Acute GN may occur after infections of the pharynx or skin (i.e., impetigo) caused by certain strains of group A beta-hemolytic streptococcal infections; this is referred to as PSGN. Systemic lupus erythematosus (SLE), vascular injury, disseminated intravascular coagulation (DIC), or diabetes may be additional causes (Ballestas & Caico, 2014). An immune-mediated antigen–antibody reaction and inflammation causes insoluble immune complexes to become trapped in the glomeruli, causing protein and RBCs to enter the urine (Ballestas & Caico, 2014). Sudden onset of hematuria, proteinuria, and RBC casts in the urine define the disease and cause the smoky or coffee-colored urine typically seen in acute GN. Often this clinical picture is accompanied by hypertension, edema, azotemia (i.e., decreased glomerular filtration rate [GFR], rising blood urea nitrogen [BUN], and creatinine), and retention of renal salt and water.

BOX 27-1 Gerontologic Considerations

Kidney Dysfunction

Changes in kidney function with normal aging increase the susceptibility of elderly patients to kidney dysfunction and kidney failure. In addition, the incidence of systemic diseases, such as atherosclerosis, hypertension, heart failure, diabetes, and cancer, increases with advancing age, predisposing older adults to kidney disease associated with these disorders. Therefore, acute problems need to be prevented if possible or recognized and treated quickly to avoid kidney damage, and nurses in all settings need to be alert for signs and symptoms of renal dysfunction in elderly patients.

Because alterations in renal perfusion, glomerular filtration, and renal clearance increase the risk for medication-associated changes in renal function or toxicities, precautions and surveillance are warranted. When elderly patients undergo diagnostic testing or when new medications (e.g., diuretic agents) are added, precautions must be taken to prevent dehydration, which can compromise marginal renal function and lead to kidney failure.

With aging, the kidney is less able to respond to acute fluid and electrolyte changes. Elderly patients may develop atypical and nonspecific signs and symptoms of disturbed renal function as well as fluid and electrolyte imbalances. Recognition of these problems is hampered further by their association with pre-existing disorders and the misconception that they are normal changes of aging (Lewis, 2013).

Treatment of PSGN is mainly supportive. The inflammation typically lasts about 2 weeks, with individuals rarely developing chronic disease (Ballestas & Caico, 2014). When acute GN is associated with chronic infections, the underlying infections must be treated (Parmar & Batuman, 2015). Hyalinization (deterioration of normal tissue) or sclerosis indicates irreversible injury.

Risk Factors

Risk factors include a family history of glomerulonephritis; a pre-existing history of known diseases, such as a streptococcal infection (27.9%) of the upper respiratory tract; other infections with organisms (Parmar & Batuman, 2015) and viral infectious diseases, such as hepatitis, mumps, and varicella zoster. Additionally, other diseases, such as Goodpasture syndrome, Wegener granulomatosis, SLE, subacute bacterial endocarditis, and sepsis, have been implicated as risk factors.

PSGN usually develops 1 to 3 weeks after acute infection with group A beta-hemolytic streptococcus. The incidence of GN is approximately 5% to 10% in persons with pharyngitis and 25% in those with skin infections. GN comprises 25% to 30% of all cases of end-stage kidney failure. About one fourth of patients present with acute nephritic syndrome. Most cases that progress do so relatively quickly, and kidney failure may occur within weeks or months of the onset of acute nephritic syndrome. Asymptomatic episodes of PSGN exceed symptomatic episodes by a ratio of 3–4:1 (Parmar & Batuman, 2015).

Clinical Manifestations and Assessment

The primary presenting features of acute glomerulonephritis are hematuria, edema, azotemia (excessive nitrogenous wastes in the blood), and proteinuria (over 3 to 5 g/day). The hematuria may be microscopic or macroscopic (visible to the eye). The urine with myoglobin (myoglobinuria) is dark and may be described as brown in color. Cola-colored or coffee colored urine develops when the released myoglobin from skeletal muscle is quickly cleared from the serum into the urine. RBC and cellular debris called casts, indicate microscopic amount of bleeding from the kidney and may be associated with glomerular injury. Glomerulonephritis may be mild, and the hematuria may be discovered incidentally through a routine microscopic urinalysis, or the disease may be severe, with AKI, oliguria (less than 400 mL), and shortness of breath. Additional assessments to detect underlying cause include assessing for pharyngitis, impetigo, or a heart murmur (endocarditis) (Parmar & Batuman, 2015).

Some degree of edema and hypertension is present in most patients. Marked proteinuria due to the increased permeability of the glomerular membrane also may occur, with associated pitting edema, and hypoalbuminemia. BUN and serum creatinine levels may increase as urine output decreases. In addition, anemia may be present.

In the more severe form of the disease, patients also complain of headache, malaise, and flank pain (pain on sides below ribs and above the pelvis). Elderly patients may experience circulatory overload with dyspnea, engorged neck veins, cardiomegaly, and pulmonary edema. Atypical symptoms include confusion, somnolence, and seizures, which often are confused with the symptoms of a primary neurologic disorder.

Cultures of throat and skin lesions to rule out Streptococcus species may be obtained. Diagnostic tests include assessing for increasing antistreptolysin O (ASO) titer, which confirms recent infection. This is elevated in 60% to 80% of patients. Titers begin to increase in 1 to 3 weeks, peak in 3 to 5 weeks, and then return to normal in 6 months. ASO titer is unrelated to severity, duration, or prognosis of disease. In patients with skin infection, anti-DNAase B (ADB) titers are more sensitive than ASO titers for infection with *Streptococcus*. The antinuclear antibody test is useful for patients with acute GN and symptoms of underlying systemic illness, such as SLE and polyarteritis nodosa. Blood culture is indicated in patients with fever, immunosuppression, history of intravenous (IV) drug use, indwelling shunts, or catheters. Other laboratory testing may reveal elevations in complement C3 and C4, hypertriglyceridemia, decreased GFR, or anemia (Parmar & Batuman, 2015).

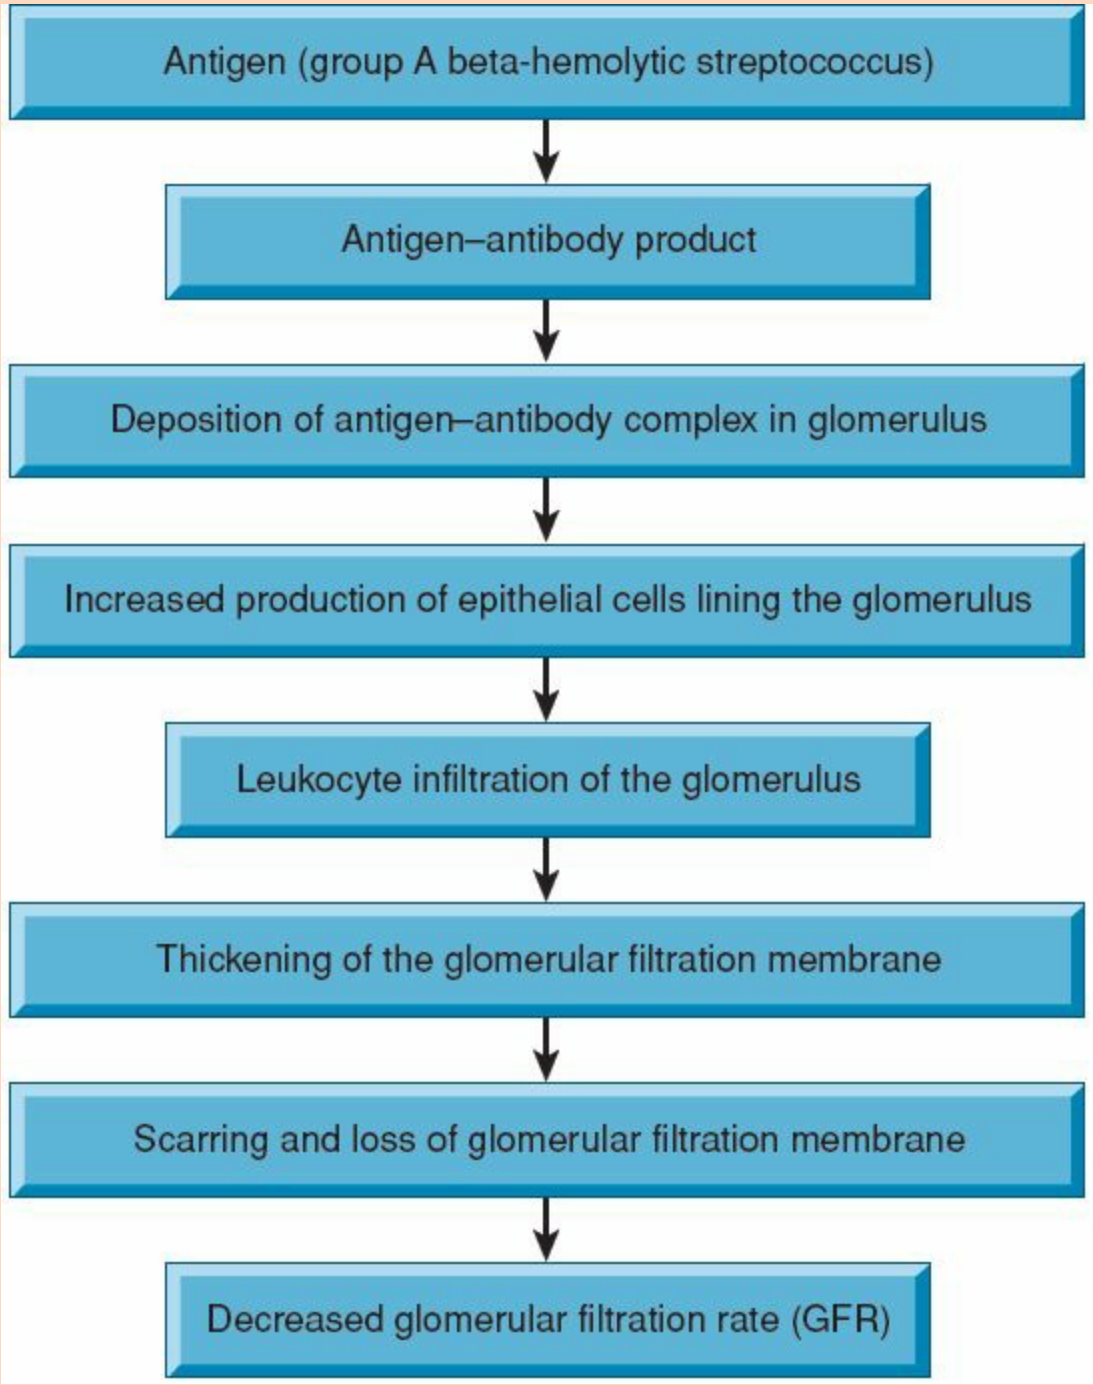
BOX 27-2 Focus on Pathophysiology

Acute Glomerulonephritis

Acute glomerulonephritis is an inflammatory disease of the glomeruli associated with an antigen–antibody response to infection. One postinfectious cause is group A beta-hemolytic streptococcal infection of the throat that precedes the onset of glomerulonephritis by 2 to 3 weeks. It may also follow impetigo (infection of the skin), visceral abscesses, and acute viral infections (upper respiratory tract infections, mumps,

varicella zoster virus, Epstein–Barr virus, hepatitis, and HIV infection). In some patients, antigens outside the body (e.g., medications, foreign serum) initiate the process, resulting in antigen–antibody complexes being deposited in the glomeruli. In other patients, the kidney tissue itself serves as the inciting antigen.

From the antigen, the below sequence occurs and results in decreased glomerular filtration rate (GFR).



Renal biopsy may be performed in patients with an individual or family history of kidney disease and patients with an atypical presentation, including massive proteinuria,

nephrotic syndrome (discussed later in this chapter), or a rapid rise in creatinine level without resolution (Parmar & Batuman, 2015).

If the patient improves, the amount of urine increases and the urinary protein and sediment diminish. The percentage of adults who recover is not well known. Some patients develop severe uremia within weeks and require dialysis for survival. Others, after a period of apparent recovery, insidiously develop chronic glomerulonephritis.

Medical and Nursing Management

Management consists primarily of treating symptoms, attempting to preserve kidney function, and treating complications promptly. When there is no evidence of malnutrition, dietary protein is restricted when renal insufficiency and nitrogen retention (elevated BUN) develop. Carbohydrates are given liberally to provide energy and reduce the catabolism of protein. Sodium is restricted when the patient has hypertension, edema, or heart failure (Parmar & Batuman, 2015). Diuretic and antihypertensive medications may be prescribed to control hypertension. Glomerular disease presenting with proteinuria should rely on treatment with ACE inhibitors or ARBs (Godara et al., 2014). Additionally, vasodilator drugs (e.g., nitroprusside, nifedipine, hydralazine, diazoxide) may be used in the presence of severe hypertension or encephalopathy. Early plasmapheresis may be used to remove antibodies and mediators of inflammation when antiglomerular basement antibodies are present (Swiatecka-Urban et al., 2014).

The nurse teaches the patient about fluid restriction for treatment of signs and symptoms of fluid retention (e.g., edema, pulmonary edema). Bed rest is recommended until signs of glomerular inflammation and circulatory congestion subside.

Pharmacologic therapy is focused on the cause of acute glomerulonephritis. If residual streptococcal infection is suspected, penicillin or erythromycin is used but does not appear to prevent the development of GN, unless given within the first 36 hours (Parmar & Batuman, 2015). Other antibiotic agents may be prescribed. Corticosteroids and immunosuppressant medications may be prescribed for patients with acute glomerulonephritis that is rapidly progressive.

Intake and output (I&O) are measured and recorded carefully. Fluids are given according to the patient's fluid losses and daily body weight. Insensible fluid loss of approximately 1 L (lungs and skin) is considered when estimating fluid loss. Diuresis usually begins about 1 week after the onset of symptoms, with a decrease in edema and BP. Proteinuria and microscopic hematuria may persist for many months. Recovery from acute glomerulonephritis occurs as inflammation abates, which takes about 2 weeks. Some patients may develop chronic glomerulonephritis characterized by oliguria, shortness of breath, weakness, and periorbital and generalized edema (anasarca). The patient should be instructed to report these symptoms to the health care provider immediately.

Nursing Alert

The most accurate indicator of fluid loss or gain in an acutely ill patient is weight, as accurate I&O and assessment of insensible losses may be difficult. A weight gain of 1 kg is equal to 1,000 mL of retained fluid (Grossman & Porth, 2014).

Nursing interventions focus on patient education about the disease process, explanations of laboratory and other diagnostic tests, and preparation for safe and effective self-care at home. Patient education is directed toward symptom management and monitoring for complications. The nurse emphasizes fluid and diet restrictions to avoid worsening of edema and hypertension. The patient is instructed to notify the primary care provider (PCP) if symptoms of kidney failure occur, including fatigue, nausea, vomiting, diminishing urine output, or at the first sign of any infection. Information for patient

education should be given verbally and in writing.

The nurse educates the patient on the importance of follow-up evaluations of BP, urinalysis for protein, and serum BUN and serum creatinine levels to evaluate for disease progression in the patient. A referral for home care may be indicated, giving the nurse an opportunity for assessment and detection of early signs and symptoms of renal insufficiency. If corticosteroids, immunosuppressant agents, or antibiotic medications are prescribed, the nurse uses the opportunity to review the dosage, desired actions, and adverse effects of medications and the precautions to be taken.

Complications

Complications of acute glomerulonephritis include hypertensive encephalopathy, heart failure, and pulmonary edema. Hypertensive encephalopathy is a medical emergency, and therapy is directed toward reducing the BP without impairing kidney function. Rapidly progressive glomerulonephritis is characterized by a rapid decline in kidney function. Without treatment, kidney failure develops in a matter of weeks or months. Signs and symptoms are similar to those of acute glomerulonephritis (hematuria and proteinuria), but the course of the disease is more severe and rapid. Crescent-shaped cells accumulate in Bowman space (the filter within the glomerulus), disrupting the filtering process. Plasma exchange (plasmapheresis) and treatment with high-dose corticosteroids and cytotoxic agents have been used to reduce the inflammatory response. Dialysis is initiated in acute glomerulonephritis if signs and symptoms of uremia are severe. The prognosis for patients with acute glomerulonephritis is favorable, with most patients recovering; however, 20% may have proteinuria for up to 1 year (Grossman & Porth, 2014).

Nursing Alert

Azotemia refers to the accumulation of nitrogen-combining compounds (BUN, creatinine) in the blood. It usually occurs before symptoms are noted. Uremia describes the clinical manifestations of kidney failure (altered fluid, electrolyte, acid–base balance; impaired body function [hypertension, anemia, pruritus, osteodystrophy, etc.]).

CHRONIC GLOMERULONEPHRITIS

Pathophysiology

Chronic glomerulonephritis is characterized by proteinuria, usually caused by repeated episodes of glomerular injury that results in renal destruction. The kidneys are reduced to as little as one fifth their normal size, consisting largely of fibrous tissue. The glomeruli and their tubules become scarred, and the branches of the renal artery are thickened. The result is severe glomerular damage that can progress to kidney failure.

