–related pressure injuries?

Evidence Summary

Medical device–related (MDR) pressure injuries are becoming more common (Kayser et al., 2018; Black and Kalowes, 2016). In 2016, the NPUAP defined a medical device–related pressure injury (MDRPI) as arising “from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device” (EPUAP, NPIAP, PPIA, 2019a). Critically ill patients and neonates are particularly vulnerable to MDR pressure injuries (Maklebust and Magnan, 2016). Because MDRPIs form faster than non-MDRPIs, timely proactive assessment and prevention measures are critical. Most MDRPIs occur at the face and head region, and the ears specifically (Kayser et al., 2018). The most common devices linked with MDRPIs are oxygen tubing and masks. Devices include nasal cannulas, cervical collars, Foley catheter and bedside collection tubing, braces, endotracheal tubes, and pulse oximetry devices (see also Table 48.5). It is important to be aware of devices that are used for patient care that could damage edematous tissue and to plan care to cushion or redistribute pressure away from susceptible skin.

Application to Nursing Practice

- Choose the correct size of medical device(s) to fit the individual, especially endotracheal tubes and oxygen equipment.
- Cushion and protect the skin with dressings in high-risk areas (e.g., nasal bridge).
- Remove or move removable devices to assess skin at least daily.
- Avoid placement of device(s) over sites of prior or existing pressure injury.
- Assess skin underneath device for edema, risks for potential for skin breakdown, and early signs of skin breakdown
- Assessment under, around, and at the edges of medical devices is critical for prevention and early intervention of these injuries. It is important that intervention such as foam padding be considered to reduce or eliminate the pressure injury (Black and Kalowes, 2016).
- Confirm that devices are not placed directly under an individual who is bedridden or immobile.

Most pressure injuries require dressings. The type of dressing is usually based on the stage of the pressure injury, the type of tissue in the wound, and

the function of the dressing (Table 48.9). Before placing a dressing on a pressure injury, it is important, based on the nursing diagnosis, to understand the goal of the treatment, the mechanism of action of the dressing, and principles of wound care.

TABLE 48.9

Dressings By Pressure Injury Stage

Pressure Injury Stage	Pressure Injury Status	Dressing	Comments ^a	Expected Change	Adjuvants
1	Intact	None Transparent dressing Hydrocolloid	Allows visual assessment. Protects from shear. Do not use transparent dressing in presence of excessive moisture. Hydrocolloid does not allow visual assessment.	Resolves slowly without epidermal loss over 7 to 14 days	Turning schedule. Support hydration. Nutritional support. Use pressure-redistribution bed or chair cushion.
2	Clean	Composite film Hydrocolloid Hydrogel covered with foam or gauze dressing.	Limits shear. Change when seal of dressing breaks; maximal wear time 7 days. Provides moist environment.	Heals through re-epithelialization	See previous stage. Manage incontinence.
3	Clean	Hydrocolloid Hydrogel covered with foam dressing	Change when seal of dressing breaks; maximum wear time 7 days. Apply over wound to protect and absorb moisture.	Heals through granulation and reepithelialization	See previous stages. Evaluate pressure-redistribution needs.
		Calcium alginate	Use when there is significant exudate. Cover with secondary dressing.		
		Gauze	Use with normal saline or other prescribed solution. Wring out excess solution; unfold to make contact with wound. Cover with dry dressing tape in place.		
4	Clean	Hydrogel covered with foam dressing	See stage 3: clean.	Heals through granulation, scar tissue development, and reepithelialization	Surgical consultation may be necessary for closure. See stages 1, 2, and 3.
		Calcium alginate	Used with significant exudate; must cover with secondary dressing		
		Gauze	See stage 3: clean.		
Unstageable	Wound covered with eschar	Adherent film	Facilitates softening of eschar.	Eschar lifts at edges as healing progresses	See previous stages. Surgical consultation may be considered for debridement.
		Gauze plus ordered solution	Delivers solution and may soften the eschar.		May be considered for slow debridement.
		Enzymes	Breaks down eschar, providing debridement.	Eschar loosens over time.	
		None	If eschar is dry and intact and debridement is not part of the plan of care, no dressing is used, allowing eschar to act as physiological cover.		

^a As with *all* occlusive dressings, wounds should not be clinically infected.

Gauze sponges are the oldest and most common dressing. They are absorbent and are especially useful in wounds to wick away wound exudate. Gauze is available in different textures and various lengths and sizes; the 4 × 4 is the most common size. Gauze can be saturated with solutions and used to clean and pack a wound. When used to pack a wound, the gauze is saturated

with the solution (usually normal saline), wrung out (leaving the gauze only moist), unfolded, and lightly packed into the wound. Unfolding the dressing allows easy wicking action. The purpose of this type of dressing is to provide moisture to the wound yet to allow wound drainage to be wicked into the dry cover gauze pad.

Another type of dressing is a self-adhesive, transparent film that traps moisture over a wound, providing a moist environment to encourage epithelial cell growth (Fig. 48.17). A transparent dressing adheres to undamaged skin, does not need a secondary dressing, and permits viewing of the wound. It is ideal for small superficial wounds such as a stage 1 pressure injury or a partial-thickness wound. Use a film dressing as a secondary dressing and for autolytic debridement of small wounds. It serves as a barrier to external fluids and bacteria but still allows the wound surface to “breathe” because oxygen passes through the transparent dressing (McNichol et al., 2018). This dressing promotes a moist environment to encourage epithelial cell growth. It adheres to undamaged skin, does not need a secondary dressing, and permits viewing of the wound.

FIG. 48.17 Transparent film dressing.

Hydrocolloid dressings are dressings with complex formulations of colloids and adhesive components. They are adhesive and occlusive. The wound contact layer of this dressing forms a gel as wound exudate is absorbed and maintains a moist healing environment. Hydrocolloids support healing in

clean granulating wounds and autolytically debride necrotic wounds; they are available in a variety of sizes and shapes. This type of dressing absorbs drainage through the use of exudate absorbers in the dressing; maintains wound moisture; slowly liquefies necrotic debris; and can be left in place for 3 to 5 days. In addition, hydrocolloid dressings are impermeable to bacteria and other contaminants, act as a preventive dressing for high-risk friction areas, and are self-adhesive and mold to the wound.

The hydrocolloid dressing is useful on shallow-to-moderately deep dermal injuries. Hydrocolloid dressings cannot absorb drainage from heavily draining wounds, and some are contraindicated for use in full-thickness and infected wounds. Most hydrocolloids leave a residue in the wound bed that is easy to confuse with purulent drainage.

Hydrogel dressings are gauze or sheet dressings impregnated with water or glycerin-based amorphous gel. This type of dressing hydrates wounds and absorbs small amounts of exudate. Hydrogel dressings are indicated for use in partial-thickness and full-thickness wounds, deep wounds with some exudate, necrotic wounds, burns, and radiation-damaged skin. They debride necrotic tissue by softening the necrotic area. They can be very useful in painful wounds because they are very soothing to a patient and do not adhere to the wound bed and thus cause little pain during removal. A disadvantage is that some hydrogels require a secondary dressing and you must take care to prevent periwound maceration. Hydrogels also come in a tube; thus you are able to squirt the gel directly into the wound base.

Many other types of dressings are available. Foam and alginate dressings are for wounds with large amounts of exudate and those that need packing. Foam dressings are also used around drainage tubes to absorb drainage. Calcium alginate dressings are manufactured from seaweed and come in sheet and rope form. The alginate forms a soft gel when in contact with wound fluid. These highly absorbent dressings are for wounds with an excessive amount of drainage and do not cause trauma when removed from the wound. *Do not use these in dry wounds, and they require a secondary dressing.* Several manufacturers produce composite dressings, which combine two different dressing types into one dressing. Research is ongoing regarding which type of dressing is best for which type of wound.

Changing Dressings

A health care provider's order for wound care indicates the dressing type, the frequency of changing, and any solutions or ointments to be applied to the wound. An order to "reinforce dressing prn" (add dressings without removing the original one) is common right after surgery, when the health care provider does not want accidental disruption of the suture line or bleeding. The medical or operating room record usually indicates whether drains are present and from which body cavity they drain.

Always know the type of wound and dressing, the presence of underlying drains or tubing, and the type of supplies needed for wound care. Poor preparation causes a break in aseptic technique (see [Chapter 28](#)) or accidental pulling of wound tissue or dislodgement of a drain. Your judgment in modifying a dressing-change procedure is important during wound care, particularly if the character of a wound changes. Notifying the health care provider of any change is essential.

Sometimes (e.g., with chronic nonsurgical wounds) you will use clean medical aseptic technique for a dressing change. The clean technique refers to the fact that the nurse maintains medical versus sterile asepsis (see [Chapter 28](#)). You will wear clean gloves, but the dressing materials are in sterile packages and are carefully placed over the wound. Deep wounds that require irrigation are usually irrigated with a sterile solution. A complete patient and wound history is essential in determining when a clean dressing technique is appropriate. For example, chronic pressure injury wounds use clean technique. On the other hand, a fresh surgical wound may require sterile technique, which requires the use of sterile gloves to prevent the introduction of microorganisms into a healing wound. After the first dressing change, describe the location of drains and the type of dressing materials and solutions to use in the patient's care plan.

Often it is necessary to teach patients how to change dressings in preparation for home care. In this situation, demonstrate dressing changes to a patient or family caregiver, and provide an opportunity for practice. Usually wound healing has progressed to the point that risks of complications such as dehiscence or evisceration are minimal. A patient needs to be able to change a dressing independently or with help from a family caregiver before discharge. Contaminated dressings in the home should be disposed of in a manner consistent with local regulations. Skill 48.3 outlines the steps for changing dry and moist dressings.

Packing a Wound

The first step in packing a wound is to assess its size, depth, and shape. These characteristics are important in determining the size and type of dressing used to pack a wound. The dressing needs to be flexible and in contact with the entire wound surface. Make sure that the type of material used to pack the wound is appropriate. If gauze is the appropriate dressing material, saturate with the ordered solution, wring out, unfold, and lightly pack into the wound. The entire wound surface needs to be in contact with part of the moist gauze dressing (see Skill 48.3).

It is important to remember not to pack a wound too tightly. Overpacking causes pressure on the wound bed tissue. Pack the wound only until the packing material reaches the surface of the wound; there should never be so much packing material that it extends higher than the wound surface. Packing

that overlaps onto the wound edges causes maceration of the skin surrounding the wound.

One treatment modality for wounds is **negative-pressure wound therapy (NPWT)** or vacuum-assisted closure (one brand name is V.A.C.). NPWT is the application of subatmospheric (negative) pressure to a wound through suction to facilitate healing and collect wound fluid (Netsch et al., 2016). The **vacuum-assisted closure (V.A.C.)** is a device that helps in wound closure by applying localized negative pressure to draw the edges of a wound together (Fig. 48.18A-B). NPWT supports wound healing by reduction of edema and fluid removal, macro deformation and wound contraction, and micro deformation and mechanical stretch perfusion (see Skill 48.4). Secondary effects include angiogenesis, granulation tissue formation, and reduction in bacterial bioburden (Netsch et al., 2016) (Fig. 48.19). The V.A.C. Instill system allows intermittent instillation of fluids into a wound and liquefies infectious material and wound debris, especially in wounds not responding to traditional NPWT (Fernandez et al., 2019).

FIG. 48.18 A, Dehisced wound before wound V.A.C. therapy. B, Dehisced wound after wound V.A.C. therapy. V.A.C., Vacuum-assisted closure. Courtesy Kinetic Concepts [KCI], San Antonio, TX.

FIG. 48.19 V.A.C. system using negative pressure to remove fluid from area surrounding wound, reducing edema and improving circulation to area. V.A.C., Vacuum-assisted closure.
Courtesy Kinetic Concepts [KCI], San Antonio, TX.

NPWT treats acute and chronic wounds, and the schedule for changing NPWT dressings varies, depending on the type of wound and amount of drainage. Wear time for the dressing is anywhere from 24 hours to 5 days. As a wound heals, granulation tissue lines its surface. The wound has a stippled or granulated appearance. The surface area sometimes increases or decreases, depending on wound location and the amount of drainage removed by the NPWT system. NPWT also enhances the adherence of split-thickness skin grafts. It is placed over a graft intraoperatively, decreasing the ability of the graft to shift and evacuating fluids that build up under it (Netsch et al., 2016). An airtight seal must be maintained (Box 48.10).

Box 48.10 Negative-Pressure Wound Therapy:

Maintaining an Airtight Seal

To avoid loss of suction (negative pressure), the wound and dressing must stay sealed after therapy is initiated. Problem seal areas include wounds

around joints; near skin creases and folds; and near moisture such as diaphoresis, wound drainage, and urine or stool. The following points may help to maintain an airtight seal:

- Clip hair on skin around wound (check agency policy).
- Fill uneven skin surfaces with a skin-barrier product such as paste or strips.
- Make sure that periwound skin surface is dry.
- Cut transparent film to extend 2.5 to 5 cm (1 to 2 inches) beyond wound perimeter.
- Frame periwound area with liquid skin barrier, solid skin barrier, or hydrocolloid dressing.
- Cut transparent dressing to fit wound.
- Avoid wrinkles when applying transparent film.
- Identify any air leaks with a stethoscope and repair them with the transparent dressing.
- Use only one or two additional layers for large leaks. Multiple layers reduce moisture vapor transmission and cause maceration of wound.

Securing Dressings

Use tape, ties, or a secondary dressing to secure a dressing over a wound site. The choice of anchoring depends on the wound size and location, the presence of drainage, the frequency of dressing changes, and the patient's level of activity.

You will most often use strips of tape to secure dressings. Nonallergenic paper and silicone tapes minimize skin reactions. Common adhesive tape adheres well to the surface of the skin, whereas elastic adhesive tape compresses closely around pressure bandages and permits more movement of a body part. Skin sensitive to adhesive tape becomes severely inflamed and denuded and, in some cases, even sloughs when the tape is removed. It is important to assess the condition of the skin under tape at each dressing change.

Tape is available in various widths such as 1.3, 2.5, 5, and 7.5 cm (½, 1, 2, and 3 inches). Choose the size that secures a dressing sufficiently. For example, a

large abdominal wound dressing needs to remain secure over a large area despite frequent stress from movement, respiratory effort, and possibly abdominal distention. Strips of 7.5-cm (3-inch) adhesive stabilize such a large dressing, so it does not continually slip off. When applying tape, ensure that it adheres to several inches of skin on both sides of the dressing and that it is placed across the middle of the dressing. When securing a dressing, press the tape gently to the skin and the topper dressing. Never apply tape over irritated or broken skin. Protect irritated skin by using a solid skin barrier and applying the tape over the barrier.

To remove tape safely, loosen the ends and gently pull the outer end parallel with the skin surface toward the wound. Gently push the skin away from the wound as the tape is loosened and removed. Adhesive remover also loosens the tape from the skin. If tape covers an area of hair growth, a patient experiences less discomfort if you pull the tape in the direction of the hair growth.

To avoid repeated removal of tape from sensitive skin, secure dressings with pairs of reusable Montgomery ties ([Fig. 48.20](#)). Each section consists of a long strip; half contains an adhesive backing to apply to the skin, and the other half folds back and contains a cloth tie or a safety pin/rubber band combination that you fasten across a dressing and untie at dressing changes. A large, bulky dressing often requires two or more sets of Montgomery ties. Another method to protect the surrounding skin on wounds that need frequent dressing changes is to place strips of hydrocolloid dressings on either side of the wound edges, cover the wound with a dressing, and apply the tape to the dressing. To provide even support to a wound and immobilize a body part, apply elastic gauze, elastic stretch net, or binders over a dressing.

FIG. 48.20 Montgomery ties. **A**, Each tie is placed at side of dressing. **B**, Securing ties encloses dressing.

Comfort Measures

A wound is often painful, depending on the extent of tissue injury, and wound care often requires the use of well-timed analgesia before any wound procedure (Krasner, 2016). Administer analgesic medications 30 to 60 minutes before dressing changes, depending on the time of peak action of a drug. In addition, several techniques are useful in minimizing discomfort during wound care. Carefully removing tape, gently cleaning wound edges, and carefully manipulating dressings and drains minimize stress on sensitive tissues. Careful turning and positioning also reduce strain on a wound.

Cleaning Skin and Drain Sites

Although a moderate amount of wound exudate promotes epithelial cell growth, some health care providers order cleaning a wound or drain site if a dressing does not absorb drainage properly or if an open drain deposits drainage onto the skin. Wound cleaning requires good hand hygiene and aseptic techniques (see Chapter 28). You can use irrigation to remove debris from a wound.

REFLECT NOW

A patient has a draining wound and requires dressing changes every 4 hours. Think about what types of dressings are effective and how to secure the dressings without further injury to a patient's skin.

Basic Skin Cleaning

Clean surgical or traumatic wounds by applying noncytotoxic solutions with sterile gauze or by irrigation. The following three principles are important when cleaning an incision or the area surrounding a drain:

1. Clean in a direction from the least contaminated area, such as from a wound or incision to the surrounding skin (Fig. 48.21) or from an isolated drain site to the surrounding skin (Fig. 48.22).

FIG. 48.21 Methods for cleaning wound site.

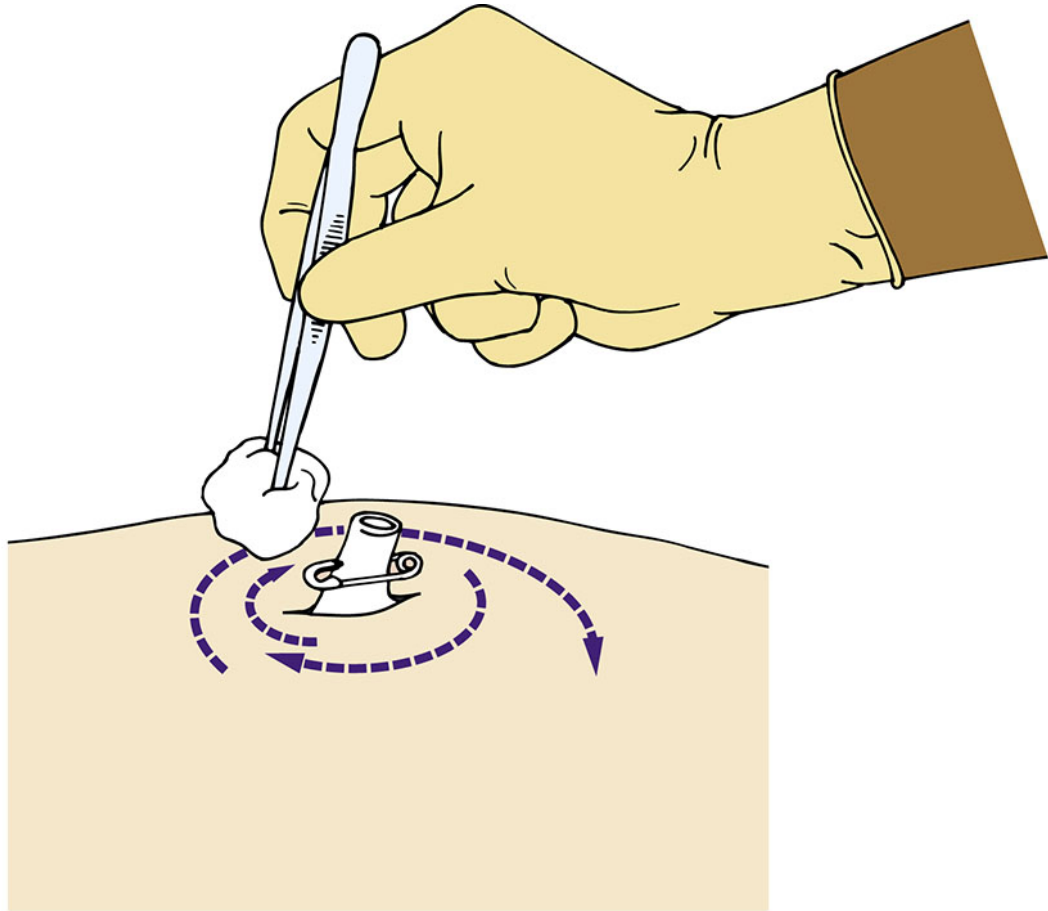

FIG. 48.22 Cleaning drain site.

2. Use gentle friction when applying solutions locally to the skin.
3. When irrigating, allow the solution to flow from the least to most contaminated area (see Skill 48.5).

After applying a solution to sterile gauze, clean away from the wound. Never use the same piece of gauze to clean across an incision or wound twice.

Drain sites are a source of contamination because moist drainage harbors microorganisms. If a wound has a dry incisional area and a moist drain site, cleaning moves from the incisional area toward the drain. Use two separate swabs or gauze pads, one to clean from the top of the incision toward the drain and one to clean from the bottom of the incision toward the drain. To clean the area of an isolated drain site, clean around the drain, moving in circular rotations outward from a point closest to the drain. In this situation the skin near the site is more contaminated than the site itself. To clean circular wounds, use the same technique as in cleaning around a drain.

Irrigation

Irrigation is a way of cleaning wounds. Use an irrigation syringe to flush the wound with a constant low-pressure flow of solution. The gentle washing action of the irrigation cleanses a wound of exudate and debris. Irrigation is particularly useful for open, deep wounds; wounds involving an inaccessible body part such as the ear canal; or when cleaning sensitive body parts such as the conjunctival lining of the eye.

Irrigation of an open wound requires sterile technique. Use a 35-mL syringe with a 19-gauge soft angiocatheter (Ramundo, 2016) to deliver the solution. This irrigation system has a safe pressure and does not damage healing wound tissue. It is important to never occlude a wound opening with a syringe because this results in the introduction of irrigating fluid into a closed space. The pressure of the fluid causes tissue damage and discomfort and possibly forces infection or debris into the wound bed. Always irrigate a wound with the syringe tip over but not in the drainage site. Make sure that fluid flows directly into the wound and not over a contaminated area before entering the wound (see Skill 48.5).

Skin Glue and Suture Care

A surgeon closes a wound by bringing the wound edges as close together as possible to reduce scar formation. Proper wound closure involves minimal trauma and tension to tissues with control of bleeding.

Skin glue is a clear gel or paste applied to the edges of clean small wounds to hold the edges of the wound together. It takes only a few minutes for the glue to set, and it usually peels off in 5 to 7 days (NHS, 2018). Patients will go home with the skin glue in place. Instruct them to avoid touching the glue for 24 hours, to try to keep the wound dry for the first 5 days, that showers are preferable to baths to avoid soaking the wound, to use a shower cap if the wound is on the head, and to pat (not rub) the wound dry if it gets wet (NHS, 2018). Skin glue is not used over joints, the hand, or the groin area. A systematic review of the use of glue compared with traditional sutures showed that medical glues appear to be a viable alternative to staples in select types of surgeries and often are associated with lower pain when compared to staples (CADTH, 2017).

Sutures are threads or metal used to sew body tissues together (Fig. 48.23). A patient's history of wound healing, the site of surgery, the tissues involved, and the purpose of the sutures determine the suture material used. For example, if a patient has had repeated surgery for an abdominal hernia, the health care provider can choose wire sutures to provide greater strength for wound closure. In contrast, a small laceration of the face calls for the use of very fine Dacron (polyester) sutures to minimize scar formation.

FIG. 48.23 Incision closed with metal staples.

Sutures are available in a variety of materials, including silk, steel, cotton, linen, wire, nylon, and Dacron. Sutures such as PDS, Vicryl, and Monocryl can be absorbed; others, such as nylon, silk and steel, are nonabsorbable and must be removed.

Sutures are placed within tissue layers in deep wounds and superficially for wound closure. Deep sutures are usually composed of an absorbable material that disappears over time. Sutures are foreign bodies and thus are capable of causing local inflammation. A surgeon tries to minimize tissue injury by using the finest suture possible and the smallest number necessary.

Policies vary within institutions as to who is able to remove sutures. If it is appropriate that the nurse remove them, a health care provider's order is required. An order for suture removal is not written until the health care provider believes that the wound has closed (usually in 7 days). Special scissors with curved cutting tips, scissors and pickups from a sterile suture removal kit, or special staple removers slide under the skin closures for suture removal. The health care provider usually specifies the number of sutures or staples to remove. If the suture line appears to be healing in certain locations better than in others, some health care providers choose to have only some sutures removed (e.g., every other one).

To remove staples, insert the tips of the staple remover under each wire staple. While slowly closing the ends of the staple remover together, squeeze

the center of the staple with the tips, freeing it from the skin, and gently lift up and out of the skin (Fig. 48.24).

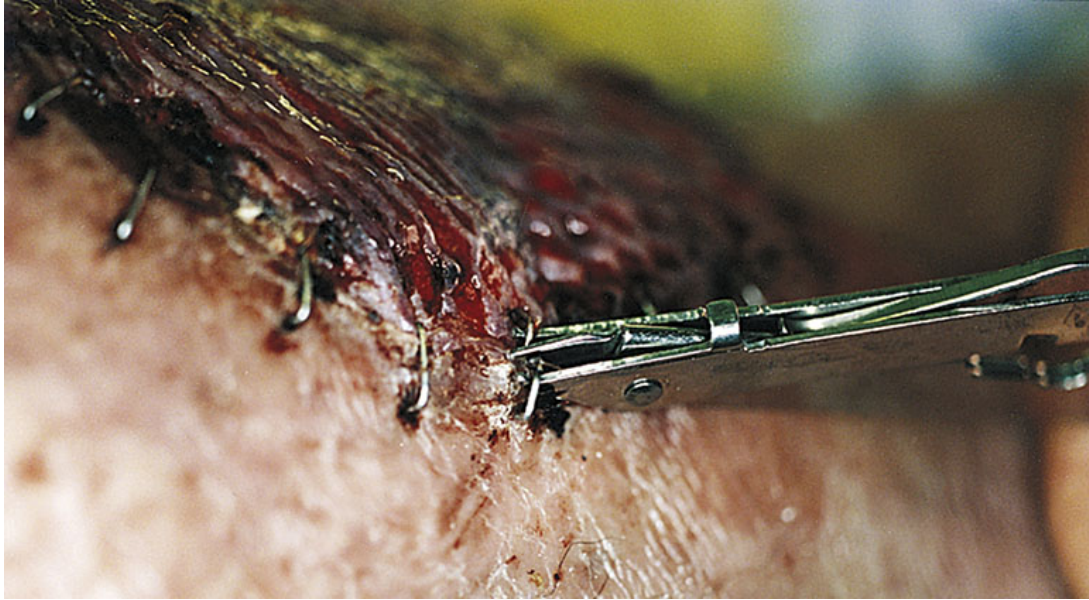

FIG. 48.24 Staple remover.

To remove sutures, first check the type of suturing used (Fig. 48.25). With intermittent suturing the surgeon ties each individual suture made in the skin. Continuous suturing, as the name implies, is a series of sutures with only two knots, one at the beginning and one at the end of the suture line. Retention sutures are placed more deeply than skin sutures, and nurses may or may not remove them, depending on agency policy. The manner in which the suture crosses and penetrates the skin determines the method for removal. *Never pull the visible part of a suture through underlying tissue.* Sutures on the surface of the skin harbor microorganisms and debris. The part of the suture beneath the skin is sterile. Pulling the contaminated part of the suture through tissues can lead to infection. Before taking out the sutures, cleanse the suture line with normal saline. Clip suture materials as close to the skin edge on one side as possible and pull the suture through from the other side (Fig. 48.26).

FIG. 48.25 Examples of suturing methods. **A**, Intermittent. **B**, Continuous. **C**, Blanket continuous. **D**, Retention.

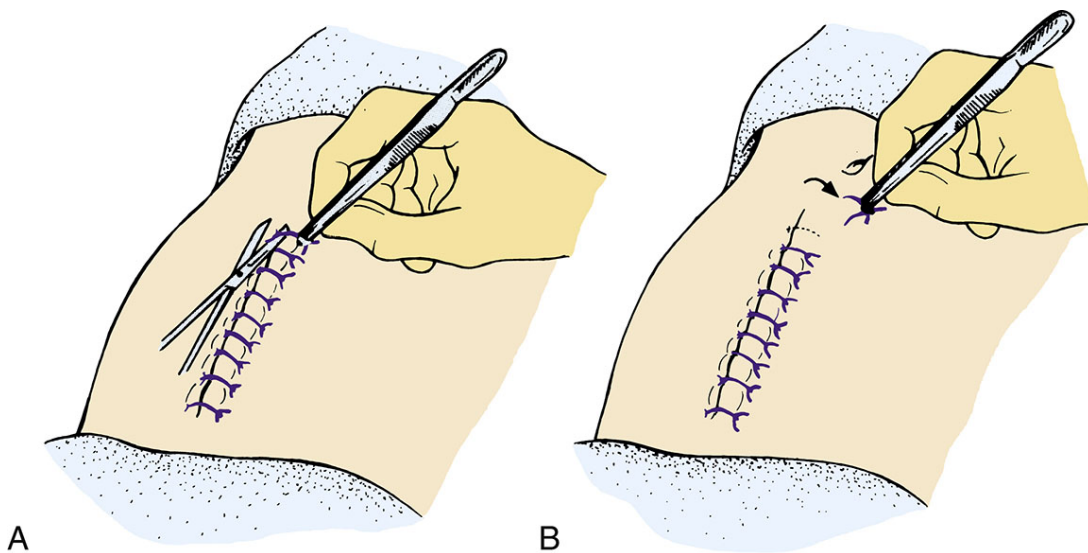

FIG. 48.26 Removal of intermittent suture. **A**, Cut suture as close to skin as possible, away from knot. **B**, Remove suture and never pull contaminated stitch through tissues.

Drainage Evacuation

When drainage interferes with healing, evacuation of the drainage is achieved by using either a drain alone or a drainage tube with continuous suction. You

may apply special skin barriers, including hydrocolloid dressings similar to those used with ostomies (see [Chapter 47](#)), around drain sites with significant drainage for skin protection. The skin barriers are soft material applied to the skin with adhesive. Drainage flows on the barrier but not directly on the skin. **Drainage evacuators** ([Fig. 48.27](#)) are convenient portable units that connect to tubular drains lying within a wound bed and exert a safe, constant low-pressure vacuum to remove and collect drainage. Ensure that suction is exerted and that connection points between the evacuator and tubing are intact. The evacuator collects drainage. Assess for volume and character every shift and as needed. When the evacuator fills, measure output by emptying the contents into a graduated cylinder, immediately reset the evacuator to apply suction, and record the output.

FIG. 48.27 Setting suction on drainage evacuator. 1, With drainage port open, raise level on diaphragm. 2, Push straight down on lever to lower diaphragm. 3, Closure of port prevents escape of air and creates vacuum pressure.

Bandages, Binders, and Slings

A simple gauze dressing is often not enough to immobilize or provide support to a wound and a larger dressing or bandage is required. Binders are bandages that are made of large pieces of material, usually elastic or cotton, to fit a

specific body part (Box 48.11). The most common type is an abdominal binder, which supports large abdominal incisions that are vulnerable to tension or stress as a patient moves or coughs (Fig. 48.28).

Box 48.11 Procedural Guidelines Applying a Binder

Delegation and Collaboration

The skill of applying a binder can be delegated to assistive personnel (AP). However, the nurse must first assess the condition of any incision, the skin, and patient's ability to breathe before binder application. The nurse directs the AP about:

- How to modify the skill, such as special wrapping or manner of securing the binder.
- Reporting patient's complaint of pain, numbness, tingling, or difficulty breathing after applying abdominal binder or any changes in patient's skin color or temperature.

Equipment

Clean gloves if wound drainage present; gauze bandage as needed; correct type and size of binder; closures for cloth binder

Steps

1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.
2. Review medical record for order for binder (check agency policy).
3. Observe patient who needs support of thorax or abdomen; observe ability to breathe deeply, cough effectively, and turn or move independently.
4. Perform hand hygiene; apply clean gloves as needed. Inspect skin for actual or potential alterations in integrity. Observe for irritation, abrasion, and skin surfaces that rub against one another.
5. Inspect any surgical dressing for intactness, presence of drainage, and coverage of incision. Change any soiled dressing before applying binder (using clean gloves).
6. Determine patient's level of comfort using scale of 0 to 10. When necessary, administer prescribed analgesic 30 minutes before dressing change.

7. Gather necessary data regarding size of patient and appropriate binder to use (see manufacturer guidelines) to ensure proper fit.
8. Assess patient's or family caregiver's knowledge, experience, and health literacy.
9. Close curtains or room door.
10. Perform hand hygiene and apply clean gloves (if likely to contact wound drainage).
11. Apply abdominal binder:
 - a. Position patient in supine position with head slightly elevated and knees slightly flexed.
 - b. Fanfold far side of binder toward midline of binder so that patient can roll over with minimal effort.
 - c. Help patient roll on side away from you toward raised side rail while firmly supporting abdominal incision and dressing with hands.
 - d. Place fanfolded ends of binder under patient.
 - e. Instruct patient or help him or her roll over folded binder. For overweight patients consider asking nurse colleague to help.
 - f. Unfold and stretch ends out smoothly on far side of bed. Then stretch out ends on near side of bed.
 - g. Instruct patient to roll back into supine position.
 - h. Adjust binder so supine patient is centered over binder, using symphysis pubis and costal margins as lower and upper landmarks.
 - i. If patient is very thin, pad iliac prominences with gauze bandage.
 - j. Close binder. Pull one end of binder over center of patient's abdomen. While maintaining tension on that end of binder, pull opposite end of binder over center and secure with Velcro closure tabs or metal fasteners. Provides continuous wound support and comfort.

CLINICAL DECISION: After binder is in place, assess patient's ability to deep breathe and cough effectively. When applied correctly, an abdominal binder over midline abdominal incisions should not affect the patient's pulmonary function.

12. Assess patient's comfort level and adjust binder as necessary. Ask patient to rate pain on scale of 0 to 10.
13. Remove and dispose of gloves and perform hand hygiene.
14. Help patient to a comfortable position.

15. Be sure nurse call system is in an accessible location within patient's reach.
16. Raise side rail (as appropriate), and lower bed to lowest position.
17. Remove binder and surgical dressing to assess skin and wound characteristics at least every 8 hours.
18. Evaluate patient's ability to ventilate properly, including deep breathing and coughing, every 4 hours to determine presence of impaired ventilation and potential pulmonary complications.
19. Document baseline and postbinder condition of skin, circulation, integrity of underlying dressing, and patient's comfort level in nurses' notes in the electronic health record (EHR) or chart. Also record type of bandage applied.
20. Report any complications (e.g., pain, skin irritation, impaired ventilation). Report reduced ventilation (e.g., pulse oximetry, pulmonary function tests), change in incision, or change in drainage to health care provider immediately.

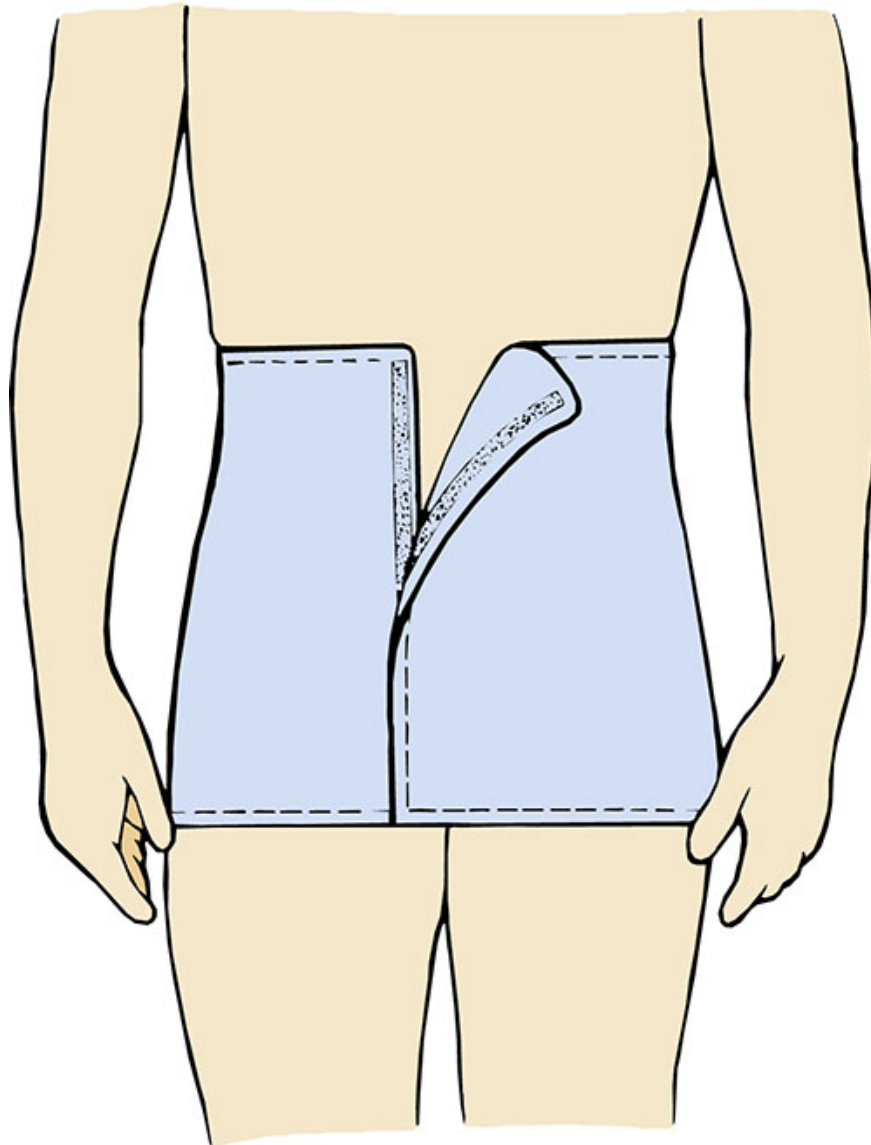

FIG. 48.28 Securing abdominal binder with Velcro.

A systematic review of studies examining the efficacy of abdominal binders found that they reduce postoperative psychological distress, but their effect on postoperative pain after abdominal laparotomy and seroma formation after ventral hernia repair was unclear (Rothman et al., 2014). A more recent study involving patients who underwent major abdominal surgery found that an abdominal binder increased patient mobility soon after surgery, and there was a measurable reduction in pain in patients who used an abdominal binder after any exercise or activity (Arici et al., 2016). Giller and colleagues (2016) found that abdominal binders provide a noninvasive intervention for enhancing recovery of walk performance, controlling pain, and reducing stress on abdominal muscles following caesarean section. The quality of scientific

evidence regarding the benefits of binders is limited, but binders are still used by many clinicians.

Binders and bandages applied over or around dressings provide extra protection and therapeutic benefits by the following:

1. Creating pressure over a body part (e.g., an elastic pressure bandage applied over an arterial puncture site)
2. Immobilizing a body part (e.g., an elastic bandage applied around a sprained ankle)
3. Supporting a wound (e.g., an abdominal binder applied over a large abdominal incision and dressing)
4. Reducing or preventing edema (e.g., a stretch pressure bandage applied to the lower leg)
5. Securing a splint (e.g., a bandage applied around hand splints for correction of deformities)
6. Securing dressings (e.g., elastic webbing applied around leg dressings after a vein stripping)

Bandages are available in rolls of various widths and materials, including gauze, elasticized knit, elastic webbing, flannel, and muslin. Gauze bandages are lightweight and inexpensive, mold easily around contours of the body, and permit air circulation to prevent skin maceration. Elastic bandages conform well to body parts but are also for exerting pressure.

Binders are bandages that are made of large pieces of material to fit a specific body part. Most binders are made of elastic or cotton. An abdominal binder and a breast binder are examples.

Principles for Applying Bandages and Binders

Correctly applied bandages and binders do not cause injury to underlying and nearby body parts or create discomfort for a patient. For example, a chest binder should not be so tight as to restrict chest wall expansion. Before applying a bandage or binder, a nurse's responsibilities include the following:

- Inspecting the skin for abrasions, edema, discoloration, or exposed wound edges
- Covering exposed wounds or open abrasions with a dressing
- Assessing the condition of underlying dressings and changing if soiled
- Assessing the skin of underlying areas that will be distal to the bandage for signs of circulatory impairment (coolness, pallor or cyanosis, diminished or absent pulses, swelling, numbness, and tingling) to provide a means for comparing changes in circulation after bandage application

After applying a bandage or binder, the nurse assesses, documents, and immediately reports changes in circulation, skin integrity, comfort level, and body function (e.g., ventilation or movement). The nurse who applies a bandage or binder loosens or readjusts it as necessary. A health care provider's order is necessary before loosening or removing a bandage applied by the health care provider. The nurse explains to the patient that any bandage or binder feels relatively firm or tight. Carefully assess a bandage to be sure that it is applied properly and providing therapeutic benefit and replace any soiled bandages.

Slings

Slings support arms with muscular sprains or fractures. A commercially manufactured sling consists of a long sleeve that extends above the elbow with a strap that fits around the neck. In the home patients can use a large triangular piece of cloth. The patient sits or lies supine during sling application (Fig. 48.29). Instruct him or her to bend the affected arm, bringing the forearm straight across the chest. The open sling fits under the patient's arm and over the chest, with the base of the triangle under the wrist and the point of the triangle at his or her elbow. One end of the sling fits around the back of the patient's neck. Bring the other end up and over the affected arm while supporting the extremity. Tie the two ends at the side of the neck so that the knot does not press against the cervical spine. Fold the loose material at the elbow evenly around the elbow and then pin to secure. Always support the lower arm and hand at a level above the elbow to prevent the formation of dependent edema.

FIG. 48.29 Application of sling.

Roll Bandage Application

Rolls of bandage secure or support dressings over irregularly shaped body parts. Each roll has a free outer end and a terminal end at the center of the roll. The rolled part of the bandage is its body, and its outer surface is placed against the patient's skin or dressing. Use a variety of bandage turns, depending on the body part to be bandaged (see Skill 48.6).

Heat and Cold Therapy

Moist heat applications are therapeutically beneficial in increasing muscle and ligament flexibility; promoting relaxation and healing; and relieving spasm, joint stiffness, and pain. Moist heat has many indications; however, it is most

commonly used following the acute phase of a musculoskeletal injury and during and after childbirth, surgery, and superficial thrombophlebitis (Petrofsky et al., 2017; Szekeres et al., 2017). Moist heat applications include warm compresses and commercial moist heat packs, warm baths, soaks, and sitz baths. Dry heat is also used to reduce pain and increase healing by increasing blood flow in tissues and can be used at a low level for a longer period with little chance of tissue injury (Petrofsky et al., 2016).

Cold therapy refers to the superficial application of cold to the surface of the skin, with or without compression and with or without a mechanical recirculating device to maintain cold temperatures (Chou et al., 2016). Cold therapy is designed to treat the localized inflammatory response of an injured body part that presents as edema, hemorrhage, muscle spasm, or pain. Improvement to joint mobility following cold therapy is related to reducing pain and swelling, inhibiting muscle spasm, and reducing muscle tension (Chatterjee, 2017; Quinlan et al., 2017). Cold therapy most commonly is used immediately after soft tissue and musculoskeletal injuries such as sprains or strains; however, it has been used in the postoperative setting with patients who have undergone orthopedic surgeries, spinal fusion, and lumbar discectomy (Quinlan et al., 2017). Research trials of cold therapy have been inconsistent and frequently found no differences compared with no cold therapy in postoperative pain or analgesic use (Chou et al., 2016).

Assessment for Temperature Tolerance

Before applying heat or cold therapies, assess a patient's physical condition for signs of potential intolerance to heat and cold. First observe the area to be treated. Assess the skin, looking for any open areas such as alterations in skin integrity (e.g., abrasions, open wounds, edema, bruising, bleeding, or localized areas of inflammation) that increase a patient's risk for injury. Because a health care provider commonly orders heat and cold applications for traumatized areas, the baseline skin assessment provides a guide for evaluating skin changes that can occur during therapy. Assess neurological function, testing for sensation to light touch, pinprick, and mild temperature variations (see Chapter 30). Sensory status reveals the ability of a patient to recognize when heat or cold becomes excessive. Assess a patient's mental status to be sure that he or she can correctly communicate any issues with the hot or cold therapy. Level of consciousness influences the ability to perceive heat, cold, and pain. If a patient is confused or unresponsive, the nurse needs to make frequent observations of skin integrity after therapy begins.

Assess for conditions that contraindicate heat or cold therapy. Do not cover an active area of bleeding with a warm application because bleeding will continue. Warm applications are contraindicated when a patient has an acute, localized inflammation such as appendicitis because the heat could cause the appendix to rupture. If a patient has cardiovascular problems, it is unwise to

apply heat to large parts of the body because the resulting massive vasodilation disrupts blood supply to vital organs.

Cold is contraindicated if the site of injury is already edematous. It further retards circulation to the area and prevents absorption of the interstitial fluid. If a patient has impaired circulation (e.g., arteriosclerosis), it further reduces blood supply to the affected area. Cold therapy is also contraindicated in the presence of neuropathy, because the patient is unable to perceive temperature change and damage resulting from temperature extremes. One other contraindication for cold therapy is shivering. Cold applications sometimes intensify shivering and dangerously increase body temperature.

If a patient has peripheral vascular disease, pay particular attention to the integrity of extremities. For example, if the health care provider's order is to apply a cold compress to a lower extremity, assess circulation to the leg by assessing for capillary refill; observing skin color; and palpating skin temperatures, distal pulses, and edematous areas. If signs of circulatory inadequacy are present, it is important for you to question the order.

When applying heat or cold pads, check electrical equipment for cracked cords, frayed wires, damaged insulation, and exposed heating components. Make sure that equipment containing circulating fluids does not have leaks. Check equipment for evenness of temperature distribution.

Bodily Responses to Heat and Cold

Exposure to heat and cold causes systemic and local responses. Systemic responses occur through heat-loss mechanisms (sweating and vasodilation) or mechanisms promoting heat conservation (vasoconstriction and piloerection) and heat production (shivering) (see [Chapter 30](#)). Local responses to heat and cold occur through stimulation of temperature-sensitive nerve endings within the skin. This stimulation sends impulses from the periphery to the hypothalamus, which becomes aware of local temperature sensations and triggers adaptive responses for maintenance of normal body temperature. If alterations occur along temperature sensation pathways, the reception and eventual perception of stimuli are altered.

The body is able to tolerate wide variations in temperature. The normal temperature of the surface of the skin is 34°C (93.2°F), but temperature receptors usually adapt quickly to local temperatures between 15° and 45°C (59° and 113°F). Pain develops when local temperatures exceed this range. Excessive heat causes a burning sensation. Cold produces a numbing sensation before pain.

The adaptive ability of the body creates the major problem in protecting patients from injury resulting from temperature extremes. A person initially feels an extreme change in temperature but within a short time hardly notices it. This is dangerous because a person insensitive to heat and cold extremes can

suffer serious tissue injury. You need to recognize patients most at risk for injuries from heat and cold applications (Table 48.10).

TABLE 48.10

Conditions That Increase Risk of Injury From Heat and Cold Application

Condition	Risk Factors
Very young or older patients	Thinner skin layers in children increase risk of burns. Older patients have reduced sensitivity to pain and may not perceive any pain associated with heat or cold applications.
Open wounds, broken skin, stomas	Subcutaneous and visceral tissues are more sensitive to temperature variations. They also contain no temperature and fewer pain receptors.
Areas of edema or scar formation	Reduced sensation to temperature stimuli occurs because of thickening of skin layers from fluid buildup or scar formation.
Peripheral vascular disease (e.g., diabetes, arteriosclerosis)	As a result of decreased peripheral circulation, extremities are less sensitive to temperature and pain stimuli because of circulatory impairment and local tissue injury. Cold application further compromises blood flow.
Confusion or unconsciousness	Reduced perception of sensory or painful stimuli. Patient may be unable to move away from or to indicate discomfort from the heat or cold application.
Spinal cord injury	Alterations in nerve pathways prevent reception of sensory or painful stimuli.
Abscessed tooth or appendix	Infection is highly localized. Application of heat causes rupture, with spread of microorganisms systemically.

Local Effects of Heat and Cold Applications

Heat and cold stimuli create different physiological responses. The choice of heat or cold therapy depends on local responses desired for wound healing (Table 48.11).

TABLE 48.11

Therapeutic Effects of Heat and Cold Applications

Physiological Response	Therapeutic Benefit	Examples of Conditions Treated
Heat Therapy		
Vasodilation Reduced blood viscosity Reduced muscle tension Increased tissue metabolism Increased capillary permeability	Improve blood flow to injured body part Promote delivery of nutrients and removal of wastes Improve delivery of leukocytes and antibiotics to wound site Promote muscle relaxation Reduce pain from spasm or stiffness Increase blood flow Provide local warmth Promote movement of waste products and nutrients	Arthritis or degenerative joint disease Localized joint pain or muscle strains Low back pain Menstrual cramping Hemorrhoid, perianal, and vaginal inflammation Local skin abscesses
Cold Therapy		
Vasoconstriction Local anesthesia Reduced cell metabolism Increased blood viscosity Decreased muscle tension	Reduce blood flow to injured site, preventing edema formation Reduce inflammation Reduce localized pain Reduce oxygen needs of tissues Promote blood coagulation at injury site Relieve pain	Immediately after direct trauma (e.g., sprains, strains, fractures, muscle spasms) Superficial laceration or puncture wound Minor burn After injections Chronic pain from arthritis, joint trauma, or delayed-onset muscle soreness; inflammation

Effects of Heat Application

Generally heat is quite therapeutic, improving blood flow to an injured part. However, if it is applied for 1 hour or more, the body reduces blood flow by a reflex vasoconstriction to control heat loss from the area. Periodic removal and reapplication of local heat restores vasodilation. Continuous exposure to heat damages epithelial cells, causing redness, localized tenderness, and even blistering.

Effects of Cold Application

The application of cold initially diminishes swelling and pain. Prolonged exposure of the skin to cold results in a reflex vasodilation. The inability of the cells to receive adequate blood flow and nutrients results in tissue ischemia. The skin initially takes on a reddened appearance, followed by a bluish-purple mottling, with numbness and a burning type of pain. Skin tissues freeze from exposure to extreme cold.

Factors Influencing Heat and Cold Tolerance

The response of the body to heat and cold therapies depends on the following factors:

- A person is better able to tolerate short exposure to temperature extremes than prolonged exposure.
- Exposed skin layers and certain areas of the skin (e.g., the neck, inner aspect of the wrist and forearm, and perineal region) are more sensitive to temperature variations. The foot and palm of the hand are less sensitive.
- The body responds best to minor temperature adjustments. If a body part is cool and a hot stimulus touches the skin, the response is greater than if the skin were already warm.
- A person has less tolerance to temperature changes to which a large area of the body is exposed.
- Tolerance to temperature variations changes with age. Patients who are very young or old are most sensitive to heat and cold.
- If a patient's physical condition reduces the reception or perception of sensory stimuli, tolerance to temperature extremes is high, but the risk of injury is also high.
- Uneven temperature distribution suggests that the equipment is functioning improperly.

Application of Heat and Cold Therapies

A prerequisite to using any heat or cold application is a health care provider's order, which includes the body site to be treated and the type, frequency, and duration of application. Safety guidelines for the use of heat and cold are summarized in [Box 48.12](#). Consult agency procedure manual for correct temperatures to use.

Box 48.12 Safety Suggestions for Applying Heat or Cold Therapy

- *Explain* to patient sensations to be felt during the procedure.
- *Prevention*: Injuries from heat and cold therapies are preventable (NQF, 2011).
- *Instruct* patient that exposed layers of skin are more sensitive to heat and cold application than intact skin. Therefore instruct patient and family to protect skin when applying heat or cold therapy.
- *Instruct* patient to report changes in sensation or discomfort immediately.
- *Provide* a timer, clock, or watch so that patient can help the nurse time the application.
- *Check* patient and skin frequently every 20 minutes during therapy. Observe for excess redness, pain, tingling.
- *Keep* the nurse call system within patient's reach.
- *Refer* to the policy and procedure manual of the institution for safe temperatures.
- *Do not* allow patient to adjust temperature settings.
- *Do not* allow patient to move an application or place hands on the wound site.
- *Do not* place patient in a position that prevents movement away from the temperature source.
- *Do not* leave unattended a patient who is unable to sense temperature changes or move from the temperature source.

Box 48.13 Choice of Dry or Moist Applications

Advantages

Moist Applications

- Moist application reduces drying of skin and softens wound exudate.
- Moist compresses conform well to most body areas.
- Moist heat penetrates deeply into tissue layers.
- Warm, moist heat does not promote sweating and insensible fluid loss.

Dry Applications

- Dry heat has less risk of burns to skin than moist applications.
- Dry application does not cause skin maceration.
- Dry heat retains temperature longer because evaporation does not occur.

Disadvantages

Moist Applications

- Prolonged exposure causes maceration of skin.
- Moist heat cools rapidly because of moisture evaporation.
- Moist heat creates greater risk for burns to skin because moisture conducts heat.

Dry Applications

- Dry heat increases body fluid loss through sweating.
- Dry applications do not penetrate deep into tissues.
- Dry heat causes increased drying of skin.

You can administer heat and cold applications in dry or moist forms. The type of wound or injury, the location of the body part, and the presence of drainage or inflammation are factors to consider in selecting

dry or moist applications. [Box 48.13](#) summarizes advantages and disadvantages of both.

Warm, Moist Compresses

Warm, moist compresses improve circulation, relieve edema, and promote consolidation of purulent drainage. A compress is a piece of gauze dressing moistened in a prescribed warmed solution.

Heat from warm compresses dissipates quickly. To maintain a constant temperature, you need to change the compress often. You can use a layer of plastic wrap or a dry towel to insulate the compress and retain heat. Moist heat promotes vasodilation and evaporation of heat from the surface of the skin. For this reason a patient can feel chilly. Always try to control drafts within the room, and keep the patient covered with a blanket or robe.

Warm Soaks

Immersion of a body part in a warmed solution promotes circulation, lessens edema, increases muscle relaxation, and provides a means to apply medicated solution. Sometimes a soak is also accompanied by wrapping the body part in dressings and saturating them with the warmed solution.

Position the patient comfortably, place waterproof pads under the area to be treated, and heat the solution to about 40.5° to 43°C (105° to 110°F). Pour solution into a clean or sterile basin or container, then immerse the body part. Cover the container and extremity with a towel to reduce heat loss. It is usually necessary to remove the cooled solution and add heated solution after about 10 minutes. The challenge is to keep the solution at a constant temperature. Never add a hotter solution while the body part remains immersed. After any soak dry the body part thoroughly to prevent maceration.

Sitz Baths

A patient who has had rectal surgery, an episiotomy during childbirth, painful hemorrhoids, or vaginal inflammation benefits from a sitz bath, a bath in which only the pelvic area is immersed in warm or, in some situations, cool fluid. The patient sits in a special tub or chair or a basin that fits on the toilet seat so the legs and feet remain out of the water. Immersing the entire body causes widespread vasodilation and nullifies the effect of local heat application to the pelvic area.

The desired temperature for a sitz bath depends on whether the purpose is to promote relaxation or to clean a wound. It is often necessary to add

warm or cool water during the procedure, which normally lasts 20 minutes, to maintain a constant temperature. Agency procedure manuals recommend safe water temperatures. A disposable sitz basin contains an attachment resembling an enema bag that allows gradual introduction of additional water.

Prevent overexposure of patients by draping bath blankets around their shoulders and thighs and controlling drafts. A patient should be able to sit in the basin or tub with feet flat on the floor and without pressure on the sacrum or thighs. Because exposure of a large part of the body to heat causes extensive vasodilation, assess the pulse and facial color and ask whether the patient feels light-headed or nauseated.

Commercial Hot and Cold Packs

Commercially prepared disposable hot packs apply warm, dry heat to an injured area. The chemicals mix and release heat when you strike, knead, or squeeze the pack. Package directions recommend the time for heat application.

Commercially prepared cold packs that are similar to the disposable hot packs for dry applications are available. They come in various shapes and sizes to fit different body parts. When using cold compresses, observe for adverse reactions such as burning or numbness, mottling of the skin, redness, extreme paleness, and a bluish skin discoloration.

Cold, Moist, and Dry Compresses

The procedure for applying cold, moist compresses is the same as that for warm compresses. Apply cold compresses for 20 minutes at a temperature of 15°C (59°F) to relieve inflammation and swelling. You can use clean or sterile compresses.

Cold Soaks

The procedure for preparing cold soaks and immersing a body part is the same as for warm soaks. The desired temperature for a 20-minute cold soak is 15°C (59°F). Control drafts and use outer coverings to protect the patient from chilling. It is often necessary to add cold water during the procedure to maintain a constant temperature.

Ice Bags or Collars

For a patient who has a muscle sprain, localized hemorrhage, or hematoma or who has undergone dental surgery, an ice bag is ideal to

prevent edema formation, control bleeding, and anesthetize the body part. Proper use of the bag requires the following steps:

1. Fill the bag with water, secure the cap, invert to check for leaks, and pour out the water.
2. Fill the bag two-thirds full with crushed ice, so you are able to easily mold it over a body part.
3. Release any air from the bag by squeezing its sides before securing the cap because excess air interferes with conduction of cold.
4. Wipe off excess moisture.
5. Cover the bag with a flannel cover, towel, or pillowcase.
6. Apply the bag to the injury site for 30 minutes; you can reapply the bag in an hour.

Evaluation

You evaluate the effectiveness of nursing interventions for reducing and treating pressure injuries and other wounds by determining the patient's response to nursing therapies, determining outcomes, and evaluating whether he or she achieved each goal. The optimal outcomes are to prevent injury to the skin, to reduce injury to the skin and underlying tissues, and possible wound healing with restoration of skin integrity.

Through the Patient's Eyes

It is important to include the patient and family caregiver in the evaluation process. Review whether their expectations of care were met. For example, is the patient satisfied with the level of comfort achieved during wound care? Chronic wounds such as pressure injuries take time to heal, so home care is likely. Do the patient and family caregiver feel comfortable or confident in being able to perform wound care at home? Does the family caregiver feel he or she has the information needed to know when to report a problem with a wound? If patient and family caregiver expectations are unmet, revise your plan of care to select the best ways to support and re-educate.

Patient Outcomes

The outcomes selected for a patient in the plan of care are the milestones you hope to achieve to meet the goals of care. Each patient will have unique outcomes depending on whether he or she has an actual wound or

is at risk to develop a wound. Evaluate nursing interventions for reducing and treating pressure injuries by determining the patient's response and comparing with expected outcomes to determine whether he or she achieved each goal ([Fig. 48.30](#)).

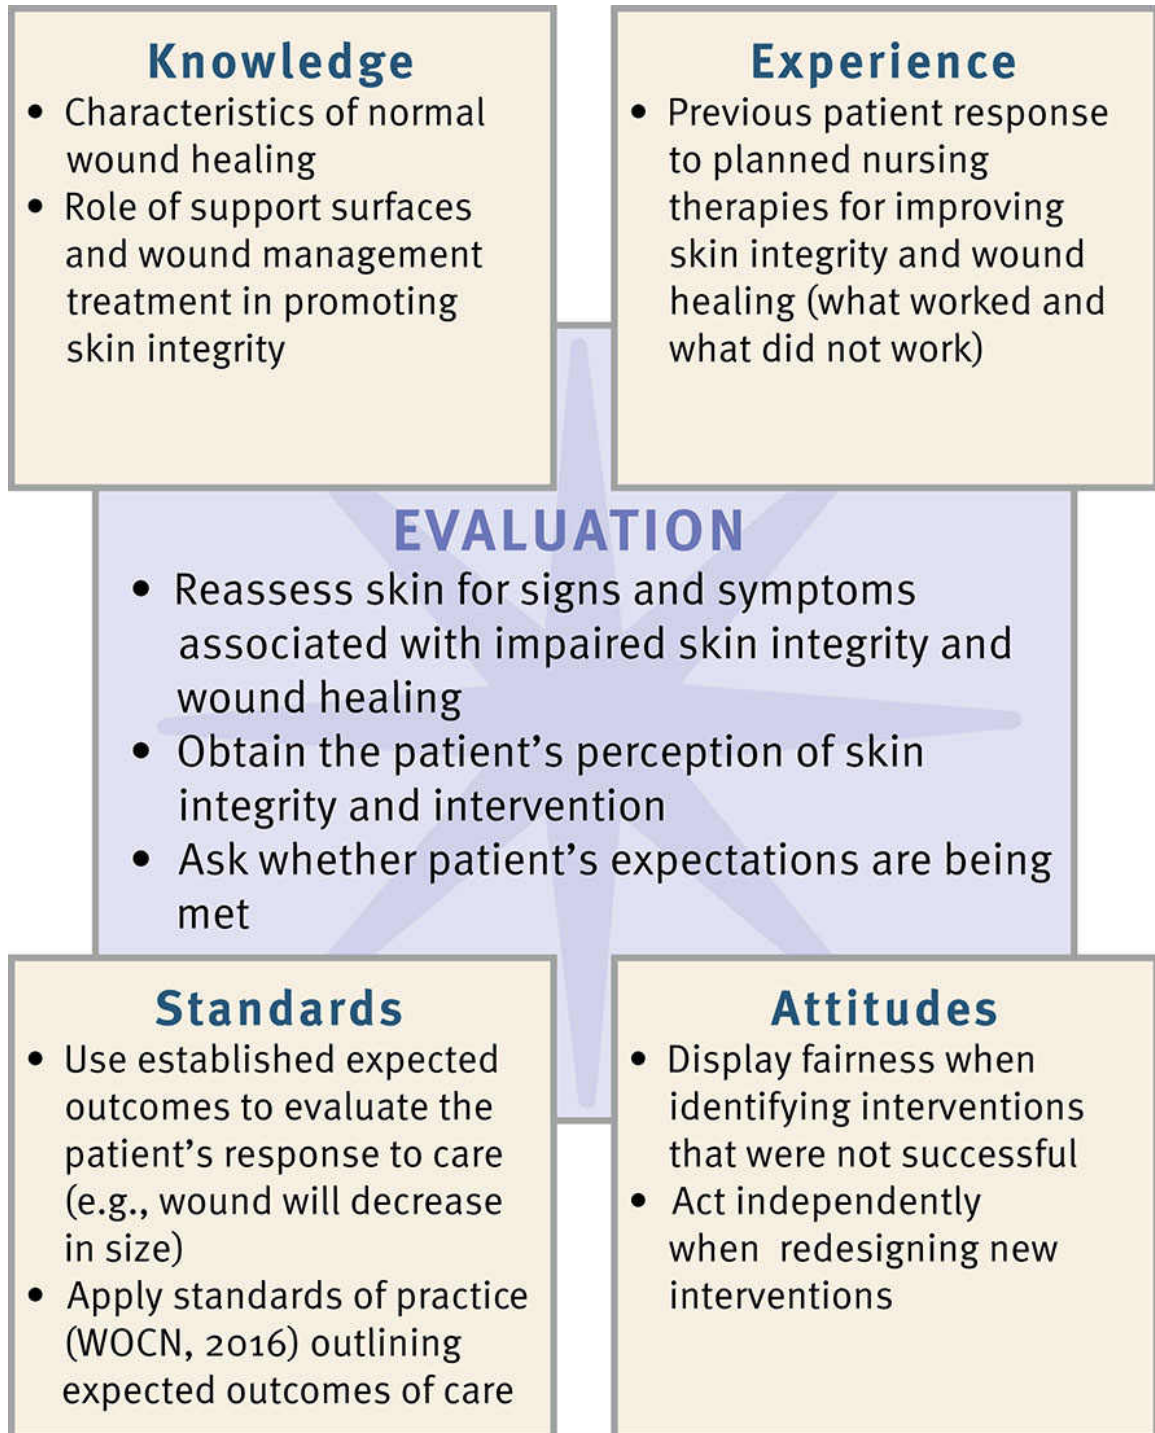

FIG. 48.30 Critical thinking model for skin integrity and wound-care evaluation.

You will evaluate patients with impaired skin integrity on an ongoing basis for factors that contribute to skin breakdown and wound status. For example, during direct patient contact, if a patient continues to be diaphoretic or incontinent, apply wound assessment skills to determine

the condition of the skin and decide whether additional therapies are needed to treat a patient's skin moisture. Use a validated wound assessment tool when appropriate. Evaluation provides information regarding the patient's progress toward wound healing or maintenance of skin integrity.

If the identified outcomes are not met for a patient with impaired skin integrity, questions to ask include the following:

- Was the etiology of the skin impairment addressed? Were the pressure, friction, shear, and moisture components identified, and did the plan of care decrease the contribution of each of these components?
- Was wound healing supported by providing the wound with a moist protected environment?
- Was nutrition assessed and a plan of care developed that provided the patient with the calories to support healing?

Finally evaluate the need for additional referrals to other experts in wound care and pressure injuries, such as nurses certified in wound care. Care of patients with a pressure injury or wound requires an interprofessional team approach.

Safety Guidelines for Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about your patient's care. When performing the skills in this chapter, remember the following points to ensure safe, individualized patient care.

- When changing wound dressings, follow proper aseptic technique. Keep a plastic bag within reach to discard dressing and prevent cross-contamination. Keep extra gloves within reach in case of contamination or additional wound assessment.
- Perform pressure injury risk assessment on all patients who have one or more risk factors when admitted to an acute care setting, home care, hospice, or extended-care facility (EPUAP, NPIAP, PPPIA,

2019b, WOCN, 2016). Use a risk assessment tool; the Braden Scale is one of the most widely used and researched scales (Bryant and Nix, 2016a).

- Inspect skin at least daily or according to agency policy, and note and document all pressure points. Modify frequency of skin and wound assessment and frequency of skin care practices based on patient's risk factors and/or wound condition.
- Use approaches to minimize friction and shear. Use lift sheets when repositioning patients to reduce rubbing skin against sheets. Raise the head of the bed no more than 30 degrees (unless medically contraindicated) to prevent sliding and shear injury (WOCN, 2016).
- When a patient has a previous history of pressure injury or skin damage, the healed area presents a greater risk for skin breakdown than healthy, unwounded skin.
- Chronic diseases, especially vascular disease and diabetes, increase a patient's risk for pressure injury development and impede wound healing.

Skill 48.1. Assessment and Prevention Strategies for Pressure Injury Development Delegation and Collaboration

The skill of pressure injury risk assessment cannot be delegated to assistive personnel (AP). Instruct the AP to:

- Frequently change patient's position and specific positions individualized for the patient.
- Keep patient's skin dry, and provide hygiene following fecal or urinary incontinence or exposure of skin to wound drainage.
- Report any changes in patient's skin, such as redness or break in the patient's skin.
- Report any redness and/or abrasion from medical devices.

Equipment

- Risk assessment tool (see agency policy)
- Pressure redistribution mattresses, bed, or chair cushion as needed

- Positioning aids
- Clean gloves

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review medical record to assess patient's risk for pressure injury formation:	Determines need to administer preventive care and identifies specific factors that place patient at risk (Haesler, 2017; EPUAP, NPIAP, PPIIA, 2019b).
a. Paralysis or immobilization caused by restrictive devices.	Patient is unable to turn or reposition independently to relieve pressure.
b. Presence of medical device such as nasogastric (NG) tube, oxygen equipment, artificial airways, drainage tubing, or mechanical devices (Doughty and McNichol, 2016).	Medical devices have potential to exert pressure on patient's nares or ears or on tissue adjacent to devices such as artificial airways and drainage tubes (Pittman et al., 2015).
(1) If not medically contraindicated, remove medical device to observe and palpate skin and tissues under and around each medical device.	Pressure area assumes same configuration as medical device (WOCN, 2016; Schalkom et al., 2015).
c. Sensory loss (e.g., hemiplegia, spinal cord injury).	Patient is unable to feel discomfort from pressure and does not independently change position.
d. Circulatory disorders (e.g., peripheral vascular diseases, vascular changes from diabetes mellitus, neuropathy).	Reduce perfusion of tissue layers of skin.
e. Fever.	Increases metabolic demands of tissues. Accompanying diaphoresis leaves skin moist.
f. Anemia.	Decreased hemoglobin level reduces oxygen-carrying capacity of blood and amount of oxygen available to tissues.
g. Malnutrition: weight loss, loss of muscle mass and or subcutaneous fat.	Inadequate nutrition leads to weight loss, muscle atrophy, and reduced tissue mass. Nutrient deficiencies result in impaired or delayed healing (Stotts, 2016a).
h. Fecal or urinary incontinence.	Skin becomes exposed to moist environment that contains bacteria. Excessive moisture macerates skin (McNichol et al., 2018; Ayello, 2017).
i. Heavy sedation and anesthesia.	Sedation alters sensory perception and patient does not perceive pressure and change position.
j. Age.	Neonates and very young children are at high risk, with the head being most common site of pressure injury occurrence (WOCN, 2016). There is loss of dermal thickness in older adults, impairing ability to distribute pressure (Pieper, 2016).
k. Dehydration.	Results in decreased skin elasticity and turgor.
l. Edema.	Edematous tissues are less tolerant of pressure, friction, and shear.
m. Existing pressure injuries.	Limit surfaces available for position changes, placing available tissues at increased risk.
n. History of pressure injury.	Tensile strength of skin from previously healed pressure injury is 80% or less; therefore, this area cannot tolerate pressure as much as undamaged skin (Doughty and Sparks, 2016).
3. Select agency-approved risk assessment tool such as the Braden Scale or Norton Scale. Perform risk assessment when patient enters health care setting and repeat on regularly scheduled basis or when there is significant change in patient's condition (see agency policy) (WOCN, 2016).	Valid and reliable risk-assessment tools evaluate patient's risk for developing a pressure injury. Identifying risk factors that contribute to the potential for skin breakdown allows you to target specific interventions for decreasing risk.
CLINICAL DECISION: In acute care settings, perform initial assessment within 8 hours of admission and reassess every 24 hours or as patient condition changes; in critical care areas perform assessment on admission and reassess every 24 hours or as patient condition changes; and in long-term and home care settings perform assessment on admission. In long-term care settings reassess weekly and then according to agency standards or when patient condition changes. In home care setting reassess every registered nurse visit.	
4. Obtain risk score (see Table 48.3) and evaluate its meaning based on patient's unique characteristics. When using the Braden scale there are risk scores identified for specific patient populations: intensive care patients ≤ 14 ; older adults ≤ 14 (Alderden et al., 2017).	Risk cutoff score depends on instrument used. Score involves identifying risk factors that contributed to it and minimizing these specific deficits (Alderden et al., 2017; Ayello, 2017).
5. Close room or pull curtains around bed.	Maintains patient privacy.
6. Perform hand hygiene. Assess condition of patient's skin, focusing on pressure points (see Fig. 48.9). Apply gloves as needed with open and/or draining wounds.	Body weight against bony prominences places underlying skin at risk for the development of skin injuries.

Table Continued

Step	Rationale
a. Inspect for skin discoloration (see Box 48.2) for patients with darkly pigmented skin) and tissue consistency (firm or boggy feel) and/or palpate for abnormal sensations (Nix, 2016).	Indicates that tissue was under pressure; hyperemia is a normal physiological response to hypoxemia in tissues.
b. Palpate discolored area on skin and under and around medical devices, release your fingertip, and look for blanching. If on palpation an area of redness blanches (lightens in color), this indicates normal reactive hyperemia; tissue is not at risk for the development of an injury. If area does not blanch, suspect tissue injury and recheck in 1 hour.	Tissue that does not blanch when palpated indicates abnormal reactive hyperemia, an indication of possible ischemic injury.
c. Inspect for pallor and mottling.	Persistent hypoxia in tissues that were under pressure, an abnormal physiological response.
d. Inspect for absence of superficial skin layers.	Represents early pressure injury formation; usually a partial-thickness wound that may have resulted from friction and/or shear.
e. Inspect for changes in skin temperature, edema, and tissue consistency, especially in individuals with darkly pigmented skin (EPAUP, NPIAP, PPIIA, 2019a).	Localized heat, edema, and induration have been identified as warning signs for pressure injury development. Because it is not always possible to observe changes in skin color on darkly pigmented skin, these additional signs should be considered in assessment (EPAUP, NPIAP, PPIIA, 2019a).
f. Inspect for wound drainage.	Wound drainage increases risk for skin breakdown because it is caustic to skin and underlying tissues.
7. Assess skin and tissue around and beneath medical devices every nursing shift for additional areas of potential pressure injury resulting from medical devices (Black and Kalowes, 2016; Black et al., 2015) (Table 48.5). NOTE: Pressure area assumes same configuration as medical device (WOCN, 2016; Schallom et al., 2015).	Patients at high risk have multiple sites for pressure necrosis from medical devices in areas other than bony prominences (Chaboyer et al., 2017; Makic, 2015). Pressure points around medical devices can cause pressure injury to underlying tissue and become full-thickness pressure injuries (Kayser et al., 2018; Black et al., 2015; Schallom et al., 2015).
a. Nares: NG tube, feeding tube, oxygen cannula.	Pressure to nares occurs from tape and other materials used to secure NG tube.
b. Ears: oxygen cannula, pillow.	Oxygen equipment is a significant risk for pressure injuries (Padula et al., 2017). Patients' ears and tips of nares are at risk for pressure injuries from nasal cannula (Black et al., 2015; Schallom et al., 2015).
c. Tongue and lips: oral airway, endotracheal (ET) tube.	Pressure can result from artificial airway and materials used to secure airway (Padula et al., 2017; Black et al., 2015).
d. Forehead: pulse oximetry device.	Adhesive can cause skin blistering.
e. Drainage or other tubing.	Stress and pressure against tissue at exit site or from tubing lying under any part of patient's body can cause skin injury (Black et al., 2015).
f. Indwelling urethral (Foley) catheter.	For female patients catheter can place pressure on labia, especially when edematous. For male patients pressure from catheter not properly anchored can put pressure on tip of penis and urethra (Black et al., 2015).
g. Orthopedic and positioning devices such as casts, neck collars, splints.	Applied devices have potential to cause pressure to underlying and adjacent skin and tissue (Black et al., 2015).
h. Compression stockings.	Compression stockings have potential to cause pressure, especially if they fit poorly or are rolled down (Black et al., 2015).
i. Immobilization device and restraints.	Pressure points can occur if the device is too tight or poorly placed or if the patient strains against the device.
8. Observe patient for preferred positions when in bed or chair.	Preferred positions result in weight of body being placed on certain bony prominences. Presence of contractures may result in pressure exerted in unexpected places.
9. Observe ability of patient to initiate and help with position changes.	Potential for pressure, friction, and shear increases when patient is completely dependent on others for position changes.
10. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
11. Assess patient's and family caregiver's understanding of what a pressure injury is and the individual risks for patient to develop pressure injuries.	Determines baseline knowledge for pressure injury risk and identifies areas for patient teaching.
Planning	
1. Explain procedure to patient before starting.	Reduces anxiety and provides opportunity for patient/family caregiver education.
2. Lower side rails. Position patient comfortably in bed in anatomical position.	Facilitates ability to perform prevention strategies.

Table Continued

Step	Rationale
Implementation	
1. Perform hand hygiene. If patient has open, draining wounds, apply clean gloves.	Use of Standard Precautions prevents accidental exposure to body fluids.
2. Implement prevention guidelines adapted from WOCN Society <i>Guideline for Prevention and Management of Pressure Ulcers</i> (2016).	Reduces patient's risk for developing pressure injury.
3. Following initial assessment, continue to inspect skin at least once a day as per agency policy.	
CLINICAL DECISION: Do not massage reddened areas because doing so may cause additional tissue trauma. Reddened areas indicate blood vessel damage, and massaging can further damage the vessel (Bryant and Nix, 2016a).	
a. If patient has darkly pigmented skin, look for color changes that differ from his or her normal skin color.	Darkly pigmented skin may not blanch. A change in color may occur at the site of pressure; this change in color differs from patient's usual skin color (EPUAP, NPIAP, PPPIA, 2019a,b) (see Box 48.2).
4. Each shift, check all medical treatment and assistive devices for potential pressure points.	Pressure from these devices increases risk on bony prominences and other areas.
a. Verify that device is correctly sized, positioned, and secured.	Incorrect size, placement, and securing of medical device can cause excessive pressure and rubbing by device on underlying skin (Makic, 2015).
b. Consider protecting underlying at-risk skin with a protective dressing (silicone, hydrocolloid).	Dressings absorb moisture from body and reduce pressure to underlying skin (Black et al., 2015; Makic, 2015).
CLINICAL DECISION: Inspect skin around and beneath orthopedic devices (e.g., cervical collar, braces, or cast). Note any abrasions or warmth in areas where devices can rub against the skin (Pitman et al., 2015; Schallom et al., 2015).	
5. Remove and dispose of gloves; perform hand hygiene. Reapply gloves if exposure to body fluids is anticipated during interventions.	Reduces transmission of microorganisms.
6. Review patient's pressure injury risk assessment score. Adapt interventions based on those risks (WOCN, 2016).	Risk scores aid in identifying interventions to lessen or eliminate present risk factors.
7. If immobility, inactivity, or poor sensory perception is a risk factor for patient, consider one of the following interventions (WOCN, 2016):	Immobility and inactivity reduce patient's ability or desire to independently change position. Poor sensory perception decreases patient's ability to feel sensation of pressure or discomfort.
a. Educate patient and family regarding specific pressure injury risk factors and prevention.	Helps patients and family understand and adhere to interventions designed to reduce pressure injury risk (Berlowitz, 2018).
b. When patient is in side-lying position in bed, use 30-degree lateral position (see Fig. 48.15). Avoid 90-degree lateral position.	Reduces direct contact of trochanter with support surface.
c. Place patient (when lying in bed) on pressure-redistribution surface.	Reduces amount of pressure exerted on tissues.
d. Place patient (when in chair) on pressure-redistribution device and shift points under pressure at least every hour (WOCN, 2016).	Reduces amount of pressure on sacral and ischial areas.
8. If friction and shear are identified as risk factors, consider the following interventions:	Friction and shear damage underlying skin.
a. Use safe patient-handling guidelines to reposition patient. For example, use slide board to transfer patient from bed to stretcher.	Proper repositioning of patient prevents creating shear from dragging patient along sheets. Slide board provides slippery surface to reduce friction. Use lift team when appropriate.
b. Ensure that heels are free from surface of bed by using a pillow under calves to elevate heels, or use a heel-suspension device; knees should be in 5- to 10-degree flexion (WOCN, 2016; Baath et al., 2015).	"Floating" heels from bed surface offload the heel completely and redistribute the weight of the leg along the calf without applying pressure on the Achilles tendon (Baath et al., 2015).
c. Maintain head of the bed at 30 degrees or lower or at the lowest degree of elevation consistent with patient's condition (do not lower HOB if patient is at risk for aspiration) (WOCN, 2016).	Decreases potential for patient to slide toward foot of bed and incur shear injury.
9. If patient receives low score on moisture subscale, consider one of the following interventions:	Continual exposure of body fluids on patient's skin increases risk for skin breakdown and pressure injury development.
a. Apply clean gloves. Clean and dry the skin as soon as possible after each incontinent episode (WOCN, 2016). Then apply moisture barrier ointment to perineum and surrounding skin.	Protects skin from fecal or urinary incontinence. Friction and shear are enhanced in the presence of moisture (McNichol et al., 2018).
b. If skin is denuded, use protective barrier paste after each incontinent episode.	Provides barrier between skin and stool/urine, allowing for healing.
c. If moisture source is from wound drainage, consider more frequent dressing changes, skin protection with protective barriers, or collection devices.	Removes frequent exposure to wound drainage from skin.
10. If friction and shear are risk factors and patient is chair bound:	Relief of pressure by changing from lying to sitting position is insufficient if sitting lasts a prolonged time. The maximum amount of time a patient can sit before there is a need to reposition is unknown (WOCN, 2016).
a. Tilt patient's chair seat to prevent sliding forward, and support arms, legs, and feet to maintain proper posture (EPUAP, NPIAP, PPPIA, 2019a).	Relieves pressure on ischial tuberosities and sacrum.
b. Limit amount of time patient spends in a chair without pressure redistribution (EPUAP, NPIAP, PPPIA, 2019a).	
Step	Rationale
c. For patients who can reposition themselves while sitting, encourage pressure redistribution every 15 minutes using chair push-ups, forward lean, or side to side (WOCN, 2016).	