Risk Factors

Risk factors include acute glomerulonephritis, diabetes, hypertensive nephrosclerosis (sclerosis [hardening] of the small blood vessels in the kidneys), hyperlipidemia, chronic tubulointerstitial injury, or hemodynamically mediated glomerular sclerosis. Secondary glomerular diseases that can have systemic effects include SLE and Goodpasture syndrome (autoimmune diseases), diabetic glomerulosclerosis, and amyloidosis (a rare disease characterized by the buildup of the protein amyloid in tissues and organs).

Clinical Manifestations and Assessment

The symptoms of chronic glomerulonephritis vary. Some patients with severe disease are asymptomatic for many years. Their condition may be discovered when hypertension is found, elevated BUN and serum creatinine levels are detected, or during a routine eye examination when vascular changes or retinal hemorrhages are discovered. The first indication of disease may be a sudden, severe nosebleed, a stroke, or a seizure. Many patients report that their feet are slightly swollen (edematous) at night. Most patients also have general symptoms, such as loss of weight and strength, increasing irritability, and an increased need to urinate at night (nocturia). Headaches, dizziness, and digestive disturbances are common.

As chronic glomerulonephritis progresses, signs and symptoms of chronic kidney failure may develop. The patient appears poorly nourished, with a yellow-gray pigmentation of the skin due to uremia. Periorbital and peripheral (dependent) edema with a normal or severely elevated BP may be noted. Mucous membranes are pale due to anemia. Cardiomegaly, a gallop rhythm, distended neck veins, and other signs and symptoms of heart failure may be present. Crackles can be heard in the lungs.

Peripheral neuropathy with diminished deep tendon reflexes and neurosensory changes occur late in the disease. The patient becomes confused and demonstrates a limited attention span. An additional late finding includes evidence of pericarditis with or without a pericardial friction rub (see Chapter 16).

A number of laboratory abnormalities occur. Urinalysis reveals a fixed specific gravity of about 1.010, variable proteinuria, and urinary casts, which are proteins secreted by damaged kidney tubules. As kidney failure progresses and the GFR falls, the following changes occur:

- Hyperkalemia due to decreased potassium excretion, acidosis, catabolism, and excessive potassium intake from food and medications
- Metabolic acidosis from decreased acid secretion by the kidney and inability to regenerate and reabsorb bicarbonate
- Anemia secondary to decreased erythropoiesis (production of RBCs)
- Hypoalbuminemia with edema secondary to protein loss through the damaged glomerular membrane
- Increased serum phosphorus level due to its decreased renal excretion
- Decreased serum calcium level (calcium and phosphorus exist in an inverse ratio in the body) and decreased vitamin D activation
- Mental status changes due to buildup of nitrogenous wastes
- Impaired nerve conduction due to electrolyte abnormalities and uremia

Nursing Alert

Microalbuminuria refers to urinary albumin excretion greater than the normal rate of 30 mg/24 hours and may precede the development of nephropathy by 5 to 7 years. A 24-hour urine check for protein is performed; dipsticks are not accurate until more than 300 to 500 mg/day protein are excreted.

The signs and symptoms of common fluid and electrolyte disturbances that can occur in patients with renal disorders and their general management strategies are listed in Table 27-1.

Chest x-rays may show cardiac enlargement and pulmonary edema. The electrocardiogram (ECG) may be normal or may indicate left ventricular hypertrophy (LVH) associated with hypertension. Signs of electrolyte disturbances, such as tall, tented T waves associated with hyperkalemia or dysrhythmia may appear. Computed tomography (CT) and magnetic resonance imaging (MRI) scans reveal a decrease in the size of the renal cortex.

Medical and Nursing Management

Treatment is directed toward reversing the renal impairment and eliminating the underlying cause, if possible. Changes in fluid and electrolyte status and in cardiac and neurologic status are reported promptly to the PCP. Often anxiety levels are extremely high for both the patient and family. Throughout the course of the disease and treatment, the nurse gives emotional support by providing opportunities for the patient and family to verbalize their concerns, have their questions answered, and explore their options for treatment if the kidneys fail.

Instructions to the patient include explanations and scheduling for follow-up evaluations of BP, urinalysis for protein and casts, serum BUN and creatinine levels. If long-term dialysis is needed, the patient and family are taught about the procedure, how to care for the access site, dietary restrictions, and other necessary lifestyle modifications. These topics are discussed later in this chapter.

The nurse in the hospital and community setting educates the patient and reinforces the importance of notifying the health care provider for worsening signs and symptoms of kidney failure, including nausea, vomiting, and diminished urine output. Specific teaching includes explanations about recommended diet and fluid modifications and medications (purpose, desired effects, adverse effects, dosage, and administration schedule). The patient is instructed to inform all health care providers about the diagnosis of glomerulonephritis so that all medical management, including pharmacologic therapy, is based on altered kidney function.

Complications

The major complication of chronic glomerulonephritis is chronic kidney failure. Glomerulonephritis is the third most common disease causing kidney failure (National Kidney Foundation, 2017).

TABLE 27-1 Common Fluid and Electrolyte Disturbances in Renal Disorders

Disturbance	Manifestations	General Management Strategies
Fluid volume excess	Acute weight gain of at least 5%, edema, crackles, shortness of breath, decreased BUN, decreased hematocrit, distended neck veins	Fluid and sodium restriction, diuretics, dialysis
Sodium deficit (often dilutional)	Nausea, malaise, lethargy, headache, abdominal cramps, apprehension, seizures	Low-sodium diet, fluid restriction, normal saline or hypertonic saline solutions during dialysis
Sodium excess	Dry, sticky mucous membranes; thirst; rough dry tongue; fever; restlessness; weakness; disorientation	Fluids, diuretics, dietary restriction
Potassium excess	Diarrhea, colic, nausea, irritability, muscle weakness, electrocardiogram (ECG) changes (tall tented T waves is usually the earliest sign on the ECG)	Dietary restriction, diuretics, IV glucose and insulin and sodium bicarbonate, cation exchange resin, calcium gluconate, dialysis
Calcium deficit	Abdominal and muscle cramps, stridor, hyperactive reflexes, tetany, positive Chvostek or Trousseau sign, tingling of fingers and around mouth, ECG changes	Diet, phosphate binders, oral or parenteral calcium salt replacement
Bicarbonate deficit	Headache, confusion, drowsiness, increased respiratory rate and depth, nausea and vomiting, warm flushed skin	Citric acid-sodium citrate, bicarbonate replacement (rare), dialysis
Protein deficit	Chronic weight loss, emotional depression, pallor, fatigue, soft flabby muscles	Diet, dietary supplements, total parenteral nutrition, albumin
Magnesium excess	Facial flushing, nausea and vomiting, sensation of warmth, drowsiness, depressed deep tendon reflexes, muscle weakness, respiratory depression, cardiac arrest	Calcium gluconate, mechanical ventilation, dialysis
Phosphorus excess	Tetany, tingling of fingers and around mouth, muscle spasms, soft tissue calcification	Diet restriction, phosphate binders

NEPHROTIC SYNDROME

Nephrotic syndrome is a cluster of clinical findings reflecting underlying damage to the glomerular capillary membrane. Nephrotic syndrome can occur with diseases or medications that affect the kidney. Although generally considered a disorder of childhood, nephrotic syndrome does occur in adults, including the elderly (Ballestas & Caico, 2014).

Pathophysiology

Nephrotic syndrome results from damage to the glomerular capillary membrane, increasing capillary permeability, which allows protein to leak out into the urine (proteinuria). The patient may lose as much as 40 g of urinary protein per day, of which 80% is albumin. Hypoalbuminemia, hyperlipidemia, and edema are typical findings. The patient becomes vulnerable to infection and may develop thrombolytic complication related to decreased albumin and loss of antithrombin (Ballestas & Caico, 2014). Figure 27-1 depicts the pathophysiology of nephrotic syndrome.

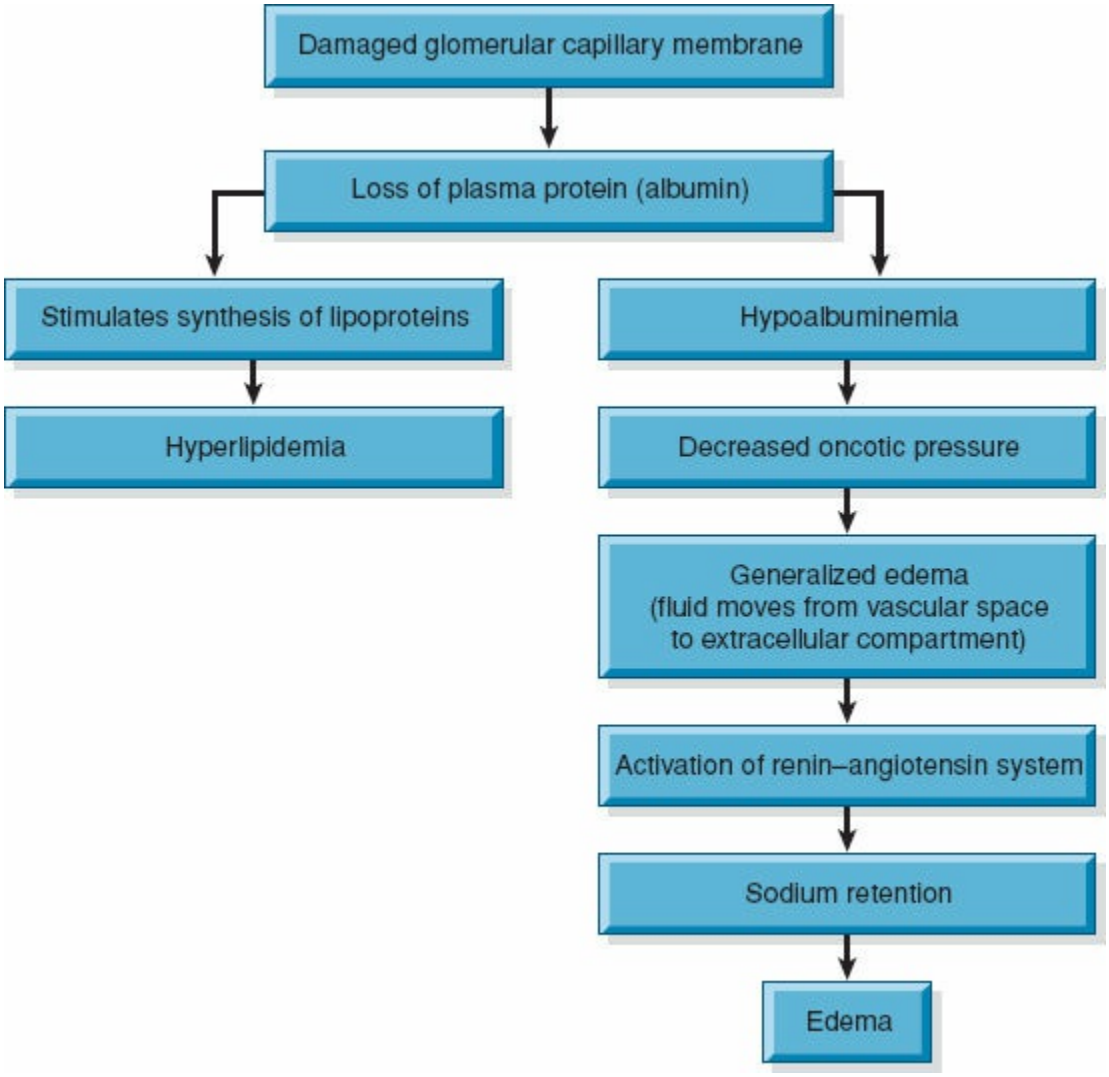


FIGURE 27-1 Sequence of events in nephrotic syndrome.

Pathophysiology Alert
The classic symptoms of nephrotic syndrome are proteinuria, edema, and hyperlipidemia. Proteinuria results primarily from damage to the glomerular capillary membrane.

The edema of nephrotic syndrome results from the loss of plasma proteins, primarily in

the form of albumin into the urine, resulting in serum hypoalbuminemia. This loss of protein causes a decrease in serum colloid osmotic pressure (COP); since there is "less particles to pull fluid into the intravascular space," the fluid stays in the tissue (edema). Additionally, renal disease itself may cause sodium retention due to enhanced sodium reabsorption by the collecting duct. The hyperlipidemia results from an increase in hepatic synthesis of lipoproteins and decreased catabolism of circulating lipoproteins (Rennke & Denker, 2013).

Risk Factors

Diabetic nephropathy is the most common cause of nephrotic syndrome; however, other glomerular diseases may be implicated. Such causes include SLE, infections/chronic glomerulonephritis, cancers, preeclampsia, drug addiction, and nephrotoxic drugs (Ballestas & Caico, 2014). Occasionally, amyloidosis of the kidney, multiple myeloma, and renal vein thrombosis may be seen.

Clinical Manifestations and Assessment

Proteinuria, predominately in the form of albuminuria, where albumin excretion exceeds 3.5 g/day, is the hallmark of nephrotic syndrome. Hypoalbuminuria is the result, leading to edema, periorbital edema, scrotal swelling, abdominal distention, weight gain, or anasarca. Fatigue and anorexia may be reported, as well as shortness of breath, pulmonary edema, or hypertension (Ballestas & Caico, 2014). The urine may contain increased white blood cells (WBCs) as well as granular and epithelial casts. The presence of hypoimmunoglobulinemia places the patient at risk for infections. Hyperlipidemia with increased high-density lipoproteins (HDL) occurs and places the patient at risk for cardiovascular disease. Hypertension, irritability, headache, and malaise occur.

The nurse can expect a variety of diagnostic tests will be performed, including urinalysis, blood chemistries including albumin and lipid levels, complete blood count (CBC), coagulation studies, renal function tests, blood glucose to exclude a diagnosis of diabetes, or renal ultrasound to evaluation for structural abnormalities (Ballestas & Caico, 2014).

Drug Alert!
Decreased serum albumin level presents decreased protein-binding sites for medications. Patients with hypoalbuminemia must be observed closely for signs of drug toxicity as the amount of free or unbound drug is increased (Grossman & Porth, 2014).

A needle biopsy of the kidney may be performed for histologic examination of renal tissue to confirm the diagnosis.

Medical and Nursing Management

Patients with nephrotic syndrome need instruction about the importance of following medication and dietary regimens so that their condition can remain stable for as long as possible. The patient who does not have hyperkalemia may be placed on a low-sodium diet containing liberal amounts of potassium. This type of diet enhances the sodium–potassium pump mechanism and assists in elimination of sodium to reduce edema. Reduction in dietary cholesterol and saturated fats helps with lipidemia. Protein intake should be moderate, sufficient to meet protein needs while avoiding excessive intake, which may accelerate renal deterioration and increase urinary protein losses. An intake of 0.7 to 0.8 g/kg/day is suggested with at least half of the protein from high biologic value (HBV) sources, such as meat, fish, poultry, milk, eggs, and soy (Dudek, 2014).

The patient is taught to report any signs of acute infection promptly (recall they have decreased immunoglobulin), such as a respiratory tract infection, to prevent further glomerular damage. For example, an untreated streptococcal infection may be a risk factor for acute poststreptococcal glomerulonephritis; pathogens in the bloodstream may lead to sepsis with resulting decreased renal perfusion. Diuretics may be prescribed for the patient with severe edema; however, caution must be used because of the risk of reducing the plasma volume to the point of impaired circulation with subsequent prerenal AKI (discussed later in the chapter). The use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blocking agents, in combination with diuretics, often reduces the degree of proteinuria (Ballestas & Caico, 2014). Statin medications have been shown to improve endothelial function and decrease proteinuria (Ballestas & Caico, 2014).

Other medications used to treat nephrotic syndrome include corticosteroids, antineoplastic agents (cyclophosphamide [Cytoxan]) or immunosuppressant medications (azathioprine [Imuran], chlorambucil [Leukeran], or cyclosporine [Neoral]). It may be necessary to repeat treatment with corticosteroids if relapse occurs. Patients should be taught to protect themselves from infection and to report any infections promptly due to immunosuppression.

Complications

Complications of nephrotic syndrome include infection secondary to loss of immunoglobulins, accelerated atherosclerosis secondary to hyperlipidemia, and a hypercoagulable state that may result in thromboembolism (Ballestas & Caico, 2014). Body image may be altered due to anasarca and edema, causing a change in appearance.

KIDNEY FAILURE

Kidney failure results when the kidneys cannot remove the body's metabolic wastes or perform their regulatory functions. This process may be acute, developing over hours to days, or chronic, developing over months to years. Kidney failure results in azotemia, metabolic derangements, acid–base disturbances, and electrolyte imbalances. Kidney failure is a systemic disease and is a final common pathway of many different kidney and urinary tract diseases. Each year, the number of deaths from irreversible renal failure increased until 2009, at which point it began to decline somewhat (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2016a).

ACUTE KIDNEY INJURY (FORMERLY KNOWN AS ACUTE RENAL FAILURE)

AKI is a clinical syndrome that is typically reversible; it is marked by an abrupt loss of kidney function and GFR over a period of hours to days. AKI occurs in 5% to 7% of patients who are hospitalized and up to 20% of patients who are critically ill. The mortality rate of 40% in patients who are critically ill has not appreciably changed over the last several decades due to an aging population, development of multisystem failure, and associated increased comorbidities (Dirkes, 2015).