Table Continued

Step	Rationale
11. Educate patient and family caregiver regarding pressure injury risk and prevention strategies (WOCN, 2016).	Helps to adhere to interventions to reduce pressure injury risk.
12. Remove gloves and discard in appropriate receptacle. Perform hand hygiene.	Reduces transmission of microorganisms.
13. Assist patient to a comfortable position.	Enhances patient comfort and relaxation.
14. Raise side rails (as appropriate) and lower bed to lowest position	Provides for patient safety and reduces the risk for falls.
15. Place call nurse call system within reach; instruct patient in use.	Assists patient or family member in calling for assistance.
Evaluation	
1. Continually observe patient's skin for areas at risk for tissue damage, noting change in color, appearance, or texture.	Enables you to evaluate success of prevention techniques.
2. Observe tolerance of patient for position change by measuring level of comfort on pain scale.	Position changes sometimes interfere with patient's sleep and rest pattern.
3. Compare subsequent risk-assessment scores and skin assessments.	Provides ongoing comparison of patient's risk level to facilitate appropriateness of plan of care.
4. Use Teach-Back: "I want you to understand why we need to assess your skin on an ongoing basis. Tell me in your own words why we will be checking your skin on a regular basis." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
1. Skin becomes mottled, reddened, purplish, or bluish. • Refer patient to wound, ostomy, and continence (WOC) nurse; registered dietitian; clinical nurse specialist (CNS); nurse practitioner (NP); and/or physical therapist as necessary. Reevaluate position changes and bed surface.	
2. Areas under pressure develop persistent discoloration, induration, or temperature changes. • Refer patient to WOC nurse, registered dietitian, CNS, NP, and/or physical therapist as necessary. • Modify patient's positioning and turning schedule.	
Recording and Reporting	
<ul style="list-style-type: none"> Record patient's risk score and skin assessments, turning intervals, pressure-redistribution support surface, care of medical devices, and moisture protection interventions in electronic health record (EHR) or chart. Report need for additional consultations (if indicated) for high-risk patient. Document your evaluation of patient learning. 	
Home Care Considerations	
<ul style="list-style-type: none"> Instruct family caregiver in use of the 30-degree lateral position and how to assist patient into the position. This position prolongs the time between position changes, resulting in fewer sleep interruptions for patient and caregiver. Individualize pressure-redistribution maneuvers for patient needs and home environment. Provide family with community resources for hospital equipment. 	

Skill 48.2. Treating Pressure injuries and Wounds • Delegation and Collaboration

The skill of treating pressure injuries and wounds cannot be delegated to assistive personnel (AP). Instruct the AP to:

- Report immediately to the nurse pain, fever, or any wound drainage.
- Report immediately to the nurse any change in skin integrity.
- Report any potential contamination to existing dressing, such as patient incontinence or dislodgement of the dressing.

Equipment

- Clean gloves
- Sterile gloves (*optional*)
- Goggles, mask, and cover gown (if splash is a risk)
- Biohazard bag for dressing disposal
- Wound-measuring device
- Cotton-tipped applicators
- Normal saline or cleansing agent (as ordered)
- Topical agent or solution (as ordered)
- Dressings
- Hypoallergenic tape if needed
- Irrigating syringe (*optional*)

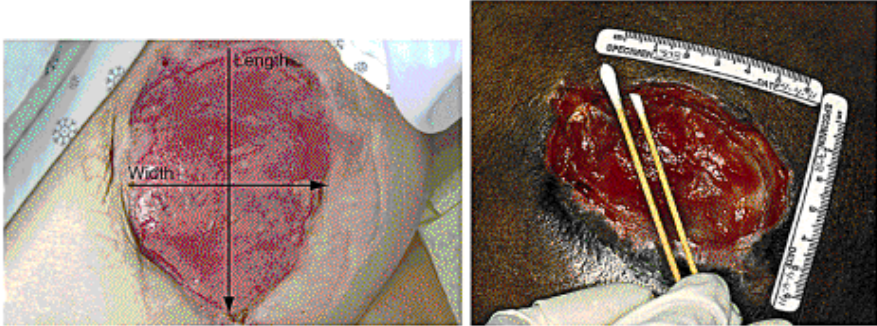

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review medical orders for type of dressing. Review previous nurses' notes in electronic health record (EHR) or chart for type of dressing applied.	Ensures administration of proper medication and treatment.
CLINICAL DECISION: Verify that the order is consistent with established wound care guidelines and outcomes for a patient. If the order is inconsistent with guidelines or varies from the identified outcome for a patient, review with the health care team.	
3. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures patient/family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
4. Assess patient's level of comfort on pain scale of 0 to 10. If patient is in pain, determine whether prn pain medication has been ordered and administer 30 minutes before dressing change.	Dressing change should not be traumatic for patient; evaluate wound pain before, during, and after wound-care management (Hopf et al, 2016).
5. Determine whether patient has allergies to topical agents.	Topical agents could contain elements that cause localized skin reactions.
6. Close room door or bedside curtains.	Provides privacy.
7. Position patient to allow dressing removal and position biohazard bag for dressing disposal. Note: This step can also be done during implementation, just before dressing change.	Provides an accessible area for dressing change. Proper disposal of old dressing promotes proper handling of contaminated waste.
8. Perform hand hygiene and apply clean gloves. Remove and discard old dressing.	Reduces transmission of microorganisms and prevents accidental exposure to body fluids.
9. Assess patient's wounds using wound parameters and continue ongoing wound assessment per agency policy. Note: This may be done during wound care procedure.	Provides baseline or comparison with previous dressing changes for condition of wound and effectiveness of wound care (WOCN, 2016).
a. Wound location: Describe body site where wound is located.	
b. Stage/classification of wound: Describe extent of tissue destruction using wound classification for surgical and traumatic wounds and stage of a pressure injury	Staging is way to assess a pressure injury based on depth of tissue destruction (Eidsberg et al., 2016). Classification of a wound provides guideline for type of dressing to apply.
c. Wound size: Measure length, width, and depth of wound per agency protocol. Use disposable measuring guide for length and width. Use cotton-tipped applicator to assess depth (see illustration).	Injury size changes as healing progresses; therefore, longest and widest areas of wound change over time. Measuring width and length by measuring consistent areas provides consistent measurement (Nix, 2016).
d. Presence of undermining, sinus tracts, or tunnels: Use sterile cotton-tipped applicator to measure depth and, if needed, a gloved finger to examine wound edges.	Wound depth determines amount of tissue loss.
e. Condition of wound bed: Describe type and percentage of tissue in wound bed. Approximate percentage of each type of tissue in wound provides critical information on progress of wound healing and choice of dressing	Approximate percentage of each type of wound provides critical information of progress of wound healing and choice of dressing. Wound with high percentage of black tissue requires debridement; yellow tissue or slough tissue may indicate presence of infection or colonization; and granulation tissue indicates that wound is moving toward healing.
f. Volume of exudate: Describe amount, characteristics, odor, and color.	Amount and type of drainage or exudate may indicate type and frequency of dressing changes (Bates-Jensen, 2016).
 <p>STEP 10 Measuring wound width, length, and undermining of skin. <small>Left image from Bryant RA, Nix DP, editors: Acute and chronic wounds: current management concepts ed 3, St Louis, 2016, Elsevier.</small></p>	

Table Continued

Step	Rationale
g. Condition of periwound skin: Examine skin for breaks, dryness, maceration, and presence of rash, swelling, redness, or warmth. Modify assessment based on patient's skin color (see Box 48.2).	Impaired skin condition at edge of a wound or pressure injury indicates progressive tissue damage. Maceration on periwound skin shows need to alter choice of wound dressing.
h. Wound edges: Examine edges for condition of tissue.	Provides information regarding epithelialization, chronicity, and etiology.
10. Remove gloves and discard in appropriate receptacle. Perform hand hygiene.	Reduces transmission of microorganisms.
CLINICAL DECISION: Repeated hand hygiene will be necessary as you assess other wounds or pressure areas. Different organisms contaminate different wounds.	
11. Assess for factors affecting wound healing: poor perfusion, immunosuppression, or preexisting infection.	Factors affect treatment and wound healing.
12. Assess patient's nutritional status (see Chapter 45). Clinically significant malnutrition is present if (1) serum albumin level is less than 3.5 g/dL, (2) lymphocyte count is less than 1800/mm³, or (3) body weight decreases more than 15% (WOCN, 2016).	Delayed wound healing occurs in poorly nourished patients.
CLINICAL DECISION: When you suspect malnutrition, obtain a nutritional consultation to modify patient's diet to promote wound healing.	
13. Assess patient's/family caregiver's understanding of wound condition, treatment plan, and complications of planned treatments.	Patient/family caregiver need to partner with health care providers to provide wound care at home as needed to prevent further skin breakdown.
Planning	
1. Provide privacy by pulling the curtain around the patient, and position the patient so that only the area currently being examined is exposed; use sheet to cover rest of the body. Instruct patient not to touch wound or sterile supplies.	Providing privacy and preparing equipment before the procedure helps to ensure a clean and distraction-free area for organizing procedure-related equipment. Prevents accidental contamination of sterile supplies.
2. Explain procedure to patient before starting.	Reduces anxiety and provides opportunity for patient/family caregiver education.
3. Organize and prepare the following equipment and supplies.	
a. Normal saline or other wound-cleaning agent in sterile solution container	Cleanses injury surface before applying topical agents and new dressing.
b. Prescribed topical agent	
(1) Enzyme debriding agents. (Follow specific manufacturer directions for frequency of application.)	Enzymes debride dead tissue to clean injury surface. Enzymes are not applied to healthy tissue.
(2) Topical antibiotics	Topical antibiotics decrease bioburden of wound and should be considered for use if no healing is noted after 2 to 4 weeks of optimal care (WOCN, 2016).
c. Select appropriate dressing based on pressure injury characteristics, principles of wound management, and patient care setting. Dressing options include (see Table 48.9):	Dressing should maintain moist environment for wound while keeping surrounding skin dry (Bryant & Nix, 2016b).
(1) Gauze—Apply as moist dressing, as a dry cover dressing over clean surgical wound, as a dry cover dressing when using enzymes or topical antibiotics, or as a means to deliver solution to wound.	Gauze delivers moisture to wound and is absorbent.
(2) Transparent film dressing—Apply over superficial injuries with minimal or no exudate and skin subjected to friction.	Maintains moist environment and offers intact skin protection.
(3) Hydrocolloid dressing	Maintains moist environment to facilitate wound healing while protecting wound base.
(4) Hydrogel—available in sheet or in tube	Maintains moist environment to facilitate wound healing.
(5) Calcium alginate	Highly absorbent of wound exudate in heavily draining wounds.
(6) Foam dressings	Protective and prevents wound dehydration; also absorbs moderate-to-large amounts of drainage.
(7) Silver-impregnated dressings/gels	Controls bacterial burden in wound.
(8) Wound fillers	Fills shallow wounds, hydrates, and absorbs.
d. Hypoallergenic tape or adhesive dressing	Used to secure nonadherent dressing. Prevents skin irritation and tearing.
Implementation	
1. Assemble supplies at bedside.	Ensures organized procedure.
2. Perform hand hygiene and apply clean gloves. Open sterile packages and topical solution containers (see Chapter 28). Keep dressings sterile. Wear goggles, mask, and moisture-proof cover gown if potential for contamination from spray exists when cleaning wound.	Reduces transmission of microorganisms.
3. Remove bed linen and arrange patient's gown to expose wound and surrounding skin. Keep remaining body parts draped.	Prevents unnecessary exposure of body parts.

Table Continued

Step	Rationale
4. Moisten gauze in cleaning solution. Clean wound thoroughly with normal saline or prescribed wound-cleaning agent from least contaminated to most contaminated area. For deep injuries or wounds, clean with saline delivered with irrigating syringe as ordered (see Skill 48.5). Dry skin around wound thoroughly using clean gauze. Remove gloves and discard.	Cleaning wound removes wound exudate and/or dressing residue and reduces surface bacteria.
5. Perform hand hygiene and apply clean or sterile gloves. (Refer to agency policy.)	Maintains aseptic technique during cleaning, measuring, and applying dressings.
6. Apply topical agents to wound using cotton-tipped applicators or gauze as ordered:	
a. Enzymes	Follow manufacturer directions for method and frequency of application. Be aware of which solutions inactivate enzymes and avoid their use in wound cleaning.
(1) Apply small amount of enzyme debridement ointment directly to necrotic areas in the pressure injury. Do not apply enzyme to surrounding healthy skin.	Thin layer absorbs and acts more effectively than thick layer. Excess medication irritates surrounding healthy skin (Bryant and Nix, 2016b). Proper distribution of ointment ensures effective action.
CLINICAL DECISION: If using an enzymatic debriding agent, do not use wound-cleaning agents with metals.	
(2) Place moist gauze dressing directly over wound followed by a dry dressing. Follow specific manufacturer recommendation for type of dressing material to use to cover a pressure injury when using enzymes. Tape dressing in place.	Protects wound and prevents removal of ointment during turning or repositioning.
b. Antibacterials (e.g., bacitracin, metronidazole, and silver sulfadiazine). Apply evenly over wound surface.	Reduces bacterial growth.
7. Apply prescribed wound dressing:	
a. Apply gauze dressing as described in Skill 48.3	Gauze is applied dry or as a damp-to-dry dressing, common for poorly healing surgical wounds and traumatic wounds.
b. Hydrogel:	Hydrogel dressings are designed to hydrate and bring moisture to wound (Bryant and Nix, 2016b).
(1) Cover surface of wound with thick layer of amorphous hydrogel or cut sheet to fit wound base.	Provides moist environment to facilitate wound healing.
(2) Apply secondary dressing such as dry gauze; tape in place.	Holds hydrogel against wound surface because amorphous hydrogel (in tube) or sheet form does not adhere to wound and requires secondary dressing to hold it in place.
(3) If using impregnated gauze, pack loosely into wound; cover with secondary gauze dressing and tape.	A loosely packed dressing delivers gel to wound base and allows any wound debris to be trapped in gauze.
c. Calcium alginate:	Alginate dressings absorb serous fluid or exudate, forming a nonadhesive hydrophilic gel, which conforms to shape of wound (Bryant and Nix, 2016b). Use in heavily draining wounds.
(1) Lightly pack wound with alginate using sterile cotton-tipped applicator or gloved finger.	The dressing swells and increases in size; tight packing can compromise blood flow to the tissues.
(2) Apply secondary dressing and tape in place.	
d. Transparent film dressing:	
(1) Be sure skin around wound is thoroughly dry.	Moisture prevents transparent dressing from adhering.
(2) Remove paper backing, taking care not to allow adhesive areas to touch one another. Do not stretch a film dressing and avoid wrinkles.	Ensures smooth application.
(3) Place film smoothly over wound and use your fingers to smooth and adhere dressing over skin.	Ensures occlusive application.
(4) Label dressing with date, your initials, and time of dressing change.	Provides guideline for timing of next dressing change.
CLINICAL DECISION: Use transparent dressings for minor cuts or abrasions and for autolytic debridement of noninfected superficial pressure injuries. A hydrocolloid dressing protects skin from friction and/or provides moisture to a wound. Some brands have custom shapes available for specific anatomical parts such as heels, elbows, and sacrum.	
e. Hydrocolloid dressing:	
(1) Select proper size wafer, allowing dressing to extend onto intact periwound skin at least 2.5 cm (1 inch). Do not stretch dressing and avoid wrinkles.	Dressing prevents shear and friction from loosening edges and circumvents need for tape along dressing borders (Bryant and Nix, 2016b).
(2) For deep wounds, apply hydrocolloid granules, impregnated gauze, or paste before the wafer.	Functions as filler material to ensure contact with all wound surfaces. Cushions wound for pain reduction and protection.

Table Continued

Step	Rationale
(3) Remove paper backing from adhesive side and place over wound. Do not stretch, and avoid wrinkles or tenting. Hold dressing in place for 30 to 60 seconds after application.	Molds dressing at body temperature (Bryant and Nix, 2016b).
(4) If cut from large piece of wafer, tape edges with nonallergenic tape.	Avoids rolling of edges of dressing or adherence to clothing.
f. Foam dressing:	
(1) Refer to manufacturer guidelines for removal and application characteristics of specific foam dressing brand.	Foam dressings collect moderate to heavy wound exudate; however, some contain an antimicrobial substance to reduce risk for bacterial colonization in wounds.
(2) Apply a skin barrier wipe to surrounding skin that will come in contact with the thin foam dressing adhesive.	Protects skin from maceration or irritation of adhesive.
(3) Cut foam sheet to extend 2.5 cm (1 inch) out onto intact periwound skin. (Verify which side of foam dressing should be placed toward wound bed and which side should face away from it; see product instructions)	Ensures proper absorption and keeps wound exudate away from wound (Bryant and Nix, 2016b).
(4) Cover with secondary dressing as needed.	Protects dressing.
8. Reposition patient comfortably off pressure injury.	Prevents pressure to injury.
9. Remove and dispose of gloves. Dispose of soiled supplies in appropriate receptacle. Perform hand hygiene.	Reduces transmission of microorganisms.
10. Assist patient to comfortable position.	Enhances patient comfort and relaxation.
11. Raise side rails (as appropriate) and lower bed to lowest position	Provides for patient safety and reduces the risk for falls.
12. Place nurse call system within reach; instruct patient in use.	Assists patient or family member in calling for assistance.
Evaluation	
1. Observe skin surrounding injury for inflammation, edema, and tenderness.	Determines progress of wound healing.
2. Compare observations of the wound with previous assessments : observing for drainage, wound size, foul odor, and tissue necrosis. Monitor patient for signs and symptoms of infection: fever and elevated white blood cell (WBC) count.	Injuries can become infected.
3. Compare subsequent injury measurements, using one of the scales designed to measure wound healing such as PUSH Tool or BWAT Assessment.	Allows comparison of serial measurements to evaluate wound healing. Provides standard method of data collection that demonstrates injury progress or lack thereof.
4. Use Teach-Back: "I want to be sure that you understand why we measure and assess your pressure injury on an ongoing basis. Tell me why we measure the injury and look at the tissue type and surrounding skin." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
1. Skin surrounding injury becomes macerated. • Reduce exposure of surrounding skin to topical agents and moisture. • Select dressing that has increased moisture-absorbing capacity.	
2. Wound becomes deeper with increased drainage and/or development of necrotic tissue. Cover with secondary dressing as needed. • Review current wound-care management. • Consult with interprofessional team regarding changes in wound-care regimen. • Obtain wound cultures.	
3. Pressure injury extends beyond original margins. • Monitor for systemic signs and symptoms of poor wound healing such as abnormal laboratory results (WBC count, levels of hemoglobin/hematocrit, serum albumin, serum prealbumin, total proteins), weight loss, and fluid imbalances. • Assess and revise current turning schedule. • Consider alternate pressure-redistribution devices.	
Recording and Reporting	
<ul style="list-style-type: none"> Record appearance and condition of the wound/pressure injury, type of topical agent or dressing used, presence of pain and how treated, and patient's response in electronic health record (EHR) or chart. Document your evaluation of patient learning. Report any deterioration in wound appearance. Describe the location of the wound; type and percentage of wound tissue; presence or absence of wound drainage, odor; type and quantity of dressings used and the location of the dressings (for the next dressing change); and patient's response. 	
Home Care Considerations	
<ul style="list-style-type: none"> Clean dressings are often used in the home setting. Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations for contaminated waste. Teach patient and family caregiver about the signs of wound infection. 	

Skill 48.3. Applying Dry and Moist Dressings

Delegation and Collaboration

The skill of applying dry and damp-to-dry dressings can be delegated to assistive personnel (AP) if the wound is chronic (see agency policy and Nurse Practice Act). However, the nurse must first assess the wound and is responsible for the care of acute new wounds, wound care requiring sterile technique, and evaluation of wound healing. Direct the AP about:

- Any unique modifications of the dressing change such as the need for use of special tape or taping techniques to secure the dressing.
- Reporting pain, fever, bleeding, or wound drainage to the nurse immediately.
- Reporting any potential contamination to existing dressing (e.g., patient incontinence or other body fluids, a dressing that becomes dislodged).

Equipment

- Clean and sterile gloves
- Sterile dressing set including scissors and forceps (check agency policy)
- Sterile drape (*optional*)
- Necessary dressings: fine-mesh gauze, 4 × 4-inch gauze, abdominal pads (ABDs)
- Sterile basin (*optional*)
- Antiseptic ointment (as prescribed)
- Wound cleanser (as prescribed)
- Sterile normal saline (or prescribed solution)
- Débriding gel as ordered
- Tape (include nonallergenic tape as necessary), Montgomery ties, or bandages as needed
- Skin barrier (*optional* if using Montgomery ties)
- Measuring device: cotton-tipped applicator, measuring guide, camera
- Adhesive remover, scissors, or hair clipper (*optional*)
- Protective waterproof underpad
- Biohazard bag

- Personal protective equipment (PPE) (i.e., gown, goggles, mask) if needed
- Additional lighting if needed (e.g., flashlight, treatment light)

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures patient/family caregiver have the capacity to obtain, communicate, and understand basic health information (CDC, 2019).
3. Assess patient for allergies, especially to antiseptics, tape, or latex.	Reduces risk for localized or systemic allergic reactions to these supplies.
4. Ask patient to rate level of pain using a pain scale of 0 to 10 and to assess character of pain. Administer prescribed analgesic as needed 30 minutes before dressing change.	Superficial wounds with multiple exposed nerves may be intensely painful, whereas deeper wounds with destruction of dermis should be less painful (Krasner, 2016). A comfortable patient is less likely to move suddenly, causing contamination to wound or supplies. Serves as baseline to measure response to dressing therapy.
5. Review medical orders for type of dressing. Review previous nurses' notes in electronic health record (EHR) or chart.	Indicates types of dressing supplies needed.
6. Review medical record to identify patient's risk for wound-healing problems, including aging, premature infant, obesity, diabetes mellitus, circulation disorders, nutritional deficit, immunosuppression, radiation therapy, high levels of stress, and use of steroids.	Physiological changes resulting from aging, chronic illness, poor nutrition, medications that affect wound healing, and cancer treatments have potential to affect wound healing (Doughty and Sparks, 2016).
7. Perform hand hygiene and apply gloves as needed.	Reduces transmission of microorganisms.
8. Assess condition of skin around wound and existing dressing (see Skill 48.2). Remove and dispose of gloves if worn and perform hand hygiene.	Provides baseline or comparison with previous dressing changes for condition of skin around wound. Helps to plan for proper dressing type and securement of supplies needed and for whether help is needed during dressing procedure.
9. Assess need, readiness, and willingness for patient or family caregiver to participate in dressing wound.	Identifies areas for patient education to prepare patient or family caregiver if dressing must be changed at home.
Planning	
1. Close room door or bedside curtains. Gather all necessary supplies.	Provides privacy and ensures organized procedure.
2. Position patient comfortably and drape to expose only wound site. Instruct patient not to touch wound or sterile supplies.	Draping provides access to wound while minimizing exposure. Dressing supplies become contaminated when touched by patient's hand.
3. Organize workspace at bedside.	Facilitates a smooth and organized dressing change.

Table Continued

Step	Rationale
4. Place disposable biohazard bag within reach of work area (see illustration). Perform hand hygiene and apply clean gloves. Apply gown, goggles, and mask if risk for splashing exists.	Ensures easy disposal of soiled dressings. Use of PPE reduces transmission of microorganisms.
5. Explain procedure to patient and/or family caregiver.	Decreases patient's anxiety.
Implementation	
1. Perform hand hygiene and gently remove tape, bandages, or ties from existing dressing. Use nondominant hand to support dressing and with your dominant hand pull tape parallel to skin and toward dressing. If dressing is over hairy area, remove in direction of hair growth. Get patient permission to clip or shave area (check agency policy). Remove any adhesive from skin.	Pulling tape toward dressing reduces stress on suture line or wound edges, irritation, and discomfort.
2. With gloved hand or forceps remove dressing one layer at a time, observing appearance and drainage of dressing. Carefully remove outer secondary dressing first; then remove inner primary dressing that is in contact with wound bed. If drains are present, slowly and carefully remove dressings (see Fig. 48.10) and avoid tension on any drainage devices. Keep soiled undersurface from patient's sight.	Purpose of primary dressing is to remove necrotic tissue and exudate. Appearance of drainage may be upsetting to patient. Avoids accidental removal of drain.
a. If bottom layer of damp-to-dry dressing adheres to wound and debridement of tissue is the goal, gently free dressing and alert patient of discomfort.	Damp-to-dry dressing should debride wound (WOCN, 2016; Wysocki, 2016).
b. If dry dressing adheres to wound that is not to be debrided, moisten with normal saline, wait 1 to 2 minutes, and remove.	Prevents injury to wound surface and periwound during dressing removal.
3. Inspect wound and periwound for appearance, color, size (length, width, and depth), drainage, edema, presence and condition of drains, approximation (wound edges are together), granulation tissue, or odor. Use measuring guide or ruler to measure size of wound (see Skill 48.2). Gently palpate wound edges for boggy or patient report of increased pain.	Assesses wound and periwound condition. Indicates status of healing.
4. Fold dressings with drainage contained inside and remove gloves inside out. With small dressings remove gloves inside out over dressing (see illustrations). Dispose of gloves and soiled dressing according to agency policy. Cover wound lightly with sterile gauze pad and perform hand hygiene.	Contains soiled dressings, prevents contact of nurse's hands with drainage, and reduces cross-contamination and transmission of microorganisms.

STEP 4 Disposable waterproof bag placed near dressing site.

STEP 4 A and B, dispose of soiled dressings by placing in gloved hand and pulling glove off over dressing and then off hand.

Step	Rationale
	Table Continued

Step	Rationale
5. Describe appearance of wound and any indicators of wound healing to patient.	Wounds may be unsettling and frightening to patients. It helps patient to know that wound appearance is as expected and whether healing is taking place.
6. Create sterile field with sterile dressing tray or individually wrapped sterile supplies on over-bed table (see Chapter 28). Pour any prescribed solution into sterile basin.	Sterile dressings remain sterile while on or within sterile surface. Preparation of all supplies before dressing change prevents break in technique during dressing change.
7. Clean wound	
a. Perform hand hygiene and apply clean gloves. Use gauze or cotton ball moistened in saline or antiseptic swab (per health care provider order) for each cleaning stroke, or spray wound surface with wound cleaner.	Prevents transfer of organisms from previously cleaned area.
b. Clean from least to most contaminated area (see Fig. 48.21).	Cleaning in this direction prevents introduction of organisms into wound.
c. Clean around any drain (if present), using circular strokes starting near drain and moving outward and away from insertion site (see Fig. 48.22).	Correct aseptic technique in cleaning prevents contamination.
8. Use sterile dry gauze to blot wound bed in same manner as in Step 7.	Drying reduces excess moisture, which could eventually harbor microorganisms.
9. Apply antiseptic ointment (if ordered) with sterile cotton-tipped applicator or gauze, using same technique to apply as for cleaning. Remove and dispose of gloves. Perform hand hygiene.	Helps reduce growth of microorganisms.
10. Apply dressing (see agency policy):	
a. Dry sterile dressing:	
CLINICAL DECISION: Dry dressings are inappropriate for debriding wounds. In the presence of drainage, a dry dressing may adhere to the wound bed and surrounding tissue, causing pain and trauma on removal. Dry dressings have the disadvantage of moisture evaporating quickly, which can cause a dressing to dry out. As a result, frequent dressing changes are usually needed, and there is an increase in infection rate when compared with semi-occlusive dressings (Bryant and Nix, 2016b).	
(1) Apply clean gloves (see agency policy).	Some agencies or condition of wounds may require sterile gloves.
(2) Apply loose woven gauze as contact layer (see illustration).	Promotes proper absorption of drainage.
(3) If drain is present, apply precut, split 4 × 4-inch gauze around drain.	Secures drain and promotes drainage absorption at site.
(4) Apply additional layers of gauze as needed.	Ensures proper coverage and optimal absorption.
(5) Apply thicker woven pad (e.g., Surgipad, abdominal [ABD] pad) (see illustration).	This dressing is used on postoperative wounds when there is excessive drainage.
b. A damp-to-dry dressing.	A damp-to-dry dressing is a moist primary dressing that brings moisture to the wound surface. The moistened gauze increases the absorptive ability of the dressing to collect exudate and wound debris while providing the wound base with moisture to facilitate healing.
(1) Apply sterile gloves (see agency policy).	Reduces transmission of infection.
(2) Place fine-mesh or loose 4 × 4-inch gauze in container of prescribed sterile solution. Wring out excess solution.	Damp gauze absorbs drainage and, when allowed to dry, traps debris.
 <p>STEP 18A(2) Placing dry gauze dressing over simple wound.</p>	 <p>STEP 18A(5) Placing abdominal pad over gauze dressing.</p>

Table Continued

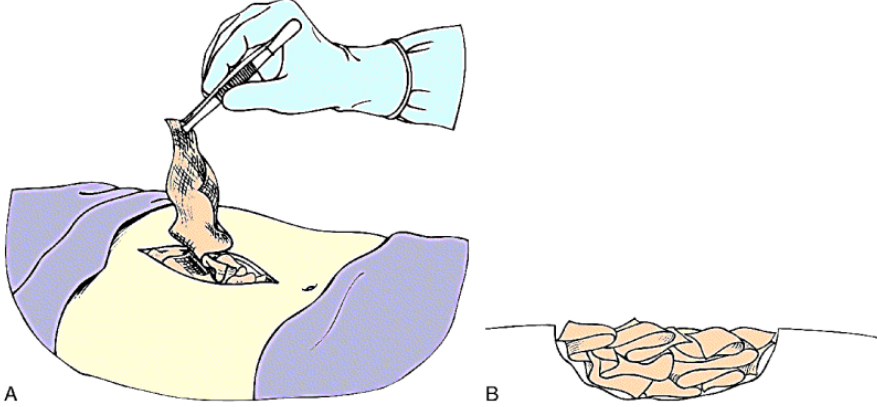

Step	Rationale
CLINICAL DECISION: If using "packing strips," use sterile scissors to cut the amount of dressing that you will use to pack the wound. Do not let the packing strip touch the side of the bottle. Place packing strip in container of prescribed sterile solution. Wring out excess solution.	
(3) Apply damp fine-mesh or open-weave gauze as single layer directly onto wound surface. If wound is deep, gently pack gauze into wound with sterile gloved hand or forceps until all wound surfaces are in contact with moist gauze, including dead spaces from sinus tracts, tunnels, and undermining (see illustration A). Be sure that gauze does not touch periwound skin (see illustration B).	Inner gauze should be damp, not dripping wet, to absorb drainage and adhere to debris. When packing a wound, gauze should conform to base and side of wound (Bryant and Nix, 2016b). Wound is loosely packed to facilitate wicking of drainage into absorbent outer layer of dressing. Moisture that escapes dressing often macerates the periwound area.
CLINICAL DECISION: Be sure to count how many pieces of gauze are packed in the wound, especially deep wounds. This ensures that all gauze from previous dressing change is removed from the wound.	
CLINICAL DECISION: When packing the wound, do not overpack or underpack (Bryant and Nix, 2016b). Packing should fill the wound but should not be above the level of the skin.	
(4) Apply dry sterile 4 × 4-inch gauze over moist gauze.	Dry layer pulls moisture from wound.
(5) Cover with ABD pad, Surgipad, or gauze.	Protects wound from entrance of microorganisms.
11. Secure dressing.	
a. Tape: Apply tape 2.5 to 5 cm (1 to 2 inches) beyond dressing. Use nonallergenic tape when necessary.	Supports wound and ensures placement and stability of dressing.
b. Montgomery ties (see Fig. 48.20).	Prevents skin irritation. Ties allow for repeated dressing changes without removal of tape.
(1) Be sure that skin is clean. Application of skin barrier is recommended.	Skin barrier (a hydrocolloid) protects intact skin from stretch and tension of adhesive tape.
(2) Expose adhesive surface of tape ends.	
 <p data-bbox="354 1264 873 1281"> STEP 10B(3) A, Packing wound with fine-mesh gauze. B, Cross-section of deep wound packed loosely with gauze roll. </p>	

Table Continued

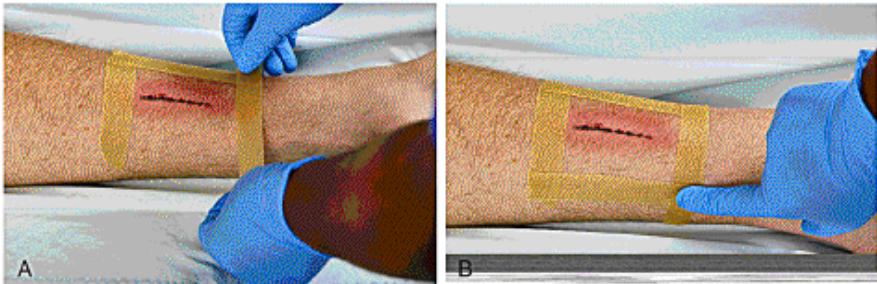

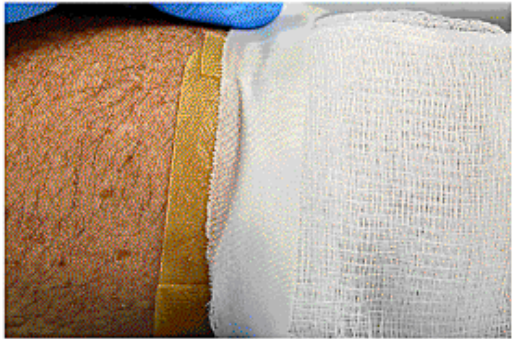

Step	Rationale
(3) Place ties on opposite sides of dressing over skin or skin barrier.	
(4) Secure dressing by lacing ties across dressing snugly enough to hold it secure but without placing pressure on skin.	
c. For protective window:	A protective window is an alternative to Montgomery ties for smaller wounds. There is less skin irritation by placing tape on window strips.
(1) Cut strip of a hydrocolloid pad into 1-cm (½-inch) strips.	
(2) Use skin barrier to wipe areas of skin where strips will be applied.	
(3) Apply hydrocolloid dressing strips to frame a “window” around the wound using four strips, one on each side, one on the top, and one on the bottom of the dressing material (see illustrations).	
(4) Apply dressing; secure tape ends to adhesive strips (see illustration).	
d. For dressing extremity, secure with roller gauze (see illustration) or elastic net.	Roller gauze conforms to contour of foot or hand.
12. Dispose of all dressing supplies. Remove cover gown and goggles; remove gloves inside out; dispose of them according to agency policy. Perform hand hygiene.	Reduces transmission of microorganisms. Clean environment enhances patient comfort.
13. Label tape over dressing with your initials and date dressing is changed.	Provides timeline for when next dressing change is to be scheduled.
14. Help patient to comfortable position.	Promotes patient’s sense of well-being.
15. Be sure nurse call system is in an accessible location within patient’s reach.	Ensures patient can call for assistance if needed.
16. Raise side rails (as appropriate) and lower bed to lowest position.	Ensures patient safety.
Evaluation	
1. Compare observations of the wound with previous assessment and observe appearance of wound for healing: measure size of wound; observe amount, color, and type of drainage and periwound erythema or swelling.	Determines rate of healing.
2. Ask patient to rate pain using a scale of 0 to 10.	Increased pain is often indication of wound complications such as infection or result of dressing pulling tissue.
3. Inspect condition of dressing at least every shift.	Determines status of wound drainage.
 <p>STEP 110(B) Apply adhesive strips to frame a “window” around wound using four strips.</p>	
 <p>STEP 110(C) Apply dressing; secure tape ends to adhesive strips.</p>	
 <p>STEP 110 Wrap roller gauze around extremity to secure dressing.</p>	

Table Continued

Step	Rationale
4. Use Teach-Back: "I want to be sure I explained why and how often you need to continue these dressing changes when you go home tomorrow. Tell me why it is important to change your dressing and how often you will do this." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
<p>1. Wound appears inflamed and tender, drainage is evident, and/or odor is present.</p> <ul style="list-style-type: none"> • Monitor patient for signs of infection (e.g., fever, increased white blood cell count). • Notify health care provider. • Obtain wound cultures as ordered. • If there is yellow, tan, or brown necrotic tissue, notify health care provider to determine need for debridement (see Table 48.2). 	
<p>2. Wound bleeds during dressing change.</p> <ul style="list-style-type: none"> • Observe color and amount of bloody drainage. If excessive, may need to apply direct dressing. • Inspect area along dressing and directly underneath patient to determine amount of bleeding. • Obtain vital signs as needed. • Notify health care provider. 	
<p>3. Patient reports sensation that "something has given way under the dressing."</p> <ul style="list-style-type: none"> • Observe wound for increased drainage or dehiscence (partial or total separation of wound layers) or evisceration (total separation of wound layers and protrusion of viscera through wound opening). • If dehiscence or evisceration occurs, protect wound. Cover with sterile saline moistened dressing. • If evisceration, do not move patient. Transfer patient to surgery in patient's bed. • Instruct patient to lie still. • Stay with patient to monitor vital signs. • Notify health care provider. 	
Recording and Reporting	
<ul style="list-style-type: none"> • Record size and appearance of wound, characteristics of drainage, presence of necrotic tissue, type of dressings applied, response to dressing change, and level of comfort in electronic health record (EHR) or chart. • Document your evaluation of patient learning. • Report any unexpected appearance of wound drainage or bright red bleeding. • Report any change in wound integrity (e.g., dehiscence or evisceration). 	
Home Care Considerations	
<ul style="list-style-type: none"> • More expensive specialty dressings are sometimes used because they decrease the frequency of dressing changes. • Clean dressings may also be used in the home setting. • Patients need to dispose of contaminated dressings in the home in a manner consistent with local regulations. • Be sure patient has a family caregiver able to assist with and/or apply dressing, and instruct caregiver on dressing procedure, signs of infection, and when to notify physician. 	

Skill 48.4. Implementation of Negative-Pressure Wound Therapy (NPWT)

Delegation and Collaboration

The skill of NPWT cannot be delegated to assistive personnel (AP). Direct the AP to:

- Use caution in positioning or turning patient to avoid tubing displacement.
- Report any change in dressing shape or integrity to the nurse.
- Report any change in patient's temperature or comfort level to the nurse.
- Report any wound fluid leakage around the edges of the adhesive drape.

Equipment

- NPWT unit (requires health care provider's order)
- NPWT dressing (gauze or foam, depending on manufacturer's recommendations; transparent dressing, adhesive drape)
- NPWT suction device
- Supplies for irrigation (see Skill 48.5)
- Tubing for connection between NPWT unit and NPWT dressing
- 3 pairs gloves, clean and sterile
- Sterile scissors
- Skin preparation/skin barrier protectant/hydrocolloid dressing/skin barrier
- Personal protective equipment (PPE): gown, mask, and goggles if splashing is a risk
- Waterproof, disposable trash biohazard bag

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review health care provider's orders for frequency of dressing change, amount of negative pressure, type of foam or gauze to use, and pressure cycle (intermittent or continuous).	Determines frequency of dressing change, negative-pressure setting, and special instructions. Health care provider's order is also necessary for reimbursement.
3. Review medical record for signs and symptoms related to condition of patient's wound.	Provides baseline to compare your findings with previous dressing change assessments and reflects wound-healing progress.
4. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures that patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
5. Assess patient's level of comfort on pain scale of 0 to 10.	Serves as baseline to measure patient's level of comfort during and after wound therapy
6. Perform hand hygiene. Apply clean gloves. Assess condition of wound and status of NPWT dressing (see Skill 48.2). Remove and dispose of gloves. Perform hand hygiene.	Provides information regarding condition of skin around wound and existing dressing, presence of complications, and proper type of supplies and help needed.
7. Assess patient's and family caregiver's knowledge of purpose of dressing and whether they will participate in dressing wound.	Identifies patient's learning needs. Prepares patient and family caregivers if dressing will need to be changed at home.
Planning	
1. Close room door or bed curtains. Position the patient so that only the area currently being examined is exposed; use sheet to cover rest of the body.	Provides privacy and comfort.
2. Administer prescribed analgesic as needed 30 minutes before dressing change.	Comfortable patient will be less likely to move suddenly, causing contamination to wound or supplies.
3. Organize dressing supplies as bedside.	Facilitates a smooth and organized procedure.
4. Explain procedure to patient and family caregiver, instructing not to touch wound or sterile supplies.	Relieves anxiety and promotes understanding of healing process. Prevents contamination of sterile supplies.
Implementation	
1. Cuff top of disposable waterproof biohazard bag and place within reach of work area.	Cuff prevents accidental contamination of top of outer bag.
2. Perform hand hygiene and apply clean gloves. If risk for spray exists, apply protective gown, goggles, and mask.	Reduces transmission of microorganisms from soiled dressings to nurse's hands.
3. Follow manufacturer directions for removal and replacement because each NPWT unit varies slightly with approach. Turn off NPWT unit by pushing therapy on/off button.	Deactivates therapy and allows for proper drainage of fluid in drainage tubing.
a. Keeping tube connectors attached to NPWT unit, raise tubing connectors; disconnect tubes from one another and drain fluids into drainage collector.	Prevents backflow of any drainage in tubing back into wound.
b. Before draining, tighten clamp on canister tube and disconnect canister and dressing tubing at connection points.	Prevents drainage from exiting tubing when removed.
4. Remove transparent film by gently stretching, and slowly pull away from skin.	Prevents injury to wound tissue. Protects periwound skin breakdown from transparent adhesive.
5. Remove old dressing one layer at a time and discard in bag. Observe drainage on dressing. Use caution to avoid tension on any drains that are present near the wound or surrounding area. Remove and dispose of gloves.	Determines type and amount of dressings needed for replacement. Prevents accidental removal of drains.
6. Perform hand hygiene and conduct a wound assessment. Observe surface area and tissue type, color, odor, and drainage within wound. Measure length, width, and depth of wound as ordered (see Skill 48.2).	Measurement of wound is necessary to assess wound healing progression and to justify continuation of NPWT for third-party payers (Netsch et al., 2016). Determines condition of wound and need for replacement of dressing.
CLINICAL DECISION: This is a time when a wound-care nurse or physician might debride the wound. Debridement of eschar or slough, if present, should be performed for removal of devitalized tissue to prepare the wound bed (Netsch et al., 2016).	
7. Remove and discard gloves bag and perform hand hygiene. Avoid having patient see old dressing because sight of wound drainage may be upsetting.	Reduces transmission of microorganisms. Lessens patient anxiety during procedure.
8. Clean wound.	
a. Perform hand hygiene and apply sterile or clean gloves, depending on agency policy and wound status.	Cleaning periwound is essential for airtight seal.
b. If ordered, irrigate wound with normal saline or other solution ordered by health care provider (see Skill 48.5). Gently blot periwound with gauze to dry thoroughly.	Irrigation removes wound debris and cleans wound bed. Cleaning and removal of infectious material showed reduced infection and improved healing (Fernandez et al., 2019).

Table Continued

Step	Rationale
CLINICAL DECISION: Health care providers may order wound cultures routinely. However, obtain wound culture when drainage is more copious, looks purulent, or has a foul odor. This may be an indication that NPWT may need to be discontinued.	
9. Apply skin protectant, barrier film, solid skin barrier sheet, or hydrocolloid dressing to periwound skin.	Maintains airtight seal needed for NPWT wound therapy. Protects periwound skin from moisture-associated skin damage (Netsch et al., 2016).
10. Fill any uneven skin surfaces (e.g., creases, scars, and skinfolds) with skin-barrier product (e.g., paste, strip).	Further helps to maintain airtight seal (Netsch et al., 2016).
11. Remove and discard gloves. Perform hand hygiene.	Prevents transmission of microorganisms.
12. Depending on type of wound, apply sterile or new clean gloves (see agency policy).	Fresh sterile wounds require sterile gloves. Chronic wounds require clean technique (WOCN, 2016).
13. Apply NPWT.	
a. Prepare NPWT filler dressing. Consult with wound-care expert for appropriate type.	Filler dressing depends on NPWT used and can include foam or gauze dressings with or without antimicrobials such as silver. Type of dressing may be adjusted based on undermining, tunneling, or sinus tracts present (Netsch et al., 2016).
(1) Measure wound and select appropriate-size dressing.	Black polyurethane (PU) foam has larger pores and is most effective in stimulating granulation tissue and wound contraction. White soft foam is denser with smaller pores and used when growth of granulation tissue needs to be restricted (Netsch et al., 2016).
(2) Using sterile scissors, cut filler gauze dressing or foam to wound size, making sure to fit exact size and shape of wound, including tunnels and undermined areas.	Proper size of dressing maintains negative pressure to entire wound (Netsch et al., 2016).
CLINICAL DECISION: In some instances, an antimicrobial product such as silver-impregnated gauze or topical antibiotic is in order. These products help reduce the bioburden of the wound.	
b. Place filler dressing in wound following manufacturer instructions. Be sure that filler dressing is in contact with entire wound base, margins, and tunneled and undermined areas. Count number of filler dressings, and document in patient's chart.	Maintains negative pressure to entire wound. Edges of dressing must be in direct contact with patient's skin. Dressing count provides the number of filler dressings that should be removed at the next dressing change.
c. Place suction device per manufacturer instructions.	
d. Apply NPWT transparent dressing over foam or gauze filler dressing.	
(1) Trim dressing to cover wound and dressing, so it will extend onto periwound skin approximately 2.5 to 5 cm (1 to 2 inches).	Prepares dressing for appropriate size of the wound.
(2) Apply transparent dressing, keeping it airtight and wrinkle-free (see illustration).	Dressing should be airtight with no wrinkles or tunnels to maintain a negative-pressure environment. A snug and tight application of the dressing must be applied to ensure an airtight seal (Box 48.10).
(3) Secure tubing to transparent film, aligning drainage holes to ensure occlusive seal. Do not apply tension.	Excessive tension may compress foam dressing and impede wound healing. It also produces shear force on periwound area (Netsch et al., 2016).
(4) Secure tubing several centimeters away from dressing, avoiding pressure points.	Drainage tubes over bony pressure prominences can cause medical device-related pressure injuries (Netsch et al., 2016; Pittman et al., 2015).
14. After wound is completely covered, connect tubing from dressing to tubing from canister and NPWT unit and set at ordered suction level.	Intermittent or continuous negative pressure varies from -75 mm Hg to -125 mm Hg, depending on the device and the characteristics of the wound (Netsch et al., 2016; WOCN, 2016).

Step	Rationale
	

STEP 13D2) Foam wound filler; transparent dressing over existing wound.
Courtesy Kinetic Concepts, Inc (KCI), San Antonio, Texas.

Table Continued

Step	Rationale
a. Remove canister from sterile packing and push unit until you hear click. <i>Note: An alarm sounds if canister is not properly engaged.</i>	
b. Connect dressing tubing to canister tubing (follow manufacturers' instructions). Make sure that both clamps are open.	
c. Place on level surface or hang from foot of bed. <i>Note: Unit alarms and deactivates therapy if it is tilted beyond 45 degrees.</i>	
d. Press power button (commonly this is a green-lit button) and set pressure as ordered.	
15. Remove and dispose of gloves. Perform hand hygiene.	Reduces transmission of microorganisms.
16. Inspect NPWT system.	
a. Verify that the system is on. This is different for each type of NPWT unit. For example, on some units the display screen shows "Therapy On." Check agency policy and procedure for specific information.	
b. Verify that all clamps are open and that all tubing is patent.	
c. Examine system to be sure that seal is intact and therapy is working.	Negative pressure is achieved when a tight seal is present (Netsch et al., 2016).
d. If a leak is present, perform hand hygiene and apply gloves. Use strips of transparent dressing to patch areas around edges of wound.	
17. Record initials, date, and time on new dressing.	Provides reference for next dressing change.
18. Discard gloves and dispose of any dressing material. Perform hand hygiene.	Prevents transmission of microorganisms.
19. Help patient to comfortable position. Patients may ambulate with NPWT.	Enhances patient comfort and relaxation.
20. Raise side rails (as appropriate) and lower bed to lowest position.	Provides for patient safety and reduces the risk for falls.
21. Place call nurse call system within reach; instruct patient in use.	Provides patient or family member a resource to call for assistance.

Evaluation	
1. Inspect condition of wound and wound bed on an ongoing basis; note drainage and odor.	Determines status of wound healing.
2. Ask patient to rate pain using scale of 0 to 10.	Determines patient's level of comfort following procedure.
3. Verify airtight dressing seal and correct negative-pressure setting.	Determines effective negative pressure being applied.
4. Measure wound drainage output in canister on regular basis.	Monitors fluid balance and wound drainage.
5. Use Teach-Back: "Before you are discharged, I want to be sure I have explained clearly what your wound should look like as it is healing and the signs of infection. Explain to me what your wound will look like as it begins to heal." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.

Unexpected Outcomes and Related Interventions	
1. Wound appears inflamed and tender, wound hemorrhages, drainage has increased, and odor is present. • Notify health care provider. • Obtain wound culture. • May need to stop NPWT.	
2. Patient reports increase in pain. • Consult with health care provider about changing analgesia. • Instill normal saline to moisten filler dressings to allow loosening from granulation tissue. • Decrease pressure setting. • Change from intermittent to continuous cycling. • Change type of NPWT system.	
3. Negative-pressure seal has broken. • Take preventive measures (Box 48.10).	

Step	Rationale
Recording and Reporting • Record appearance of wound (characteristics of wound bed and drainage), placement of NPWT, negative pressure setting, and patient's response in electronic health record (EHR) or chart. • Report brisk, bright bleeding; evidence of poor wound healing; and possible wound infection to health care provider.	

- Report on location of NPWT, time of dressing change if done, and any interventions, such as reinforcement of dressing.
- Discuss whether the patient or caregiver is participating in changing the NPWT dressing.
- Document your evaluation of patient learning

Home Care Considerations

- Be sure that patient and family members understand the importance of maintaining a seal on the NPWT dressing and that they have been educated on how to seal the dressing and know whom to call if the alarm alerts them to a leak of the system and they are unable to seal.
- Review how to attach the device to a wall outlet to recharge the battery.
- Instruct the patient and family members on the schedule for the NPWT change.

Skill 48.5. Performing Wound Irrigation

Delegation and Collaboration

The skill of wound irrigation cannot be delegated to assistive personnel (AP) unless it is a chronic wound (see agency policy). It is the nurse's responsibility to assess and document wound characteristics. Direct the AP to:

- Notify the nurse when the wound is exposed, so an assessment can be completed.
- Report to the nurse the patient's pain, presence of blood, drainage.

Equipment

- Irrigation/cleansing solution per order (volume 1.5 to 2 times the estimated wound volume)
- Irrigation delivery system (per order), depending on amount of desired pressure: sterile irrigation 35-mL syringe with sterile soft angiocatheter or 19-gauge needle (WOCN, 2016) or handheld shower.
- Personal protective equipment (PPE): sterile gloves, gown, and goggles if splash or spray risk exists
- Waterproof underpad if needed
- Dressing supplies (see Skills 48.2 and 48.3)
- Disposable waterproof biohazard bag
- Wound assessment supplies (see Skill 48.2)

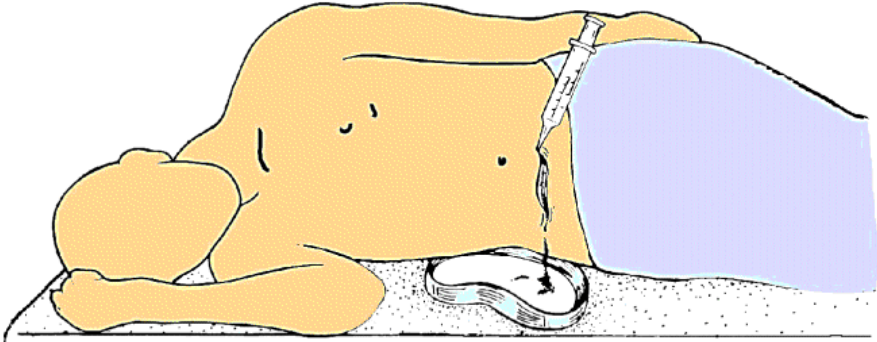

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review health care provider's order for irrigation of open wound and type of solution to be used.	Open-wound irrigation requires medical order, including type of solution(s) to use.
3. Review medical record for signs and symptoms related to patient's open wound.	Provides ongoing data to indicate change in wound status (Nix, 2016).
a. Extent of impairment of skin integrity, including size of wound	
b. Verify number of drains present.	Awareness of drain position facilitates safe dressing removal and determines need for special dressings.
c. Drainage, including amount, color, consistency, and any odor noted	Ongoing data; drainage should decrease in healing wound. When drainage increases, it is often related to infection (Doughty and Sparks et al., 2016).
d. Wound tissue color	Color represents type of tissue present in the wound; red tissue indicates healthy tissue; white, brown, or black tissue is devitalized tissue. Proper selection of wound-care products on basis of wound color facilitates removal of necrotic tissue and promotes new tissue growth (Nix, 2016).
e. Culture reports. Infected wound is colonized with bacteria.	Culture reports identify type of bacteria and proper treatment. Ongoing wound cultures document resolution of infectious process (Stotts, 2016b).
4. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures patient has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
5. Assess patient's level of comfort using pain scale of 0 to 10.	Serves as baseline to measure patient's level of comfort before wound irrigation.
6. Assess patient for history of allergies to antiseptics, solutions, medications, tapes, or dressing material.	Known allergies suggest applying sample of prescribed wound treatment as skin test before flushing wound with large volume of solution or selecting different tape or dressing material.
7. Assess patient's and family caregiver's understanding of need for irrigation and of signs of wound infection.	Determines extent of instruction required.
Planning	
1. Perform hand hygiene and administer prescribed analgesic as needed 30 minutes before dressing change.	Comfortable patient will be less likely to move suddenly, causing contamination of wound or supplies.
2. Gather appropriate supplies for wound irrigation and dressing.	Ensures an organized procedure.
3. Explain procedure to patient and family caregiver, instructing not to touch wound or sterile supplies.	Relieves anxiety and promotes understanding of healing process. Prevents contamination of sterile supplies.
4. Close room door or bedside curtains, perform hand hygiene, and position patient.	Maintains privacy.
a. Position patient comfortably to permit gravitational flow of irrigating solution over wound and into collection receptacle (see illustration).	Directing solution from top to bottom of wound and from cleanest to contaminated area prevents further infection. Position also avoids fluid retention in the wound as the flow of the irrigant moves away from the wound.
 <p>STEP 4A Patient position for wound irrigation.</p>	

Table Continued

Step	Rationale
b. Ensure that irrigant is at room temperature, and position patient so that wound is vertical to collection basin.	Room temperature solution increases comfort and reduces vasoconstriction response in tissues
c. Place padding or extra towel on bed under area where irrigation will take place.	Protects bedding from becoming wet.
Implementation	
1. Perform hand hygiene.	Reduces transmission of microorganisms.
2. Form cuff on waterproof biohazard bag and place near bed.	Cuffing helps to maintain large opening, thereby permitting placement of contaminated dressings without touching bag itself.
3. Apply gown, mask, goggles as indicated; apply clean gloves and remove old dressing. Clean wound (see Skill 48.2).	Reduces transmission of microorganisms. Protects from splashes or sprays of blood and body fluids. While cleaning wound, use meticulous hand hygiene and proper infection control procedures before and after removing soiled dressings to limit risk for health care-acquired infection (Jaszarowski and Murphree, 2016).
4. Discard old dressing and gloves in biohazard bag. Perform hand hygiene.	Reduces transmission of microorganisms.
5. Apply clean or sterile gloves (check agency policy). Perform wound assessment (see Skill 48.2) and examine recent charted assessment of patient's open wound.	Provides ongoing wound-healing data. Use sterile precautions when sterile gloves are needed.
6. Expose area near wound only.	Provides privacy and prevents chilling of patient.
7. Irrigate wound with wide opening:	The cleansing solution is introduced directly into the wound with a syringe, a syringe and catheter, or a pulsed lavage device.
a. Fill 35-ml syringe with irrigation solution.	Irrigating wound uses mechanical force, which helps with separation and removal of necrotic debris and surface bacteria (Jaszarowski and Murphree, 2016). Flushing wound helps remove debris and facilitates healing by secondary intention.
b. Attach 19-gauge angiocatheter.	Catheter lumen delivers ideal pressure for cleaning and removing debris with minimal risk for tissue injury (Ramundo, 2016). Mechanical debridement is achieved with irrigation pressures delivered between 4 and 15 psi (WOCN, 2016).
CLINICAL DECISION: Pulsatile high-pressure lavage is an alternative to using the 35-ml syringe and the 19-gauge angiocatheter. A pulsatile lavage machine combines intermittent high-pressure lavage with suction to loosen necrotic tissue and facilitate removal by other methods of debridement (Ramundo, 2016).	
c. Hold syringe tip 2.5 cm (1 inch) above upper end of wound and over area being cleaned.	Prevents syringe contamination. Careful placement of syringe prevents unsafe pressure of flowing solution.
d. Using continuous pressure, flush wound; repeat Steps 7a to 7d until solution draining into basin is clear.	Flushing wound helps to remove debris; clear solution indicates removal of all debris.
8. Irrigate deep wound with very small opening:	
a. Attach soft catheter to filled irrigation syringe.	Catheter permits direct flow of irrigant into wound. Expect wound to take longer to empty when opening is small.
b. Gently insert tip of catheter into opening about 1.3 cm (0.5 inch).	Prevents tip from touching fragile inner wall of wound.
CLINICAL DECISION: Do not force catheter into the wound because this will cause tissue damage.	
c. Using slow, continuous pressure, flush wound.	Use of slow mechanical force of stream of solution loosens particulate matter on wound surface and promotes healing (Ramundo, 2016).
CLINICAL DECISION: Pulsatile high-pressure lavage is often the irrigation of choice for necrotic wounds. Pressure settings should be set per provider order, usually between 4 and 15 psi, and should not be used on skin grafts, exposed blood vessels, muscle, tendon, or bone. Use with caution if patient has coagulation disorder or is taking anticoagulants (Ramundo, 2016).	
d. While keeping catheter in place, pinch it off just below syringe.	Avoids contamination of sterile solution.
e. Remove and refill syringe. Reconnect to catheter and repeat until solution draining into basin is clear.	
9. Clean wound with handheld shower:	
a. With patient seated comfortably in shower chair or standing if condition allows, adjust spray to gentle flow; make sure that water is warm.	Useful for patients able to shower with help or independently. May be accomplished at home.
b. Shower for 5 to 10 minutes with shower head 30 cm (12 inches) from wound.	Ensures that wound is cleaned thoroughly.
10. When indicated, obtain cultures after cleaning with nonbacteriostatic saline.	WOCN (2016) recommends using quantitative bacterial cultures (tissue biopsy or swab cultures). The most common types of wound cultures are swab technique, aspirated wound fluid, or tissue biopsy.

Table Continued

Step	Rationale
CLINICAL DECISION: Obtain a wound culture if indicated by the presence of inflammation around the wound, purulent odor or drainage, new drainage, or a febrile patient.	
11. Dry wound edges with gauze; dry patient after shower.	Prevents maceration of surrounding tissue from excess moisture.
12. Remove and dispose of gloves. Perform hand hygiene. Apply clean or sterile gloves (see agency policy). Apply appropriate dressing and label with time, date, and nurse's initials.	Reduces transmission of microorganisms. Maintains protective barrier and healing environment for wound.
13. Remove mask, goggles, and gown.	Prevents transfer of microorganisms.
14. Dispose of equipment and soiled supplies; remove and dispose of gloves. Perform hand hygiene.	Reduces transmission of microorganisms.
15. Help patient to comfortable position.	
16. Raise side rails (as appropriate) and lower bed to lowest position.	Provides for patient safety and reduces the risk for falls.
17. Place nurse call system within reach; instruct patient in use.	Assists patient or family member in calling for assistance.
Evaluation	
1. Have patient rate level of comfort on scale of 0 to 10.	Patient's pain should not increase as a result of wound irrigation.
2. Monitor type of tissue in wound bed.	Identifies wound healing progress and determines type of wound cleaning and dressing needed.
3. Inspect dressing periodically (see agency policy).	Determines patient's response to wound irrigation and need to modify plan of care.
4. Evaluate periwound skin integrity.	Determines whether extension of wound has occurred or signs of infection are present (warm red periwound skin).
5. Observe for presence of retained irrigant.	Retained irrigant is medium for bacterial growth and subsequent infection.
6. Use Teach-Back: "I want to be sure that I explained how to irrigate your wound. You are going to be doing this at home; please show me how you will irrigate the wound with this syringe." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family caregiver's level of understanding of instructional topic.
Unexpected Outcomes and Related Interventions	
1. Bleeding or serosanguineous drainage appears. • Flush wound during next irrigation using less pressure. • Notify health care provider of bleeding.	
2. Increased pain or discomfort occurs. • Decrease force of pressure during wound irrigation. • Assess patient for need for additional analgesia before wound care.	
3. Suture line opening extends. • Notify health care provider. • Reevaluate amount of pressure to use for next wound irrigation.	
Recording and Reporting	
<ul style="list-style-type: none"> Record wound assessment before and after irrigation, amount and type of solution used, irrigation device used, patient tolerance of the procedure, and type of dressing applied after irrigation in electronic health record (EHR) or chart. Document your evaluation of patient learning. Report the location of the wound irrigated; discuss the type of solution used, the quality of the return irrigation, and the last time the wound was irrigated. Immediately report to the attending health care provider any evidence of fresh bleeding, sharp increase in pain, retention of irrigant, or signs of shock. 	
Home Care Considerations	
<ul style="list-style-type: none"> Teach the patient and family caregiver how to make normal saline, especially if cost is an issue. You make normal saline by using 8 tsp of salt in 1 gallon of distilled water. Instruct the family caregiver on irrigation technique, and have the caregiver demonstrate. Be sure the patient and family know signs of infection and when to notify the health care provider. 	

Skill 48.6. Applying Gauze OR Elastic Bandage Delegation and Collaboration

The skill of applying a gauze or an elastic bandage for compression cannot be delegated to assistive personnel (AP). A nurse assesses the

condition of any wound or dressing before applying a bandage. The skill of applying bandages to secure nonsterile dressings can be delegated to AP (refer to agency policy). Direct the AP about:

- Modifying the bandage application, such as with special taping.
- Reviewing what to observe and report back to the nurse (e.g., patient's complaint of pain, numbness, or tingling after application or changes in patient's skin color or temperature).

Equipment

- Correct width and number of gauze or elastic bandages
- Clips or adhesive tape
- Clean gloves if wound drainage is present
- *Option:* Pillow

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and account number) according to agency policy. Compare identifiers with information on patient's MAR or medical record.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Review patient's medical record for specific orders related to application of gauze or elastic bandage. Note area to be covered, type of bandage required, frequency of change, and previous response to treatment.	Ensures use of correct products.
3. Assess patient's/family caregiver's knowledge, experience, and health literacy level.	Ensures patient/family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
4. Assess patient's level of comfort (pain scale of 0 to 10).	Serves as baseline to measure patient's level of comfort when dressing change is performed.
5. Perform hand hygiene. Observe adequacy of circulation to extremity by palpating temperature of skin and pulses, presence of edema, and sensation (distal to area to be bandaged). Observe skin color and movement of body part to be wrapped.	Assesses status of circulation to extremity. Impaired circulation from constricting bandage may delay wound healing. Detection of change to circulation requires frequent observation.
CLINICAL DECISION: Impaired circulation may result in pain, coolness to touch when compared with the opposite side of the body, cyanosis or pallor of skin, diminished or absent pulses, edema or localized pooling, and numbness and/or tingling of body part.	
6. Apply clean gloves (if drainage or break in skin is present). Inspect skin of area to be bandaged for alterations in integrity as indicated by presence of abrasion, discoloration, or chafing. Pay close attention to areas over bony prominences and areas around medical devices.	It is important to determine whether any new skin alterations are present so that the plan of care can be altered as needed. Bony prominences and pressure areas from medical devices are areas at high risk for skin injury.
7. Inspect the condition of any wound for appearance, size, and presence and character of drainage, and be sure that it is covered with a proper dressing. If not, reapply dressing (check agency policy for type of gloves to use). Remove and dispose of gloves and perform hand hygiene.	An ongoing wound assessment is necessary to judge the progress or lack of progress of the wound toward healing and to plan the appropriate interventions.
8. Assess for size of bandage: a. Gauze or basic elastic bandage to secure a dressing: Assess size of area to be covered. Each successive roll of gauze/elastic should overlap previous layer. Use smaller widths for upper extremities, larger widths for lower extremities.	A bandage too small or too large for the area may not provide the necessary support to stabilize underlying dressings.
b. Elastic bandage to provide simple compression: Assess circumference of lower extremity before or shortly after patient gets out of bed in the morning or after patient has been in bed for at least 15 minutes. Select width that will cover and overlap without bulkiness.	An elastic bandage that is too large may not provide sufficient support to immobilize and protect an injured extremity. An elastic bandage that is too small may compromise circulation to the distal extremity.
9. Assess patient's and family caregiver's knowledge of purpose of dressing and whether they will participate in dressing wound.	Identifies patient's learning needs. Prepares patient and family caregivers if dressing will need to be changed at home.
Planning	
1. Close room door and pull curtain around the patient's bed. Position patient so that only the affected wound or extremity is exposed; use sheet to cover rest of the body.	Provides privacy and places patient in a position of comfort.
2. Perform hand hygiene and administer prescribed analgesic as needed 30 minutes before applying bandage.	Comfortable patient will be less likely to move suddenly, causing wound or supply contamination or extremity pain.
3. Gather and organize equipment at bedside.	Ensures a clean and distraction-free procedure.
4. Explain procedure to patient before starting.	Reduces anxiety and provides opportunity for patient/family caregiver education.
Table Continued	

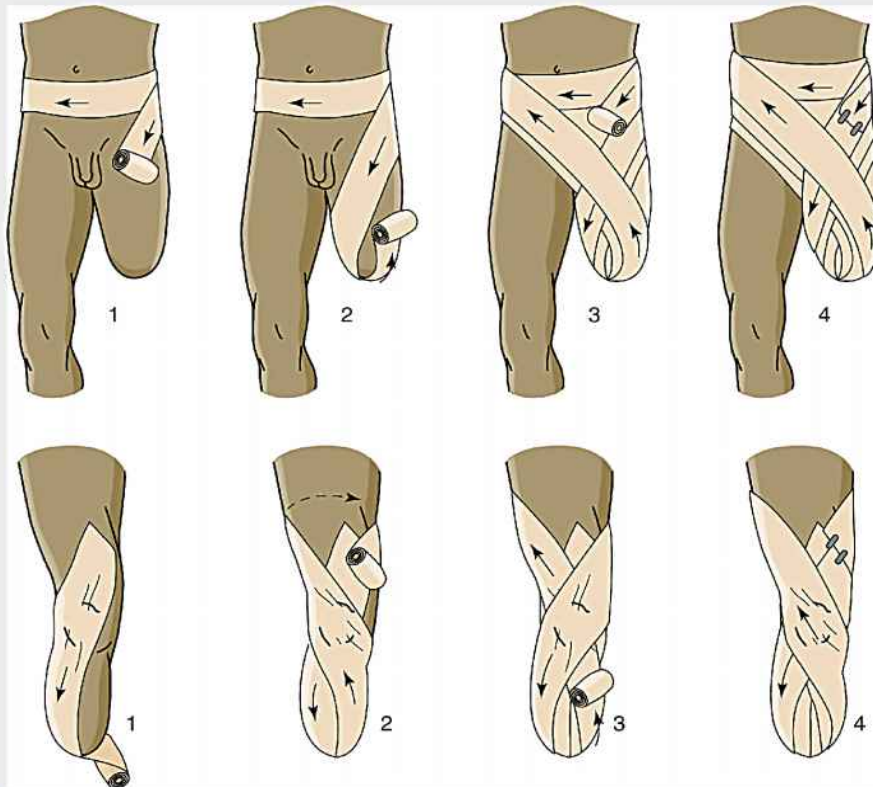

Step	Rationale
Implementation	
1. Perform hand hygiene and apply clean gloves if drainage is present.	Reduces transmission of microorganisms.
2. Apply gauze or elastic bandage to secure dressings:	
a. Make sure that primary dressing over wound is securely in place.	Wound needs to remain protected once bandage in place.
b. Hold roll of bandage in your dominant hand and use other hand to lightly hold beginning layer.	Maintains appropriate and consistent bandage tension.
c. Apply bandage from distal point toward proximal boundary, using appropriate turns to cover various shapes of body parts.	Bandage is applied in this manner so that it conforms evenly to body part and promotes venous return.
(1) Spiral dressing is often used to cover cylindrical body parts, such as a wrist. Roll gauze, overlapping each layer by one-half to two-thirds the width of the bandage (see illustration)	
(2) Use figure-eight dressing to cover joint because a snug fit provides support and immobilization to an injured joint. To apply overlap turns, alternate ascending and descending over bandaged part, each turn crossing previous one to form a figure-eight.	
CLINICAL DECISION: Double-check your tension and ensure that bandage is snug but not tight and that primary dressing or splint is positioned correctly. A tight bandage may cause numbness and tingling from impaired circulation and/or pressure on peripheral nerves.	
(3) Unroll and very slightly stretch bandage.	Maintains bandage tension.
(4) Overlap turns by one-half to two-thirds width of bandage roll.	Prevents uneven bandage tension and circulatory impairment.
(5) Secure bandage with clip before applying additional rolls.	
(6) End bandage with two circular turns; secure end of gauze or elastic bandage to outside layer of bandage, not skin, with tape or clips (see illustration).	
CLINICAL DECISION: Keep toes or fingertips uncovered and visible for follow-up circulatory assessment, except in cases in which toes or fingers are treated because of wounds.	
<p>3. Apply elastic bandage over amputated stump (see illustrations):</p> <p>a. Elevate stump with pillow or support it with the help of another person.</p> <p>b. Secure bandage by wrapping twice around proximal end of stump or person's waist (depending on size of stump)</p> <p>c. Make half turn with bandage perpendicular to its edge.</p> <p>d. Bring body of bandage over distal end of stump.</p> <p>e. Continue to fold bandage over stump, wrapping from distal to proximal points.</p> <p>f. Secure with metal clips, Velcro if provided, or tape,</p>	Elevation promotes venous return. Bandage turns are designed for uniform bandage tension.
 <p data-bbox="355 1549 594 1562">STEP 2C(1) Apply bandage from distal to proximal.</p>	 <p data-bbox="1154 1247 1273 1272">STEP 2C(6) Secure with tape or closure device.</p>

Table Continued

Step	Rationale
4. Remove and dispose of gloves if worn and perform hand hygiene.	Reduces transmission of microorganisms.
5. Help patient to comfortable position.	
6. Raise side rails (as appropriate) and lower bed to lowest position.	Provides for patient safety and reduces the risk for falls.
7. Place nurse call system within reach; instruct patient in use.	Assists patient or family member in calling for assistance.
Evaluation	
1. Assess degree of tightness of bandage and presence of wrinkles, looseness, and of drainage.	Identifies any pressure areas that may cause tissue injury.
2. When bandage application is complete, at least twice during next 8 hours, and then at least every shift assess distal extremity circulation.	Early detection of circulatory impairment promotes neurovascular functioning.
a. Observe skin color for pallor or cyanosis and palpate skin for warmth.	Pallor and cyanosis and cool skin as compared to other extremity indicate diminished blood flow.
b. Palpate distal pulses and compare bilaterally.	Documents status of circulatory flow.
c. Ask patient to rate any pain on scale of 0 to 10 and to describe any numbness, tingling, or other discomfort to evaluate for neurological and vascular changes.	Signs of neurovascular changes that indicate impaired venous return.
3. Observe mobility of extremity.	Determines whether bandage is too tight, which restricts movement, or if joint immobilization is attained.
4. Use Teach-Back: "I want to be sure I explained how to apply the elastic roll to your sprained ankle. Show me how you would apply this elastic roll to your ankle." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.	Determines patient's/family's level of understanding of instructional topic.

STEP 3 Top, correct method for bandaging midhigh amputation stump. Note that bandage must be anchored around patient's waist. Bottom, correct method for bandaging midsole amputation stump. Note that bandage need not be anchored around waist.
 From Monahan F et al: *Phipp's medical-surgical nursing: health and disease perspectives* ed 8, St Louis, 2006, Mosby.

Table Continued

Step	Rationale
Unexpected Outcomes and Related Interventions	
<p>1. Impaired circulation distal to elastic bandage</p> <ul style="list-style-type: none"> • Release bandage • Palpate extremity and assess pulse, temperature, and capillary refill. Note: If abnormal, notify health care provider. • Reapply bandage with less pressure. 	
<p>2. Patient complains of pain or numbness in extremity.</p> <ul style="list-style-type: none"> • Unwrap bandage, check extremity temperature, note color of tissue, compare to other extremity, and check pulse. • Rewrap with less tension and assess patient's response. Note: If same complaint is present, notify health care provider. 	
<p>Recording and Reporting</p> <ul style="list-style-type: none"> • Record patient's level of comfort, circulation status, type of bandage applied, presence of swelling, and range of motion at baseline and after bandage application on flow sheet in nurses' notes in electronic health record (EHR) or chart. • Document your evaluation of patient learning. • Report any changes in neurological or circulatory status to health care provider. 	
<p>Home Care Considerations</p> <ul style="list-style-type: none"> • Demonstrate to patient or family caregiver how to correctly apply bandage so that it is not too tight. • Instruct patient or family caregiver about the signs of impaired circulation. • Elastic bandages that reduce swelling are best applied to the feet and ankles in the morning, before getting out of bed. • Instruct patient and family caregiver to remove an elastic bandage daily and inspect skin beneath it twice daily. 	

Key Points

- It is important to understand what risk factors may contribute to pressure injury formation in order to plan interventions to reduce or eliminate risk factors and prevent pressure injury formation.
- Pressure injury stages describe the depth of tissue injury, which will guide treatment.
- Most wounds heal in a normal trajectory, but chronic wounds may fail to heal; an overview of normal wound healing is key to understanding how to assess and plan care for the patient with a wound.
- Valid and reliable risk-assessment tools assess a patient's risk for developing a pressure injury and are completed on admission to a health care agency and on a regularly scheduled basis.
- Primary and secondary intention wounds differ in each phase of wound healing, which impacts the plan of care.
- Assessment of the patient with a wound will include the systemic and local complications that affect wound healing and must be addressed with the appropriate interventions that address those complications.
- Many factors that affect wound healing need to be considered in managing the patient with a wound. The negative factors, such as diabetes and smoking, need to be addressed, and the positive effects, such as an adequate protein intake, need to be supported.

- Acute wounds are usually traumatic or surgical and should move predictably through the wound healing process. Chronic wounds are caused by vascular compromise, reinjury, or chronic inflammation and fail to close or heal in a timely fashion.
- A wound assessment provides the foundation for developing a care plan, including selection of the correct treatment or dressing.
- Perform wound irrigation in a manner that avoids further injury to tissue.
- Exposure to heat and cold causes normal systemic and local responses but can also cause injury to the skin if applied too long or incorrectly.
- An elastic bandage applied too tightly can result in circulatory impairment.

Reflective Learning

- What will you include in a plan of care for impaired sacral skin integrity?
- During postclinical conference you discuss skin impairment from medical devices. How do medical devices create pressure injuries? How can you reduce these risks?
- A patient has a foul-smelling tan-colored drainage from a recent hip incision; the staples were removed, and an order was written for moist saline gauze dressing to the area 3 times a day. What are the critical wound assessment factors?

Review Questions

1. When repositioning an immobile patient, the nurse notices redness over the hip bone. What is indicated when a reddened area blanches on fingertip touch?
 1. A local skin infection requiring antibiotics
 2. Sensitive skin that requires special bed linen
 3. A stage 3 pressure injury needing the appropriate dressing
 4. Blanching hyperemia, indicating the attempt by the body to overcome the ischemic episode
2. Match the pressure injury stages with the correct definition.

1. Stage 1	a. Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible, and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage (MASD), including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive-related skin injury (MARS), or traumatic wounds (skin tears, burns, abrasions).
2. Stage 2	b. Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.
3. Stage 3	c. Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occurs. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.
4. Stage 4	d. Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.