In recent years, AKI has gained increasing recognition as a major risk factor for the development of chronic kidney disease (CKD). The clearest example of this relationship comes in cases of severe dialysis-requiring AKI where patients fail to recover kidney function. Acute tubular necrosis (ATN) without recovery is the primary diagnosis for 2% to 3% of cases of kidney failure annually (USRDS, 2014). AKI is frequently superimposed on CKD and, therefore, plays a key role in progression of CKD (discussed shortly).

Manifestations of AKI include oliguria or anuria with resulting azotemia (increased serum creatinine, BUN, and other nitrogenous waste products). Acidemia, fluid volume excess, alterations in calcium and phosphorus balance and BP alterations develop rapidly. Erythropoiesis fails with resulting anemia.

Pathophysiology

Although the exact pathogenesis of AKI is not always known, this condition may be reversible if identified and treated before kidney function is impaired permanently. AKI is classified by its etiology, which helps to focus the treatment.

Classification of Acute Kidney Injury

The major classifications of AKI are prerenal azotemia caused by hypoperfusion of the kidney; intrarenal or intrinsic causes, in which the renal parenchyma or nephron is damaged; and postrenal causes, in which outflow of urine is obstructed. Common causes of each type of AKI are summarized in Box 27-3.

BOX 27-3 Causes of Acute Kidney Injury

Prerenal Failure

- Volume depletion resulting from:
  - Hemorrhage
  - Renal losses (diuretics, osmotic diuresis)
  - GI losses (vomiting, diarrhea, nasogastric suction)
- Impaired cardiac efficiency resulting from:
  - Myocardial infarction
  - Heart failure
  - Dysrhythmias
  - Cardiogenic shock
- Vasodilation resulting from:
  - Sepsis
  - Anaphylaxis
  - Antihypertensive medications or other medications that cause vasodilation

Intrarenal Failure

- Prolonged renal ischemia resulting from:
  - Pigment nephropathy (associated with the breakdown of blood cells containing pigments that occlude kidney structures)
  - Myoglobinuria (trauma, crush injuries, burns)
  - Hemoglobinuria (transfusion reaction, hemolytic anemia)
- Rhabdomyolysis
- Nephrotoxic agents such as:
  - Aminoglycoside antibiotics (gentamicin, tobramycin)

- Antirejection medications (cyclosporine, tacrolimus)
- Radiopaque contrast agents
- Heavy metals (lead, mercury)
- Solvents and chemicals (ethylene glycol, carbon tetrachloride, arsenic)
- NSAIDs
- ACE inhibitors

- Infectious processes such as:
  - Acute pyelonephritis
  - Acute glomerulonephritis

Postrenal Failure

- Urinary tract obstruction, including:
  - Calculi (stones)
  - Tumors
  - Benign prostatic hyperplasia (BPH)
  - Strictures
  - Blood clots

Prerenal AKI, which occurs in 60% of cases, is caused by reduced blood flow to the kidney with resulting decrease in the GFR and urine output (Dirkes, 2015). Common clinical situations are volume-depletion states, which include dehydration; hemorrhage or gastrointestinal (GI) losses; decreased cardiac output such as occurs with myocardial infarction, heart failure, or cardiogenic shock; and vasodilated states, such as sepsis or anaphylaxis. To maintain adequate renal perfusion the mean arterial pressure (MAP) must be 65 mm Hg (Dirkes, 2015). For patients with a history of hypertension and/or renal vascular diseases, higher pressures may be required to maintain renal perfusion.

Intrarenal or intrinsic AKI is the result of actual parenchymal damage to the glomeruli or kidney tubules. ATN is the most common cause of intrarenal AKI in the patient who is hospitalized. Ischemia due to decreased renal perfusion and MAP below 65 mm Hg (Dirkes, 2015), accounts for more than 50% of cases of ATN. In the early period of renal ischemia, kidney function can be restored completely by improving renal blood flow, typically with IV fluids. If left untreated or when fluid resuscitation is inadequate, ATN will ensue (Wolfson, 2014, p. 1298). Additionally, nephrotoxic agents, such as aminoglycosides and radiocontrast agents, may cause ATN through direct damage to the nephron. Conditions such as burns, crush injuries, infections, and severe blood transfusion reactions can lead to rhabdomyolysis with myoglobinuria. With burns and crush injuries, myoglobin (a protein released from muscle when injury occurs) and hemoglobin are liberated, causing obstruction of renal tubules, renal toxicity, and ischemia. The term rhabdomyolysis, in which breakdown of skeletal muscle is seen, may be used to describe this event. Severe transfusion reactions may also cause intrarenal failure; hemoglobin released through hemolysis filters through the glomeruli and becomes concentrated in the kidney tubules to such a degree that precipitation of hemoglobin occurs. Additionally,

hyperglycemic hyperosmolar nonketotic coma (see Chapter 30), in which as much as 25% of total body water can be lost, is associated with ATN as well as conditions where there is third spacing of fluids (fluid sequestered in a nonfunctional area) such as in pancreatitis and peritonitis (Wolfson, 2014). Certain medications, especially nonsteroidal anti-inflammatory drugs (NSAIDs) and ACE inhibitors or ARBs, also may predispose a patient to intrarenal damage. These medications interfere with the normal autoregulatory mechanisms of the kidney and may cause hypoperfusion and eventual ischemia.

Postrenal AKI is the result of a mechanical obstruction that develops anywhere in the renal system. This may result from ureteral blockage, such as from bilateral renal calculi, benign prostatic hyperplasia (BPH), strictures, tumors, or congenital defects (Dirkes, 2015). Pressure rises in the kidney tubules and hydronephrosis occurs, compressing normal renal tissue and resulting in a decrease in the GFR. Any sudden or complete cessation of urine output with an indwelling catheter should alert the nurse to possible obstruction. The catheter should be inspected and kinks removed or the catheter irrigated or changed to reestablish urine flow.

Phases of AKI

There are four clinical phases of AKI: initiation or onset, oliguric, diuretic, and recovery. The onset phase begins with the triggering event and ends when cellular injury and oliguria develop. Common events include significant fluid or blood loss, burns, or diabetes insipidus (Dirkes, 2015). A small number of patients develop nonoliguric renal failure, usually associated with nephrotoxic agents; it may also occur with burns, traumatic injury, and the use of halogenated anesthetic agents.

The oliguric period is accompanied by fluid overload and an increase in the serum concentration of wastes, such as urea, creatinine, organic acids, and the electrolytes potassium, phosphorous, and magnesium. The average time period for oliguria is 8 to 14 days, but it may last longer (Dirkes, 2015). Because the minimum amount of urine needed to rid the body of fluid and metabolic waste products is 500 mL in 24 hours (Hall, 2016), renal replacement therapy (RRT), such as dialysis, may be needed until kidney function returns.

The diuretic phase occurs when the cause of acute renal failure (ARF) is corrected. This phase is marked by a gradual increase in urine output, which signals that glomerular filtration has started to recover. Urine output may be normal, or the patient may excrete large amounts of dilute urine along with electrolytes. The patient should be observed closely for dehydration, which may damage the kidney further, as well as for hypokalemia (Dirkes, 2015). Abnormal laboratory values plateau and begin to decline.

The recovery period is signaled by the improvement of kidney function and energy level and may take 6 to 12 months (Grossman & Porth, 2014). If residual damage to the glomerular basement membrane occurs, residual renal impairment may result.

Clinical Manifestations and Assessment

Almost every system of the body is affected when there is failure of the renal regulatory mechanisms. The patient may appear critically ill and lethargic. Table 27-2 summarizes common clinical findings in all three categories of AKI.

Assessment of the patient with AKI includes evaluation for changes in the urine output, diagnostic tests that evaluate the kidney contour and function, and a variety of laboratory values. See Chapter 26 for information about the normal characteristics of urine, diagnostic findings, and laboratory values in the renal system.

TABLE 27-2 Comparing Clinical Findings Among Categories of Acute Kidney Injury

	Categories		
Characteristics	**Prerenal**	**Intrarenal**	**Postrenal**
Etiology	Hypoperfusion	Parenchymal damage	Obstruction
Blood urea nitrogen value	Increased proportion (greater than 20:1) blood urea nitrogen (BUN) to creatinine	Increased	Increased
Creatinine	Normal or slightly increased	Increased	Increased
Urine output	Decreased	Varies, often decreased	Varies, may be decreased, or sudden anuria
Urine sodium	Typically decreased	Typically increased	Varies
Urinary sediment	Normal, few hyaline casts	Abnormal casts and debris	Usually normal
Urine osmolality	Increased to 500 mOsm	Approximately 350 mOsm, similar to serum	Varies, increased or equal to serum
Urine-specific gravity	Increased	Low normal	Varies

In AKI, oliguria (less than 400 mL a day) is typically present. Hematuria may be present, and the urine has a low specific gravity due to the kidney's inability to concentrate the urine (Grossman & Porth, 2014). Patients with AKI have decreased urine sodium levels and urinary casts, and other cellular debris may be present.

The BUN level increases steadily at a rate dependent on the degree of protein catabolism, renal perfusion, and fluid or protein intake. Nausea, vomiting, lethargy, headache, muscle twitching, and seizures may occur. Serum creatinine, a more sensitive indicator of kidney function than BUN, increases with glomerular damage and is used to monitor kidney function and disease progression.

Patients with oliguria and anuria (less than 50 mL/day) are at high risk for hyperkalemia, a potassium level of more than 5.1 mEq/L (5.1 mmol/L). Hyperkalemia develops as the damaged kidney cannot excrete potassium; protein catabolism and acidosis result in the release of intracellular potassium into the serum, worsening hyperkalemia. The ECG may reveal changes, including tall, tented, or peaked T waves, absent P wave, widened QRS, or bradydysrhythmia. Additional symptoms of hyperkalemia may include weakness, diarrhea, dysrhythmias, and cardiac arrest. The nurse should be aware of exogenous sources of potassium, such as IV infusions, or medications, such as potassium penicillin, as well as dietary sources (avocado, brussels sprouts, okra, spinach (green leafy

vegetables), potatoes, pumpkin, spinach, sweet potatoes, tomatoes, yams, apricots, bananas, nectarines, orange juice, prune juice) (Dudek, 2014).

As metabolic acidosis develops, normal renal buffering mechanisms fail, resulting in hyperventilation. The patient may breathe more rapidly and deeply to "blow off" CO_2 in an attempt to restore normal serum pH. Hyperventilation as compensation for acidosis may lead to respiratory fatigue or failure, requiring mechanical ventilation.

Serum phosphate levels increase. Calcium levels may decrease in response to decreased absorption of calcium from the intestine as well as a compensatory mechanism for the elevated blood phosphate levels. Anemia is another common laboratory finding in AKI, as a result of reduced erythropoietin production, uremic GI lesions, reduced RBC lifespan, and blood loss, usually from the GI tract.

Nursing Alert

Monitor urine output hourly; output should measure at least 0. 5 mL/kg/hr. Urine output directly reflects GFR in the kidney and, therefore, is a sensitive and early biomarker of AKI (Dirkes, 2015).

Prevention

Prevention of AKI is essential as AKI mortality rates as high as 60% or more, especially in patients where multisystem failure is observed (Box 27-4).

The nurse assesses for use of potentially nephrotoxic agents and exposure to environmental toxins. Patients taking nephrotoxic medications, such as aminoglycosides (gentamicin, tobramycin, neomycin), amphotericin B, vancomycin, cyclosporine, certain antineoplastics (Adams & Urban, 2016) or anesthetics, heavy metals such as cisplatin or bismuth, or radiologic contrast agents, should be monitored closely for changes in kidney function. BUN and serum creatinine levels should be obtained at baseline, during treatment, and after therapy is complete, if indicated.

Chronic use of analgesics, particularly NSAIDs, may cause interstitial nephritis (inflammation within the renal tissue) and papillary necrosis. Patients with heart failure or cirrhosis with ascites are at particular risk for NSAID-induced kidney failure. Increased age, pre-existing kidney disease, and the coadministration of nephrotoxic agents increase the risk for kidney damage.

BOX 27-4 Health Promotion

Preventing Acute Kidney Injury

- Provide adequate hydration to patients at risk of dehydration:
  - Perioperative patients
  - Patients on fluid restriction
  - Patients undergoing diagnostic studies with or requiring contrast agents (e.g., barium enema, intravenous pyelograms, angiography), especially elderly patients who may have marginal renal reserve
  - Patients with neoplastic disorders and those receiving chemotherapy
  - Patients with metabolic disorders, such as gout, glycosuria
  - Prevent and treat hypotension or shock promptly with blood and fluid replacement
- Monitor hourly urine output of patients who are critically ill to detect the onset of kidney failure as early as possible. When available, monitor central venous and arterial pressures
- Continually assess renal laboratory values
- Properly identify patients to prevent transfusion reactions, which can precipitate myoglobinuria
- Prevent and treat infections promptly. Infections can lead to sepsis and renal damage
- Intervene promptly with wounds, burns, and other precursors of sepsis
- To prevent infections from ascending in the urinary tract, give meticulous care to patients with indwelling catheters. Remove catheters as soon as possible
- To prevent toxic drug effects, closely monitor dosage, duration of use, and blood

levels of all medications metabolized or excreted by the kidneys

Radiocontrast-induced nephropathy is a major cause of hospital-acquired AKI (Adams & Urban, 2016); therefore, those at risk should be identified prior to procedures where contrast media is used (BUN and serum creatinine should be assessed before contrast dye is administered). Patients with creatinine levels greater than 2 mg/dL should receive preprocedure hydration and receive as low a dose of contrast as possible for the study. *N*-acetylcysteine given before and after contrast administration appears to decrease the incidence of contrast nephropathy (Wolfson, 2014, p. 1300). The nurse should withhold Metformin prior to procedures requiring IV contrast. While metformin is not nephrotoxic, if AKI occurs after a procedure, the acidosis associated with kidney failure may worsen in the presence of this medication.

Promising diagnostic biomarkers allow early detection of AKI. The level of urine or serum neutrophil gelatinase-associated lipocalin (NGAL) increases after an episode of poor kidney perfusion. NGAL levels increase 24 to 48 hours before serum creatinine rises, indicating renal dysfunction before kidney failure. Cystatin C level, assessed in urine and serum, is considered an early predictor of AKI as well as of increased mortality. Tissue inhibitor metalloproteinase-2 (TIMP-2) appears in urine within 12 hours of an injury due to ischemia or sepsis, indicating a seven-fold risk of AKI (Dirkes, 2015). Currently, studies are underway to determine the application of these biomarkers.

Medical and Nursing Management

The kidneys have a remarkable ability to recover from insult. Management includes maintaining fluid and electrolyte balance, avoiding fluid excesses, and supporting the patient until repair of renal tissue and restoration of function occur. Dialysis may be used on a temporary basis to restore homeostasis.

The underlying cause is identified, treated, and eliminated when possible. If the cause of AKI is related to prerenal factors, then treatment consists of optimizing renal perfusion by repletion of intravascular volume with fluids or treating decreased cardiac output (keeping the MAP above 65 mm Hg). Adequate blood flow to the kidneys in patients with prerenal causes of AKI may be restored by IV fluids or transfusions of blood products. If AKI is caused by hypovolemia secondary to hypoproteinemia, an infusion of albumin may be prescribed. Treatment of postrenal failure is aimed at restoring normal outflow of urine by relieving the obstruction. Surgery, such as prostatectomy, percutaneous nephrostomy tubes, stents or indwelling catheters, may be used. Intrarenal azotemia is treated with supportive therapy, removal of causative agents, and aggressive fluid resuscitation in cases of shock, infection, and rhabdomyolysis. Early dialysis may be required to control rapidly developing complications, such as fluid volume excess (hypertension, CHF, pericarditis, and pulmonary edema), metabolic acidosis, or hyperkalemia. While this is expected to be a temporary intervention, a small portion of patients do not recover kidney function and may develop chronic kidney failure.

The nurse observes for fluid excess manifested by dyspnea, crackles, tachycardia, hypertension, and distended neck veins, as well as generalized edema in the presacral and pretibial areas and any dependent region of the body. The central venous pressure (CVP), where measured, will be elevated. Fluid and sodium should be restricted in patients with FVE and oliguria or anuria to prevent fluid overload and pulmonary edema. The nurse observes for signs and symptoms of pericarditis (chest pain that increases when lying down or fever and pericardial friction rub) or pericardial effusion (feeling of pressure in the chest, engorged neck veins, distant [muffled] heart sounds, equalizing pressure in heart chambers, pulsus paradoxus), which generally is associated with the need to initiate dialysis. Emergency pericardiocentesis may be required (refer to Chapter 15). Diuretics, such as furosemide (Lasix), may be prescribed to initiate diuresis and maintain renal perfusion when intravascular volume deficits have been corrected. Careful attention to intake and output is required as well as cautious estimates of insensible loss (refer to Chapter 4).

Pharmacologic Therapy

Hyperkalemia may be reduced by administering polystyrene sulfonate (Kayexalate) orally, via NG tube, or by retention enema (Adams & Urban, 2016). Kayexalate, a cation-exchange resin which works by exchanging sodium ions for potassium ions in the intestinal tract. Typically Sorbitol is combined with Kayexalate to draw water into the bowel, inducing diarrhea and excretion of potassium. The patient should retain the Kayexalate enema for 30 to 45 minutes. For symptomatic hyperkalemia, IV insulin, given with glucose to prevent hypoglycemia, may be administered to temporarily shift potassium back into the cells. Calcium may be administered to treat the cardiotoxicity that has developed secondary

to hyperkalemia since it directly antagonizes the membrane effects of hyperkalemia. Albuterol sulfate (Ventolin HFA) by nebulizer can lower plasma potassium concentration by 0.5 to 1.5 mEq/L. It is important to understand that hyperkalemia is the most common metabolic cause of death in patients with AKI (Wolfson, 2014).