3. After surgery the patient with a closed abdominal wound reports a sudden “pop” after coughing. When the nurse examines the surgical wound site, the sutures are open, and pieces of small bowel are noted at the bottom of the now-opened wound. Which are the priority nursing interventions? (Select all that apply.)
 1. Notify the health care provider.

2. Allow the area to be exposed to air until all drainage has stopped.
 3. Place several cold packs over the area, protecting the skin around the wound.
 4. Cover the area with sterile, saline-soaked towels immediately.
 5. Cover the area with sterile gauze and apply an abdominal binder.
4. What is the correct sequence of steps when performing wound irrigation to a large open wound?
 1. Use slow, continuous pressure to irrigate wound.
 2. Attach 19-gauge angiocatheter to syringe.
 3. Fill syringe with irrigation fluid.
 4. Place biohazard bag near bed.
 5. Position angiocatheter over wound.
 5. Which skin-care measures are used to manage a patient who is experiencing fecal and/or urinary incontinence? (Select all that apply.)
 1. Frequent position changes
 2. Keeping the buttocks exposed to air at all times
 3. Using a large absorbent diaper, changing when saturated
 4. Using an incontinence cleaner
 5. Applying a moisture barrier ointment
 6. Which of the following describes a hydrocolloid dressing?
 1. A seaweed derivative that is highly absorptive
 2. Premoistened gauze placed over a granulating wound

3. A debriding enzyme that is used to remove necrotic tissue
 4. A dressing that forms a gel that interacts with the wound surface
7. Which of the following is an indication for a binder to be placed around a surgical patient with a new abdominal wound? (Select all that apply.)
1. Collection of wound drainage
 2. Providing support to abdominal tissues when coughing or walking
 3. Reduction of abdominal swelling
 4. Reduction of stress on the abdominal incision
 5. Stimulation of peristalsis (return of bowel function) from direct pressure
8. When is the application of a warm compress to an ankle muscle sprain indicated? (Select all that apply.)
1. To relieve edema
 2. To reduce shivering
 3. To improve blood flow to an injured part
 4. To protect bony prominences from pressure injuries
 5. To immobilize area
9. What is the removal of devitalized tissue from a wound called?
1. Debridement
 2. Pressure distribution
 3. Negative-pressure wound therapy
 4. Sanitization

10. Which of the following are measures to reduce tissue damage from shear? (Select all that apply.)
1. Use a transfer device (e.g., transfer board)
 2. Have head of bed elevated when transferring patient
 3. Have head of bed flat when repositioning patient
 4. Raise head of bed 60 degrees when patient positioned supine
 5. Raise head of bed 30 degrees when patient positioned supine

Sensory Alterations

OBJECTIVES

- Differentiate among the processes of reception, perception, and reaction to sensory stimuli.
- Compare and contrast sensory deprivation and sensory overload.
- Discuss factors influencing sensory function.
- Discuss how sensory function affects an individual's level of wellness.
- Discuss the components that make up assessment of the sensory system.
- Assess patients for signs and symptoms of sensory alterations.
- Identify nursing diagnoses and outcomes relevant to patients with sensory alterations.
- Discuss health promotion strategies for normal sensory function.
- Plan and implement nursing interventions for patients with sensory deficits, sensory deprivation, and sensory overload.
- Discuss strategies to maintain a safe environment for patients with altered sensation.

Strabismus, p. 1309

Tactile, p. 1300

Imagine the world without sight, hearing, the ability to feel objects, or the ability to sense aromas around you. People rely on a variety of sensory stimuli to give meaning and order to events occurring in their environment. The senses form the perceptual base of our world.

Stimulation comes from many sources in and outside the body, particularly through the senses of sight (visual), hearing (**auditory**), touch (**tactile**), smell (**olfactory**), and taste (**gustatory**). The body also has a **kinesthetic** sense that enables a person to be aware of the position and movement of body parts without seeing them. **Stereognosis** is a sense that allows a person to recognize the size, shape, and texture of an object.

Although the ability to speak is not a sense, it is similar because sometimes patients lose the ability to interact meaningfully with other human beings. Meaningful stimuli allow a person to learn about the environment and are necessary for healthy functioning and normal development. When sensory function is altered, a person's ability to relate to and function within the environment changes drastically.

Many patients seeking health care have preexisting sensory alterations. Others develop them because of medical treatment (e.g., hearing loss from antibiotic use or hearing or visual loss from brain tumor removal) or hospitalization. The health care environment is a place of unfamiliar sights, sounds, and smells and minimal contact with family and friends. If patients feel depersonalized and are unable to receive meaningful stimuli, serious sensory alterations sometimes develop.

As a nurse you meet the needs of patients with existing sensory alterations and recognize those most at risk for developing sensory

problems. You also help patients who have partial or complete loss of a major sense to find alternate ways to function safely within their environment.

Scientific Knowledge Base

Normal Sensation

The nervous system continually receives thousands of stimuli from sensory nerve organs, relays the information through appropriate neurological channels, and integrates the information into a meaningful response. Sensory stimuli reach the sensory organs to elicit an immediate reaction or store information in the brain for future use. The nervous system must be intact for sensory stimuli to reach appropriate brain centers and for an individual to perceive the sensation. After interpreting the significance of a sensation, the person is then able to react to the stimulus. [Table 49.1](#) summarizes normal hearing and vision.

TABLE 49.1

Normal Hearing and Vision

Function	Anatomy and Physiology
Ear	
Transmits to brain a pattern of all sounds received from the environment, the relative intensity of these sounds, and the direction from which they originate	<p>Two ears provide stereophonic hearing to judge sound direction.</p> <p>The external ear canal shelters the eardrum and maintains relatively constant temperature and humidity to maintain elasticity.</p> <p>The middle ear is an air-containing space between the eardrum and oval window. It contains three small bones (ossicles).</p> <p>The eardrum and ossicles transfer sound to the fluid-filled inner ear.</p> <p>Movement of the stapes in the oval window creates vibrations in the fluid that bathes the membranous labyrinth, which contains the end organs of hearing and balance.</p> <p>The union of the vestibular (balance) and cochlear (hearing) parts of the labyrinth explains the combination of hearing and balance symptoms that occur with inner ear disorders.</p> <p>Vibration of the eardrum transmits through the bony ossicles. Vibrations at the oval window transmit in perilymph within the inner ear to stimulate hair cells that send impulses along the eighth cranial nerve to the brain.</p>
Eye	
Transmits a pattern of light to the brain that is reflected from solid objects in the environment and becomes transformed into color and hue	<p>Light rays enter the convex cornea and begin to converge.</p> <p>An adjustment of light rays occurs as they pass through the pupil and lens.</p> <p>Change in the shape of the lens focuses light on the retina.</p> <p>The retina has a pigmented layer of cells to enhance visual acuity.</p> <p>The sensory retina contains the rods and cones (i.e., photoreceptor cells sensitive to stimulation from light).</p> <p>Photoreceptor cells send electrical potentials by way of the optic nerve to the brain.</p>

Reception, perception, and reaction are the three components of any sensory experience. Reception begins with stimulation of a nerve cell called a *receptor*, which is usually for only one type of stimulus such as light, touch, taste, or sound. In the case of special senses, the receptors are grouped close together or located in specialized organs such as the taste buds of the tongue or the retina of the eye. When a nerve impulse is created, it travels along pathways to the spinal cord or directly to the

brain. For example, sound waves stimulate hair cell receptors within the organ of Corti in the ear, which causes impulses to travel along the eighth cranial nerve to the acoustic area of the temporal lobe. Sensory nerve pathways usually cross over to send stimuli to opposite sides of the brain.

The actual perception or awareness of unique sensations depends on the receiving region of the cerebral cortex, where specialized neurons interpret the quality and nature of sensory stimuli. When a person becomes conscious of a stimulus and receives the information, perception takes place. Perception includes integration and interpretation of stimuli based on a person's experiences. A person's level of consciousness influences perception and interpretation of stimuli. Any factors lowering consciousness impair sensory perception. If sensation is incomplete, such as blurred vision, or if past experience is inadequate for understanding stimuli such as pain, the person can react inappropriately to the sensory stimulus.

It is impossible to react to all stimuli entering the nervous system. The brain prevents sensory bombardment by discarding or storing sensory information. A person usually reacts to stimuli that are most meaningful or significant at the time. After continued reception of the same stimulus, a person stops responding, and the sensory experience goes unnoticed. For example, a person concentrating on reading a good book is not aware of background music. This adaptability phenomenon occurs with most sensory stimuli except for those of pain.

The balance between sensory stimuli entering the brain and those actually reaching a person's conscious awareness maintains a person's well-being. Sensory alterations occur when an individual attempts to react to every stimulus within the environment or if the variety and quality of stimuli are insufficient.

Sensory Alterations

The most common sensory alterations are sensory deficits, sensory deprivation, and sensory overload. A patient's ability to function and relate effectively within the environment is seriously impaired when the patient has more than one sensory alteration.

Sensory Deficits

A deficit in the normal function of sensory reception and perception is a **sensory deficit**. When a person loses visual or hearing acuity, he or she withdraws by avoiding communication or socialization with others to

cope with the sensory loss. It becomes difficult for the person to interact safely with the environment until he or she learns new skills. When a deficit develops gradually or when considerable time has passed since the onset of an acute sensory loss, a person learns to rely on unaffected senses. Some senses may even become more acute to compensate for an alteration. For example, a patient who is blind develops an acute sense of hearing to compensate for visual loss.

Patients with sensory deficits often change behavior in adaptive or maladaptive ways. For example, a patient with a hearing impairment turns the unaffected ear toward the speaker to hear better, whereas another patient avoids people because he or she is embarrassed about not being able to understand what other people say. [Box 49.1](#) summarizes common sensory deficits and their influence on those affected.

Box 49.1 Common Sensory Deficits

Visual Deficits

Presbyopia: A gradual decline in the ability of the lens to accommodate or focus on close objects. Individual is unable to see near objects clearly.

Cataract: Cloudy or opaque areas in part of the lens or the entire lens that interfere with passage of light through the lens, causing problems with glare and blurred vision. Cataracts usually develop gradually, without pain, redness, or tearing in the eye.

Computer vision syndrome or digital eye strain: Describes a group of eye and vision-related problems that result from prolonged computer, tablet, e-reader, and cell phone use. Most commonly causes eye strain, headaches, blurred vision, and dry eyes.

Dry eyes: Result when tear glands produce too few tears, resulting in itching, burning, or even reduced vision.

Glaucoma: A slowly progressive increase in intraocular pressure that, if left untreated, causes progressive pressure against the optic nerve, resulting in peripheral visual loss, decreased visual acuity with difficulty adapting to darkness, and a halo effect around lights.

Diabetic retinopathy: Pathological changes occur in the blood vessels of the retina, resulting in decreased vision or vision loss caused by hemorrhage and macular edema.

Macular degeneration: Condition in which the macula (specialized part of the retina responsible for central vision) loses its ability to function efficiently. First signs include blurring of reading matter, distortion or loss of central vision, and distortion of vertical lines.

Hearing Deficits

Presbycusis: A common progressive hearing disorder in older adults.

Cerumen accumulation: Buildup of earwax in the external auditory canal. Cerumen becomes hard and collects in the canal and causes conduction deafness.

Balance Deficit

Dizziness and disequilibrium: Common condition in older adulthood, usually resulting from vestibular dysfunction. Frequently a change in position of the head precipitates an episode of vertigo or disequilibrium.

Taste Deficit

Xerostomia: Decrease in salivary production that leads to thicker mucus and a dry mouth. Often interferes with the ability to eat and leads to appetite and nutritional problems.

Neurological Deficits

Peripheral neuropathy: Disorder of the peripheral nervous system, characterized by symptoms that include numbness and tingling of the affected area and stumbling gait.

Stroke: Cerebrovascular accident caused by clot, hemorrhage, or emboli disrupting blood flow to the brain. Creates altered proprioception with marked incoordination and imbalance. Loss of sensation and motor function in extremities controlled by the affected area of the brain also occurs. A stroke affecting the left hemisphere of the brain results in symptoms on the right side, such as difficulty with speech. A stroke on the right hemisphere has

symptoms on the left side, which may include visual spatial alterations, such as loss of half of a visual field or inattention and neglect, especially to the left side.

Sensory Deprivation

The reticular activating system in the brainstem mediates all sensory stimuli to the cerebral cortex; thus patients are able to receive stimuli even while sleeping deeply. Sensory stimulation must be of sufficient quality and quantity to maintain a person's awareness. Three types of **sensory deprivation** are reduced sensory input (sensory deficit from visual or hearing loss), the elimination of patterns or meaning from input (e.g., exposure to strange environments), and restrictive environments (e.g., bed rest) that produce monotony and boredom (Touhy and Jett, 2018).

There are many effects of sensory deprivation (Box 49.2). In adults the symptoms are similar to those of psychological illness, confusion, severe electrolyte imbalance, or the influence of psychotropic drugs. Therefore, always be aware of a patient's existing sensory function and the quality of stimuli within the environment.

Box 49.2 Effects of Sensory Deprivation

Cognitive

- Reduced capacity to learn
- Inability to think or problem solve
- Poor task performance
- Disorientation/confusion
- Bizarre thinking
- Increased need for socialization, altered mechanisms of attention

Affective

- Boredom
- Restlessness
- Increased anxiety

- Emotional lability
- Panic
- Increased need for physical stimulation

Perceptual

- Changes in visual/motor coordination
- Reduced color perception
- Less tactile accuracy
- Changes in ability to perceive size and shape
- Changes in spatial and time judgment

Sensory Overload

When a person receives multiple sensory stimuli and cannot perceptually disregard or selectively ignore some stimuli, **sensory overload** occurs. Excessive sensory stimulation prevents the brain from responding appropriately to or ignoring certain stimuli. Because of the multitude of stimuli leading to overload, a person no longer perceives the environment in a way that makes sense. Overload prevents meaningful response by the brain; the patient's thoughts race, attention scatters in many directions, and anxiety and restlessness occur. As a result, overload causes a state similar to sensory deprivation. However, in contrast to deprivation, overload is individualized. The amount of stimuli necessary for healthy function varies with each individual. People are often subject to environmental overload more at one time than another. A person's tolerance to sensory overload varies with level of fatigue, attitude, and emotional and physical well-being.

A patient who is acutely ill, especially one in a critical care unit, easily experiences sensory overload. A patient in constant pain or who requires frequent monitoring of vital signs is also at risk. Multiple stimuli combine to cause overload even if you offer a comforting word or provide a gentle back rub. Some patients do not benefit from nursing intervention because their attention and energy are focused on more stressful stimuli. In a critical care unit where the activity is constant, the lights are frequently on. Patients can hear sounds from monitoring equipment, staff conversations, equipment alarms, and the activities of people entering the unit.

It is easy to confuse the behavioral changes associated with sensory overload with mood swings or simple disorientation. Look for symptoms

such as racing thoughts, scattered attention, restlessness, and anxiety. Patients in intensive care units (ICUs) sometimes constantly play with tubes and dressings. Constant reorientation and control of excessive stimuli become an important part of a patient's care.

REFLECT NOW

Compare and contrast the symptoms of patients who have sensory deprivation with those of patients who experience sensory overload.

Nursing Knowledge Base

Factors Influencing Sensory Function

Many factors influence the capacity to receive or perceive stimuli. You will consider the influence these conditions or factors have on patients' sensation when delivering patient care.

Age

Infants and children are at risk for visual and hearing impairment because of several genetic, prenatal, and postnatal conditions. Early intense visual and auditory stimulation can adversely affect visual and auditory pathways and alter the developmental course of other sensory organs in high-risk neonates (Hockenberry et al., 2019). Visual changes during adulthood include presbyopia and the need for glasses for reading. These changes usually occur from ages 40 to 50. In addition, the cornea, which assists with light refraction to the retina, becomes flatter and thicker, which often leads to astigmatism. Pigment is lost from the iris, and collagen fibers build up in the anterior chamber, which increases the risk of glaucoma by decreasing the resorption of intraocular fluid. Other normal visual changes associated with aging include reduced visual fields, increased glare sensitivity, impaired night vision, reduced depth perception, and reduced color discrimination.

Hearing changes begin at the age of 30. Changes associated with aging include decreased hearing acuity, speech intelligibility, and pitch discrimination. Low-pitched sounds are easiest to hear, but it is difficult to hear conversation over background noise. It is also difficult to discriminate the consonants (*z, t, f, g*) and high-frequency sounds (*s, sh, ph, k*). Vowels that have a low pitch are easiest to hear. Speech sounds are distorted, and there is a delayed reception and reaction to speech. A concern with normal age-related sensory changes is that older adults with a deficit are sometimes inappropriately diagnosed with dementia (Touhy and Jett, 2018).

Gustatory and olfactory changes begin around age 50 and include a decrease in the number of taste buds and sensory cells in the nasal lining. Reduced taste discrimination and sensitivity to odors are common.

Proprioceptive changes common after age 60 include increased difficulty with balance, spatial orientation, and coordination. The person cannot avoid obstacles as quickly, and the automatic response to protect and brace oneself when falling is slower. There are also tactile changes,

including declining sensitivity to pain, pressure, and temperature secondary to peripheral vascular disease and neuropathies.

Meaningful Stimuli

Meaningful stimuli reduce the incidence of sensory deprivation. In the home meaningful stimuli include pets, music, television, pictures of family members, and a calendar and clock. The same stimuli need to be present in health care settings. Note whether patients have roommates or visitors. The presence of others offers positive stimulation. However, a roommate who constantly watches television, persistently tries to talk, or continuously keeps lights on contributes to sensory overload. The presence or absence of meaningful stimuli influences alertness and the ability to participate in care.

Amount of Stimuli

Excessive stimuli in an environment cause sensory overload. The frequency of observations and the number of procedures performed in an acute health care setting are often stressful. If a patient is in pain or restricted by a cast or traction, overstimulation frequently is a problem. In addition, a room that is near repetitive or loud noises (e.g., an elevator, stairwell, or nurses' station) contributes to sensory overload.

Social Interaction

The amount and quality of social contact with supportive family members and significant others influence sensory function. The absence of visitors during hospitalization or residency in an extended-care facility influences the degree of isolation a patient feels. This is a common problem in hospital intensive care settings, where visiting is often restricted. The ability to discuss concerns with loved ones is an important coping mechanism for most people. Therefore the absence of meaningful conversation results in feelings of isolation, loneliness, anxiety, and depression for a patient. Often this is not apparent until behavioral changes occur.

Environmental Factors

A person's occupation places him or her at risk for hearing, visual, and peripheral nerve alterations. Individuals who have occupations involving exposure to high noise levels (e.g., factory or airport workers) are at risk for noise-induced hearing loss and need to be screened for hearing

impairments. Hazardous loud noise is common in work settings and recreational activities. Noisy recreational activities that weaken hearing ability include target shooting and hunting, woodworking, and listening to loud music. Individuals who have occupations involving risk of exposure to chemicals or flying objects (e.g., welders) are at risk for eye injuries and need to be screened for visual impairments. Sports activities and consumer fireworks also place individuals at risk for eye injuries. Occupations that involve repetitive wrist or finger movements (e.g., heavy assembly line work, long periods of computer use) cause pressure on the median nerve, which runs from the forearm into the palm of the hand, resulting in carpal tunnel syndrome. Carpal tunnel syndrome alters tactile sensation and is one of the most common industrial or work-related injuries.

A patient who is hospitalized is sometimes at risk for sensory alterations because of exposure to environmental stimuli or a change in sensory input. Patients who are immobilized by bed rest or who have a chronic disability are unable to experience all the normal sensations of free movement. Another group at risk includes patients isolated in a health care setting or at home because of conditions such as bone marrow transplant or active tuberculosis (see [Chapter 28](#)). These patients stay in private rooms and are often unable to enjoy normal interactions with visitors.

Cultural Factors

Some sensory alterations occur more commonly in select cultural groups. Analysis of data from the National Health Interview Survey (NHIS), Centers for Disease Control and Prevention (CDC), and National Center for Health Statistics showed that African Americans had a higher prevalence of visual impairment due to glaucoma than Hispanics and non-Hispanic whites. African-American children and adolescents also have higher rates of blindness and visual impairment than other ethnicities ([USDHHS, 2018b](#)). Cultural disparities in vision impairment are significant, in part because vision impairment is associated with a decrease in physical and mental health and quality of life ([Box 49.3](#)) ([Tseng, YC et al., 2018](#)). Changes in hearing and visual acuity also impact a person's health literacy and his or her ability to understand medications, procedures, and restorative and home care interventions, which are further complicated when English is a second language.

Box 49.3 Cultural Aspects of Care Disparities in Eye Care

By the year 2050, non-Hispanic white individuals, women, and older adults will experience the highest rate of visual impairments and blindness. Data also suggest that Hispanic individuals will have the highest prevalence of visual impairment among minorities. This change from African Americans to Hispanics is related to the growing population of Hispanic individuals (Varma et al., 2016). Unfortunately, some individuals do not receive the vision services necessary to improve their quality of life. Findings from the National Health and Aging Trends Survey reveal that Medicare beneficiaries who are older and nonwhite are less likely to report the use of eyeglasses. People with lower socioeconomic and educational levels are also less likely to report the use of eyeglasses (Otte et al., 2018). A disparity also exists between patients with Medicaid and those with private health care insurance. Individuals with Medicaid have been found to be less successful in obtaining eye care appointments (Yoon et al., 2018). These findings are critical since the early diagnosis of visual impairments allows for early intervention to help prevent irreversible causes of vision loss (Umfress et al., 2016).

Implications for Patient-Centered Care

- Encourage patients to discuss changes in visually acuity or other eye or vision issues by asking a few focused questions.
- Educate patients on age-related eye diseases and conditions, eye care services, and the importance of taking care of their eyes (Umfress et al., 2016).
- Collaborate with the interprofessional team to help improve access to eye care services.
- Follow up with patients to reiterate important points and to check on their progress.
- Provide written eye care instructions in type that uses large fonts (14-point type or larger) and sharp contrast to improve readability (Umfress et al., 2016).

Critical Thinking

Successful critical thinking requires a synthesis of knowledge and information gathered from patients, experience, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care. Patients' conditions are always changing. During assessment consider all critical thinking elements that help you make appropriate nursing diagnoses (Fig. 49.1). In the case of sensory alterations, integrate knowledge of the pathophysiology of sensory deficits, factors that affect sensory function, and therapeutic communication principles. This knowledge enables you to conduct appropriate assessments, anticipate what to recognize when a patient describes a sensory problem, and make judgments of abnormalities. For example, knowing the typical symptoms caused by a cataract helps you recognize the pattern of visual changes that a patient with cataracts reports.

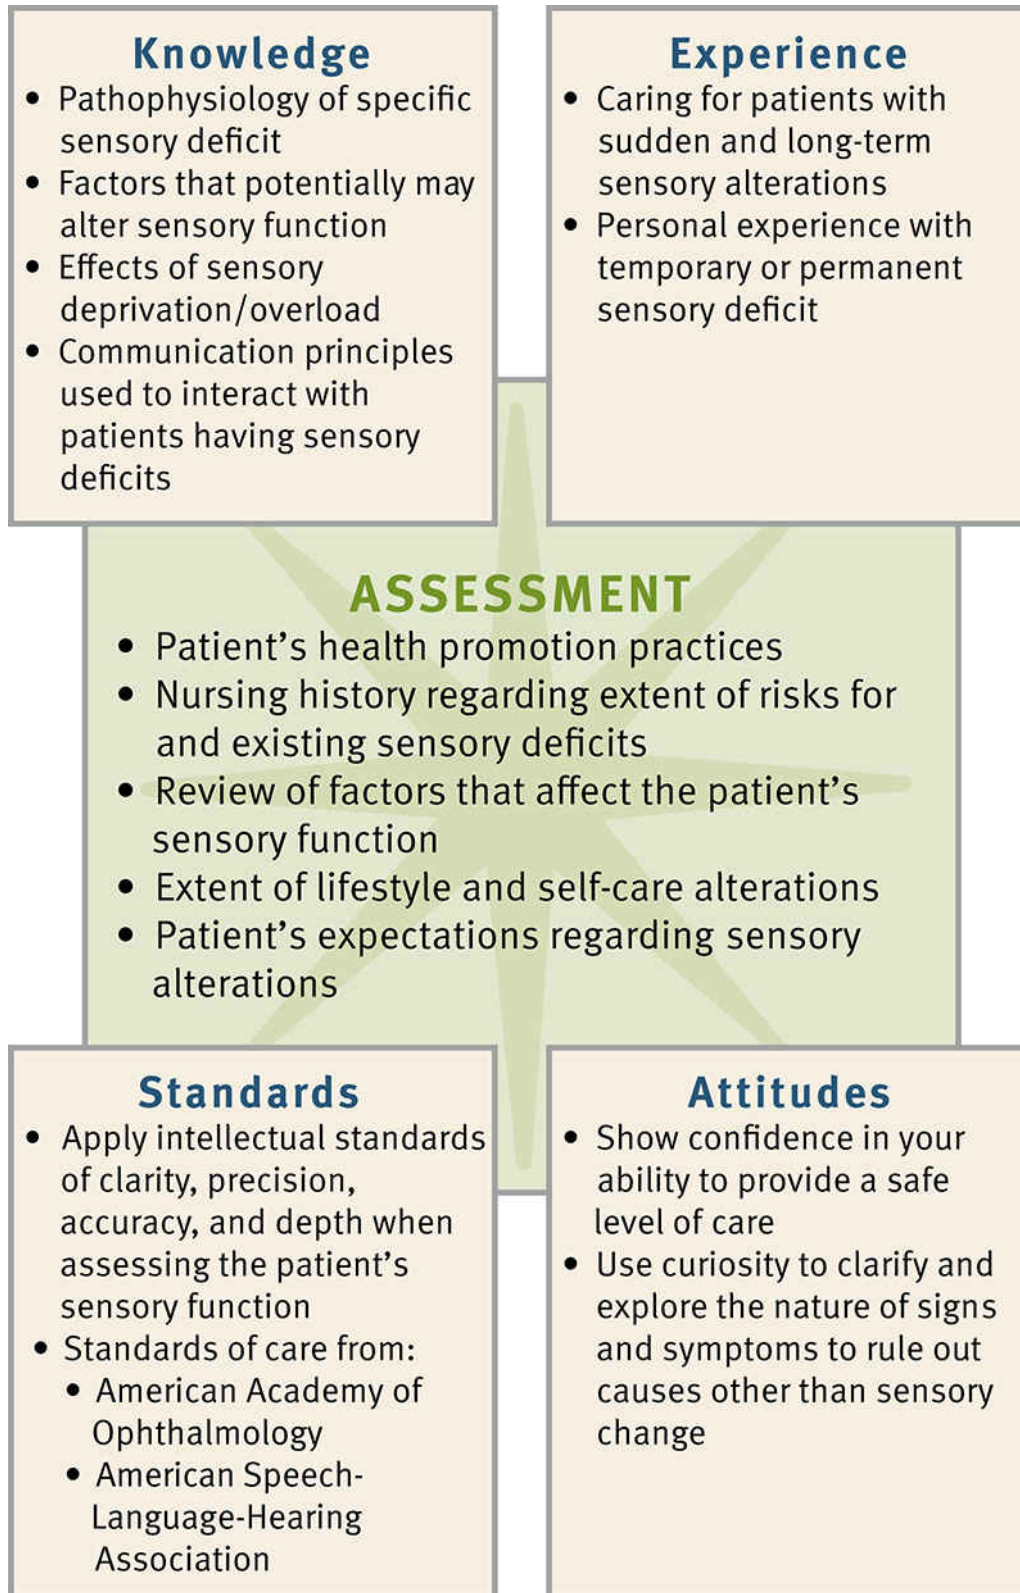

FIG. 49.1 Critical thinking model for sensory alterations assessment.

Previous experiences in caring for patients with sensory deficits help you recognize limitations in a patient's functioning and how these limitations affect the ability to carry out daily activities. For example, after caring for one patient with a hearing impairment, you are able to conduct a more effective assessment of the next patient by using previously successful approaches that promote the patient's ability to hear your questions.

When you apply critical thinking attitudes and standards during assessment, you establish a thorough and accurate database from which to make decisions. For example, perseverance is necessary to learn details about how visual changes influence a patient's ability to socialize. Evidence-based standards of care and practice such as those from the American Academy of Ophthalmology and the American Speech-Language-Hearing Association provide criteria for screening sensory problems and establishing standards for competent, safe, effective care and practice. Use critical thinking to conduct a thorough assessment; then plan, implement, and evaluate care that enables a patient to function safely and effectively.

REFLECT NOW

The parents of a toddler share with you their plan to take the toddler to a fireworks show. What recommendations would you share with the parents, and why?

◆ **Nursing Process**

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care.

◆ **Assessment**

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make appropriate and relevant nursing diagnoses and patient-centered clinical decisions required for safe nursing care.

Through the Patient's Eyes

When conducting an assessment, value the patient as a full partner. This will ensure a more thorough database so that you can plan, implement, and evaluate care. Patients are often hesitant to admit sensory losses. Therefore start gathering information by establishing a therapeutic rapport with the patient. Elicit his or her values, preferences, and expectations regarding his or her sensory impairment. Many patients have a definite plan as to how they want their care delivered. Some patients expect caregivers to recognize and appropriately manage and adjust their environment to meet their sensory needs. This includes helping the family and patient ultimately learn and adapt to a changed lifestyle based on the specific sensory impairment. Determine from the patient which interventions if any were helpful in the past in managing limitations. Assess the patient's expertise with his or her own health and symptoms. Always remember that patients with sensory alterations have strengthened their other senses and expect caregivers to anticipate their needs (e.g., for safety and security).

When assessing a patient with or at risk for sensory alteration, first consider the pathophysiology of existing deficits and the factors influencing sensory function to anticipate how to approach his or her assessment. For example, if a patient has a hearing disorder, adjust your communication style and focus your assessment on relevant criteria related to hearing deficits. Collect a history that also assesses the patient's current sensory status and the degree to which a sensory deficit affects the patient's lifestyle, psychosocial adjustment, developmental status, self-care

ability, health promotion habits, and safety. Also focus the assessment on the quality and quantity of stimuli within the patient's environment.

People at Risk

Determine if your patient is at risk for a sensory alteration. Older adults are a high-risk group because of normal physiological changes involving sensory organs. However, be careful not to automatically assume that a patient's sensory problem is related to advancing age. For example, adult sensorineural hearing loss is often caused by exposure to excess and prolonged noise or metabolic, vascular, and other systemic alterations. Some patients benefit from a referral to an audiologist or **otolaryngologist** when serious hearing problems are identified during assessment.

Other individuals at risk for sensory alterations include those living in a confined environment such as a nursing home. For example, an individual with poor hearing who is confined to a wheelchair, has decreased energy, and avoids contact with others is at significant risk for sensory deprivation. Quality nursing homes or centers offer meaningful stimulation through group activities, environmental design, and mealtime gatherings to better manage sensory alterations in their residents.

Patients who are acutely ill are also at risk because of an unfamiliar and unresponsive environment. This does not mean that all patients in the hospital have sensory alterations. However, you need to carefully assess patients exposed to continued sensory stimulation (e.g., ICU settings, long-term hospitalization, or multiple therapies). Assess a patient's environment within both the health care setting and the home, looking for factors that pose risks or need adjustment to provide safety and more appropriate sensory stimulation.

Sensory Alterations History

The nursing history includes assessment of the nature and characteristics of sensory alterations or any problem related to an alteration ([Box 49.4](#)). When taking the history, consider the ethnic or cultural background of the patient because certain alterations are higher in some cultural groups.

Box 49.4 Nursing Assessment Questions

Nature of the Problem

- Describe the problem you are having with your vision/hearing.
- What have you tried to correct the vision/hearing difficulty?
- Do you use any devices to improve your vision/hearing?
- How effective are your glasses or hearing aids? If you are having problems, describe them for me.

Signs and Symptoms

- Ask a patient with visual alterations: Do you require books with large print or on audiotape? Are you able to prepare a meal or write a check? Do you notice any eye irritation or drainage?
- Ask a patient with hearing alterations: Which types of sounds or tones do you have difficulty hearing? Do people tell you that they have to “shout” for you to hear them? Do people ask you not to talk so loud? Do you have a ringing, crackling, or buzzing in your ears? Is there pain: sharp, dull, burning, itching? Have you noticed any redness, swelling, or drainage?

Onset and Duration

- When did you notice the problem? How long has it lasted?
- Does it come and go, or is it constant?
- What makes the problem better or worse?

Predisposing Factors

- Do you work or participate in any activities that have the potential for vision/hearing injury? If so, how do you protect your hearing and vision?
- Do you have a family history of cataracts, glaucoma, macular degeneration, or hearing loss?
- When was your last vision/hearing examination?

Effect on Patient

- What effect has your vision/hearing problem had on your work, family, or social life?
- Have changes in your vision/hearing affected your feelings of independence?
- How does your vision/hearing problem make you feel about yourself?
- Do you have problems with routine care of glasses, contact lenses, or hearing aids?

During the history it is useful to have a patient self-rate his or her sensory deficit by asking, “Rate your hearing as excellent, good, fair, poor, or bad.” Then, based on the patient’s self-rating, explore his or her perception of a sensory loss more fully. This provides an in-depth look at how the sensory loss influences the patient’s quality of life. In the case of hearing problems, a screening tool such as the Hearing Handicap Inventory for the Elderly (HHIE-S) effectively identifies patients needing audiological intervention ([Servidoni et al., 2018](#)). The HHIE-S is a 5-minute, 10-item questionnaire that assesses how an individual perceives the social and emotional effects of hearing loss. The higher the HHIE-S score, the greater the handicapping effect of a hearing impairment.

A nursing history also reveals any recent changes in a patient’s behavior. Frequently friends or family are the best resources for this information. Ask the family the following questions:

- Has your family member shown any recent mood swings (e.g., outbursts of anger, nervousness, fear, or irritability)?
- Have you noticed the family member avoiding social activities?

Mental Status

Assessment of mental status is valuable when you suspect sensory deprivation or overload. Observation of a patient during history taking, during the physical examination (see [Chapter 30](#)), and while providing nursing care offers valuable data about a patient’s behaviors and mental status. Observe the patient’s physical appearance and behavior, measure cognitive ability, and assess his or her emotional status. Use the Mini-Mental State Examination (MMSE) to measure disorientation, change in problem-solving abilities, and altered conceptualization and abstract thinking (see [Chapter 30](#)). For example, a patient with severe sensory deprivation is not always able to carry on a conversation, remain attentive,

or display recent or past memory. An important step toward preventing cognition-related disability is education by nurses about disease process, available services, and assistive devices.

Physical Assessment

To identify sensory deficits and their severity, use physical assessment techniques to assess vision; hearing; olfaction; taste; and the ability to discriminate light touch, temperature, pain, and position (see [Chapter 30](#)). [Table 49.2](#) summarizes specific assessment techniques for identifying sensory deficits. You gather more accurate data when the examination room is private, quiet, and comfortable for the patient. In addition, rely on personal observation to detect sensory alterations. Patients with a hearing impairment may seem inattentive to others, respond with inappropriate anger when spoken to, believe people are talking about them, answer questions inappropriately, have trouble following clear directions, and have monotonous voice quality or speak unusually loud or soft.

TABLE 49.2

Assessment of Sensory Function

Assessment Activities	Behavior Indicating Deficit (Children)	Behavior Indicating Deficit (Adults)
Vision		
<p>Ask patient to read newspaper, magazine, or lettering on menu.</p> <p>Ask patient to identify colors on color chart or crayons.</p> <p>Observe patients performing ADLs.</p>	<p>Self-stimulation, including eye rubbing, body rocking, sniffing or smelling, arm twirling; hitching (using legs to propel while in sitting position) instead of crawling</p>	<p>Poor coordination, squinting, underreaching or overreaching for objects, persistent repositioning of objects, impaired night vision, accidental falls</p>
Hearing		
<p>Assess patient's hearing acuity (see Chapter 30) using spoken word and tuning fork tests.</p> <p>Assess for history of tinnitus.</p> <p>Observe patient conversing with others.</p> <p>Inspect ear canal for hardened cerumen.</p> <p>Observe patient behaviors in a group.</p>	<p>Frightened when unfamiliar people approach, no reflex or purposeful response to sounds, failure to be awakened by loud noise, slow or absent development of speech, greater response to movement than to sound, avoidance of social interaction with other children</p>	<p>Blank looks, decreased attention span, lack of reaction to loud noises, increased volume of speech, positioning of head toward sound, smiling and nodding of head in approval when someone speaks, use of other means of communication such as lip-reading or writing, complaints of ringing in ears</p>
Touch		
<p>Check patient's ability to discriminate between sharp and dull stimuli.</p> <p>Assess whether patient is able to distinguish objects (coin or safety pin) in the hand with eyes closed.</p> <p>Ask whether patient feels unusual sensations.</p>	<p>Inability to perform developmental tasks related to grasping objects or drawing, repeated injury from handling of harmful objects (e.g., hot stove, sharp knife)</p>	<p>Clumsiness, overreaction or underreaction to painful stimulus, failure to respond when touched, avoidance of touch, sensation of pins and needles, numbness</p> <p>Unable to identify object placed in hand</p>
<p>Assess patients at risk for carpal tunnel syndrome for numbness, tingling, weakness, and pain in hands.</p>		<p>Decreased grip strength may make it difficult to form a fist, grasp small objects, or perform other manual tasks. Usually starts gradually, with frequent burning, tingling, or itching numbness in the palm of the hand and the fingers, especially the thumb and the index and middle fingers (NINDS, 2019)</p>
Smell		
<p>Have patient close eyes and identify several nonirritating odors (e.g., coffee, vanilla).</p>	<p>Difficulty in discriminating noxious odors; difficult to assess until child is 6 or 7 years old</p>	<p>Failure to react to noxious or strong odor, increased body odor, decreased sensitivity to odors</p>
Taste		
<p>Ask patient to sample and distinguish different tastes (e.g., lemon, sugar, salt). (Have patient drink or sip water and wait 1 minute between each taste.)</p>	<p>Inability to tell whether food is salty or sweet; possible ingestion of strange-tasting things</p>	<p>Change in appetite, excessive use of seasoning and sugar, complaints about taste of food, weight change</p>

ADLs, Activities of daily living.

Ability to Perform Self-Care

Assess patients' functional abilities in their home environment or health care setting, including the ability to perform feeding, dressing, grooming,

and toileting activities. For example, assess whether a patient with altered vision is able to find items on a meal tray and read directions on a prescription. Can a patient recovering from a stroke manipulate buttons or zippers for dressing? Also determine a patient's ability to perform instrumental activities of daily living (IADLs) such as reading bills and writing checks, differentiating money denominations, and driving a vehicle at night. If a patient seems to have a sensory deficit, does he or she show concern for grooming? Does a patient's loss of balance prevent rising from a toilet seat safely? If a sensory alteration impairs a patient's functional ability, providing resources within the home is a necessary part of discharge planning. Your findings may indicate the need for an occupational therapy consultation.

Health Promotion Habits

Assess the daily routines that patients follow to maintain sensory function. Which type of eye and ear care is a part of a patient's daily hygiene? For individuals who participate in sports (e.g., ice hockey, lacrosse) or recreational activities (e.g., motorcycle riding) or who work in a setting in which ear or eye injury is a possibility (e.g., chemical exposure, welding, glass or stone polishing, or constant exposure to loud noise), determine whether they wear safety glasses or hearing-protective devices (HPDs).

It is also important to assess a patient's adherence to routine health screening. When was the last time the patient had an eye examination or hearing evaluation? For adults routine screening of visual and hearing function is imperative to detect problems early. This is especially true in the case of glaucoma, which, if undetected, leads to permanent vision loss. Recommended screening guidelines usually occur based on age. When a patient begins to show a hearing deficit, incorporate routine screening in regular examinations.

Environmental Hazards

Patients with sensory alterations are at risk for injury if their living environments are unsafe. For example, a patient with reduced vision cannot see potential hazards clearly. A patient with proprioceptive problems loses balance easily. A patient with reduced sensation cannot perceive hot-versus-cold temperatures. The condition of the home, the rooms, and the front and back entrances is often problematic to the patient with sensory alterations. Assess his or her home for common hazards, including the following:

- Uneven, cracked walkways leading to front/back door
- Extension and phone cords in the main route of walking traffic
- Loose area rugs and runners placed over carpeting
- Bathrooms without shower or tub grab bars
- Water faucets unmarked to designate hot and cold
- Unlit stairways, lack of handrails
- Poor lighting in stairways, halls, and entrance doors

In the hospital environment caregivers often forget to rearrange furniture and equipment to keep pathways from the bed and chair to the bathroom and entrance clear. It is helpful to walk into a patient's room and look for safety hazards:

- Is the nurse call system within easy, safe reach?
- Are intravenous (IV) poles on wheels and easy to move?
- Are suction machines, IV pumps, or drainage bags positioned so that a patient can rise from a bed or chair easily?
- Are bedside tables and areas clutter free?

An additional problem faced by patients who are visually impaired is the inability to read medication labels and syringe markings. Ask the patient to read a label to determine whether he or she is able to read the dosage and frequency. If a patient has a hearing impairment, check to see whether the sounds of a doorbell, telephone, smoke alarm, and alarm clock are easy to discriminate.

Communication Methods

To understand the nature of a communication problem, you need to know whether a patient has trouble speaking, understanding, naming, reading, or writing. Patients with existing sensory deficits often develop alternate ways of communicating. To interact with a patient and promote interaction with others, understand his or her method of communication. Vision becomes almost a primary sense for people with hearing impairments. As a result, face-to-face communication is essential (Fig. 49.2).

FIG. 49.2 Nurse sits at eye level so that patient with hearing impairment can communicate.

Patients with visual impairments are unable to observe facial expressions and other nonverbal behaviors to clarify the content of spoken communication. Instead they rely on voice tones and inflections to detect the emotional tone of communication. Some patients with visual deficits learn to read Braille. Patients with **aphasia** have varied degrees of inability to speak, interpret, or understand language. **Expressive aphasia**, a motor type of aphasia, is the inability to name common objects or express simple ideas in words or writing. For example, a patient understands a question but is unable to express an answer. Sensory or **receptive aphasia** is the inability to understand written or spoken language. A patient is able to express words but is unable to understand the questions or comments of others. Global aphasia is the inability to understand language or communicate orally.

The temporary or permanent loss of the ability to speak is extremely traumatic to an individual. Assess for alternate communication methods and whether they cause anxiety. Patients who have undergone laryngectomies often write notes, use communication boards or laptop computers, speak with mechanical vibrators, or use esophageal speech. Patients with endotracheal or tracheostomy tubes have a temporary loss of

speech. Most use a notepad to write their questions and requests. However, some patients are unable to write messages. Determine whether the patient has developed a sign-language system or symbols to communicate needs.

Social Support

Determine whether a patient lives alone and how often family or friends visit. Assess the patient's social skills and level of satisfaction with the support given by family and friends. Is the patient satisfied with the support available? Is he or she able to solve problems with family members? Is there a family caregiver who offers support when the patient requires assistance because of a sensory loss? The long-term effects of sensory alterations influence family dynamics and a patient's willingness to remain active in society.

Use of Assistive Devices

Assess the use of assistive devices (e.g., use of a hearing aid or glasses) and whether they currently are in working order. Assess whether the patient thinks that these devices are beneficial. This includes learning how often the patient uses the devices, the patient's or family caregiver's method of caring for and cleaning the devices routinely (see [Chapter 40](#)), and the patient's knowledge of what to do when a problem develops. When you identify that a patient has an assistive device, remember that just because the individual has a device, it does not mean that it works or that the patient uses it or benefits from it.

Other Factors Affecting Perception

Factors other than sensory deprivation or overload cause impaired perception (e.g., medications or pain). Assess the patient's medication history, which includes prescribed and over-the-counter medications and herbal products. Also gather information regarding the frequency, dose, method of administration, and last time the patient took the medications. Some antibiotics (e.g., streptomycin, gentamicin, and tobramycin) are **ototoxic** and permanently damage the auditory nerve, whereas chloramphenicol sometimes irritates the optic nerve. Opioid analgesics, sedatives, and antidepressant medications often alter the perception of stimuli. Conduct a thorough pain assessment when you suspect that pain is causing perceptual problems (see [Chapter 44](#)).

REFLECT NOW

How would you assess a patient who recently became confused and is having hallucinations for sensory alterations?

Nursing Diagnosis

After assessment review all available data and look critically for patterns and trends suggestive of a nursing diagnosis or health problem relating to sensory alterations (e.g., visual problems [Box 49.5]). Validate findings to ensure accuracy of a diagnosis. Determine the factor that likely caused or is creating a patient's health problem. The etiology or related factor of a nursing diagnosis is a condition that nursing interventions can affect. The etiology needs to be accurate; otherwise nursing therapies are ineffective.

Box 49.5 Nursing Diagnostic Process Risk for Injury

Assessment Activities	Assessment Findings
Assess patient's visual acuity.	Reduced ability to see objects clearly; needs brighter light to read; has trouble distinguishing edges of stairs
Visit home setting and inspect for hazards that pose risks to patient.	Lighting in rooms, hallways, and stairwells very dim; carpet in living room old, edges curled up; steps leading up to front entrance of home
Review medical record from clinic visit.	Bilateral cataracts

Some patients have health care problems for which sensory alteration is the etiology, such as with the diagnosis of *Risk for Injury*. You select nursing diagnoses by recognizing the way in which sensory alterations affect a patient's ability to function (e.g., *Self Care Deficit*). In addition, most patients present themselves to health care professionals with multiple diagnoses (Fig. 49.3). In the concept map example, a patient with a cataract has the nursing diagnoses of *Risk for Injury*, *Anxiety*, *Fear*, and *Risk for Fall*.

The sensory alteration caused by the cataract is an etiology for both risk for injury and risk for falls. Furthermore, fear occurs as a response to a perceived risk of falling. You need to recognize patterns of data that reveal health problems created by a patient’s sensory alteration. Examples of nursing diagnoses that apply to patients with sensory alterations include the following:

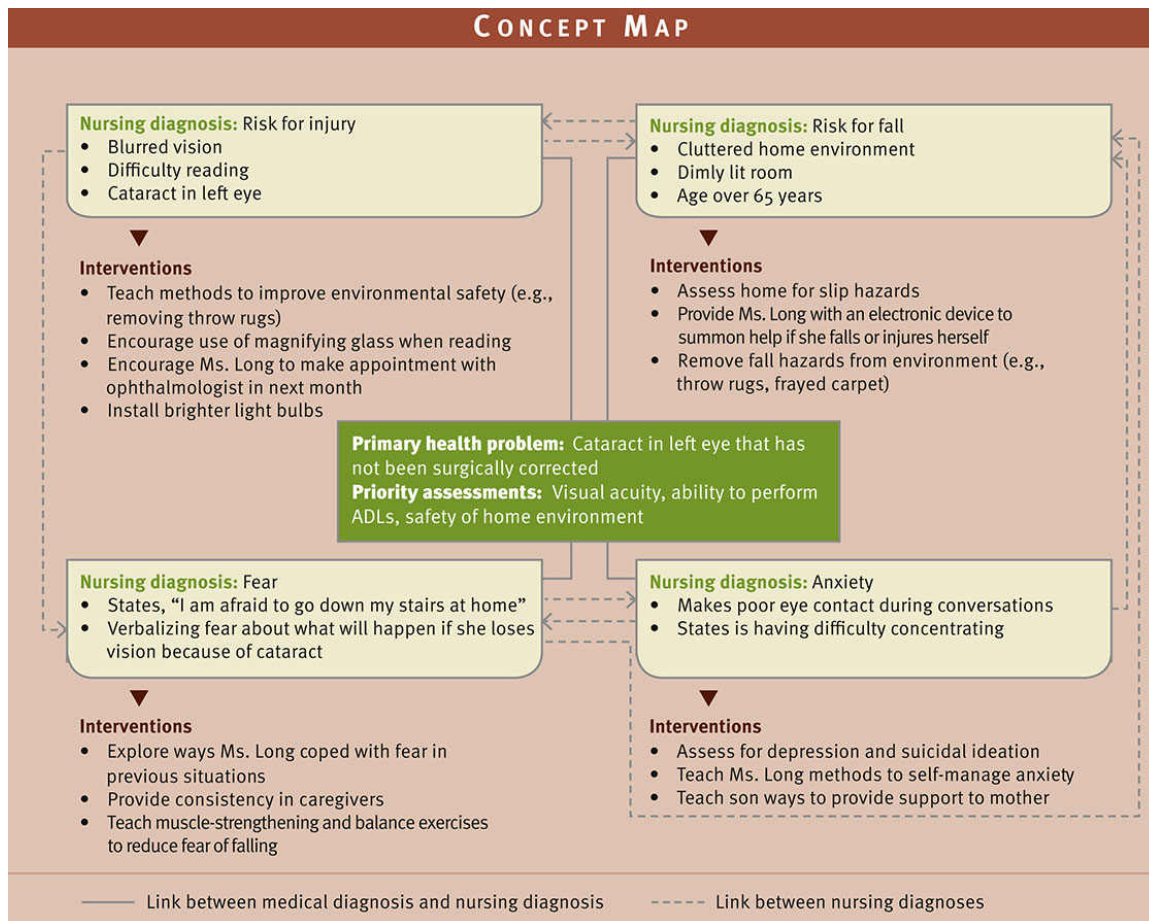

FIG. 49.3 Concept map for Ms. Long.

- *Risk for Injury*
- *Risk for Fall*
- *Impaired Verbal Communication*
- *Impaired Socialisation*
- *Impaired Mobility*

• Planning

During planning synthesize information from multiple resources (Fig. 49.4). Reflect on knowledge gained from the assessment and knowledge of how sensory deficits affect normal functioning. In this way you are able to recognize the extent of a patient's deficit and know the types of interventions most likely to be helpful. Also consider the role that health professionals play in planning care and the available community resources that will be useful. Previous experience in caring for patients with sensory alterations is invaluable.

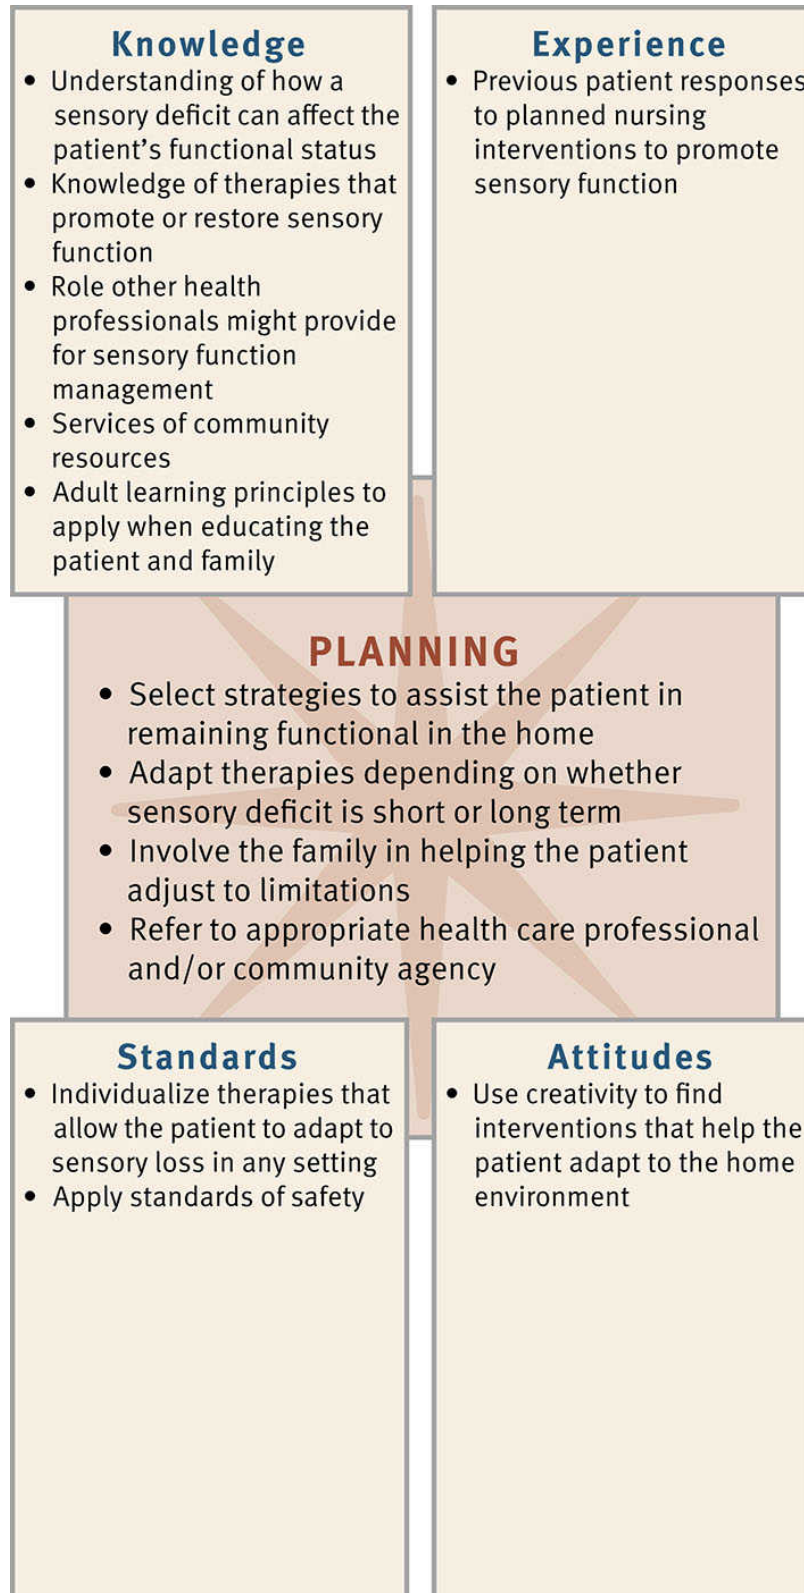

FIG. 49.4 Critical thinking model for sensory alterations planning.

When applying critical thinking to planning care, professional standards are particularly useful. These standards recommend evidence-based interventions for the patient's condition. For example, patients who have visual deficits and are hospitalized are often placed on a fall-prevention protocol that incorporates research-based precautions to ensure patient safety.

Goals and Outcomes

During planning develop an individualized plan of care for each nursing diagnosis (see the [Nursing Care Plan](#)). Partner with your patient to develop a realistic plan that incorporates what you know about his or her sensory problems and the extent to which he or she can maintain or improve sensory function. Goals and outcomes need to be realistic and measurable. An example of a goal of care for a patient with an actual or potential sensory alteration is "The patient will achieve improvement in hearing acuity within 2 weeks." Associated outcomes for this goal include the following:

- The patient and family report using communication techniques to send and receive messages within 2 days.
- The patient successfully demonstrates correct technique for cleaning a hearing aid within 1 week.
- The patient self-reports improved hearing acuity.

Setting Priorities

Consider the type and extent of sensory alteration affecting a patient when determining priorities of care. For example, a patient who enters the emergency department after experiencing eye trauma has priorities of reducing anxiety and preventing further injury to the eye. In contrast, a patient who is being discharged from an outpatient surgery department following cataract removal has the priority of learning about self-care restrictions. Safety is always a top priority. The patient also helps prioritize aspects of care—for example, a patient might wish to learn ways to communicate more effectively or to participate in favorite hobbies given his or her limitation.

Some sensory alterations are short term (e.g., a patient experiencing sensory overload in an ICU). Thus appropriate interventions are likely to be temporary (e.g., frequent reorientation or introduction of pleasant stimuli such as a back rub). Some sensory alterations such as permanent

visual loss require long-term goals of care for patients to adapt. Patients who have sensory alterations at the time of entering a health care setting are usually most informed about how to adapt interventions to their lifestyles. For example, allow patients who are blind to control whichever parts of their care they can. Sometimes it becomes necessary for a patient to make major changes in self-care activities, communication, and socialization to ensure safe and effective nursing care.

QSEN: Building Competency in Safety

Ms. Long's church asks you to provide a presentation on fall prevention for older adult members of the congregation. Many members also have impaired vision. How will you develop a program to educate this elderly population and communicate observations or concerns related to fall hazards to them?

Teamwork and Collaboration

When developing a plan of care, consider all resources available to patients. The family plays a key role in providing meaningful stimulation and in learning ways to help the patient adjust to any limitations. Engaging the family or designated surrogate is a fundamental skill of patient-centered care ([Institute for Patient- and Family-Centered Care, 2016](#)). You also refer patients to other health care professionals when appropriate. For example, if a patient has a major loss of sensory function and is also unable to manage medical needs such as medication self-administration or dressing changes, you make a referral to home care. Valuing interprofessional collaboration is an essential nurse competency that results in better patient health outcomes and greater patient and family satisfaction ([Interprofessional Education Collaborative Expert Panel, 2016](#)). Numerous community-based resources (e.g., local chapter of the Society for the Blind and Visually Impaired and the Area Agency on Aging) are also available. Try to arrange for a volunteer to visit a patient or have printed materials made available that describe ways to cope with sensory problems.

Implementation

Nursing interventions involve patients and their families so that patients are able to maintain a safe, pleasant, and stimulating sensory environments. The most effective interventions enable a patient with sensory alterations to function safely with existing deficits and continue a normal lifestyle. Patients can learn to adjust to sensory impairments at any age with the proper support and resources. Use measures to maintain a patient's sensory function at the highest level possible.

Health Promotion

Good sensory function begins with prevention. When a patient seeks health care, provide education about interventions that reduce the risk for sensory losses. Also recommend relevant visual and hearing guidelines. Remember to assess a patient's capacity to process and understand the health information to ensure that the patient makes appropriate decisions regarding his or her health.

Screening

An estimated 4.2 million adults in the world have uncorrectable vision impairment, including blindness. By the year 2050, this number is expected to more than double (Varma et al., 2016). This raises questions about the etiology of vision impairments, as well as strategies to improve access to early screening programs. Preventable blindness is a worldwide health issue that begins with children and requires appropriate screening. Four recommended interventions are: (1) screening for rubella, syphilis, chlamydia, and gonorrhea in women who are considering pregnancy; (2) advocating for adequate prenatal care to prevent premature birth (with the danger of exposure of the infant to excessive oxygen); (3) administering eye prophylaxis in the form of erythromycin ointment approximately 1 hour after an infant's birth; and (4) periodic screening of all children, especially newborns through preschoolers, for congenital blindness and visual impairment caused by refractive errors and **strabismus** (Hockenberry et al., 2019).

Visual impairments are common during childhood. The most common visual problem is a **refractive error** such as nearsightedness. The nurse's role is one of detection, education, and referral. Parents need to know the signs of visual impairment (e.g., failure to react to light and reduced eye contact from the infant). Instruct parents to report these signs to their health care provider immediately. When follow-up is available, vision screening of school-age children and adolescents can detect early visual

impairments ([Rodriguez et al., 2018](#)). School nurses are usually responsible for vision testing.

In the United States glaucoma is the second leading cause of blindness in the general population and the primary cause of blindness in African Americans. If left undetected and untreated, it leads to permanent vision loss. The [CDC \(2018\)](#) recommends that people with diabetes have a dilated eye exam every year. Individuals who are at a higher risk for glaucoma should have a dilated eye exam every two years. Individuals at a higher risk include the following: African Americans 40 years and older and all adults older than 60, especially Mexican Americans and people with a family history of glaucoma. Individuals who have had eye surgery or who have other health concerns or conditions are also at risk for the development of vision problems.

Hearing impairment is one of the most common disabilities in the United States. The prevalence of hearing loss is nearly 50% in those older than 75 years of age ([NIDCD, 2018](#)). Deafness or hearing impairment affects not only older adults but also children. Children at risk include those with a family history of childhood hearing impairment, perinatal infection (rubella, herpes, or cytomegalovirus), low birth weight, chronic ear infection, and Down syndrome. Advise pregnant women of the importance of early prenatal care, avoidance of ototoxic drugs, and testing for syphilis or rubella.

Children with chronic middle ear infections, a common cause of impaired hearing, need to receive periodic auditory testing. Warn parents of the risks and to seek medical care when a child has symptoms of earache or respiratory infection.

Because aging is associated with degenerative changes in the ear, patients need to have hearing screenings at least every decade through age 50 and every 3 years thereafter ([American Speech-Language-Hearing Association, n.d.](#)). Once a patient reports a hearing loss, regular testing also becomes necessary. In addition, a patient who works or lives in a high-noise level environment requires annual screening. Occupational health nurses play a key role in the assessment of the auditory system and the initiation of prompt referrals. The early identification and treatment of problems help older adults be more active and healthier.

Preventive Measures

Trauma is a common cause of blindness in children. Penetrating injury from propulsive objects such as firecrackers or slingshots or from penetrating wounds from sticks, scissors, or toy weapons are just a few

examples. Provide patient education to parents and children about ways to avoid eye trauma, such as avoiding the use of toys with long, pointed projections and instructing children not to walk or run while carrying pointed objects. Instruct patients that they can find safety equipment in most sports shops and large department stores.

Adults are at risk for eye injury while playing sports and working in jobs involving exposure to chemicals or flying objects. The Occupational Safety and Health Administration ([OSHA, n.d.](#)) has guidelines for workplace safety. Employers are required to have eyewash stations and to have employees wear eye goggles and/or use equipment such as HPDs to reduce the risk of injury. *Healthy People 2020* ([USDHHS, 2018a](#)) identifies goals that include reducing new cases of work-related, noise-induced hearing loss. Occupational health nurses reinforce the use of devices. In addition, nurses need to routinely assess patients for noise exposure and provide hearing conservation classes for teachers, students, and patients.

Another means of prevention involves regular immunization of children against diseases capable of causing hearing loss (e.g., rubella, mumps, and measles). Nurses who work in health care providers' offices, schools, and community clinics instruct patients about the importance of early and timely immunization. Use caution when administering ototoxic drugs in all populations.

The average American worker spends 7 hours a day on the computer either in the office or working from home. To help prevent or alleviate digital eye strain, the [American Optometric Association \(2019\)](#) recommends following the 20-20-20 rule; take a 20-second break to view something 20 feet away every 20 minutes. Educate patients at risk for computer eye strain to adopt preventive eye care and computer viewing practices ([Box 49.6](#)).

BOX 49.6 Preventing Computer or Digital Eye Strain

Eye Care

- Encourage patients to ask their optometrist or ophthalmologist if they might benefit from glasses prescribed specifically for computer use.
- Persons already wearing glasses may find their current prescription does not provide optimal vision for viewing a computer.

- Special lens designs, lens powers, or lens tints/coatings may help to maximize visual abilities and comfort.
- Vision therapy may be needed. Vision therapy, also called visual training, is a prescribed program of visual activities to improve visual abilities. It trains the eyes and brain to work together more effectively.

Computer Viewing

- Improve the conditions for using computers.
- Optimally, a computer screen should be located 15 to 20 degrees below eye level (about 4 or 5 inches) as measured from the center of the screen and 20 to 28 inches from the eyes.
- Reference materials should be placed above the keyboard and below the monitor. If such placement is not possible, a document holder can be used next to the monitor.
- Position the computer screen to avoid glare, particularly from overhead lighting or windows. Use blinds or drapes on windows and use lower wattage light bulbs in desk lamps.
- If there is no way to minimize glare from light sources, consider using an antiglare screen filter.
- Chairs should be comfortably padded and conform to the body. Chair height should be adjusted so that the feet rest flat on the floor. If a chair has arms, adjust armrests to provide support while typing. The wrists should not rest on the keyboard.
- Rest the eyes when using the computer for long periods—15 minutes for every 2 hours of continuous computer use. In addition, for every 20 minutes of computer viewing, look into the distance for 20 seconds to allow the eyes to refocus.

Adapted from American Optometric Association: Computer Vision Syndrome, 2019, <https://www.aoa.org/patients-and-public/caring-for-your-vision/protecting-your-vision/computer-vision-syndrome>

Use of Assistive Devices

Patients who wear corrective contact lenses, eyeglasses, or hearing aids need to make sure that they are clean, accessible, and functional (see [Chapter 40](#)). It is helpful to have a family member or friend who also

knows how to care for and clean an assistive aid. A contact lens wearer must clean lenses frequently (see [Chapter 40](#)) and use the appropriate solutions for cleaning and disinfection. Contact lens wearers are subject to serious eye infections caused by infrequent lens disinfection, contamination of lens storage cases or contact lens solutions, and use of homemade saline. Swimming while wearing lenses also creates a serious risk of infection. Reinforce proper lens care in any health maintenance discussion.

Older adults are often reluctant to use hearing aids. Reasons cited most often include cost, appearance, insufficient knowledge about

Nursing Care Plan

Risk for Injury

Assessment

Ms. Long is a 70-year-old retired widow who lives in a one-level home with her son. Their home has a walkout basement. Ms. Long enjoys reading and sewing, but she is experiencing reduced vision, which is affecting her ability to participate in these activities. She is fearful of falling and visited an ophthalmologist a year ago.

Assessment Activities	Assessment Findings ^a
Ask Ms. Long to describe her visual acuity and vision changes.	Ms. Long states, "My left eye has a film over it that makes my vision blurred . I am having difficulty reading and driving at night ."
Ask Ms. Long to describe life changes that have occurred since the change in vision.	Ms. Long states, "I can no longer drive at night. I'm afraid to use the stairs at home because I can't judge steps clearly ."
Ask Ms. Long the results of the visit to the ophthalmologist.	Ms. Long states, "I was told I had a cataract of the left eye , and surgery was recommended."
Conduct a home hazard assessment.	There is clutter in the home, dim lighting , and stairs with poor lighting and a broken handrail .

^a **Assessment Findings** are shown in bold type.

Nursing Diagnosis:

Risk for injury

Planning

Goal	Expected Outcomes (NOC) ^b
	Safe Home Environment
Ms. Long will maintain independence in a safe home environment.	Ms. Long and her son make recommended changes in lighting, repair the broken handrail, and reduce clutter in the home environment within 4 weeks.
	Ms. Long reports an increased sense of home safety and independence within 4 weeks.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic) ^c	Rationale
Environmental Management	
Teach Ms. Long and her son methods to improve environmental safety, such as installing handrails along stairs, raising toilet seats, removing throw rugs, and painting stairs.	Home environmental and health-related factors place a patient at risk for falls. Environmental safety modifications reduce the risk of falls and injury (Powell-Cope et al., 2018).
Teach Ms. Long to use a light over the shoulder for reading and sewing.	Warm incandescent lighting helps reduce eye strain and increase enjoyment (Touhy and Jett, 2016).
Explain use of a pocket magnifier, and offer list of locations where Ms. Long can purchase one.	Magnifier enlarges visual images when reading or doing close work (Touhy and Jett, 2016).
Have Ms. Long make appointment with ophthalmologist within the next 4 weeks.	Adults over the age of 60 need a routine eye examination yearly (American Optometric Association, 2018).
Emotional Support	
Encourage Ms. Long to discuss with family and friends how a loss of vision affects her independence and lifestyle.	Visual impairments are associated with mobility and activity limitations, social restrictions, and reduced quality of life (Nael et al., 2017; Ya-Chuan et al., 2018).

^c Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Ask Ms. Long to describe the changes made in the home to reduce environmental hazards.	Ms. Long responds that she removed the clutter and placed handrails at the entryway. She also placed lighting behind her chair, and there are 100-watt lights in the living room. She has a specific craft light that provides additional “over-the-shoulder” lighting.	Ms. Long and her son made recommended changes in the home environment, resulting in improved home safety.
Ask Ms. Long whether she is able to maintain a degree of independence with the environmental and lifestyle modifications.	Ms. Long states, “I’m more independent at home, and I am able to enjoy my hobbies. Until surgery I don’t mind having someone drive for me.”	Ms. Long reported an increased sense of home safety and independence.

hearing aids, amplification of competing noise, and unrealistic expectations. Neuromuscular changes in the older adult such as stiff fingers, enlarged joints, and decreased sensory perception also make the handling and care of a hearing aid difficult. Fortunately today there are a wide variety of aids that not only enhance a person's hearing but also are cosmetically acceptable and useful for people with manual dexterity issues. [Chapter 40](#) summarizes the types of hearing aids available and tips for proper care and use.

Acknowledging a need to improve hearing is a person's first step. Give patients useful information on the benefits of hearing aid use. A person who understands the need for good hearing will likely be influenced to wear hearing aids. It is also important to have a significant other available to assist with hearing aid adjustment ([Box 49.7](#)). Federal regulations require prospective hearing aid users younger than 18 years of age to have a medical examination before hearing aids are purchased. Prospective hearing aid users 18 years of age and older need a medical evaluation by a licensed physician ([US Food and Drug Administration, 2018a](#)). Hearing aid dispensers should have prospective users consult their health care provider or an otolaryngologist for the following conditions: visible congenital or traumatic deformity of the ear, active drainage in the last 90 days, sudden or progressive hearing loss within the last 90 days, acute or chronic dizziness, unilateral sudden hearing loss within the last 90 days, visible cerumen accumulation or a foreign body in the ear canal, pain or discomfort in the ear, or an audiometric air-bone gap of 15 decibels or greater ([US Food and Drug Administration, 2018b](#)).

Box 49.7 Patient Teaching **Effective Use of a Hearing Aid**

Objective

- Patient and family member will describe the steps to take for correct care and use of a hearing aid.

Teaching Strategies

- Show patient and family member locations on hearing aid device where damage (e.g., cracks, fraying) is likely to occur: earmold or case, earphone, dials, cord, and connection plugs.
- Instruct patient and family on how to assess the integrity of the aid each day.
- Demonstrate battery replacement: Have an extra set of unused batteries available.
- Instruct patient to store batteries in a dry, secure place away from pets and children.
- Instruct patient to clean ear canal daily.
- Instruct patient not to use hair spray or other hair products when hearing aid is in place.
- Review method to check volume: Turn dial to maximum gain and check. Is voice clear?
- Review factors to report to hearing aid laboratory: static, distortion of sound, poor volume quality.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Tell me what we discussed about storage of your hearing aid.
- Tell me how you check the volume of your hearing aid.
- Tell me what we discussed about ways to clean and protect your hearing aid.
- Tell me what we discussed about battery removal and cleaning of your hearing aid.

Promoting Meaningful Stimulation

Life becomes more enriching and satisfying when meaningful and pleasant stimuli exist within the environment. You can help patients adjust to their environment in many ways to make it more stimulating. You do this best by considering the normal physiological changes that accompany sensory deficits.

Vision

The pupil's ability to adjust to light diminishes as a result of the normal changes of aging; thus older adults are often very sensitive to glare. Suggest the use of yellow or amber lenses and shades or blinds on windows to minimize glare. Wearing sunglasses outside obviously reduces the glare of direct sunlight. Other interventions to enhance vision for patients with visual impairment include warm incandescent lighting and colors with sharp contrast and intensity.

The ability to read is important. Therefore allow patients to use their glasses whenever possible (e.g., during procedures and instruction). Some patients with reduced visual acuity need more than corrective lenses. A pocket magnifier helps a patient read most printed material. Telescopic-lens eyeglasses are smaller, easier to focus, and have a greater range. Many books and other publications are available in large-print formats. If a patient has a legal document or other important document that he or she wishes to read, standard copying machines have enlarging capabilities. Software is also available that converts text into artificial voice output (Touhy and Jett, 2016).

With aging a person experiences a change in color perception. Perception of the colors blue, violet, and green usually declines. Brighter colors such as red, orange, and yellow are easier to see. Offer suggestions of ways to decorate a room and paint hallways or stairwells so the patient is able to differentiate surfaces and objects in a room.

Hearing

To maximize residual hearing function, work closely with a patient to suggest ways to modify the environment. For example, patients can amplify the sound of telephones and televisions. An innovative way to enrich the lives of patients with hearing impairments is recorded music. Some patients with severe hearing loss are able to hear music recorded in the low-frequency sound cycles.

One way to help an individual with a hearing loss is to ensure that the problem is not impacted cerumen. With aging cerumen thickens and builds up in the ear canal. Excessive cerumen occluding the ear canal causes **conductive hearing loss**. Wax-removal medication, such as carbamide peroxide (Debrox Earwax Removal Kit, Murine Ear Wax Removal System) can be effective. Because these drops can irritate the delicate skin of the eardrum and ear canal, use them only as directed (Mayo Clinic, 2019). In the home setting, suggest patients use an eyedropper to apply a few drops of baby oil, mineral oil, glycerin, or

hydrogen peroxide in the ear canal to soften the cerumen ([Mayo Clinic, 2019](#)).

Taste and Smell

Promote the sense of taste by using measures to enhance remaining taste perception. Good oral hygiene keeps the taste buds well hydrated. Well-seasoned, differently textured food eaten separately heightens taste perception. Flavored vinegar or lemon juice adds tartness to food. Always ask a patient which foods are most appealing. Improving taste perception improves food intake and appetite as well.

Stimulation of the sense of smell with aromas such as brewed coffee, cooked garlic, and baked bread heightens taste sensation. Patients need to avoid blending or mixing foods because these actions make it difficult to identify tastes. Older people need to chew food thoroughly to allow more food to contact remaining taste buds.

Improve smell by strengthening pleasant olfactory stimulation. Make a patient's environment more pleasant with smells such as cologne, mild room deodorizers, fragrant flowers, and sachets. Consult with patients to find out which scents they can tolerate. The removal of unpleasant odors (e.g., bedpans or soiled dressings) also improves the quality of a patient's environment.

Touch

Patients with reduced tactile sensation usually have the impairment over a limited part of their bodies. Providing touch therapy stimulates existing function. If a patient is willing to be touched, hair brushing and combing, a back rub, and touching the arms or shoulders are ways to increase tactile contact. When sensation is reduced, a firm pressure is often necessary for a patient to feel a nurse's hand. Turning and repositioning also improve the quality of tactile sensation.

If a patient is overly sensitive to tactile stimuli (**hyperesthesia**), minimize irritating stimuli. Keeping bed linens loose to minimize direct contact with a patient and protecting the skin from exposure to irritants are helpful measures. Physical therapists can recommend special wrist splints for patients to wear to dorsiflex their wrists and relieve nerve pressure when they have numbness and tingling or pain in the hands, as with carpal tunnel syndrome. For patients who use computers, special keyboards and wrist pads are available to decrease the pressure on the median nerve, aid in pain relief, and promote healing.

Establishing Safe Environments

When sensory function becomes impaired, individuals become less secure within their home and workplace. Security is necessary for a person to feel independent. Make recommendations for improving safety within a patient's living environment without restricting independence. During a home visit or while completing an examination in the clinic, offer several useful suggestions for home safety. The nature of the actual or potential sensory loss determines the safety precautions you take.

Adaptations for Visual Loss

When a patient experiences a decrease in visual acuity, peripheral vision, adaptation to the dark, or depth perception, safety is a concern. With reduced peripheral vision a patient cannot see panoramically because the outer visual field is less discrete. With reduced depth perception a person is unable to judge how far away objects are located. This is a special danger when he or she walks down stairs or over uneven surfaces.

Driving is a particular safety hazard for older adults with visual alterations. Reduced peripheral vision prevents a driver from seeing a car in an adjacent lane. A sensitivity to glare creates a problem for driving at night with headlights. Vision is a primary consideration for safety, but there are other factors as well. In the case of older adults, decreased reaction time, reduced hearing, and decreased strength in the legs and arms further compromise driving skills. Some safety tips to share with those who continue to drive include the following: drive in familiar areas, do not drive during rush hour, avoid interstate highways for local drives, drive defensively, use rear-view and side-view mirrors when changing lanes, avoid driving at dusk or night, go slow but not too slow, keep the car in good working condition, and carry a preprogrammed cellular phone.

The presence of visual alterations makes it difficult for a person to conduct normal activities of daily living within the home. Because of reduced depth perception, patients can trip on throw rugs, runners, or the edge of stairs. Teach patients and family members to keep all flooring in good condition, and advise them to use low-pile carpeting. Thresholds between rooms need to be level with the floor. Recommend the removal of clutter to ensure clear pathways for walking, and arrange furniture so that a patient can move about easily without fear of tripping or running into objects. Suggest that stairwells have a securely fastened banister or handrail extending the full length of the stairs.

Front and back entrances to the home, work areas, and stairwells need to be lighted properly. Light fixtures need high-wattage bulbs with wider illumination. Stairwells need a light switch at both the top and bottom of the stairs. It is also important to be sure that lighting on the stairs does not cast shadows. Have a family member paint the edge of steps so that the patient can see each step, especially the first and last, clearly. When possible, have patients replace steps inside and outside the home with ramps.

An added consideration is to administer eye medications safely (see [Chapter 31](#)). Patients need to closely adhere to regular medication schedules for conditions such as glaucoma. Labels on medication containers need to be in large print. Make sure that a friend or spouse is familiar with dosage schedules in case a patient is unable to self-administer a medication. Patients with visual impairments often have difficulty manipulating eyedroppers.

Adaptations for Reduced Hearing

Patients hear important environmental sounds (e.g., doorbells and alarm clocks) best if they are amplified or changed to a lower-pitched, buzzerlike sound. Lamps designed to turn on in response to sounds such as doorbells, burglar alarms, smoke detectors, and babies crying are also available. Family members or anyone else who calls the patient regularly needs to learn to let the phone ring for a longer period. Amplified receivers for telephones and telephone communication devices (TCDs) are available that use a computer and printer to transfer words over the telephone for the hearing impaired. Both sender and receiver need to have the special device to complete a call.

Adaptations for Reduced Olfaction

The patient with a reduced sensitivity to odors is often unable to smell leaking gas, a smoldering cigarette, fire, or spoiled food. Advise patients to use smoke detectors and take precautions such as checking ashtrays or placing cigarette butts in water. In addition, teach patients to check food package dates, inspect the appearance of food, and keep leftovers in labeled containers with the preparation date. Pilot gas flames need to be checked visually.

Adaptations for Reduced Tactile Sensation

When patients have reduced sensation in their extremities, they are at risk for impaired skin integrity and injury from exposure to temperature

extremes. Always caution these patients about the use of heating and cooling devices (see [Chapter 48](#)). The temperature setting on the home water heater should be no higher than 48.8° C (120° F). If a patient also has a visual impairment, it is important to be sure that water faucets are clearly marked “hot” and “cold” or use color codes (i.e., red for hot and blue for cold). Discourage the use of heating pads in this population.

Communication

A sensory deficit often causes a person to feel isolated because of an inability to communicate with others. It is important for individuals to be able to interact with people around them. The nature of the sensory loss influences the methods and styles of communication that nurses use during interactions with patients ([Box 49.8](#)). You also teach communication methods to family members and significant others. For patients with visual deficits or blindness, speak normally, not from a distance, and be sure to have sufficient lighting.

Box 49.8 Communication Methods

Patients With Aphasia

- Listen to patient and provide sufficient time for him or her to communicate.
- Do not shout or speak loudly (hearing loss is not the problem).
- If patient has problems with comprehension, use simple, short questions and facial gestures to give additional clues.
- Speak of things familiar and of interest to patient.
- If patient has problems speaking, ask questions that require simple yes or no answers or blinking of the eyes. Offer pictures or a communication board so patient can point.
- Speak slowly and give patient time to understand; be calm and patient; do not pressure or tire him or her.
- Avoid patronizing and childish phrases.

Patients With an Artificial Airway

- Use pictures, objects, or word cards so patient can point.
- Offer a pad and pencil or Magic Slate for patient to write messages.
- Do not shout or speak loudly.
- Give patient time to write messages because patients tire easily.
- Provide an artificial voice box (vibrator) for patient with a laryngectomy to use to speak.

Patients With Hearing Impairment

- Get patient's attention. Do not startle him or her when entering the room. Do not approach patient from behind. Be sure that he or she knows that you want to speak.
- Face patient and stand or sit on the same level. Be sure that your face and lips are illuminated to promote lipreading. Keep hands away from mouth.
- Be sure that the environment is not noisy.
- Be sure that patients keep eyeglasses clean, so they are able to see your gestures and face.
- If patient wears a hearing aid, make sure that it is in place and working.
- Speak slowly and articulate clearly. Sometimes people with hearing loss take longer to process verbal messages.
- Use a normal tone of voice and inflections of speech. Do not speak with something in your mouth.
- When you are not understood, rephrase rather than repeat the conversation.
- Use visible expressions. Speak with your hands, face, and eyes.
- Do not shout. Loud sounds are usually higher pitched and often impede hearing by accentuating vowel sounds and concealing consonants. If you need to raise your voice, speak in lower tones.
- Talk toward patient's best or normal ear.
- Use written information to enhance the spoken word.
- Do not restrict the hands of patient who is deaf. Never have intravenous lines in both of patient's hands if the preferred method of communication is sign language.
- Avoid eating, chewing, or smoking while speaking.

- Avoid speaking from another room or while walking away.

The patient with a hearing impairment is often able to speak normally. To more clearly hear what a person communicates, family and friends need to learn to move away from background noise, rephrase rather than repeat sentences, be positive, and have patience. In a group setting it is better to form a semicircle in front of the patient so that he or she can see who is speaking next; this helps foster group involvement. On the other hand, some patients who are deaf have serious speech alterations. Some use sign language or lipreading, wear special hearing aids, write with a pad and pencil, or learn to use a computer for communication. Special communication boards that contain common terms (e.g., *pain, bathroom, dizzy, or walk*) help patients express their needs.

Patient education is one aspect of communication. Teaching booklets are available in large print for patients with visual loss. The patient who is blind often requires more frequent and detailed verbal descriptions of information. This is particularly true if there are no instructional booklets written in Braille. Patients with visual impairments can also learn by listening to audiotapes or the sound part of a televised teaching session. Patients with hearing impairments often benefit from written instructional materials and visual teaching aids (e.g., posters and graphs). Demonstrations by the nurse are very useful. Hospitals are required to make professional interpreters available to read sign language for patients who are deaf.

Acute Care

When patients enter acute care settings for therapeutic management of sensory deficits or as a result of traumatic injury, use different approaches to maximize sensory function existing at the time. Safety is an obvious priority until a patient's sensory status is either stabilized or improved. For example, patients with sensory deficits have a high risk for falls in the acute care environment. It is very important to know the extent of any existing sensory impairment before the acute episode of illness so that you are able to reinforce what the patient already knows about self-care or to plan for more instruction before and after discharge.

Orientation to the Environment

A patient with a sensory impairment requires a complete orientation to the immediate environment. Provide reorientation as needed to the

institutional environment by ensuring that name tags on uniforms are visible, addressing the patient by name, explaining where the patient is (especially if patients are transported to different areas for treatment), and using conversational cues to time or location. Reduce the tendency for patients to become confused by offering short, simple, repeated explanations and reassurance. Encourage family members and visitors to help orient patients to the hospital surroundings.

Patients with serious visual impairment need to feel comfortable in knowing the boundaries of the immediate environment. Normally people see physical boundaries within a room. Patients who are blind or severely visually impaired often touch the boundaries or objects to gain a sense of their surroundings. The patient needs to walk through a room and feel the walls to establish a sense of direction. Help patients by explaining objects within the hospital room such as furniture or equipment. It takes time for a patient to absorb room arrangement. He or she often needs to reorient again as you explain the location of key items (e.g., nurse call system, telephone, and chair). Remember to approach the patient from the front to avoid startling him or her.

It is important to keep all objects in the same position and place. After an object is moved even a short distance, it no longer exists for a person who is blind. Simply moving a chair creates a safety hazard. Ask the patient whether any item needs to be rearranged to make ambulation easier. Clear traffic patterns to the bathroom. Give the patient extra time to perform tasks. He or she moves slowly to remain safe and needs a detailed description of how to perform an activity. .

Patients confined to bed are at risk for sensory deprivation. Normally, movement gives an awareness of self through vestibular and tactile stimulation. Movement patterns influence sensory perception. The limited movement of bed rest changes how a person interprets the environment; surroundings seem different, and objects seem to assume shapes different from normal. A person who is on bed rest requires routine stimulation through range-of-motion exercises, positioning, and participation in self-care activities (as appropriate). Comfort measures, such as washing the face and hands and providing back rubs, improve the quality of stimulation and lessen the chance of sensory deprivation. Planning time to talk with patients is also essential. Explain unfamiliar environmental noises and sensations. A calm, unhurried approach gives you quality time to help reorient and familiarize the patient with care activities. The patient who is well enough to read will benefit from a variety of reading materials.

Communication

The most common language disorder following a stroke is aphasia. Depending on the type of aphasia, the inability to communicate is often frustrating and frightening (see [Box 49.8](#)). Initially you need to establish very basic communication and recognize that it does not indicate intellectual impairment or degeneration of personality. Explain situations and treatments that are pertinent to the patient because he or she is able to understand the speaker's words. Because a stroke often causes partial or complete paralysis of one side of a patient's body, the patient needs special assistive devices. A variety of communication boards for different levels of disability are available. Sensitive pressure switches activated by the touch of an ear, nose, or chin control electronic communication boards ([Touhy and Jett, 2018](#)). Make referrals to speech therapists to develop appropriate rehabilitation plans.

In acute care hospitals or long-term care facilities, nurses often care for patients with artificial airways (such as an endotracheal tube) (see [Chapter 41](#)). The placement of an endotracheal tube prevents a patient from speaking. In this case the nurse uses special communication methods to facilitate the patient's ability to express needs. The patient is sometimes completely alert and able to hear and see the nurse normally. Giving him or her time to convey any needs or requests is very important. Use creative communication techniques (e.g., a communication board or electronic tablet) to foster and strengthen the patient's interactions with health care personnel, family, and friends.

Controlling Sensory Stimuli

Patients need time for rest and freedom from stress caused by frequent monitoring and repeated tests. Reduce sensory overload by organizing the patient's plan of care. Combine activities such as dressing changes, bathing, and vital sign measurement in one visit to conserve a patient's energy and prevent fatigue. A patient also needs scheduled time for rest and quiet. Planning for rest periods often requires cooperation from family, visitors, and health care colleagues. Coordination with laboratory and radiology departments minimizes the number of interruptions for procedures. A creative solution to decrease excessive environmental stimuli that prevents restful, healing sleep is to institute "quiet time" in ICUs. Quiet time means dimming the lights throughout the unit, closing the shades, and shutting the doors. Data collected from one hospital that implemented a quiet time protocol found decreased sleep disorders of the

patients hospitalized in the ICU and improved sleep quality (Chamanzari et al., 2016) (Box 49.9).

Box 49.9 Evidence-Based Practice Quiet Time and Improved Patient Well-Being

PICOT Question: Does a “quiet time” intervention compared with routine intensive care unit practices improve sleep quality and satisfaction with care in hospitalized patients?

Evidence Summary

A quiet environment promotes rest and healing, but many factors contribute to a noisy hospital environment. The number of patient rooms and design of the unit, as well as admissions and discharges throughout the day, influence noise levels in health care settings. One strategy suggested to reduce noise to recommended levels is a “quiet time” intervention. “Quiet time” is observed in a number of different ways, but Goeren et al. (2018) found that limiting conversations, eliminating environmental noise, and dimming the lights are strategies that can be implemented to reduce noise. While it can be challenging to create a daily period without distractions, current evidence shows “quiet time” interventions have improved patients’ well-being, as well as satisfaction with care (Applebaum et al., 2016; McGough et al., 2018). “Quiet time” interventions have also been found to improve patients’ sleep quality and improve restfulness (Lim, 2018).

Application to Nursing Practice

- Encourage visitors to take breaks to allow their loved ones time to rest.
- Designate areas away from patient rooms for phone conversations and for the health care team to conduct student teaching sessions (Goeren et al., 2018).
- Collaborate with the interprofessional team to provide “quiet time” for patients (Goeren et al., 2018).
- Review alarm parameters and adjust the default settings as appropriate (Goeren et al., 2018).
- Modify your workflow to establish a restful environment for patients during “quiet time.”

When patients experience sensory overload or deprivation, their behavior is often difficult for family or friends to accept. Encourage the family not to argue with or contradict the patient but to calmly explain location, identity, and time of day. Engaging a patient in a normal discussion about familiar topics helps in reorientation. Anticipating patient needs such as voiding helps reduce uncomfortable stimuli.

Try to control extraneous noise in and around a patient's room. It is often necessary to ask a roommate to lower the volume on a television or to move the patient to a quieter room. Keep equipment noise to a minimum. Turn off bedside equipment not in use such as suction and oxygen equipment. Avoid making abrupt loud noises such as dropping objects or causing the over-bed table to suddenly adjust to the lowest level. Nursing staff also need to control laughter or conversation outside the patients' rooms. Allow patients to close their room doors.

When a patient leaves an acute care setting for the home environment, communicate with colleagues in the home care setting about the patient's existing sensory deficits and the interventions that helped the patient adapt to sensory problems. You achieve continuity of care when the patient has to make only minimal changes in the home setting.

Safety Measures

A patient with recent visual impairment often requires help with walking. The presence of an eye patch, frequently instilled eyedrops, and the swelling of eyelid structures following surgery are just a few factors that cause a patient to need more help than usual. A sighted guide gives confidence to patients with visual impairments and ensures safe mobility. [Bosma Enterprises \(n.d.\)](#) lists several suggestions for a sighted guide:

1. Ask the patient if he or she wants a "sighted guide." If assistance is accepted, offer your arm. Tap the back of your hand against his or her hand. The person will then grasp your arm directly above the elbow ([Fig. 49.5](#)).

FIG. 49.5 Nurse helps to ambulate patient with visual impairment.
From Sorrentino SA, Remmert LN: *Mosby's essentials for nursing assistants*, ed 6, St Louis, 2019, Elsevier.

2. Relax and walk at a comfortable pace. Walk one step ahead of the person you are guiding, except at the top and bottom of stairs and

streets. At these places pause and stand alongside the person. Be sure that the person has a strong grasp on your arm.

3. While walking with a patient, describe the surroundings and ensure that obstacles have been removed. Never leave a patient with a visual impairment standing alone in an unfamiliar area.
4. To guide a person to a seat, place his or her hand on the back of the seat. The person you are guiding will find the seat by following along your arm.

It is important to teach family members techniques for helping with ambulation. Nursing staff also need to ensure that the patient knows where the nurse call system is before leaving him or her alone. Place necessary objects in front of the patient to prevent falls caused by reaching over the bedside. Appropriate use of side rails is also an option.

Nurses often rely on patients in health care settings to report unusual sounds such as a suction apparatus running improperly or an IV pump alarm. However, a patient with a hearing loss does not always hear these sounds and thus requires more frequent visits by nurses. The patient also benefits from learning to use vision to discover sources of danger. It is wise to note on the intercom system at the nurse's station and in the medical record if the patient is deaf and/or blind. A patient lacking the ability to speak cannot call out for assistance. Patients need to have message boards and nurse call system close at hand.

Patients with reduced tactile sensation risk injury when their conditions confine them to bed because they are unable to sense pressure on bony prominences or the need to change position. These patients rely on nurses for timely repositioning, moving tubes or devices on which the patient is lying, and turning to avoid skin breakdown. When a patient is less able to sense temperature variations, use extra caution in applying heat and cold therapies (see [Chapter 48](#)) and preparing bathwater. Check the condition of the patient's skin frequently.

Restorative and Continuing Care

Maintaining Healthy Lifestyles

After a patient has experienced a sensory loss, it becomes important to understand the implications of the loss and make adjustments needed to continue a normal lifestyle. Sensory impairments need not prevent a person from leading an active, rewarding life. Many of the interventions

applicable to health promotion such as adapting the home environment are useful after a patient leaves an acute care setting.

Understanding Sensory Loss

Patients who have experienced a recent sensory loss need to understand how to adapt so that their living environments are safe and appropriately stimulating. All family members need to understand how a patient's sensory impairment affects normal daily activities. Family and friends are more supportive when they understand sensory deficits and factors that worsen or lessen sensory problems. For example, they need to learn how to communicate with someone who has a hearing loss. Community resources are available to provide information to help patients with personal management needs. The American Foundation for the Blind, American Red Cross, and National Association for Speech and Hearing offer resource materials and product information.

Socialization

The ability to communicate is gratifying. It tests a person's intellect, opens opportunities, and allows him or her to exchange the feelings that he or she has about others. When sensory alterations hinder interactions, a person feels ineffective and loses self-esteem. When patients feel socially unaccepted, they perceive sensory losses as seriously impairing their quality of life.

Interacting with others becomes a burden for many patients with sensory alterations. They lose the motivation to engage in social situations, resulting in a deep sense of loneliness. Use therapies to reduce loneliness, particularly in older adults (Box 49.10). These principles support the *Healthy People 2020* objective to increase the proportion of adults with disabilities reporting sufficient emotional support. In addition, family members need to learn to focus on a person's ability to interact rather than on his or her disability. For example, do not assume that a person who is hard of hearing does not want to speak. A person who is blind can still enjoy a walk through a park with a companion describing the sights around them.

Box 49.10 Focus on Older Adults Principles for Reducing Loneliness in Patients with Sensory

Impairments

- Spend time with a person in silence or conversation.
- When it is culturally appropriate, use physical contact (e.g., holding a hand, embracing a shoulder) to convey caring.
- Recommend alterations in living arrangements if physical isolation is a factor.
- Help patients keep contact with people important to them.
- Provide information about support groups or groups that provide assistive services.
- Arrange for security escort services as needed.
- Introduce the idea of bringing a companion such as a pet into the home when appropriate.
- Link a person with organizations attuned to the social needs of older adults.

Promoting Self-Care

The ability to perform self-care is essential for self-esteem. Frequently family members and nurses believe that people with sensory impairments require assistance, when in fact they are able to help themselves. To help with meals, arrange food on the plate and condiments, salad, or drinks according to numbers on the face of a clock (Fig. 49.6). A patient can also use this method to place personal care items on the bedside or on the bathroom vanity. It is easy for a patient to become oriented to the items after a nurse or family member explains the location of each item.

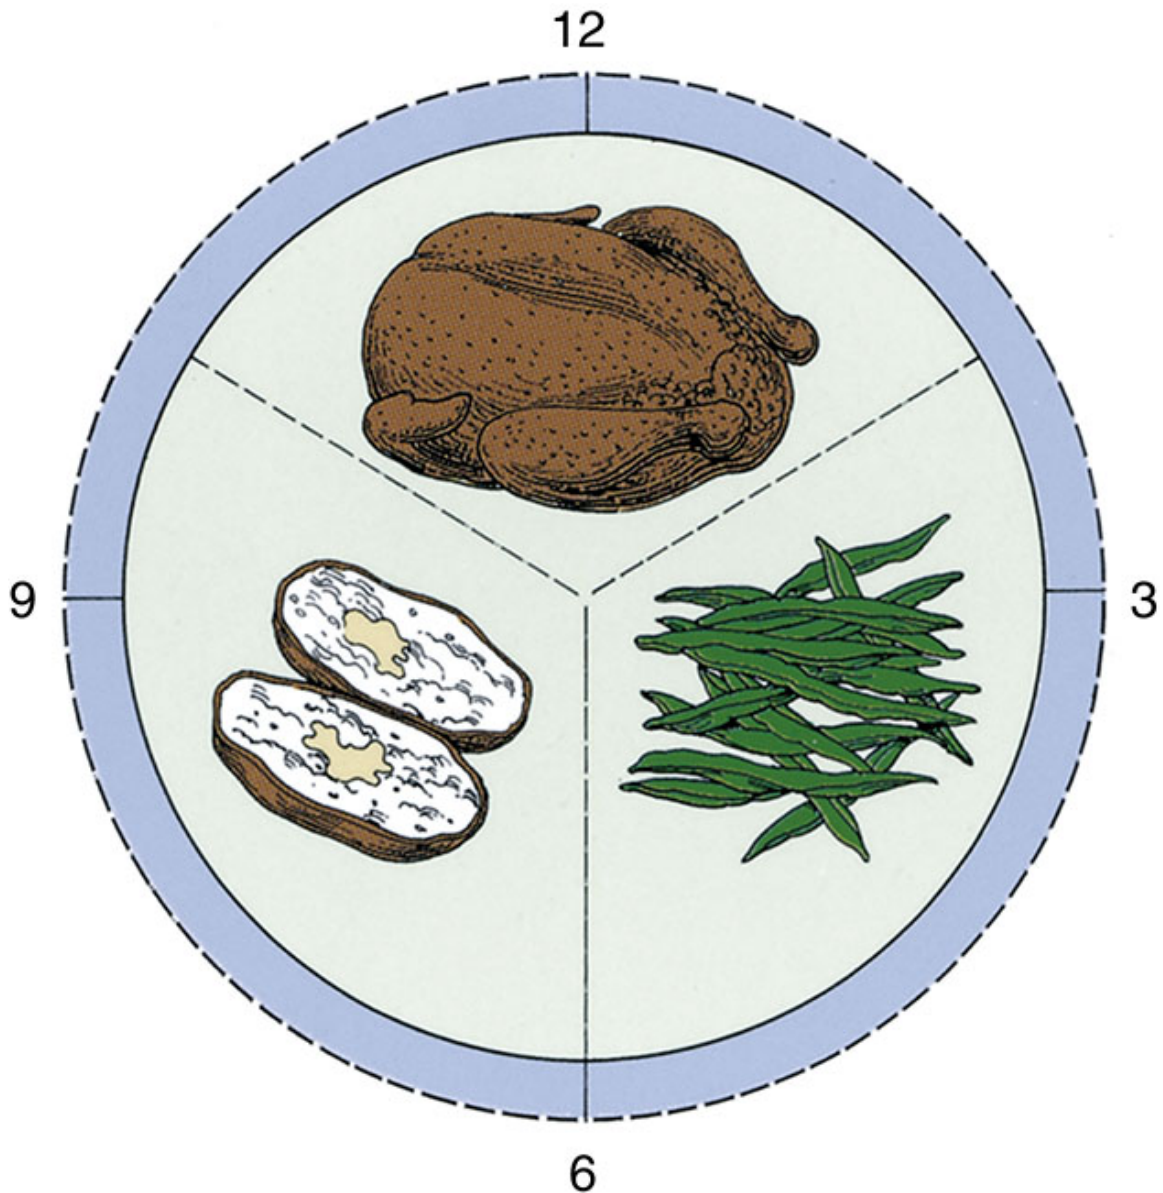

FIG. 49.6 Location of food using clock as frame of reference.

Help patients reach toilet facilities safely. Safety bars need to be installed near the toilet. It is often helpful to have the bar a different color than the wall for easier visibility. Never place towels on a safety bar because they interfere with a person's grasp. Toilet paper needs to be within easy reach. Sharply contrasting colors within the room help the partially sighted and promote functional independence. General principles for promoting self-care in older adults also include the assurance of adequate lighting and the control of glare by using shades and blinds (Touhy and Jett, 2016).

If the sense of touch is diminished, a patient can dress more easily with zippers or Velcro strips, pullover sweaters or blouses, and elasticized

waists. If a patient has partial paralysis and reduced sensation, he or she dresses the affected side first. Encourage family members responsible for selecting clothing for patients with visual impairments to follow the patient's preferences. Any sensory impairment has a significant influence on body image, and it is important for a patient to feel well groomed and attractive. Some patients need assistance with basic grooming such as brushing, combing, and shampooing hair. Others need assistance with medication administration, clothing identification, and learning to manage routine procedures such as blood pressure and glucose monitoring. An assortment of low-vision devices is now available. It is important for you to make appropriate referrals to allow patients to maintain a maximum degree of independence.

Patients with proprioceptive problems often lose their balance easily. Make sure that bathrooms have nonskid surfaces in the tub and shower. Install grab bars either vertically or horizontally in tubs and showers, depending on how a patient is able to grasp or hold onto the bar. Instruct family members to supervise ambulation and sitting, make frequent checks to prevent falls, and caution the patient against leaning forward.

Evaluation

Through the Patient's Eyes

It is important to evaluate whether patients perceive that care measures maintained or improved their ability to interact and function within the environment. The patient is the source for evaluating whether their expectations were met. He or she is the only one who knows whether sensory abilities are improved and which specific interventions or therapies are most successful in facilitating a change in his or her performance. Ask patients for example, "Have we been able to meet your expectation of keeping you safe given your vision losses?" or "Tell me how we can improve ways to communicate with you."

If you have developed a positive relationship with a patient successfully, notice that subtle behaviors often indicate the level of his or her satisfaction. You may notice that the patient responds appropriately, such as by smiling. However, it is important for you to ask the patient whether his or her sensory needs have been met. For example, ask, "Have we done all we can do to help improve your ability to hear?" If the patient's expectations have not been met, ask, "How can the health care team better meet your needs?" Working closely with the patient and family enables you to redefine expectations that can be met realistically within the limits

of the patient's condition and therapies. You have been effective when the patient's goals and expectations have been met.

Patient Outcomes

To evaluate the effectiveness of specific nursing interventions, use critical thinking and make comparisons with baseline sensory assessment data to evaluate if sensory alterations have changed (Fig. 49.7). It is your responsibility to determine whether expected outcomes have been met. For example, use evaluative data to determine whether care measures improve or at least maintain a patient's ability to interact and function within the environment. The nature of a patient's sensory alterations influences how you evaluate the outcome of care. When caring for a patient with a hearing deficit, use proper communication techniques and then evaluate whether he or she has gained the ability to hear or interact more effectively. When expected outcomes have not been achieved, there is a need to change interventions or alter the patient's environment. If outcomes are unmet, it is important to ask questions such as "How are you feeling emotionally?" or "Do you feel that you are at risk for injury?" Collaborate with family members to determine whether a patient's ability to function within the home has improved.

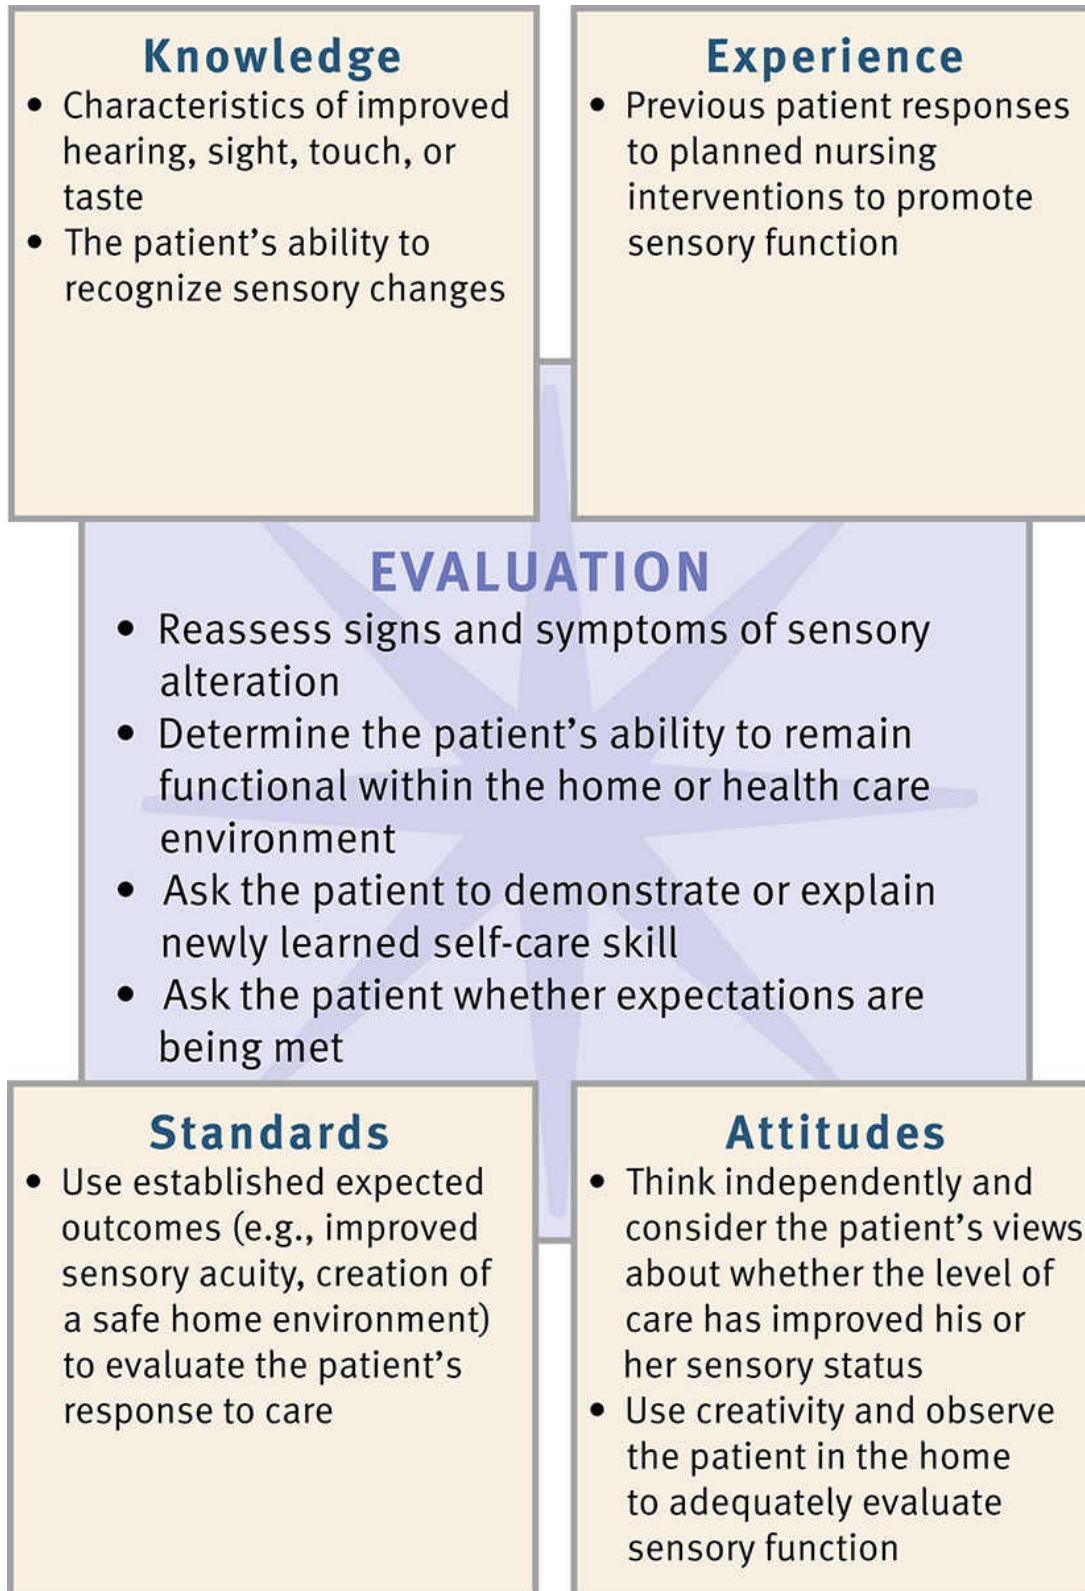

FIG. 49.7 Critical thinking model for sensory alterations evaluation.

If you have directed nursing care at improving or maintaining sensory acuity, evaluate the integrity of the sensory organs and the patient's ability to perceive stimuli. Evaluate interventions designed to relieve problems associated with sensory alterations on the basis of a patient's ability to function normally without injury. When you directly or indirectly (through education) alter a patient's environment, evaluate by observing whether the patient makes environmental changes. When designing patient teaching to improve sensory function, it is important to determine whether the patient is following recommended therapies and meeting mutually set goals. Asking a patient to explain or demonstrate self-care skills is an effective evaluative measure. It is often necessary to reinforce previous instruction if learning has not taken place. If outcomes are unmet, these are examples of questions to ask:

- "How often do you wear your hearing aids/corrective lenses?"
- "Are you able to participate in a small group discussion?"
- "Are you able to read the newspaper without squinting?"

The results of your evaluation will determine whether to continue the existing plan of care, make modifications, or end the use of select interventions.

Key Points

- Your senses receive information from your environment. Sensory information is converted into nerve signals that travel to the brain and are turned into meaningful sensations.
- Sensory alterations occur when external stimuli are meaningless or deficient (sensory deprivation) or when there is excessive stimulation (sensory overload).
- Many factors affect sensory function. Aging results in a gradual decline of acuity in all senses.
- Sensory alterations can limit a patient's ability to interact and function within the environment.

- A thorough assessment of the sensory system allows for the development and implementation of an individualized plan of care.
- When conducting an assessment, gather information by establishing a therapeutic rapport with the patient.
- Nursing diagnoses are selected by recognizing the way that sensory alterations affect a person's ability to function.
- Preventive actions and the early identification of sensory alterations require periodic health screenings.
- Individualized plans of care with both patient and family involvement influence the quality of sensory experiences.
- An assessment of hazards in the environment is important to reduce the risk of injury among patients with sensory deficits. Proper support and resources are necessary for a person to adjust to a sensory impairment.

Reflective Learning

- Consider a patient experience you have encountered and describe three strategies that you implemented to minimize sensory overload.
- Consider a patient experience you provided to a patient with a sensory alteration. What could you do differently next time to better support and encourage the same patient or a different one?
- Consider a patient experience you provided to a patient with a hearing impairment. What were some of the most challenging moments? What were your limitations, if any?

Review Questions

1. A patient has been on contact isolation for 4 days because of a hospital-acquired infection. He has had few visitors and few opportunities to leave his room. His ambulation is also still limited. Which are the correct nursing interventions to reduce sensory deprivation? (Select all that apply.)
 1. Teaching how activities such as reading and using crossword puzzles provide stimulation
 2. Moving him to a room away from the nurses' station
 3. Turning on the lights and opening the room blinds
 4. Sitting down, speaking, touching, and listening to his feelings and perceptions
 5. Providing auditory stimulation for the patient by keeping the television on continuously
2. The home care nurse is instructing an assistive personnel about interventions to facilitate location of items for patients with vision impairment. Which are effective strategies for enhancing a patient's impaired vision? (Select all that apply.)
 1. Use of fluorescent lighting
 2. Use of warm incandescent lighting
 3. Use of yellow or amber lenses to decrease glare
 4. Use of adjustable blinds, sheer curtains, or draperies
 5. Indirect lighting to reduce glare
3. An older adult patient with bilateral hearing loss wears a hearing aid in her left ear. Which of the following approaches best facilitates communication with her? (Select all that apply.)
 1. Talk to the patient at a distance so he or she may read your lips.
 2. Keep your arms at your side; speak directly into the patient's left ear.
 3. Face the patient when speaking; demonstrate ideas you wish to convey.

4. Position the patient so that the light is on his or her face when speaking.
 5. Verify that the information that has been given has been clearly understood.
4. A patient is returning to an assisted-living apartment following a diagnosis of declining, progressive visual loss. Although she is familiar with her apartment and residence, she reports feeling a little uncertain about walking alone. There is one step into her apartment. Her children are scheduling themselves to be available to their mom for the next 2 weeks. Which of the following approaches will you teach the children to assist ambulation? (Select all that apply.)
1. Walk one-half step behind and slightly to her side.
 2. Have her grasp your arm just above the elbow and walk at a comfortable pace.
 3. Stand next to your mom at the top and bottom of stairs.
 4. Stand one step ahead of mom at the top of the stairs.
 5. Place yourself alongside your mom and hold onto her waist.
5. A new nurse is going to help a patient walk down the corridor and sit in a chair. The patient has an eye patch over the left eye and poor vision in the right eye. What is the correct order of steps to help the patient safely walk down the hall and sit in the chair?
1. Tell patient when you are approaching the chair.
 2. Walk at a relaxed pace.
 3. Guide patient's hand to nurse's arm, resting just above the elbow.
 4. Position yourself one-half step in front of patient.
 5. Position patient's hand on back of chair.
6. A patient with progressive vision impairments had to surrender his driver's license 6 months ago. He comes to the medical clinic

for a routine checkup. He is accompanied by his son. His wife died 2 years ago, and he admits to feeling lonely much of the time. Which of the following interventions reduce loneliness? (Select all that apply.)

1. Sharing information about senior transportation services
 2. Reassuring the patient that loneliness is a normal part of aging
 3. Maintaining distance while talking to avoid overstimulating the patient
 4. Providing information about local social groups in the patient's neighborhood
 5. Recommending that the patient consider making living arrangements that will put him closer to family or friends
7. A nurse is performing an assessment on a patient admitted to the unit following treatment in the emergency department for severe bilateral eye trauma. During patient admission the nurse's priority interventions include which of the following? (Select all that apply.)
1. Conducting a home-safety assessment and identifying hazards in the patient's living environment
 2. Reinforcing eye safety at work and in activities that place the patient at risk for eye injury
 3. Placing necessary objects such as the nurse call system and water in front of the patient to prevent falls caused by reaching
 4. Orienting the patient to the environment to reduce anxiety and prevent further injury to the eye
 5. Alerting other nurses and health care providers about patient's visual status during hand-off reports
8. An older adult is admitted from a skilled nursing home to a medical unit with pneumonia. A review of the medical record

reveals that he had a stroke affecting the right hemisphere of the brain 6 months ago and was placed in the skilled nursing home because he was unable to care for himself. Which of these assessment findings does the nurse expect to find? (Select all that apply.)

1. Slow, cautious behavioral style
2. Inattention and neglect, especially to the left side
3. Cloudy or opaque areas in part of the lens or the entire lens
4. Visual spatial alterations such as loss of half of a visual field
5. Loss of sensation and motor function on the right side of the body

9. A nurse is performing a home care assessment on a patient with a hearing impairment. The patient reports, "I think my hearing aid is broken. I can't hear anything." After determining that the patient's hearing aid works and that the patient is having trouble managing the hearing aid at home, which of the following teaching strategies does the nurse implement? (Select all that apply.)

1. Demonstrate hearing aid battery replacement.
2. Review method to check volume on hearing aid.
3. Demonstrate how to wash the earmold and microphone with hot water.
4. Discuss the importance of having wax buildup in the ear canal removed.
5. Recommend a chemical cleaner to remove difficult buildup.

10. Identify the measures to ensure safety for a patient who has no sensation on one side of the body.

Perioperative Nursing Care

OBJECTIVES

- Describe the three phases of perioperative nursing.
- Explain the rationale for a nursing assessment of a patient's surgical risk factors.
- Identify co-morbid conditions that increase patient risks for postoperative complications.
- Explain the approach for assessing a patient's potential psychological response to impending surgery.
- Explain the influence a preoperative teaching plan can have on a patient's surgical recovery.
- Explain the rationale for postoperative exercises and early ambulation.
- Describe how a nurse's intraoperative assessment promotes patient safety
- Explain the differences between intraoperative phases.
- Describe the components of SBAR communication for perioperative hand-off.
- Identify nursing care priorities for postoperative patients.
- Describe the principles for providing education to surgical patients during the restorative phase of recovery

Perioperative nursing includes a registered nurse's planned patient-centered approach in providing care to patients preoperatively, intraoperatively, and postoperatively. Through the application of national practice standards, the registered nurse's role in providing quality patient care before, during, and after surgery is crucial in maintaining patient safety. The perioperative nurse utilizes the nursing process to guide the delivery of care to patients in hospitals, surgical centers, and/or health care providers' offices. Nursing goals in the preoperative area are based on the following:

- Quality improvement and evidence-based practices through the application of current research and the generation of ideas for new research knowledge
- Patient safety through high-quality care
- Teamwork and collaboration
- Effective communication and interactions with a patient, the patient's family members, and the surgical team, fostering shared decision making
- The nursing process to deliver timely assessment and interventions in all phases of surgery
- Advocacy for a patient and the patient's family
- Cost containment

Perioperative nursing includes multiple intersecting processes guided by theoretical knowledge, ethical principles, ongoing research, specialized clinical skills, and caring practices ([Association of periOperative Registered Nurses, 2018a](#)). A nurse working within the perioperative setting responds to complex and fluctuating clinical needs during a crucial period of a patient's surgical experience. A nurse who works in any perioperative setting relies on clinical reasoning skills to maintain surgical asepsis, communicate effectively with members of the surgical team, and emphasize patient safety in each phase of surgery. Effective teaching and discharge planning involving patients and their family members prevent or minimize complications and contribute to quality outcomes. The nursing process provides a basis for perioperative nursing, allowing nurses to individualize patient care strategies throughout the perioperative period. A patient's smooth transition from admission into the health care system through recovery is the aim of quality perioperative care.

Care of a patient having surgery has shifted from a hospital- to home-based focus. Often recovery occurs in the home or in rehabilitation settings within long-term care centers. When care is in the home, responsibility shifts to the patient and/or family caregiver. As the length of hospital stay decreases, the educational needs of a patient undergoing a surgical procedure increase. Patients return home with complex medical/surgical conditions that require education and follow-up. Proper patient and family education is essential to ensuring positive surgical outcomes.

Scientific Knowledge Base

Classification of Surgery

The types of surgical procedures are classified according to seriousness, urgency, and purpose ([Table 50.1](#)). Although surgeries are classified as major or minor, any procedure can be considered major from the perspective of the patient and/or the family. Some procedures fall into more than one classification. For example, a colon resection to remove a malignant tumor is major in seriousness, urgent in urgency, and ablative in purpose. In many instances, the classifications intersect. Urgent procedures are major in seriousness. Frequently, the same procedure is performed for different reasons on different patients. For example, a gastrectomy may be performed as an emergency procedure to resect a bleeding ulcer or as an urgent procedure to remove a malignant tumor. Knowing the classifications assists in planning appropriate perioperative care.

TABLE 50.1**Classification of Surgical Procedures**

Classification Type	Description	Example
Seriousness		
Major	Involves extensive reconstruction or alteration in body parts; poses great risks to well-being	Coronary artery bypass, colon resection, removal of larynx, resection of lung lobe
Minor	Involves minimal alteration in body parts; designed to correct deformities; involves minimal risks to well-being.	Cataract extraction, facial plastic surgery, tooth extraction
Urgency		
Elective	Performed on basis of patient's choice; is not essential and is not always necessary for health	Bunionectomy; facial plastic surgery; hernia repair; breast reconstruction
Urgent	Necessary for patient's health; often prevents development of additional problems (e.g., tissue destruction or impaired organ function); not necessarily emergency	Excision of cancerous tumor; removal of gallbladder for stones; vascular repair for obstructed artery (e.g., coronary artery bypass)
Emergency	Must be done immediately to save life or preserve function of body part	Repair of perforated appendix or traumatic amputation; control of internal hemorrhaging
Purpose		
Diagnostic	Surgical exploration performed to confirm diagnosis; often involves removal of tissue for further diagnostic testing	Exploratory laparotomy (incision into peritoneal cavity to inspect abdominal organs); breast mass biopsy
Ablative	Excision or removal of diseased body part	Amputation; removal of appendix or an organ such as gallbladder (cholecystectomy)
Palliative	Relieves or reduces intensity of disease symptoms; does not produce cure	Colostomy; debridement of necrotic tissue; resection of nerve roots
Reconstructive/restorative	Restores function or appearance to traumatized or malfunctioning tissues	Internal fixation of fractures; scar revision
Procurement for transplant	Removal of organs and/or tissues from a person pronounced brain dead or from living donors for transplantation into another person	Kidney, heart, or liver transplant
Constructive	Restores function lost or reduced as result of congenital anomalies	Repair of cleft palate; closure of atrial septal defect in heart
Cosmetic	Performed to improve personal appearance	Blepharoplasty for eyelid deformities; rhinoplasty to reshape nose

The surgical classification describes the condition of a patient facing impending surgery. The **American Society of Anesthesiologists (ASA)** assigns classification on the basis of a patient's physiological condition independent of the proposed surgical procedure (Table 50.2). The classification is a risk assessment that allows surgeons and anesthesia providers to consider factors that influence how surgery will be performed. Anesthesia involves risks even in healthy patients; however, some patients, including but not limited to those with metabolic and cardiac dysfunction, are at higher risk.

TABLE 50.2**ASA Physical Status (PS) Classification**

Asa Ps Class	Definition	Characteristics
ASA I	A normal healthy patient	No physiological, biological, organic disturbance; healthy, nonsmoking; no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional changes (e.g., current smoker, social alcohol drinker, pregnancy, obesity [BMI 30-39], well-controlled DM/HTN, mild lung disease)
ASA III	A patient with severe systemic disease	Substantive functional changes with one or more moderate-to-severe diseases (e.g., poorly controlled DM or HTN, COPD, morbid obesity [BMI 40 or greater], active hepatitis, alcohol dependence or abuse, implanted pacemaker, or moderate reduction of cardiac ejection fraction)
ASA IV	A patient with severe systemic disease that is a constant threat to life	Examples include recent (less than 3 months) MI, CVA, TIA, ongoing cardiac ischemia or severe valve dysfunction, sepsis, disseminated intravascular coagulation, end-stage renal disease not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Examples include ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel with significant cardiac pathology
ASA VI	A patient declared brain dead whose organs are being removed for donor purpose	Wide variety of dysfunctions that are being managed to optimize blood flow to the heart and organs (e.g., aggressive fluid replacement and blood pressure medications)

Modified from American Society of Anesthesiologists: *ASA Physical Status Classification System*, October 15, 2014,
<http://www.asahq.org/resources/clinical-information/asa-physical-status-classification-system>. Accessed July 15, 2018.

Surgical Risk Factors

Numerous factors create risks for patients planning surgery. Risk factors can affect patients in any phase of the perioperative experience. One common risk factor for all patients is the surgical stress response. Understanding the physiology of the stress response ([Chapter 37](#)) and risk factors that affect patients' responses to surgery is necessary to anticipate patient needs and the types of preparation required preoperatively.

Smoking

Surgical patients who smoke are at a higher risk for developing pneumonia, atelectasis, and delayed wound healing (Wechter et al., 2016). Chronic smoking increases the amount and thickness of airway secretions, thus increasing the risk of aspiration. After surgery, a patient who smokes has greater difficulty clearing the airways of mucus, thus contributing to the development of pneumonia. Smoking decreases the amount of oxygen that reaches the cells in the surgical wound. As a result, the wound may heal more slowly and is more likely to become infected (Wechter et al., 2016). Further, current research suggests that surgical patients who use electronic cigarettes, also known as “vaping,” are at risk for delayed wound healing and vascular necrosis (Fracol et al., 2017). Although decades of research correlate cigarette smoking to poor patient outcomes in all phases of the perioperative experience, some preoperative patients are unaware of the surgical risks associated with smoking. Recent studies suggest the need for health care providers to implement systematic and planned measures targeted at educating preoperative patients on the surgical risks of smoking all forms of cigarettes (Fracol et al., 2017).

Age

Very young and older patients are at greater surgical risk as a result of an immature or a declining physiological status (Mistry et al., 2017; Linnaus and Ostlie, 2016). Both populations often present problems in temperature control during surgery. General anesthetics inhibit shivering and cause vasodilation, which results in heat loss. These anesthetic changes coupled with age-related physiological factors increase the risk for unintended hypothermia. Infants also have difficulty in maintaining normal circulatory blood volume, causing risks for dehydration and overhydration.

Older adults account for the majority of surgeries performed in the United States (Lin et al., 2016). Their risks are significant. Among persons age 65 and over, chronic health conditions (co-morbidities) such as hypertension, heart disease, cancer, and diabetes are surgical risk factors (National Center for Health Statistics, 2017). Older patients often experience diminished cardiac, pulmonary, and renal function, which decreases older adults’ ability to maintain homeostasis perioperatively (Table 50.3). Baroreceptor function, which regulates blood pressure, may be insufficient and cause postural hypotension and dizziness, increasing fall risks. Decreased respiratory function, impaired functional reserve of the pulmonary system, and decreased cough reflex increase the risk for aspiration, infection, and bronchospasm. Further, dehydration and fluid

imbalance (common in nursing home residents) require a need for hydration if the patient is unable to drink before surgery ([Nicholas, 2014](#)).

TABLE 50.3**Physiological Factors That Place the Older Adult at Risk During Surgery**

Alterations	Risks	Nursing Implications
Cardiovascular System		
Degenerative change in myocardium and valves	Decreased cardiac reserve puts older adults at risk for decreased cardiac output, especially during times of stress (AORN, 2015)	Assess baseline vital signs for tachycardia, fatigue, and arrhythmias (AORN, 2015).
Rigidity of arterial walls and reduction in sympathetic and parasympathetic innervation to the heart	Alterations predispose patient to postoperative hemorrhage and rise in systolic and diastolic blood pressure	Maintain adequate fluid balance to minimize stress to the heart. Ensure that blood pressure level is adequate to meet circulatory demands.
Increased calcium and cholesterol deposits within small arteries; thickened arterial walls	Predispose patient to clot formation in lower extremities	Instruct patient in techniques of leg exercises and proper turning. Apply elastic stockings or intermittent pneumatic compression (IPC) devices. Administer anticoagulants as ordered by health care provider. Provide education regarding effects, side effects, and dietary considerations.
Integumentary System		
Decreased subcutaneous tissue and increased fragility of skin	Prone to pressure injuries and skin tears	Assess skin every 4 hours; pad all bony prominences during surgery. Turn or reposition at least every 2 hours.
Pulmonary System		
Decreased respiratory muscle strength and cough reflex (AORN, 2015)	Increased risk for atelectasis	Instruct patient in proper technique for coughing, deep breathing, and use of spirometer. Ensure adequate pain control to allow for participation in exercises.
Reduced range of movement in diaphragm	Residual capacity (volume of air left in lung after normal breath) increased, reducing amount of new air brought into lungs with each inspiration	When possible, have patient ambulate and sit in chair frequently.
Stiffened lung tissue and enlarged air spaces	Blood oxygenation reduced	Obtain baseline oxygen saturation; measure throughout perioperative period.
Gastrointestinal System		
Gastric emptying delayed	Increases risk for reflux and indigestion (AORN, 2015)	Position patient with head of bed elevated at least 45 degrees. Reduce size of meals in accordance with ordered diet.
Renal System		
Decreased renal function, with reduced blood flow to kidneys	Increased risk of shock when blood loss occurs; increased risk for fluid and electrolyte imbalance (AORN, 2015)	For patients hospitalized before surgery, determine baseline urinary output for 24 hours.
Reduced glomerular filtration rate and excretory times	Limited ability to eliminate drugs or toxic substances	Assess for adverse response to drugs.
Decreased bladder capacity	Increased risk for urgency, incontinence, and urinary tract infections (AORN, 2015). (Sensation of need to void often does not occur until bladder is filled.)	Instruct patient to notify nurse immediately when sensation of bladder fullness develops. Keep nurse call system and bedpan within easy reach. Toilet every 2 hours or more frequently if indicated.
Neurological System		
Sensory losses, including reduced tactile sense and increased pain tolerance	Decreased ability to respond to early warning signs of surgical complications	Inspect bony prominences for signs of pressure that patient is unable to sense. Orient patient to surrounding environment. Observe for nonverbal signs of pain.
Febrile response during surgery (AORN, 2015)	Increased risk of undiagnosed infection	Ensure careful, close monitoring of patient temperature; provide warm blankets; monitor heart function; warm intravenous fluids (AORN, 2015).
Decreased reaction time	Confusion and delirium after anesthesia; increased risk for falls	Allow adequate time to respond, process information, and perform tasks. Perform fall-risk screening and institute fall precautions. Screen for delirium with validated tools. Orient frequently to reality and surroundings.
Metabolic System		
Lower basal metabolic rate	Reduced total oxygen consumption	Ensure adequate nutritional intake when diet is resumed but avoid intake of excess calories.
Reduced number of red blood cells and hemoglobin levels	Reduced ability to carry adequate oxygen to tissues	Administer necessary blood products as needed. Monitor blood test results and oxygen saturation.
Change in total amounts of body potassium and water volume	Greater risk for fluid or electrolyte imbalance	Monitor electrolyte levels and supplement as necessary. Provide cardiac monitoring (telemetry) as needed.

Association of PeriOperative Registered Nurses: AORN position statement on care of the older adult in perioperative settings: position statement, 2015.

<https://www.aorn.org/guidelines/clinical-resources/position-statements>. Accessed July 18, 2018.

Nutrition

Tissue repair and resistance to infection depend on adequate nutrition. Surgery increases the need for nutrients (Weimann et al., 2017). Patients who are thin or obese are often deficient in protein and vitamins, putting them at greater risk for complications following surgery (Lewis et al., 2017). After surgery, a patient requires at least 1500 kcal/day to maintain energy reserves. This intake is difficult to attain when a patient's food and/or fluid intake is limited after surgery or if a patient experiences postoperative nausea and vomiting (PONV). Postoperatively, patients gradually increase their dietary intake (once gastrointestinal activity returns) over 1 to 2 days ~~3 to 5~~ days after surgery until they can tolerate normal meals. Patients who enter surgery malnourished are more likely to have poor tolerance for anesthesia, negative nitrogen balance, delayed postoperative recovery, infection, and delayed wound healing. Current recommendations suggest replacing iron, vitamin B₁₂, and folate at least 28 days before scheduled elective surgery (Weimann et al., 2017). Some studies indicate that recovery can also be enhanced by regulating the metabolic status of a patient before surgery (e.g., minimizing metabolic stress and insulin resistance by giving carbohydrate-based drinks and fluid loading) and after surgery (e.g., early oral feeding and giving prokinetic medications to enhance gastric motility, resulting in improved enteral feeding tolerance) (Weimann et al., 2017).

Obesity

Patients who are morbidly obese typically live up to 14 years less than their average-weight counterparts (Hales et al., 2017). According to the National Center for Health Statistics (2017), the prevalence of obesity among US adults was 39.8%. Approximately 18.5% of America's youth were obese in 2015–2016 (Hales et al., 2017). As a patient's weight increases, his or her ventilatory and cardiac function diminish, increasing the risk for postoperative **atelectasis**, pneumonia, and death. Obstructive sleep apnea (OSA), hypertension, coronary artery disease, diabetes mellitus, and heart failure are **co-morbid** conditions in the **bariatric** population. Patients who are obese often have difficulty resuming normal physical activity after surgery because of the pain and fatigue caused by

surgery in addition to preexisting impaired physical mobility. This combination of factors increases the risk of developing venous thromboembolism (VTE). Obesity is a significant risk factor for wound infections, surgical blood loss, and a longer operation time (Tjeertes et al., 2015).

Excess weight placed on skin over bony prominences restricts blood flow and poses risks for pressure injuries to form on the operating table. Obesity also increases the risk of poor wound healing, wound infection, dehiscence, and evisceration because fatty tissue contains a poor blood supply, slowing the delivery of essential nutrients and antibodies needed for wound healing (see Chapter 48). In addition, surgeons often have difficulty closing surgical wounds because of the thick adipose layer.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) is a chronic sleep disorder characterized by periodic episodes of narrowing or collapse of the upper airway (American Academy of Sleep Medicine, 2014). It occurs when muscles in the throat relax during sleep, causing soft tissue in the back of the throat to collapse and block the upper airway. A combination of structural and neuromuscular function, OSA results in pauses in breathing (apnea) that last at least 10 seconds during sleep. Most apneic episodes last between 10 and 30 seconds, but some may continue for 1 minute or longer, leading to significant **oxygen desaturation**. During an apnea episode, there is increasing negative intrathoracic pressure (down to -80 mm Hg), which makes it difficult for the heart to pump effectively against such a negative pressure; thus cardiac output decreases. In response to the oxygen desaturation, there is an arousal, which ends the apnea. The arousal is accompanied by a huge increase in sympathetic output, which causes a significant increase in blood pressure (American Academy of Sleep Medicine, 2014; Downey, 2018).

Patients with OSA often have co-morbid conditions such as asthma, atherosclerosis, myocardial infarction, heart failure, hypertension, atrial fibrillation, chronic kidney disease, and behavioral disorders, such as decreases in attention, vigilance, concentration, motor skills, and verbal and visuospatial memory (National Institute of Health, 2018). Some evidence suggests that the lack of sleep (for various reasons) may play a role in some older adults' mental decline a (National Institute of Health, 2018). The disorder hinders daily functioning because of chronic fatigue and sleepiness and adversely affects health and longevity. Patients who suffer from OSA develop numerous complications, including

hypertension, heart disease, vascular disease, neurological disease, and diabetes ([Raveendran and Chung, 2015](#)). Further, research suggests OSA is associated with insulin resistance, glucose tolerance, and type 2 diabetes independent of obesity ([Kent et al., 2015](#)).

Patients with OSA who are to undergo surgery present a significant risk. Receiving sedatives, opioid analgesics, and general anesthesia causes relaxation of the upper airway and may worsen OSA. The risk is higher when a patient is sedated and lying on his or her back. Patients have experienced severe apnea and hypoxemia, leading to death following surgical and diagnostic procedures under conscious sedation. Careful screening of patients at risk or symptomatic for OSA is essential before surgery ([Raveendran and Chung, 2015](#)). There is no evidence to suggest all surgical patients should be screened for OSA ([US Preventive Services Task Force, 2017](#)).

Immunosuppression

Patients with conditions that alter immune function (e.g., primary immune deficiency, acquired immunodeficiency syndrome [AIDS], cancer, bone marrow alterations, and organ transplants) are at an increased risk for developing infection after surgery. The risk for infection increases when patients receive radiation or chemotherapy for cancer treatment, take immunosuppressive medications to treat AIDS or prevent rejection after organ transplant, or require steroids to treat a variety of inflammatory or autoimmune conditions ([Hannaman and Ertl, 2013](#)). Radiation sometimes is given before surgery to reduce the size of a cancerous tumor so that it can be removed surgically. Ideally, a surgeon waits to perform surgery until 4 to 6 weeks after completion of radiation treatments because of the unavoidable effects that radiation has on normal tissue. Radiation thins the layers of the skin, destroys collagen, and impairs tissue perfusion. Otherwise, the patient may face serious wound-healing problems.

Fluid and Electrolyte Imbalance

The body responds to surgery as a form of trauma. Severe protein breakdown causes a negative nitrogen balance (see [Chapter 45](#)) and hyperglycemia. Both of these effects decrease tissue healing and increase the risk of infection. As a result of the adrenocortical stress response, the body retains sodium and water and loses potassium in the first 2 to 5 days after surgery. The severity of the stress response influences the degree of fluid and electrolyte imbalance. Extensive surgery results in a greater

stress response. A patient who is hypovolemic before surgery or who has serious electrolyte alterations is at significant risk during and after surgery. For example, an excess or depletion of potassium increases the chance of dysrhythmias during or after surgery. The risk of fluid and electrolyte alterations is even greater in patients with preexisting diabetes mellitus, renal disease, or gastrointestinal (GI) or cardiovascular abnormalities (see [Chapter 42](#)).

Postoperative Nausea and Vomiting (PONV)

The experience of having nausea and vomiting after surgery is uncomfortable and often immobilizing. PONV affects approximately 30% of patients in recovery rooms after surgery ([Fetzer, 2015](#)). It can lead to serious complications, including pulmonary aspiration, dehydration, and arrhythmias resulting from fluid and electrolyte imbalance. A patient who vomits frequently after surgery runs the risk of dehiscing surgical sutures. Patients predisposed to developing PONV are women, individuals with a history of PONV or motion sickness, nonsmoking status, and younger age. Anesthesia-related risk factors include the use of volatile anesthetics (e.g., nitrous oxide), duration of anesthesia, and perioperative opioid use. Certain types of surgery (e.g., abdominal procedures [cholecystectomies] and gynecological surgery) are also associated with PONV ([Gan et al., 2014](#)). Ambulatory surgery patients generally have less PONV. However, nausea and vomiting may occur after an ambulatory patient has left a surgical setting. This postdischarge nausea and/or vomiting (PDNV) may be particularly hazardous for ambulatory surgery patients because they no longer have immediate access to fast-onset intravenous antiemetic medications ([Apfel et al., 2012](#)). Screening for PONV is crucial. Patients with four or more risk factors have a higher incidence of PONV ([Rothrock, 2019](#)). Management of PONV begins before surgery.

Venous Thromboembolism

In 2008, the Centers for Medicare and Medicaid Services ruled that deep vein thrombosis (DVT) (clot formed in the deep veins) after total knee and hip surgery is a **never event** and refused to pay for hospital-acquired DVTs ([CMS, 2010](#)). If a patient develops a DVT after surgery, Medicare and some private insurance companies withhold payment to the hospital because DVTs are typically preventable. [The Joint Commission \(2017\)](#) has an updated set of accountability measures (i.e., quality measures that produce the greatest positive impact on patient outcomes when hospitals

demonstrate improvement in them). One of the accountability measures is treatment and prevention of venous thromboembolism (VTE). Some VTEs are subclinical (without symptoms), whereas others present as sudden pulmonary embolus or symptomatic DVT. Patients most at risk for developing VTE are those who undergo surgical procedures with a general anesthetic and undergo a surgical time of more than 90 minutes, or 60 minutes if the surgery involves the pelvis or lower limb; acute surgical admissions with inflammatory or intraabdominal conditions; and those expected to have significant reduction in mobility after surgery. In addition, patients are at higher risk if they have one or more risk factors (Streiff et al., 2016):

- Active cancer or cancer treatment
- Age over 60 years
- Critical care admission
- Dehydration
- Known clotting disorders
- Obesity (body mass index [BMI] of 30 kg/m² or greater)

REFLECT NOW

A nurse conducts a preoperative assessment for an 85-year-old patient who is accompanied by a caregiver. The patient's caregiver assists the patient with ambulation and answers the nurse's questions.

A review of the patient's medical record reveals recent episodes of sleep apnea. What questions should the nurse ask to assess this patient's risks for surgical complications? Which risk factors place this patient at risk for surgical complications?

Nursing Knowledge Base

Perioperative Communication

Continuity of care is pertinent when caring for surgical patients. Based on the delivery of care model utilized in the perioperative setting, some nurses may follow patients through the preoperative and intraoperative phases of surgery. In some instances, perioperative nurses follow patients through the postanesthesia care unit (PACU), assessing a patient's health status before surgery, identifying specific patient needs, teaching and counseling, preparing for the operating room (OR), and following a patient's recovery. However, different nurses and other health care providers also care for a patient during each phase of the surgical experience. A smooth communication "hand-off" between caregivers is needed to ensure continuity of care and reduce risk of medical errors (Benjamin et al., 2016). Transitions from one care provider to another place patients at risk for injuries, missed care, and errors in translating information. Nursing research shows that having a standardized checklist or protocol for hand-off communication between perioperative health care providers minimizes these risks (Scott et al., 2017). TJC National Patient Safety Goals address the importance of accurate patient identification and communication (TJC, 2020).

Glycemic Control and Infection Prevention

Evidence supports a relationship between wound and tissue infection and surgical patients' blood glucose levels. Poor control of blood glucose levels (specifically hyperglycemia) during and after surgery increases patients' risks for adverse outcomes, such as wound infection and mortality. Controlling blood sugars perioperatively reduces mortality in patients with or without diabetes who have general surgery and in patients who have cardiac surgery (van den Boom et al., 2018). Perioperative evaluation of patients coupled with appropriate insulin administration is a critical standard of care.

Pressure Injury Prevention

Patients who have surgery pose a unique challenge in pressure injury prevention (Shaw et al., 2014). Nursing research reveals that patients are at risk intraoperatively for pressure injuries as a result of intrinsic, extrinsic, and specific OR risk factors (EPUAP, NPIAP, PPIA, 2019; Primiano et al., 2011):

Intrinsic risks (patient's tolerance to a pressure injury insult)—altered nutrition (albumin levels <3 g/dL), decreased mobility, older age, decreased mental status, infection, incontinence, impaired sensory perception, and co-morbidities such as diabetes, malnutrition, and weight (Kim et al., 2017; Saghaleini et al., 2018).

Extrinsic risks (variables that increase tissue susceptibility to sustain external pressure)—temperature, friction and shearing forces, and moisture.

OR risk factors—length of surgery, position on OR table, positioning devices used, warming devices, anesthetic agents, intraoperative hemodynamics, and length of time on the OR bed.

A preoperative assessment should include screening for these risk factors. Registered nurses assist in preventing pressure injuries intraoperatively by carefully positioning patients and using pressure-relieving surfaces. Positioning is a shared responsibility among the surgeon, the anesthesia provider, and OR nurses. The optimal position often involves a compromise between the best position for surgical access and the position a patient can tolerate (Welch, 2018). After surgery, perform a careful skin assessment and use appropriate pressure-reduction strategies (see Chapter 48).

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Clinical judgments require you to anticipate information, analyze the data, and make decisions regarding your patient's care. During assessment, consider all elements that build toward making an appropriate nursing diagnosis ([Fig. 50.1](#)).

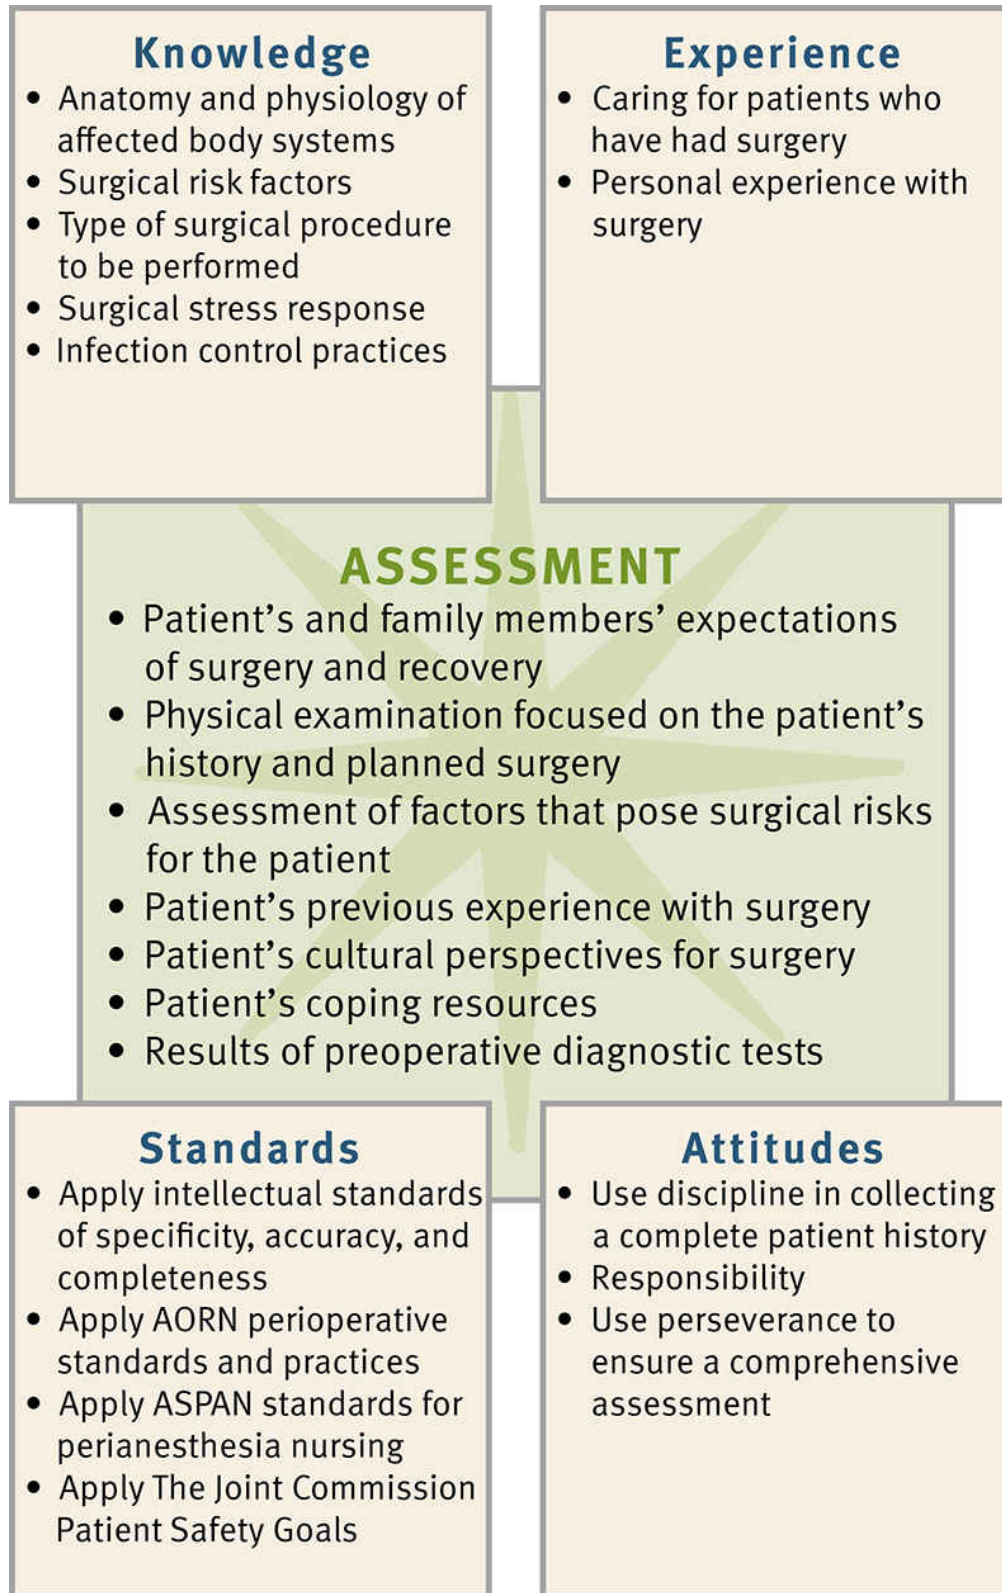

FIG. 50.1 Critical thinking model for surgical patient assessment. *AORN*, Association of periOperative Registered Nurses; *ASPAN*, American Society of PeriAnesthesia Nurses.

When caring for a patient having surgery, integrate knowledge regarding the patient's specific clinical situation along with previous experiences in caring for surgical patients. Apply this knowledge using a patient-centered care approach, partnering with your patient to make clinical decisions. Using critical thinking attitudes (see [Chapter 15](#)) ensures that a plan of care is comprehensive and incorporates evidence-based principles for successful perioperative care. A key attitude for a perioperative nurse is responsibility (i.e., being responsible not only for standards of care but being a patient advocate as well). The use of professional perioperative standards developed by the **Association of periOperative Registered Nurses (AORN)** (<http://www.aorn.org>) and the **American Society of PeriAnesthesia Nurses (ASPAN)** (<http://www.aspan.org/>) provide valuable guidelines for perioperative management and evaluation of process and outcomes. TJC Hospital National Patient Safety Goals include two sets of recommendations for perioperative care: prevent infection and prevent mistakes in surgery ([TJC, 2020](#)). Always review these guidelines within the context of new emerging evidence-based practice, agency policies, and the scope of practice of the state in which you practice.

REFLECT NOW

Think about a patient you cared for during his or her surgical experience. Develop a communication handoff for your patient that you would use to report to the nurse on the next shift.

Preoperative Surgical Phase

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care. Patients having surgery enter the health care setting in different levels of health. For example, a patient enters the hospital or ambulatory surgery center (ASC) on a predetermined day feeling relatively healthy and prepared to face elective surgery, while another person in a motor vehicle crash faces emergency surgery with no time to prepare. The ability to establish rapport and maintain a professional relationship with a patient and the patient's family is essential during the preoperative phase. Patients having surgery meet many health care personnel, including surgeons, nurse anesthetists, anesthesiologists, surgical technologists, and nurses. All play a role in a patient's care and recovery. Family members attempt to provide support through their presence but face many of the same stressors as the patient. As a nurse you need to form a caring relationship (see [Chapter 7](#)) and effectively communicate (see [Chapter 24](#)) with the patient and family to gain the patient's trust. This helps you to learn the depth of information needed to provide a patient-centered plan of care. Cultural sensitivity is equally important in developing a patient-centered plan of care reflecting the patient's physical, psychological, emotional, sociocultural, and spiritual well-being (see [Chapter 9](#)). You will learn to recognize a patient's degree of surgical risk, coordinate diagnostic tests, identify nursing diagnoses and nursing interventions, and establish outcomes in collaboration with patients and their families. It is a nurse's responsibility to communicate pertinent data and the plan of care to surgical team members.

Many hospitals have developed Enhanced Recovery After Surgery (ERAS) protocols. The protocols are interprofessional and based on published scientific evidence. Elements of an ERAS protocol might include minimally invasive surgical approaches instead of large incisions, management of fluids to seek fluid balance rather than large volumes of intravenous fluids, avoidance of or early removal of drains and tubes, early mobilization, and the serving of drinks and food the day of an operation ([Ljungqvist et al., 2017](#)). An ERAS protocol will include standards for preoperative and postoperative care.

• **Assessment**

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure that you make patient-centered clinical decisions required for safe nursing care. The goal of the preoperative assessment is to identify a patient's normal preoperative function and the presence of any surgical risks and to recognize, prevent, and minimize possible postoperative complications. The extent of a nurse's assessment depends on the patient's condition, the surgical setting, the time the nurse has with a patient, and the urgency of a procedure. Ambulatory and same-day surgical programs offer challenges in gathering a complete assessment in a short time. In these settings, an interprofessional team approach is essential. Patients are admitted only hours before surgery; consequently, it is important for a nurse to organize and verify data obtained before surgery and implement a perioperative plan of care. This occurs both in ASCs and with patients who require a hospital stay.

Most surgical assessments begin before admission in the health care provider's office, preadmission clinic, anesthesia clinic, or by telephone. Some patients answer a self-report inventory before arriving at a center. Other times a health care provider performs a physical examination or orders laboratory tests. Nurses begin to teach, answer questions, and complete paperwork before surgery to streamline patient care on the day of surgery. When surgery is emergent with little time available, you prioritize an assessment based on the patient's presenting clinical condition and risk factors.

Through the Patient's Eyes

When possible it is important to determine a patient's expectations of surgery and recovery. Ask a patient what he or she hopes to gain as a result of surgery. Explore with questions such as "Tell me the type of surgery you are having in your own words" or "Do you understand the expected care and how long you will stay in the hospital after surgery? If not, what do you want to know?" or "Do you expect full pain relief or simply to have your pain reduced after surgery?" and "Do you expect to be independent immediately after surgery, or do you expect to be fully dependent on the nurse or your family?" These are only a few of the questions to ask to establish a plan of care that matches a patient's needs and expectations. Listen to the patient's explanation, be attentive, and explain expectations of surgery. Form a relationship with each patient to

foster collaboration and shared decision making. Assessing patient expectations gives you a better understanding of the patient's health and health care needs.

Nursing History

A preoperative nursing history includes information similar to that described in [Chapter 30](#). If a patient is unable to relay all of the necessary information, rely on family members (if appropriate) as resources. As with any admission to a health care agency, include information about advance directives. Ask if a patient has a durable power of attorney for health care or a living will (see [Chapter 23](#)) and include a copy in the patient's medical record. Often directives are modified before surgery but are reestablished after postoperative stabilization. To help ensure a thorough and accurate nursing assessment, electronic health records (EHRs) provide standardized documentation forms for data. Be sure to use all drop-down menus to most clearly portray a patient's history, but also be willing to enter full-text descriptions as needed.

Medical History

A review of a patient's medical history includes past illnesses and surgeries and the primary reason for seeking medical care. The medical history screens surgical candidates for major medical conditions that increase the risk of complications during or after surgery ([Table 50.4](#)). For example, a patient who has a history of heart failure is at risk for a further decline in cardiac function during and after surgery. The patient with heart failure in the preoperative period often requires beta-blocker medications, intravenous (IV) fluids infused at a slower rate, or administration of a diuretic after blood transfusions. [Box 50.1](#) provides a list of assessment questions for a patient with a cardiac history. If a patient has surgical risks from medical conditions, surgery as an outpatient may be inadvisable, or special precautions will be necessary. In addition, the nurse asks about a family history of anesthetic complications such as malignant hyperthermia (an inherited disorder and life-threatening condition) that may occur during surgery.

TABLE 50.4**Medical Conditions That Increase Risks of Surgery**

Type of Condition	Reason for Risk
Bleeding disorders (thrombocytopenia, hemophilia)	Increases risk of hemorrhage during and after surgery.
Diabetes mellitus	Increases susceptibility to infection and impairs wound healing from altered glucose metabolism and associated circulatory impairment. Stress of surgery often results in hyperglycemia (Lewis et al., 2017).
Heart disease (recent myocardial infarction, dysrhythmias, heart failure) and peripheral vascular disease	Stress of surgery causes increased demands on myocardium to maintain cardiac output. General anesthetic agents depress cardiac function.
Hypertension	Increases risk for cardiovascular complications during anesthesia (e.g., stroke, inadequate tissue oxygenation).
Obstructive sleep apnea	Administration of opioids increases risk of airway obstruction after surgery. Patients desaturate as revealed by drop in oxygen saturation by pulse oximetry.
Upper respiratory infection	Increases risk of respiratory complications during anesthesia (e.g., pneumonia and spasm of laryngeal muscles).
Renal disease	Alters excretion of anesthetic drugs and their metabolites, increasing risk for acid-base imbalance and other complications.
Liver disease	Alters metabolism and elimination of drugs administered during surgery and impairs wound healing and clotting time because of alterations in protein metabolism.
Fever	Predisposes patient to fluid and electrolyte imbalances and sometimes indicates underlying infection.
Chronic respiratory disease (emphysema, bronchitis, asthma)	Reduces patient's means to compensate for acid-base alterations (see Chapter 42). Anesthetic agents reduce respiratory function, increasing risk for severe hypoventilation.
Immunological disorders (leukemia, acquired immunodeficiency syndrome [AIDS], bone marrow depression, and use of chemotherapeutic drugs or immunosuppressive agents)	Increases risk of infection and delayed wound healing after surgery.
Abuse of alcohol, opioid addiction	Alcohol abuse is associated with liver dysfunction and may interfere with the effects of anesthesia. Opioid addiction may result in health care and self-care neglect. Consequently, patients may have underlying diseases that may affect wound healing.
Chronic pain	Regular use of pain medications often results in higher tolerance. Increased doses of analgesics are sometimes necessary to achieve postoperative pain control.

Data from Mohabir PK: Preoperative evaluation, 2018, *Merck manual professional version*. <https://www.merckmanuals.com/professional/special->

[subjects/care-of-the-surgical-patient/preoperative-evaluation](#). Last revised April 2018. Accessed August 3, 2018; and Lewis S, et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 10, St Louis, 2017, Elsevier.

Box 50.1 Nursing Assessment Questions: Cardiac History

Nature of the Problem

- Do you have a history of heart attack, heart failure, angina (chest pain), irregular heartbeat, or valve disease?
- Which medications do you take?
- Are you taking any vitamins or other supplements?
- Have you had any recent medical testing or procedures on your heart (e.g., cardiac catheterization or echocardiogram)?
- Do you smoke cigarettes, including e-cigarettes? If so, how often and how many per day?

Signs and Symptoms

- Are you having any chest pain?
- How do you sleep at night (position, use of pillows, awakened with chest pain)?
- Do your feet swell?
- Are you short of breath, or do you have any difficulty breathing?

Onset and Duration

- How often do you have chest pain, when does it start, how long does it last, what alleviates it?
- When do your feet swell (all the time, end of the day, only after a busy day)?

- When do you become short of breath?

Severity

- On a scale of 0 to 10 (with 0 being no pain and 10 the worst pain), what number do you give your chest pain?
- Describe your usual activity level. Can you climb stairs; can you do housework?
- Do you exercise regularly? What exercise?

Self-Management and Culture

- Have you changed your activity level, sleep patterns, diet, or fluid intake recently?
- Are you taking any herbal or over-the-counter medications?

Through the Patient's Eyes

- How are you feeling about your upcoming surgery? Has it affected your symptoms?
- Are you currently having any additional stress?

Surgical History

A review of a patient's past experience with surgery reveals physical and potential psychological responses that may occur during the planned procedure. Complications such as anaphylaxis or malignant hyperthermia during previous surgeries alert you to the need for preventive measures and the availability of appropriate emergency equipment. For example, if a patient experienced an allergic reaction to latex during a previous surgery, the nurse should document the patient's history and ensure that a latex-free environment is provided for the patient during hospitalization.

A history of postoperative complications such as persistent vomiting or uncontrolled pain will lead to the selection of more appropriate medications (as ordered by the medical team). Reports of severe anxiety before a previous surgery identify the need for additional emotional support, medications, and preoperative teaching. Always inform the

surgeon and/or anesthesiologist of these findings, especially when medications may be indicated.