High anion-gap acidosis may require sodium bicarbonate therapy—if the serum bicarbonate concentration is below 15 mmol/L or arterial pH is less than 7.2 (Longo et al., 2015)—or dialysis. Phosphate-binding agents, such as calcium acetate (PhosLo) or aluminum hydroxide gel (short term only), are given to decrease the absorption of phosphate from the intestinal tract.

Because kidney failure alters the metabolism and action of many drugs, often in ways that are not predictable, medications that are excreted via the kidney require dosage adjustment to prevent toxicity. Commonly used agents requiring adjustment are antibiotics, especially aminoglycosides, digoxin, ACE inhibitors, and magnesium-containing agents.

Nutritional Therapy

AKI causes impaired glucose use and protein synthesis and increased tissue catabolism. Azotemia may cause nausea and vomiting. Weight loss may result from negative nitrogen balance. Dietary proteins are restricted (Dudek, 2015), and caloric requirements are met with high-carbohydrate meals due to their protein-sparing effect. Dietary restrictions include foods and fluids containing potassium, such as bananas, citrus, tomatoes, or melons. Foods containing phosphorus, including dairy products, beans, nuts, legumes, and carbonated beverages, are restricted as well. Caffeine also is restricted. The patient may require enteral or parenteral nutrition.

Suspect fluid retention if the patient develops hypertension, crackles, edema, or weight gain. Administering fluids (PO or IV) may require replacing both sensible and insensible loss. Insensible loss is estimated at 1 L. Fluid replacement in kidney disease may be based on urine output, any GI losses (gastric drainage or diarrhea), plus insensible losses, thus meticulous attention is paid to accurate intake and output. Metabolism and the oxidation process produce about 200 to 500 mL of fluid per day, which may decrease the fluid requirements, whereas fever may increase the fluid requirement (Dudek, 2015). As AKI resolves, results of blood chemistry tests are used to determine the amounts of sodium, potassium, and water needed for replacement. Following the diuretic phase, the patient is placed on a high-carbohydrate diet with sufficient protein to promote nitrogen balance. The patient is encouraged to resume activities gradually.

Nursing Alert
If the caloric intake is insufficient to prevent the breakdown of body protein, accumulation of additional nitrogenous waste develops, which may increase uremic symptoms.

The nurse monitors for complications, participates in emergency treatment of imbalances of fluids and electrolytes, assesses the patient's progress and response to treatment, and provides physical and emotional support. Additionally, the nurse keeps family members informed about the patient's condition, helps them understand the

treatments, and provides psychological support. AKI is a serious problem, and the nurse must continue to provide interventions for the underlying disorder (e.g., burns, shock, trauma, obstruction of the urinary tract, etc.).

Reducing Metabolic Rate

Bed rest may be indicated to reduce exertion and the metabolic rate during the most acute stage of the disorder. Fever and infection, both of which increase the metabolic rate and catabolism, are prevented or treated promptly.

Nursing Alert
Fever increases the insensible water loss by increasing water vapor in the lungs and allowing more water to be lost from the respiratory mucosa (Grossman & Porth, 2014).

Promoting Pulmonary Function

Attention is given to pulmonary function, and the patient is assisted to turn, cough, and deep breathe frequently to prevent atelectasis and respiratory tract infection. Drowsiness and lethargy may prevent the patient from moving and turning without encouragement and assistance. Maintaining a patent airway through oral or endotracheal suction may be necessary.

Preventing Infection

Asepsis is essential with invasive lines and catheters to minimize the risk of infection and subsequent increased metabolism. Uremia impairs host defenses, particularly leukocyte function, and infection is a significant cause of morbidity and mortality in patients with AKI (Wolfson, 2014, p. 1301). Any fever warrants an assessment and notification of the provider. Sepsis disrupts blood flow, causing cell ischemia and death (Dirkes, 2015). An indwelling urinary catheter is avoided whenever possible because of the high risk of urinary tract infection (UTI) associated with its use.

Providing Skin Care

The skin may be dry or susceptible to breakdown as a result of edema; therefore, meticulous skin care is important. Additionally, excoriation and itching of the skin may result from the deposit of uremic toxins in the patient's tissues. Turning the patient frequently, bathing the patient with cool water, and keeping the patient's skin clean and well moisturized and the fingernails trimmed to avoid excoriation are comforting and prevent skin breakdown.

Nursing Alert
The nurse recognizes that edematous tissue is fragile and must assess any edematous area for evidence of erythema to prevent skin breakdown.

Providing Support

While AKI is considered potentially reversible, there is variability in the length of time that the patient is ill and the duration of treatment. The patient and family need assistance, explanation, and support during this period. The nurse provides frequent explanations of the purpose and rationale of the treatments, as rising BUN leads to confusion and lethargy. Both the patient and family are included in teaching to allay anxiety and fear. Consistent with the goal of Healthy People 2020, which is to increase the number of patients hospitalized with AKI who receive a renal evaluation within 6 months of discharge, the nurse explains the importance of follow-up with a nephrologist (Healthy People 2020, 2017).

Gerontologic Considerations

The prevalence of renal dysfunction in Americans older than 70 years of age is 15% (Dirkes, 2015). The incidence and mortality of AKI is increased in older patients who are hospitalized due to a decrease in the number of functional nephrons and renal blood flow as well as to atherosclerosis of the renal arteries. This is especially so in those with comorbidities, such as diabetes, hypertension, and heart disease (Dirkes, 2015). The older individual is particularly susceptible to AKI due to limited renal reserve to counteract insults to their kidney function, such as sepsis and hydration. Diuretics and NSAIDs increase the risk of AKI threefold, as do ACE inhibitors (Lewis, 2013). It is estimated that 50% of hospitalizations are avoidable; hospitalization is associated with increased mortality (Lewis, 2013). The older patient with systemic infection accompanied by vomiting or diarrhea should be kept hydrated, and NSAIDs, diuretics, ACE inhibitors or ARBs should be withheld (Lewis, 2013).

Nurses need to be aware of the risk of AKI in elderly patients, especially those undergoing diagnostic testing or procedures that can result in dehydration. Suppression of thirst, decreased mobility with lack of access to drinking water, and confusion contribute to the older patient's failure to consume adequate fluids, which may lead to dehydration and further compromise of kidney function.

Nursing Alert
Muscle mass and GFR can decrease with age; therefore, even small elevations in creatinine may indicate significant renal impairment in the elderly and should be investigated.

CHRONIC KIDNEY DISEASE AND END-STAGE KIDNEY DISEASE

Kidney failure is a progressive and irreversible deterioration in renal function taking place over months to years. Kidney failure results in the body's inability to maintain metabolic and fluid and electrolyte balance, resulting in azotemia and subsequent uremia. CKD is the term used with kidney damage or decreased renal function for 3 months or more with evidence of irreversible nephron loss and scarring. More than 10% of adults in the United States—over 20 million people—may have CKD, of varying levels of progression which may lead to ESKD (CDC, 2015). When end-stage kidney failure is reached, RRT with dialysis or kidney transplant is needed to sustain life. Chronic renal insufficiency (CRI) occurs when the GFR has been reduced moderately but not to a degree sufficient to cause clear-cut clinical symptoms (Wolfson, 2014).

There were 114,813 new cases of kidney failure reported in 2012, representing a decrease of 3.7% from the previous year. Despite this decrease, at the end of 2012, there were 636,905 dialysis and transplant patients receiving treatment; 449,342 individuals are receiving hemodialysis or peritoneal dialysis (PD) and 186,303 have functioning renal transplants (USRDS, 2014). Healthy People 2020 has set goals related to kidney failure, including:

- Decreasing the percentage of the US population with CKD,
- Increasing awareness of kidney disease among people with reduced kidney function,
- Decreasing the number of new individuals requiring dialysis, and
- Decreasing morbidity and mortality related to CKD (Healthy People 2020.gov).

BOX 27-5 Stages of Chronic Kidney Disease

Stages are based on the GFR. The normal GFR is 120–130 mL/min corrected for body size (per 1.73 m^2).
Stage 1: GFR ≥90 mL/min; hematuria, proteinuria, or abnormal renal anatomy
Stage 2 (Mild CKD): GFR = 60–89 mL/min; hematuria, proteinuria or abnormal renal anatomy; nephrons highly susceptible to failure
Stage 3a (Moderate CKD): 45–59 mL
Stage 3b (Moderate CKD): GFR = 30–44 mL/min;
Stage 4 (Severe CKD): GFR = 15–29 mL/min;
Stage 5 (End Stage CKD): GFR <15 mL/min/1.73 m^2 or dialysis dependent

Adapted from Lewis, R. (2013). An overview of chronic kidney disease in older people. Nursing Older People, *25*(10), 31–38.

The incidence of CKD is increasing most rapidly in people who are 65 years of age and above, more than doubling between 2000 and 2008, while the incidence of recognized CKD among those who are 20 to 64 years of age is less than 0.5%. CKD in African

Americans is three times higher than in Caucasians; incidence rates for Native Americans have started to decline (NIDDK, 2016b).

Pathophysiology

As renal function declines, the end products of protein metabolism, normally excreted in urine, accumulate in the blood. Uremia develops and adversely affects every system in the body. The greater the buildup of waste products, the more severe the symptoms. Box 27-5 outlines stages of CKD. The disease tends to progress in patients who excrete significant amounts of protein or those who have elevated BP more rapidly than in those without these conditions.

Risk Factors

While the number of new patients with end-stage kidney failure appears to be stabilizing in the United States, the need to reduce both the incidence and prevalence of this devastating complication of kidney disease even further cannot be overemphasized. Undoubtedly the key to success is prevention of both CKD and AKI (USRDS, 2014). Healthy People 2020 identifies five risk factors for kidney failure:

1. Diabetes
2. Hypertension
3. Proteinuria
4. Family history
5. Increasing age

It also identifies diabetes (36%) and hypertension (24%) as the two major causes. Other causes include chronic glomerulonephritis, pyelonephritis, obstruction of the urinary tract, hereditary lesions such as in polycystic kidney disease, vascular and autoimmune disorders (such as SLE), infections, medications, or toxic agents. Men are 50% more likely to develop CKD than are women (CDC, 2014). Comorbid conditions that develop during CKD contribute to the high morbidity and mortality among patients with kidney failure (CDC, 2014). Environmental and occupational agents that have been implicated in kidney failure include lead, cadmium, mercury, and chromium.

When targeting health education for prevention of CKD, the nurse includes evidence that early detection and treatment of kidney disease may prevent—or at least delay—the progression of chronic kidney failure to end-stage kidney failure. ACE inhibitors or angiotensin receptor blockers (ARBs) are used to slow the progression of kidney failure. Strict control of blood glucose delays and possibly even prevents the progression of diabetic nephropathy (Lewis, 2013).

Clinical Manifestations and Assessment

Patients with significant kidney damage may be asymptomatic until the GFR reaches 20% to 50% (Adams & Urban, 2016; Grossman & Porth, 2014). Virtually every body system is affected by CKD. Severity of signs and symptoms depends on the degree of renal impairment, other underlying conditions, and the patient's age. Clinical manifestations of uremia do not generally appear until the GFR is reduced to approximately 15% to 20% of normal (Wolfson, 2014). Uremia has particular effects on a variety of organ systems that are detailed below. Some can be managed with dialysis while others cannot.

Systemic Manifestations

- *Neurologic manifestations:* Neurologic changes include lethargy, altered level of consciousness, inability to concentrate, muscle twitching, agitation, confusion, and seizures. Peripheral neuropathy and cramps are present in some patients. Restless leg syndrome and painful or "burning" feet can occur in the early stage of uremic peripheral neuropathy.
- *Cardiovascular manifestations:* Hypertension results from retention of sodium and water due to activation of the renin–angiotensin–aldosterone system; fluid volume excess causes heart failure and pulmonary edema. Pericarditis (with or without pericardial fluid accumulation) is caused by irritation of the pericardium by uremic toxins and may require dialysis. Cardiovascular disease is the predominant cause of death in patients with kidney failure (Wolfson, 2014). In patients receiving chronic hemodialysis, approximately 45% of overall mortality is attributable to cardiac disease, and about 20% of these cardiac deaths are due to acute myocardial infarction (Choi, Park, & Ha, 2014).

Nursing Alert
Abrupt weight gain or a body weight considerably over "dry weight" (typically more than 5 lb) is the most reliable clue of fluid volume excess (Wolfson, 2014).

- *GI manifestations:* GI signs and symptoms are common and include anorexia, nausea, vomiting, and hiccups. The patient's breath may have the odor of ammonia or urine (uremic fetor), or the patient may complain of a metallic taste in the mouth.
- *Immunologic manifestations:* Defective granulocytes, B- and T-cell function, and impaired phagocytosis can lead to impaired immune and inflammatory response.
- *Hematology manifestations:* Anemia, secondary to decreased erythropoietin (hormone that stimulates RBC production by the bone marrow) production. Increased bleeding risk because of defective platelet adhesiveness. In general, a normal amount of platelets are seen; however, bleeding time is prolonged.
- *Genitourinary manifestations:* Erectile dysfunction, decreased libido, pain during intercourse (women), and amenorrhea may result.
- *Dermatologic manifestations:* Pruritus is common. Uremic frost, the deposit of urea

crystals on the skin, is uncommon today because of early and aggressive treatment of kidney failure with dialysis. The skin may be bronze or waxy yellow or gray, particularly in dark-skinned individuals. The precise mechanisms have not been identified for many of these diverse signs and symptoms.

Musculoskeletal manifestations: Bone and joint problems are associated with disturbances of calcium and phosphate metabolism, resulting in renal osteodystrophy, a clinical entity encompassing several overlapping varieties of bone disease that can cause bone pain or frank fractures (Wolfson, 2014). Box 27-6 summarizes the signs and symptoms seen in kidney failure.

BOX 27-6 Focused Assessment

Chronic Kidney Failure

Be alert for the following signs and symptoms:

Neurologic
- Weakness and fatigue
- Confusion or behavior changes
- Inability to concentrate
- Disorientation
- Tremors
- Seizures
- Asterixis
- Restless leg syndrome
- Burning of soles of feet

Integumentary
- Gray-bronze skin color
- Dry, flaky skin
- Pruritus
- Ecchymosis or purpura
- Thin, brittle nails
- Coarse, thinning hair

Cardiovascular
- Hypertension
- Pitting edema (feet, hands, sacrum)
- Periorbital edema
- Engorged neck veins
- Pericarditis/pericardial friction rub

- Pericardial effusion or tamponade
- Hyperkalemia
- Hyperlipidemia

Pulmonary
- Crackles
- Thick, tenacious sputum
- Depressed cough reflex
- Pleuritic pain
- Shortness of breath
- Tachypnea
- Kussmaul-type respirations
- Uremic pneumonitis

Gastrointestinal
- Ammonia odor to breath ("uremic fetor")
- Metallic taste
- Mouth ulcerations and bleeding
- Anorexia, nausea, and vomiting
- Hiccups
- Constipation or diarrhea
- Bleeding from GI tract

Hematologic
- Anemia
- Thrombocytopenia

Reproductive
- Erectile dysfunction
- Amenorrhea
- Testicular atrophy
- Infertility
- Decreased libido

Musculoskeletal
- Muscle cramps
- Loss of muscle strength
- Renal osteodystrophy
- Bone pain
- Bone fractures

- Foot drop

Glomerular Filtration Rate

As glomerular filtration decreases, the serum creatinine and BUN levels increase; the creatinine clearance decreases. Serum creatinine is the more sensitive indicator of kidney function because of its constant production in the body. The BUN is affected not only by kidney disease but also by protein intake in the diet, tissue catabolism, fluid intake, parenteral nutrition, and medications such as corticosteroids. Calculation of GFR is discussed in Chapter 26, and the stages of CKD based on GFR can be found in Box 27-5.

Sodium and Water Retention

Some patients retain sodium and water, thus increasing the risk for edema, heart failure, and hypertension. Dilutional hyponatremia typically occurs. Hypertension also may result from activation of the renin–angiotensin–aldosterone system and the concomitant increased secretion of aldosterone. Episodes of vomiting and diarrhea may cause sodium and water depletion, which worsens the uremic state.

Acidosis

In advanced kidney disease, metabolic acidosis occurs because the kidneys are unable to excrete hydrogen ions (H^+). Decreased acid secretion results from the inability of the kidney tubules to excrete ammonia (NH_3^-) and to reabsorb bicarbonate (HCO_3^-). There is also decreased excretion of phosphates and other organic acids.

Anemia

Anemia is caused by inadequate production of erythropoietin by the damaged kidney. Erythropoietin, normally produced by the kidneys, stimulates bone marrow to produce RBCs. Anemia is exacerbated further by the shortened lifespan of RBCs due to uremia, nutritional deficiencies, and the patient's tendency to bleed, particularly from the GI tract. The nurse should assess for fatigue, shortness of breath, and chest pain.