Risk Factors

Knowledge of potential surgical risk factors and risk factors for complications (e.g., pressure injuries) provides focus for the preoperative assessment. The assessment data from careful screening of patients will contain information useful for necessary precautions in planning perioperative care. Consider any risk factors described earlier that may contribute to negative outcomes, and collaborate closely with the health care provider to identify necessary therapies. For example, some patients need to stop taking estrogen-containing oral contraceptives or hormone-replacement therapy 4 weeks before elective surgery to reduce the risk of thromboembolism (Streiff et al., 2016). Carefully screen patients who have signs and symptoms of suspected OSA. Include the patient's sleeping partner as appropriate to assess for signs of OSA such as snoring. Also, determine the patient's use of continuous positive airway pressure (CPAP), noninvasive positive-pressure ventilation (NIPPV), or apnea monitoring at home. Instruct patients who use CPAP or NIPPV to bring their machine to the hospital or surgery center. Many hospitals are now making OSA screening mandatory, using evidence-based tools such as the STOP-BANG sleep apnea assessment tool (Box 50.2) (Chung et al., 2013, 2016). Screen patients with simple questions regarding snoring, apnea during sleep, frequent arousals during sleep, morning headaches, daytime somnolence, and chronic fatigue (Ganzberg, 2016; Helvig et al., 2014).

Box 50.2 The STOP-BANG Questionnaire

BMI, Body mass index.

Height _____ cm /inches Weight _____ lb/kg

Age _____

Male/Female

BMI _____

Collar size of shirt: S, M, L, XL, or _____ cm /inches

Neck circumference^a _____ cm

1. Snoring

- Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
Yes No
2. **Tired**
Do you often feel *tired*, fatigued, or sleepy during daytime?
Yes No
3. **Observed**
Has anyone *observed* you stop breathing during your sleep?
Yes No
4. **Blood Pressure**
Do you have or are you being treated for high blood pressure?
Yes No
5. **BMI**
BMI more than 35 kg/m²?
Yes No
6. **Age**
Age over 50 years old?
Yes No
7. **Neck circumference (measure with approved measuring tape)^a**
Neck circumference greater than 40 cm?
Yes No
8. **Gender**
Gender male?
Yes No
- Score of 4**—High sensitivity of 88% for identifying severe obstructive sleep apnea (OSA)
Score of 5 or more—High risk of OSA; a score of 6 is more specific

^a Neck circumference is measured by staff.

Modified from Chung F, et al: Predictive performance of the STOP-BANG score for identifying obstructive sleep apnea in obese patients, *Obes Surg* 23(12):2050, 2013; Chung F, et al: STOP-Bang questionnaire: a practical approach to screen for obstructive sleep apnea, *Chest* 149(3):631, 2016.

Some patients need a detailed nutritional assessment to determine surgical risk. If a patient presents with signs of malnutrition, perform a

nutritional screening using your agency's tool, or confer with a registered dietitian (see [Chapter 45](#)).

Medications

Review a patient's medications to determine if he or she is taking any medications that increase the risk for surgical complications ([Table 50.5](#)). Include all prescribed, OTC, and herbal medications in your assessment. Many medications interact unpredictably with anesthetic agents during surgery ([Burchum and Rosenthal, 2019](#)). Sometimes surgeons temporarily discontinue or adjust doses of a patient's prescription, over-the-counter (OTC) medications, and/or herbal supplements before surgery. Nurses in an outpatient setting should verify with surgeons which, if any, medications patients should take the morning of surgery. Often preprinted instruction sheets given to patients in physician offices contain this information. When working in an acute care setting, confirm with the surgeon all discontinued medications. If a patient is having inpatient surgery, all prescription medications taken before surgery are discontinued automatically after surgery unless reordered. It is important that as a patient moves through different areas (e.g., holding area to the OR), a complete list of medications is communicated accurately during hand-off report ([TJC, 2020](#)).

TABLE 50.5**Medications with Special Implications for the Surgical Patient**

Drug Class	Effects During Surgery
Antibiotics	Potentiate (enhance action of) anesthetic agents. If taken within 2 weeks before surgery, aminoglycosides (gentamicin, neomycin, tobramycin) may cause mild respiratory depression from depressed neuromuscular transmission.
Antidysrhythmics	Medications (e.g., beta blockers) can reduce cardiac contractility and impair cardiac conduction during anesthesia.
Anticoagulants	Medications such as warfarin or aspirin alter normal clotting factors and thus increase risk of hemorrhaging. Discontinue at least 48 hours before surgery.
Anticonvulsants	Long-term use of certain anticonvulsants (e.g., phenytoin and phenobarbital) alters metabolism of anesthetic agents.
Antihypertensives	Medications such as beta blockers and calcium channel blockers interact with anesthetic agents to cause bradycardia, hypotension, and impaired circulation. They inhibit synthesis and storage of norepinephrine in sympathetic nerve endings.
Corticosteroids	With prolonged use, corticosteroids cause adrenal atrophy, reducing the ability of the body to withstand stress. Before and during surgery, dosages are often increased temporarily.
Insulin	A patient's insulin requirements fluctuate after surgery. For example, some patients need increased doses due to the stress response from surgery. Other patients need less insulin due to decreased nutritional intake following surgery.
Diuretics	Diuretics such as furosemide potentiate electrolyte imbalances (particularly potassium) after surgery.
Nonsteroidal antiinflammatory drugs (NSAIDs)	NSAIDs (e.g., ibuprofen) inhibit platelet aggregation and prolong bleeding time, increasing susceptibility to postoperative bleeding.
Herbal therapies: ginger, ginkgo, ginseng	These herbal therapies have the ability to affect platelet activity and increase susceptibility to postoperative bleeding. Ginseng increases hypoglycemia with insulin therapy.

Data from Kuwajerwala K: *Perioperative medication management*, Medscape, 2018. <https://emedicine.medscape.com/article/284801-overview#a4>. Last reviewed January 9, 2018. Accessed August 3, 2018.

Allergies

Allergies to medications, latex, and topical agents used to prepare the skin for surgery create significant risks for patients during surgery. An allergic response to any agent is potentially fatal, depending on severity. Latex allergies are on the rise, with 1% to 6% of the general population and 8% to 12% of the health care workforce sensitive to latex (OSHA, n.d.). Patients most at risk for a latex allergy include people with a genetic predisposition to latex allergy, children with spina bifida, patients with urogenital abnormalities or spinal cord injury (because of a long history of urinary

catheter use), patients with a history of multiple surgeries, health care professionals, and workers who manufacture rubber products. Patients with an allergy to certain foods such as bananas, chestnuts, kiwifruit, avocados, potatoes, strawberries, nectarines, tomatoes, and wheat often have a cross-sensitivity to latex ([Cleveland Clinic, 2017](#)). Symptoms of a latex allergy vary in severity (e.g., contact dermatitis with redness, inflammation, and blisters; contact urticaria with pruritus, redness, and swelling; hay fever–like symptoms; and anaphylaxis). When you identify a patient allergy, provide an allergy identification band at the time of admission that remains on until discharge. List all allergies in the patient’s medical record. It is also common to list allergies on the front of paper charts.

Smoking Habits

Screen all patients for a history of smoking, including cigarettes, cigars, electronic cigarettes, and pipes. This is usually included in the nursing health history. Use “pack-years” as a guide to determine the number of cigarette packs smoked per day and the number of years the patient has smoked. In addition, ask the patient about the use and frequency of other nicotine products such as snuff and chewing tobacco. Use this information to plan for aggressive pulmonary hygiene, including more frequent turning, deep breathing, coughing, and the use of incentive spirometry after surgery.

Alcohol Ingestion and Substance Use and Abuse

Habitual use of alcohol or illegal drugs and the misuse of prescription drugs predispose patients to adverse reactions to anesthetic agents. Some patients experience a cross-tolerance to anesthetic agents and analgesics, resulting in the need for higher-than-usual doses. Patients with a history of excessive alcohol ingestion are often malnourished, which delays wound healing. These patients are also at risk for liver disease, portal hypertension, and esophageal varices (which increase the risk of bleeding). A patient who habitually uses alcohol and is required to remain in the hospital longer than 24 hours is also at risk for acute alcohol withdrawal and its more severe form, delirium tremens (DTs).

It is important to assess all age-groups because there is a high prevalence of at-risk drinking and binge drinking (17% overall) in adults ages 18 years and older ([CDC, 2018](#)). It is common for patients to not disclose their use of alcohol or illegal drug use. Begin the assessment by

asking the patient if he or she consumes wine, beer, whiskey, and other forms of alcohol. Assess the number of drinks the patient has during a typical day or week. Also ask about the use of illegal drugs and the use of prescription drugs, including the type, frequency, and method of delivery. Some health care facilities require the use of screening tools such as the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) to assess a patient's use of illegal drugs, smoking, and/or misuse of prescription drugs or the Alcohol Use Disorders Identification Test (AUDIT) to screen for alcohol use problems ([World Health Organization, 2018](#); [American Society of Addiction Medicine, 2019](#)). Your findings will help in the planning of anesthetic and pain management. However, it is important postoperatively to consider opportunities to counsel those patients whose use of alcohol or illicit drugs is excessive.

Pregnancy

During preoperative assessment, routinely ask women of childbearing age who are scheduled for surgery about their last menstrual period and if it was "typical" for them. Also ask if they have had unprotected sex in the past month. Because many women do not know they are pregnant early in the first trimester, many institutions require a pregnancy test when a patient is scheduled for surgery. If a woman is pregnant, the perioperative plan of care addresses not one, but two patients: the mother and the developing fetus. A pregnant patient has surgery only on an emergent or urgent basis. Because all of a mother's major systems are affected during pregnancy, the risk for intraoperative complications increases. General anesthesia is administered with caution because of the increased risk of fetal death and preterm labor. Regional anesthesia is used in preference to general anesthesia when appropriate ([Movasaghi et al., 2016](#)). Psychological assessment of mother and family is also essential.

Perceptions and Knowledge Regarding Surgery

A patient's past experience with surgery influences potential physical and psychological responses to a procedure. Assess the patient's previous experiences with surgery as a foundation for anticipating his or her needs, providing teaching, addressing fears, and clarifying concerns. Ask him or her to discuss the previous type of surgery, level of discomfort, extent of disability, and overall level of care required. Address any complications that the patient experienced. Prior anesthesia records are a useful source of information if previous surgical problems occurred.

The surgical experience affects the family unit as a whole. Understanding a patient's and family's knowledge and expectations (following discharge) allows you to plan teaching and provide individualized emotional support measures. In many instances, patients fear surgery. Some fears are the result of past hospital experiences, warnings from friends and family, or lack of knowledge. Assess the patient's understanding of planned surgery, its implications, and planned postoperative activities. Ask questions, such as "Tell me what you think will happen before and after surgery" or "Explain what you know about surgery." Nurses face ethical dilemmas when patients are misinformed or unaware of the reason for surgery. Confer with the surgeon if a patient has an inaccurate perception or knowledge of the surgical procedure before the patient is sent to the surgical suite. Further, determine whether the health care provider explained routine preoperative and postoperative procedures, and assess the patient's readiness and willingness to learn. Reinforce the patient's knowledge of the surgical procedure and postoperative expectations.

Support Sources

Have your assessment include the identification of the patient's primary family caregiver or family support person. The patient usually cannot immediately assume the same level of physical activity enjoyed before surgery. With **ambulatory surgery**, patients and/or family caregivers assume responsibility for postoperative care immediately. The family caregiver is an important resource for a patient with physical limitations and provides the emotional support needed to motivate the patient to return to his or her previous state of health. Ask the family caregiver what type of support he or she provides. Is it sufficient to meet the patient's needs? What level of instruction or support is required?

Sometimes the family caregiver remembers preoperative and postoperative teaching better than the patient. Patients having ambulatory surgery will receive a postdischarge phone call to evaluate their recovery. Sometimes patients, especially older adults, are unable to hear or reach a phone after surgery. Ask if a family member will be staying with the patient to answer the phone. The nurse's responsibility is to fully prepare a patient and any family caregiver for patient self-care if the patient returns home. This includes providing information that allows the patient to anticipate any problems, know how to act, and be able to perform care measures (e.g., medication administration, dressing changes, exercises).

Often a family member becomes the patient's coach, offering valuable support after surgery when a patient's participation in care is vital.

Occupation

Surgery often results in physical changes and restrictions that prevent a person from immediately returning to work. Assess the patient's occupational history to anticipate the possible effects of surgery on recovery, the time it will take to return to work, and eventual work performance. Explain postoperative restrictions set by the health care provider, such as lifting, walking, or climbing stairs, and the projected time frame for a patient to be able to return to work. When a patient is unable to return to a job, refer the patient to a social worker and/or occupational therapist for job-training programs or to seek economic assistance.

Preoperative Pain Assessment

Surgical manipulation of tissues, treatments, and positioning on the OR table contribute to postoperative pain. However, patients also often present preoperatively with painful conditions. Conduct a comprehensive pain assessment before surgery (see [Chapter 44](#)), including the character of any existing pain and the patient's and family's expectations for pain management after surgery. Ask patients to describe their perceived tolerance to pain, past experiences, and prior successful interventions.

Review of Emotional Health

Surgery is psychologically stressful and creates anxiety in patients and their families. Patients often feel powerless over their situation. Potential disruptions in lifestyle, a lengthy recovery period at home, and uncertainty about the long-term effects of surgery on a patient's life place stress on patients and their families. When a patient has a chronic illness, the family is either fearful that surgery will result in further disability or hopeful that it will improve the patient's lifestyle. To understand the effect of surgery on a patient's and family's emotional health, assess the patient's feelings about surgery, self-concept, body image, and coping resources.

It is difficult to assess a patient's feelings thoroughly when ambulatory surgery is scheduled because a nurse does not have much time to establish a therapeutic relationship with a patient. You can address these concerns initially with the patient during a home visit or on the telephone before surgery. In a hospital room, choose a private time for discussion after

completing admitting procedures or diagnostic tests. Explain that it is normal to have fears and concerns. A patient's ability to share feelings partially depends on your willingness to listen, be supportive, and clarify misconceptions. Assure patients of their right to ask questions and seek information.

Self-Concept

Patients with a positive self-concept are more likely to approach surgical experiences with optimism. A person's personal and social identity coupled with a sense of competence in meeting one's own basic needs is a powerful resource for coping with the stress of surgery. Assess self-concept by asking patients to identify personal strengths and weaknesses (see [Chapter 33](#)). Patients who quickly criticize or scorn their own personal characteristics may have little self-regard or may be testing your opinion of their character. If the patient is testing your opinion of their character, focus on the facts and remain positive. Poor self-concept hinders the ability to adapt to the stress of surgery and may aggravate feelings of guilt or inadequacy.

Body Image

Surgery or surgical removal of any body part often leaves permanent scars, alteration in body function, or concern over mutilation. Change in or loss of body functions (e.g., with a colostomy or amputation) compounds a patient's fears. Assess patients' perceptions of anticipated body image alterations from surgery. Individuals respond differently, depending on their culture, self-concept, and self-esteem (see [Chapter 33](#)).

Some surgeries, such as removal of a breast, an ostomy, or removal of the prostate gland, may change the physical or psychological aspects of a patient's sexuality. In addition, some surgeries, such as a hernia repair, require patients to temporarily refrain from sexual intercourse until they return to normal physical activity. Encourage patients to express concerns about their sexuality. A patient facing even temporary sexual dysfunction requires understanding and support. Hold discussions about the patient's sexuality with his or her sexual partner so that the partner gains a shared understanding of how to cope with limitations in sexual function (see [Chapter 34](#)).

Coping Resources

Assessment of patients' feelings and self-concept reveals whether they have the ability to cope with the stress of surgery. Thus, ask patients about

sources of stress in their lives, how they typically deal with stressful situations, and how stress affects their daily lives. Physiologically, stress causes activation of the endocrine system, resulting in the release of hormones and catecholamines, which increases blood pressure, heart rate, and respiration. Platelet aggregation also occurs, along with many other physiological responses. All patients will be affected physiologically by the stress response. If your patient has limited coping resources, your assessment findings will guide you in planning for stress management postoperatively by offering healthy coping strategies (see [Chapters 32 and 37](#)), initiating more frequent or comprehensive discussions about surgery, and involving social work or clergy as needed.

Cultural and Spiritual Factors

Culture is a system of beliefs and values developed over time and passed on through many generations (see [Chapter 9](#)). Each patient is unique in how he or she perceives and reacts to the surgical experience. Research shows that sometimes there is a discrepancy between the information provided before surgery and a patient's expectation, which highlights why nurses need to listen to patients to identify their expectations ([Tocher, 2014](#)). If you do not acknowledge and plan for cultural and spiritual differences in the perioperative plan of care, your patient may not achieve desired surgical outcomes ([Box 50.3](#)). To bridge cultural differences, the nurse explores and respects patients' beliefs as well as their meaning of illness, preferences, and needs. Understanding a patient's cultural and ethnic heritage helps the nurse care for a patient having surgery. Although it is important to recognize and plan for differences on the basis of culture, it is also necessary to recognize that members of the same culture are individuals and do not always hold these shared beliefs.

Box 50.3 Cultural Aspects of Care Providing Culturally Sensitive Care for the Patient Having Surgery

Patients' culture and religion influence their health care beliefs (Douglas et al., 2014). The nurse's approach to perioperative care should respect patients' cultural values and involve partnering with the patient to provide a patient-centered care plan. The use of a wide variety of resources within a health care agency, in the literature, and from the

Internet helps complement the data needed for nurses to provide culturally sensitive care.

Implications for Patient-Centered Care

- A cultural assessment for preoperative patients includes questions related to the patient's primary language, feelings regarding surgery and pain, pain management expectations, support system, and feelings toward self-care with postoperative implications (e.g., Does the patient relate to the concept of pain? Does the patient have feelings about gender of caregiver? Does the patient follow a custom of giving family members control over decisions? Does the patient have religious convictions that affect perioperative care, such as opposition to the administration of blood products?).
- Use sensitivity if a professional interpreter is needed to communicate with non-English-speaking patients because some patients may have difficulty sharing personal health information with people who are younger or of a specific gender.
- Use materials and teaching techniques that are culturally relevant and language-appropriate to communicate and assess the non-English-speaking patient for factors such as pain, general comfort, temperature, and need to void.
- Provide assessment tools and preoperative and postoperative educational materials in a variety of languages.

Physical Examination

Conduct a partial or complete physical examination, depending on the amount of time available and the patient's preoperative condition. [Chapter 30](#) describes physical assessment techniques. Assessment focuses on a patient's medical history and on body systems that the surgery is likely to affect. While completing a nursing assessment, you validate existing information, reinforce basic preoperative teaching, and review standard discharge instructions. Individualized instruction occurs after all assessment data are collected.

General Survey

Observe a patient's gestures and body movements (gait, posture, purposeful movement), which may reflect decreased energy or weakness caused by illness. Height, body weight, and history of recent weight loss

are important indicators of nutritional status and are used to calculate medication dosages. Preoperative vital signs, including pulse oximetry and blood pressure while sitting and standing, provide important baseline data with which to compare alterations that occur during and after surgery, including response to anesthetics and medications and fluid and electrolyte abnormalities (see [Chapter 42](#)). An elevated temperature is cause for concern. If a patient has an underlying infection, elective surgery is often postponed until the infection is treated or resolved. An elevated body temperature also alters drug metabolism and increases the risk for fluid and electrolyte changes. Notify the surgeon immediately if a patient has an elevated temperature.

Head and Neck

To determine if a patient is dehydrated, assess the patient's oral mucous membranes. Dehydration increases the risk for serious fluid and electrolyte imbalances during surgery. Inspect the area between the gums and cheek, the soft palate, and the nasal sinuses. Sinus drainage that is yellow or greenish may indicate respiratory or sinus infection. To rule out the presence of local or systemic infection, palpate the cervical lymph nodes and note any enlargement, which indicates systemic disease.

During the examination of the oral mucosa, identify any loose or capped teeth because they can become dislodged during endotracheal intubation. Note the presence of dentures, prosthetic devices, or piercings, so they can be removed before surgery, especially if the patient receives general anesthesia.

Integument

The overall condition of the skin reveals a patient's level of hydration. Carefully inspect the skin, especially over bony prominences such as the heels, elbows, sacrum, back of head, and scapula. In patients who are obese, separate the body folds to ensure that you examine the skin thoroughly. During surgery, patients often lie in a fixed position for several hours, placing them at increased risk for pressure injuries (see [Chapter 48](#)). Although physiological blood and lymphatic flow rates vary among patients, capillary pressures may increase to as much as 150 mm Hg during prolonged, unrelieved pressure without a position change. The normal pressure needed to keep capillaries open (10.5 to 22.5 mm Hg) was identified in classic research ([Shore, 2000](#)). When the intensity of pressure exerted on capillaries exceeds 10.5 to 22.5 mm Hg, ischemic injury to the skin can develop. Consider the type of surgery a patient will undergo and

the position that is required on the OR table (Fig. 50.2) to identify areas at risk for pressure injury formation.

FIG. 50.2 Examples of patient positions requiring a lithotomy position during surgery. **A**, Low. **B**, Standard. **C**, High. **D**, Exaggerated.

From Rothrock J: *Alexander's care of the patient in surgery*, ed 16, St Louis, 2019, Mosby.

Multiple factors affect skin integrity during and after surgery. For example, chronic use of steroids increases a patient's susceptibility to skin tears. Older adults are at high risk for alteration in skin integrity from decrease in epidermis, positioning (pressure forces), and repositioning on the OR table (shearing forces).

Thorax and Lungs

Assess a patient's breathing pattern and chest excursion to detect presence of a decline in ventilation. When ventilation is reduced, a patient is at increased risk for respiratory complications (e.g., atelectasis) after surgery. Auscultation of breath sounds indicates whether the patient has pulmonary congestion or narrowing of airways, which can postpone a surgery. Breath sounds provide an important baseline for a patient's condition. Certain anesthetics potentially cause laryngeal muscle spasm. If you auscultate wheezing in the airways before surgery, a patient is at risk for further airway narrowing during surgery and after extubation

(removal of the endotracheal tube). Notify the health care provider of any abnormalities noted during the assessment, especially if a decline in function is noted.

Heart and Vascular System

If a patient has a history of heart disease, assess the character of the apical pulse and listen to heart sounds. Assessment of peripheral pulses, capillary refill, and color and temperature of extremities is particularly important for all patients undergoing vascular or orthopedic surgery and for patients who will have constricting bandages or casts on an extremity after surgery. Screen a patient for causative factors of DVT formation as verified in coagulation laboratory tests ([AORN, 2018a](#)). If peripheral pulses are not palpable, use a Doppler instrument for assessment of their presence ([McLendon and Attia, 2017](#)). Acceptable capillary refill occurs in less than 2 seconds. Postoperative changes in circulatory status in a patient who had adequate circulation before surgery indicate impaired circulation.

Abdomen

Alterations in GI function after surgery often result in decreased or absent bowel sounds and abdominal distention. Assess the patient's usual abdominal anatomy for size, shape, symmetry, and presence of distention before surgery. Ask how often the patient has bowel movements, and inquire about the color and consistency of stools. Auscultate bowel sounds over all four abdominal quadrants.

Neurological Status

A surgical patient's level of consciousness changes as a result of anesthesia, sedatives, and complications that may develop during surgery. Preoperative assessment of baseline neurological status is important for all patients. The baseline neurological status helps with the assessment of ascent (awakening) from anesthesia. Patients should normally regain consciousness and return to normal preop states. However, it is also critical to assess neurological status to readily identify when patients develop delirium postoperatively. Delirium is an acute confusional state—not a degenerative process, but rather one linked with a specific medical condition that has caused changes to an individual's normal homeostasis and bodily function ([Koutoukidis et al., 2017](#)).

Observe a patient's level of orientation, alertness, mood, and ease of speech, noting whether he or she answers questions appropriately and is

able to recall recent and past events. Patients who have surgery for neurological disease (e.g., brain tumor or aneurysm) may demonstrate an impaired level of consciousness or altered behavior.

If a patient is scheduled for spinal or regional anesthesia, preoperative assessment of gross motor function and strength is important. Spinal anesthesia causes temporary paralysis of the lower extremities (see [Chapter 44](#)). Be aware of a patient entering surgery with weakness or impaired mobility of the lower extremities and communicate this to the perioperative team so that care providers do not become alarmed when full motor function does not return as the anesthetic wears off.

Diagnostic Screening

Patients often undergo diagnostic tests and procedures for preexisting abnormalities before surgery. Patients scheduled for elective or ambulatory surgery usually have tests done several days before surgery. Testing done the day of surgery is usually limited to tests designed to rule out or monitor potential problems, such as glucose monitoring for a patient with diabetes or an electrocardiogram (ECG) for patients with heart disease. If tests reveal severe problems, a surgeon or anesthesiologist will postpone surgery until the condition stabilizes. As a preoperative nurse you coordinate the completion of tests and verify that a patient is properly prepared. Be familiar with the purpose of diagnostic tests, know a patient's results, and alert a surgeon or anesthesiologist when findings are abnormal.

A patient's medical history, physical assessment findings, and surgical procedure determine the types of tests ordered. For example, a type and cross-match for blood are indicated before surgery for procedures in which blood loss is expected (e.g., hip replacements) in case a patient needs a blood transfusion during surgery. The surgeon designates the number of blood units to have available during surgery. [Table 50.6](#) gives the purpose and normal values for common blood tests.

TABLE 50.6**Common Laboratory Tests for Surgical Patients**

Test	Normal Values ^a	Significance	
		Low	High
Complete Blood Count (CBC)			
Hemoglobin (Hgb)	Female: 12-16 g/dL; male: 14-18 g/dL	Anemia	Polycythemia (elevated red blood cell count)
Hematocrit (Hct)	Female: 36%-47%; male: 40%-52%	Fluid overload	Dehydration
Platelet count	150,000-400,000/mm ³	Decreased clotting	Increased risk of blood clot
White blood cell count	5000-10,000/mm ³	Decreased ability to fight infection	Infection
Blood Chemistry			
Sodium (Na)	136-145 mEq/L	Fluid overload	Dehydration
Potassium (K)	3.5-5.0 mEq/L	Cardiac rhythm irregularities	Cardiac rhythm irregularities
Chloride (Cl)	98-106 mEq/L	Follows shifts in sodium blood levels	Follows shifts in sodium blood levels
Carbon dioxide (CO ₂)	23-30 mEq/L	Affects acid-base balance in blood	Affects acid-base balance in blood
Blood urea nitrogen (BUN)	10-20 mg/dL	Liver disease/fluid overload	Renal disease/dehydration
Glucose	74-106 mg/dL fasting	Insulin reaction, inadequate glucose intake	Diabetes mellitus and stress of surgery
Creatinine	0.5-1.1 mg/dL	Malnutrition	Renal disease
Coagulation Studies			
International Normalized Ratio (INR)	0.8-1.1	Risk of clot	Risk of bleeding
Prothrombin time (PT)	11-12.5 sec; 85%-100%	Risk of clot	Risk of bleeding
Partial thromboplastin time (PTT)	60-70 sec	Risk of clot	Risk of bleeding
Activated PTT	30-40 sec	Risk of clot	Excess heparin; risk of spontaneous bleeding (activated PTT)

^a Normal ranges vary slightly among laboratories.

From Pagana KD et al.: *Mosby's diagnostic and laboratory test reference*, ed 14, St Louis, 2019, Elsevier.

Maintenance of circulating blood volume is critical for any patient undergoing surgery and is accomplished with administration of whole blood or blood components. Patients undergoing elective surgery who will most likely need blood products will have a pre-transfusion type and screen sample taken 1 to 7 days before surgery (see agency policy) (Rothrock, 2019). This test ensures blood compatibility (if a transfusion is needed) and avoids antibodies that may emerge in response to exposure through transfusions or a patient's disease. Autotransfusion (i.e., the reinfusion of a patient's own blood intraoperatively) is more common today (Rothrock, 2019). During intraoperative autotransfusion (cell salvage), blood is collected as it is lost during the surgery and reinfused to the patient after it is filtered and washed. Predated (up to 1 month before surgery) autologous blood donation is in decreasing use (Rothrock, 2019).

REFLECT NOW

In preparing a preoperative patient for surgery, what are three questions you should ask a patient to identify the patient's religious and cultural preferences for surgery? If you have cared for a surgical patient, consider any specific patient behaviors that demonstrated religious and/or cultural practices.

• Nursing Diagnosis

Following assessment you group patterns of assessment findings to identify nursing diagnoses relevant for a surgical patient (Box 50.4). A patient with preexisting health problems is likely to have a variety of risk diagnoses. For example, a patient with type 2 diabetes who has fasting glucose levels exceeding 110 mg/dL is at risk for *Impaired Skin Integrity*. The nature of the surgery and assessment of the patient's health status provide assessment findings and risk factors for a number of nursing diagnoses. For example, because a patient will have a surgical incision and an intravenous (IV) infusion, there is a risk for developing infection at the surgical site, in the bloodstream (sepsis), or phlebitis (at the IV site). A diagnosis of *Risk for Infection* requires the nurse's attention from admission through recovery.

Box 50.4 Nursing Diagnostic Process Fear Related to Insufficient Knowledge and Previous Surgical Experience

Assessment Activities	Assessment Findings
Ask patient to describe previous surgical experiences.	Apprehension over anesthesia and postoperative pain
Ask patient about understanding of preoperative education/preparation before admission.	Expresses feeling of dread, worry over complications that may result; unaware of preoperative testing
Observe patient's nonverbal behavior, including body movements.	Maintains poor eye contact, wrings hands when discussing surgery

The related factors for problem-focused or negative diagnoses establish directions for nursing care that is provided during one or all surgical phases. For example, the diagnosis of *Impaired Mobility related to incisional pain* requires different interventions than the diagnosis *Impaired Mobility related to decreased muscle strength*. Preoperative nursing diagnoses allow nursing staff to take precautions and interventions so that care provided during the intraoperative and postoperative phases is consistent with the patient's needs.

Nursing diagnoses made before surgery may focus on the potential risks a patient may experience after surgery. Preventive care is essential to manage the surgical patient effectively. The following are common nursing diagnoses relevant to the patient having surgery:

- *Impaired Airway Clearance*
- *Anxiety*
- *Impaired Skin Integrity*
- *Risk for Infection*
- *Acute Pain*

• **Planning**

During the planning phase, synthesize information to establish a plan of care based on a patient's nursing diagnoses (see the Nursing Care Plan). Apply critical thinking in the selection of nursing interventions (Fig. 50.3). For example, apply knowledge of adult learning principles, standards for preoperative education (AORN, 2018a), and a patient's unique learning needs and anticipated needs after discharge to formulate a well-designed **preoperative teaching plan** for the diagnosis of *Anxiety*. Critical thinking ensures that a patient's plan of care integrates your knowledge, previous experiences, clinical reasoning, and established standards of practice. Previous experience in caring for surgical patients helps establish

approaches to patient care (e.g., measures to prevent complications and how to anticipate and reduce a patient's anxiety). Use professional standards when selecting interventions for the nursing plan of care. These standards often use evidence-based guidelines for preferred nursing interventions.

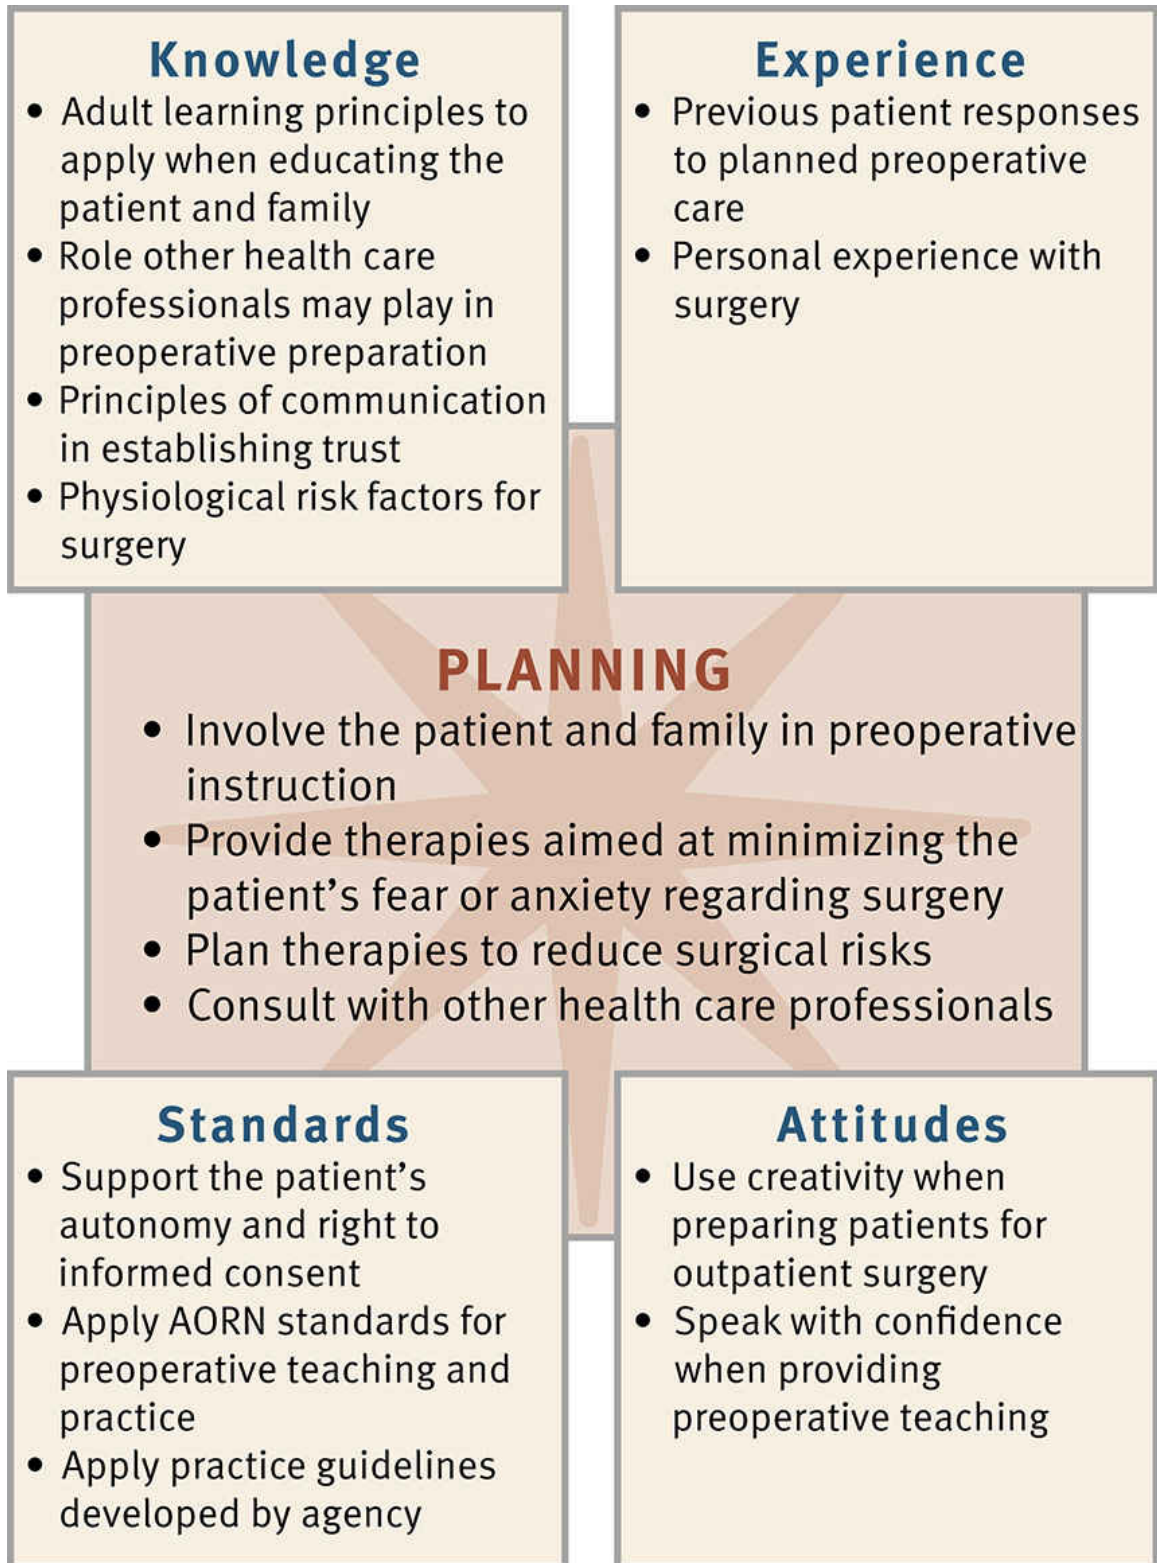

FIG. 50.3 Critical thinking model for surgical patient planning. AORN, Association of periOperative Registered Nurses.

Successful planning requires a patient-centered approach involving the patient and family to set realistic expectations for care. Early involvement of a patient and family caregiver when developing the surgical care plan minimizes surgical risks and postoperative complications and improves transition of care through discharge. A patient informed about the planned surgical experience is less likely to be fearful and is better able to participate in the postoperative recovery phase so that expected outcomes are met.

Goals and Outcomes

Establish goals and outcomes of care based on the individualized nursing diagnoses. Review and modify the plan during the intraoperative and postoperative periods. Outcomes established for each goal of care provide measurable evidence to gauge a patient's progress toward meeting stated goals. As an example, the goal "Patient will be able to perform postoperative exercises on the day of surgery" is measured through the following expected outcomes:

- Patient performs deep-breathing and coughing exercises on awakening from anesthesia.
- Patient performs postoperative leg exercises and early ambulation 12 hours after surgery.
- Patient performs incentive spirometry on return to patient care unit after surgery.
- Patient verbalizes rationale for early ambulation 24 hours after surgery.

Nursing Care Plan

Anxiety

Assessment

Mr. Cooper is a 72-year-old patient scheduled for admission in 5 days for elective bowel resection to remove a cancerous tumor. You are the nurse in the ambulatory surgical center. During your initial encounter you note he is alert and oriented to person, place, and time. The patient has not had major surgery before. He lives at home with his wife, to whom he has been married 42 years.

Assessment Activities	Assessment Findings ^a
Ask Mr. Cooper what he understands about his surgical procedure.	He learned from his surgeon that he will have an incision down the middle of his abdomen that will take approximately 6 to 9 weeks to heal. Mr. Cooper states, “I probably will need a colostomy; however, I am worried about how one works and what it will look like. Will I be able to take care of myself?”
Ask Mr. Cooper about his knowledge of preoperative preparation and what he expects after surgery.	He correctly verbalizes understanding of medicines to take the morning of surgery and NPO status before surgery. Mr. Cooper indicated he is unsure about the length of time he will remain hospitalized, his diet after surgery, and plans for bowel elimination.
Assess Mr. Cooper’s concerns about surgery.	He appears slightly anxious with reduced eye contact. His heart rate is 106 beats per minute and his blood pressure is 150/90 mm Hg (normal for patient 82 to 86 beats per minute, BP 130/78). He states, “This surgery will change my entire life. It is serious.”

^a **Assessment Findings** are shown in bold type.

Nursing Diagnosis:

Anxiety related to insufficient information about surgery

Planning

Goals	Expected Outcomes (NOC) ^b
	Anxiety Level
Mr. Cooper will exhibit reduced anxiety.	Patient will maintain eye contact during instructions. Patient will verbalize anxiety over change ostomy will have on body function.
	Knowledge: Treatment Procedures
Mr. Cooper will express understanding of expected postoperative care by the morning of surgery.	Mr. Cooper describes the importance of and demonstrates postoperative exercises by the morning of surgery. Mr. Cooper describes the need for a colostomy and progression of diet immediately after surgery.
Mr. Cooper will describe how ostomy functions and expectations regarding ostomy care by postoperative day two.	Mr. Cooper will explain location and expected output of colostomy. Patient will discuss plans for ostomy pouching and skin care by day two after surgery.

^b Outcome classification labels from Moorhead S, et al: *Nursing Outcomes Classification (NOC)*, ed 6, St Louis, 2018, Elsevier.

Interventions (Nic)^C	Rationale
Anxiety Reduction	
Encourage verbalization of fears and concerns. Help patient identify specific aspects of surgery that cause him to be anxious.	Minimizing apprehension over relevant concerns helps to relieve patient anxiety and allows for focusing instruction on those concerns.
Refer patient to ostomy specialist in ambulatory care center to reinforce factual information about diagnosis and ostomy care.	Specialist plays an active role in helping patients perform self-care for their ostomy and adjust to it psychologically (Heideman, 2017).
Preoperative Teaching	
Provide Mr. Cooper, for home viewing, a compact disc (CD) program that explains a colostomy and the preoperative and postoperative routines to expect. Make a follow-up call 24 hours before surgery to the patient encouraging him to ask questions and express concerns.	Preoperative education is effective in reducing patients' postoperative anxiety and improving their knowledge (Ramesh et al., 2017; Rothrock, 2019).
Explain purpose and demonstrate to Mr. Cooper how to perform postoperative exercises.	Demonstration is an effective method to reinforce instruction (Tait et al., 2014).
Ostomy specialist will schedule visit morning of surgery to discuss with patient location and expected progress and output of colostomy, and plans for postop ostomy care.	Assists patient in having a realistic sense of postoperative condition and expectations for his involvement in care (Butcher et al., 2018)

^C Intervention classification labels from Butcher HK, et al: *Nursing Interventions Classification (NIC)*, ed 7, St Louis, 2018, Elsevier.

Evaluation

Evaluation Activity	Patient Response/Finding	Outcome Status
Observe Mr. Cooper's nonverbal behavior and ask how he feels about surgery during instructional time.	Patient has numerous questions but maintains eye contact. At end of discussion states, "I am still a bit uneasy, but I think I am understanding more what to expect."	Patient maintains eye contact during instruction. Patient able to verbalize general concern. Requires ongoing discussion.
Ask Mr. Cooper to describe postoperative activities to expect.	He verbalizes understanding of purpose for postoperative exercises ("helps me to breath and be active") after surgery.	Mr. Cooper describes importance of exercises.
Observe Mr. Cooper demonstrate postoperative exercises.	He correctly demonstrates leg exercises and turning, coughing, and deep breathing (TCDB). Is having difficulty using incentive spirometer unassisted.	Mr. Cooper demonstrates leg exercises, turning, coughing and deep breathing. Needs further teaching and practice on incentive spirometer use.
Ostomy specialist asks Mr. Cooper to describe location and expected function of colostomy.	Patient describes area on abdomen where colostomy is to be located and type of stool that will be collected in ostomy pouch.	Mr. Cooper explains location and expected output of colostomy.

Setting Priorities

Use clinical judgment to prioritize nursing diagnoses and interventions based on the unique needs of each patient. Patients requiring emergent surgery often experience changes in their physiological status that require urgent reprioritizations. For example, if a patient's blood pressure begins to drop, hemodynamic stabilization becomes a priority over education and stress management. Ensure that the approach to each patient is thorough and reflects an understanding of the implications of a patient's age, physical and psychological health, educational level, cultural and religious practices, and stated and/or written wishes concerning advance medical directives.

Teamwork and Collaboration

For patients having surgery, the health care team needs to collaborate to ensure continuity of care. Preoperative planning ideally occurs days before admission to a hospital or surgical center. The collaboration between the health care provider's office, the surgical center, or hospital is crucial to prepare a patient for a procedure. Preoperative instruction gives patients time to think about their surgical experience, make necessary physical preparations (e.g., altering diet or discontinuing medication use), and ask questions about postoperative procedures. A patient having ambulatory

surgery usually returns home on the day of surgery. Thus, well-planned preoperative care ensures that he or she is well informed and able to be an active participant during recovery. The family or significant others also play an active supportive role for a patient.

Collaboration among health care team members is very important when patients are admitted to a hospital for inpatient surgery. This is especially true for patients who have special problems (e.g., morbid obesity or advanced lung disease). Well-planned preoperative and postoperative care helps to ensure continuity of care during a patient's stay and after discharge. This means that nurses can anticipate expected interventions and the involvement of other professionals who will be taking part in the patient's care. The need for and implications for inpatient care are discussed with the patient and family before the surgery. Planning might include the use of an ERAS protocol. The postoperative plan of care for inpatients will focus on preventing postoperative complications but will also include interventions to inhibit exacerbations of co-morbid conditions. Postoperative care involves an interprofessional team whose members focus on patients' early recovery.

• **Implementation**

Preoperative nursing interventions provide patients (and families) with a complete understanding of the surgery and anticipated postoperative activities. During this time, you prepare patients physically and psychologically for surgical intervention and recovery.

Informed Consent

Except in emergencies, surgery cannot be performed legally or ethically until a patient fully understands a surgical procedure and all implications. Surgical procedures are not performed without documentation of a patient's informed consent in the medical record. In some instances, the patient's medical power of attorney may give consent if the patient is unable to do so. Persons with only general power of attorney cannot sign surgical consents. When a consent is obtained preoperatively, it must be done before a patient receives any form of sedation to ensure a clear level of consciousness at the time of signing. [Chapter 23](#) discusses a nurse's responsibilities for **informed consent**. It is the surgeon's responsibility to explain the procedure, associated risks, benefits, alternatives, and possible complications before obtaining the patient's oral and documented informed consent ([TJC, 2019](#)). The patient also needs to know who will

perform the procedure. To ensure that a patient understands the information about the surgery, [TJC \(2019\)](#) recommends that consent materials be written at a fifth-grade or lower reading level. After the patient or power of attorney signs the consent form, place it in the medical record. The record goes to the OR with the patient. If you have concerns about a patient's understanding of surgery, report these concerns to the operating surgeon or anesthesia provider before the patient goes to surgery ([ACRP, 2017](#)).

Privacy and Social Media

Although patients can now access their medical records electronically, confidentiality risks exist. Inappropriate discussions of a patient and any planned surgery in elevators, cafeterias, or social settings may end up being communicated "worldwide" ([NCSBN, 2018](#)). Nurses have the obligation to protect every patient's privacy by avoiding inappropriate discussions and not using social media to convey patient information. Posting patient information and photos on websites is prohibited; 26 state boards of nursing have taken disciplinary action against nurses who practice such behaviors ([Rothrock, 2019](#)), which are direct violations of federal and state patient privacy laws.

Health Promotion

Health promotion activities during the preoperative phase focus on health maintenance, patient safety, prevention of complications, and anticipation of the continued care needed after surgery.

Preoperative Teaching

Patient education is an important aspect of a patient's surgical experience (see [Chapter 25](#)). The topics and principles discussed depend on the type of surgery scheduled, whether a procedure is inpatient or outpatient, and the ability of a patient to attend to and learn the content provided. Providing patient education about pain reduces a patient's preoperative anxiety, which is frequently associated with postoperative pain ([Chou et al., 2016](#)). Education about the surgical experience increases patient satisfaction and knowledge, speeds up the recovery process, and facilitates a return to functioning ([Lewis et al., 2017](#)). Structured teaching throughout the perioperative period influences the following:

- *Ventilatory function*: Teaching improves the ability and willingness to deep breathe and cough effectively.
- *Physical functional capacity*: Teaching increases understanding and willingness to ambulate and resume activities of daily living.
- *Sense of well-being*: Patients who are prepared for surgery have less anxiety and report a greater sense of psychological well-being (Chou et al., 2016).
- *Length of hospital stay*: Being informed reduces a patient's length of hospital stay by preventing or minimizing complications.
- *Anxiety about pain and its management*: Patients who learn about pain and ways to relieve it before surgery are less anxious about it, ask for what they need, and require less analgesia after surgery (Chou et al., 2016).

The health care provider's office or hospital often provides preoperative information and instructions by telephone calls and home mailings. Instructions are available as preprinted teaching guidelines and checklists or in the form of videotapes or educational websites. The American College of Surgeons developed a patient education website titled *Surgical Patient Education Program*, which provides patient information and education materials on types of surgeries, health resources, insurance information, and even some home care skills training (American College of Surgeons, 2018). When a patient is scheduled for surgery (outpatient or inpatient), preadmission nurses call patients up to 1 week before the surgery to clarify questions and reinforce explanations (Rothrock, 2019). For example, they:

- Describe the time for a patient to arrive at the hospital or surgical center and the time of surgery (approximately).
- Explain the extent and purpose of food and fluid restrictions.
- Teach about physical preparation (e.g., bowel preparation, bathing or showering with antiseptic).
- Explain procedures performed in preanesthesia (holding area) just before transport to the OR (IV line insertion, preoperative medications).

Including family members in preoperative instruction is advisable. Often a family member is the coach for postoperative exercises when a patient returns from surgery. A family often has better retention of preoperative teaching and will be with the patient and able to help him or

her in recovery. If anxious relatives do not understand routine postoperative events, it is likely that their anxiety heightens the patient's fear and concerns. Preoperative preparation of family members lessens anxiety and misunderstanding.

Reasons for Preoperative Instructions and Exercises

Patients are better prepared to participate in their recovery when they receive rationale for preoperative and postoperative procedures. Patients who undergo surgery need to learn how to promote a healthy recovery and prevent complications, which will allow them to return to a normal lifestyle as soon as possible. For example, a patient needs to know how recommended care activities (e.g., regular antibiotics, wound care) in the home will prevent wound infection, avoid wound-healing complications (e.g., activity restrictions prevent wound stress), and maintain a level of health (e.g., diet and progressive exercise allowed). Patients having surgery also need to know the signs of complications and when to call their surgeon.

Patients who have inpatient surgery need to additionally understand what is required to facilitate their recovery, including pain control, early ambulation, diet progression, wound care, and postoperative exercises (e.g., diaphragmatic breathing, incentive spirometry, coughing, turning, and leg exercises). Postoperative exercises and early ambulation help to prevent pulmonary and vascular complications and deconditioning (see [Skill 50.1](#)). Ideally instruction begins before surgery. After you explain each exercise, demonstrate it for the patient and use teach-back to confirm his or her understanding. Guide the patient through each exercise. Ask the patient to perform a return demonstration of the skill if possible, to reinforce it and increase the confidence in performing it.

Changes in the circulatory system, a patient's immobility during surgery, and a patient's underlying health condition create risks for development of DVT. Patients need to know which precautions to take after surgery to avoid DVT (e.g., leg exercises and use of compression hose or intermittent pneumatic compression [IPC] devices). Teach about the purposes and the specific nursing care associated with the devices (see [Chapter 39](#)).

Preoperative Routines

Explain the preoperative routines that a patient can expect. Knowing which tests and procedures are planned and why they are planned increases a patient's sense of control. Explain that an anesthesiologist will

visit to complete a preanesthesia assessment either during the preoperative admission process or in the presurgical care unit of a hospital or surgical center.

Patients typically do not consume food or fluids by mouth for several hours before surgery to reduce the risk of vomiting and aspirating emesis during surgery. Instruct patients to eat and drink sufficient amounts during the week before surgery to ensure adequate fluid and nutrient intake. This is especially important for older adults living in long-term care settings, who often do not stay adequately hydrated. Recommend foods high in protein with sufficient amounts of carbohydrates, fat, and vitamins. Explain to patients and their families the importance of following oral intake instructions for food and liquids before surgery.

Surgical Procedure

After the surgeon explains the basic purpose of a surgical procedure and its steps, some patients may ask additional questions. First, clarify the information the patient discussed with the surgeon. Avoid using technical medical terms because this adds to a patient's confusion. Avoid saying anything that contradicts the surgeon's explanation. If a patient has little or no understanding about the surgery, notify the surgeon that the patient requires further explanation.

Time of Surgery

The scheduled operative time is only an anticipated time. Unanticipated delays occur for many reasons that often have nothing to do with the patient. Emphasize that the scheduled time is a rough estimate and that the actual time can be sooner or later. Make the family aware that delays occur for various reasons and do not necessarily indicate a problem. Communicate excessive delays when they do occur.

Postoperative Unit and Location of Family During Surgery and Recovery

Few patients are admitted to a hospital unit before surgery unless their case is emergent or a complication develops before the scheduled surgery. Even then it is common for patients to be assigned to a different room after surgery. When surgery is elective, patients and families will come to the surgical center admission area first. During the admission process, the patient and family will find out which patient care unit the patient most likely will be admitted to after surgery. Be sure to explain where the family can wait and where the surgeon will come to find family members after

surgery. In many institutions, the circulating nurse gives periodic reports to the family in the waiting room for surgeries that are expected to be prolonged. Many hospitals use pagers to inform family through text messages about patient progress. If a patient will be taken to a special unit, it helps to orient the patient and family members to the environment of the unit before surgery.

Anticipated Postoperative Monitoring and Therapies

Inform a patient and family about routine postoperative monitoring and therapies (e.g., frequency of vital signs, IV therapy, dressings and drains, planned activity, and physical therapy). If they understand the frequency of anticipated monitoring and procedures, they are less apprehensive when nurses perform care activities. Try not to overprepare or underprepare a patient. It is easier to prepare a patient appropriately in elective cases when a surgeon has care guidelines such as an ERAS protocol for a specific procedure and you have adequate time for patient education. You cannot predict all of a patient's care requirements. Contradictions between your explanations and reality cause anxiety for a patient.

Sensory Preparation

Provide patients with information about the sensations typically experienced after surgery. Preparatory information helps them anticipate the steps of a procedure and thus form realistic images of the surgical experience. For example, warn that the OR is very bright and cold. Patients often undergo prewarming or are given warm blankets. A patient will have a cuff for a noninvasive blood pressure monitor placed around his or her arm. The monitor makes a hum and a beep, and the cuff tightens to take a reading. Informing a patient about these and other sensations in the OR reduces anxiety before the patient is anesthetized, which helps reduce the amount of anesthetic needed for induction. Postoperative sensations include blurred vision from ophthalmic ointment in the eyes, expected pain at the surgical site and in areas of the body affected by prolonged positioning, the tightness of dressings, dryness of the mouth, and the sensation of a sore throat resulting from an endotracheal tube (when one is inserted).

Postoperative Activity Resumption

The type of surgery determines how quickly patients can resume normal physical activity and regular eating habits. Explain what to expect after

surgery. It is normal in most surgical cases for patients to progress their diet gradually. Many hospitals implement early mobility protocols to prevent hospital deconditioning. One example is the Go–Evaluate–Team Up–Unite–Promote (GETUP) program. It includes resources at the institution and how the nurse will implement a mobility program, evaluate the patient’s capabilities (scale/tool/evaluation method), team up interprofessionally for progressive mobility, unite the patient and family members in mobility progression, and promote progress ([Florida Hospital Association, 2018](#); [Chua et al., 2017](#); [Malarvizhi and Hemavathy, 2015](#)). Some early ambulation protocols are more aggressive than others.

Pain-Relief Measures

Pain following surgery is one of a patient’s most common fears. Even in local procedures (e.g., **laparoscopy**), air inflation into the abdomen causes significant discomfort in the area of surgery. The family is also concerned for the patient’s comfort. Pain after surgery is expected. Inform the patient and family of the need to manage pain and the types of therapies likely to be used so that patients can resume activity quickly knowing they will receive pain relief (e.g., splinting, and relaxation exercises). Teach patients before surgery the type of pain to expect and how to use a pain scale, so they are prepared to rate their pain after surgery (see [Chapter 44](#)). Patient-controlled analgesia (PCA) may be ordered to provide patients with control over pain. Explain and demonstrate to a patient how to operate a PCA device and the importance of administering medication as soon as pain becomes persistent (see [Chapter 44](#)). Patients who receive epidural analgesia need a thorough understanding of how it will affect their movement and sensation after surgery.

Some patients avoid taking pain-relief drugs after surgery for fear of the negative side effects or of becoming dependent on the drugs. Listen to their concerns and encourage patients to use analgesics as ordered. Unless pain is controlled, it is difficult for a patient to participate in postoperative therapy. Because of the well-publicized problem of opioid addiction, many patients are reluctant to take opioids even for short, appropriate time frames. There are states in the United States passing legislation that would create a “nonopioid directive” that patients can place in their medical files, formally notifying health care professionals they do not want to be prescribed or administered opioid medications ([STATnews, 2017](#)). When it is anticipated that patients will have severe pain postoperatively, have a serious discussion about how health care providers will gradually reduce

the amount of opioids to use and switch to less addictive medication as patients progress.

Encourage patients to take pain medications at ordered intervals. Optimal pain management is based on patient assessment data throughout the perioperative experience and customized based on assessment findings and the surgical procedure involved, with follow-up evaluation and adjustments as needed.

Multimodal approaches to postoperative pain management vary depending on the patient, setting, and surgical procedure (Roger et al., 2016). Multimodal approaches include opioids and one or more additional pain-management methods, such as a peripheral nerve block, acetaminophen, gabapentin, nonsteroidal antiinflammatory drugs (NSAIDs), cyclooxygenase-2 (COX-2) inhibitors or ketamine (American Society of Anesthesiologists, 2018). When pain is not addressed regularly, it often becomes excruciating, and analgesics do not provide relief at the dose ordered. When educating patients, explain the length of time it takes for pain medications to take effect. Information from preoperative pain assessment is helpful when teaching about nonpharmacological pain-relief measures (such as positioning and splinting). Remember that pain is subjective, and you must accept patients' perception of pain.

Rest

Rest is essential for normal healing. Anxiety about surgery interferes with the ability to relax and sleep. Meet each patient's individual needs. If a patient is in the hospital, make the environment as quiet and comfortable as possible. The surgeon may order a sedative-hypnotic or antianxiety agent for the night before surgery. Sedative-hypnotics promote sleep. Antianxiety agents (e.g., alprazolam) act on the cerebral cortex and limbic system to relieve anxiety. The advantage of ambulatory surgery is that a patient can sleep at home or in a nearby hotel (for out-of-towners) the night before surgery.

Feelings Regarding Surgery

Some patients feel like part of an assembly line before surgery as a result of frequent staff visits and physical preparation for surgery. The patient has few opportunities to reflect on the experience. Recognize the patient as a unique individual. The patient and family need time to express feelings and concerns about surgery and to ask questions. The patient's level of anxiety influences the frequency of discussions. While delivering preoperative instruction, encourage expression of concerns, be patient, and

listen attentively. The family may wish to discuss concerns without the patient present so that their fears do not frighten the patient and vice versa. Establishing a trusting and therapeutic relationship with a patient and family allows this process to happen.

Acute Care

Acute care activities in the preoperative phase focus on the preparation of a patient on the morning of surgery or before an emergent surgery.

Minimizing Risk for Surgical Wound Infection

A surgical site infection (SSI) is one of the National Quality Forum (NQF) incidents that hospitals report (NQF, 2015). As of 2008, the CMS (Centers for Medicaid and Medicare Services, 2018) no longer pays higher reimbursement for hospitalizations complicated by certain types of surgical site infections (e.g., mediastinitis after heart surgery, select orthopedic procedures) if they were not present on admission. Thus, there is great emphasis within hospitals on preventing the occurrence of SSIs. Antibiotics are sometimes ordered in the preoperative period. A reduction in wound infection rates occurs when an antibiotic is administered 60 minutes before the surgical incision is made and the antibiotics are stopped within 24 hours after surgery (Berríos-Torres et al., 2017). The surgeon orders a specific time before surgery for the patient to have an oral or IV antibiotic.

Preoperative care involves skin antisepsis (i.e., removing soil and transient microorganisms at the surgical site) to reduce the risk of a patient developing an SSI (Berríos-Torres et al., 2017). Routine components of skin antisepsis include preoperative bathing (showers or baths) and hair management, both of which reduce the number of microorganisms on the skin. Most patients bathe the evening before surgery or that morning. There is no one antiseptic agent found to be most effective (Berríos-Torres et al., 2017), but 2% chlorhexidine (CHG) in 70% alcohol is becoming the preferred antiseptic, with povidone iodine as an alternative when CHG is contraindicated (Kapadia et al., 2016; Poulin et al., 2014). Patients who have head and neck surgery typically shampoo the hair before surgery to reduce resident flora on the scalp.

The AORN (2018a) recommends that the nurse remove the hair at the surgical site only in select clinical situations. The current evidence supports leaving hair at the surgical site in place unless it interferes with exposure, closure, or dressing of the surgical site. When hair removal is required, clipping it is likely to result in less SSI than removal with a razor

(AORN, 2018a). Use single-use clipper heads for each patient, and remove hair as close to the time of surgery as possible.

Maintaining Normal Fluid and Electrolyte Balance

A patient having surgery is vulnerable to fluid and electrolyte imbalance as a result of the stress of surgery, inadequate preoperative intake, and the potential for excessive fluid losses during surgery (see [Chapter 42](#)). The American Society of Anesthesiologists (ASA) has recommendations for fluid and food intake before nonemergent procedures requiring general and regional anesthesia or sedation/analgesia. These recommendations include fasting from intake of clear liquids for 2 or more hours, breast milk for 4 hours, formula and nonhuman milk for 6 hours, and a light meal of toast and clear liquids for 6 hours. A patient also cannot have any meat or fried foods 8 hours before surgery, unless explicitly specified by the anesthesiologist or surgeon (ASA, 2017). When a patient is hospitalized before surgery, remove all fluids and solid foods as ordered from the bedside and post a sign over the bed to alert personnel to fasting restrictions.

Despite the ASA standards, many surgeons still have patients maintain nothing by mouth after midnight. Ensure that you follow the health care provider's orders. During general anesthesia the muscles relax, and gastric contents can reflux into the esophagus. The anesthetic reduces the patient's gag reflex. Therefore, a patient is at risk for aspiration of food or fluids from the stomach into the lungs. The surgeon's orders will provide additional guidance for routine procedures (e.g., IV line placement and preoperative medications). Some patients are allowed to take specific medications (e.g., anticoagulants, cardiovascular medications, anticonvulsants, and antibiotics) with a sip of water as ordered by their health care providers. Allow patients time to rinse their mouths with water or mouthwash and brush their teeth immediately before surgery as long as they do not swallow water. Notify the surgeon and anesthesia provider if a patient eats or drinks during the fasting period.

If a patient cannot eat because of GI alterations or impairments in consciousness, the health care provider may order intravenous fluids. The health care provider assesses serum electrolyte levels to determine the type of IV fluids and electrolyte additives to administer before and during surgery. Patients with severe nutritional imbalances sometimes require supplements with concentrated protein and glucose such as total parenteral nutrition (see [Chapter 45](#)).

Preventing Bowel Incontinence and Contamination

Some patients receive a bowel preparation (e.g., a cathartic or enema) if the surgery involves the lower GI system. Manipulation of parts of the GI tract during surgery results in absence of peristalsis for 24 hours and sometimes longer. Enemas and cathartics (see [Chapter 47](#)) such as a polyethylene glycol electrolyte solution clean the GI tract to prevent intraoperative incontinence. An empty bowel reduces risk of injury to the intestines and minimizes contamination of the operative wound if colon surgery is planned or a part of the bowel is incised or opened accidentally. In addition, bowel cleansing reduces postoperative constipation. If a surgeon's order reads "give enemas until clear," this means that a nurse administers enemas until the enema return solution contains no solid fecal material. Too many enemas given over a short time can cause serious fluid and electrolyte imbalances (see [Chapter 42](#)). Most agencies limit the number of enemas (usually three) that a nurse may administer successively. Verify a patient's potassium level following bowel preparation. Diarrhea may cause hypokalemia.

Preparation On the Day of Surgery

You will commonly complete several routine procedures before releasing patients for surgery.

Hygiene

Basic hygiene measures provide additional comfort before surgery. If a patient is unwilling to take a complete bath, a partial bath is refreshing and removes irritating secretions or drainage from the skin. Provide a clean hospital gown as a patient cannot wear personal nightwear to the OR because it is restrictive and is a flammable hazard. When a patient is NPO for hours before surgery, his or her mouth is often very dry. Offer the patient nonalcohol-based mouthwash and toothpaste, again cautioning the patient not to swallow water.

Preparation of Hair and Removal of Cosmetics

During major surgery an anesthesiologist positions a patient's head to place an endotracheal tube into the airway (see [Chapter 41](#)). This involves manipulation of the hair and scalp. To avoid injury, ask the patient to remove hairpins or clips before leaving for surgery. Electrocautery is frequently used during surgery. Hairpins and clips can become an exit source for the electricity and cause burns. Remove hairpieces or wigs as

well. Patients can braid long hair and wear disposable hats to contain hair before entering the OR.

During and after surgery, the anesthesia provider and nurse assess skin and mucous membranes to determine a patient's level of oxygenation, circulation, and fluid balance. A pulse oximeter is often applied to a finger to monitor oxygen saturation (see [Chapter 30](#)). Anesthesia providers also use end-tidal carbon dioxide, by way of capnography, to assess patients' physical status. When using a pulse oximeter, have patients remove all makeup (lipstick, powder, blush, nail polish) and at least one artificial fingernail to expose normal skin and nail color. Anything in or around the eye irritates or injures the eye during surgery. Have patients remove contact lenses, false eyelashes, and eye makeup. Give the patient's eyeglasses to the family immediately before the patient leaves for the OR. Document all valuables per agency policy.

Removal of Prostheses

It is easy for any type of prosthetic device to become lost or damaged during surgery. Have patients remove all removable prosthetics (e.g., artificial limbs, partial or complete dentures, artificial eyes, and hearing aids) for safekeeping just before leaving for surgery. If a patient has a brace or splint, check with the health care provider to determine whether it should remain in place. For many patients it is embarrassing to remove dentures, wigs, or other devices that enhance personal appearance. Offer privacy as a patient removes personal items. Patients are sometimes allowed to keep these until they reach the preoperative holding area. Place dentures in special containers labeled with the patient's name and other identification required by the agency for safekeeping to prevent loss or breakage. In many agencies, the nurse completes an inventory of all prosthetic devices or personal items and places them in a secured area. It is also common practice for nurses to give prostheses to family members. Document these actions in the appropriate portion of medical record per agency policy.

Safeguarding Valuables

If a patient has valuables, give them to family members or place in a secure designated location. Hospitals require patients to sign a release to free the facilities of responsibility for lost valuables. Prepare a list with a clear description of items, place a copy with a patient's medical record (see agency policy), and give a copy to a designated family member. Describe any jewelry, including color of stones or metal. For example, if the patient

is wearing a silver ring with a red stone, document the ring as silver with a red stone and not as a ruby. There have been instances in which patients claim loss of a diamond, for example, when the actual stone was not a diamond. Patients are often reluctant to remove wedding rings or religious medals. A wedding band can be taped in place, but this is not the preferred practice. If there is a risk that the patient will experience swelling of the hand or fingers (mastectomy, hand surgery, fluid shifts), remove the band. Many hospitals allow patients to pin religious medals to their gowns, although the risk of loss increases. Remove other metal items such as piercings to reduce the risk of burns.

Preparing the Bowel and Bladder

Some patients receive an enema or cathartic agent the morning of surgery (see [Chapter 47](#)). If so, give at least 1 hour before a patient leaves for surgery, allowing time for him or her to defecate without rushing. Instruct a patient to urinate just before leaving for the OR and before giving preoperative medications. An empty bladder reduces discomfort and the risk of incontinence during surgery and makes abdominal organs more accessible to the surgeon. If a patient is unable to void, record this information on the preoperative checklist. The surgeon may order insertion of an indwelling catheter if the surgery is to be lengthy or the incision is in the lower abdomen (see [Chapter 46](#)).

Vital Signs

Monitor preoperative vital signs before surgery. The anesthesia provider uses these values as a baseline for intraoperative vital signs. If preoperative vital signs are abnormal, surgery is sometimes postponed. Notify the surgeon of any abnormalities before sending a patient to surgery. In addition, assess the patient for the presence and character of pain (see [Chapter 44](#)). Many patients have pain before surgery caused by the condition requiring surgery.

Prevention of Deep Vein Thrombosis—Antiembolism Devices

Preventing DVTs is a priority quality measure. The [AORN \(2018a\)](#) recommends that each health care organization implement a DVT prevention protocol. A patient's condition and type of surgery determine the preventive measures taken before surgery. For example, patients who have cardiac, GI, genitourinary (GU), gynecological (GYN), neurological, and orthopedic surgeries will likely have mechanical VTE prophylaxis applied the morning of surgery. This includes application of one of the

following devices: antiembolism stockings (thigh or knee length), foot-impulse devices, or intermittent pneumatic compression (IPC devices: thigh or knee length) (Zhao et al., 2014; Kozek-Langenecker, 2018)). In addition, some patients receive pharmacological VTE prophylaxis, which includes medications such as low-molecular-weight heparin (LMWH) (Wan et al., 2015). The health care provider will screen patients carefully for the risk of bleeding before ordering pharmacological VTE prophylaxis.

When correctly sized and applied, antiembolism devices reduce the risk for DVT. Antiembolic stockings maintain compression of small veins and capillaries of the legs. The constant compression forces blood into larger vessels, thus promoting venous return and preventing venous stasis. The nurse attaches **intermittent pneumatic compression (IPC) stockings** to an air pump that inflates and deflates the stockings, allowing intermittent pressure sequentially from the ankle to the knee and alternating calves, mimicking normal venous return when walking (see Chapter 39). Foot-inflation devices simulate natural walking by compressing the plantar venous plexus (AORN, 2018a). Do not use antiembolism devices when patients have an allergy to the material (e.g., latex) or an unusual leg size or shape or a history of peripheral arterial disease, peripheral arterial bypass grafting, or peripheral neuropathy (Lim and Davies, 2014).

Administering Preoperative Medications

The increase in ambulatory surgeries has reduced the use of preoperative medications. However, the anesthesia provider or surgeon may order preanesthetic drugs (“on-call medications,” “preops”) to reduce patient anxiety, the amount of general anesthesia required, respiratory tract secretions, and the risk of nausea, vomiting, and possible aspiration. Typically, the nurse administers preoperative medications before a patient leaves for the OR. Complete all nursing care measures first. Preoperative drugs such as benzodiazepines, opioids, antiemetics, and anticholinergics usually cause dry mouth, drowsiness, and dizziness but do not induce sleep. To maintain patient safety, keep side rails in the up position, the bed in the low position, and the call light within easy reach. Instruct the patient to stay in bed until the surgical nursing assistant or transporter arrives. If the patient needs to get out of bed to void, explain the importance of using the call light to ask for assistance. A patient can easily fall, thinking nothing is wrong. Be sure that the patient has signed surgical consent before administering drugs that will alter consciousness.

Documentation and Hand-Off

Before a patient goes to the OR, an accurate medical record is essential to ensure safe and appropriate patient care. Check the contents of the medical record for the presence of ordered laboratory and imaging test results, accuracy and completeness of consent forms, and the preoperative checklist that agencies use as a tool to document all preoperative preparation activities. Carefully document surgical preparatory interventions and the patient's response to care. Once a patient is ready to go to the OR, a written (or electronic) record is inadequate to communicate information to the receiving health care team. The transfer of information about the patient from one health care provider to another requires an effective hand-off (AORN, 2018a). [Box 50.5](#) lists critical elements for hand-offs from preoperative to intraoperative providers. The [AORN \(2018a\)](#) and [TJC \(2020\)](#) recommend that hand-off reports occur in person to ensure that the right patient receives the right surgery at the right surgical site.

Box 50.5 Example of Elements of a Preoperative-to-Intraoperative Hand-Off Using SBAR Communication Situation

- Name of patient, date of birth
- Name of operative procedure to be performed, including site and modifiers
- Pertinent documents (e.g., consent, test results) present and consistent

Background

- Elements of patient history pertinent to surgery
- Medical clearance
- Patient allergies and NPO status
- Patient's vital signs and pain level
- Medication profile and medications taken today; laboratory results; imaging results
- Code status of patient

Assessment

- Patient's current level of understanding of the surgery
- Special patient needs, risks, or precautions
- Pertinent cultural or emotional factors
- Anesthesia requests

Recommendations

- State whether the patient has been seen before surgery by a surgeon and anesthesia care provider.
- Determine if the patient is ready for surgery.
- Allow chance for all staff members to ask questions and voice concerns.

Adapted from Amato-Vealey EJ, et al: Hand-off communication: a requisite for patient safety, *AORN J* 88(5):766, 2008.

Eliminating Wrong Site and Wrong Procedure Surgery

Because of errors made in the past with patients undergoing the wrong surgery or having surgery performed on the wrong site, TJC instituted Universal Protocol guidelines for preventing such mishaps. The Universal Protocol is part of TJC's ongoing National Patient Safety Goals (TJC, 2020). The preoperative-to-intraoperative hand-off described previously is an example of part of the protocol. Implement the Universal Protocol whenever an invasive surgical procedure is to be performed no matter the location (e.g., hospital, ASC, or health care provider office). The three principles of the protocol are (1) a preoperative verification that ensures all relevant documents (e.g., consent forms, allergies, medical history, physical assessment findings) and results of laboratory tests and diagnostic studies are available before the start of the procedure and that the type of surgery scheduled is consistent with the patient's expectations; (2) marking the operative site with indelible ink to mark left and right distinction, multiple structures (e.g., fingers), and levels of the spine; and (3) a "time-out" just before starting the procedure for final verification of the correct patient, procedure, site, and any implants (TJC, 2020). The

marking and “time-out” most commonly occur in the holding area, just before the patient enters the OR. The individual who is performing the surgery and who is accountable for it must personally mark the site and involves the patient if possible (TJC, 2020). All members of the surgical/procedure team perform the time-out. This protocol includes the patient or a legally designated representative in the entire process. If the patient refuses a mark, document this on the procedure checklist.

Building Competency in Evidence-Based Practice

You are a nurse in a surgical preoperative area. A patient asks, “After a previous surgery on my colon, I got an infection in the incision. What is the chance that I will get an infection or another complication after this surgery?” The patient verified that the previous surgery was uneventful but that within 48 hours after surgery the patient developed a fever of 103.6° F. The patient’s question poses an important practice issue. Use the PICOT evidence-based practice framework and identify the question that will guide your inquiry of the evidence.

• Evaluation

The nurse caring for a patient in the preoperative area evaluates initial patient outcomes (Fig. 50.4). Because limited time is available to evaluate outcomes before surgery, compare the patient’s current status with expected outcomes to determine whether new or revised interventions and/or nursing diagnoses need to be implemented intraoperatively.

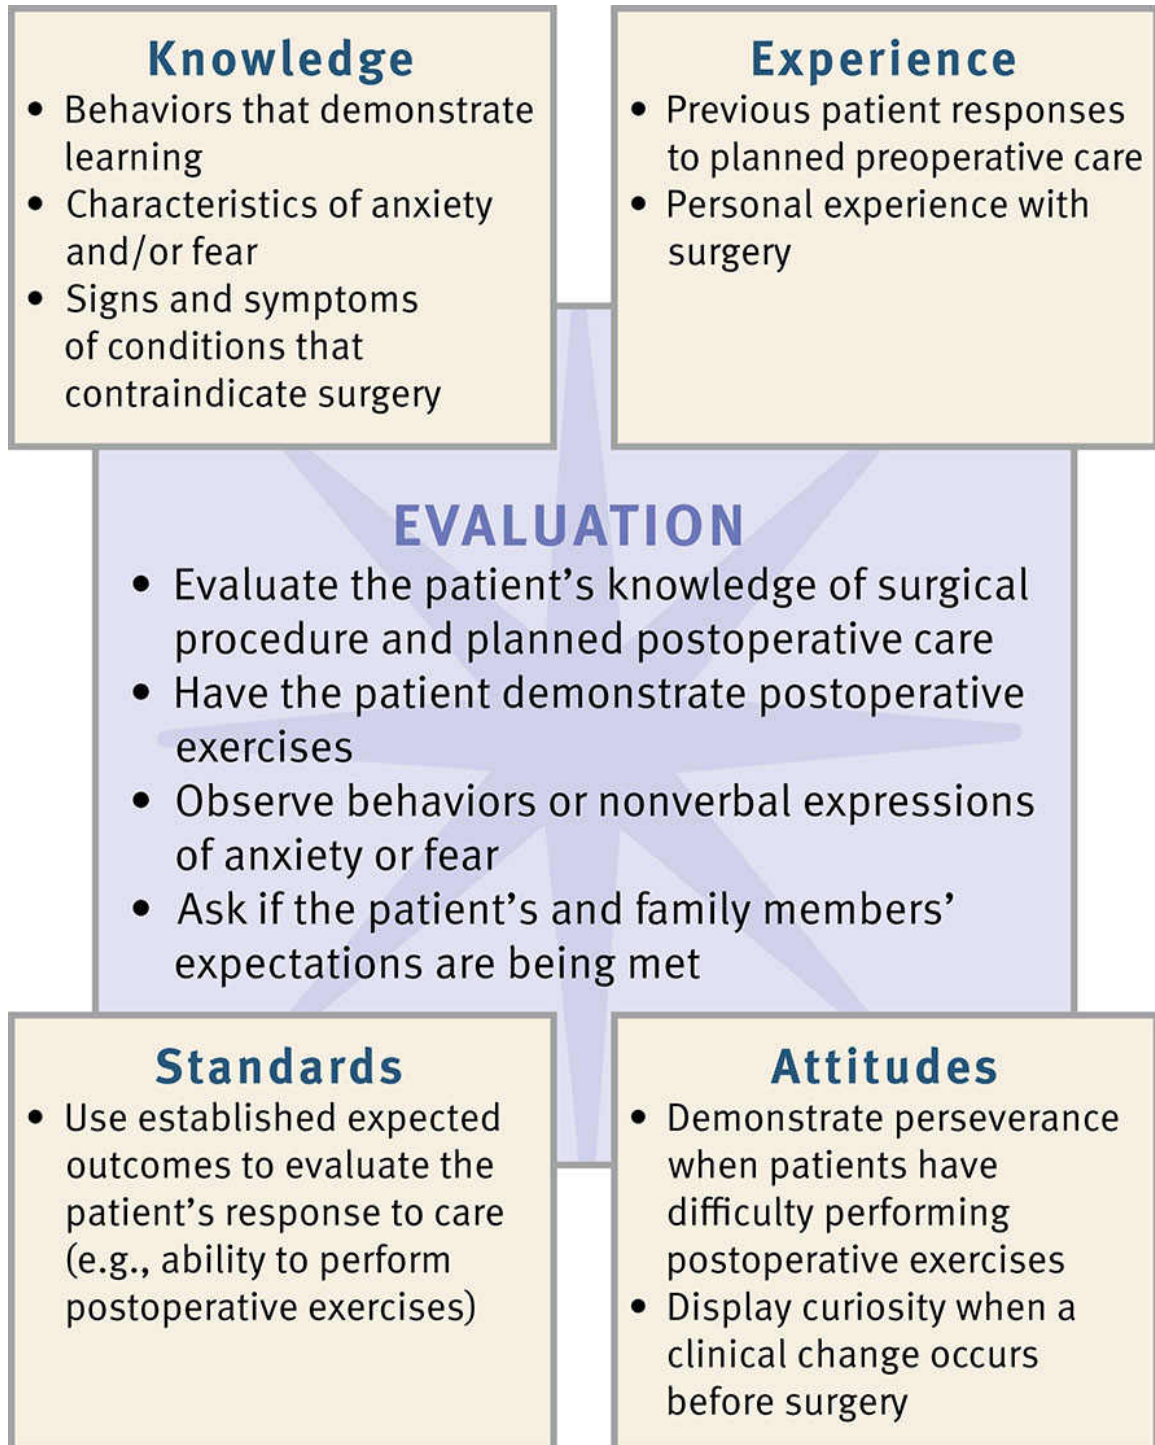

FIG. 50.4 Critical thinking model for surgical patient evaluation.

Through the Patient's Eyes

Evaluate whether the patient's expectations were met with respect to surgical preparation. For example, ask patients if they require additional

information, if they desire to have their family members more involved, and if they have any unidentified needs. During evaluation, include a discussion of any misunderstandings so that patient concerns can be clarified. When patients have expectations about pain control, this is a good time to reinforce how it will be managed after surgery.

Patient Outcomes

Evaluate a patient's response to interventions designed for preoperative nursing diagnoses such as *Lack of Knowledge* and *Anxiety*. For example, ask the patient to describe the reason for postoperative exercises and the type of care activities to expect when he or she returns from surgery. Observe the patient's behaviors and discuss concerns to see if anxiety remains. Your evaluation is comprehensive to determine if further instruction or emotional support is needed after surgery. Interventions continue during and after surgery; thus the evaluation of many goals and outcomes does not occur until after surgery.

Transport to the Operating Room

Personnel in the OR notify the nursing unit or ambulatory surgery area when it is time for surgery. Inpatient facilities have transporters who bring stretchers to deliver patients to the preoperative care unit. In ambulatory care a patient simply walks into the preop suite if able and not medicated. A transporter or nurse in the holding area checks the patient's identification bracelet for two identifiers (name, birthday, or hospital number) (refer to institutional or agency policy) against the patient's medical record to ensure that the correct person is going to surgery. Because some patients receive preoperative sedatives, the nurses, assistive personnel, and transporter help the patient transfer from bed to stretcher to prevent falls. Provide the family an opportunity to visit before the patient is transported to the OR. Direct the family to the appropriate waiting area.

Preanesthesia Care Unit

In most hospitals, a patient enters a **preanesthesia care unit (PCU)** or presurgical care unit (PSCU) (sometimes called the *holding area*) outside the OR where preoperative preparations are completed. Nurses in the PCU are members of the OR staff and wear surgical scrub suits, hats, and footwear in accordance with infection control policies. In some ambulatory surgical settings, a perioperative primary nurse admits the patient, circulates during the operative procedure, and manages the patient's recovery and discharge.

If an IV catheter is not present already, a nurse or anesthesia provider inserts one into a vein to establish a route for fluid replacement, IV drugs, or blood products. The nurse also administers preoperative medications at this time. He or she monitors vital signs, including pulse oximetry. The anesthesia provider usually performs a patient assessment. Because of the preoperative medications, explain to the patient that he or she will begin to feel drowsy. The temperature in the PCU and adjacent OR suites is usually cool; therefore offer the patient an extra blanket or warming blanket. The patient will stay in the PCU only briefly.

Intraoperative Surgical Phase

Care of a patient intraoperatively requires careful preparation and knowledge of the events that occur during surgery. Another important feature of intraoperative care is safety of OR personnel. The OR environment poses unique risks resulting from the procedures followed. Members of the surgical team can suffer injury from skin sticks or cuts (e.g., needle or scalpel) or mucous membrane exposure (splashing of irrigated fluids) to contaminated body fluids. Proper use of personal protective equipment is critical. When nurses participate in laser surgical procedures, they use special safety precautions (e.g., use of laser protective eyewear or shields) to prevent injury to the eyes and skin.

Nursing Roles During Surgery

There are two traditional nursing roles in the OR: circulating nurse and scrub nurse (Fig. 50.5). The **circulating nurse** is an RN who does not scrub in and uses the nursing process in the management of patient care activities in the OR suite. The circulating nurse also manages patient positioning, antimicrobial skin preparation, medications, implants, placement and function of IPC devices, specimens, warming devices, and surgical counts of instruments and dressings (AORN, 2018a). The **scrub nurse** is either an RN or surgical technologist who is often certified (CST). The scrub nurse must have a thorough knowledge of each step of a surgical procedure and the ability to anticipate each instrument and supply needed by the surgeons (Rothrock, 2019). A circulating nurse and scrub nurse partner together to ensure patient safety by minimizing risk of error. The team also works together to ensure cost-efficient use of supplies.

FIG. 50.5 Nurses in operating room
© 2011 Jupiterimages Corporation.

A new role in the OR includes the RN first assistant (RNFA). This is an expanded role that requires formal academic education ([AORN, 2018b](#)). The RNFA collaborates with the surgeon by handling and cutting tissue, using instruments and medical devices, providing exposure of the surgical area and hemostasis, and suturing ([Rothrock, 2019](#)).

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care for intraoperative patients.

◆ Assessment

The circulating nurse in the OR thoroughly assesses the patient and critically analyzes findings to make patient-centered clinical decisions required for safe nursing care. Assessment focuses on a patient's immediate clinical status, skin integrity (over surgical site and dependent areas where patient will lie on operating table bed), and joint function (when unusual positions on the OR table are required). This allows the nurse to anticipate problems that predispose the patient to injury if he or she is positioned on the OR table incorrectly. Because patients are unable to speak for themselves while under general anesthesia, this assessment in the OR is very important for their safety. As the nurse, review the preoperative care plan to establish or revise the intraoperative care plan as indicated.

REFLECT NOW

One of the goals of preoperative nursing care is to prevent intraoperative and postoperative complications. Consider the surgical risk factors discussed in preoperative assessment and identify their relationship to potential complications that operating room nurses must prevent.

◆ Nursing Diagnosis

Review preoperative nursing diagnoses and modify them to individualize the care plan in the OR. The following are common nursing diagnoses relevant to the patient intraoperatively:

- *Impaired Airway Clearance*
- *Risk for Deep Vein Thrombosis*
- *Risk for Perioperative Positioning Injury*
- *Risk for Impaired Skin Integrity*
- *Risk for Latex Allergy*

• Planning

Goals and Outcomes

Patient-centered goals and outcomes of preoperative nursing diagnoses extend into the intraoperative phase. For example, a goal for the nursing diagnosis of *Impaired Airway Clearance* is “Airway will remain free of secretions.” An expected outcome for this goal is: The patient will maintain a clear, open airway as evidenced by clear breath sounds, a respiratory rate of 12 to 20 breaths/minute, and the ability to effectively cough up secretions. How the patient responds during surgery will influence whether outcomes need to be adjusted.

Setting Priorities

The circulating nurse uses judgment to provide a safe operative experience for the patient. Ensuring an aseptic environment, conducting instrument and sponge counts according to policy, managing tissue and specimens correctly, and ensuring proper use of equipment and instruments are top priorities. If an unsafe practice occurs (e.g., break in sterility, missing sponge in wound), the circulating nurse is integral in ensuring the safety of the patient and operative personnel.

Teamwork and Collaboration

For optimal patient safety the preoperative health care team communicates assessment findings and patient problems via a formal hand-off with the surgical team to ensure a smooth transition in care (see [Box 50.5](#)). For example, alerting the operative team of a latex allergy or risk factors for complications during surgery (smoker) requires collaboration and timely communication among all team members.

• Implementation

A primary focus of intraoperative care is to prevent injury and complications related to anesthesia, surgery, positioning, and equipment

use. The perioperative nurse is an advocate for the patient during surgery and always protects his or her dignity and rights.

Acute Care

Physical Preparation

A patient is usually still awake and notices health care providers in their surgical attire and masks when entering the OR. The staff members transfer a patient to the OR bed by being sure that the stretcher and bed are locked in place. Explain to the patient all the activities that will be performed before implementing the activities. Remember that a patient may be partially sedated as a result of medications; use caution. After safely securing the patient on the OR table with safety straps, the nurse applies monitoring devices such as continuous ECG electrodes, a pulse oximeter sensor, and blood pressure cuff. For ECG, place electrodes on the chest and extremities correctly to record electrical activity of the heart accurately. The anesthesia provider will use the cuff to monitor the patient's blood pressure. An electronic monitor in the OR will display the patient's heart rate, vital signs, and pulse oximetry continuously. Capnography is also used frequently to measure the patient's ongoing end-tidal carbon dioxide values. Now is also the time to apply antiembolism devices. The nurse also assists with the insertion of temperature probes via the bladder, esophagus, or rectum if required to continuously measure a patient's body temperature.

If a patient is to have a surgical procedure that uses a high-frequency electric current to heat biological tissue to cut or coagulate the tissue, a disposable or reusable grounding pad must be placed on the patient's skin. The grounding pad, adhered to the patient's skin away from the surgical site, is intended to safely return the electrical current from the patient back to the generator through a cord or cable. Correct placement of the pad prevents burns to the skin.

Intraoperative Warming

The unplanned occurrence of perioperative hypothermia is now minimized with the use of active intraoperative warming. Prevention of hypothermia (core temperature less than 36° C [96.8° F]) helps to reduce complications such as shivering, cardiac arrest, blood loss, SSI, pressure injuries, and mortality (Rightmyer and Singbartl, 2016). Evidence suggests that prewarming for a minimum of 30 minutes may reduce the occurrence

of hypothermia ([Rightmyer and Singbartl, 2016](#)). The nurse in the OR applies warm cotton blankets, forced-air warmers, or circulating-water mattresses to patients. Forced-air warmers tend to be effective when used before surgery or intraoperatively.

Latex Sensitivity/Allergy

As the incidence and prevalence of **latex sensitivity** and allergy increase, the need for recognition of potential sources of latex is extremely critical. All medical supplies contain a label notifying the consumer of the latex content. The OR and PCU have many products that contain latex (e.g., gloves, IV tubing, syringes, and rubber stoppers on bottles and vials). It is also present in common objects such as adhesive tape, disposable electrodes, endotracheal tube cuffs, protective sheets, and ventilator equipment. Signs and symptoms of a latex reaction include local effects ranging from urticaria and flat or raised red patches to vesicular, scaling, or bleeding eruptions. Acute dermatitis is sometimes present. Rhinitis and/or rhinorrhea are other common reactions to mild and severe latex allergy. Immediate hypersensitivity reactions are life threatening, with the patient exhibiting focal or generalized urticaria and edema, bronchospasm, and mucus hypersecretion, all of which can compromise respiratory status. Vasodilation compounded by increased capillary permeability sometimes leads to circulatory collapse and eventual death. The draping of a patient during surgery blocks the ability to visualize the skin. Thus, be prepared to investigate any unexplained acute deterioration in a previously healthy patient for possible latex allergy.

A latex-free cart is available in an OR to create a latex-safe environment. All of the contents must be latex free. The Association of Surgical Technologists (AST) recommends that when facilities are not latex safe, nurses need to take steps to prepare an OR the night before to avoid the release of latex particles ([AST, 2018](#)). Any patient with a latex allergy should receive scheduling priority and be the first case in the morning. It is important to know that patients may develop anaphylaxis 30 to 60 minutes after being exposed to latex. [Box 50.6](#) lists latex precautions.

Box 50.6 Latex Avoidance Precautions

- Health care workers can transmit the allergen by hand to patients after touching any object with latex. *Caution:* Keep the powder from the gloves away from patients because the powder acts as a carrier for the latex protein. Do not snap gloves on and off.
- Identify patients who are latex sensitive. The operating room (OR) needs to be labeled latex free to prevent personnel from bringing rubber products (e.g., wristbands, chart labels) into the room.
- Develop programs to educate health care workers in the care of latex-sensitive patients.

Recommendations for Patient Care (Patients with Latex Allergy or Latex Risk)

The Operating Room

- Notify the OR of patients who have potential latex allergies. Remove all latex products from the OR and bring a latex-free cart (if available) into the room.
- Use a latex-free reservoir bag, airways and endotracheal tubes, and laryngeal mask airways.
- Use a nonlatex anesthesia breathing circuit with plastic mask and bag.
- Place all monitoring devices and cords/tubes (oximeter, blood pressure, electrocardiograph wires) in stockinette and secure with tape to prevent direct skin contact. Rinse items sterilized in ethylene oxide before use. Residual ethylene oxide reacts and can cause an allergic response in a patient with a latex allergy.

Intravenous Line Preparation

- Use intravenous (IV) tubing without latex ports; use stopcocks if available.
- If unable to obtain IV tubing without latex ports, cover latex ports with tape.
- Cover all rubber injection ports on IV bags with tape and label as follows: *Do not inject or withdraw fluid through the latex port. Note: Pulmonary artery catheters (especially the balloon), central venous catheters, and arterial lines may contain latex components.*

Operating Room Patient Care

- Use nonlatex gloves. (*Caution:* Not all substitutes are equally impermeable to bloodborne pathogens; ensure that substitute gloves provide appropriate protection.)
- Use nonlatex tourniquets or nonlatex examination gloves or polyvinyl chloride tubing.
- Draw medication directly from opened multidose vials (remove stoppers) if medications are not available in ampules.
- The rubber allergen can possibly move from the plunger of a syringe into the medication, which sometimes causes an allergic reaction. The intensity of this reaction increases over time. Therefore, nurses draw up medications immediately before the beginning of the surgery or just before administration.
- Use latex-free or glass syringes.
- Use stopcocks to inject drugs rather than latex ports.
- Notify pharmacy and central supply that your patient is latex sensitive so these departments can use appropriate procedures when preparing medications and instruments. Also, notify radiology, respiratory therapy, housekeeping, food service, and postoperative care units so that they will take appropriate precautions to protect the patient.
- Place clear and readily visible signs on the doors of the OR to inform all who enter that the patient has a latex allergy.

Modified from *Perioperative Standards and Recommended Practices: AORN latex guideline*, Denver, 2018, AORN.

Introduction of Anesthesia

The nature and extent of a patient's surgery and current physical status influence the type of anesthesia administered during surgery. Know the complications to anticipate after surgery for each type ([Table 50.7](#)).

TABLE 50.7**Examples of Complications of Anesthesia**

Type	Complications
General	Aspiration of vomitus, cardiac irregularities, decreased cardiac output, hypotension, hypothermia, hypoxemia, laryngospasm, malignant hyperthermia, nephrotoxicity, and respiratory depression
Regional: epidural, spinal and caudal blocks	Hypotension, hypothermia, injury to spinal cord, respiratory paralysis, spinal headache
Local	Hives, rash, anaphylaxis
Conscious sedation	Aspiration, decreased level of consciousness, hypoxemia, respiratory depression

General Anesthesia

Under **general anesthesia** a patient loses all sensation, consciousness, and reflexes, including gag and blink reflexes. The patient's muscles relax and the patient experiences amnesia. Amnesia is a protective measure that allows patients to forget any unpleasant events of the procedure. An anesthesia provider gives general anesthetics by IV infusion and inhalation routes through the three phases of anesthesia: induction, maintenance, and emergence. Surgery requiring general anesthesia involves major procedures with extensive tissue manipulation. During emergence, anesthetics are decreased, and the patient begins to awaken. Because of the short half-life of today's medications, emergence often occurs in the OR. The duration of anesthesia depends on the length of surgery.

Regional Anesthesia

Regional anesthesia results in loss of sensation in an area of the body by anesthetizing sensory pathways. This type of anesthesia is accomplished by injecting a local anesthetic along the pathway of a nerve from the spinal cord. A patient requires careful monitoring during and immediately after regional anesthesia for return of sensation and movement distal to the point of anesthetic injection. The circulating nurse protects the patient's limbs from injury until sensation returns. Serious complications such as respiratory paralysis occur if the level of anesthesia rises, moving upward in the spinal cord. Elevation of the upper body helps prevent respiratory paralysis. Some patients have a sudden fall in blood pressure, which results from extensive vasodilation caused by the anesthetic blocking

sympathetic vasomotor nerves and pain and motor nerve fibers. Remember that grounding pad burns and other trauma can occur on the anesthetized part of the body without the patient being aware of the injury. It is necessary to observe frequently the position of the extremities and the condition of the skin.

Local Anesthesia

Local anesthesia involves loss of sensation at the desired site (e.g., a skin growth or the cornea of the eye) by inhibiting peripheral nerve conduction. It is commonly used in ambulatory surgery. A local can also be used in addition to general or regional anesthesia. The anesthetic agent (e.g., lidocaine) inhibits nerve conduction until the drug diffuses into the circulation. It is injected locally or applied topically. The patient experiences a loss in pain and touch sensation in the area of injection. Patients are at risk for having drug interactions and allergic effects. It is necessary to monitor patients continually during a local procedure. The frequency of observation and monitoring of patients is tailored to the patient, procedure, and the medications used (Kim and Kim, 2016).

Moderate (Conscious) Sedation

IV moderate sedation (i.e., **conscious sedation**) is used routinely for short-term surgical, diagnostic, and therapeutic procedures that do not require complete anesthesia but rather a depressed level of consciousness. A patient maintains spontaneous ventilation and a patent airway and requires no interventions during conscious sedation (Rothrock, 2019). In addition, the patient responds appropriately to physical (light touch) and verbal stimuli. The preferred sedative for conscious sedation is short-acting IV sedatives such as midazolam.

Advantages of conscious sedation include adequate sedation, reduction of fear and anxiety, amnesia, relief of pain and noxious stimuli, elevation of pain threshold, enhanced patient cooperation, stable vital signs, and rapid recovery. Nurses assisting with the administration of conscious sedation need to demonstrate competency in the care of these patients. Knowledge of anatomy, physiology, cardiac dysrhythmias, procedural complications, and pharmacological principles related to the administration of individual agents is essential. The nurse needs to assess, diagnose, and intervene in the event of unexpected reactions, such as an adverse reaction to a medication, and demonstrate skill in airway management and oxygen delivery. Resuscitation equipment must be readily available when using conscious sedation.

Positioning the Patient for Surgery

A patient will be placed on an operating room table in a position that offers access to the surgical site. Prevention of positioning injuries requires anticipation of the position and surgical approach to be used, the positioning equipment available to be used, and whether a patient has conditions causing risk for injury (AORN, 2018a). When possible, the position during surgery should be one that would be comfortable with the patient fully awake. Patients should be questioned about limited range of motion and their ability to lie comfortably in the expected position. If questions arise, the patient should be placed in the anticipated position as a trial before sedation or induction of anesthesia. If the operating table will be tilted either top to bottom, side to side, or moved into the sitting position (e.g., during breast reconstruction) during surgery, the anticipated position should be practiced before skin preparation and draping to make sure that supports and straps are secure and that the patient tolerates the position physiologically.

During general anesthesia, the nursing personnel and surgeon often wait to position a patient until the full stage of relaxation so that an injury is less likely to be caused by moving and lifting the patient's body parts. Ideally, a patient's position provides clear access to the operative site; sustains adequate circulatory and respiratory function; and ensures the patient's safety, comfort, and skin integrity. If a patient has conditions such as morbid obesity, malnourishment, existing pressure injuries, or chronic disease, special considerations are needed in positioning. It is important for the circulating nurse to assess circulatory, respiratory, integumentary, musculoskeletal, and neurological structures during surgery (AORN, 2018a).

An alert person maintains normal range of joint motion by pain and pressure receptors. If a joint is extended too far, pain stimuli provide a warning that muscle and joint strain is too great. In a patient who is anesthetized, normal defense mechanisms cannot guard against joint damage, muscle stretch, and strain. The muscles are so relaxed that it is relatively easy to place a patient in a position that the individual normally could not assume while awake. He or she often remains in a given position for several hours. Although it is sometimes necessary to place a patient in an unusual position, try to maintain correct alignment and protect skin from pressure, abrasion, and other injuries. Special mattresses, use of foam padding, and attachments to the OR table provide protection to extremities and bony prominences. Positioning should not impede normal

movement of the diaphragm or interfere with circulation to body parts. If restraints are necessary, pad the skin to prevent trauma.

Documentation of Intraoperative Care

Throughout the surgical procedure, the circulating nurse keeps an accurate record of patient care activities and procedures performed by OR personnel (e.g., surgical count status, special equipment, IV and irrigation fluids, specimens, and medications). A standardized documentation format helps practitioners ensure continuity of information from the OR to the postanesthesia care unit (PACU) or recovery area ([AORN, 2018a](#)). The AORN recommends the use of verbal and standardized forms to transfer patient information between care providers.

Evaluation

The circulating nurse conducts an ongoing evaluation to ensure that interventions such as patient position are implemented correctly during the intraoperative phase of surgery.

Through the Patient's Eyes

While a patient is undergoing surgery, it is important to keep the family informed. Pagers are used in some settings to text updates to family members. Hospitals vary on their policies for when and how often families are given updates of the patient's condition. Families expect an estimate of when surgery begins, how the surgery is progressing, and the length of time it will likely last. When you give an update to family members, ask if they have further questions or concerns and if their needs are being met.

Patient Outcomes

During surgery the anesthesia provider continuously monitors vital signs. The circulating nurse monitors and records intake and output (I&O), specimens obtained, medications and irrigations, type of dressing packing, and other treatments. Measurement of the patient's body temperature during and at completion of the surgery provides data to achieve the goal of keeping the patient normothermic. The circulating nurse will inspect the skin under the grounding pad and at areas where positioning exerts pressure.

Postoperative Surgical Phase

There are three phases of anesthesia recovery. Phase I (immediate recovery) begins when a patient leaves the operating room (OR). It extends from the time a patient leaves the OR to the time he or she is stabilized in the PACU or ambulatory recovery area, meets discharge criteria, and is transferred to a nursing unit or other location. During phase I close monitoring is required; for the first 1 to 2 hours the focus is on assessing for the aftereffects of anesthesia, including airway clearance, cardiovascular complications, fluid management, temperature control, and neurological function. A patient's condition can change rapidly; assessments must be timely, knowledgeable, and accurate. When a patient has progressed beyond these elements of care, they can progress to the phase II level of care in which plans and care are provided to progress the patient home ([ASPAN, 2018](#)). This may be in the same physical location as phase I care, when a patient has had ambulatory surgery. Many PACUs provide blended levels of care, in which both levels of care are provided in the same location ([ASPAN, 2018](#)).

Phase III recovery (convalescence) focuses on providing ongoing care for patients who are hospitalized and require extended observation or intervention after transfer from phase I or phase II. Interventions are directed toward preparing the patient for self-care or care by family members. Phases of recovery are not locations but levels of care ([ASPAN, 2018](#)).

The type of anesthesia, nature of surgery, and a patient's previous condition determine the phases of recovery and the length of time spent on an acute care nursing unit. Typically, at the end of surgery the anesthesia provider and the circulating nurse accompany the patient to the PACU and provide a thorough hand-off report to the nursing staff.

Immediate Postoperative Recovery (Phase I)

When a PACU nurse receives a patient during hand-off, he or she obtains data from the surgical team to prepare for proper support of a patient's recovery status. This includes anticipating possible clinical problems based on assessment and being sure that special equipment needed for nursing care is available. Careful planning allows the nursing staff to consider placement of patients in the PACU. For example, patients who undergo spinal anesthesia are aware of their surroundings and benefit from being in a quieter part of the PACU, away from patients needing frequent monitoring. The nurse isolates patients with serious infections, such as tuberculosis, from other patients. Use Standard Precautions for infection control (see [Chapter 28](#)) for all patients.

When a patient is admitted to phase I recovery, personnel notify the nurses on the acute care nursing unit of his or her arrival. This allows the nursing staff to inform family members. Family members usually remain in the designated waiting area so that they are accessible when the surgeon arrives to explain the patient's condition. *It is the surgeon's responsibility to describe the patient's status, the results of surgery, and any complications that occurred.* The nurse is a valuable resource to the family for clarifying explanations if complications occur in the operative phase.

When a patient enters the PACU, the nurse and members of the surgical team discuss his or her status. A standardized approach or tool for "hand-off" communications helps to provide accurate information about a patient's care, treatment and services, current condition, and any recent or anticipated changes ([Rothrock, 2019](#)). The hand-off is interactive, interprofessional, and done at the patient's bedside, allowing for a communication exchange that gives caregivers the chance to dialogue and ask questions. The surgical team's report includes topics such as the type of anesthesia provided, vital sign trends, intraoperative medications, IV fluids, estimated blood and urine loss, and pertinent information about the surgical wound (e.g., dressings, tubes, drains) ([Rothrock, 2019](#)). The

information obtained from hand-off report allows a recovery nurse to anticipate how quickly a patient should regain consciousness, any likely complications, and what his or her analgesic needs will be. A report on IV fluids or blood products administered during surgery from the anesthesia provider or perfusionist alerts the nurse to the patient's fluid and electrolyte balance. The surgeon or anesthesia provider often reports special concerns (e.g., whether the patient is at risk for hemorrhaging or infection) and whether there were complications during surgery such as excessive blood loss or cardiac irregularities. The circulating nurse also reports intraoperative patient positioning and condition of the skin. Frequently, this report takes place while PACU nurses are admitting the patient. The PACU nurse attaches the patient to monitoring equipment such as the noninvasive blood pressure monitor, ECG monitor, and pulse oximeter. Patients often receive some form of oxygen in this immediate recovery period.

After receiving hand-off communication from the OR, the PACU nurse conducts a complete systems assessment during the first few minutes of PACU care (Garrett, 2016) (Box 50.7). Patients will begin to gradually awaken while in the PACU. Try to arouse a patient by calling his or her name in a moderate tone of voice. If that is not successful, waken him or her by using touch or gently moving a body part. If painful stimulation is needed to arouse a patient, notify anesthesia immediately. Perform assessments at least every 15 minutes or more frequently, depending on the patient's condition and unit policy. This assessment continues until discharge from the PACU. Perform assessments quickly and thoroughly and target them to a patient's unique needs and type of surgery.

Box 50.7 Initial Postanesthesia Care Assessment: Parameters to Assess

Initial assessment in the PACU includes documentation of the following:

- Integration of data received at hand-off for transfer of care
- Vital signs
- Respiratory status—airway patency, breath sounds, type of artificial airway, mechanical ventilator settings, oxygen saturation, and end-tidal CO₂ values
- Intake and output
- Pain/sedation/comfort assessment (including psychoemotional status), presence of nausea or vomiting
- Neurological function: level of consciousness (may use Glasgow Coma scale), pupillary response (if indicated)
- Position of the patient
- Condition and color of skin, status of any suspected pressure areas
- Patient safety needs
- Neurovascular status: peripheral pulses and sensation of extremity or extremities
- Condition of surgical dressings or suture line, drains, tubes, receptacles
- Amount, appearance, and type of drainage
- Muscular response and strength/mobility
- Fluid therapy—location of intravenous (IV) lines, patency of IV lines, amount and type of solution (crystalloids or blood products) infused, next fluid to be administered
- Procedure-specific assessments, such as expected drainage amount, specific positioning aids for orthopedic surgery

Adapted from Rothrock JC: *Alexander's care of the patient in surgery*, ed 16, St, Louis, 2019, Elsevier.

As patients awaken, they expectorate the oral airway, or the nurse asks the patient to expectorate the airway. The ability to do so signifies the return of a normal gag reflex. Before removing an artificial airway (or before the patient removes it), suction the back of the airway so that secretions are not retained. Be alert for nausea and

vomiting, which may precipitate regurgitation. Avoid any rapid movement of the patient and keep his or her head elevated while lying on the side.

One of the greatest concerns is airway obstruction. A number of factors contribute to obstruction, including history of OSA; weak pharyngeal/laryngeal muscle tone from anesthetics; secretions in the pharynx, bronchial tree, or trachea; and laryngeal or subglottic edema. After anesthesia, a patient's tongue causes the majority of airway obstructions. Ongoing assessment of airway patency is crucial even during phase III recovery. Patients remain in a side-lying position until airways are clear. Continue to assess respiratory status and breath sounds. Older patients, smokers, and patients with a history of respiratory disease are prone to developing complications such as atelectasis or pneumonia. Patients with OSA are often required to have continuous pulse oximetry while receiving IV opioids to detect oxygen desaturation quickly. Use of the Pasero Opioid-Induced Sedation Scale (POSS) in the PACU helps assess patients more accurately and meets the pain needs of the patient while preventing oversedation ([Kobelt et al., 2014](#)).

Normally a patient who received general anesthesia does not drink fluids in the PACU because of reduced peristalsis, risk of nausea and vomiting, and grogginess from general anesthesia. In the case of ambulatory surgery, once a patient awakens in the recovery area and feels no nausea, ice chips or clear liquids in small amounts will be given. For patients at high risk for the development of nausea and vomiting or those who must not vomit, the nurse administers a combination of antiemetics, as ordered by the surgeon, to block multiple receptors. A combination of antiemetic medications is often more effective than a single agent ([Matsota et al., 2015](#)). If a patient has an NG tube, keep it patent by irrigating it as ordered (see [Chapter 47](#)). Occlusion of an NG tube results in accumulation of gastric contents within the stomach, increasing risk of regurgitation and aspiration.

You will determine a patient's status and eventual readiness for discharge from the PACU based on vital sign stability compared with the preoperative data. Other outcomes for discharge include body temperature control, good ventilation and oxygenation status,

orientation to surroundings, absence of complications, minimal pain and nausea, controlled wound drainage, adequate urine output, and fluid and electrolyte balance. Patients with more extensive surgery requiring anesthesia of longer duration usually recover more slowly. It is common for hospitals and ambulatory care centers to use objective scoring systems such as the Efficacy Safety Score to identify when patients are ready for discharge (Skraastad et al., 2017). Other standard tools include the modified Aldrete scoring system originally developed in 1970 (Aldrete, 1998) or the modified **postanesthesia recovery score (PARS)** and the DASAIM discharge assessment tool (Phillips et al., 2011). Health care providers use forms of both tools. Each assessment tool has criteria assessed at select time intervals (e.g., 5, 15, 30, 45, and 60 minutes) and on discharge from the PACU (see agency policy). A patient must receive a predetermined score before discharge from the PACU. If the patient's condition is still poor after 2 or 3 hours or if the stay lengthens, the surgeon may transfer him or her to an intensive care unit (ICU).

When a patient is discharged from the PACU and requires continued monitoring and care, another hand-off communication occurs at the patient's bedside between the PACU nurse and the nurse in the ambulatory care phase II area, acute nursing unit, or in an ICU. The nurses verify the patient's identification using two identifiers. The hand-off includes review of vital signs, the type of surgery and anesthesia performed, blood loss, level of consciousness, general physical condition, medications administered during surgery and in PACU, and the presence of IV lines, drainage tubes, and dressings. The PACU nurse's report helps the receiving nurse anticipate special patient needs and obtain necessary equipment. It is important to have uninterrupted time to review the recent pertinent events and ask questions. It is also important at this time for the patient's family members to be informed as soon as possible of the patient's transfer plan.

The PACU staff transport the patient to either the final recovery phase II area in an ambulatory setting or on a stretcher to an inpatient nursing unit. Staff members from the unit help to safely transfer the patient (see [Chapter 38](#)). The PACU nurse shows the

receiving nurse the recovery room record and reviews the patient's condition and course of care. The PACU nurse also reviews the surgeon's orders that require attention. *Before the PACU nurse leaves the acute care area, the staff nurse assuming care for the patient takes a complete set of vital signs to compare with PACU findings.* Minor vital sign variations normally occur after transporting the patient.

Recovery in Ambulatory Surgery (Phase II)

After patients stabilize and no longer require close monitoring, phase II recovery begins. This may occur in the same recovery area of the PACU for ambulatory patients or a different nearby location. With new anesthetic agents and minimally invasive surgical techniques, *fast-track surgery* is becoming more common, with patients experiencing a more rapid awakening in the OR, quicker recovery, and reduced morbidity (Nanavati and Prabhakar, 2014). Because of this, many ambulatory surgery patients can bypass phase I and immediately enter phase II in the recovery area.

In ambulatory surgery, phase II recovery is performed in a room equipped with medical recliner chairs, side tables, and foot rests. Kitchen facilities for preparing light snacks and beverages are usually located in the area, along with bathrooms. The phase II environment promotes a patient's and family's comfort and well-being until discharge. Nurses continue to monitor patients' vital signs and level of responsiveness but not at the same intensity as during phase I. In phase II recovery, you will initiate postoperative teaching with patients and family members (Box 50.8).

Box 50.8 Patient Teaching Postoperative

Instructions for an Ambulatory Surgical Patient Objective

- Patient will describe signs and symptoms of postoperative problems to report to health care provider.

Teaching Strategies

- Give instruction sheet with contact information, including health care provider's telephone number, telephone number of surgery center, and follow-up appointment date and time. Provide an instruction sheet with clear, focused explanations.
- Allow patient and family to ask questions.
- Individualize standard instructions to patient's specific needs
- Explain signs and symptoms of infection to family members.
- Explain name, dose, schedule, and purpose of medications and possible side effects. Provide printed drug information.
- Explain activity restrictions, diet progression, wound care guidelines, and the signs of any associated problems.

Evaluation

Use the principles of teach-back to evaluate patient/family caregiver learning:

- Patient explains when and how to call health care provider with problems.
- Patient recites date for follow-up appointment.
- Patient and family member describe signs and symptoms of infection.
- Patient verbalizes name of drug, dose, when to take, and common side effects.
- Patient demonstrates proper activity/movement and wound care.

Patients are discharged to home following ambulatory surgery after they meet certain criteria, such as a designated score on the PARS assessment tool. Patients with known OSA or at high risk for the condition are not discharged from the recovery area to home until they are no longer at risk for postoperative respiratory depression, which may require a longer stay ([ASA, 2014](#)). Postoperative nausea and vomiting (PONV) sometimes occur once the patient is home, even if the symptoms were not present in the

surgery center. Options for therapy include the transcutaneous AccuPoint electrical stimulation or the prophylactic use of drugs such as ondansetron, aprepitant, dolasetron, or a transdermal scopolamine patch ([Rothrock, 2019](#)).

Review written postoperative instructions and prescriptions with the patient and family caregiver before releasing the patient, and ensure that they verbalize understanding of these instructions. Always discharge the patient to a responsible adult who can drive the patient home.

Recovery of Inpatients: Postoperative Recovery and Convalescence

Inpatients remain in the PACU until their condition stabilizes; they then return to the postoperative nursing unit for either continuing phase II or phase III convalescence. Nursing care focuses on returning the patient to a relatively functional level of wellness as soon as possible. The speed of recovery depends on the type or extent of surgery, risk factors, pain management, and postoperative complications.

◆ Nursing Process

Apply the nursing process and use a critical thinking approach in your care of patients. The nursing process provides a clinical decision-making approach for you to develop and implement an individualized plan of care. Once a surgical patient is transferred to an acute care nursing unit, ongoing postoperative care is essential to support recovery.

◆ Assessment

During the assessment process, thoroughly assess each patient and critically analyze findings to ensure you make patient-centered clinical decisions required for safe postoperative nursing care. Apply critical thinking while you synthesize information from the preoperative nursing assessment, knowledge regarding the surgical procedure performed, and events occurring during surgery and phase I recovery. A variation from the patient's norm possibly indicates the onset of surgically related complications.

Before a patient arrives on the nursing unit, prepare the bed and room for his or her return if he or she is returning to the same nursing unit. The nurse is better prepared to care for the patient after surgery if the room is readied before the patient's return. A postoperative bedside unit includes the following:

1. Sphygmomanometer and/or automated noninvasive blood pressure monitor, stethoscope, and thermometer
2. Emesis basin
3. Incentive spirometer
4. Clean gown, washcloth, towel, and facial tissues
5. IV pole and infusion pump (if needed)
6. Suction equipment (if needed)
7. Oxygen equipment and oximetry monitor (if needed)
8. Extra pillows for positioning the patient comfortably
9. Bed pads to protect bed linen from drainage
10. Bed raised to stretcher height with bed linens pulled back and furniture moved to accommodate the stretcher and equipment (such as IV lines)

When a patient arrives on the acute care unit, monitor vital signs according to institution policy. Generally, you check vital signs every 15

minutes twice, every 30 minutes twice, hourly for 2 hours, and then every 4 hours or per orders. As the patient's condition stabilizes, the nurses usually assess the patient at least once a shift until discharge. Always base the frequency of assessment on a patient's current condition. *Do not assume that further monitoring is unnecessary if the patient appears normal during the initial assessment.* A patient's condition can change rapidly, especially during the postoperative period.

Thoroughly document the initial nursing assessment findings. Enter patient data into the medical record on flow sheets, surgical assessment drop-down menus, or written progress notes. The initial findings provide a baseline for comparing postoperative changes.

Through the Patient's Eyes

When a patient initially returns to the acute care nursing unit, the family and patient have expectations of receiving prompt and attentive care. There is also the expectation that you will explain the patient's immediate status and the plan of care for the next few hours. Seeing the patient return from surgery is a relief in many ways, but if the patient has had complications or is not responding well, anxiety easily returns. As a patient stabilizes, it is important to assess the patient's and family's expectations for recovery and convalescence once he or she returns home. Be sure to review their expectations for management of pain and other symptoms. What do they expect from staff during the hospitalization? What are their expectations after the patient is discharged from the hospital? Who is the primary family caregiver and is he or she prepared to assume care at discharge? Make the patient and family partners in your assessment so that you can gather information necessary to develop a relevant plan of care. For example, ask the patient's caregivers to share their work schedules (if applicable) to determine whether the patient will have someone to provide transportation for follow-up appointments and outpatient rehabilitation (if prescribed), prepare meals, and assist with medication administration (if necessary).

Airway and Respiration

The priority in the care of a patient during phase III recovery is to maintain a patent airway. Assess airway patency, respiratory rate, rhythm, depth of ventilation, symmetry of chest wall movement, breath sounds, and color of mucous membranes and compare findings with data from the PACU. Be aware that certain anesthetic agents can still cause respiratory

depression during this phase. A patient may present with snoring, little or no air movement on auscultation of the lungs, retraction of intercostal muscles, and decreased oxygen saturation. Be alert for shallow, slow breathing and a weak cough. If breathing is unusually shallow, place your hand near the patient's nose or mouth to feel exhaled air. Normal pulse oximetry values range between 92% and 100% saturation. Postoperative confusion is frequently secondary to hypoxia, especially in older adults. When a patient is responsive, assess his or her initial ability to use an incentive spirometer and note the volume achieved.

Circulation

The patient is at risk for cardiovascular complications resulting from actual or potential blood loss from the surgical site, side effects of anesthesia, electrolyte imbalances, and depression of normal circulatory-regulating mechanisms and ischemia. Careful assessment of heart rate and rhythm, along with blood pressure, reveals a patient's cardiovascular status. Compare vital signs from preoperative condition and phase I recovery with postoperative values during phase III. If a patient's blood pressure drops progressively with each check or if the heart rate changes or becomes irregular, notify the health care provider. An ECG rhythm strip of the heart is obtained after surgery, compared with preoperative ECG tracings, and placed in the medical record.

Assess circulatory perfusion by noting capillary refill, pulses, and the color and temperature of the nail beds and skin. If a patient had vascular surgery or has casts or constricting devices that may impair circulation, assess peripheral pulses and capillary refill distal to the site of surgery. For example, after surgery to the femoral artery, assess posterior tibial and dorsalis pedis pulses. In addition, compare pulses in the affected extremity with those in the unaffected extremity.

A common early circulatory problem is bleeding or hemorrhage. Blood loss may occur internally or externally through a drain or incision. Either type of hemorrhage results in a fall in blood pressure; elevated heart and respiratory rates; thready pulse; cool, clammy, pale skin; and restlessness. Notify the surgeon if these changes occur. Maintain IV fluid infusion. Monitor the patient's vital signs every 15 minutes or more frequently until the patient's condition stabilizes. Continue oxygen therapy. The surgeon may consider medications or volume replacement and order blood counts and coagulation studies.

Temperature Control

The OR and recovery room environments are extremely cool. A patient's anesthetically depressed level of body function results in a lowering of metabolism and fall in body temperature. When patients begin to awaken more fully, they complain of feeling cold and uncomfortable. Older adults and pediatric patients are at higher risk for developing problems associated with postoperative hypothermia (temperature less than 36° C [96.8° F]). Also, closely assess the body temperature of other at-risk patients, including those of female gender, patients with burns, patients who received general anesthesia, patients who are cachexic or had low temperatures intraoperatively, and those whose surgery involved the use of cold irrigants ([Rothrock, 2019](#)).

In rare instances a genetic disorder known as **malignant hyperthermia** (MH), a life-threatening complication of anesthesia, develops. It is a hypermetabolic state occurring within skeletal muscle cells that become triggered by anesthesia. It results in an increase in intracellular calcium ion concentration. It is a potentially lethal condition that can occur in patients receiving various inhaled anesthetic agents and succinylcholine. The hyperthermic condition results in high carbon dioxide levels, metabolic and respiratory acidosis, increased oxygen consumption, production of heat, activation of the sympathetic nervous system, high serum potassium levels, and multiple organ dysfunction and failure. Early signs of malignant hyperthermia include tachypnea, tachycardia, heart arrhythmias, hyperkalemia, hypercarbia, and muscular rigidity. Later signs include elevated temperature, myoglobinuria, and multiple organ failure ([AANA, 2018](#)). In nearly all cases, the first signs and symptoms of MH occur in the operating room during induction of anesthesia; however, MH may also occur in the early postoperative period or after repeated exposures to anesthesia ([Rosenberg et al., 2013](#); [Sinha et al., 2017](#)). Without prompt detection and treatment, it is potentially fatal.

Monitor temperature closely in the acute care area. Because an elevated temperature may be the first indication of an infection, assess the patient for a potential source of infection, including the IV site (if present), the surgical incision/wound, and the respiratory and urinary tracts. Notify the health care provider because further evaluation is often necessary.

Fluid and Electrolyte Balance

Because of the risk for fluid and electrolyte abnormalities after surgery, assess a patient's hydration status and monitor for signs of electrolyte alterations (see [Chapter 42](#)). Monitor and compare laboratory values with the patient's baseline. Maintain the patency of IV infusions. The patient's

only source of fluid intake immediately after surgery is through IV catheters until the gag reflex and bowel sounds resume. Inspect the patient's catheter insertion site to ensure that the catheter is properly positioned within a vein, fluid flows freely, and the site is free of phlebitis or infiltration. Accurate recording of I&O assesses renal and circulatory function. Measure all sources of output, including urine, drainage from surgically placed drains, and gastric and wound drainage; note any insensible loss from diaphoresis. Assess daily weight for the first several days after surgery and compare with the preoperative weight. If the patient has a known cardiac history such as heart failure, continue daily weights. It is important to use a consistent scale, amount of clothing, and time of day to obtain accurate weight measurement.

Neurological Functions

After leaving the PACU a patient will still be drowsy. As anesthetic agents begin to metabolize, his or her reflexes return, muscle strength is regained, and a normal level of orientation returns. Monitor neurological status routinely by assessing whether the patient is oriented to self and the hospital and responds to questions appropriately. Assess pupil and gag reflexes, hand grips, and movement of extremities (see [Chapter 30](#)). If a patient had surgery involving part of the neurological system, conduct a more thorough neurological assessment. For example, if the patient had low-back surgery, assess leg movement, sensation, and strength.

Patients with regional anesthesia experience a return in motor function before tactile sensation returns. Typically, patients will have remained in the PACU until sensation and voluntary movement of the lower extremities return. Check the patient's sensation to touch (see [Chapter 30](#)). Knowing where regional anesthesia was introduced helps you check the distribution of the spinal nerves affected. Typically assess sensation by touching the patient bilaterally in the same area (e.g., lower arm on both sides or leg on both sides) and note where the patient feels touch. Test the sense of touch by using hand pressure or a gentle pinch of the skin. Extremity strength assessment continues to be important if a patient had spinal or epidural anesthesia.

Skin Integrity and Condition of the Wound

During recovery and acute postoperative care, assess the condition of the skin, noting pressure areas, rashes, petechiae, abrasions, or burns. A rash often indicates a drug sensitivity or allergy. Abrasions or petechiae

sometimes result from a clotting disorder or inappropriate positioning or restraining that injures skin layers. Burns may indicate that an electrical cautery grounding pad was placed incorrectly on the patient's skin. Document burns or serious injury to the skin on an occurrence or adverse-event report according to agency policy (see [Chapter 23](#)). Note if the patient is complaining of any burning or pain in the eye, which could indicate a corneal abrasion.

After surgery, a patient may have only butterfly tape, skin staples, or even glue to close small wounds (see [Chapter 48](#)). Look at the incision carefully and notice any drainage or swelling. Most surgical wounds that are larger have dressings that protect the wound site and collect drainage. Observe the amount, color, odor, and consistency of drainage on dressings. It is most common to see serosanguineous drainage immediately after surgery. Estimate the amount of drainage by noting the number of saturated gauze sponges. If drainage appears on the outer surface of a dressing, another way of assessing it is to mark the outer perimeter of the drainage with tape or to mark and date it with the time noted. This way the nurse can easily note whether drainage is increasing (see [Chapter 48](#)). However, this is not the most accurate measure of volume of fluid lost. Reinforce the dressing as needed and call the surgeon if wound drainage is leaking through the dressing.

Many surgeons prefer to change surgical dressings the first time so that they can inspect the incisional area. This applies to both outpatients and inpatients. You have the opportunity on the acute care nursing unit to view and thoroughly assess and document the status of the incision/wound at the time of this initial dressing change. Assess whether wound edges are approximated and whether bleeding or drainage is present. It is also important to assess the patient's mobility level. If he or she is unable or unwilling to turn because of pain from the incisional area, pressure injury development is a concern. Institute the use of the Braden Scale or another assessment tool to determine a patient's risk of developing pressure injuries.

Metabolism

Research over the past decade shows that postoperative hyperglycemia (blood glucose greater than 180 mg/dL) is associated with surgical wound infection and longer hospital stays in surgical patients. Maintaining normoglycemia or a glucose level less than 150 mg/dL and reducing blood glucose variability are recommended as an evidence-based practice for safe and effective patient management ([Sudhakaran and Surani, 2015](#)).

Nurses need to monitor blood glucose levels routinely based on surgeon order or hospital policy.

Genitourinary Function

Depending on the surgery, some patients do not regain voluntary control over urinary function for 6 to 8 hours after anesthesia. An epidural or spinal anesthetic often prevents a patient from feeling bladder fullness. Palpate the lower abdomen just above the symphysis pubis for bladder distention. Another option is to use a bladder scan or ultrasound to assess bladder volume. If the patient has a urinary catheter, there should be a continuous flow of urine of approximately 30 to 50 mL/hr in adults (see agency policy). Observe the color and odor of urine. Surgery involving parts of the urinary tract normally causes bloody urine for at least 12 to 24 hours, depending on the type of surgery. A urine output of less than 0.5 mL/kg/hr is reported to the surgeon or health care provider (Lewis et al., 2017).

Gastrointestinal Function

General anesthetics slow GI motility and often cause nausea. In addition, manipulation of the intestines during abdominal surgery further impairs peristalsis. Faint or absent bowel sounds are typical immediately after surgery. Normally patients who undergo abdominal or pelvic surgery have decreased peristalsis for at least 24 hours or longer (Rothrock, 2019). **Paralytic ileus** (i.e., loss of function of the intestine), which causes abdominal distention, is always possible after surgery. Auscultate bowel sounds in all four quadrants, noting faint or absent bowel sounds. Inspect the abdomen for distention caused by accumulation of gas. Ask whether a patient is passing flatus, an important sign indicating return of normal bowel function. The return of flatus is usually more indicative of normal bowel function return than the return of bowel sounds (Rothrock, 2019). If a nasogastric (NG) tube is in place for decompression, assess the patency of the tube and the color and amount of drainage (see Chapter 47).

Mobility

Postoperative mobility is necessary to promote respiratory, circulatory, and gastrointestinal function. Immobility may result in deconditioning and increase the patient's risk for hospital-acquired conditions (e.g., pressure injuries) and falls (Pashikanti and Von Ah, 2012). Current research concludes that the use of an early mobilization protocol improves

outcomes for patients recovering from major surgery (Rupich et al., 2018). Assess the patient's range of motion, ability to move in the bed and sit on the side of the bed, gait, and balance. As a result of current research indicating improved outcomes in surgical patients, many hospitals have implemented early ambulation protocols to prevent hospital-acquired conditions. Thus, early ambulation protocols have become common practice on many surgical floors.

Comfort and Sleep

As patients awaken from general anesthesia, the sensation of pain becomes prominent. They perceive pain before regaining full consciousness. Acute incisional pain causes them to become restless and is often responsible for temporary changes in vital signs. It is difficult for patients to begin coughing and deep-breathing exercises when they experience incisional pain. The patient who had regional or local anesthesia usually does not experience pain initially because the incisional area is still anesthetized. Ongoing assessment of the patient's discomfort and the evaluation of pain-relief therapies (pharmacological and nonpharmacological) are essential throughout the postoperative course (Box 50.9). Use a pain scale for assessing postoperative pain, evaluating the response to analgesics, and objectively documenting pain severity (see Chapter 44). Using preoperative pain assessments as a baseline, evaluate the effectiveness of interventions throughout the patient's recovery.

Box 50.9 Evidence-Based Practice Prevention of Acute Pain in the Postsurgical Patient

PICOT Question: In postoperative patients, how effective is preoperative education/pain management planning, compared to traditional/as-needed pain management approaches in controlling postoperative pain?

Evidence Summary

Evidence suggests postoperative pain is managed inadequately in more than 80% of patients in the United States. However, the type of surgery performed, analgesics/anesthetic interventions prescribed, and time elapsed after surgery influence postoperative pain (Gan, 2017).

Correlation exists between poorly controlled acute postoperative pain and increased morbidity, functional and quality-of-life impairment, delayed recovery time, prolonged duration of opioid use, and higher health care

costs (Gan, 2017). The presence and intensity of acute pain during the intraoperative and postoperative periods are predictive of the development of chronic pain. More effective analgesic/anesthetic measures in the perioperative period are needed to prevent the progression to persistent pain (Gan, 2017). Studies suggest local anesthetics and nonopioid analgesics are beneficial as preventive interventions (Gan, 2017).

The American Pain Society, the American Society of Anesthesiologists, and the American Society for Regional Anesthesia have endorsed pain management recommendations that are based on the principal that optimal management starts in the preoperative period with assessment of the patient and development of a patient-centered plan (Chou et al., 2016). Of the 32 recommendations, four of the recommendations impact nursing practice (Chou et al., 2016). The panel recommends:

- Individualized patient-centered and family-centered/caregiver plans reflecting and documenting the goals for postoperative management.
- Patient assessments in the preoperative phase for medical and psychiatric co-morbidities, medications, history of chronic pain, substance abuse, and previous postoperative treatment regimens and responses.
- The use of a validated pain assessment tool to track responses to postoperative pain treatments and adjust treatment plans accordingly.
- Multimodal analgesia, or the use of a variety of analgesic medications and techniques combined with nonpharmacological interventions, for the treatment of postoperative pain in children and adults.
- The use of cognitive behavioral modalities in adults as part of a multimodal approach.

Application to Nursing Practice

- Use patient-centered educational programs for patients and their families preoperatively. Educational modalities within the preoperative program could range from single episodes of face-to-face instruction to the provision of written materials, videos, audiotapes, or Web-based educational information for more intensive

multicomponent preoperative interventions, including individualized and supervised exercise, education, and telephone calls.

- Conduct a comprehensive history and physical examination to develop an individually customized pain management plan through teamwork and collaboration with other members of the interprofessional team. The pain management plan is based on factors unique to the patient, such as the type of surgery or surgical site, the patient's previous experiences with surgery and postoperative treatment, medication allergies and intolerances, cognitive status, co-morbidities, preferences for treatment, and treatment goals.
- Pain assessment includes quantifying the intensity of pain. Pain assessments determine which interventions have been effective for the patient's pain, how the pain affects the patient's function, the type of pain (e.g., neuropathic, visceral, somatic, muscle spasms), and barriers to effective pain management, such as cultural or language differences, cognitive deficits, or patient misconceptions about pain management.
- A variety of analgesic medications and techniques that target different mechanisms of action may be combined with nonpharmacological interventions to offer more effective pain relief compared with single-modality interventions.
- Cognitive behavioral modalities are effective as adjunctive treatments in postoperative patients. These include guided imagery (i.e., relaxation), hypnosis, and music.

Postoperatively, it is common for patients to experience sleep disturbances, often resulting from preoperative co-morbidity, type of anesthesia, severity of surgical trauma, postoperative pain, and environmental stress ([Su and Wang, 2017](#)). Some studies have shown that postoperative patients who experience sleep disorders are at higher risk for experiencing delirium, pain sensitivity, cardiovascular issues, and delayed recovery. In addition, noise that occurs in the hospital prevents patients from sleeping ([DuBose and Hadi, 2016](#)). Implement nonpharmacological and pharmacological measures (as prescribed) to promote a patient's postoperative sleep.

• Nursing Diagnosis

Determine the status of preoperative nursing diagnoses by clustering new postoperative assessment data. Then either revise or resolve preoperative diagnoses and identify relevant new diagnoses after surgery. A previously defined diagnosis such as *Risk for Impaired Skin Integrity* may continue as a postoperative problem, particularly if your assessment reveals continued risks such as reduced mobility or excess diaphoresis. It is common to identify new nursing diagnoses after surgery because of the risks or problems associated with it. Also consider the assessed needs of a patient's family when you identify nursing diagnoses. In the formulation of nursing diagnoses, be accurate in identifying a related factor (when appropriate). For example, *Impaired Mobility related to reduced lower-extremity strength* compared with *Impaired Mobility related to exercise intolerance* requires different nursing interventions. Potential nursing diagnoses for the postoperative patient include the following:

- *Impaired Airway Clearance*
- *Risk for Infection*
- *Impaired Mobility*
- *Impaired Skin Integrity*
- *Acute Pain*

• Planning

During the recovery phase, use current physical assessment data and analysis of the preoperative nursing history to plan the patient's care. The surgeon's postoperative orders and surgical team's report of the patient's operative condition also provide valuable data. In many institutions, early recovery after surgery (ERAS) protocols are being used, incorporating standard postoperative orders. Typical postoperative orders include:

- Frequency of vital signs monitoring and special assessments.
- Types of IV fluids and rates of infusion.
- Postoperative medications (especially those for pain and nausea).
- Resumption of preoperative medications as condition allows (some oral medications are converted to the IV route with appropriate dose adjustment).
- Fluids and food allowed by mouth.
- Level of activity that the patient can resume, including progressive mobility protocols.

- Measures to prevent deep vein thrombosis (e.g., sequential compression devices).
- Position that the patient is to maintain while in bed.
- I&O and daily weights.
- Laboratory tests and x-ray film studies.
- Special directions (e.g., surgical drains to suction, tube irrigations, dressing changes).

Goals and Outcomes

Review nursing diagnoses when establishing goals, expected outcomes, and interventions for your patient. Measurable outcomes provide specific guidelines for determining a patient's progress toward recovery from surgery. For example, a patient recovering from knee replacement surgery with the diagnosis of *Impaired Mobility related to pain and lower-extremity weakness* has specific outcomes that include targeted ambulation (e.g., steps to take and distance down hallway), pain relief, and improved range of joint movement. After meeting each outcome, a patient ultimately achieves the goal of independent ambulation at a preoperative level or better. At times, goals and outcomes extend from the recovery period into the home setting. The nurse considers all goals of care established during the preoperative surgical phase that are still relevant. For example, a goal for the diagnosis of *Risk for Infection* would be "Patient will remain free of infection after surgery." Expected outcomes for this goal include:

- Patient's incision remains closed and intact.
- Patient's incision remains free of infectious drainage.
- Patient remains afebrile.

Setting Priorities

During the convalescent phase of recovery from general anesthesia, priorities for the first 24 hours include maintenance of respiratory, circulatory, and neurological status; wound management; pain control; and early mobility. Most surgeons are aggressive in increasing a patient's activity as soon as possible. If a patient is to be placed on an early mobility protocol, patients and families need to understand that the patient is not being rushed unnecessarily but that early mobility prevents hospital deconditioning. As a patient progresses, focus priorities on the advancement of patient activity (e.g., mobility, diet tolerance) to return the patient to preoperative functioning or better. A patient generally has

multiple nursing diagnoses (Fig. 50.6). Reestablish priorities as the status of the patient’s health problems change.

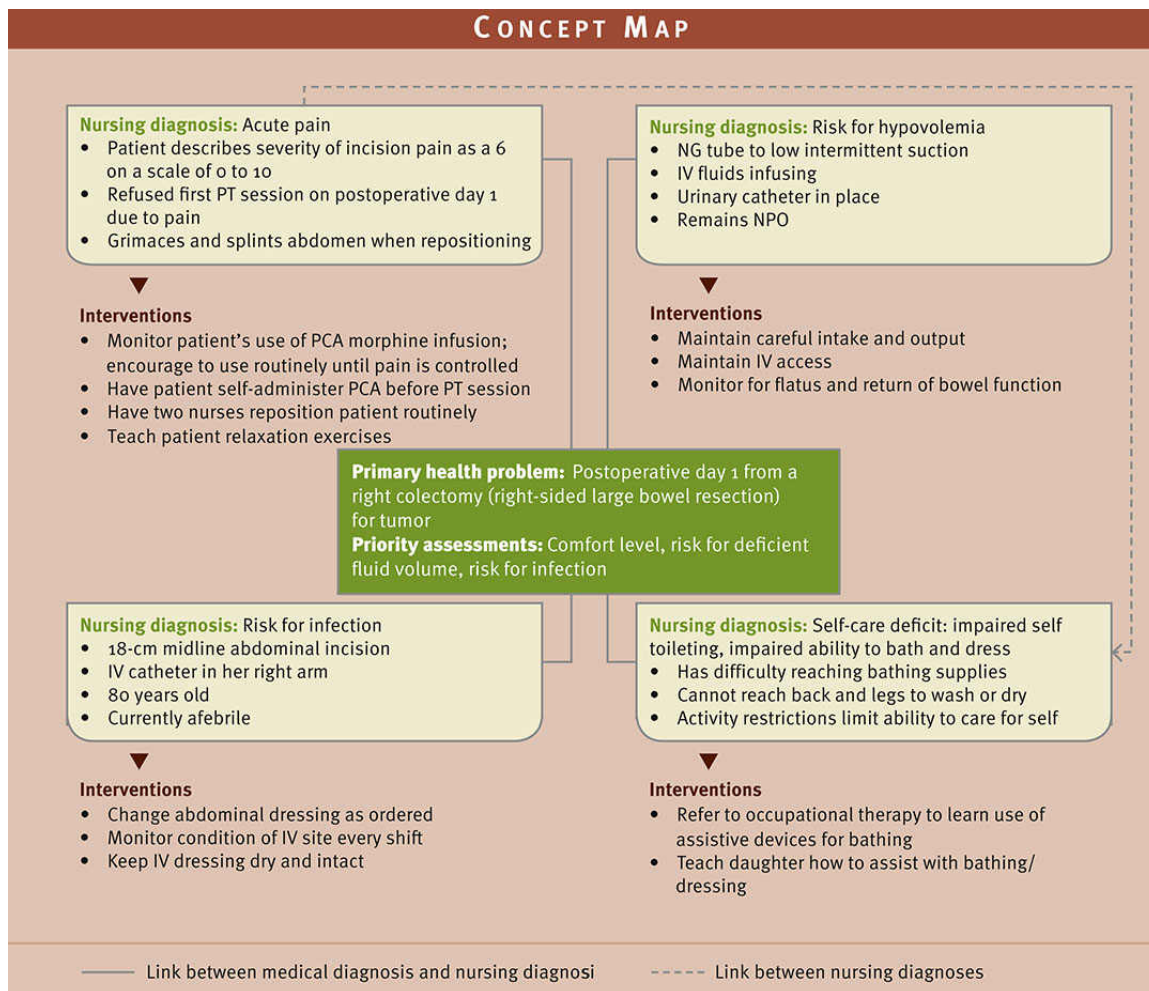

FIG. 50.6 Concept map for Mr. Cooper. IV, Intravenous; NG, nasogastric; PCA, patient-controlled analgesia; PT, physical therapy.

Teamwork and Collaboration

During Phase III recovery collaborate on the plan of care with respiratory therapy, physical therapy, occupational therapy, dietary, social work, home care, and others. Include family caregivers as much as possible, especially if they will be assuming care responsibilities in the home. The goal of an interprofessional approach to care is to help the patient return to the best possible level of functioning with a smooth transition to home, rehabilitation, or long-term care. Acute care settings often have a nurse or

social worker in a case-manager role to coordinate interprofessional care so that the most appropriate resources are available to patients.

Implementation

Acute Care

Primary causes for postoperative complications include impaired healing of the surgical wound, the effects of prolonged immobilization during surgery and recovery, and the influence of anesthesia and analgesics. If a patient has surgical risks before surgery, the likelihood of complications is greater (Box 50.10). Your aim is to direct postoperative nursing interventions at preventing complications so that the patient returns to the highest level of functioning possible. Failure of a patient to become actively involved in recovery adds to the risk of complications (Table 50.8). Virtually any body system can be affected. Consider the interrelationship of all systems and therapies provided.

Box 50.10 Focus on Older Adults **Care of the Older Adult After Surgery**

- Decreased cardiac reserve decreases cardiac output during physiological stress, which may result in a delay in recovery from tachycardia and the inability to tolerate fluid depletion (AORN, 2015).
- Preexisting medical conditions combined with reduction in physiological reserve are predictors for poor postoperative outcomes in older adults.
- During the perioperative period, assess for changes that occur as a result of infection, hemorrhage, alterations in blood pressure, and fluid/electrolyte abnormalities. Ongoing, focused assessments are necessary.
- Older patients are at greater risk for postoperative delirium associated with an acute onset. Reduced level of consciousness, reduced ability to maintain attention, perceptual disturbances, and memory impairment characterize the typical presentation (Meiner and Yeager, 2019; AORN, 2015).
- Implement individualized measures to help the older adult achieve rest, sleep, and orientation in the postoperative period to reduce the

risk of delirium development.

- Altered and unexpected drug responses are often related to different pharmacokinetics in the older adult. The possibility of high risk for adverse medication events with the administration of anesthetic agents and postoperative analgesics, especially narcotics, is likely (AORN, 2015). “Start low and go slow” is the guiding principle when medicating older adults because of their slow drug-clearance capability.

TABLE 50.8**Postoperative Complications**

Complication	Cause
Respiratory System	
Atelectasis: Collapse of alveoli with retained mucus secretions. Signs and symptoms include elevated respiratory rate, dyspnea, fever, crackles auscultated over involved lobes of lungs, and productive cough.	Inadequate lung expansion. Anesthesia, analgesia, and immobilized position prevent full lung expansion. There is greater risk in patients with upper abdominal surgery who have pain during inspiration and repress deep breathing.
Pneumonia: Inflammation of alveoli involving one or several lobes of lung. Development in lower dependent lobes of lung is common in patient who is immobilized after surgery. Signs and symptoms include fever, chills, productive cough, chest pain, purulent mucus, and dyspnea.	Poor lung expansion with retained secretions or aspirated secretions. Common resident bacterium in respiratory tract is <i>Diplococcus pneumoniae</i> , which causes most cases of pneumonia.
Hypoxemia: Inadequate concentration of oxygen in arterial blood. Signs and symptoms include restlessness, confusion, dyspnea, hypertension or hypotension, tachycardia or bradycardia, diaphoresis, and cyanosis.	Anesthetics and analgesics depress respirations. Increased retention of mucus with impaired ventilation occurs because of pain or poor positioning. Patients with obstructive sleep apnea are at increased risk for hypoxemia.
Pulmonary embolism: Embolus blocking pulmonary arterial blood flow to one or more lobes of lung. Signs and symptoms include dyspnea, sudden chest pain, cyanosis, tachycardia, and drop in blood pressure.	Same factors lead to formation of thrombus or embolus. Patients with preexisting circulatory or coagulation disorders and who are immobile are at risk.
Circulatory System	
Hemorrhage: Loss of large amount of blood externally or internally in short period of time. Signs and symptoms include hypotension, weak and rapid pulse, cool and clammy skin, rapid breathing, restlessness, and reduced urine output.	Slipping of suture or dislodged clot at incisional site. Patients with coagulation disorders are at greater risk.
Hypovolemic shock: Inadequate perfusion of tissues and cells from loss of circulatory fluid volume. Signs and symptoms are same as for hemorrhage.	Hemorrhage usually causes hypovolemic shock after surgery.
Thrombophlebitis: Inflammation of vein often accompanied by clot formation. Veins in legs are most commonly affected. Signs and symptoms include swelling and inflammation of involved site and aching or cramping pain. Vein feels hard, cordlike, and sensitive to touch.	Prolonged sitting or immobilization aggravates venous stasis. Trauma to vessel wall and hypercoagulability of blood increase risk of vessel inflammation.
Thrombus: Formation of clot attached to interior wall of a vein or artery, which can occlude the vessel lumen. Symptoms include localized tenderness along distribution of the venous system, swollen calf or thigh, calf swelling > 3 cm (1.2 inches) compared to asymptomatic leg, pitting edema in symptomatic leg, and decrease in pulse below location of thrombus (if arterial).	Venous stasis (see discussion of thrombophlebitis) and vessel trauma. Venous injury is common after surgery of hips and legs, abdomen, pelvis, and major vessels. Patients with pelvic and abdominal cancer or traumatic injuries to the pelvis or lower extremities are at high risk for thrombus formation.
Embolus: Piece of thrombus that has dislodged and circulates in bloodstream until it lodges in another vessel (commonly lungs, heart, brain, or mesentery).	Thrombi form from increased coagulability of blood (e.g., polycythemia and use of birth-control pills containing estrogen).
Musculoskeletal System	
Hospital-associated deconditioning (HAD): Deficits in physical function secondary to immobilization during an acute hospitalization are collectively defined as hospital-associated deconditioning (HAD).	Older adults are particularly vulnerable. During an acute hospitalization, older adults spend approximately 83% of their hospital stay in bed and only 12% of their time in a chair. Prolonged immobility is associated with declines in muscle strength and muscle mass and with reduced cognitive function, muscle protein synthesis, and physical function (Falvey et al., 2015).
Gastrointestinal System	
Paralytic ileus: Nonmechanical obstruction of the bowel caused by physiological, neurogenic, or chemical imbalance associated with decreased peristalsis. Common in initial hours after abdominal surgery.	Handling of intestines during surgery leads to loss of peristalsis for a few hours to several days.
Abdominal distention: Retention of air within intestines and abdominal cavity during gastrointestinal surgery. Signs and symptoms include increased abdominal girth, patient complaints of fullness, and "gas pains."	Slowed peristalsis from anesthesia, bowel manipulation, or immobilization. During laparoscopic surgeries influx of air for procedure causes distention and pain up to shoulders.
Nausea and vomiting: Symptoms of improper gastric emptying or chemical stimulation of vomiting center. Patient complains of gagging or feeling full or sick to stomach.	Abdominal distention, fear, severe pain, medications, eating or drinking before peristalsis returns, and initiation of gag reflex.
Genitourinary System	
Urinary retention: Involuntary accumulation of urine in bladder as result of loss of muscle tone. Signs and symptoms include inability to void, restlessness, and bladder distention. It appears 6-8 hours after surgery.	Effects of anesthesia and narcotic analgesics. Local manipulation of tissues surrounding bladder and edema interfere with bladder tone. Poor positioning of patient impairs voiding reflexes.
Urinary tract infection: Infection of the urinary tract as a result of bacterial or yeast contamination. Signs and symptoms include dysuria, itching, abdominal pain, possible fever, cloudy urine, presence of white blood cells, and leukocyte esterase positive on urinalysis.	Most frequently a result of catheterization of the bladder.
Integumentary System	
Wound infection: Invasion of deep or superficial wound tissues by pathogenic microorganisms; signs and symptoms include warm, red, and tender skin around incision; fever and chills; purulent material exiting from drains or from separated wound edges. Infection usually appears 3-6 days after surgery.	Infection is caused by poor aseptic technique or contaminated wound or surgical site before surgical exploration. For example, with a bowel perforation patient is at increased risk for a wound infection because of bacterial contamination from the large intestine.
Complication	
Wound dehiscence: Separation of wound edges at suture line. Signs and symptoms include increased drainage and appearance of underlying tissues. This usually occurs 6-8 days after surgery.	Malnutrition, obesity, preoperative radiation to surgical site, old age, poor circulation to tissues, and unusual strain on suture line from coughing or positioning.

Wound evisceration: Protrusion of internal organs and tissues through incision. Incidence usually occurs 6-8 days after surgery.	See discussion of wound dehiscence. Patient with dehiscence is at risk for developing evisceration.
Skin breakdown: Result of pressure or shearing forces. Patients are at increased risk if alterations in nutrition and circulation are present, resulting in edema and delayed healing.	Prolonged periods on the operating room (OR) table and in the bed after surgery lead to pressure breakdown. Skin breakdown results from shearing during positioning on the OR table and improperly pulling patient up in bed.
Nervous System	
Intractable pain: Pain that is not amenable to analgesics and pain-alleviating interventions.	Intractable pain may be related to the wound or dressing, anxiety, or positioning.
Malignant hyperthermia: Severe hypermetabolic state and rigidity of the skeletal muscles caused by an increase in intracellular calcium ion concentration.	Rare genetic condition triggered with exposure to inhaled anesthetic agents and the depolarizing muscle relaxant succinylcholine.

Hospitals have instituted purposeful hourly rounds to improve nurse responsiveness and patient satisfaction. Purposeful rounds include the *4 Ps* (i.e., *pain, potty, positioning, and periphery*). Nursing staff ask patients about their pain and if they need to toilet, the patients are positioned for comfort, and an environmental check is done of the periphery to ensure that possessions such as a phone and call light are in reach (Mitchell et al., 2014). However, some patient care providers have expanded the *4 Ps* model to *7 Ps*, adding *plan, personal needs, and presence* to the care model. The three additional activities in the *7 Ps* model include the patient’s daily priorities and personal needs and the nurse’s accessibility to the patient. The implementation of purposeful rounding improves patient safety by decreasing the occurrence of patient preventable events and proactively addresses problems before they occur (Daniels, 2016).

Maintaining Respiratory Function

To prevent respiratory complications, begin pulmonary interventions early. The benefits of thorough preoperative teaching are reached when patients can participate actively in postoperative exercises. When patients awoken from anesthesia, help them maintain a patent airway. Position the patient on one side with the face downward and the neck slightly extended to facilitate a forward movement of the tongue and the flow of mucus secretions out of the mouth. A small folded towel supports the head. Another positioning technique to promote a patent airway involves elevating the head of the bed slightly and extending the patient’s neck slightly, with the head turned to the side. In the PACU, the nurse may need to perform a jaw-thrust maneuver and/or chin lift continuously to maintain the patient’s airway. Never position a patient with arms over or across the chest because this reduces maximum chest expansion.

Place patients with known OSA or at risk for OSA in the lateral, prone, or upright position, never the supine position, throughout the perioperative period (Olson et al., 2018). Suction artificial airways and the oral cavity for secretions of mucus (see Chapter 41). Avoid continually

eliciting the gag reflex, which might cause vomiting. The following interventions promote expansion of the lungs:

- Encourage diaphragmatic breathing exercises every hour while patients are awake.
- Administer CPAP or NIPPV to patients who use this modality at home (Olson et al., 2018).
- Instruct patients to use an incentive spirometer for maximum inspiration. The patient should try to reach the inspiratory target volume achieved before surgery on the spirometer.
- Encourage early ambulation. Walking causes patients to assume a position that does not restrict chest wall expansion and stimulates an increased respiratory rate. Ambulation increases peristalsis.
- Help patients who are restricted to bed to turn on their side every 1 to 2 hours while awake and to sit on the side of the bed when possible.
- Keep the patient comfortable. A patient who is comfortable can participate in deep breathing and coughing. Administer analgesics on time so that pain does not become severe.

The following measures promote removal of pulmonary secretions if they are present:

- Encourage coughing exercises every 1 to 2 hours while patients are awake, and maintain pain control to promote a deep, productive cough. *For patients who have had eye, intracranial, or spinal surgery, coughing may be contraindicated because of the potential increase in intraocular or intracranial pressure.*
- Provide oral hygiene to facilitate expectoration of mucus. The oral mucosa becomes dry when patients are NPO or placed on limited fluid intake.
- Initiate orotracheal or nasotracheal suction for patients who are too weak or unable to cough (see [Chapter 41](#)).
- Administer oxygen as ordered and monitor oxygen saturation with a pulse oximeter. Continue to monitor oxygen saturation for patients at risk for respiratory compromise from OSA (Olson et al., 2018). Administer oxygen to patients at risk for or diagnosed with OSA until they can maintain their baseline oxygen saturation while breathing room air.

Preventing Circulatory Complications

Some patients are at greater risk of venous stasis because of the nature of their surgery or medical history. The following interventions promote normal venous return and circulatory blood flow:

- Provide pain medications as prescribed and nonpharmacological therapies to ensure that patients ambulate early. Early ambulation promotes venous return and circulatory blood flow.
- Encourage patients to perform leg exercises at least every hour while awake. Exercise may be contraindicated in an extremity with a vascular repair or realignment of fractured bones and torn cartilage.
- Apply graded compression stockings or IPC devices as ordered by the health care provider. Remove the stockings or device at least once per shift. Perform a thorough reassessment of the skin of the lower extremities at this time.
- Encourage early ambulation. Most patients ambulate after surgery, depending on the severity of surgery and their conditions. Early ambulation protocols require patients to ambulate sometimes within 2 to 3 hours of having surgery ([Resnick et al., 2016](#)). The degree of activity allowed progresses as the patient's condition improves. Encourage ambulation even if a patient has an epidural catheter or PCA device.
- Before ambulation, assess the patient's vital signs at rest. Abnormalities such as hypotension or certain arrhythmias may contraindicate ambulation. If vital signs are at baseline, first help the patient sit on the side of the bed. A patient's complaint of dizziness is a sign of postural hypotension. A recheck of blood pressure determines whether ambulation is safe. Assist with ambulation by standing on the patient's strong side and making sure that he or she is able to walk steadily. Patients may be able to walk only a few feet the first few times out of bed. This usually improves each time. Assess a patient's tolerance to activity by periodically assessing how he or she responds to exercise. Using the baseline resting heart rate, compare it with the heart rate as the patient ambulates. Also note the heart rhythm. You can assess exercise tolerance by knowing the patient's maximum heart rate and then consider an appropriate target rate. One simple method to calculate a predicted maximum heart rate is by using this formula ([AHA, 2015](#)):

$$200 - \text{Patient's age} = \text{Predicted maximum heart rate}$$

The predicted maximum heart rate should then be multiplied by 50% to 85%, depending on the patient's condition and progress with exercise, to obtain a target rate.

Example: A 70-year-old patient has an average resting heart rate of 84 beats/min. The patient's predicted maximum heart rate equals:

$$220 - 70 = 150 \text{ beats/min}$$

The patient's **target heart rate** will range from 50% to 85% of the maximum heart rate, or in this example:

$$75 \text{ to } 128 \text{ beats/min}$$

By comparing resting rate with the patient's actual rate during exercise, you can determine whether it is in a safe target range. Remember that a patient's acute surgical condition may not allow him or her to reach a target rate. *Confer with the patient's surgeon or physical therapist about a safe heart rate target.* Always ask patients how they feel during exercise and whether they note chest pain or shortness of breath.

- Avoid positioning patients in a manner that interrupts blood flow to extremities. Do not place pillows or rolled blankets under a patient's knees while in bed. Compression of the popliteal vessels can cause thrombi. When patients sit in chairs, elevate their legs on footstools. Never allow a patient to sit with one leg crossed over the other.
- Administer anticoagulant drugs as ordered. Patients at greatest risk for thrombus formation often receive prophylactic doses of

anticoagulants such as LMWH (e.g., enoxaparin) or low-dose unfractionated heparin (LDUH) for anticoagulation.

- Promote adequate fluid intake orally or intravenously (IV). Adequate hydration prevents concentrated accumulation of formed blood elements such as platelets and red blood cells. When the plasma volume is low, these elements gather and form small clots within blood vessels.

Promoting Early Mobility

Many surgical postoperative protocols now include early mobility guidelines, which are designed to minimize or prevent hospital-acquired deconditioning (HAD) (see [Chapter 39](#)). Using early mobility protocols is associated with improved outcomes such as reduced deep vein thrombosis, reduced length of stay in patients with community-acquired pneumonia, and maintained or improved functional status from admission to discharge in the elderly and patients who undergo major surgery ([Pashikanti and Von Ah, 2012](#)). Explain to patients and family members how quickly patients will begin activities such as range-of-motion exercises, sitting on the side of the bed, and assisted ambulation, and the projected distance for walking independently. Activities will typically begin within 12 hours of a patient's return to the inpatient nursing unit. Also assure patients that appropriate mobility aids will be used and that assistance by nursing staff will ensure their safety ([Pashikanti and Von Ah, 2012](#)). There are patients who will not be able to initiate early mobility until their conditions have stabilized. Explain that it is normal for a patient to progress gradually in activity. If a patient tolerates activity, activity levels progress more quickly.

Achieving Rest and Comfort

Pain control is a priority to facilitate a patient's recovery. Without pain control, a patient will not move or ambulate as readily or as early or initiate coughing exercises after surgery. The anesthesia provider orders medications for pain management in the PACU. IV opioid analgesics such as morphine sulfate are the drugs of choice immediately postoperative. Advances have been made in the use of multimodal analgesia (more than one analgesic), which combines different drug classes delivered through various routes, including use of local anesthetics alone or in combination with other nerve blocks or therapies such as PCA. The goal is to enhance

the efficacy of pain control while minimizing the side effects of each modality (Tan et al., 2015).

A patient's pain increases after surgery as the effects of anesthesia diminish. The patient becomes more aware of the surroundings and more perceptive of discomfort. The incisional area is only one source of pain. Irritation from drainage tubes, tight dressings, or casts and the muscular strains caused from positioning on the OR table also cause discomfort.