Calcium and Phosphorus Imbalance

Hyperphosphatemia with resulting hypocalcemia develops in kidney failure. The decreased serum calcium level causes increased secretion of parathormone from the parathyroid glands, causing calcium to leave the bone. Bone weakness and fractures may result. The active metabolite of vitamin D (1,25-dihydroxycholecalciferol), normally manufactured by the kidney, decreases as kidney failure progresses, impairing calcium absorption. Uremic bone disease or renal osteodystrophy develops from the complex changes in the balance of calcium, phosphate, and parathormone.

Medical Management

The goal of management is to maintain kidney function and homeostasis for as long as possible while continuing to treat the underlying disorder(s). Avoidance of risk factors, dietary modification, BP control, adequate treatment of the associated conditions, and where needed, preparation for RRT, are utilized (Godara et al., 2014). Renal replacement therapy is planned for as kidney disease progresses and is discussed in detail later in the chapter.

Pharmacologic Therapy

Complications can be prevented or delayed by administering prescribed phosphate-binding agents, calcium supplements, antihypertensive and cardiac medications, anticonvulsants, and erythropoietin (Epogen/Procrit).

Calcium and Phosphorus Binders

Hyperphosphatemia and hypocalcemia are treated with medications that bind dietary phosphorus in the GI tract. Binders, such as calcium carbonate (Os-Cal) or calcium acetate (PhosLo), are prescribed. If the calcium–phosphorus product exceeds 55 mg/dL, a polymeric phosphate binder, such as sevelamer hydrochloride (Renagel) or sevelamer carbonate (Renvela), may be used. The calcium-phosphorus product is calculated by multiplying the serum calcium (corrected for albumin—see Nursing Alert below) by the phosphate level. The nurse plans to administer phosphate binders with food for them to be effective. Parathyroid agents, such as cinacalcet (Sensipar), which mimics calcium, may be given for secondary hyperparathyroidism of kidney failure. The medication "tricks" the parathyroid glands into sensing high calcium levels, causing reduced production of parathyroid hormone (PTH). When PTH decreases, bone resorption diminishes (Adams & Urban, 2016).

Nursing Alert

Calcium exists as either bound to albumin or in its free form, which is termed ionized. *Ionized calcium is physiologically active whereas calcium bound to albumin is inactive. Standard laboratory tests measure the total calcium (ionized and bound). If serum albumin is low, as it is in patients with nephrotic syndrome and other processes such as starvation or renal cachexia, a lower total calcium is seen on laboratory results. An ionized calcium level may be ordered or a correction for this perceived calcium deficit may be used.*

To correct the calcium level, the nurse adds 0.8 g/dL to the total calcium value for every gram of albumin below 4.0 g/dL, using this formula:

Corrected calcium = serum total calcium (mg/dL) + 0.8 × (4 – serum albumin [g/dL])

Note: a normal serum calcium level is 8 to 10 mg/dL, which may vary slightly by laboratory; a normal serum albumin is 3.5 to 5.2 g/dL.

Example: Patient has albumin of 2 g/dL (20 g/L), and total serum calcium concentration of 8

mg/dL.

Formula: 8 mg/dL + 0.8 (4 – 2 g/dL)

8 + 0.8(2)
8 + 1.6
9.6 mg/dL = corrected calcium level

Pathophysiology Alert
The parathyroid glands regulate blood calcium. Secondary hyperparathyroidism may develop in patients with kidney failure. The parathyroid glands respond to hypocalcemia by increasing the secretion of PTH. PTH attempts to elevate the blood calcium by stimulating the release of calcium from the bones. Thus, the nurse should observe for bone pain, osteoporosis, and pathologic bone fractures.

Pathophysiology Alert
Under normal circumstances, hypocalcemia results in enhanced calcium uptake by renal collecting tubules. However in kidney failure, the collecting tubes are unable to reabsorb calcium, and activation of vitamin D also is impaired. With decreased renal synthesis of 1,25-dihydroxyvitamin D (also known as calcitriol, the active form of vitamin D), the intestinal absorption of calcium is decreased. Thus kidney diseases place patients at risk for hypocalcemia, secondary hyperparathyroidism, and hyperphosphatemia.

Antihypertensive and Cardiovascular Agents

Hypertension is managed by restriction of sodium and fluids as well as antihypertensive agents. Diuretics (in patients with some residual kidney function) and inotropics, such as digoxin (Lanoxin) or dobutamine (Dobutrex), may be used. Care must be taken to prevent digoxin toxicity in patients with renal impairment.

Nursing Alert
A therapeutic serum level of digoxin is 0.8 to 2 ng/mL (1.0 to 2.6 nmol/L) for patients with congestive heart failure (CHF) and 1.5 to 2.5 ng/mL (2.0 to 3.2 nmol/L) for patients with arrhythmias. The nurse is aware that signs and symptoms of digoxin toxicity may include nausea, vomiting, anorexia, green/yellow visual distortion (a commonly reported symptoms in hospitalized patients) (Fischbach & Dunning, 2014).

Anticonvulsants Agents

IV diazepam (Valium), lorazepam (Ativan), or phenytoin (Dilantin) usually is administered to control seizures, which may develop as azotemia worsens. The side rails of the bed should be raised and bed in low position to protect the patient. If a seizure occurs, the nurse protects the patient's head, loosens constrictive clothing, and removes patient's eyeglasses. The nursing management of the patient with seizures is discussed in Chapter 46.

Erythropoietin

Anemia associated with CKD is treated with recombinant human erythropoietin (e-poietin, Epogen/Procrit) or darbepoetin alfa (Aranesp). Therapy is initiated to achieve a hematocrit of 33% to 38% and a target hemoglobin of >11 g/dL, to alleviate the symptoms of anemia (Adams & Urban, 2016). Hemoglobin values above 12 g increase the risk of death and serious thromboembolic and cardiovascular events. E-poietin is administered intravenously at the end of dialysis or subcutaneously. Blood transfusions are indicated for patients with chest pain or extreme dyspnea. Adverse effects seen with erythropoietin therapy include headache, arthralgia, nausea, hypertension, increased clotting, seizures, and depletion of body iron stores (Adams & Urban, 2016). The expected outcome for patients receiving e-poietin is decreased fatigue, higher-energy levels, increased feeling of well-being, better tolerance of dialysis, and improved tolerance of exercise.

Nursing Alert

The use of erythropoietin (Epogen/Procrit) has been shown to have a significant effect on hematocrit levels. Patients with CKD whose anemia is untreated typically have hemoglobin concentrations in the range of 6 to 8 g/dL, and erythropoietin administration has demonstrated success in correcting the anemia. However, a black-box warning about erythropoietin-stimulating agents (ESAs) suggests that clinicians and patients with CKD "weigh the benefits of ESAs to decrease the need for transfusions against the increased risks for serious, adverse cardiovascular events" associated with ESAs (FDA, 2017; Berns, 2016). The lowest dose of ESA sufficient to reduce the need for transfusion is recommended. Although a target Hgb range is not provided, it is suggested that for dialysis patients receiving ESA treatment should be initiated when the Hgb level is below 10 g/dL and dose interrupted or reduced for Hb >11 gm (or >10 gm in non dialysis patients) (fda.gov, 2017). Hgb levels >11 g/dL are associated with adverse cardiovascular events which include hypertension, increased risk for stroke, and vascular thrombosis (FDA, 2017).

Iron, in the form of iron sucrose (Venofer) and ferric gluconate (Ferrlecit), may be prescribed to promote an adequate response to erythropoietin. Hypertension that cannot be controlled is a contraindication to recombinant erythropoietin therapy.

Nutritional Therapy

The diet for patients with kidney disorders includes limiting protein as well as restrictions on fluids, sodium, potassium, and phosphorus. Protein restriction to 0.8 g/kg/day of ideal body weight can slow the progression of renal disease and improve the symptoms of uremia, including nausea and vomiting. At least 50% of the allowed protein must be of high biologic value (HBV), including eggs, meats, and plant-based proteins. There is controversy over the degree of protein restriction: too little protein and malnutrition can cause loss of strength, muscle mass, and weight (Grossman & Porth, 2014). Protein restriction is difficult for most patients; the nurse should give positive feedback and express confidence in the patient's ability to adhere to the eating plan. Dietary protein is increased slightly during dialysis to compensate for loss of protein and amino acids in the dialysate. At the same time, adequate caloric intake and vitamin supplementation must be ensured because a protein-restricted diet does not provide the necessary complement of vitamins,

and dialysis results in loss of water-soluble vitamins. Calories are supplied by carbohydrates and fat to prevent wasting.

The patient must adhere to a daily fluid allowance of approximately 500 to 800 mL plus the previous day's 24-hour urine output (recall insensible loss is 1 L per day). WE CAN GO WITH TYPICAL FLUID ALLOWANCE OF 1000 ML/DAY (COULD VARY). OK TO LEAVE OFF PREVIOUS DAY'S OUTPUT. The nurse teaches the patient different strategies to control intake and thirst, such as sucking on hard candies or mints, chewing gum, rinsing the mouth with refrigerated water, sucking on a lemon wedge, using small glasses instead of large ones, and moisturizing the lips.

Potassium restriction involves limiting citrus, tomatoes, melons, green leafy vegetables, and potatoes. Also phosphorus is restricted; this is contained in dairy, peas, beans, nuts (including peanut butter), and cola products. Sodium is contained in many canned and processed foods and in smoked foods lunchmeats, as well as in MSG.

Nursing Alert

Patients with kidney disease must be aware that some salt substitutes contain potassium chloride and should be avoided.

Dialysis

The patient with increasing symptoms of kidney failure is referred to a dialysis or transplantation center early in the course of progressive disease. Dialysis is initiated when the patient cannot maintain homeostasis with conservative treatment; dialysis is discussed in detail later in the chapter.

Nursing Management

The patient with CKD requires astute nursing care to avoid the complications of reduced kidney function and the stresses and anxieties of dealing with a life-threatening illness.

Nursing care and education are directed toward fluid and electrolyte imbalance, dietary management, and promoting positive feelings by encouraging increased self-care and greater independence. It is extremely important to provide frequent, clear explanations and information to the patient and family concerning kidney failure, treatment options, and potential complications. A plan of nursing care for a patient with kidney failure is available online at http://thepoint.lww.com/Honan2e.

Teaching Patients Self-Care

Encouraging self-management is an essential role of the nurse when caring for patients with kidney failure. Nurses in home care, dialysis centers, hospitals, and outpatient settings all provide ongoing education and reinforcement while monitoring the patient's progress and adherence to the treatment regimen. The nurse includes the patient's beliefs, values, and concerns in the treatment regimen to improve patient outcomes.

The nurse and dietician reinforce the diet parameters for patients with renal disorders as well as fluid restrictions, explaining the correlation between symptoms and nonadherence. The patient can be encouraged to take BP measurements and daily weights at home to illustrate the effect of prescribed antihypertensives and fluid restriction with BP elevations or SOB.

The patient and family should report the following symptoms of worsening kidney function to the health care provider:

- Signs and symptoms of worsening kidney failure, including nausea, vomiting, change in usual urine output, or ammonia/urine odor to the breath
- Signs and symptoms of hyperkalemia, including muscle weakness, diarrhea, abdominal cramps
- If receiving dialysis, signs and symptoms of access problems, such as clotted fistula or graft or signs of infection at the site

Continuing Care

The nurse teaches the patient to follow-up with examinations and treatments to prevent and detect progression of renal disease as well as reinforce care for the primary disorder. The patient and family should be alerted to symptoms of worsening condition, have treatment options explained, and be offered psychoemotional support. The home care nurse has the opportunity to assess the patient's environment, emotional status, and the coping strategies used by the patient and family to deal with the changes in family roles often associated with chronic illness. Assessment, ongoing education, and reinforcement of the diet for patients with renal disorders are performed. Reminders about the need for health-promoting activities and health screening, particularly cardiovascular health, are important when caring for the patient with kidney failure.

Gerontologic Considerations

The age and number of patients with CKD over 60 years of age have increased steadily each year, while the incidence of those under 40 years of age remains at 0.5% (USRDS, 2014). The number of patients aged 75 years and older being treated for end-stage kidney failure has doubled. The increased incidence of diabetes and hypertension is one cause of this increase. Other common causes of kidney failure in the elderly population include renovascular disease (27%) and urinary tract obstruction by the prostate (22%) (Lewis, 2013). The signs and symptoms of renal disease in the elderly may be nonspecific. Comorbid disorders, such as heart failure or dementia, can delay diagnosis and complicate treatment. Hemodialysis and PD have been used effectively in treating elderly patients. Although there is no specific age limitation for renal transplantation, concomitant disorders, such as coronary artery disease or peripheral vascular disease, have made that treatment less common for the elderly. Treatment for those with CKD should be adapted to suit the patient's comorbidities and life expectancy (Lewis, 2013). Older persons are more prone to "white coat hypertension" (refer to Chapter 13); therefore 24-hour monitors should be used to validate a diagnosis of hypertension. Systolic hypertension also is common in the elderly; overtreatment can result in diastolic hypotension or orthostatic hypotension, which may lead to dizziness, falls, and risk for fracture (Lewis, 2013).

ACE inhibitors and ARBs have renal protective effects, yet the use of these medications in the elderly should be undertaken with caution. If the patient's serum creatinine increases by 25% or more with the use of these agents, then the medication should be discontinued (Lewis, 2013).

Knowing that CKD is a risk factor for cardiovascular disease, the elderly should receive advice on lifestyle modification and medications, such as antiplatelet and lipid-lowering medications.

Only 1% of older individuals with stage 3 kidney disease progress to kidney failure (Lewis, 2013); rather, they die from other causes. Of those over 75 years of age who choose RRT, 50% die within a year of starting treatments. The patient and family must be aware that RRT cannot restore health (Lewis, 2013).

Available diagnostic criteria and treatment guidelines are not tailored specifically to the older adult. Tight control of BP and polypharmacy may place the elderly and infirm at risk for complications. Individuals over 75 years of age without proteinuria and stable estimated glomerular filtration rates (eGFR) of 45 to 60 mL/min should be managed as are those without CKD (Lewis, 2013).

Nursing Alert

The eGFR is a calculation based on blood creatinine level and other variables such as age, sex, and race (e.g., African American vs. non–African American), whereas the GFR requires a creatinine clearance test (timed urine collection of 24 hours) and the serum creatinine in order to compare blood and urine creatinine concentrations.

When an elderly patient refuses dialysis or transplantation, conservative management with nutritional therapy, fluid control, and medications may be used. Advanced directives

and end-of-life care based on quality of life should be explored. This end-of-life care may be in order for those for whom conservative management is no longer effective or those who choose to withdraw from RRT (Lewis, 2013).

Complications

Complications of chronic kidney failure necessitate a collaborative approach to care and include the following:

- Hyperkalemia due to decreased excretion, metabolic acidosis, catabolism, and excessive intake (diet, medications, fluids)
- Pericarditis, pericardial effusion, and pericardial tamponade due to retention of uremic waste products and inadequate dialysis
- Hypertension due to retention of sodium and water and malfunction of the renin–angiotensin–aldosterone system
- Anemia due to decreased production of erythropoietin, decreased RBC lifespan, bleeding in the GI tract from irritating toxins and ulcer formation, and blood loss during hemodialysis
- Bone disease and metastatic and vascular calcifications due to retention of phosphorus, low levels of serum calcium, abnormal metabolism of vitamin D, and elevated levels of aluminum

RENAL REPLACEMENT THERAPIES

Renal replacement therapy is a term used to encompass life-supporting treatments for kidney failure, including hemodialysis, PD, hemofiltration, and renal transplantation. While these treatment modalities are discussed within the context of kidney failure, hemodialysis and PD may be employed to restore homeostasis in patients with AKI as well.

As end-stage kidney disease (ESKD) approaches, the patient's very survival is threatened. Choosing a treatment option for kidney failure can be overwhelming. Applying best practices and health care navigation for patient with end-stage renal disease may improve their ability to make informed decisions and increase the numbers of those pursuing transplant (Skelton, Waterman, Davis, Peipert, & Fish, 2015). The *My Life, My Dialysis Choice Decision Aid* from the nonprofit Medical Education Institute, Inc. shifts the discussion from *how* to do dialysis to *why* a particular RRT option may be a better fit for the patient's lifestyle (Schatell, 2015). Additionally, there is a need to normalize discussions about concerns, fears, preferences, priorities, and future care for those with kidney failure throughout the disease process. For individuals struggling to maintain career and family life and roles while undergoing hemodialysis, there is a need for advanced care planning early in the trajectory of the disease to facilitate development of realistic goals. For those over 65 years of age receiving hemodialysis, recognizing that 25% will die within the year means preferences and priorities for future care should be elicited (Bristowe et al., 2015).

DIALYSIS

Dialysis is used to remove fluid and uremic waste products from the body when the kidneys are unable to do so. Methods of therapy include hemodialysis, PD, and continuous renal replacement therapy (CRRT).

Whether kidney disease is acute or chronic, dialysis becomes necessary in uremia upon the development of hyperkalemia, fluid overload, or impending pulmonary edema, acidosis, pericarditis, or severe confusion/encephalopathy. It also may be used to remove certain medications or other toxins due to poisoning or medication overdose.

The decision to initiate dialysis is reached after thoughtful discussion with the patient, family, providers, and others (social work, spiritual adviser, etc.), as appropriate. Many potentially life-threatening issues are associated with the need for dialysis. The nurse can assist the patient and family by answering their questions, clarifying the information provided, and supporting their decision. Often the lifestyle changes that patients requiring long-term hemodialysis need to make are overwhelming.