After assessing that a patient is in discomfort, check to be sure whether the ordered dose of analgesic is within the recommended range. Patients have the most surgical pain in the first 24 to 48 hours after surgery. IV PCA or epidural analgesia may be ordered. A PCA device delivers analgesic medications by IV or subcutaneous infusion. The PCA system allows patients to administer their own IV analgesics from a specially prepared pump (see Chapter 44). If patients gain a sense of control over their pain, they usually have fewer postoperative problems. Many patients receive regional analgesia, such as epidural analgesia, continuously throughout the recovery period, especially for thoracic and abdominal surgery. Studies show that continuous epidural analgesia provides superior pain relief in terms of less analgesic use, better postoperative pain relief (especially in the first 24 hours), less sedation, and faster return of GI function (Cummings et al., 2018; Hwang et al., 2018). Epidural techniques are especially useful in patients with OSA who are at increased risk of airway compromise and postoperative complications with the use of systemic opioids after surgery. Nonsteroidal antiinflammatory agents are an alternative to systemic opioids in patients with OSA (ASA, 2014). Monitor patients closely for side effects and educate them and family caregivers regarding the pain-management therapy and expected response.

As the patient begins to tolerate oral fluids, surgical protocols usually include changing pain medication from IV or epidural to oral administration. Do not overlook the importance of nonpharmacological interventions (see Chapter 44). Assess which care routines contribute to pain and use nonpharmacological measures to address this pain. An example is to lower the head of the bed and use a pillow for incisional splinting while turning a patient with recent abdominal surgery. Other methods to promote pain relief include positioning, back rubs, distraction, or imagery. Remember, *do not assume that a patient's pain is incisional*. When a patient without PCA or an epidural analgesic asks for pain medication, obtain orders to provide analgesics as often as allowed around-the-clock (ATC) in the first 24 to 48 hours after surgery to improve pain control. If

pain medications are not relieving discomfort, notify the health care provider for additional orders. Nurses need to recognize potential complications of analgesics and know what to do if they occur.

Temperature Regulation

Unless intraoperative warming is used, patients are usually still cool when arriving in the surgical unit. Provide warmed blankets or heated air blankets if no other warming device is available. Increasing a patient's body temperature raises metabolism and improves circulatory and respiratory function.

Sometimes shivering is a side effect of certain anesthetic agents instead of hypothermia. Clonidine in small increments can decrease shivering as prescribed by the health care provider. When this happens, encourage your patient to use deep breathing and coughing to help to expel retained anesthetic gases.

If a patient develops signs or symptoms of malignant hyperthermia, recognize this as a potential emergency. Be prepared to administer dantrolene sodium as ordered by the health care provider ([Malignant Hyperthermia Association of the United States, 2018](#)). The medication is administered to prevent muscle stiffness and spasms caused by the rapid rise in body temperature and severe muscle contractions that accompany malignant hyperthermia.

Patients are at risk for infection after surgery for various reasons. If a patient becomes febrile, be aggressive in providing routine postoperative nursing interventions. For example, deep breathing and coughing, early ambulation, prompt removal of indwelling urinary catheter (if appropriate), and aseptic care of the surgical wound decrease the risk of postoperative infections. If a patient no longer requires intravenous fluids, prompt removal of IV catheters also reduces infection rates. Since microorganisms require time to incubate, infections are rare within the first 48 hours after surgery. If the health care provider suspects an infection, he or she orders wound and or blood cultures.

Maintaining Neurological Function

Deep breathing and coughing expel retained anesthetic gases and facilitate a patient's return to consciousness. Continue monitoring the patient's level of consciousness and responsiveness to questions. When patients are elderly, know the status of their renal function because delayed renal clearance of operatively administered anesthetic agents slows awakening. As a patient regains consciousness, orientation to the environment is

important in maintaining the patient's mental status. Reorient the patient, explain that surgery is completed, and describe procedures and nursing measures.

Maintaining Fluid and Electrolyte Balance

Immediately after surgery, patients receive fluids only IV. It is important to maintain patency of IV infusions postoperatively (see [Chapter 42](#)). The nurse typically removes an IV catheter once a patient awakens after ambulatory surgery and can tolerate water without GI upset. A more seriously ill patient on a surgical unit requires IV fluids for a longer period to achieve hydration and electrolyte balance and sometimes to receive antibiotics. Some patients require blood products after surgery, depending on the amount of blood loss during surgery. A surgeon orders a prescribed solution and rate for each IV infusion. As a patient begins to take and tolerate oral fluids, the nurse decreases the IV rate as ordered by the surgeon. When patients no longer need a continuous IV infusion, the nurse will most likely saline lock the IV line (as ordered by the surgeon) to preserve the site for the administration of medications such as antibiotics or other types of intravenous therapy (see [Chapter 42](#)). In order to continuously monitor fluid status, measure contents of urinary catheter, NG tube, or wound drainage collection devices every 8 hours for output recording. Measure and empty wound drainage devices more often if drainage is excessive.

Promoting Normal Gastrointestinal Function and Adequate Nutrition

A patient likely begins to take ice chips or sips of fluids when arriving on an acute surgical care unit. If fluids are tolerated, the diet progresses with clear liquids next. Interventions for preventing GI complications promote the return of normal elimination and faster return of normal nutritional intake. It takes several days for a patient who has had GI surgery (e.g., a colon resection) to resume a normal diet. Normal peristalsis often does not return for 2 to 3 days. In contrast, the patient whose GI tract is unaffected directly by surgery can resume dietary intake after recovering from the effects of anesthesia. The following measures promote the return of normal elimination:

- Advance a patient's dietary intake gradually. Most surgeons rely on the return of flatus or bowel sounds to order a normal diet. Use

patient assessment data to determine how quickly to advance the patient's diet. For example, provide clear liquids such as water, apple juice, broth, or tea after nausea subsides. Ingesting large amounts of fluids leads to distention and vomiting. If a patient tolerates liquids without nausea, advance the diet as ordered. Patients who had abdominal surgery are usually NPO the first 24 to 48 hours. As flatus and peristalsis return, provide clear liquids, followed by full liquids, a light diet of solid foods, and finally a patient's usual diet. Encourage intake of foods high in protein and vitamin C.

- Promote ambulation and exercise. Physical activity stimulates a return of peristalsis. A patient who has abdominal distention and "gas pain" may obtain relief when walking.
- Maintain an adequate fluid intake. Fluids keep fecal material soft for easy passage. Fruit juices and warm liquids are especially effective.
- Promote adequate food intake by stimulating a patient's appetite; remove sources of noxious odors and provide small servings of nonspicy foods.
- Avoid moving a patient suddenly to minimize nausea.
- Help the patient get into a comfortable position during mealtime. If possible, have him or her sit to minimize pressure on the abdomen.
- Provide frequent oral hygiene. Adequate hydration and cleaning of the oral cavity eliminate dryness and bad tastes.
- Administer fiber supplements, stool softeners, and rectal suppositories as ordered. If constipation or distention develops, the health care provider orders cathartics or enemas to stimulate peristalsis.
- Provide meals when the patient is rested and free from pain. Often a patient loses interest in eating if mealtime follows exhausting activities such as ambulation, coughing and deep-breathing exercises, or extensive dressing changes. When a patient has pain, the associated nausea often causes a loss of appetite.

Promoting Urinary Elimination

The depressant effects of anesthetics and analgesics impair the sensation of bladder fullness. A full bladder is painful and causes a patient awakening from surgery to be restless or agitated. Patients who have abdominal surgery or surgery of the urinary system often have indwelling catheters

inserted until voluntary urination returns. Patients without a catheter need to void within 8 to 12 hours after surgery; otherwise it is sometimes necessary to insert a straight catheter. If a patient has an indwelling urinary catheter, the goal is to remove it as soon as possible because of the high risk for the development of a catheter-associated urinary tract infection (CAUTI). The [Centers for Disease Control and Prevention \(2016\)](#) recommend that in operative patients who have an indication for an indwelling catheter the catheter should be removed as soon as possible postoperatively, preferably within 24 hours, unless there are appropriate indications for continued use. The following measures promote normal urinary elimination (see [Chapter 46](#)):

- Help patients assume their normal position to void if possible.
- Check a patient frequently for the need to void when a catheter is not in place. The feeling of bladder fullness is often sudden, and you need to respond promptly when a patient calls for assistance.
- Assess for bladder distention. If a patient does not void within 8 to 12 hours of surgery or if bladder distention is present, you will insert a straight urinary catheter if you have an order from a health care provider. Continued difficulty in voiding sometimes requires an indwelling catheter, which increases the risk for a UTI. Although the evidence is inconclusive, some agencies use bladder ultrasound to assess bladder volume and assist in the decision to place a urinary catheter.
- Monitor I&O. If a patient has an indwelling catheter, expect an output of about 30 to 50 mL/hr. Another way to gauge adequacy of output is by determining a patient's weight. An accepted level of urinary output is at least 0.5 mL/kg/hr to 1 mL/kg/hr for adults ([MDCalc, 2018](#); [Lewis et al., 2017](#)). If the urine is dark, concentrated, and low in volume, notify a health care provider. Patients easily become dehydrated as a result of fluid loss from surgical wounds and inadequate fluid intake. Measure I&O for several days after surgery until a patient achieves normal fluid intake and urinary output.

Skin and Wound Care

Wound healing is complicated by impaired circulation, inadequate nutrition and metabolic alterations (see [Chapter 48](#)). All of these factors can affect rate of healing and risk for infection. A wound also undergoes

considerable physical stress on the suture line and wound bed. Strain on sutures from coughing, vomiting, distention, and movement of body parts can disrupt wound layers. Protecting a wound promotes healing. A critical time for wound healing is 24 to 72 hours after surgery, after which a seal is established. If infection of a clean surgical wound occurs, you will usually find symptoms of infection 4 to 5 days after surgery. Monitor surgical patients on an ongoing basis for fever, tenderness at a wound site, and presence of local drainage on dressings (i.e., yellow, green or brown, and odorous). A clean surgical wound usually does not regain strength against normal stress for 15 to 20 days after surgery.

Surgical dressings (if present) remain in place the first 24 hours after surgery to reduce the risk of infection. During this time, add an extra layer of gauze on top of the original dressing if drainage develops. After that, use aseptic technique during dressing changes and wound care (see [Chapter 48](#)). Time any dressing change to begin 5 to 30 minutes after giving a patient pain medication (depending on route—5 minutes IV, 30 minutes oral). Keep surgical drains patent so that accumulated secretions can escape from the wound bed.

Maintaining/Enhancing Self-Concept

The appearance of wounds, bulky dressings, drains, and tubes threatens a patient's self-concept. The effects of surgery, such as disfiguring scars, often create permanent changes in a patient's body image. If surgery leads to impairment in body function, a patient's role within the family can change significantly. Observe patients for behaviors reflecting alterations in self-concept (see [Chapter 33](#)). Some patients show revulsion toward their appearance by refusing to look at incisions, carefully covering dressings with bedclothes, or refusing to get out of bed because of tubes and devices. The fear of being unable to return to a functional family role causes some patients to avoid participation in the plan of care.

A family often plays an important role in efforts to improve a patient's self-concept. Explain the patient's appearance to the family and ways to avoid nonverbal expressions of revulsion or surprise. Encourage the family to accept the patient's needs and support his or her independence. The following measures help to maintain a patient's self-concept:

- Provide privacy during dressing changes or inspection of the wound. Keep room curtains closed around the bed and drape the patient to expose only the dressing or incisional area.

- Maintain the patient's hygiene. Wound drainage and antiseptic solutions from the surgical skin preparation dry on the surface of the skin, causing foul odor and skin irritation. A complete bath the first day after surgery renews the patient. Offer a clean gown and washcloth. Keep the patient's hair neatly combed and offer frequent oral hygiene every 2 hours while awake, especially if the patient is NPO.
- Prevent drainage devices from overflowing.
- Maintain a pleasant environment. Being in pleasant, comfortable surroundings heightens self-concept. Store or remove unused supplies. Keep the patient's bedside orderly and clean.
- Offer opportunities for the patient to discuss feelings about appearance. A patient who avoids looking at an incision possibly needs to discuss fears or concerns. A patient having surgery for the first time is often more anxious than one who has had multiple surgeries. When a patient looks at an incision for the first time, make sure that the area is clean. Eventually he or she will be able to care for the incision site by applying simple dressings or bathing the affected area.
- Provide the family with opportunities to discuss ways to promote the patient's self-concept. Encouraging independence is sometimes difficult for a family member who has a strong desire to help the patient in any way. Family members are more able to be supportive during dressing changes when they know about the appearance of a wound or incision. Help family members know when it is appropriate to discuss future plans. This allows the patient and family to discuss realistic plans for a patient's return home.

Restorative and Continuing Care

In the postoperative period, the nurse, patient, and family collaborate to prepare the patient for discharge. Patients often must continue wound care, follow activity or diet restrictions, continue medication therapy, and observe for signs and symptoms of complications at home. Education for the preparation of patients to assume self-care is an ongoing process throughout hospitalization. It is important to provide specific, culturally appropriate, and accurate verbal and written discharge instructions to enhance the ability of patients to care for themselves at home (Marcus, 2014). Make education relevant. For example, if a patient has a limitation on what he or she can lift, understand the type of lifting normally done by

the patient (e.g., picking up a small child or pet). Help patients anticipate how to apply restrictions at home.

Boston University School of Medicine developed a model for the hospital discharge process ([National Academies of Science, 2014](#)). The model involved development of 11 components for discharge instructions that formed a checklist, which has been adopted by the National Quality Forum. The 11 components include:

1. Make appointments for follow-up care.
2. Plan for the follow-up of results from pending tests.
3. Organize postdischarge services and equipment.
4. Identify the correct medications and plan for patient to obtain those medications.
5. Reconcile the discharge plan with national guidelines.
6. Teach a written discharge plan the patient can understand.
7. Educate the patient about diagnoses and medications.
8. Assess the degree of the patient's understanding of the plan.
9. Expedite transmission of the discharge summary to the primary care physician.
10. Provide telephone reinforcement.
11. Review appropriate steps for what to do if a problem arises.

Provide a wide variety of written educational materials for all patients after surgery. For example, offer materials with more pictures and illustrations for patients who do not speak English or have limited reading ability. Ensure that all materials are sensitive to various cultures and religions. Patients receive a copy of signed discharge instructions, and one copy remains in the medical or electronic record.

Surgical recovery is slowed if patients are deconditioned and then fail to exercise regularly. It is important to keep frail older adults active after surgery by offering assistive devices and referral to rehabilitation ([AORN, 2015](#)). A person is considered frail if he or she has three of the following: unintentional weight loss, low physical activity, slowed motor performance, weakness, and fatigue or exercise intolerance. Aerobic exercise and physical resistance training sometimes improve patients' gait speed and ability to perform ADLs ([Van Abbema et al., 2015](#)). Collaborate with physical and occupational therapists in finding strategies to help patients adhere to recommended exercise and active ADL programs. Involve family caregivers in the patient's exercise program.

Some patients need home care assistance after discharge. For example, nurses make referrals to home care for skilled nursing requirements when patients need ongoing wound care, IV therapy, or drain management. In addition, patients who are more physically dependent often require assistance from assistive personnel to provide bathing and hygiene needs. The case coordinator or social worker at the hospital helps with discharge coordination. Encourage patients to show their discharge instructions to home care providers.

Other patients, especially older adults, sometimes require discharge to a rehabilitation or skilled nursing center after their hospital recovery. During their recovery, patients work to gain mobility and recovery of their independent living skills. In addition, nurses provide wound care and other specialized services. A case coordinator or social worker works with the patient, family, and nurse to coordinate transfer to the skilled nursing center.

Evaluation

Through the Patient's Eyes

Consult with a patient and family to gather evaluation data and remember that evaluation is ongoing. Ask specific questions that evaluate patient expectations and perceptions during your hourly rounds. For example, you ask, "Is your pain being managed well?" "How well are you sleeping?" and "Is there anything I can do for you at this time?" Evaluate your patient's level of comfort and ensure that the patient understands all aspects of nursing care. Resolve any concerns or issues and answer the patient's and family caregiver's questions before discharge.

Patient Outcomes

Evaluate the effectiveness of care based on the patient-centered expected outcomes established after surgery for each nursing diagnosis. If a patient fails to progress as expected, revise his or her care plan based on evaluation findings and the patient's needs.

Make sure to evaluate for pain relief using a pain scale. Determine the efficacy of both pharmacological and nonpharmacological measures. Use appropriate evaluative measures; inspect the condition of a wound, monitor usage of the incentive spirometer, measure the distance or number of times that a patient can ambulate, and monitor the amount of fluid and food intake.

Part of an evaluation is to determine the extent to which the patient and family caregiver learn self-care measures. Use the teach-back method of patient education by having the patient restate information that you taught in his or her own words (Bastable, 2019). If a patient must perform any skill at home such as a dressing change or exercise, evaluate through return demonstration (see Chapter 25).

Many agencies call patients at home 24 hours after discharge to help evaluate patient outcomes. This allows for monitoring the progress of a patient's recovery and for identifying the development of complications. This also allows the nurse to evaluate and reinforce a patient's understanding of restrictions, wound care, medications, and necessary follow-up.

Safety Guidelines for Nursing Skills

Ensuring patient safety is an essential role of the professional nurse. To ensure patient safety, communicate clearly with the members of the health care team, assess and incorporate the patient's priorities of care and preferences, and use the best evidence when making decisions about the patient's care. When performing the skill in this chapter, remember the following points to ensure safe, individualized patient-centered care:

- Coughing and deep breathing are sometimes contraindicated after brain, spinal, head, neck, or eye surgery (prevents intracranial and intraocular pressure increases).
- Patients who are severely obese sometimes have more improved lung function and vital capacity in the reverse Trendelenburg or side-lying position.
- Report any signs of VTE such as pain, tenderness, redness, warmth, or swelling in the upper or lower extremities to the medical team immediately.

Skill 50.1. Teaching and Demonstrating Postoperative Exercises

Delegation and Collaboration

The skills of preoperative teaching cannot be delegated to assistive personnel (AP). AP can reinforce and help patients perform postoperative

exercises. The nurse instructs the AP about:

- Any precautions or safety issues unique to the patient (e.g., fall risks, mobility limitations, bleeding precautions).
- Informing the nurse of any identified concerns (e.g., inability to perform exercise).

Equipment

- Pillow
- Incentive spirometer
- Preoperative education flow sheet
- Positive expiratory pressure (PEP) device
- Stethoscope

Step	Rationale
Assessment	
1. Identify patient using at least two identifiers (e.g., name and birthday or name and medical record number) according to agency policy.	Ensures correct patient. Complies with The Joint Commission standards and improves patient safety (TJC, 2020).
2. Identify patient's cognitive level, language, and culture. If patient does not speak English or is deaf, have a professional interpreter available to assist you.	These factors may alter patient's ability to understand meaning of surgery and can affect postoperative healing if full understanding is not present.
3. Assess patient's/family caregiver's knowledge, experience, and health literacy.	Ensures patient/family caregiver has the capacity to obtain, communicate, process, and understand basic health information (CDC, 2019).
4. Ask about previous experience with surgery and anesthesia; have patient clarify whether any undesirable outcomes occurred.	Information helps to prevent recurrent problems, particularly if the patient had problems with understanding instructions or plan of care.
5. Assess patient's understanding of the intended surgery and anesthesia. Ask patient to offer a description rather than asking a simple yes or no question (e.g., "Tell me what your surgery will involve"). Ask about patient's and family caregiver's expectations of surgery and care. Include questions concerning time frame for surgery and recovery, fears, cultural practices, and religious or spiritual beliefs.	Patients may have misconceptions and incomplete knowledge. Asking about fears, cultural practices, and religious or spiritual beliefs allows you to anticipate priorities of care and adapt teaching and support accordingly.
6. Assess patient's risk factors for postoperative respiratory complications (nursing history and ability to breathe deeply, cough). Check nursing history for patient's height and age.	General anesthesia predisposes patient to respiratory problems (Mills, 2018). Presence of underlying respiratory conditions or patient's inability to perform postoperative respiratory exercises increases the risk for pulmonary complications. Height and age are used to set incentive spirometer parameters.
7. Assess patient's anxiety related to surgery by noting responses and observing nonverbal behavior.	Directs you to provide additional emotional support, which may be needed to facilitate the patient's readiness to learn.
8. Assess family caregiver's ability and willingness to learn and support patient following surgery.	Family caregiver's presence after surgery is an important factor in patient recovery. Caregiver can coach patient through postoperative exercise, help with medication administration, and observe for postoperative complications.
9. Assess patient's medical record for type of surgery and approach.	The surgical procedure itself may require patients to limit activities postoperatively. Anticipating any limitations that might affect how patient can perform postoperative exercises allows you to adapt your instruction preoperatively.
Planning	
1. Perform hand hygiene. Prepare equipment and room for instructions and demonstrations.	Reduces transmission of microorganisms. A well-equipped room provides a conducive environment to learning.
2. Provide patient privacy	Maintaining privacy promotes patient dignity and respect.
3. Position the patient in a semi-Fowler's position or upright on the side of the bed as tolerated.	Appropriate positioning allows for increased participation in postoperative exercises and optimal comfort.
4. Plan teaching session for when the patient is not in pain.	Pain distracts patients from focusing on learning. Decreased pain promotes patient participation in the postoperative exercises.
5. Prepare health literacy-appropriate teaching materials. Provide instruction when family caregiver is present (if appropriate).	Promotes patient understanding of instructions. Family caregiver can be important resource for patient's recovery postoperatively.
Implementation	
1. Inform patient and family caregiver of date, time, and location of surgery; anticipated length of surgery; additional time in postanesthesia recovery area; and where to wait.	Accurate information helps reduce stress of uncertainty associated with surgery.
2. Encourage and answer questions patient and family caregiver ask.	Responding to patient and family caregiver questions helps to decrease anxiety and demonstrates your concern for them.
3. Instruct patient about preoperative bowel or skin preparations as needed in the home. Check medical orders and agency policies regarding number of preoperative showers and agent to be used for each shower (2% chlorhexidine gluconate is used most often). Following each preoperative shower, instruct patient to rinse the skin thoroughly and dry with a fresh clean, dry towel. Patient should don clean clothing.	Proper skin preparation is critical in preventing surgical site infections (SSIs). Rinsing skin removes residual antiseptic preparation that may cause skin irritation. After use, towels contain microorganisms that can grow in presence of moisture. Using fresh towel after each shower and donning clean clothing minimizes risk of reintroducing microorganisms to clean skin (AORN, 2018a; Berrios-Torres et al., 2017).
4. Instruct patient about extent and purpose of food and fluid restrictions for period specified by health care provider before surgery. For example, clear liquids may be ingested up to 2 hours before procedures requiring general anesthesia, regional anesthesia, or procedural sedation and analgesia. A light meal may be ingested for up to 6 hours before elective procedures requiring general anesthesia, regional anesthesia, or procedural sedation. (ASA, 2017).	During general anesthesia muscles relax, and gastric contents can reflux into esophagus, leading to aspiration. Anesthetic eliminates patient's ability to gag.
5. Describe perioperative routines (e.g., time-out procedure, operative site marking, insertion of IV catheter and therapy, urinary catheterization, hair clipping or removal, laboratory tests, transport to operating room [OR]).	Allows patient to anticipate and recognize routine procedures, reducing anxiety. Empowers patient with information about what the staff does to keep patient safe for operative process.
6. Describe planned effect of preoperative medications.	Provides information about what to expect, decreasing anxiety.
Step	
7. Review which routine medications patient needs to discontinue at home before surgery.	Some medications are discontinued before surgery to minimize effects that can cause surgical risks. For example, anticoagulants may increase bleeding and are usually discontinued several days before surgery. Insulin dosages are usually adjusted because of reduced intake of food before

	surgery.
8. Describe perioperative sensations and sounds to expect in holding area or OR (e.g., blood pressure cuff tightening, electrocardiogram [ECG] leads, cool room, and beep of monitors).	Misconceptions and concerns about perioperative sensations and sounds have been ranked high among preoperative patients for causing anxiety.
9. Describe pain-control methods to be used after surgery. Discuss what pain is acceptable; explain that patient will not be pain-free but that pain will be managed. Explain use of PCA (when appropriate).	Patients are fearful of postoperative pain. Explaining pain-management techniques reduces fear. This helps you understand what degree of pain the patient feels is acceptable, and allows you to educate the patient that although he or she will not be pain-free, the pain will be managed.
10. Describe what patient will experience after surgery (e.g., where patient will be upon awakening; that frequent vital signs will be taken; presence of dressing, catheters, drains, tubes; alternating pressure from sequential compression device; postoperative exercises; and the activity level to be expected).	Provides objective description of what patient can expect after surgery so that patient is prepared.
11. Explain any early mobility protocol; purpose and normal progression from sitting on side of bed to ambulation. Demonstrate how to sit on side of bed. Clarify that protocol starts early during recovery.	Full patient participation is essential for early ambulation to be successful.
12. Perform hand hygiene.	Reduces transmission of microorganisms.
13. Teach turning:	
a. Instruct patient on turning and sitting up (especially suited for abdominal and thoracic surgery):	Promotes circulation and ventilation.
(1) Have patient turn onto right side, assume supine position, and move to side of bed (in this case left side) if permitted by surgery. Instruct patient to move by bending knee and pressing heels against mattress to raise and move buttocks (see illustration). Top side rails on both sides of bed should be in upright position.	Positioning begins on side of bed so that turning to other side does not cause patient to roll toward edge of bed. Buttocks lift prevents shearing force against sheets. If patient's bed has a turn-assist feature, use it to help position him or her.
(2) Have patient splint incision with right hand or with right hand with pillow over incisional area; keep right leg straight and flex left knee up (see illustration); grab right side rail with left hand, pull toward right, and roll onto right side. Reverse process to turn to left side.	Supports incision and decreases discomfort while turning.
(3) Instruct patient to turn every 2 hours from side to side while awake. Often patient requires assistance with turning after surgery.	Reduces risk of vascular, pulmonary, and pressure injury complications.
CLINICAL DECISION: Some patients, such as those who have had back surgery or vascular repair, are restricted from flexing their legs after surgery. Some patients are restricted from turning or may need help for positioning.	
(4) To sit up on right side of bed, elevate head of bed and have patient turn onto right side. While lying on right side, patient pushes on mattress with left arm and swings feet over edge of bed with nurse's help. To sit up on left side of bed, reverse this process. Assess if patient feels dizzy while sitting up. Return to bed if dizziness occurs (see Chapter 38).	Sitting position lowers diaphragm to permit fuller lung expansion. Screening for dizziness detects orthostatic hypotension.
CLINICAL DECISION: Caution patient to always use the nurse call system to ask for assistance when sitting on side of bed to reduce risk of a fall.	
14. Teach coughing and deep breathing:	Patient may hesitate to take deep breaths because of weakness or pain, resulting in secretions remaining in bases of lungs. Collection of secretions increases risk of pulmonary atelectasis and pneumonia. This is especially important for patients with a history of smoking, pneumonia, or chronic obstructive pulmonary disease (COPD) or patients who are confined to bed rest.
a. Assist patient to high-Fowler's position in bed with knees flexed, or have patient sit on side of bed or chair in upright position.	Sitting position facilitates diaphragmatic expansion.
b. Instruct patient to place palms of hands across from one another lightly along lower border of rib cage or upper abdomen (see illustration).	Allows patient to feel rise and fall of abdomen during deep breathing.
c. Have patient take slow, deep breaths, inhaling through nose. Explain that patient will feel normal downward movement of diaphragm during inspiration. Demonstrate as follows:	Helps to prevent hyperventilation or panting. Slow, deep breath allows for more complete lung expansion.
(1) Have patient avoid using chest and shoulder muscles while inhaling.	Increases unnecessary energy expenditure and does not promote full lung expansion.
(2) Have patient take slow, deep breath through the nose, hold for count of 3 seconds, and slowly exhale through mouth as if blowing out candle (pursed lips).	Resistance during exhalation helps to prevent alveolar collapse.
(3) Have patient repeat breathing exercise 3 to 5 times.	Repetition reinforces learning.

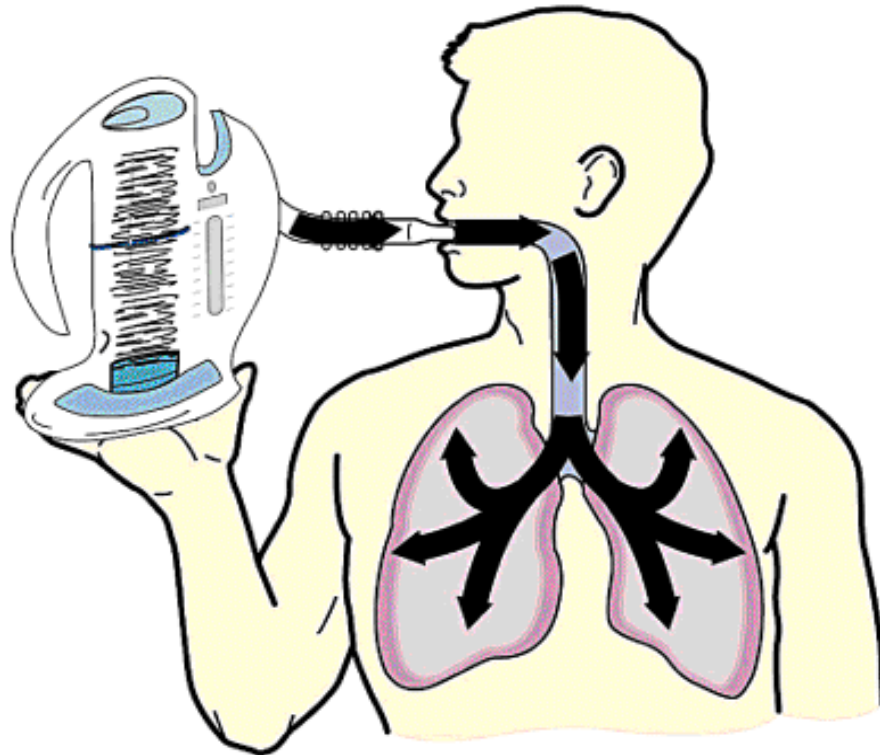

Step	Rationale
(4) Have patient take two slow, deep breaths, inhaling through nose and exhaling through pursed lips.	Deep breaths expand lungs fully to aid gas exchange and remove anesthetic agent so that patient regains consciousness (Lewis et al., 2017). Deep breaths also move air behind mucus to facilitate coughing.
(5) Have patient inhale deeply a third time and hold breath to count of 3. Cough fully for two to three consecutive coughs without inhaling between coughs.	Coughing prevents alveolar collapse and moves respiratory secretions to larger airways for expectoration (Lewis et al., 2017).
 <p data-bbox="354 537 737 562">STEP 12A(1) Buttocks 90° for moving to side of bed. From Lovelands D, Perry SE: Maternity and women's health care ed 9, St Louis, 2007, Mosby.</p>	 <p data-bbox="954 474 1263 512">STEP 12A(2) Leg position when turning to right. From Lovelands D, Perry SE: Maternity and women's health care, ed 9, St Louis, 2007, Mosby.</p>
 <p data-bbox="354 1092 1068 1108">STEP 14E Deep-breathing exercise—placement of hands on upper abdomen during inhalation. (Copyright © Mosby's Clinical Skills: Essentials Collection.)</p>	
d. Caution patient against just clearing throat without deep breathing.	Clearing throat does not remove mucus from deeper airways.
e. Have patient practice several times. Instruct patient to perform turning, coughing, and deep breathing every 1 to 2 hours while awake (Lewis et al., 2017). Have family caregiver coach patient to exercise.	Allows for full chest expansion and increased perfusion of both lungs (Lewis et al., 2017). Decreases risk of postoperative pneumonia developing.
15. Teach use of an incentive spirometer	Provides visual aid of respiratory effort. Encourages deep breathing to loosen secretions in lung bases.
a. Explain purpose of incentive spirometer and how it works. Position patient in sitting position in chair or in reclining position with head of bed elevated at least 45 degrees.	Promotes cooperation. Facilitates diaphragm lowering and lung expansion.
b. Set targeted tidal volume on the incentive spirometer according to manufacturer directions. Explain that this is the volume level to be reached with each breath.	Establishes goal of volume level necessary for adequate lung expansion. Manufacturers determine target on basis of patient height and age.
c. Explain how to place mouthpiece of incentive spirometer so that lips completely cover mouthpiece. Have patient demonstrate until position is correct (see illustration).	Validates patient's understanding of instructions and evaluates psychomotor skills.
d. Instruct patient to exhale completely; then position mouthpiece so that lips completely cover it, and inhale slowly, maintaining constant flow through unit until reaching targeted tidal volume (see illustration).	Promotes complete inflation of lungs and minimizes atelectasis. Aiming toward target volume offers visual feedback of respiratory effort.
e. Once maximum inspiration is reached, have patient hold breath for 2 to 3 seconds and exhale slowly. Compare what patient achieves to set target.	Promotes alveolar inflation. Establishes measure of normal maximum breath by patient. Used to determine outcome postoperatively.

Step

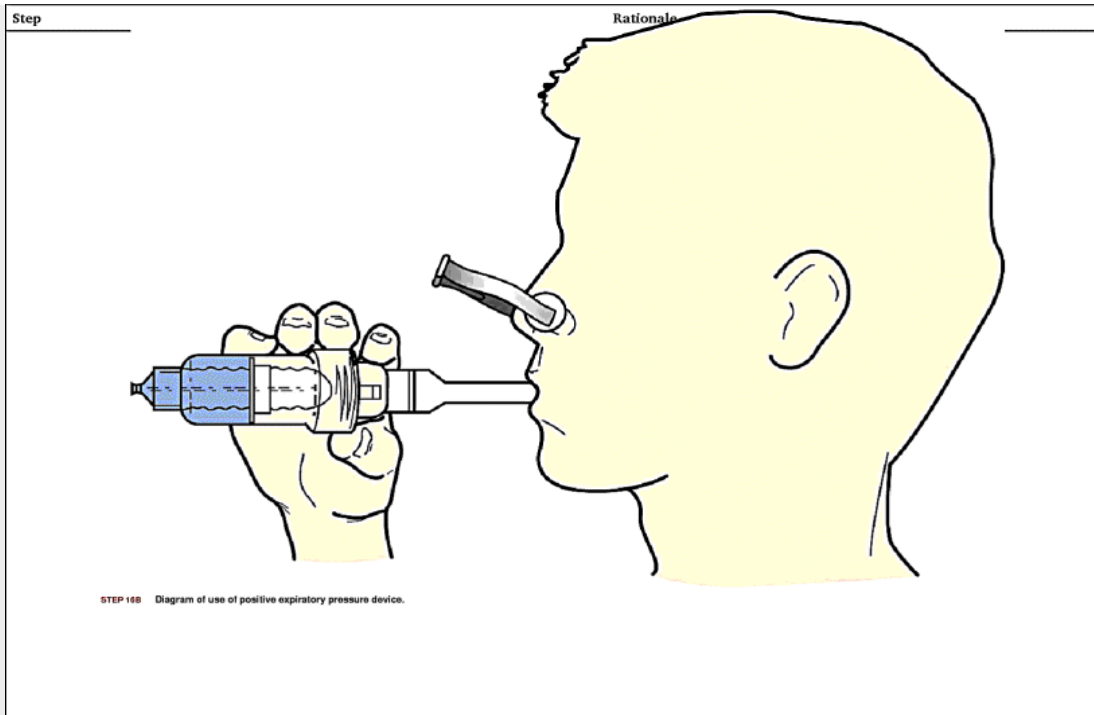

C 3E16 Rationale

STEP 100 Patient demonstrates incentive spirometry.

STEP 100 Diagram of use of incentive spirometer.

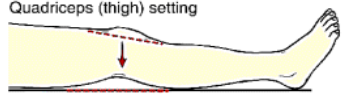

<p>f. Instruct patient to breathe normally for short period between each of the 10 breaths taken on incentive spirometer. Repeat every hour while awake.</p>	<p>Prevents hyperventilation and fatigue.</p>
<p>16. Teach positive expiratory pressure (PEP) therapy:</p>	
<p>a. Explain purpose of PEP device and how it works. Set PEP device for setting ordered.</p>	<p>Promotes cooperation. Higher settings require more effort.</p>
<p>b. Instruct patient to assume semi-Fowler's or high-Fowler's position in bed or to sit in a chair. Place nose clip on patient's nose (see illustration).</p>	<p>Promotes optimum lung expansion and expectoration of mucus.</p>
<p>c. Have patient place lips around mouthpiece. Instruct patient to take full breath and exhale 2 or 3 times longer than inhalation. Repeat pattern for 10 to 20 breaths.</p>	<p>Ensures that patient does all breathing through mouth. Ensures that patient uses device properly.</p>
<p>d. Remove device from mouth and have patient take slow, deep breath and hold for 3 seconds.</p>	<p>Promotes lung expansion before coughing.</p>
<p>e. Instruct patient to exhale with a deep cough. Repeat exercise every 2 hours while awake.</p>	<p>Coughing promotes bronchial hygiene by increasing expectoration of secretions.</p>
<p>17. Teach controlled coughing:</p>	
<p>a. Explain importance of maintaining upright position in bed or chair; have patient lean slightly forward.</p>	<p>Position facilitates diaphragm excursion and enhances thorax and abdominal expansion.</p>
<p>b. Demonstrate coughing. Fold arms across abdomen and take a slow, deep breath, inhaling through the nose</p>	<p>Expands lungs.</p>
<p>c. To exhale: lean forward, pressing your arms against your abdomen. Cough 2 or 3 times without inhaling between coughs. Cough through a slightly open mouth (see illustration). Coughs should be short and sharp (Cleveland Clinic, 2017).</p>	<p>Clearing throat does not remove mucus from deeper airways. Full, forceful cough is most effective in removing mucus.</p>
<p>d. Breathe in again by "sniffing" slowly and gently through the nose.</p>	<p>Prevents mucus from moving back down airways.</p>
<p>e. Caution patient against just clearing throat instead of coughing deeply. Have patient rest a few minutes and repeat exercise</p>	<p>Clearing throat does not remove mucus from deeper airways.</p>
<p>f. If surgical incision is thoracic or abdominal, teach patient to place either hands or pillow over incisional area and place hands over pillow to splint incision (see illustration). During breathing and coughing exercises, press gently against incisional area for splinting and support.</p>	<p>Surgical incision cuts through muscles, tissues, and nerve endings. Deep-breathing and coughing exercises place additional stress on suture line and cause discomfort. Splinting incision with hands or pillow provides firm support and reduces incisional pulling and pain.</p>
<p>g. Instruct patient to cough 2 to 3 times every 2 hours while awake and to continue to practice coughing exercises, splinting imaginary incision (see illustration).</p>	<p>Deep coughing with splinting effectively expectorates mucus with minimal discomfort.</p>

Step	Rationale
<p data-bbox="305 222 829 264">h. Instruct patient to examine sputum for consistency, odor, amount, and color changes and to notify a nurse if any changes are noted.</p>  <p data-bbox="360 579 711 594">STEP 170 Controlled coughing with placement of hands on upper abdomen.</p>	<p data-bbox="867 222 1344 264">Sputum consistency, odor, amount, and color changes may indicate presence of pulmonary complication such as pneumonia.</p>  <p data-bbox="954 520 1154 535">STEP 177 Technique for splinting incisions.</p>

<p data-bbox="289 892 448 907">18. Teach leg exercises:</p>	
<p data-bbox="266 924 1333 966">CLINICAL DECISION: Leg exercises are recommended for patients restricted to bed or during times when patients are ambulatory but resting in bed or in a chair. The ideal exercise to promote venous return and improve lung vital capacity is early mobility (see Chapter 38).</p>	
<p data-bbox="305 976 850 1039">a. Instruct patient to perform leg exercises every 1 to 2 hours while awake: ankle rotation, dorsiflexion and plantar flexion, leg extension and flexion, and straight leg raises.</p>	<p data-bbox="867 976 1352 1018">Leg exercises facilitate venous return from lower extremities and reduce risk of circulatory complications such as venous thromboembolism.</p>
<p data-bbox="305 1050 480 1064">b. Position patient supine.</p>	
<p data-bbox="305 1081 829 1123">c. Instruct patient to rotate each ankle in complete circle and draw imaginary circles with big toe 5 times (see illustration).</p>	<p data-bbox="867 1081 1016 1096">Promotes joint mobility.</p>
<p data-bbox="305 1134 850 1176">d. Alternate dorsiflexion and plantar flexion while instructing patient to feel calf muscles tighten and relax (see illustration). Repeat 5 times.</p>	<p data-bbox="867 1134 1352 1176">Helps maintain joint mobility and promote venous return to prevent thrombus formation.</p>
<p data-bbox="305 1186 850 1228">e. Perform quadriceps setting by tightening thigh and bringing knee down toward mattress and relaxing (see illustration). Repeat 5 times.</p>	<p data-bbox="867 1186 1352 1228">Quadriceps-setting exercises contract muscles of upper legs, maintain knee mobility, and improve venous return to heart.</p>
<p data-bbox="305 1239 850 1281">f. Instruct patient to alternate raising legs straight up from bed surface. Leg should be kept straight (see illustration). Repeat 5 times.</p>	<p data-bbox="867 1239 1352 1281">Causes quadriceps muscle contraction and relaxation, which help promote venous return.</p>
<p data-bbox="305 1291 829 1333">g. Explain to patient the expected progression of activity for early mobility and when it will begin.</p>	<p data-bbox="867 1291 1352 1333">Early mobility protocols usually advance from bedrest to sitting on side of bed to sitting in chair and progressive ambulation. (see Chapter 38).</p>

STEP 176 Patient splinting abdomen with pillow. (From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 8, St Louis, 2014, Mosby.)

Step	Rationale
<p>Foot circles</p>  <p>STEP 18C Foot circles. From Lewis S, et al: <i>Medical-surgical nursing: assessment and management of clinical problems</i>, ed 9, St Louis, 2014, Mosby.</p>	<p>Quadriceps (thigh) setting</p>  <p>STEP 18E Quadriceps (thigh) setting. From Lewis S, et al: <i>Medical-surgical nursing: assessment and management of clinical problems</i>, ed 9, St Louis, 2014, Mosby.</p>
<p>Alternate dorsiflexion and plantar flexion</p>  <p>STEP 18D Alternate dorsiflexion and plantar flexion. From Lewis S, et al: <i>Medical-surgical nursing: assessment and management of clinical problems</i>, ed 9, St Louis, 2014, Mosby.</p>	<p>Hip and knee movements</p>  <p>STEP 18F Hip and leg lift. From Lewis S, et al: <i>Medical-surgical nursing: assessment and management of clinical problems</i>, ed 9, St Louis, 2014, Mosby.</p>
<p>19. Have patient continue to practice exercises before surgery at least every 2 hours while awake. Teach patient to coordinate turning and leg exercises with diaphragmatic breathing and use of incentive spirometer.</p>	<p>Leg exercises stimulate circulation, which prevents venous stasis to help prevent formation of deep vein thrombosis (DVT). Coordinating exercises helps patient continuously work toward best outcomes for recovery.</p>
<p>20. Answer questions and verify patient's expectations of surgery. Coach expectations as needed.</p>	<p>Can reduce postoperative anxiety or anger.</p>
<p>21. Reinforce therapeutic coping strategies (e.g., meditation, calming conversation [Aust et al., 2016], listening to music).</p>	<p>Therapeutic coping strategies that self-distract patients reduce preoperative anxiety.</p>
<p>22. Help patient to a comfortable position.</p>	<p>Gives patient a sense of well-being.</p>
<p>23. Be sure nurse call system is in an accessible location within patient's reach.</p>	<p>Ensures patient can call for assistance if needed.</p>
<p>24. Raise side rails (as appropriate) and lower bed to lowest position.</p>	<p>Ensures patient safety.</p>
<p>25. After completion of preoperative teaching, appropriately dispose of supplies and equipment and perform hand hygiene.</p>	<p>Reduces transmission of microorganisms.</p>
<p>Evaluation</p>	
<p>1. If possible, observe patient demonstrating splinting, turning and sitting, deep breathing, use of incentive spirometer, PEP therapy, and leg exercises.</p>	<p>Validates patient's ability to correctly perform postoperative exercises and use devices.</p>
<p>2. Ask family member(s) to describe postoperative exercises patient is to perform.</p>	<p>Demonstrates learning.</p>
<p>2. Ask family caregiver to describe how he/she can coach patient with exercises at home before surgery.</p>	<p>Demonstrates understanding of role family member can play to support patient.</p>
<p>3. Use Teach-Back: "I want to be sure I explained what you need to know about the exercises we want you to perform after surgery. Tell me which exercises you will do and how to do them." Revise your instruction now or develop a plan for revised patient/family caregiver teaching if patient/family caregiver is not able to teach back correctly.</p>	<p>Determines patient's/family caregiver's level of understanding of instructional topic.</p>
<p>Unexpected Outcomes and Related Interventions</p>	
<p>1. Patient or caregiver identifies incorrect surgical procedure, site, date, or time of surgery. • Provide correct information verbally and in writing for patient and family caregiver.</p>	
<p>2. Patient incorrectly performs/describes postoperative exercise(s). • Explain and demonstrate correct exercise technique. • Explain importance of the postoperative exercise as it pertains to patient recovery. • Instruct patient to repeat demonstration after clarification.</p>	
<p>Recording and Reporting</p>	

Step	Rationale
	• Document preoperative teaching on the appropriate form within the patient's medical record. There is often a preoperative education flow sheet or designated agency form where this information should be documented.
	• Document evaluation of patient learning.
	• Report patient's inability to identify procedure and site of surgery, as well as understanding of postoperative exercise(s) and teaching to health care provider.
Home Care Considerations	
	• Incorporate teaching of family members to help patient implement postoperative exercises at home. Be sure family has access to resources (e.g., dressing supplies, dietary food options) at home to support patient appropriately.

Key Points

- Perioperative nursing includes the preoperative, intraoperative, and postoperative phases.
- The assessment of risk factors such as history of smoking, obesity, and obstructive sleep apnea allows a nurse to anticipate patient needs and the types of preparation required preoperatively to prevent intraoperative and postoperative complications.
- Malnutrition, diabetes, obesity, smoking, age, obstructive sleep apnea, and cardiac disorders increase patients' risks for perioperative complications.
- A nurse assesses a patient's potential psychological response by identifying the patient's previous experiences with surgery to anticipate his or her needs, providing teaching, addressing fears, and clarifying concerns
- A standard preoperative teaching plan includes instruction that influences maintenance of ventilatory function, physical functional capacity, and sense of well-being, as well as the reduction of patient anxiety and the patient's length of hospital stay.
- Postoperative exercises prevent pulmonary and vascular complications and deconditioning.
- An intraoperative assessment that focuses on a patient's immediate clinical status, skin integrity, and joint function allows the nurse to anticipate problems that predispose the patient to injury if he or she is not positioned on the OR table correctly.

- The primary differences between intraoperative phases are the level of monitoring and progressive change in focus from acute recovery to preparing patients for convalescence and recovery.
- Hand-off communication ensures that each patient receives the right surgery at the right surgical site by verifying the patient's situation (S) (the patient's problem and type of surgery), background (B) (history), assessment data (A), and recommendations (R) for the interventions that need to be implemented.
- Standardized protocols for hand-off communication between perioperative health care providers minimize surgical risks and promotes seamless transition between each surgical phase.
- Postoperative priorities include maintenance of a patent airway, circulatory and perfusion regulation, temperature control, pain control, fluid and electrolyte balance, and wound care.
- Postoperative patient education should be relevant and specific, culturally appropriate, and accurate to enhance the ability of patients to care for themselves at home.
- When caring for patients who had ambulatory surgery, prioritize education because of the limited time available, including involvement of the family or support system.

Reflective Learning

- Consider a postoperative patient who you cared for during your clinical rotation. Reflect on the priorities and

outcomes that you set for the patient during your care. What nursing interventions were most successful in achieving the established outcomes for the patient?

- Reflect on a clinical situation when you provided discharge teaching for a patient following surgery. What were the major concerns of the patient and caregiver? How did you address their concerns?
- Discuss how you were aware of the cultural background and incorporated the cultural beliefs of your patient when you developed a preoperative teaching plan. What teaching strategies did you find most effective?

Review Questions

1. The nurse prepares a patient with type 2 diabetes for a surgical procedure. The patient weighs 112.7 kg (248 lb) and is 5 feet, 2 inches in height. Which factors increase this patient's risk for surgical complications? (Select all that apply.)
 1. Obesity
 2. Prolonged bleeding time
 3. Delayed wound healing
 4. Ineffective vital capacity
 5. Immobility secondary to height
2. Which assessment questions should the nurse ask a preoperative patient preparing for surgery? (Select all that apply.)
 1. "Are you experiencing any pain?"
 2. "Do you exercise on a daily basis?"

3. "When do you regularly take your medications?"
 4. "Do you have any medication allergies?"
 5. "Do you use drugs and/or tobacco products?"
3. Communication between a nurse caring for a patient in the preoperative holding area and the circulating nurse in the operating room (OR) can best be enhanced by which of the following? (Select all that apply.)
 1. Documenting assessment findings in the medical record
 2. Using a standardized SBAR tool
 3. Being responsive in using nonverbal communication techniques
 4. Giving specific information to a transport technician
 5. Listening to the OR nurse's questions
 4. Which postoperative intervention best prevents atelectasis?
 1. Use of intermittent compression stockings
 2. Heel-toe flexion
 3. Use of the incentive spirometer
 4. Abdominal splinting when coughing
 5. An 85-year-old patient returns to the inpatient surgical unit after leaving the PACU. Which of the following place the patient at risk during surgery? (Select all that apply.)
 1. Stiffened lung tissue
 2. Reduced diaphragmatic excursion
 3. Increased laryngeal reflexes
 4. Reduced blood flow to kidneys
 5. Increased cholinergic transmission

6. A postoperative patient experiences tachypnea during the first hour of recovery. Which nursing intervention is a priority?
 1. Elevate the head of the patient's bed.
 2. Give ordered oxygen through a mask at 4 L/min.
 3. Ask the patient to use an incentive spirometer.
 4. Position the patient on one side with the face down and the neck slightly extended so that the tongue falls forward.

7. Which is the best intervention the nurse should implement to promote bowel function?
 1. Early ambulation
 2. Deep-breathing exercises
 3. Repositioning on the left side
 4. Lowering the head of the patient's bed

8. Match the nursing interventions on the left with the complication to be prevented on the right. An intervention may apply to more than one complication.

Nursing Intervention	Complication
1. Offering glasses or hearing aid	a. Deep vein thrombosis
2. Early ambulation	b. Wound infection
3. Strict aseptic technique	c. Delirium
4. Deep breathing exercise	d. Atelectasis
5. Hydration	

9. A nurse cares for a postoperative patient in the PACU. Upon assessment, the nurse finds the surgical dressing is saturated with serosanguineous drainage. Which interventions are a priority? (Select all that apply.)

1. Notify surgeon.
2. Maintain the intravenous fluid infusion.
3. Provide 2 L/min of oxygen via nasal cannula.
4. Monitor the patient's vital signs every 5 to 10 minutes.
5. Reinforce the dressing.

10. A patient who returned from surgery 3 hours ago following a kidney transplant is reporting pain at a 7 on a scale of 0 to 10. The nurse has tried repositioning with no improvement in the patient's pain report. Unmanaged surgical pain can lead to which of the following problems? (Select all that apply.)

1. Delayed ambulation
2. Reduced ventilation
3. Catheter-associated urinary tract infection
4. Retained pulmonary secretions
5. Reduced appetite

Glossary

A

abduction Movement of a limb away from the body.

abrasion Scraping or rubbing away of epidermis; may result in localized bleeding and later weeping of serous fluid.

absorption Passage of drug molecules into the blood. Factors influencing drug absorption include route of administration, ability of the drug to dissolve, and conditions at the site of absorption.

acceptance Fifth stage of Kübler-Ross's stages of grief and dying. An individual comes to terms with a loss rather than submitting to resignation and hopelessness.

accessory muscles Muscles in the thoracic cage that assist with respiration.

accommodation Process of responding to the environment through new activity, thinking, and changing the existing schema or developing a new schema to deal with the new information. For example, a toddler whose parent consistently corrects him when he calls a horse a "doggie" accommodates and forms a new schema for horses.

accountability State of being answerable for one's actions—a nurse answers to himself or herself, the patient, the profession, the employing institution such as a hospital, and society for the effectiveness of nursing care performed.

accreditation Process whereby a professional association or nongovernmental agency grants recognition to a school or

institution for demonstrated ability to meet predetermined criteria.

acculturation The process through which an individual or group transitions from one culture to develop the traits of another culture.

acne Inflammatory, papulopustular skin eruption, usually occurring on the face, neck, shoulders, and upper back.

acromegaly Chronic metabolic condition caused by overproduction of growth hormone and characterized by gradual, marked enlargement and elongation of bones of the face, jaw, and extremities.

active listening Listening attentively with the whole person—mind, body, and spirit. It includes listening for main and supportive ideas; acknowledging and responding; giving appropriate feedback; and paying attention to the other person's total communication, including the content, intent, and feelings expressed.

active range-of-motion (ROM) exercise Exercise to the joint by the patient while doing activities of daily living or during joint assessment.

active strategies of health promotion Activities that depend on the patient's motivation to adopt a specific health program.

active transport Movement of materials across the cell membrane by means of chemical activity that allows the cell to admit larger molecules than would otherwise be possible.

activities of daily living (ADLs) Activities usually performed in the course of a normal day in the patient's life such as eating, dressing, bathing, brushing the teeth, or grooming.

activity tolerance Type and amount of exercise or work that a person is able to perform without undue exertion or injury.

actual loss Loss of an object, person, body part or function, or emotion that is overt and easily identifiable.

acuity recording Mechanism by which entries describing patient care activities are made over a 24-hour period. The activities are then translated into a rating score, or acuity score, that allows for a comparison of patients who vary by severity of illness.

acute care Pattern of health care in which a patient is treated for an acute episode of illness, for the sequelae of an accident or other trauma, or during recovery from surgery.

acute illness Illness characterized by symptoms that are of relatively short duration, are usually severe, and affect the functioning of the patient in all dimensions.

adduction Movement of a limb toward the body.

adolescence Period in development between the onset of puberty and adulthood. It usually begins between 11 and 13 years of age.

adult day care center Facility for the supervised care of older adults; provides activities such as meals and socialization during specified day hours.

advanced practice registered nurse (APRN) Generally the most independently functioning nurse. An APRN has a master's degree in nursing; advanced education in pathophysiology, pharmacology, and physical assessment; and certification and expertise in a specialized area of practice.

advanced sleep phase syndrome Common in older adults; a disturbance in sleep manifested by early waking in the morning with an inability to get back to sleep. It is thought that this syndrome is caused by advancing of the circadian rhythm of the body.

adventitious sounds Abnormal lung sounds heard with auscultation.

adverse effect Harmful or unintended effect of a medication, diagnostic test, or therapeutic intervention.

adverse reaction Any harmful, unintended effect of a medication, diagnostic test, or therapeutic intervention.

advocacy Process whereby a nurse objectively provides patients with the information they need to make decisions and supports the patients in whatever decisions they make.

afebrile Without fever.

affective learning Acquisition of behaviors involved in expressing feelings about attitudes, appreciation, and values.

afterload Resistance to left ventricular ejection; the work the heart must overcome to fully eject blood from the left ventricle.

age-related macular degeneration Progressive disorder in which the macula (the specialized portion of the retina responsible for central vision) degenerates as a result of aging and loses its ability to function efficiently. First signs include blurring of reading matter, distortion or loss of central vision, sensitivity to glare, and distortion of objects.

agnostic Individual who believes that any ultimate reality is unknown or unknowable.

airborne precautions Safeguards designed to reduce the risk of transmission of infectious agents through the air that a person breathes.

alarm reaction Mobilization of the defense mechanisms of the body and mind to cope with a stressor; the initial stage of the general adaptation syndrome.

aldosterone Mineralocorticoid steroid hormone produced by the adrenal cortex with action in the renal tubule to regulate sodium and potassium balance in the blood.

allergic reaction Unfavorable physiological response to an allergen to which a person has previously been exposed and has developed antibodies.

alopecia Partial or complete loss of hair; baldness.

Alzheimer's disease Disease of the brain parenchyma that causes a gradual and progressive decline in cognitive functioning.

AMBULARM Device used for the patient who climbs out of bed unassisted and is in danger of falling. This device is worn on the leg and signals when the leg is in a dependent position such as over the side rail or on the floor.

amino acid Organic compound of one or more basic groups and one or more carboxyl groups. Amino acids are the building blocks that construct proteins and the end products of protein digestion.

anabolism Constructive metabolism characterized by conversion of simple substances into more complex compounds of living matter.

analgesic Relieving pain; drug that relieves pain.

analogies Resemblances made between things otherwise unlike.

anaphylactic reaction Hypersensitive condition induced by contact with certain antigens.

aneurysm Localized dilations of the wall of a blood vessel; usually caused by atherosclerosis, hypertension, or a congenital weakness in a vessel wall.

anger Second stage of Kübler-Ross's stages of grief and dying. During this stage an individual resists loss by expressing extreme displeasure, indignation, or hostility.

angiotensin Polypeptide occurring in the blood, causing vasoconstriction, increased blood pressure, and the release of

aldosterone from the adrenal cortex.

anion gap Difference between the concentrations of serum cations and anions; determined by measuring the concentrations of sodium cations and chloride and bicarbonate anions.

anions Negatively charged electrolytes.

anthropometric measurements Body measures of height, weight, and skinfolds to evaluate muscle atrophy.

anthropometry Measurement of various body parts to determine nutritional and caloric status, muscular development, brain growth, and other parameters.

antibodies Immunoglobulins essential to the immune system that are produced by lymphoid tissue in response to bacteria, viruses, or other antigens.

anticipatory grief Grief response in which the person begins the grieving process before an actual loss.

antidiuretic hormone (ADH) Hormone that decreases the production of urine by increasing the resorption of water by the renal tubules. ADH is secreted by cells of the hypothalamus and stored in the posterior lobe of the pituitary gland.

antiembolic stockings Elasticized stockings that prevent formation of emboli and thrombi, especially after surgery or during bed rest.

antigen Substance, usually a protein, that causes the formation of an antibody and reacts specifically with that antibody.

antipyretic Substance or procedure that reduces fever.

anxiolytics Drugs used primarily to treat episodes of anxiety.

aphasia Abnormal neurological condition in which language function is defective or absent; related to injury to speech center

in cerebral cortex, causing receptive or expressive aphasia.

apical pulse Heartbeat as listened to with the bell or diaphragm of a stethoscope placed on the apex of the heart.

apnea Absence of respirations for a period of time.

apothecary system System of measurement. The basic unit of weight is a grain. Weights derived from the grain are the gram, ounce, and pound. The basic measure for fluid is the minim. The fluidram, fluid ounce, pint, quart, and gallon are measures derived from the minim.

approximate To come close together, as in the edges of a wound.

arcus senilis Opaque ring, gray to white in color, that surrounds the periphery of the cornea. The condition is caused by deposits of fat granules in the cornea. Occurs primarily in older adults.

asepsis Absence of germs or microorganisms.

aseptic technique Any health care procedure in which added precautions are used to prevent contamination of a person, object, or area by microorganisms.

assault Unlawful threat to bring about harmful or offensive contact with another.

assertive communication Type of communication based on a philosophy of protecting individual rights and responsibilities. It includes the ability to be self-directive in acting to accomplish goals and advocate for others.

assessment First step of the nursing process. Activities required in the first step are data collection, validation, sorting, and documentation. The purpose is to gather information for health problem identification.

assimilation The process in which an individual adapts to the host's cultural values and no longer prefers the traditions, values, and

beliefs of the culture of origin.

assisted living Residential living facilities in which each resident has his or her own room and shares dining and social activity areas.

associative play Form of play in which a group of children participates in similar or identical activities without formal organization, direction, interaction, or goals.

atelectasis Collapse of alveoli, preventing the normal respiratory exchange of oxygen and carbon dioxide.

atheist Individual who does not believe in the existence of God.

atherosclerosis Common arterial disorder characterized by yellowish plaques of cholesterol, lipids, and cellular debris in the inner layers of the walls of the large- and medium-size arteries.

atrioventricular (AV) node Part of the cardiac conduction system located on the floor of the right atrium; receives electrical impulses from the atrium and transmits them to the bundle of His.

atrophied Wasted or reduced size or physiological activity of a part of the body caused by disease or other influences.

attachment Initial psychosocial relationship that develops between parents and the neonate.

attentional set Mental state that allows the learner to focus on and comprehend a learning activity.

auditory Related to or experienced through hearing.

auscultation Method of physical examination; listening to the sounds produced by the body, usually with a stethoscope.

auscultatory gap Disappearance of sound when obtaining a blood pressure; typically occurs between the first and second Korotkoff

sounds.

authority Right to act in areas in which an individual has been given and accepts responsibility.

autologous transfusion Procedure in which blood is removed from a donor and stored for a variable period before it is returned to the donor's own circulation.

autonomy Ability or tendency to function independently.

B

back-channeling Active listening technique that prompts a respondent to continue telling a story or describing a situation. Involves use of phrases such as "Go on," "Uh-huh," and "Tell me more."

bacteremia Presence of bacteria in the bloodstream.

bacteriuria Presence of bacteria in the urine.

balance Position in which the person's center of gravity is correctly positioned so that falling does not occur.

bandages Available in rolls of various widths and materials, including gauze, elasticized knit, elastic webbing, flannel, and muslin. Gauze bandages are lightweight and inexpensive, mold easily around contours of the body, and permit air circulation to underlying skin to prevent maceration. Elastic bandages conform well to body parts but can also be used to exert pressure over a body part.

bargaining Third stage of Kübler-Ross's stages of grief and dying. A person postpones the reality of a loss by attempting to make deals in a subtle or overt manner with others or with a higher being.

baridi Condition among the Bena people of Tanzania attributed to disrespectful behavior within the family or transgression of cultural taboos. The person experiences physical and psychological symptoms and is usually treated by a traditional healer, who has the person make a public admission or an apology or who treats the person with herbal remedies.

basal cell carcinoma Malignant epithelial cell tumor that begins as a papule and enlarges peripherally, developing a central crater that erodes, crusts, and bleeds. Metastasis is rare.

basal metabolic rate (BMR) Amount of energy used in a unit of time by a fasting, resting subject to maintain vital functions.

battery Legal term for touching another's body without consent.

bed boards Boards placed under the mattress of a bed that provide extra support to the mattress surface.

bed rest Placement of the patient in bed for therapeutic reasons for a prescribed period.

benchmarking Identifying best practices and comparing them with current organizational practices to improve performance. This process helps to support the claims of quality care delivery by the institution.

beneficence Doing good or actively promoting doing good; one of the four principles of the ethical theory of deontology.

benign breast disease (fibrocystic) Benign condition characterized by lumpy, painful breasts and sometimes nipple discharge. Symptoms are more apparent before the menstrual period. Known to be a risk factor for breast cancer.

bereavement Response to loss through death; a subjective experience that a person suffers after losing a person with whom there has been a significant relationship.

biases and prejudices Beliefs and attitudes associating negative permanent characteristics to people who are perceived as different from oneself.

bi-level positive airway pressure (BiPAP) Ventilatory support used to treat patients with obstructive sleep apnea, patients with congestive heart failure, and preterm infants with underdeveloped lungs.

bilineally Kinship that extends to both the mother's and father's sides of the family.

binders Bandages made of large pieces of material to fit specific body parts.

bioethics Branch of ethics within the field of health care.

biological clock Cyclical nature of body function. Functions controlled from within the body are synchronized with environmental factors; same meaning as biorhythm.

biological half-life Time it takes for the body to lower the amount of unchanged medication by half.

biotransformation Chemical changes that a substance undergoes in the body such as by the action of enzymes.

blanchable hyperemia Redness of the skin caused by dilation of the superficial capillaries. When pressure is applied to the skin, the area blanches, or turns a lighter color.

body image Peoples' subjective concept of their physical appearance.

body mechanics Coordinated efforts of the musculoskeletal and nervous systems to maintain proper balance, posture, and body alignment.

bone resorption Destruction of bone cells and release of calcium into the blood.

borborygmi Audible abdominal sounds produced by hyperactive intestinal peristalsis.

botanica Place that sells religious and herbal remedies.

bradycardia Slower-than-normal heart rate; heart contracts fewer than 60 times/min.

bradypnea Abnormally slow rate of breathing.

bronchospasm Excessive and prolonged contraction of the smooth muscle of the bronchi and bronchioles, resulting in an acute narrowing and obstruction of the respiratory airway.

bruit Abnormal sound or murmur heard while auscultating an organ, gland, or artery.

buccal Of or pertaining to the inside of the cheek or the gum next to the cheek.

buccal cavity Consists of the lips surrounding the opening of the mouth, the cheeks running along the side walls of the cavity, the tongue and its muscles, and the hard and soft palate.

buffer Substance or group of substances that can absorb or release hydrogen ions to correct an acid-base imbalance.

bundle of His Part of the cardiac conduction system that arises from the distal portion of the atrioventricular (AV) node and extends across the AV groove to the top of the intraventricular septum, where it divides into right and left bundle branches.

C

cachexia Malnutrition marked by weakness and emaciation, usually associated with severe illness.

capitation Payment mechanism in which a provider (e.g., health care network) receives a fixed amount of payment per enrollee.

capnography Also known as end-tidal CO₂ monitoring, it provides instant information about how effectively CO₂ is eliminated by the pulmonary system, how effectively it is transported through the vascular system, and how effectively CO₂ is produced by cellular metabolism. Capnography is measured near the end of exhalation.

carbohydrates Dietary classification of foods comprising sugars, starches, cellulose, and gum.

carbon monoxide Colorless, odorless, poisonous gas produced by the combustion of carbon or organic fuels.

cardiac index Adequacy of the cardiac output for an individual. It takes into account the body surface area (BSA) of the patient.

cardiac output (CO) Volume of blood expelled by the ventricles of the heart, equal to the amount of blood ejected at each beat multiplied by the number of beats in the period of time used for computation (usually 1 minute).

cardiopulmonary rehabilitation Actively assisting the patient with achieving and maintaining an optimal level of health through controlled physical exercise, nutritional counseling, relaxation and stress management techniques, prescribed medications and oxygen, and compliance.

cardiopulmonary resuscitation (CPR) Basic emergency procedures for life support consisting of artificial respiration and manual external cardiac massage.

care To feel concern for or interest in one who has sorrow or difficulties.

care bundle A group of interventions related to a disease process or condition that when implemented together result in better patient outcomes than when the interventions are implemented individually.

caring Universal phenomenon that influences the way we think, feel, and behave in relation to one another.

carriers People or animals who harbor and spread an organism that causes disease in others but do not become ill themselves.

case management Organized system for delivering health care to an individual patient or group of patients across an episode of illness and/or a continuum of care; includes assessment and development of a plan of care, coordination of all services, referral, and follow-up; usually assigned to one professional.

case management plan Multidisciplinary model for documenting patient care that usually includes plans for problems, key interventions, and expected outcomes for patients with a specific disease or condition.

catabolism Breakdown of body tissue into simpler substances.

cataplexy Condition characterized by sudden muscular weakness and loss of muscle tone.

cataracts Abnormal progressive condition of the lens of the eye characterized by loss of transparency.

cathartics Drugs that act to promote bowel evacuation.

catheterization Introduction of a catheter into a body cavity or organ to inject or remove fluid.

cations Positively charged electrolytes.

center of gravity Midpoint or center of the weight of a body or object.

centigrade Denotes temperature scale in which 0° is the freezing point of water and 100° is the boiling point of water at sea level; also called Celsius.

cerumen Yellowish or brownish waxy secretion produced by sweat glands in the external ear.

chancres Skin lesions or venereal sores (usually primary syphilis) that begin at the site of infection as papules and develop into red, bloodless, painless ulcers with a scooped-out appearance.

change-of-shift report Report that occurs between two scheduled nursing work shifts. Nurses communicate information about their assigned patients to nurses working on the next shift of duty.

channel Method used in the teaching-learning process to present content: visual, auditory, taste, smell. In the communication process, a method used to transmit a message: visual, auditory, touch.

charting by exception (CBE) Charting methodology in which data are entered only when there is an exception from that which is normal or expected; reduces time spent documenting in charting. It is a shorthand method for documenting normal findings and routine care.

chest percussion Striking the chest wall with a cupped hand to promote mobilization and drainage of pulmonary secretions.

chest physiotherapy (CPT) Group of therapies used to mobilize pulmonary secretions for expectoration.

chest tube Catheter inserted through the thorax into the chest cavity for removing air or fluid; used after chest or heart surgery or pneumothorax.

Cheyne-Stokes respiration Occurs when there is decreased blood flow or injury to the brainstem.

chronic illness Illness that persists over a long time and affects physical, emotional, intellectual, social, and spiritual functioning.

circadian rhythm Repetition of certain physiological phenomena within a 24-hour cycle.

circular transactional communication process Communication model that enhances the linear communication by enabling the sender and receiver to view perceptions, attitudes, and potential reactions of others via a mental picture. This is a continuous and interactive activity.

circulating nurse Assistant to the scrub nurse and surgeon whose role is to provide necessary supplies; dispose of soiled instruments and supplies; and keep an accurate count of instruments, needles, and sponges used.

civil law Statutes concerned with protecting a person's rights.

climacteric Physiological, developmental change that occurs in the male reproductive system between the ages of 45 and 60.

clinical criteria Objective or subjective signs and symptoms, clusters of signs and symptoms, or risk factors.

clinical decision making Problem-solving approach that nurses use to define patient problems and select appropriate treatment.

clinical-decision support systems Computerized programs used within the health care setting to support decision making.

Clinical Information System (CIS) A computer-based system that collects, stores, and manipulates data to allow health care providers to make informed decisions about patient care.

closed-ended question Form of question that limits a respondent's answer to one or two words.

clubbing Bulging of the tissues at the nail base caused by insufficient oxygenation at the periphery, resulting from conditions such as chronic emphysema and congenital heart disease.

code of ethics Formal statement that delineates a profession's guidelines for ethical behavior. A code of ethics sets standards or expectations for the professional to achieve.

cognitive learning Acquisition of intellectual skills that encompass behaviors such as thinking, understanding, and evaluating.

collaborative interventions Therapies that require the knowledge, skill, and expertise of multiple health care professionals.

collaborative problem Physiological complication that requires the nurse to use nursing- and health care provider-prescribed interventions to maximize patient outcomes.

colloid osmotic pressure Abnormal condition of the kidney caused by the pressure of concentrations of large particles such as protein molecules that will pass through a membrane.

colon Portion of the large intestine from the cecum to the rectum.

colonization Presence and multiplication of microorganisms without tissue invasion or damage.

comforting Acts toward another individual that display both an emotional and physical calm. The use of touch, the establishment of presence, the therapeutic use of silence, and the skillful and gentle performance of a procedure are examples of comforting nursing measures.

common law One source for law that is created by judicial decisions as opposed to those created by legislative bodies (statutory law).

communicable disease Any disease that can be transmitted from one person or animal to another by direct or indirect contact or

by vectors.

communication Ongoing, dynamic series of events that involves the transmission of meaning from sender to receiver.

community-based nursing Acute and chronic care of individuals and families to strengthen their capacity for self-care and promote independence in decision making.

community health nursing Nursing approach that combines knowledge from the public health sciences with professional nursing theories to safeguard and improve the health of populations in the community.

co-morbidity A chronic, long-term condition existing simultaneously with and usually independently of another medical condition.

compassion The feeling that arises when a person is confronted with another's suffering and feels motivated to relieve that suffering. Compassion shows kindness, caring, and a willingness to help others.

competence Specific range of skills necessary to perform a task.

complete bed bath Bath in which the entire body of a patient is washed in bed.

compress Soft pad of gauze or cloth used to apply heat, cold, or medications to the surface of a body part.

computer-based patient record Comprehensive computerized system used by all health care practitioners to permanently store information pertaining to a patient's health status, clinical problems, and functional abilities.

concentration Relative content of a component within a substance or solution.

concentration gradient Gradient that exists across a membrane, separating a high concentration of a particular ion from a low concentration of the same ion.

concept map Care-planning tool that assists in critical thinking and forming associations between a patient's nursing diagnoses and interventions.

confianza Trust.

confidentiality Act of keeping information private or secret; in health care the nurse shares information about a patient only with other nurses or health care providers who need to know private information about a patient to provide care for him or her; information can only be shared with the patient's consent.

conjunctivitis Highly contagious eye infection. The crusty drainage that collects on eyelid margins can easily spread from one eye to the other.

connectedness Having close spiritual relationships with oneself, others, and God or another spiritual being.

connotative meaning Shade or interpretation of the meaning of a word influenced by the thoughts, feelings, or ideas that people have about the word.

conscious sedation Administration of central nervous system–depressant drugs and/or analgesics to provide analgesia, relieve anxiety, and/or provide amnesia during surgical, diagnostic, or interventional procedures.

constipation Condition characterized by difficulty in passing stool or an infrequent passage of hard stool.

consultation Process in which the help of a specialist is sought to identify ways to handle problems in patient management or in planning and implementing programs.

Contact Precautions Safeguards designed to reduce the risk of transmission of epidemiologically important microorganisms by direct or indirect contact.

content The product and information obtained from the system.

continent urinary diversion (CUR) Surgical diversion of the drainage of urine from a diseased or dysfunctional bladder. Patient uses a catheter to drain the pouch.

continuous positive airway pressure (CPAP) Ventilatory support used to treat patients with obstructive sleep apnea, patients with congestive heart failure, and preterm infants with underdeveloped lungs.

convalescence Period of recovery after an illness, injury, or surgery.

coping Making an effort to manage psychological stress.

core temperature Temperature of deep structures of the body.

cough Sudden, audible expulsion of air from the lungs. The person breathes in, the glottis is partially closed, and the accessory muscles of expiration contract to expel the air forcibly.

counseling Problem-solving method used to help patients recognize and manage stress and enhance interpersonal relationships. It helps patients examine alternatives and decide which choices are most helpful and appropriate.

crackles Fine bubbling sounds heard on auscultation of the lung; produced by air entering distal airways and alveoli, which contain serous secretions.

crime Act that violates a law and that may include criminal intent.

criminal law Concerned with acts that threaten society but may involve only an individual.

crisis Transition for better or worse in the course of a disease, usually indicated by a marked change in the intensity of signs and symptoms.

crisis intervention Use of therapeutic techniques directed toward helping a patient resolve a particular and immediate problem.

critical pathways Tools used in managed care that incorporate the treatment interventions of caregivers from all disciplines who normally care for a patient. Designed for a specific care type, a pathway is used to manage the care of a patient throughout a projected length of stay.

critical period of development Specific phase or period when the presence of a function or reasoning has its greatest effect on a specific aspect of development.

critical thinking Active, purposeful, organized, cognitive process used to carefully examine one's thinking and the thinking of other individuals.

crutch gait Gait achieved by a person using crutches.

cue Information that a nurse acquires through hearing, visual observations, touch, and smell.

cultural and linguistic competence Set of congruent behaviors, attitudes, and policies that come together in a system or agency or among professionals that enables effective work in cross-cultural situations.

cultural assessment Systematic and comprehensive examination of the cultural care values, beliefs, and practices of individuals, families, and communities.

cultural awareness Gaining in-depth awareness of one's own background, stereotypes, biases, prejudices, and assumptions about other people.

cultural care accommodation or negotiation Adapting or negotiating with the patient/family to achieve beneficial or satisfying health outcomes.

cultural care preservation or maintenance Retaining and/or preserving relevant care values so that patients are able to maintain their well-being, recover from illness, or face handicaps and/or death.

cultural care repatterning or restructuring Reordering, changing, or greatly modifying a patient's/family's customs for a new, different, and beneficial health care pattern.

cultural competence Process in which the health care professional continually strives to achieve the ability and availability to work effectively with individuals, families, and communities.

cultural encounters Engaging in cross-cultural interactions; refining intercultural communication skills; gaining in-depth understanding of others and avoiding stereotypes; and managing cultural conflict.

cultural imposition Using one's own values and customs as an absolute guide in interpreting behaviors.

cultural knowledge Obtaining knowledge of other cultures; gaining sensitivity to, respect for, and appreciation of differences.

cultural pain Feeling that a patient has after a health care worker disregards the patient's valued way of life.

cultural respect Behavior that is respectful and responsive to the needs of the diverse patient.

cultural skills Communication, cultural assessment, and culturally competent care.

culturally congruent care Care that fits people's valued life patterns and sets of meanings generated from the people themselves.

Sometimes this differs from the professionals' perspective on care.

culturally ignorant or blind Uneducated about other cultures.

culture Integrated patterns of human behavior that include the language, thoughts, communications, actions, customs, beliefs, values, and institutions of racial, ethnic, religious, or social groups.

culture-bound syndromes Illnesses restricted to a particular culture or group because of its psychosocial characteristics.

culture care theory Leininger's theory that emphasizes culturally congruent care.

culturological nursing assessment Systematic and comprehensive examination of the cultural care values, beliefs, and practices of individuals, families, and communities.

cutaneous stimulation Stimulation of a person's skin to prevent or reduce pain perception. A massage, warm bath, hot and cold therapies, and transcutaneous electrical nerve stimulation are some ways to reduce pain perception.

cyanosis Bluish discoloration of the skin and mucous membranes caused by an excess of deoxygenated hemoglobin in the blood or a structural defect in the hemoglobin molecule.