Although the costs of dialysis usually are reimbursable, limitations on the patient's ability to work, resulting from illness and dialysis, usually impose a great financial burden on the patient and family.

HEMODIALYSIS

Hemodialysis is the most common method of dialysis. Treatments usually occur three times a week and take about 3 to 5 hours per treatment. The trend in managing CKD is to initiate treatment before the signs and symptoms associated with uremia become severe.

Description

Hemodialysis functions as an artificial kidney, removing toxic nitrogenous substances and excess water from the blood. The patient's blood is diverted to a machine, where toxins are removed, and then the blood is returned to the patient's body. Hemodialysis requires a semipermeable membrane found in the hollow fiber dialyzer, or artificial kidney, to replace the function of the impaired kidneys. The dialyzer contains thousands of tiny cellophane tubules through which the blood flows; a dialysate solution circulates around the tubules. The exchange of wastes from the blood to the dialysate occurs through the semipermeable membrane by way of osmosis, diffusion, and ultrafiltration (Fig. 27-2). The toxins and wastes in the blood are removed by diffusion, in which particles move from an area of higher concentration in the blood to an area of lower concentration in the dialysate. The dialysate is a solution made up of electrolytes in their ideal extracellular concentrations. The electrolyte level in the patient's blood can be brought under control by adjusting the dialysate. The semipermeable membrane impedes the diffusion of large molecules, such as RBCs and proteins, keeping them in the bloodstream.

Excess water is removed from the blood by osmosis, in which water moves from an area of lower concentration of particulates in the blood (dilute) toward an area of higher concentration of particulates in the dialysate. In ultrafiltration, water moves under high pressure to an area of lower pressure to facilitate water removal. This process is accomplished by applying negative pressure or a suctioning force to the dialysis membrane.

The anticoagulant heparin is administered to keep blood from clotting in the dialysis circuit. When this is dangerous to the patient, such as in patients with thrombocytopenia, saline flushes may be used. At the end of the treatment, the dialysate, excess fluid, and waste products are discarded.

Vascular Access

Access to the patient's vascular system must be established to allow blood to be removed, cleansed, and returned to the patient's vascular system at rates between 300 and 550 mL/min. Several types of access are available.

Temporary Vascular Access Devices

Immediate access to the patient's circulation for emergency hemodialysis is achieved by inserting a double-lumen large-bore catheter into the subclavian, internal jugular, or femoral vein (Fig. 27-3). This method of vascular access involves some risk, such as hematoma, pneumothorax, infection, thrombosis of the subclavian vein, or inadequate flow. For the patient with end-stage kidney failure, the nurse should emphasize that these are "bridge" catheters and not permanent access; they are used while a method for permanent vascular access is created and heals.

Nursing Alert
Temporary vascular access devices for dialysis (e.g., Quinton catheter or permacath) typically are flushed with heparin by the dialysis nurse at the end of the treatment to maintain device patency. Typically the nurse should not use these devices for routine access. If, however, a life-threatening emergency occurs and no other access is available, the nurse MUST know that the catheter is NEVER flushed before ASPIRATING THE CATHETER PORTS to prevent systemic anticoagulation.

The Fistula First Project (National Vascular Access Improvement Initiative) was designed to increase permanent access with AV fistula placement in 66% of long-term dialysis patients by 2009. The AVF First Breakthrough Initiative (FFBI) has made dramatic progress, increasing permanent access to nearly 60% by 2011 (Vassalotti et al., 2012).

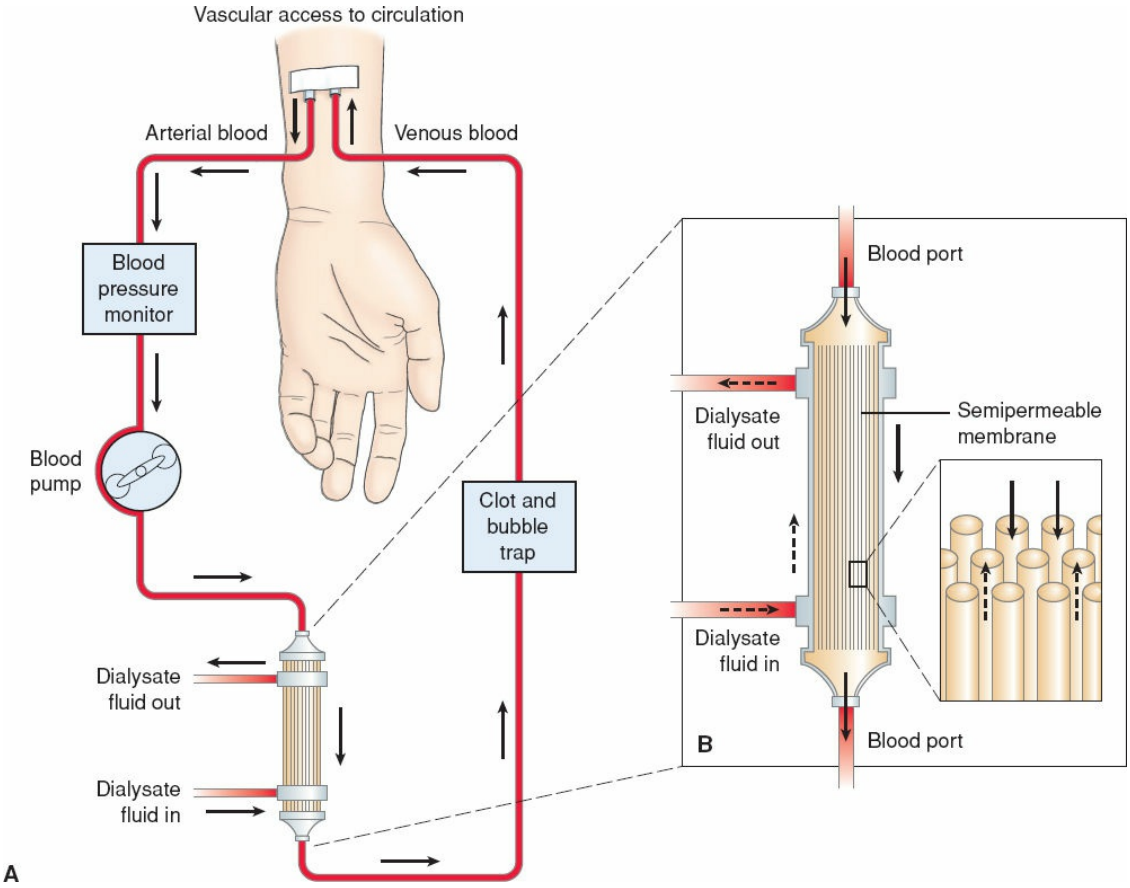

FIGURE 27-2 Hemodialysis system. A. Blood from an artery is pumped into (B) a dialyzer where it flows through the cellophane tubes, which act as the semipermeable membrane (*inset*). The dialysate, which has the same chemical composition as the blood except for urea and waste products, flows in around the tubules. The waste products in the blood diffuse through the semipermeable membrane into the dialysate.

Arteriovenous Fistula

The gold standard for permanent access is a surgically created arteriovenous fistula, usually placed in the forearm. The fistula is created by joining (anastomosing) an artery to a vein (Fig. 27-4). The venous segment of the fistula will dilate in response to increased arterial pressure to provide for rapid removal and return of blood. When performing dialysis, two large-bore (14- to 16-gauge) needles are inserted into the fistula; the arterial segment of the fistula is used for flow to the dialyzer and the venous segment for reinfusion of the dialyzed blood. The fistula should be given heal and mature (4 to 6 weeks is preferable). The patient is encouraged to perform exercises, such as squeezing a rubber ball, to help the access mature and to increase the size of these vessels.

Arteriovenous Graft

An arteriovenous graft can be created by subcutaneously inserting synthetic graft material between an artery and vein (see Fig. 27-4). The synthetic graft material that is used most commonly is expanded polytetrafluoroethylene (Gortex). Usually, a graft is created when the patient's vessels are not suitable for creation of a fistula, such as in the patient with diabetes. Infection and thrombosis are the most common complications of arteriovenous

grafts.

Ideally, the surgical access is created 2 to 3 months before the need for RRT so the access can mature (niddk.nih.gov, 2014). Patients should be given information about the access and about potential changes in body image, which can trigger noncompliance or depression.

Nursing Alert

Failure of the permanent dialysis access (fistula or graft) accounts for most hospital admissions of patients undergoing chronic hemodialysis. Thus, protection of the dialysis access is of high priority.

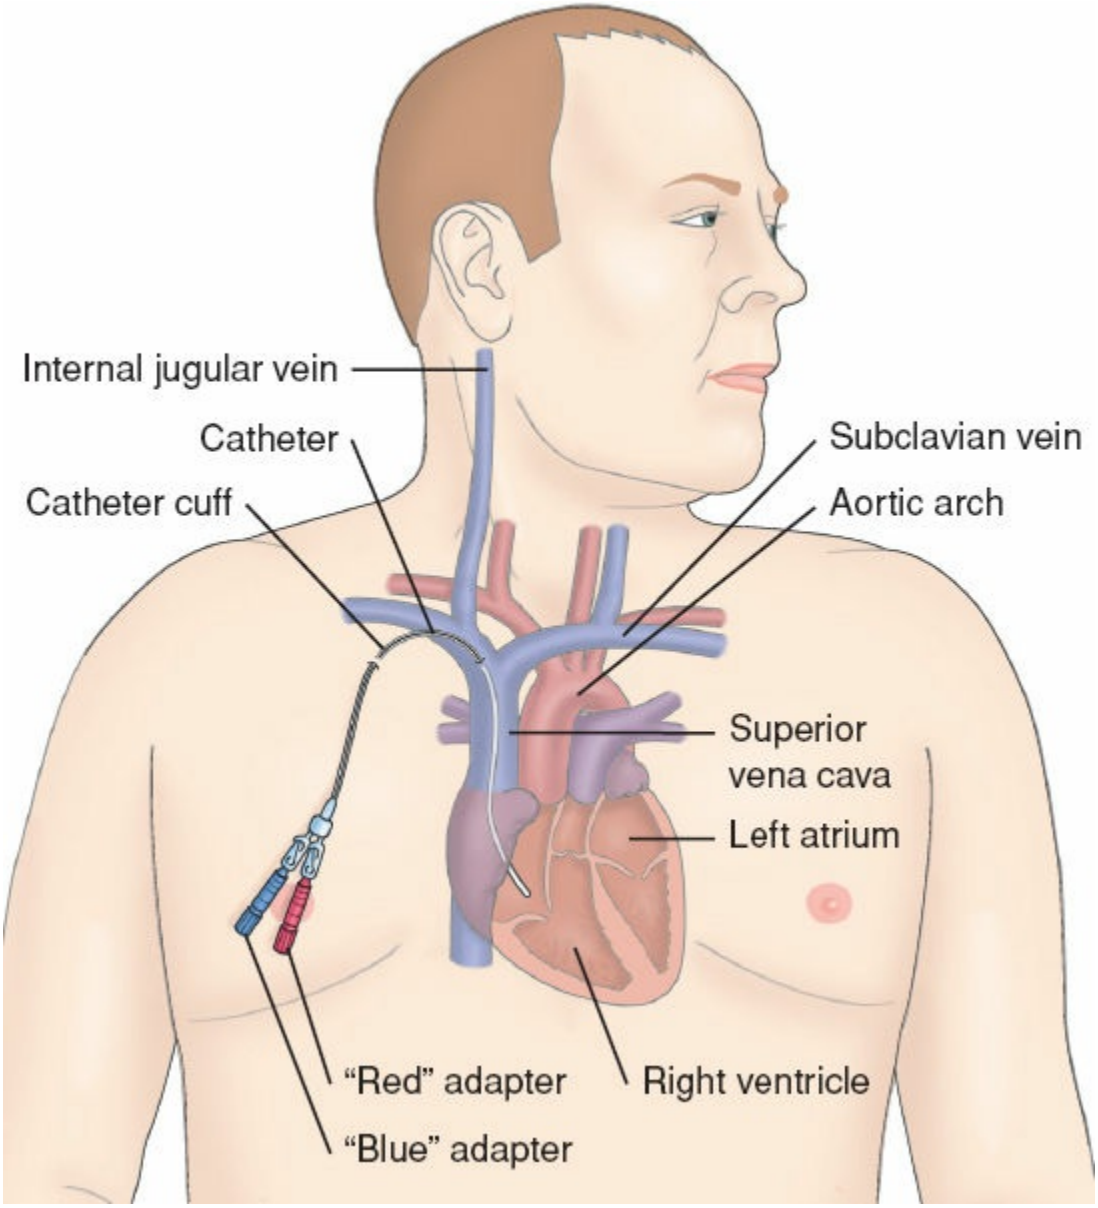

FIGURE 27-3 Double-lumen, cuffed hemodialysis catheter used in acute hemodialysis. The red adapter is attached to a blood line through which blood is pumped from the patient's body to the dialyzer. After the blood passes through the dialyzer (artificial kidney), it returns to the patient's body through the blue adapter.

Patient Education

The nurse teaches the patient with a fistula or graft to check daily for a thrill, a vibrating or buzzing sensation, over the graft and to notify the health care provider or dialysis center if this is absent. The nurse assesses for a thrill and a bruit, a swishing sound heard with the stethoscope. Further teaching includes avoiding compression of the site; not permitting blood to be drawn, an IV to be inserted, or BP to be taken on the extremity with the dialysis access; not to wear tight clothing or carry bags or pocketbooks on that side; and not to lie on or sleep on the area. The patient is taught to observe the site daily for redness, swelling, bleeding, drainage, heat, or pain and to report these promptly to the health care provider.

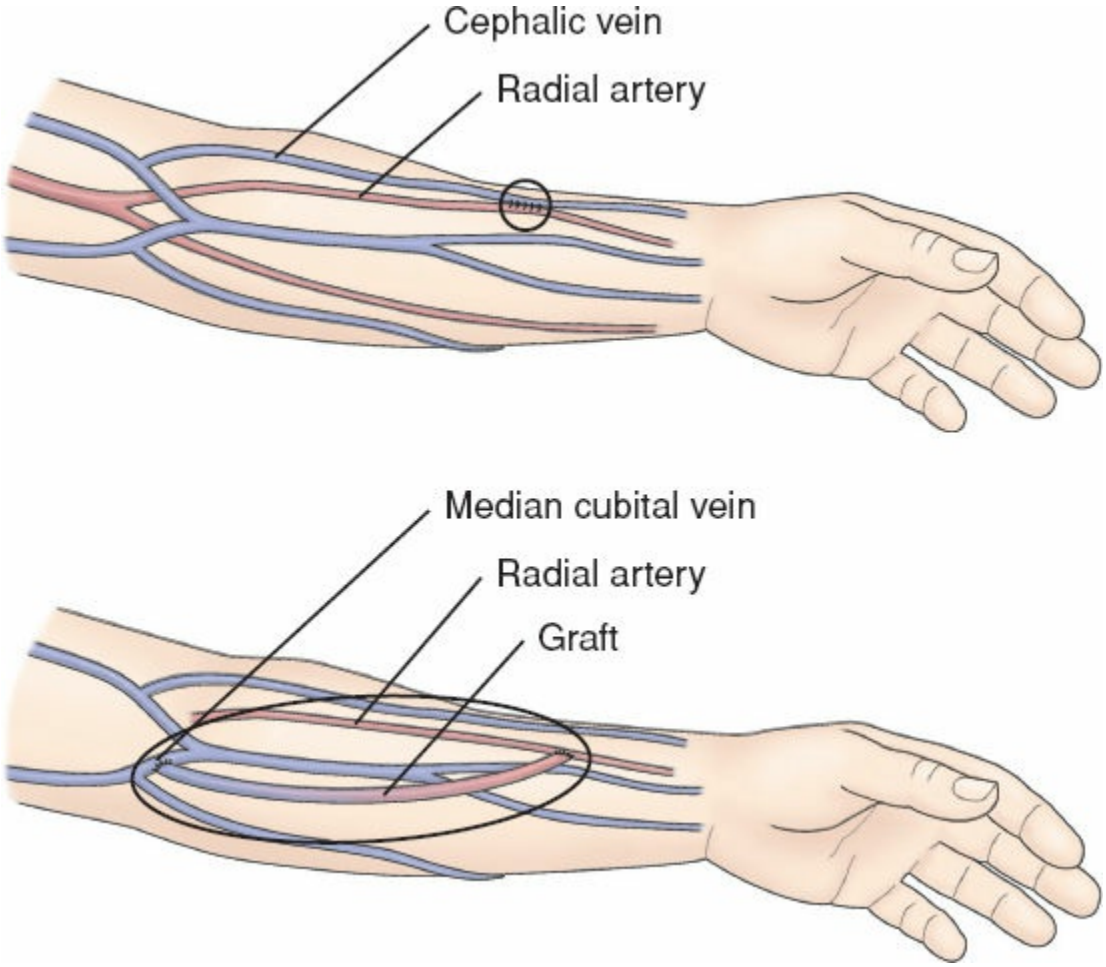

FIGURE 27-4 An internal arteriovenous fistula (top) is created by a side-to-side anastomosis of the artery and vein. A graft (bottom) can also be established between the artery and vein.

Clotting of the dialysis access increases the risk of life-threatening imbalance of fluids and electrolytes as lack of patency means dialysis cannot be performed. If this occurs, fibrinolysis, surgical thrombectomy, or revision is indicated.

Medical and Nursing Management

During dialysis, the patient, the dialyzer, and the dialysate bath require constant monitoring for complications. The dialysis nurse uses this time for assessing, monitoring, supporting, and educating the patient. The nurse may use this time to discuss the diet for patients with renal disorders or to reinforce fluid restriction, which may cause interdialytic weight gain (Box 27-7). The nurse palpates the fistula or graft for a thrill and auscultates for a bruit or swishing sound, indicating patency of the access.

Pharmacologic Therapy

Just as many medications are excreted wholly or in part by the kidneys, many medications are removed from the blood during hemodialysis; therefore, dosage adjustments may be needed. Metabolites of drugs that are bound to protein are not removed during dialysis. Removal of other drug metabolites depends on the weight and size of the molecule.

Patients undergoing hemodialysis who require medications, for example, cardiac glycosides, antibiotic agents, antiarrhythmic medications, or antihypertensive agents, are monitored closely to ensure that the blood and tissue levels of these medications are maintained without toxic accumulation. The nurse plans to administer these medications after dialysis to avoid their removal.

Evaluating for medications that may promote complications during dialysis is part of nursing care. For example, if an antihypertensive agent is taken prior to dialysis, dangerous hypotension may occur during dialysis. Administration of many medications that are taken once daily can be delayed until after the dialysis treatment. Collaboration with the hospital pharmacist is important.

Nutritional and Fluid Therapy

Diet is an important factor for patients on hemodialysis because of the effects of uremia. With the initiation of hemodialysis, the patient usually requires restriction of dietary protein, sodium, potassium, phosphorous, and fluid. Protein intake is more liberal during hemodialysis but still restricted to about 1.2 to 1.3 g/kg/day of ideal body weight; therefore, protein must be of high biologic quality and consist of the essential amino acids to prevent poor protein use and to maintain a positive nitrogen balance (Dudek, 2014). Examples of foods high in biologic protein content are typically from animal sources and include eggs, meat, milk, cheese, poultry, and fish. Usually sodium is restricted to 1 to 3 g/day; fluids are restricted to replace insensible losses (Grossman & Porth, 2014). The goal for patients on hemodialysis is to keep their interdialytic weight gain under 1.5 kg (recall dialysis is typically every 2 to 3 days). Water-soluble vitamins may need to be replaced as they are dialyzed out; these are available in a single gelcap containing vitamins B, C, pyridoxine, folate, riboflavin, biotin, and other supplements (Nephrocaps) (USNLM, n.d.).

BOX 27-7 Nursing Research

Bridging the Gap to Evidence-Based Practice

Interdialytic Laughter Yoga Therapy for haemodialysis patients: a pre-post intervention feasibility study

Bennet, P., Parsons, T., Ben-Moshe, R., Neal, M., Weinberg, M., Gilbert, K., … Hutchinson, M. (2015). Interdialytic laughter yoga therapy for haemodialysis patients: A pre-post intervention feasibility study. *BMC Complementary and Alternative Medicine*, *15*, 176.

Purpose

Laughter can provide a positive respite from negative emotional effects associated with illness by improving mood and quality of life and reducing depression. The effects of laughter have been manifested as the same outcome whether the laughter is spontaneous or simulated. The authors undertook a feasibility study to determine if laughter yoga, which incorporates clapping, movement of the extremities, deep breathing, neck and shoulder stretches, smiling, and laughter as well as meditation-relaxation, can improve life satisfaction and reduce stress and anxiety in healthy participants receiving hemodialysis.

Design

A 4-week feasibility study was developed with 18 participants with end-stage kidney disease who had been receiving hemodialysis for at least 3 months. Of individuals who completed the study, there were 10 men and seven women, 20 to 89 years of age. The interdialytic intervention was offered by yoga therapists for 30 minutes, three times weekly. Primary outcomes measured at the first and last Laughter Yoga sessions included quality of life, subjective mood, depression, anxiety, and stress. Secondary outcomes were blood pressure, intradialytic hypotensive episodes, and lung function in the form of forced expiratory volume (FEV). Dialysis nurses exposed to the intervention also rated the outcomes using a survey of attitudes and perceptions.

Findings

The authors found nonsignificant increases in happiness, mood, and optimism with a decrease in stress. Of note is that only 13 of 17 individuals completed the first questionnaire, while nine individuals completed the second questionnaire; the researchers' decision was to not pursue the data further and burden those with chronic illness more. Additional findings revealed episodes of intradialytic hypotension decreased by 80%. There were no changes in lung function; however, there was no pulmonary compromise, which is common in those receiving dialysis. The nurses' feedback revealed Laughter Yoga had a positive impact on patients' mood, and they would recommend this to their patients. The authors determined a minimum of 207 participants would be required to detect key changes in the psychological variables measured.

Nursing Implications

Laughter Yoga is a safe, low-intensity and inexpensive form of intradialytic physical activity that has the potential to improve mood and decrease anxiety in hemodialysis

settings. Nurses spontaneously participated in the Laughter Yoga sessions as well; engagement of nurses is important in connection with long-term use of this intervention. A strong sense of humor has been shown to assist patients with coping with stressful life events and increasing the likelihood of survival into old age. While the sample size was small, further studies with larger groups may be of benefit as sustained intradialytic physical activity has been rarely successful in groups with end-stage kidney disease.

Dietary restriction is a difficult lifestyle change for many patients with kidney failure. Patients often feel stigmatized in social situations because they may feel there are few food choices available for their diet. If the restrictions are ignored, life-threatening complications, such as hyperkalemia, hypertension, and pulmonary edema, may result. The nurse who cares for a patient with symptoms or complications resulting from dietary indiscretion should avoid harsh, judgmental, or punitive tones when communicating with the patient. Rather, the nurse emphasizes the correlation between dietary indiscretion and the outcome, such as hypertension or dyspnea, and promotes self-management of the disease.

Providing Psychosocial Care

Often patients requiring long-term hemodialysis are concerned about the unpredictability of the illness and the disruption to their lives. Financial problems, difficulty working, waning sexual desire and impotence, poor-quality sleep, depression from chronic illness, and fear of dying may occur. Younger patients have concerns about marriage, having children, and the burden on their families. Dialysis treatments and restrictions in food and fluid intake often impose challenges to the patient and family. The time required for dialysis and physician visits as well as fatigue and chronic illness can create conflict, frustration, guilt, and depression. The nurse can encourage caregivers and patients to express concerns, anger, or negative feelings; if not expressed, anger may be directed inward and lead to depression, despair, or suicide. If anger is projected outward to other people, it may destroy already-threatened family relationships.

Depression is a common comorbidity in patients receiving dialysis. Inflammation, uremic toxins, sleep disturbances, pain, fatigue, anorexia, adverse medication effects, dietary constraints, changes in sexual function, role strain, and fear of death may contribute to the development of depression. Depression has been linked to nonadherence to dialysis treatment. Counseling, therapy, and pharmacologic treatment as well as deep slow breathing as a relaxation technique may relieve depression (Tsai et al., 2015). Also a mental health provider with expertise in the care of patients receiving dialysis may be helpful. The sense of loss that the patient experiences cannot be underestimated because every aspect of a "normal life" is disrupted.

Some patients use denial to deal with the overwhelming array of medical issues. Labeling a patient "noncompliant" does not demonstrate respect for the impact of kidney failure and its treatment on the patient and family, nor does it encourage positive coping strategies. The idea of "perfect compliance" should be replaced with the term *adherence*, which is more neutral and encourages the patient to share difficulties, such as indiscretion in fluid intake, so it can be dealt with during dialysis.

Patients and their families should be encouraged to discuss end-of-life options. Only between 21% and 25% of patients on hemodialysis have an advanced directive or living will. The ANNA Ethics Committee has developed an end-of-life module to foster the nurse's role in these discussions (ANNA, 2017).

Teaching Self-Care

The diagnosis of CKD and the need for dialysis may be overwhelming. Many patients with kidney failure have depressed mentation, a shortened attention span, a decreased level of concentration, and altered perception. Therefore, teaching should occur in brief, 10- to 15-minute sessions, with time added for clarification, repetition, reinforcement, and questions from the patient and family. The nurse needs to convey a nonjudgmental attitude to enable the patient and family to discuss feelings about those treatment options and the material taught.

One study indicated that higher levels of knowledge and greater degree of self-management were associated with significant improvement of function and well-being. Teaching materials at all reading levels are available on the National Kidney Foundation and National Institute of Health web sites (www.kidney.org, 2015).

Home Hemodialysis

Although most patients who require hemodialysis undergo the procedure in an outpatient setting, home hemodialysis is an option for some. Patients delivering their own hemodialysis have been shown to increase emotional wellness, energy level, and social functioning. Home hemodialysis allows the patient set the schedule, decreases travel and wait times at the dialysis center, and, if done slowly through the night, increases removal of more phosphorus and wastes. Thus, the patient may not require as much dietary restriction or antihypertensive therapy (NIDDK, nd).

According to the NIDDK, a patient learns to perform treatments at the dialysis center, working with a dialysis nurse. Most people who do home hemodialysis have a family member, neighbor, or close friend who trains with them at the clinic. The dialysis center supplies the machine and equipment, such as dialysis solution, that will be delivered to the home once or twice a month. The training staff makes sure the patient is confident about performing each task before doing home hemodialysis. Someone from the clinic will be available to answer phone calls 24 hours a day. The health care team never forces a patient to use home hemodialysis because this treatment requires significant changes in the home and family. Home hemodialysis must be the patient's and family's decision. During training, the patient and caregiver learn to:

- Prepare equipment and supplies
- Place the needle in the vascular access
- Monitor the machine
- Check BP and pulse
- Keep records of the treatments
- Clean the equipment and the room where dialysis is done
- Order supplies

In addition, training includes how to prepare, operate, and disassemble the dialysis machine; maintain and clean the equipment; administer medications (e.g., heparin) into the machine lines; and handle emergency problems, such as hemodialysis dialyzer rupture, electrical or mechanical problems, hypotension, shock, and seizures.

Before home hemodialysis is initiated, resources are assessed in the home environment, household, and community. The home is surveyed to see if electrical outlets, plumbing facilities, and storage space are adequate. The home must have room for the HD machine, supplies, and, in some cases, a water purification machine. Modifications may be needed to enable the patient and caregiver to perform dialysis safely and to deal with emergencies.

Once home dialysis is initiated, the home care nurse visits periodically to evaluate adherence with the recommended techniques, to assess the patient for complications, to reinforce previous teaching, and to provide reassurance. The patient may report to the dialysis center monthly to see the nephrologist, dialysis nurse, and dietitian. Blood tests will be done to evaluate and adjust hemodialysis treatments.

Continuing Care

The health care team's goal in treating patients undergoing hemodialysis is to maximize the patients' vocational potential, functional status, and quality of life. Many patients can resume relatively normal lives, doing the things that are important to them: traveling, exercising, working, or actively participating in family activities. Outcome goals for renal rehabilitation include employment for those able to work, improved physical functioning of all patients, improved understanding about adaptation and options for living well, increased control over the effects of kidney disease and dialysis, and resumption of activities enjoyed before dialysis. Nurses must shift patient care away from the traditional paradigm of management by the health care team to one of self-management.

Complications

Although hemodialysis can prolong life, it does not alter the natural course of the underlying kidney disease, nor does it completely replace kidney function. The patient is subject to a number of problems and complications. A leading cause of death among patients undergoing maintenance hemodialysis is atherosclerotic cardiovascular disease (USRDS, 2014). Disturbances of lipid metabolism (hypertriglyceridemia) appear to be accentuated by hemodialysis. Anemia and fatigue contribute to diminished physical and emotional well-being, lack of energy and drive, and apathy. Gastric ulcers and other GI problems result from the physiologic stress of chronic illness, medication, and related problems. Disturbed calcium metabolism leads to renal osteodystrophy that produces bone pain and fractures. Other problems include fluid overload associated with heart failure, malnutrition, infection, neuropathy, and pruritus.

Up to 85% of people undergoing hemodialysis experience major sleep problems that further complicate their overall health status. Early-morning or late-afternoon dialysis may be a risk factor for developing sleep disturbances. Interventions, such as changing the temperature of the dialysate bath, may prevent temperature elevation, and limiting napping during dialysis may reduce sleep problems in people receiving hemodialysis. Some centers are offering nocturnal dialysis for 6 to 8 hours nightly.

Other complications during dialysis may include:

- Hypotension associated with nausea and vomiting, diaphoresis, tachycardia, and dizziness due to acute reduction in circulating intravascular volume and the failure of the patient's homeostatic mechanisms to compensate for it
- Painful muscle cramping, usually late in dialysis, as fluid and electrolytes rapidly leave the extracellular space
- Exsanguination if blood lines separate or dialysis needles become dislodged
- Dysrhythmias resulting from changes in electrolytes and pH or from removal of dysrhythmia medications during dialysis
- Air embolism, a rare circumstance, but can occur if air enters the vascular system
- Chest pain, particularly in patients with anemia or arteriosclerotic heart disease
- Dialysis disequilibrium resulting from shifts of cerebral fluid, resulting in headache, nausea and vomiting, restlessness, decreased level of consciousness, and seizures. This is more likely to occur in patients with AKI or when BUN levels are very high.
- Dialyzer clotting, which can be prevented by adjusting heparin doses

ADDITIONAL RENAL REPLACEMENT THERAPIES

Continuous RRT (Joannidis & Forni, 2015) is used with patients demonstrating hemodynamic instability such as hypotension, or in those who cannot tolerate the rapid fluid shifts that may occur with hemodialysis. CRRT (Fig. 27-5) circulates the blood outside the body through a filter similar to the hemodialysis filter. A pump is used to assist blood flow. The types of CRRT include continuous venovenous hemofiltration (CVVH),

continuous venovenous hemofiltration with dialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). Slow, continuous ultrafiltration (SCUF) is performed primarily to remove fluid (Richardson & Whatmore, 2014).

Continuous Venovenous Hemofiltration

CVVH is used to manage AKI. Blood from a double-lumen venous catheter is pumped through a hemofilter and then returned to the patient's body through the same catheter. CVVH provides continuous, slow fluid removal (ultrafiltration); therefore, hemodynamic effects are mild and better tolerated by patients with unstable conditions. CVVH does not require arterial access, and critical care nurses can set up, initiate, maintain, and terminate the system.

FIGURE 27-5 Diapact® CRRT System.

Continuous Venovenous Hemofiltration with Dialysis

CVVHD is similar to CVVH. Blood is pumped from a double-lumen venous catheter through a hemofilter and then returned to the patient's body through the same catheter. In addition to the benefits of ultrafiltration, CVVHD uses a dialysate to create a concentration gradient, thus facilitating the removal of uremic toxins and fluid. The access required is the same as for emergency hemodialysis (Richardson & Whatmore, 2014). Critical care nurses perform this procedure after competency has been validated.

Continuous Venovenous Hemodiafiltration

An additional modification of the techniques described previously is called CVVHDF. In this technique patients are connected to the CRRT machine, and their blood is pumped through the filter with dialysate running in a counter current flow outside of the hemofilter. Replacement fluid is pumped in after the filter. Using this technique, the end products of nitrogen metabolism (urea, creatinine, uric acid) are removed as well as the ultrafiltrate, which refers to the fluid removed through a semipermeable membrane.

RRT may be intermittent or continuous and described as IRRT or CRRT, respectively. There is some evidence suggesting a worse renal outcome when intermittent therapies are used (Joannidis & Forni, 2015).

Continuous Ultrafiltration

During SCUF, the patient is connected to a machine with a highly permeable filter that primarily removes water (ultrafiltration). This treatment is indicated when the patient has significant fluid overload (Richardson & Whatmore, 2014), such as a patient with heart failure (HF) refractory to diuretics. Since the ultrafiltrate is not replaced it corresponds to fluid loss in the patient.

Nursing Alert
It is important to secure the central venous catheter used for CRRT to prevent dislodgement. The catheter may be sutured and covered with secure dressing (Richardson & Whatmore, 2014).

PERITONEAL DIALYSIS

The goals of PD are to remove toxic substances and metabolic wastes and to reestablish normal balance of fluids and electrolytes. PD may be performed chronically on an outpatient basis or for patients who are acutely ill, although the latter is falling out of favor. Patients who are unable or unwilling to undergo hemodialysis or renal transplantation, or who do not have access to the bloodstream, can benefit from PD. In addition, patients who do not tolerate the rapid changes in fluids, electrolytes, and metabolism that occur during hemodialysis experience fewer of these problems with the slower rate of PD. Therefore, patients with diabetes or cardiovascular disease, many older patients (Lewis, 2013), and those who may be at risk for adverse effects of systemic heparin are likely candidates for PD. Additionally, severe hypertension, heart failure, and pulmonary edema not responsive to usual treatment regimens have been treated successfully with PD.