D

DAR (data, action, patient response) Format used in focus charting for recording patient information.

data analysis Logical examination of and professional judgment about patient assessment data; used in the diagnostic process to derive a nursing diagnosis.

data cluster Set of signs or symptoms that are grouped together in logical order.

database Store or bank of information, especially in a form that can be processed by computer.

debridement Removal of dead tissue from a wound.

decentralized management Organizational philosophy that brings decisions down to the level of the staff. Individuals best informed about a problem or issue participate in the decision-making process.

decision making Process involving critical appraisal of information that begins with recognizing a problem and ends with generating, testing, and evaluating a conclusion. Comes at the end of critical thinking.

deconditioning Physiological change following a period of inactivity, bed rest or sedentary lifestyle. It results in functional losses in such areas as mental status, degree of continence, and ability to accomplish activities of daily living.

defecation Passage of feces from the digestive tract through the rectum.

defendant Individual or organization against whom legal charges are brought in a court of law.

defining characteristics The observable assessment cues that cluster as manifestations of a problem-focused or health promotion nursing diagnosis.

dehiscence Separation of the edges of a wound, revealing underlying tissues.

dehydration Excessive loss of water from the body tissues accompanied by a disturbance of body electrolytes.

delegation Process of assigning another member of the health care team to be responsible for aspects of patient care (e.g., assigning nurse assistants to bathe a patient).

delirium Acute state of confusion that is potentially reversible and often has a physical cause.

dementia Generalized impairment of intellectual functioning that interferes with social and occupational functioning.

denial Unconscious refusal to admit an unacceptable idea.

denotative meaning Meaning of a word shared by individuals who use a common language. For example, the word *baseball* has the same meaning for all individuals who speak English, but the word *code* primarily denotes cardiac arrest to health care providers.

dental caries Abnormal destructive condition in a tooth caused by a complex interaction of food, especially starches and sugars, with bacteria that form dental plaque.

deontology Traditional theory of ethics that proposes to define actions as right or wrong based on the characteristics of fidelity to promises, truthfulness, and justice. The conventional use of ethical terms such as *justice*, *autonomy*, *beneficence*, and *nonmaleficence* constitutes the practice of deontology.

depression (1) Reduction in happiness and well-being that contributes to physical and social limitations and complicates the treatment of concomitant medical conditions. It is usually reversible with treatment. (2) Fourth stage of Kübler-Ross's stages of grief and dying. In this stage the person realizes the full impact and significance of the loss.

dermis Sensitive vascular layer of the skin directly below the epidermis; composed of collagenous and elastic fibrous connective tissues that give the dermis strength and elasticity.

determinants of health Many variables that influence the health status of individuals or communities.

detoxify To remove the toxic quality of a substance. The liver acts to detoxify chemicals in drug compounds.

development Qualitative or observable aspects of the progressive changes that one makes in adapting to the environment.

developmental crises Crises associated with normal and expected phases of growth and development (e.g., the response to menopause); same as maturational crises.

diabetic retinopathy Disorder of retinal blood vessels. Pathological changes secondary to increased pressure in the blood vessels of the retina result in decreased vision or vision loss caused by hemorrhage and macular edema.

diagnosis-related group (DRG) Classifications based on a hospitalized patient's primary and secondary medical diagnoses that are used as the basis for establishing Medicare reimbursement for patient care.

diagnostic process Mental steps (data clustering and analysis, problem identification) that follow assessment and lead directly to the formulation of a diagnosis.

diagnostic reasoning Process that enables an observer to assign meaning to and classify phenomena in clinical situations by integrating observations and critical thinking.

diaphoresis Secretion of sweat, especially profuse secretion associated with an elevated body temperature, physical exertion, or emotional stress.

diaphragmatic breathing Respiration in which the abdomen moves out while the diaphragm descends on inspiration.

diarrhea Increase in the number of stools and the passage of liquid, unformed feces.

diastolic Pertaining to diastole, or the blood pressure at the instant of maximum cardiac relaxation; the pressure of the blood in the arteries when the heart is filling

dietary reference intake (DRI) Information on each vitamin or mineral to reflect a range of minimum-to-maximum amounts that avert deficiency or toxicity.

diffusion Movement of molecules from an area of high concentration to one of lower concentration.

digestion Breakdown of nutrients by chewing, churning, mixing with fluid, and chemical reactions.

direct care interventions Treatments performed through interaction with the patient. For example, a patient may require medication administration, insertion of an intravenous infusion, or counseling during a time of grief.

discharge planning Activities directed toward identifying future proposed therapy and the need for additional resources before and after returning home.

discrimination Prejudicial outlook, action, or treatment.

disease Malfunctioning or maladaptation of biological or psychological processes.

disinfection Process of destroying all pathogenic organisms except spores.

disorganization and despair One of Bowlby's four phases of mourning in which an individual endlessly examines how and why the loss occurred.

distress Damaging stress; one of the two types of stress identified by Selye.

disuse osteoporosis Reductions in skeletal mass routinely accompanying immobility or paralysis.

diuresis Increased rate of formation and excretion of urine.

documentation Written entry into the patient's medical record of all pertinent information about him or her. These entries validate the patient's problems and care and exist as a legal record.

dominant culture Customs, values, beliefs, traditions, and social and religious views held by a group of people that prevail over another secondary culture.

dorsiflexion Flexion toward the back.

drainage evacuators Convenient portable units that connect to tubular drains lying within a wound bed and exert a safe, constant, low-pressure vacuum to remove and collect drainage.

Droplet Precautions Safeguards designed to reduce the risk of droplet transmission of infectious agents.

dysmenorrhea Painful menstruation.

dysphagia Difficulty swallowing; commonly associated with obstructive or motor disorders of the esophagus.

dyspnea Sensation of shortness of breath.

dysrhythmia Deviation from the normal pattern of the heartbeat.

dysuria Painful urination resulting from bacterial infection of the bladder and obstructive conditions of the urethra.

E

ecchymosis Discoloration of the skin or bruise caused by leakage of blood into subcutaneous tissues as a result of trauma to underlying tissues.

ectropion Eversion of the eyelid that exposes the conjunctival membrane and part of the eyeball.

edema Abnormal accumulation of fluid in interstitial spaces of tissues.

egocentric Developmental characteristic wherein a toddler is only able to assume the view of his or her own activities and needs.

electrocardiogram (ECG) Graphic record of the electrical activity of the myocardium.

electrolyte Element or compound that, when melted or dissolved in water or other solvent, dissociates into ions and can carry an electrical current.

electronic health record (EHR) An electronic record of patient health information generated whenever a patient accesses medical care in any health care delivery setting.

electronic infusion device Piece of medical equipment that delivers intravenous fluids at a prescribed rate through an intravenous catheter.

electronic medical record Part of the electronic health record that contains patient data gathered in a health care setting at a specific time and place.

embolism Abnormal condition in which a blood clot (embolus) travels through the bloodstream and becomes lodged in a blood vessel.

emerging adulthood The time from adolescence to the young adult when responsibilities of a stable job, marriage, and parenthood begin. It includes five features: the age of identity exploration, the

age of instability, the age of self-focus, the age of feeling in between, and the age of possibilities.

emic world view The inside perspective of a cultural encounter.

emotional intelligence Assessment and communication technique used to better understand and perceive emotions of themselves. This assists in building a therapeutic relationship.

empathy Understanding and acceptance of a person's feelings and the ability to sense the person's private world.

empowered Gave legal authority to or enabled an individual or group; promoted self-actualization of an individual or group.

endogenous infections Infections produced within a cell or organism.

endorphins Hormones that act on the mind and produce a sense of well-being and reduction of pain.

endotracheal tube Short-term artificial airways to administer mechanical ventilation, relieve upper airway obstruction, protect against aspiration, or clear secretions.

enema Procedure involving introduction of a solution into the rectum for cleansing or therapeutic purposes.

enteral nutrition (EN) Provision of nutrients through the gastrointestinal tract when the patient cannot ingest, chew, or swallow food but can digest and absorb nutrients.

entropion Condition in which the eyelid turns inward toward the eye.

environment All of the many factors (e.g., physical and psychological) that influence or affect the life and survival of a person.

epidermis Outer layer of the skin that has several thin layers in different stages of maturation; shields and protects the underlying tissues from water loss, mechanical or chemical injury, and penetration by disease-causing microorganisms.

epidural infusion Type of nerve block anesthesia in which an anesthetic is intermittently or continuously injected into the lumbosacral region of the spinal cord.

erythema Redness or inflammation of the skin or mucous membranes that is a result of dilation and congestion of superficial capillaries; sunburn is an example.

eschar Thick layer of dead, dry tissue that covers a pressure injury or thermal burn. It may be allowed to be sloughed off naturally, or it may need to be surgically removed.

ethical dilemma Dilemma existing when the right thing to do is not clear. Resolution requires the negotiation of differing values among those involved in the dilemma.

ethical principles Set of guidelines for the expectations of a profession and the standards of behavior for its members.

ethics Principles or standards that govern proper conduct.

ethics of care Delivery of health care based on ethical principles and standards of care.

ethnic/cultural identity Individuals identify consciously or unconsciously with those with whom they feel a common bond because of similar traditions, behaviors, values, and beliefs.

ethnicity Shared identity related to social and cultural heritage such as values, language, geographical space, and racial characteristics.

ethnocentrism Tendency to hold one's own way of life as superior to that of others.

ethnohistory Significant historical experiences of a particular group.

etic world view The outside perspective of a cultural encounter.

etiology Study of all factors that may be involved in the development of a disease.

eupnea Normal respirations that are quiet, effortless, and rhythmical.

eustress Stress that protects health; one of the two types of stress identified by Selye.

evaluation Determination of the extent to which established patient goals have been achieved.

evidence-based knowledge Knowledge that is derived from the integration of best research, clinical expertise, and patient values.

evidence-based practice Use of current best evidence from nursing research, clinical expertise, practice trends, and patient preferences to guide nursing decisions about care provided to patients.

evisceration Protrusion of visceral organs through a surgical wound.

exacerbations Increases in the gravity of a disease or disorder as marked by greater intensity in signs or symptoms.

excessive daytime sleepiness Extreme fatigue felt during the day. Signs of this include falling asleep at inappropriate times such as while eating, talking, or driving. May indicate a sleep disorder.

excoriation Injury to the surface of the skin caused by abrasion.

exhaustion stage Phase that occurs when the body can no longer resist the stress (i.e., when the energy necessary to maintain adaptation is depleted).

exogenous infection Infection originating outside an organ or part.

exostosis Abnormal benign growth on the surface of a bone.

expected outcomes Expected conditions of a patient at the end of therapy or a disease process, including the degree of wellness and the need for continuing care, medications, support, counseling, or education.

extended care facility Institution devoted to providing medical, nursing, or custodial care for an individual over a prolonged period such as during the course of a chronic disease or the rehabilitation phase after an acute illness.

extension Movement by certain joints that increases the angle between two adjoining bones.

extracellular fluid (ECF) Portion of body fluids composed of the interstitial fluid and blood plasma.

exudate Fluid, cells, or other substances that have been discharged from cells or blood vessels slowly through small pores or breaks in cell membranes.

F

face-saving Way of speaking or acting that preserves dignity.

Fahrenheit Denotes temperature scale in which 32° is the freezing point of water and 212° is the boiling point of water at sea level.

faith Set of beliefs and a way of relating to self, others, and a Supreme Being.

fajita Cotton binder used on a newborn's abdomen among Hispanics and Filipinos to prevent gas and umbilical hernia.

family Group of interacting individuals composing a basic unit of society.

family as context Nursing perspective in which the family is viewed as a unit of interacting members having attributes, functions, and goals separate from those of the individual family members.

family caregiving A family process that occurs in response to an illness and encompasses multiple cognitive, behavioral, and interpersonal processes.

family diversity The uniqueness of each family unit. For example, some families experience marriage for the first time and then have children in later life

family durability A system of support and structure within a family that extends beyond the walls of the household.

family dynamics The interactions between family members which is affected by a family's makeup (configuration), structure, function, problem-solving, and coping capacity.

family forms Patterns of people considered by family members to be included in the family.

family function Focuses on the processes used by the family to achieve its goals. Some processes include communication among family members, goal setting, conflict resolution, caregiving, nurturing, and use of internal and external resources.

family hardiness Internal strengths and durability of the family unit; characterized by a sense of control over the outcome of life events and hardships, a view of change as beneficial and growth-producing, and an active rather than passive orientation in responding to stressful life events.

family health Determined by the effectiveness of the family's structure, the processes that the family uses to meet its goals, and internal and external forces.

family as patient Nursing approach that takes into consideration the effect of one intervention on all members of a family.

family resiliency Family's ability to cope with expected and unexpected stressors.

family structure Based on organization (i.e., ongoing membership) of the family and the pattern of relationships.

farmacia Place to obtain prescribed medications.

febrile Pertaining to or characterized by an elevated body temperature.

fecal immunochemical test (FIT) A screening test for colon cancer. It detects occult blood in the stool and is not affected by medication or foods ingested.

fecal impaction Accumulation of hardened fecal material in the rectum or sigmoid colon.

fecal incontinence Inability to control passage of feces and gas from the anus.

fecal occult blood test (FOBT) Measures microscopic amounts of blood in the feces.

feces Waste or excrement from the gastrointestinal tract.

feedback Process in which the output of a given system is returned to the system.

felony Crime of a serious nature that carries a penalty of imprisonment or death.

feminist ethics Ethical approach that focuses on the nature of relationships to guide participants in making difficult decisions, especially relationships in which power is unequal or in which a point of view has become ignored or invisible.

fever Elevation in the hypothalamic set point so that body temperature is regulated at a higher level.

fictive Nonblood kin; considered family in some collective cultures.

fidelity Agreement to keep a promise.

fight-or-flight response Total physiological response to stress that occurs during the alarm reaction stage of the general adaptation syndrome. Massive changes in all body systems prepare a human being to choose to flee or remain and fight the stressor.

filtration Straining of fluid through a membrane.

fistula Abnormal passage from an internal organ to the surface of the body or between two internal organs.

flashback Recollection so strong that the individual thinks that he or she is actually experiencing the trauma again or seeing it unfold before his or her eyes.

flatus Intestinal gas.

flora Microorganisms that live on or within a body to compete with disease-producing microorganisms and provide a natural immunity against certain infections.

flow sheets Documents on which frequent observations or specific measurements are recorded.

fluctuance Soft, boggy feeling when tissue is palpated; usually a sign of tissue infection.

fluid volume deficit (FVD) Fluid and electrolyte disorder caused by failure of bodily homeostatic mechanisms to regulate the retention and excretion of body fluids. The condition is characterized by decreased output of urine, high specific gravity of urine, output of urine that is greater than the intake of fluid in

the body, hemoconcentration, and increased serum levels of sodium.

fluid volume excess (FVE) Fluid and electrolyte disorder characterized by an increase in fluid retention and edema, resulting from failure of bodily homeostatic mechanisms to regulate the retention and excretion of body fluids.

focus charting Charting methodology for structuring progress notes according to the focus of the note (e.g., symptoms and nursing diagnosis). Each note includes data, actions, and patient response.

focused cultural assessment Method of evaluating a patient's ethnohistory, biocultural history, social organization, and religious and spiritual beliefs to find issues that are most relevant to the problem at hand.

food poisoning Toxic processes resulting from the ingestion of a food contaminated by toxic substances or bacteria-containing toxins.

food security All members of a household have access to sufficient safe, nutritious food to maintain a healthy lifestyle.

foot boots Soft, foot-shaped devices designed to reduce the risk of footdrop by maintaining the foot in dorsiflexion.

footdrop Abnormal neuromuscular condition of the lower leg and foot characterized by an inability to dorsiflex, or evert, the foot.

friction Effects of rubbing or the resistance that a moving body meets from the surface on which it moves; a force that occurs in a direction to oppose movement.

functional health illiteracy Inability of an individual to obtain, interpret, and understand basic information about health.

functional health patterns Method for organizing assessment data based on the level of patient function in specific areas (e.g., mobility).

functional nursing Method of patient care delivery in which each staff member is assigned a task that is completed for all patients on the unit.

future orientation Time dimension emphasized by dominant American culture. It is characterized by direct communication and is focused on task achievement, whereas past orientation communication is circular and indirect and is focused on group harmony.

G

gait Manner or style of walking, including rhythm, cadence, and speed.

gastrostomy feeding tube Insertion of a feeding tube through a stoma into the stomach to provide enteral nutrition.

general adaptation syndrome (GAS) Generalized defense response of the body to stress; consists of three stages: alarm, resistance, and exhaustion.

general anesthesia Intravenous or inhaled medications that cause the patient to lose all sensation and consciousness.

genomics Describes the study of all the genes in a person and interactions of those genes with one another and with that person's environment.

geriatrics Branch of health care dealing with the physiology and psychology of aging and the diagnosis and treatment of diseases affecting older adults.

gerontology Study of all aspects of the aging process and its consequences.

gingivae Gums of the mouth; mucous membrane with supporting fibrous tissue that overlies the crowns of unerupted teeth and

encircles the necks of teeth that have erupted.

glaucoma Abnormal condition of elevated pressure within an eye caused by obstruction of the outflow of aqueous humor. If untreated, it often results in peripheral visual loss, decreased visual acuity with difficulty adapting to darkness, and a halo effect around lights.

globalization Worldwide scope or application.

glomerulus Cluster or collection of capillary vessels within the kidney involved in the initial formation of urine.

gluconeogenesis Formation of glucose or glycogen from substances that are not carbohydrates such as protein or lipid.

glucose Primary fuel for the body; needed to carry out major physiological functions.

glycogen Polysaccharide that is the major carbohydrate stored in animal cells.

glycogenesis Process for storing glucose in the form of glycogen in the liver.

goals Desired results of nursing actions set realistically by the nurse and patient as part of the planning stage of the nursing process.

Good Samaritan laws Legislation enacted in some states to protect health care professionals from liability in rendering emergency aid unless there is proven willful wrong or gross negligence.

graduated measuring container Receptacle for volume measurement.

granny midwives Amateur health practitioners that assist in labor and delivery.

granulation tissue Soft, pink, fleshy projections of tissue that form during the healing process in a wound not healing by primary

intention.

graphic record Charting mechanism that allows for the recording of vital signs and weight in such a manner that caregivers can quickly note changes in the patient's status.

grief Form of sorrow involving the person's thoughts, feelings, and behaviors that occurs as a response to an actual or perceived loss.

grieving process Sequence of affective, cognitive, and physiological states through which the person responds to and finally accepts an irretrievable loss.

grounded Connection between the electric circuit and the ground, which becomes part of the circuit.

growth Measurable or quantitative aspect of an individual's increase in physical dimensions as a result of an increase in number of cells. Indicators of growth include changes in height, weight, and sexual characteristics.

guided imagery Method of pain control in which the patient creates a mental image, concentrates on that image, and gradually becomes less aware of pain.

gustatory Pertaining to the sense of taste.

H

halal Foods permissible for Muslims to eat.

hand rolls Rolls of cloth that keep the thumb slightly adducted and in opposition to the fingers.

hand-wrist splints Splints individually molded for the patient to maintain proper alignment of the thumb, slight adduction of the wrist, and slight dorsiflexion.

haram Foods prohibited by Muslim religious standards.

health Dynamic state in which individuals adapt to their internal and external environments so that there is a state of physical, emotional, intellectual, social, and spiritual well-being.

health belief model Conceptual framework that describes a person's health behavior as an expression of his or her health beliefs.

health beliefs Patient's personal beliefs about levels of wellness that can motivate or impede participation in changing risk factors, participating in care, and selecting care options.

health care–acquired infection Infection that was not present or incubating at the time of admission to a health care setting.

health care problems Any conditions or dysfunctions that the patient experiences as a result of illness or treatment of an illness.

health disparities Preventable differences in the burden of disease, injury, violence, or opportunities to achieve optimal health that are experienced by socially and economically disadvantaged populations.

health informatics Application of computer and information science in all basic and applied biomedical sciences to facilitate the acquisition, processing, interpretation, optimal use, and communication of health-related data.

health literacy Patients' reading and mathematics skills, comprehension, ability to make health-related decisions, and successful functioning as a consumer of health care.

health promotion Activities such as routine exercise and good nutrition that help patients maintain or enhance their present level of health and reduce their risk of developing certain diseases.

health promotion model Defines health as a positive, dynamic state, not merely the absence of disease. The health promotion model

emphasizes well-being, personal fulfillment, and self-actualization rather than reaction to the threat of illness.

health status Description of health of an individual or community.

heat exhaustion Abnormal condition caused by depletion of body fluid and electrolytes resulting from exposure to intense heat or the inability to acclimatize to heat.

heat stroke Continued exposure to extreme heat that raises the core body temperature to 40.5° C (105° F) or higher.

hematemesis Vomiting of blood, indicating upper gastrointestinal bleeding.

hematoma Collection of blood trapped in the tissues of the skin or an organ.

hematuria Abnormal presence of blood in the urine.

hemolysis Breakdown of red blood cells and release of hemoglobin that may occur after administration of hypotonic intravenous solutions, causing swelling and rupture of erythrocytes.

hemoptysis Coughing up blood from the respiratory tract.

hemorrhoids Permanent dilation and engorgement of veins within the lining of the rectum.

hemostasis Termination of bleeding by mechanical or chemical means or the coagulation process of the body.

hemothorax Accumulation of blood and fluid in the pleural cavity between the parietal and visceral pleurae.

hernia Protrusion of an organ through an abnormal opening in the muscle wall of the cavity that surrounds it.

hilots Amateur health practitioners who assist in labor and delivery among Filipinos.

holistic Of or pertaining to the whole; considering all factors.

holistic health Comprehensive view of the person as a biopsychosocial and spiritual being.

home care Health service provided in the patient's place of residence to promote, maintain, or restore health or minimize the effects of illness and disability.

homeostasis State of relative constancy in the internal environment of the body; maintained naturally by physiological adaptive mechanisms.

hope Confident but uncertain expectation of achieving a future goal.

hospice System of family-centered care designed to help terminally ill people be comfortable and maintain a satisfactory lifestyle throughout the terminal phase of their illness.

Hoyer lift Mechanical device that uses a canvas sling to easily lift dependent patients for transfer.

humidification Process of adding water to gas.

humor Coping strategy based on an individual's cognitive appraisal of a stimulus that results in behavior such as smiling, laughing, or feelings of amusement that lessen emotional distress.

hydrocephalus Abnormal accumulation of cerebrospinal fluid in the ventricles of the brain.

hydrostatic pressure Pressure caused by a liquid.

hyperactive/overactive bladder Common bladder complaint that occurs more frequently with aging and includes the symptoms of urgency, frequency, nocturia, and urge incontinence.

hypercalcemia Greater-than-normal amount of calcium in the blood.

hypercapnia Greater-than-normal amounts of carbon dioxide in the blood; also called hypercarbia.

hyperextension Position of maximal extension of a joint.

hyperglycemia Elevated serum glucose levels.

hypertension Disorder characterized by an elevated blood pressure persistently exceeding 120/80 mm Hg.

hyperthermia Situation in which body temperature exceeds the set point.

hypertonic Situation in which one solution has a greater concentration of solute than another; therefore the first solution exerts greater osmotic pressure.

hypertonicity Excessive tension of the arterial walls or muscles.

hyperventilation Respiratory rate in excess of that required to maintain normal carbon dioxide levels in the body tissues.

hypnotics Class of drug that causes insensibility to pain and induces sleep.

hypostatic pneumonia Pneumonia that results from fluid accumulation as a result of inactivity.

hypotension Abnormal lowering of blood pressure that is inadequate for normal perfusion and oxygenation of tissues.

hypothermia Abnormal lowering of body temperature below 35° C, or 95° F, usually caused by prolonged exposure to cold.

hypotonic Situation in which one solution has a smaller concentration of solute than another; therefore the first solution exerts less osmotic pressure.

hypotonicity Reduced tension of the arterial walls or muscles.

hypoventilation Respiratory rate insufficient to prevent carbon dioxide retention.

hypovolemia Abnormally low circulating blood volume.

hypoxemia Arterial blood oxygen level less than 60 mm Hg; low oxygen level in the blood.

hypoxia Inadequate cellular oxygenation that may result from a deficiency in the delivery or use of oxygen at the cellular level.

I

identity Component of self-concept characterized by one's persisting consciousness of being oneself, separate and distinct from others.

idiosyncratic reaction Individual sensitivity to effects of a drug caused by inherited or other bodily constitution factors.

illness (1) Abnormal process in which any aspect of a person's functioning is diminished or impaired compared with his or her previous condition. (2) The personal, interpersonal, and cultural reaction to disease.

illness behavior Ways in which people monitor their bodies, define and interpret their symptoms, take remedial actions, and use the health care system.

illness prevention Health education programs or activities directed toward protecting patients from threats or potential threats to health and minimizing risk factors.

immobility Inability to move about freely; caused by any condition in which movement is impaired or therapeutically restricted.

immunity Quality of being insusceptible to or unaffected by a particular disease or condition.

immunization Process by which resistance to an infectious disease is induced or augmented.

implementation Initiation and completion of the nursing actions necessary to help the patient achieve health care goals.

impression management Ability to interpret others' behavior within their own context of meanings and behave in a culturally congruent way to achieve desired outcomes of communication.

incentive spirometry Method of encouraging voluntary deep breathing by providing visual feedback to patients of the inspiratory volume they have achieved.

incident rates Rate of new cases of a disease in a specified population over a defined period of time.

incident report Confidential document that describes any patient accident while the person is on the premises of a health care agency. (See occurrence report.)

independent practice association (IPA) Managed care organization that contracts with physicians or health care providers who usually are members of groups and whose practices include fee-for-service and capitated patients.

indirect care interventions Treatments performed away from the patient but on behalf of the patient or group of patients.

induration Hardening of a tissue, particularly the skin, because of edema or inflammation.

infection Invasion of the body by pathogenic microorganisms that reproduce and multiply.

inference (1) Judgment or interpretation of informational cues. (2) Taking one proposition as a given and guessing that another proposition follows.

infiltration Dislodging an intravenous catheter or needle from a vein into the subcutaneous space.

inflammation Protective response of body tissues to irritation or injury.

informed consent Process of obtaining permission from a patient to perform a specific test or procedure after describing all risks, side effects, and benefits.

infusion pump Device that delivers a measured amount of fluid over a period of time.

infusions Introduction of fluid into the vein, giving intravenous fluid over time.

inhalation Method of medication delivery through the patient's respiratory tract. The respiratory tract provides a large surface area for drug absorption. Inhalation can be through the nasal or oral route.

injections Parenteral administration of medication; four major sites of injection: subcutaneous, intramuscular, intravenous, and intradermal.

inpatient prospective payment system (IPPS) Payment mechanism for reimbursing hospitals for inpatient health care services in which a predetermined rate is set for treatment of specific illnesses.

input For the nursing process, the data or information that comes from a patient's assessment.

insensible water loss Water loss that is continuous and not perceived by the person.

insomnia Condition characterized by chronic inability to sleep or remain asleep through the night.

inspection Method of physical examination by which the patient is visually and systematically examined for appearance, structure, function, and behavior.

instillation To cause to enter drop by drop or very slowly.

institutional ethics committee Interdisciplinary committee that discusses and processes ethical dilemmas that arise within a health care institution.

instrumental activities of daily living (IADLs) Activities necessary for independence in society beyond eating, grooming, transferring, and toileting; include such skills as shopping, preparing meals, banking, and taking medications.

integrated delivery network (IDN) Set of providers and services organized to deliver a coordinated continuum of care to the population of patients served at a capitated cost.

interpersonal communication Exchange of information between two persons or among persons in a small group.

interstitial fluid Fluid that fills the spaces between most of the cells of the body and provides a substantial portion of the liquid environment of the body.

interview Organized, systematic conversation with the patient designed to obtain pertinent health-related subjective information.

intracellular fluid Liquid within the cell membrane.

intra dermal (ID) Injection given between layers of the skin into the dermis. Injections are given at a 5- to 15-degree angle.

intramuscular (IM) Injections given into muscle tissue. The intramuscular route provides a fast rate of absorption that is related to the greater vascularity of the muscle. Injections are given at a 90-degree angle.

intraocular Method of medication delivery that involves inserting a medication disk similar to a contact lens into the patient's eye.

intrapersonal communication Communication that occurs within an individual (i.e., people "talk with themselves" silently or form an idea in their own mind).

intravascular fluid Fluid circulating within blood vessels of the body.

intravenous Injection directly into the bloodstream. Action of the drug begins immediately when given intravenously.

intravenous fat emulsions Soybean- or safflower oil-based solutions that are isotonic and may be infused with amino acid and dextrose solution through a central or peripheral line.

intubation Insertion of a breathing tube through the mouth or nose into the trachea to ensure a patent airway.

intuition Inner sensing that something is so.

irrigation Process of washing out a body cavity or wounded area with a stream of fluid.

ischemia Decreased blood supply to a body part such as skin tissue or to an organ such as the heart.

isolation Separation of a seriously ill patient from others to prevent the spread of an infection or protect the patient from irritating environmental factors.

isometric exercises Activities that involve muscle tension without muscle shortening, do not have any beneficial effect on preventing orthostatic hypotension but may improve activity tolerance.

isotonic Situation in which two solutions have the same concentration of solute; therefore both solutions exert the same

osmotic pressure.

J

jaundice Yellow discoloration of the skin, mucous membranes, and sclera caused by greater-than-normal amounts of bilirubin in the blood.

jejunostomy tube Hollow tube inserted into the jejunum through the abdominal wall for administration of liquefied foods to patients who have a high risk of aspiration.

joint contracture Abnormality that may result in permanent condition of a joint; is characterized by flexion and fixation; and is caused by disuse, atrophy, and shortening of muscle fibers and surrounding joint tissues.

joints Connections between bones; classified according to structure and degree of mobility.

judgment Ability to form an opinion or draw sound conclusions.

justice Ethical standard of fairness.

K

Kardex Trade name for card-filing system that allows quick reference to the particular need of the patient for certain aspects of nursing care.

karma Asian Indian belief that attributes mental illness to past deeds in one's previous life.

knowing the patient An in-depth knowledge of the patient's patterns of responses; fosters skilled clinical decision making.

Korotkoff sound Sound heard during the taking of blood pressure using a sphygmomanometer and stethoscope.

Kussmaul respiration Increase in both rate and depth of respirations.

kyphosis Exaggeration of the posterior curvature of the thoracic spine.

L

la cuarentena Period of rest and restricted physical activity after childbirth that usually lasts 40 days.

laceration Torn, jagged wound.

language Code that conveys specific meaning as words are combined.

laryngospasm Sudden uncontrolled contraction of the laryngeal muscles, which in turn decreases airway size.

lateral violence Hostile, aggressive, and harmful verbal and nonverbal behavior by a nurse to another nurse via attitudes, actions, words, or behaviors. This behavior includes criticizing, intimidations, blaming, fighting, public humiliation, isolating, withholding assistance, or undermining efforts in completing assignments. This leaves the nurse feeling bullied, inadequate and powerless.

law Rule, standard, or principle that states a fact or relationship between factors.

laxatives Drugs that act to promote bowel evacuation.

learning Acquisition of new knowledge and skills as a result of reinforcement, practice, and experience.

learning objective Written statement that describes the behavior that a teacher expects from an individual after a learning activity.

left-sided heart failure Abnormal condition characterized by impaired functioning of the left ventricle caused by elevated pressures and pulmonary congestion.

leukoplakia Thick, white patches observed on oral mucous membranes.

licensed practical nurse (LPN) Also known as the licensed vocational nurse (LVN) or in Canada, registered nurse's assistant (RNA); trained in basic nursing skills and the provision of direct patient care.

licensed vocational nurse (LVN) The LVN is the same as a licensed practical nurse (LPN), an individual trained in the United States in basic nursing techniques and direct patient care who practices under the supervision of a registered nurse. The LVN is licensed by a board after completing what is usually a 12-month educational program and passing a licensure examination. In Canada an LVN is called a certified nursing assistant.

lipids Compounds that are insoluble in water but soluble in organic solvents.

lipogenesis Process during which fatty acids are synthesized.

living wills Instruments by which a dying person makes wishes known.

local anesthesia Loss of sensation at the desired site of action.

logroll Maneuver used to turn a reclining patient from one side to the other or completely over without moving the spinal column out of alignment.

lordosis Increased lumbar curvature.

M

maceration Softening and breaking down of skin from prolonged exposure to moisture.

mal de ojo Evil eye.

malignant hyperthermia Autosomal-dominant trait characterized by often fatal hyperthermia in affected people exposed to certain anesthetic agents.

malpractice Injurious or unprofessional actions that harm another.

malpractice insurance Type of insurance to protect the health care professional. In case of a malpractice claim, the insurance pays the award to the plaintiff.

managed care Health care system in which there is administrative control over primary health care services. Redundant facilities and services are eliminated, and costs are reduced. Preventive care and health education are emphasized.

Maslow's hierarchy of needs Model developed by Abraham Maslow that is used to explain human motivation.

matrilineal Kinship that is limited to only the mother's side.

maturation Genetically determined biological plan for growth and development. Physical growth and motor development are a function of maturation.

maturational loss Loss, usually of an aspect of self, resulting from the normal changes of growth and development.

Medicaid State medical assistance to people with low incomes, based on Title XIX of the Social Security Act. States receive matching federal funds to provide medical care and services to people meeting categorical and income requirements.

medical asepsis Procedures used to reduce the number of microorganisms and prevent their spread.

medical diagnosis Formal statement of the disease entity or illness made by the physician or health care provider.

medical record Patient's chart; a legal document.

Medicare Federally funded national health insurance program in the United States for people over 65 years of age. The program is administered in two parts. Part A provides basic protection against costs of medical, surgical, and psychiatric hospital care. Part B is a voluntary medical insurance program financed in part from federal funds and in part from premiums contributed by people enrolled in the program.

medication abuse Maladaptive pattern of recurrent medication use.

medication allergy Adverse reaction such as rash, chills, or gastrointestinal disturbances to a medication. Once a drug allergy occurs, the patient can no longer receive that particular medication.

medication dependence Maladaptive pattern of medication use in the following patterns: using excessive amounts of the medication, increased activities directed toward obtaining the medication, or withdrawal from professional or recreational activities.

medication error Any event that could cause or lead to a patient's receiving inappropriate drug therapy or failing to receive appropriate drug therapy.

medication interaction Response that occurs when one drug modifies the action of another drug. The interaction can potentiate or diminish the actions of another drug, or it may alter the way a drug is metabolized, absorbed, or excreted.

melanoma Group of malignant neoplasms, primarily of the skin, that are composed of melanocytes. Common in fair-skinned people having light-colored eyes and in those who have been sunburned.

melena Abnormal black, sticky stool containing digested blood that is indicative of gastrointestinal bleeding.

menarche Onset of a girl's first menstruation.

Ménière's disease Chronic disease of the inner ear characterized by recurrent episodes of vertigo; progressive sensorineural hearing loss, which may be bilateral; and tinnitus.

menopause Physiological cessation of ovulation and menstruation that typically occurs during middle adulthood in women.

message Information sent or expressed by sender in the communication process.

metabolic acidosis Abnormal condition of high hydrogen ion concentration in the extracellular fluid caused by either a primary increase in hydrogen ions or a decrease in bicarbonate.

metabolic alkalosis Abnormal condition characterized by the significant loss of acid from the body or increased levels of bicarbonate.

metabolism Aggregate of all chemical processes that take place in living organisms and result in growth, generation of energy, elimination of wastes, and other functions concerned with the distribution of nutrients in the blood after digestion.

metacommunication Dependent not only on what is said but also on the relationship to the other person involved in the interaction. It is a message that conveys the sender's attitude toward self and the message and the attitudes, feelings, and intentions toward the listener.

metastasize Spread of tumor cells to distant parts of the body from a primary site (e.g., lung, breast, or bowel).

metatheory An area of study that examines the relationships of various components that make up the knowledge of a discipline,

including philosophical, theoretical, and empirical components that provide a broad overview of the discipline.

metered-dose inhaler (MDI) Device designed to deliver a measured dose of an inhalation drug.

metric system Logically organized decimal system of measurement; metric units can easily be converted and computed through simple multiplication and division. Each basic unit of measurement is organized into units of 10.

microorganisms Microscopic entities such as bacteria, viruses, and fungi that are capable of carrying on living processes.

micturition Urination; act of passing or expelling urine voluntarily through the urethra.

milliequivalent per liter (mEq/L) Number of grams of a specific electrolyte dissolved in 1 L of plasma.

mindfulness A moment-to-moment present awareness with an attitude of nonjudgment, acceptance, and openness. Mindfulness meditative practices are effective in reducing psychological and physical symptoms or perceptions of stress.

mind mapping Graphic approach to represent the connections between concepts and ideas (e.g., nursing diagnoses) that are related to a central subject (e.g., the patient's health problems).

minerals Inorganic elements essential to the body because of their role as catalysts in biochemical reactions.

minimum data set (MDS) Required by the Omnibus Budget Reconciliation Act of 1987, the MDS is a uniform data set established by the Department of Health and Human Services. It serves as the framework for any state-specified assessment instruments used to develop a written and comprehensive plan of care for newly admitted residents of nursing facilities.

minimum effective concentration (MEC) The plasma level of a medication below which the effect of the medication does not occur.

misdemeanor Lesser crime than a felony; the penalty is usually a fine or imprisonment for less than 1 year.

mobility Person's ability to move about freely.

moderate sedation/analgesia/conscious sedation Administration of central nervous system depressant drugs and/or analgesics to provide analgesia, relieve anxiety, and/or provide amnesia during surgical, diagnostic, or interventional procedures. Routinely used for diagnostic or therapeutic procedures that do not require complete anesthesia but simply a decreased level of consciousness.

monosaturated fatty acid Fatty acid in which some of the carbon atoms in the hydrocarbon chain are joined by double or triple bonds. Monounsaturated fatty acids have only one double or triple bond per molecule and are found as components of fats in such foods as fowls, almonds, pecans, cashew nuts, peanuts, and olive oil.

morals Personal conviction that something is absolutely right or wrong in all situations.

motivation Internal impulse that causes a person to take action.

motivational interviewing Interview technique used to identify patients' thoughts, beliefs, fears, and current health care behavior with the aim of helping them to identify improved self-care behaviors.

mourning Process of grieving.

murmurs Blowing or whooshing sounds created by changes in blood flow through the heart or abnormalities in valve closure.

muscle tone Normal state of balanced muscle tension.

myocardial contractility Measure of stretch of the cardiac muscle fiber. It can also affect stroke volume and cardiac output. Poor contraction decreases the amount of blood ejected by the ventricles during each contraction.

myocardial infarction Necrosis of a portion of cardiac muscle caused by obstruction in a coronary artery.

myocardial ischemia Condition that results when the supply of blood to the myocardium from the coronary arteries is insufficient to meet the oxygen demands of the organ.

N

NANDA International North American Nursing Diagnosis Association, organized in 1973. It formally identifies, develops, and classifies nursing diagnoses.

narcolepsy Syndrome involving sudden sleep attacks that a person cannot inhibit. Uncontrollable desire to sleep may occur several times during a day.

nasogastric (NG) tube Tube passed into the stomach through the nose to empty the stomach of its contents or deliver medication and/or nourishment.

nebulization Process of adding moisture to inspired air by adding water droplets.

necessary losses Losses that every person experiences.

necrotic Of or pertaining to the death of tissue in response to disease or injury.

negative health behaviors Practices actually or potentially harmful to health such as smoking, drug or alcohol abuse, poor diet, and

refusal to take necessary medications.

negative nitrogen balance Condition occurring when the body excretes more nitrogen than it takes in.

negligence Careless act of omission or commission that results in injury to another.

neonate Stage of life from birth to 1 month of age.

nephrons Structural and functional units of the kidney containing renal glomeruli and tubules.

neurotransmitter Chemical that transfers the electrical impulse from the nerve fiber to the muscle fiber.

Never Events Serious incidents that are wholly preventable because guidance or safety recommendations that provide strong systemic protective barriers are available at a national level and should have been implemented by all health care providers.

nociceptors Somatic and visceral free nerve endings of thinly myelinated and unmyelinated fibers. They usually react to tissue injury but may also be excited by endogenous chemical substances.

nocturia Urination at night; can be a symptom of renal disease or may occur in persons who drink excessive amounts of fluids before bedtime.

nonblanchable hyperemia Redness of the skin caused by dilation of the superficial capillaries. The redness persists when pressure is applied to the area, indicating tissue damage.

noninvasive positive-pressure ventilation (NPPV) Used to prevent using invasive artificial airways (endotracheal [ET] tube or tracheostomy) in patients with acute respiratory failure, cardiogenic pulmonary edema, or exacerbation of chronic obstructive pulmonary disease. It has also been used following extubation of an ET tube.

nonmaleficence Fundamental ethical agreement to do no harm.
Closely related to the ethical standard of beneficence.

nonrapid eye movement (NREM) sleep Sleep that occurs during the first four stages of normal sleep.

nonshivering thermogenesis Occurs primarily in neonates. Because neonates cannot shiver, a limited amount of vascular brown adipose tissue present at birth can be metabolized for heat production.

nonverbal communication Communication using expressions, gestures, body posture, and positioning rather than words.

normal sinus rhythm (NSR) The wave pattern on an electrocardiogram that indicates normal conduction of an electrical impulse through the myocardium.

numbing One of Bowlby's four phases of mourning. It is characterized by a lack of feeling or by feeling stunned by a loss; may last a few days or many weeks.

nurse-initiated interventions Response of the nurse to the patient's health care needs and nursing diagnoses. This type of intervention is an autonomous action based on scientific rationale that is executed to benefit the patient in a predicted way related to the nursing diagnosis and patient-centered goals.

Nurse Practice Acts Statutes enacted by the legislature of any of the states or the appropriate officers of the districts or possessions that describe and define the scope of nursing practice.

Nursing Clinical Information System (NCIS) A system that incorporates the principles of nursing informatics to support the work that nurses do by facilitating documentation of nursing process activities and offering resources for managing nursing care delivery.

nursing diagnosis Formal statement of an actual or potential health problem that nurses can legally and independently treat; the second step of the nursing process, during which the patient's actual and potential unhealthy responses to an illness or condition are identified.

nursing health history Data collected about a patient's present level of wellness, changes in life patterns, sociocultural role, and mental and emotional reactions to illness.

nursing intervention Any treatment based on clinical judgment and knowledge that a nurse performs to enhance patient outcomes.

Nursing Outcomes Classification A systematic organization of nurse-sensitive outcomes into groups or categories based upon similarities, dissimilarities, and relationships among the outcomes.

nursing process Systematic problem-solving method by which nurses individualize care for each patient. The five steps of the nursing process are assessment, diagnosis, planning, implementation, and evaluation.

nursing-sensitive outcomes Outcomes that are within the scope of nursing practice; consequences or effects of nursing interventions that result in changes in the patient's symptoms, functional status, safety, psychological distress, or costs.

nurturant Behavior that involves caring for or fostering the well-being of another individual.

nutrients Foods that contain elements necessary for body function, including water, carbohydrates, proteins, fats, vitamins, and minerals.

O

obesity Abnormal increase in the proportion of fat cells, mainly in the viscera and subcutaneous tissues of the body.

objective data Information that can be observed by others; free of feelings, perceptions, prejudices.

occurrence report Confidential document that describes any patient accident while the person is on the premises of a health care agency. (See incident report.)

olfactory Pertaining to the sense of smell.

oncotic pressure Total influence of the protein on the osmotic activity of plasma fluid.

open-ended question Form of question that prompts a respondent to answer in more than one or two words.

operating bed Table for surgery.

operating room (1) Room in a health care facility in which surgical procedures requiring anesthesia are performed. (2) Informal: a suite of rooms or an area in a health care facility in which patients are prepared for surgery, undergo surgical procedures, and recover from the anesthetic procedures required for the surgery.

ophthalmic Drugs given into the eye in the form of either eye drops or ointments.

ophthalmoscope Instrument used to illuminate the structures of the eye to examine the fundus, which includes the retina, choroid, optic nerve disc, macula, fovea centralis, and retinal vessels.

opioid Drug substance derived from opium or produced synthetically that alters perception of pain and that, with repeated use, may result in physical and psychological dependence (narcotic).

oral hygiene Condition or practice of maintaining the tissues and structures of the mouth.

orthopnea Abnormal condition in which a person must sit or stand to breathe comfortably.

orthostatic hypotension Abnormally low blood pressure occurring when a person stands.

osmolality Concentration or osmotic pressure of a solution expressed in osmoles or milliosmoles per kilogram of water.

osmolarity Osmotic pressure of a solution expressed in osmoles or milliosmoles per kilogram of the solution.

osmoreceptors Neurons in the hypothalamus that are sensitive to the fluid concentration in the blood plasma and regulate the secretion of antidiuretic hormone.

osmosis Movement of a pure solvent through a semipermeable membrane from a solution with a lower solute concentration to one with a higher solute concentration.

osmotic pressure Drawing power for water, which depends on the number of molecules in the solution.

osteoporosis Disorder characterized by abnormal rarefaction of bone, occurring most frequently in postmenopausal women, sedentary or immobilized individuals, and patients on long-term steroid therapy.

ostomy Surgical procedure in which an opening is made into the abdominal wall to allow the passage of intestinal contents from the bowel (colostomy) or urine from the bladder (urostomy).

other provider interventions Therapies that require the combined knowledge, skill, and expertise of multiple health care providers; also called *interdependent interventions*.

otoscope Instrument with a special ear speculum used to examine the deeper structures of the external and middle ear.

ototoxic Having a harmful effect on the eighth cranial (auditory) nerve or the organs of hearing and balance.

outcome Condition of a patient at the end of treatment, including the degree of wellness and the need for continuing care, medication, support, counseling, or education.

outliers Patients with extended lengths of stay beyond allowable inpatient days or costs.

outpatient Patient who has not been admitted to a hospital but receives treatments in a clinic or facility associated with the hospital.

output The product and information obtained from the system.

oxygen desaturation A decrease in oxygen concentration in the blood resulting from any condition that affects the exchange of carbon dioxide and oxygen.

oxygen saturation Amount of hemoglobin fully saturated with oxygen, given as a percent value.

oxygen therapy Procedure in which oxygen is administered to a patient to relieve or prevent hypoxia.

P

pain Subjective, unpleasant sensation caused by noxious stimulation of sensory nerve endings.

palliative care Level of care that is designed to relieve or reduce intensity of uncomfortable symptoms but not to produce a cure. Palliative care relies on comfort measures and use of alternative

therapies to help individuals become more at peace during end of life.

pallor Unnatural paleness or absence of color in the skin.

palpation Method of physical examination whereby the fingers or hands of the examiner are applied to the patient's body to feel body parts underlying the skin.

palpitations Bounding or racing of the heart associated with normal emotions or a heart disorder.

Papanicolaou (Pap) smear Painless screening test for cervical cancer. Specimens are taken of squamous and columnar cells of the cervix.

parallel play Form of play among a group of children, primarily toddlers, in which each one engages in an independent activity that is similar to but not influenced by or shared with the others.

paralytic ileus Usually temporary paralysis of intestinal wall that may occur after abdominal surgery or peritoneal injury and that causes cessation of peristalsis; leads to abdominal distention and symptoms of obstruction.

parenteral administration Giving medication by a route other than the gastrointestinal tract.

parenteral nutrition (PN) Administration of a nutritional solution into the vascular system.

parteras Lay midwives.

partial bed bath Bath in which body parts that might cause the patient discomfort if left unbathed (i.e., face, hands, axillary areas, back, and perineum) are washed in bed.

passive range-of-motion (PROM) exercises Range of movement through which a joint is moved with assistance.

passive strategies of health promotion Activities that involve the patient as the recipient of actions by health care professionals.

pathogenicity Ability of a pathogenic agent to produce a disease.

pathogens Microorganisms capable of producing disease.

pathological fractures Fractures resulting from weakened bone tissue; frequently caused by osteoporosis or neoplasms.

patient-centered care Concept to improve work efficiency by changing the way that patient care is delivered.

patient- and family-centered care Model of nursing care in which mutual partnerships between the patient, family and health care team are formed to plan, implement and evaluate the nursing and health care delivered.

patient-controlled analgesia (PCA) Drug delivery system that allows patients to self-administer analgesic medications on demand.

patrilineal, patrilineally Kinship that is limited to only the father's side.

pay for performance Quality improvement program that rewards excellence through financial incentives to motivate change to achieve measurable improvements and improve patient care quality and safety.

perceived loss Loss that is less obvious to others. Although easily overlooked or misunderstood, a perceived loss results in the same grief process as an actual loss.

perception An individual's mental image or concept of elements in their environment, including information gained through the senses.

percussion Method of physical examination whereby the location, size, and density of a body part is determined by the tone obtained from the striking of short, sharp taps of the fingers.

perfusion (1) Passage of a fluid through a specific organ or an area of the body. (2) Therapeutic measure whereby a drug intended for an isolated part of the body is introduced via the bloodstream. (3) Relates to the ability of the cardiovascular system to pump oxygenated blood to the tissues and return deoxygenated blood to the lungs.

perineal care Procedure prescribed for cleaning the genital and anal areas as part of the daily bath or after various obstetrical and gynecological procedures.

perioperative nursing Refers to the role of the operating room nurse during the preoperative, intraoperative, and postoperative phases of surgery.

peripherally inserted central catheter (PICC) Alternative intravenous access when the patient requires intermediate-length venous access greater than 7 days to 3 months. Intravenous access is achieved by inserting a catheter into a central vein by way of a peripheral vein.

peristalsis Rhythmical contractions of the intestine that propel gastric contents through the length of the gastrointestinal tract.

peritonitis Inflammation of the peritoneum produced by bacteria or irritating substances introduced into the abdominal cavity by a penetrating wound or perforation of an organ in the gastrointestinal or reproductive tract.

PERRLA Acronym for “pupils equal, round, reactive to light, accommodation”; the acronym is recorded in the physical examination if eye and pupil assessments are normal.

personalismo Personalistic.

petechiae Tiny purple or red spots that appear on skin as minute hemorrhages within dermal layers.

pharmacokinetics Study of how drugs enter the body, reach their site of action, are metabolized, and exit from the body.

phlebitis Inflammation of a vein.

physician-initiated interventions Based on the physician's response to a medical diagnosis, the nurse responds to his or her written orders.

PIE note Problem-oriented medical record; the four interdisciplinary sections are the database, problem list, care plan, and progress notes.

placebos Dosage form that contains no pharmacologically active ingredients but may relieve pain through psychological effects.

plaintiff Individual who files formal charges against an individual or organization for a legal offense.

planning Process of designing interventions to achieve the goals and outcomes of health care delivery.

plantar flexion Toe-down motion of the foot at the ankle.

pleural friction rub Adventitious lung sound caused by inflamed parietal and visceral pleura rubbing together on inspiration.

pneumothorax Collection of air or gas in the pleural space.

point of maximal impulse (PMI) Point where the heartbeat can most easily be palpated through the chest wall. This is usually the fourth intercostal space at the midclavicular line.

point of view Way of looking at issues that reflects an individual's culture and societal influences.

poison Any substance that impairs health or destroys life when ingested, inhaled, or absorbed by the body in relatively small amounts.

poison control center One of a network of facilities that provides information regarding all aspects of poisoning or intoxication, maintains records of their occurrence, and refers patients to treatment centers.

polypharmacy Use of a number of different drugs by a patient who may have one or several health problems.

polyunsaturated fatty acid Fatty acid that has two or more carbon double bonds.

population Collection of individuals who have in common one or more personal or environmental characteristics.

positive health behaviors Activities related to maintaining, attaining, or regaining good health and preventing illness. Common positive health behaviors include immunizations, proper sleep patterns, adequate exercise, and nutrition.

postanesthesia care unit (PACU) Area adjoining the operating room to which surgical patients are taken while still under anesthesia.

postmortem care Care of a patient's body after death.

postural drainage Use of positioning along with percussion and vibration to drain secretions from specific segments of the lungs and bronchi into the trachea.

postural hypotension Abnormally low blood pressure occurring when an individual assumes the standing posture; also called orthostatic hypotension.

posture Position of the body in relation to the surrounding space.

power of attorney for health care Person designated by the patient to make health care decisions for the patient if the patient becomes unable to make his or her own decisions.

preadolescence Transitional developmental stage that occurs between childhood and adolescence.

preanesthesia care unit Area outside the operating room where preoperative preparations are completed.

preload Volume of blood in the ventricles at the end of diastole, immediately before ventricular contraction.

preoperative teaching Instruction regarding a patient's anticipated surgery and recovery that is given before surgery. Instruction includes, but is not limited to, dietary and activity restrictions, anticipated assessment activities, postoperative procedures, and pain-relief measures.

presbycusis Hearing loss associated with aging. It usually involves both a loss of hearing sensitivity and a reduction in the clarity of speech.

presbyopia Gradual decline in ability of the lens to accommodate or focus on close objects; reduces ability to see near objects clearly. This condition commonly develops with advancing age.

prescriptions Written directions for a therapeutic agent (e.g., medication, drugs).

presence Deep physical, psychological, and spiritual connection or engagement between a nurse and patient.

present time orientation Time dimension that focuses on what is happening here and now. Communication patterns are circular, and this time orientation is in conflict with the dominant organizational norm in health care that emphasizes punctuality and adherence to appointments.

pressure injury Inflammation, sore, or ulcer in the skin over a bony prominence.

presurgical care unit (PSCU) Area outside the operating room where preoperative preparations are completed.

preventive nursing actions Nursing actions directed toward preventing illness and promoting health to avoid the need for primary, secondary, or tertiary health care.

primary appraisal Evaluating an event for its personal meaning related to stress.

primary care First contact in a given episode of illness that leads to a decision regarding a course of action to resolve the health problem.

primary health care Combination of primary and public health care that is accessible to individuals and families in a community and provided at an affordable cost.

primary intention Primary union of the edges of a wound, progressing to complete scar formation without granulation.

primary nursing Method of nursing practice in which the patient's care is managed for the duration by one nurse who directs and coordinates other nurses and health care personnel. When on duty, the primary nurse cares for the patient directly.

primary prevention First contact in a given episode of illness that leads to a decision regarding a course of action to prevent worsening of the health problem.

problem-focused diagnosis A clinical judgment concerning an undesirable human response to a health condition/life process that exists in an individual, family or community.

problem identification One of the steps of the diagnostic process in which the patient's health care problem is recognized as a result

of data analysis based on professional knowledge and experience.

problem-oriented medical record (POMR) Method of recording data about the health status of a patient that fosters a collaborative problem-solving approach by all members of the health care team.

problem solving Methodical, systematic approach to explore conditions and develop solutions, including analysis of data, determination of causative factors, and selection of appropriate actions to reverse or eliminate the problem.

productive cough Sudden expulsion of air from the lungs that effectively removes sputum from the respiratory tract and helps clear the airways.

professional standards review organization (PSRO) Focuses on evaluation of nursing care provided in a health care setting. The quality, effectiveness, and appropriateness of nursing care for the patient are the focus of evaluation.

prone Position of the patient lying face down.

proprioception Ability of the body to sense its position and movement in space.

prostaglandins Potent hormonelike substances that act in exceedingly low doses on target organs. They can be used to treat asthma and gastric hyperacidity.

proteins Any of a large group of naturally occurring, complex, organic nitrogenous compounds. Each is composed of large combinations of amino acids containing the elements carbon; hydrogen; nitrogen; oxygen; usually sulfur; and occasionally phosphorus, iron, iodine, or other essential constituents of living cells. Protein is the major source of building material for muscles, blood, skin, hair, nails, and the internal organs.

proteinuria Presence in the urine of abnormally large quantities of protein, usually albumin. Persistent proteinuria is usually a sign of renal disease or renal complications of another disease, hypertension, or heart failure.

protocol Written and approved plan specifying the procedures to be followed during an assessment or in providing treatment.

pruritus Symptom of itching; an uncomfortable sensation leading to the urge to scratch.

psychomotor learning Acquisition of ability to perform motor skills.

ptosis Abnormal condition of one or both upper eyelids in which the eyelid droops; caused by weakness of the levator muscle or paralysis of the third cranial nerve.

puberty Developmental period of emotional and physical changes, including the development of secondary sex characteristics and the onset of menstruation and ejaculation.

public health nursing Nursing specialty that requires the nurse to care for the needs of populations or groups.

public communication Interaction of one individual with large groups of people.

pulmonary hygiene More frequent turning, deep breathing, coughing, use of incentive spirometry, and chest physical therapy (PT) if ordered.

pulse deficit Condition that exists when the radial pulse is less than the ventricular rate as auscultated at the apex or seen on an electrocardiogram. The condition indicates a lack of peripheral perfusion for some of the heart contractions.

pulse pressure Difference between the systolic and diastolic pressures, normally 30 to 40 mm Hg.

Purkinje network Complex network of muscle fibers that spread through the right and left ventricles of the heart and carry the impulses that contract those chambers almost simultaneously.

pursed-lip breathing Deep inspiration followed by prolonged expiration through pursed lips.

pyrexia Abnormal elevation of the temperature of the body above 37° C (98.6° F) because of disease; same as fever.

pyrogens Substances that cause a rise in body temperature, as in the case of bacterial toxins.

Q

QSEN The Quality and Safety in the Education of Nurses (QSEN) initiative is the commitment of nursing to the competencies outlined in the Institute of Medicine report related to nursing education. QSEN encompasses six competencies: patient-centered care, teamwork, collaboration, evidence-based practice, quality improvement, and safety.

quality improvement Monitoring and evaluation of processes and outcomes in health care or any other business to identify opportunities for improvement.

quality indicator Quantitative measure of an important aspect of care that determines whether quality of service conforms to requirements or standards of care.

R

race Common biological characteristics shared by a group of people.

racial identity One's self-identification with one or more social groups in which a common heritage with a racial group is shared.

Ramadan Religious observance held during the ninth month of the Islamic calendar year. It involves fasting from sunrise to sunset.

range of motion (ROM) Range of movement of a joint from maximum extension to maximum flexion as measured in degrees of a circle.

rapid eye movement (REM) sleep Stage of sleep in which dreaming and rapid eye movements are prominent; important for mental restoration.

reaction Component of the pain experience that may include both physiological responses, as in the general adaptation syndrome, and behavioral responses.

reality orientation Therapeutic modality for restoring an individual's sense of the present.

receiver Person to whom message is sent during the communication process.

reception Neurophysiological components of the pain experience in which nervous system receptors receive painful stimuli and transmit them through peripheral nerves to the spinal cord and brain.

record Written form of communication that permanently documents information relevant to health care management.

recovery Period of time immediately following surgery when the patient is closely observed for effects of anesthesia, changes in vital signs, and bleeding. The recovery area is usually in the postanesthesia care unit.

referent Factor that motivates a person to communicate with another individual.

reflection Process of thinking back or recalling an event to discover the meaning and purpose of that event. Useful in critical

thinking.

refractive error Defect in the ability of the lens of the eye to focus light such as occurs in nearsightedness and farsightedness.

regional anesthesia Loss of sensation in an area of the body supplied by sensory nerve pathways.

registered nurse (RN) In the United States a nurse who has completed a course of study at a state-approved, accredited school of nursing and has passed the National Council Licensure Examination (NCLEX-RN).

regression Return to an earlier developmental stage or behavior.

regulatory agencies Local, state, provincial, or national agencies that inspect and certify health care agencies as meeting specified standards. These agencies can also determine the amount of reimbursement for health care delivered.

rehabilitation Restoration of an individual to normal or near-normal function after a physical or mental illness, injury, or chemical addiction.

reinforcement Provision of a contingent response to a learner's behavior that increases the probability of recurrence of the behavior.

related factor Any condition or event that accompanies or is linked with the patient's health care problem.

relaxation Act of being relaxed or less tense.

reminiscence Recalling the past to assign new meaning to past experiences.

remissions Partial or complete disappearances of the clinical and subjective characteristics of chronic or malignant disease; remission may be spontaneous or the result of therapy.

renal calculi Calcium stones in the renal pelvis.

renin Proteolytic enzyme produced by and stored in the juxtaglomerular apparatus that surrounds each arteriole as it enters a glomerulus. The enzyme affects the blood pressure by catalyzing the change of angiotensinogen to angiotensin, a strong repressor.

reorganization Last phase of Bowlby's phases of mourning. During this phase, which sometimes requires a year or more, the person begins to accept unaccustomed roles, acquire new skills, and build new relationships.

report Transfer of information from the nurses on one shift to the nurses on the following shift. Report may also be given by one of the members of the nursing team to another health care provider (e.g., a physician or therapist).

reservoir Place where microorganisms survive, multiply, and await transfer to a susceptible host.

residual urine Volume of urine remaining in the bladder after a normal voiding; the bladder normally is almost completely empty after micturition.

resistance stage Third stage of the stress response, when the person attempts to adapt to the stressor. The body stabilizes; hormone levels stabilize; and heart rate, blood pressure, and cardiac output return to normal.

resource utilization group (RUG) Method of classification for health care reimbursement for long-term care facilities.

respeto Respectful.

respiration Exchange of oxygen and carbon dioxide during cellular metabolism.

respiratory acidosis Abnormal condition characterized by increased arterial carbon dioxide concentration, excess carbonic acid, and increased hydrogen ion concentration.

respiratory alkalosis Abnormal condition characterized by decreased arterial carbon dioxide concentration and hydrogen ion concentration.

respite care Short-term health services to dependent older adults either in their homes or in an institutional setting.

responsibility Carrying out duties associated with a particular role.

restorative care Health care settings and services in which patients who are recovering from illness or disability receive rehabilitation and supportive care.

restraint Device to aid in the immobilization of a patient or patient's extremity.

return demonstration Demonstration after the patient has first observed the teacher and then practiced the skill in mock or real situations.

rhonchi Abnormal lung sound auscultated when the patient's airways are obstructed with thick secretions.

right-sided heart failure Abnormal condition that results from impaired functioning of the right ventricle; characterized by venous congestion in the systemic circulation.

risk factor Any internal or external variable that makes a person or group more vulnerable to illness or an unhealthy event.

risk management Function of hospital or other health facility administration that is directed toward identification, evaluation, and correction of potential risks that could lead to injury of patients, staff members, or visitors and result in property loss or damage.

risk nursing diagnosis A clinical judgment concerning the vulnerability of an individual, family, group, or community for developing an undesirable human response to health conditions/life processes.

role performance Way in which a person views his or her ability to carry out significant roles.

root cause analysis Process of data collection and analysis that aids in finding the real cause of the problem and working on dealing with it rather than just dealing with its effects.

S

Sabbath From sundown on Friday to sundown on Saturday, this religious observance is a day of rest and worship for Jews and some Christian sects.

sandbags Sand-filled plastic tubes that can be shaped to body contours. They can immobilize an extremity or maintain body alignment.

saturated fatty acid Fatty acid in which each carbon in the chain has an attached hydrogen atom.

scientific method Codified sequence of steps used in the formulation, testing, evaluation, and reporting of scientific ideas.

scientific rationale Reason why a specific nursing action was chosen based on supporting literature.

scoliosis Lateral spinal curvature.

scope of nursing practice A professional definition of what a nurse is licensed to perform.

scrub nurse Registered nurse or operating room technician who assists surgeons during operations.

secondary appraisal Evaluating one's possible coping strategies when confronted with a stressor.

secondary intention Wound closure in which the edges are separated; granulation tissue develops to fill the gap; and, finally, epithelium grows in over the granulation, producing a larger scar than results with primary intention.

secondary prevention Level of preventive medicine that focuses on early diagnosis, use of referral services, and rapid initiation of treatment to stop the progress of disease processes.

sedatives Medications that produce a calming effect by decreasing functional activity, diminishing irritability, and allaying excitement.

segmentation Alternating contraction and relaxation of gastrointestinal mucosa.

self-concept Complex, dynamic integration of conscious and unconscious feelings, attitudes, and perceptions about one's identity, physical being, worth, and roles; how a person perceives and defines self.

self-esteem Feeling of self-worth characterized by feelings of achievement, adequacy, self-confidence, and usefulness.

self-transcendence Sense of authentically connecting to one's inner self.

sender Person who initiates interpersonal communication by conveying a message.

sensible water loss Loss of fluid from the body through the secretory activity of the sweat glands and the exhalation of humidified air from the lungs.

sensory deficits Defects in the function of one or more of the senses, resulting in visual, auditory, or olfactory impairments.

sensory deprivation State in which stimulation to one or more of the senses is lacking, resulting in impaired sensory perception.

sensory overload State in which stimulation to one or more of the senses is so excessive that the brain disregards or does not meaningfully respond to stimuli.

sequential compression stockings Plastic stockings attached to an air pump that inflates and deflates the stockings, applying intermittent pressure sequentially from the ankle to the knee.

serum half-life Time needed for excretion processes to lower the serum drug concentration by half.

sexual dysfunction Inability or difficulty in sexual functioning caused by physiological or psychological factors or both.

sexual identity How a person thinks about himself or herself sexually; it includes gender identity, gender role, and sexual orientation

sexual orientation Clear, persistent erotic preference for a person of one sex or the other.

sexuality "A function of the total personality ... concerned with the biological, psychological, sociological, spiritual and culture variables of life ..." (Sex Information and Education Council of the United States, 1980).

sexually transmitted infection Infectious process spread through sexual contact, including oral, genital, or anal sexual activity.

shear Force exerted against the skin while the skin remains stationary and the bony structures move.

side effect Any reaction or consequence that results from medication or therapy.

side rails Bars positioned along the sides of the length of the bed or stretcher to reduce the patient's risk of falling.

simpatia Friendly.

sinoatrial (SA) node Called the *pacemaker of the heart* because the origin of the normal heartbeat begins at the SA node. The SA node is in the right atrium next to the entrance of the superior vena cava.

situational crisis Unexpected crisis that arises suddenly in response to an external event or a conflict concerning a specific circumstance.

situational loss Loss of a person, thing, or quality resulting from a change in a life situation, including changes related to illness, body image, environment, and death.

sitz bath Bath in which only the hips or buttocks are immersed in fluid.

skilled nursing facility Institution or part of an institution that meets criteria for accreditation established by the sections of the Social Security Act that determine the basis for Medicaid and Medicare reimbursement for skilled nursing care, including rehabilitation and various medical and nursing procedures.

sleep State marked by reduced consciousness, diminished activity of the skeletal muscles, and depressed metabolism.

sleep apnea Cessation of breathing for a time during sleep.

sleep deprivation Condition resulting from a decrease in the amount, quality, and consistency of sleep.

SOAP note Progress note that focuses on a single patient problem and includes subjective and objective data, analysis, and planning; most often used in the problem-oriented medical record (POMR).

social determinants of health Factors that contribute to a person's current state of health. These factors may be biological, socioeconomic, psychosocial, behavioral, or social in nature.

socializing Interacting with friends or other people; communicating with others to form relationships and help people feel relaxed.

solute Substance dissolved in a solution.

solution Mixture of one or more substances dissolved in another substance. The molecules of each of the substances disperse homogeneously and do not change chemically. A solution may be a liquid, gas, or solid.

solvent Any liquid in which another substance can be dissolved.

source record Organization of a patient's chart so that each discipline (e.g., nursing, medicine, social work, or respiratory therapy) has a separate section in which to record data. Unlike POMR, the information is not organized by patient problems. The advantage of a source record is that caregivers can easily locate the proper section of the record in which to make entries.

sphygmomanometer Device for measuring the arterial blood pressure that consists of an arm or leg cuff with an air bladder connected to a tube, a bulb for pumping air into the bladder, and a gauge for indicating the amount of air pressure being exerted against the artery.

spiritual distress State of being out of harmony with a system of beliefs, a Supreme Being, or God.

spiritual well-being Individual's spirituality that enables a person to love, have faith and hope, seek meaning in life, and nurture relationships with others.

spirituality Spiritual dimension of a person, including the relationship with humanity, nature, and a Supreme Being.

standard of care Minimum level of care accepted to ensure high-quality care to patients. Standards of care define the types of therapies typically administered to patients with defined problems or needs.

Standard Precautions Guidelines recommended by the Centers for Disease Control and Prevention (CDC) to reduce risk of transmission of bloodborne and other pathogens in hospitals.

standardized care plans Written care plans used for groups of patients who have similar health care problems.

standing order Written and approved documents containing rules, policies, procedures, regulations, and orders for the conduct of patient care in various stipulated clinical settings.

statutory law Of or related to laws enacted by a legislative branch of the government.

stenosis Abnormal condition characterized by the constriction or narrowing of an opening or passageway in a body structure.

stereotypes Generalizations that are made about individuals without further assessment.

sterilization (1) Rendering a person unable to produce children; accomplished by surgical, chemical, or other means. (2) A technique for destroying microorganisms using heat, water, chemicals, or gases.

stoma Artificially created opening between a body cavity and the surface of the body (e.g., a colostomy formed from a portion of the colon pulled through the abdominal wall).

stress Physiological or psychological tension that threatens homeostasis or a person's psychological equilibrium.

stressor Any event, situation, or other stimulus encountered in a person's external or internal environment that necessitates

change or adaptation by the person.

striae Streaks or linear scars that result from rapid development of tension in the skin.

stroke volume (SV) Amount of blood ejected by the ventricles with each contraction. It can be affected by the amount of blood in the left ventricle at the end of diastole (preload), the resistance to left ventricular ejection (afterload), and myocardial contractility.

subacute care Level of medical specialty care provided to patients who need a greater intensity of care than that provided in a skilled nursing facility but who do not require acute care.

subcultures Various ethnic, religious, and other groups with distinct characteristics from the dominant culture.

subcutaneous (sub-Q) Injection given into the connective tissue under the dermis. The subcutaneous tissue absorbs drugs more slowly than those injected into muscle. Injections are usually given at a 45-degree angle.

subjective data Information gathered from patient statements; the patient's feelings and perceptions. Not verifiable by another except by inference.

sublingual Route of medication administration in which the medication is placed underneath the patient's tongue.

Sunrise Model A model developed by Leininger that aids the health care practitioner in designing care decisions and actions in a culturally congruent fashion.

supine Position of the patient in which the patient is resting on his or her back.

suprainfection Secondary infection usually caused by an opportunistic pathogen.

suprapubic catheter Catheter surgically inserted through abdomen into bladder.

surfactant Chemical produced in the lungs to maintain the surface tension of the alveoli and keep them from collapsing.

surgical asepsis Procedures used to eliminate any microorganisms from an area. Also called *sterile technique*.

sympathy Concern, sorrow, or pity felt by the nurse for the patient. Sympathy is a subjective look at another person's world that prevents a clear perspective of all sides of the issues confronting that person.

synapse Region surrounding the point of contact between two neurons or between a neuron and an effector organ.

syncope Brief lapse in consciousness caused by transient cerebral hypoxia.

synergistic effect Effect resulting from two drugs acting synergistically. The effect of the two drugs combined is greater than the effect that would be expected if the individual effects of the two drugs acting alone were added together.

systolic Pertaining to or resulting from ventricular contraction.

T

tachycardia Rapid regular heart rate ranging between 100 and 150 beats/min.

tachypnea Abnormally rapid rate of breathing.

tactile Relating to the sense of touch.

tactile fremitus Tremulous vibration of the chest wall during breathing that is palpable on physical examination.

teaching Implementation method used to present correct principles, procedures, and techniques of health care; to inform patients about their health status; and to refer patients and family to appropriate health or social resources in the community.

team nursing Decentralized system in which the care of a patient is distributed among the members of a team. The charge nurse delegates authority to a team leader, who must be a professional nurse.

teratogens Chemical or physiological agents that may produce adverse effects in the embryo or fetus.

tertiary prevention Activities directed toward rehabilitation rather than diagnosis and treatment.

therapeutic communication Process in which the nurse consciously influences a patient or helps the patient to a better understanding through verbal and/or nonverbal communication.

therapeutic effect Desired benefit of a medication, treatment, or procedure.

therapeutic range The safe therapeutic range is between the minimum effective concentration and the toxic concentration.

thermogenesis The physiological process of heat production in the body.

thermoregulation Internal control of body temperature.

threshold Point at which a person first perceives a painful stimulus as being painful.

thrill Continuous palpable sensation like the purring of a cat.

thrombus Accumulation of platelets, fibrin, clotting factors, and the cellular elements of the blood attached to the interior wall of a vein or artery, sometimes occluding the lumen of the vessel.

tinnitus Ringing heard in one or both ears.

tissue ischemia Point at which tissues receive insufficient oxygen and perfusion.

tolerance Point at which a person is not willing to accept pain of greater severity or duration.

tort Act that causes injury for which the injured party can bring civil action.

total patient care Nursing delivery of care model originally developed during Florence Nightingale's time. In the model a registered nurse (RN) is responsible for all aspects of care for one or more patients. The RN works directly with the patient, family, physician or health care provider, and health care team members. The model typically has a shift-based focus.

touch To come in contact with another person, often conveying caring, emotional support, encouragement, or tenderness.

toxic effect Effect of a medication that results in an adverse response.

tracheostomy Procedure whereby a surgical incision is made into the trachea and a short artificial airway (a tracheostomy tube) is inserted.

transcendence The belief that there is a force outside of and greater than the person that exists beyond the material world.

transcultural Concept of care extending across cultures that distinguishes nursing from other health disciplines.

transcultural nursing Distinct discipline developed by Leininger that focuses on the comparative study of cultures to understand similarities and differences among groups of people.

transcutaneous electrical nerve stimulation (TENS) Technique in which a battery- powered device blocks pain impulses from reaching the spinal cord by delivering weak electrical impulses directly to the surface of the skin.

transdermal disk Medication delivery device in which the medication is saturated on a waferlike disk, which is affixed to the patient's skin. This method ensures that the patient receives a continuous level of medication.

transfer report Verbal exchange of information between caregivers when a patient is moved from one nursing unit or health care setting to another. The report includes information necessary to maintain a consistent level of care from one setting to another.

transformational leadership A leadership style that focuses on change and innovation through effective communication and team building. Engagement, empowerment, and accountability are critical to team effectiveness.

transfusion reaction Systemic response by the body to the administration of blood incompatible with that of the recipient.

trapeze bar Metal triangular-shaped bar that can be suspended over a patient's bed from an overhanging frame; permits patients to move up and down in bed while in traction or some other encumbrance.

trimester Referring to one of the three phases of pregnancy.

trochanter roll Rolled towel support placed against the hips and upper leg to prevent external rotation of the legs.

trough The lowest serum concentration of a medication before the next medication dose is administered.

turgor Normal resiliency of the skin caused by the outward pressure of the cells and interstitial fluid.

U

unconscious/implicit bias A bias that an individual is unaware of and that happens outside his or her control; it is influenced by personal background, cultural environment, and personal experiences.

unsaturated fatty acid Fatty acid in which an unequal number of hydrogen atoms are attached and the carbon atoms attach to one another with a double bond.

ureterostomy Diversion of urine away from a diseased or defective bladder through an artificial opening in the skin.

urge incontinence A type of urinary incontinence that results from sudden, involuntary contraction of the muscles of the urinary bladder, resulting in an urge to urinate.

urinal Receptacle for collecting urine.

urinary diversion Surgical diversion of the drainage of urine such as a ureterostomy.

urinary incontinence Inability to control urination.

urinary reflux Abnormal, backward flow of urine.

urinary retention Retention of urine in the bladder; condition frequently caused by a temporary loss of muscle function.

urine hat Receptacle for collecting urine that fits toilet.

urometer Device for measuring frequent and small amounts of urine from an indwelling urinary catheter system.

urosepsis Organisms in the bloodstream.

utilitarianism Ethic that proposes that the value of something is determined by its usefulness. The greatest good for the greatest

number of people constitutes the guiding principle for action in a utilitarian model of ethics.

utilization review (UR) committees Physician-supervised committees to review admissions, diagnostic testing, and treatments provided by physicians or health care providers to patients.

V

validation Act of confirming, verifying, or corroborating the accuracy of assessment data or the appropriateness of the care plan.

Valsalva maneuver Any forced expiratory effort against a closed airway such as when an individual holds his or her breath and tightens his or her muscles in a concerted, strenuous effort to move a heavy object or change positions in bed.

value Personal belief about the worth of a given idea or behavior.

valvular heart disease Acquired or congenital disorder of a cardiac valve characterized by stenosis and obstructed blood flow or valvular degeneration and regurgitation of blood.

variance Unexpected event that occurs during patient care and that is different from CareMap predictions. Variances or exceptions are interventions or outcomes that are not achieved as anticipated. Variance may be positive or negative.

variant Differing from a set standard.

vascular access devices Catheters, cannulas, or infusion ports designed for long-term, repeated access to the vascular system.

vasoconstriction Narrowing of the lumen of any blood vessel, especially the arterioles and the veins in the blood reservoirs of the skin and abdominal viscera.

vasodilation Increase in the diameter of a blood vessel caused by inhibition of its vasoconstrictor nerves or stimulation of dilator nerves.

venipuncture Technique in which a vein is punctured transcutaneously by a sharp rigid stylet (e.g., a butterfly needle), a cannula (e.g., an angiocatheter that contains a flexible plastic catheter), or a needle attached to a syringe.

ventilation Respiratory process by which gases are moved into and out of the lungs.

verbal communication Sending of messages from one individual to another or to a group of individuals through the spoken word.

vertigo Sensation of dizziness or spinning.

vibration Fine, shaking pressure applied by hands to the chest wall only during exhalation.

Virchow's triad The three broad categories of factors that are thought to contribute to formation of a venous thrombosis: hypercoagulability, hemodynamic changes, and endothelial injury or dysfunction.

virulence Ability of an organism to rapidly produce disease.

visual Related to or experienced through vision.

vital signs Temperature, pulse, respirations, and blood pressure.

vitamins Organic compounds essential in small quantities for normal physiological and metabolic functioning of the body. With few exceptions, vitamins cannot be synthesized by the body and must be obtained from the diet or dietary supplements.

voiding Process of urinating.

vulnerable populations Collection of individuals who are more likely to develop health problems as a result of excess risks, limits

in access to health care services, or being dependent on others for care.

W

wellness Dynamic state of health in which an individual progresses toward a higher level of functioning, achieving an optimum balance between internal and external environments.

wellness education Activities that teach people how to care for themselves in a healthy manner.

wellness nursing diagnosis Clinical judgment about an individual, group, or community in transition from a specific level of wellness to a higher level of wellness.

wheezes, wheezing Adventitious lung sounds caused by a severely narrowed bronchus.

work redesign Formal process used to analyze the work of a certain work group and change the actual structure of the jobs performed.

workplace violence The act or threat of violence, ranging from verbal abuse to physical assault, directed toward persons at work or on duty.

worldview Cognitive stance or perspective about phenomena characteristic of a particular cultural group.

wound culture Specimen collected from a wound to determine the specific organism that is causing an infectious process.

Y

yearning and searching Second phase of Bowlby's phases of mourning. It is characterized by emotional outbursts of tearful

sobbing and acute distress.

Z

Z-track injection Technique for injecting irritating preparations into muscle without tracking residual medication through sensitive tissues.