During PD, the thin, serous peritoneal membrane that covers the abdominal organs and lines the abdominal wall serves as the semipermeable or dialyzing membrane (Porth, 2015). Sterile dialysate fluid is introduced into the peritoneal cavity through a peritoneal or Tenckhoff catheter (Fig. 27-6). Diffusion across the semipermeable membrane removes urea creatinine and metabolic end products normally excreted by the kidneys. Excess fluid is removed through osmosis as water moves from an area of lower particle concentration in the patient's blood to an area of higher concentration across a semipermeable membrane into the dialysate. Dialysis solutions are available in concentrations of 1.5%, 2.5%, and 4.25% dextrose. This concentration gradient for fluid removal is created by varying concentrations of glucose; the higher the dextrose concentration, the greater the osmotic gradient and the more water will be removed. PD is a slower process than hemodialysis; therefore, it takes longer to reach equilibrium.

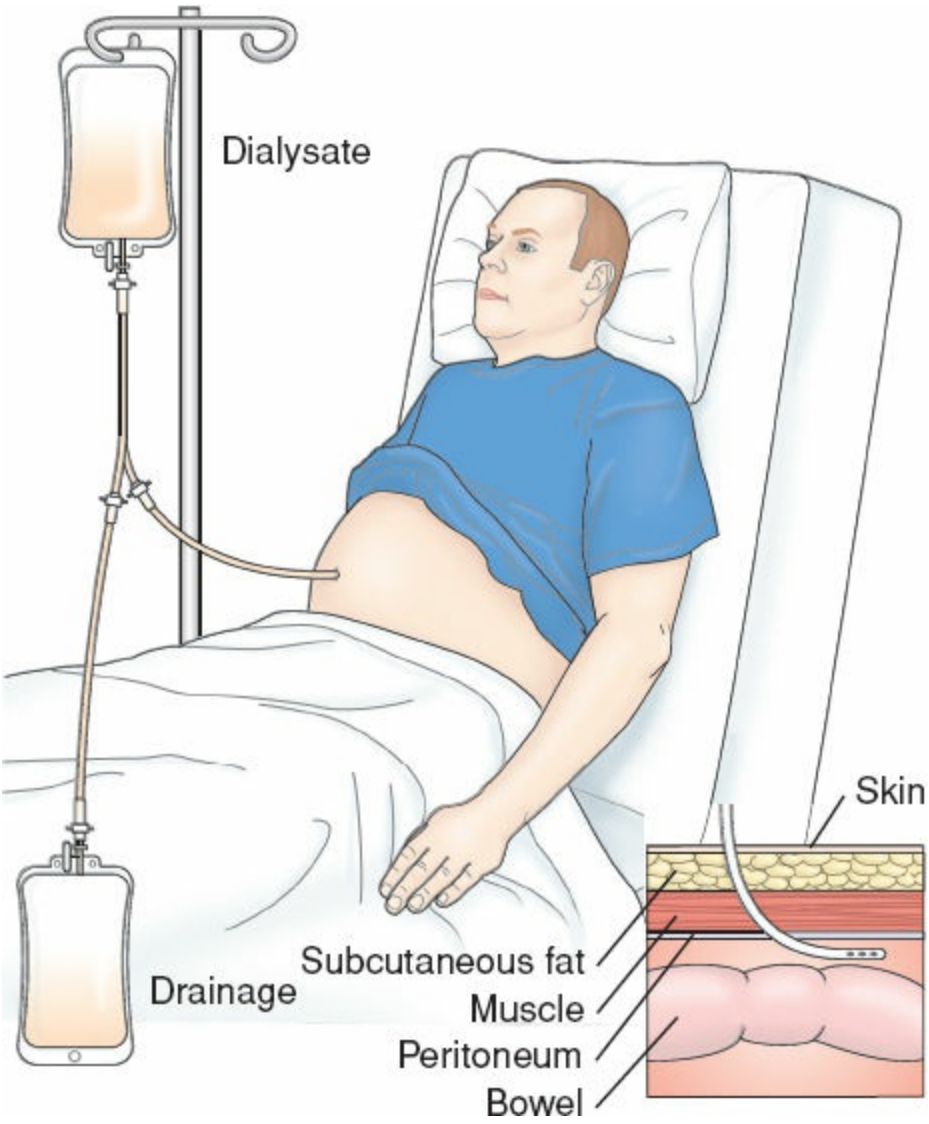

FIGURE 27-6 In peritoneal dialysis (PD) and in acute intermittent PD, dialysate is infused into the peritoneal cavity by gravity, after which the clamp on the infusion line is closed. After a dwell time (when the dialysate is in the peritoneal cavity), the drainage tube is unclamped and the fluid drains from the peritoneal cavity, again by gravity. A new container of dialysate is infused as soon as drainage is complete. The duration of the dwell time depends on the type of PD.

When assessing a patient for suitability for PD, the nurse must evaluate whether the patient's home is clean and has space for storage of equipment. Patients or caregivers must be able to lift dialysate bags, have appropriate cognitive function and dexterity to work the machine, and maintain asepsis (Lewis, 2013). Therefore, PD, while gentler on the cardiovascular system, is offered less often to the elderly than hemodialysis.

Procedure

Preparing the Patient

Insertion of the peritoneal catheter may be performed at the bedside or in the operating room, depending on acuity of the patient. A broad-spectrum antibiotic may be administered prior to the procedure to prevent postoperative infection. The patient is encouraged to empty the bladder and bowel prior to catheter insertion to reduce the risk of puncturing internal organs. Baseline vital signs, weight, and serum electrolyte levels are recorded. The nurse also assesses the patient's anxiety about the procedure and provides support and instruction.

Preparing the Equipment

Aseptic technique is imperative during PD. The nurse assembles the equipment, including the dialysate and any medications to be added. Heparin may be added to prevent occlusion of the peritoneal catheter, potassium chloride to prevent hypokalemia, and antibiotics to prevent or treat peritonitis. The osmotic agent in the dialysate is glucose, which may be absorbed; therefore, regular insulin may be added.

Nursing Alert
It is important to remember that peritoneal solutions contain varying concentrations of glucose. Because 30% to 40% of patients receiving PD are diabetic, glycemic monitoring is critical.

Before medications are added, the dialysate is warmed to the temperature dictated by hospital policy to prevent abdominal discomfort and to dilate the vessels of the peritoneum to increase urea clearance. Dry heating with a heating cabinet or incubator is recommended. Microwave heating of the fluid is *not* recommended because of the danger of burning the peritoneum. The nurse primes the PD tubing with the dialysate to prevent air from entering the peritoneal cavity.

Catheters used for long-term PD (i.e., Tenckhoff) usually are made of silicone and are radiopaque to permit visualization on x-ray. The catheter has two cuffs, which stabilize the catheter, limit movement, prevent leaks, and provide a barrier against microorganisms. One cuff is placed just distal to the peritoneum, and the other cuff is placed subcutaneously. The subcutaneous tunnel (5 to 10 cm long) further protects against bacterial infection (Fig. 27-7).

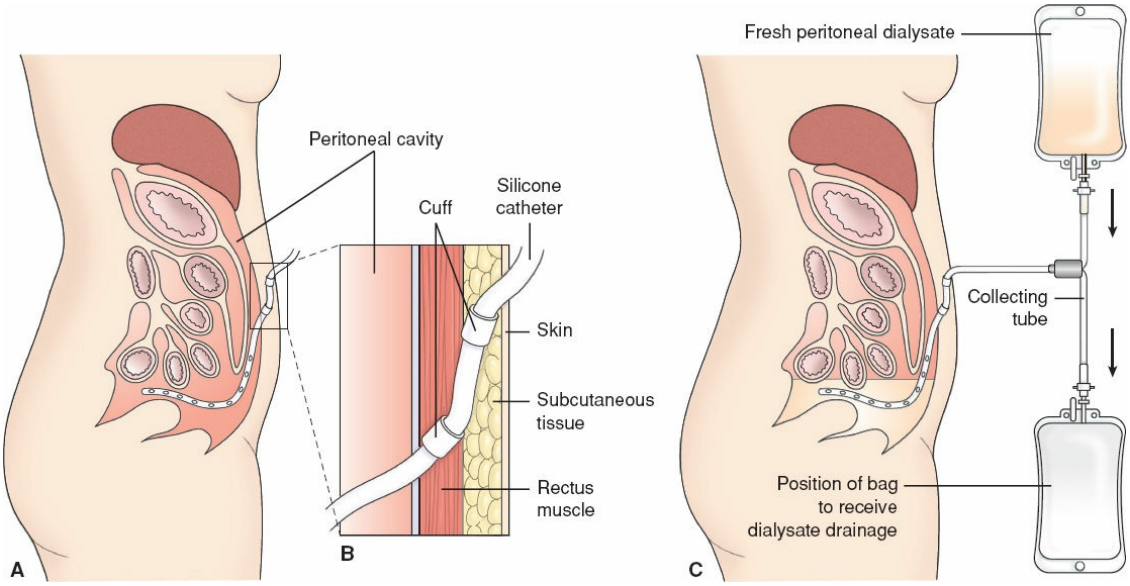

FIGURE 27-7 Continuous ambulatory peritoneal dialysis. A. The peritoneal catheter is implanted through the abdominal wall. B. Dacron cuffs and a subcutaneous tunnel provide protection against bacterial infection. C. Dialysate flows by gravity through the peritoneal catheter into the peritoneal cavity. After a prescribed period of time, the fluid is drained by gravity and discarded. Then new solution is infused into the peritoneal cavity until the next drainage period. Dialysis thus continues on a 24-hour-a-day basis during which the patient is free to move around and engage in his or her usual activities.

Performing the Exchange

PD involves a series of exchanges or cycles. An exchange is defined as the infusion, dwell, and drainage of the dialysate. This cycle is repeated throughout the course of the dialysis. The dialysate is infused by gravity into the peritoneal cavity. Usually a period of about 5 to 10 minutes is required to infuse 2 L of fluid. The prescribed dwell, or equilibration time, allows both diffusion and osmosis to occur. At the end of the dwell time, the drainage portion of the exchange begins. The solution drains from the peritoneal cavity by gravity through a closed, sterile system. Usually drainage is completed in 10 to 30 minutes. The effluent or drainage fluid is normally clear, colorless, or straw-colored. Bloody drainage may be seen in the first few exchanges after insertion of a new catheter but should not occur after that time. Cloudy drainage may indicate infection.

The number of cycles or exchanges, their frequency, and concentration of dialysate solution are prescribed based on the patient's physical status, fluid balance, and acuity of illness.

Complications

Peritonitis

Peritonitis is the most serious complication of PD. The nurse assesses for cloudy drainage or effluent, low-grade fever, abdominal pain, malaise (Wolfson, 2014), and rebound tenderness.

Nursing Alert

To detect rebound tenderness, the nurse presses one hand firmly into the abdominal wall and quickly withdraws the hand. Rebound tenderness exists when pain occurs upon removal and is associated with inflammation of the peritoneal cavity. Other disorders should be considered as etiology for a patient's symptoms along with peritonitis. Patients on PD are at increased risk for abdominal wall or inguinal hernia because of chronically increased intra-abdominal pressures; previous abdominal surgery is also a risk factor for hernia or intestinal obstruction secondary to adhesions (Wolfson, 2014).

A sample of fluid is obtained for analysis, and the diagnosis of peritonitis is confirmed by the finding of more than 100 WBCs/mm^3 in the peritoneal fluid with more than 50% neutrophils, or by a positive result on Gram staining (Wolfson, 2014, p. 1310). Treatment is based on culture and sensitivity of the peritoneal fluid. Antimicrobial therapy with a cephalosporin or aminoglycoside may be administered intravenously and/or added to the dialysate. Hypotension and other signs of shock may occur. Regardless of which organism causes peritonitis, the patient with peritonitis loses large amounts of protein through the peritoneum. Acute malnutrition and delayed healing may result. Therefore, attention must be given to detecting and treating peritonitis promptly.

Leakage

Leakage of dialysate around the catheter site must be corrected because the area acts as a pathway for bacteria to enter the peritoneal cavity. Usually, the leak stops spontaneously if dialysis is withheld for several days to give the incision and exit site time to heal. If necessary, leakage of dialysate around the catheter site may be managed with extra sutures and a decrease in the amount of dialysate used. Increases in intra-abdominal pressure, such as vomiting, coughing, and straining during bowel movements, should be avoided as these may delay healing. Leakage through the exit site or into the abdominal wall can occur for months or years after catheter placement.

Bleeding

A bloody effluent (drainage) may be expected in the initial outflow or observed occasionally in young, menstruating women (retrograde menstruation, or endometriosis). Bleeding is common during the first few exchanges after a new catheter insertion because some blood enters the abdominal cavity following insertion. During menstruation, the hypertonic fluid pulls blood from the uterus, through the opening in the fallopian tubes, into the peritoneal cavity. Some patients have had bloody effluent after an enema or from minor trauma.

Invariably, bleeding stops in 1 to 2 days and requires no specific intervention. More frequent exchanges during this time may be necessary to prevent blood clots from obstructing the catheter. Gross bleeding at any time indicates a more serious problem and must be investigated immediately.

Incomplete Recovery of Fluid

If the fluid drains slowly or the volume drained is less than the amount inserted, the nurse turns the patient from side to side, elevates the head of the bed, or repositions the patient to facilitate drainage. The nurse should ensure the patient empties the colon through regular bowel movements as the tip of the catheter may come up against the bowel, preventing adequate drainage. The catheter itself should never be repositioned.

Another measure to promote drainage includes checking the patency of the catheter by inspecting for kinks, closed clamps, or an air lock. The nurse must ensure that the PD catheter remains secure and that the dressing remains dry.

Nursing Alert

The most common reason for outflow delay or failure to drain dialysate is constipation, which typically is treated with oral laxatives or an enema. There is an increased risk of constipation for patients on PD because of restrictions on fluid or diet as well as the administration of medications, such as phosphate binders. After resolution of the constipation, the nurse should educate the patient about monitoring his or her bowel pattern and having an established bowel regimen. Current studies on constipation in PD patients are limited; best practice has yet to be established.

BOX 27-8 Assessing Suitability for Continuous Ambulatory Peritoneal Dialysis (CAPD)

Although CAPD is not suitable for all patients with kidney failure, it is a viable therapy for those who can perform self-care and exchanges and who can fit therapy into their own routines. Often, patients report having more energy and feeling healthier once they begin CAPD. Nurses can be instrumental in helping patients with kidney failure find the dialysis therapy that best suits their lifestyle. Those considering CAPD need to investigate the advantages and disadvantages along with the indications and contraindications for this form of therapy.

Advantages

- Freedom from a dialysis machine
- Control over daily activities
- Opportunities to avoid dietary restrictions, increase fluid intake, raise serum hematocrit values, improve BP control, avoid venipuncture, and gain a sense of well-being

Disadvantages

- Continuous dialysis 24 hours a day, 7 days a week

Indications

- Patient's willingness, motivation, and ability to perform dialysis at home
- Strong family or community support system (essential for success), particularly if the patient is an older adult
- Special problems with long-term hemodialysis, such as dysfunctional or failing vascular access devices, excessive thirst, severe hypertension, postdialysis headaches, and severe anemia requiring frequent transfusion
- Interim therapy while awaiting kidney transplantation
- Kidney failure secondary to diabetes because hypertension, uremia, and hyperglycemia are easier to manage with CAPD than with hemodialysis

Contraindications

- Adhesions from previous surgery (adhesions reduce clearance of solutes) or systemic inflammatory disease
- Chronic backache and pre-existing disc disease, which could be aggravated by the pressure of dialysis fluid in the abdomen
- Risk of complications, for example, in patients receiving immunosuppressive medications, which impede healing of the catheter site, and in patients with a colostomy, ileostomy, nephrostomy, or ileal conduit because of the risk of peritonitis. The risk for complications is not an absolute contraindication for CAPD therapy but must be taken into consideration.
- Diverticulitis, because CAPD has been associated with rupture of the diverticulum
- Severe arthritis or poor hand strength, necessitating assistance in performing the exchange; however, patients who are blind or partially blind and those with other physical limitations can learn to perform CAPD.

Other Complications

Hypertriglyceridemia is common in patients undergoing long-term PD as well as in long-term hemodialysis. Cardiovascular disease is a major cause of morbidity and mortality and is managed with beta blockers, ACE inhibitors, aspirin, and statins.

Other complications that may occur with long-term PD include abdominal hernias (incisional, inguinal, diaphragmatic, and umbilical). The persistently elevated intra-abdominal pressure also aggravates symptoms of hiatal hernia and hemorrhoids. Low back pain and anorexia from fluid in the abdomen and a constant sweet taste related to glucose absorption also may occur.

Approaches to Peritoneal Dialysis

PD can be performed using several different approaches: acute continuous or intermittent PD, continuous ambulatory PD (CAPD), and continuous cyclic PD (CCPD).

Continuous Ambulatory Peritoneal Dialysis

CAPD works on the same principles as other forms of PD; however, there are less extreme fluctuations in the patient's laboratory values with CAPD than with intermittent PD or hemodialysis because the dialysis is constantly in progress. CAPD is performed at home by the patient or a trained caregiver; the procedure allows the patient reasonable freedom and control of daily activities (Box 27-8).

The patient performs exchanges four or five times a day, 24 hours a day, 7 days a week, at intervals scheduled throughout the day. The dialysate dwells for the prescribed period of time; 4 to 6 hours is common. The patient is free to ambulate and participate in activities of daily living. At the end of the dwell time, the dialysate is drained from the peritoneal cavity into the empty sterile bag. Box 27-9 provides nursing management for CAPD.

Continuous Cyclic Peritoneal Dialysis

CCPD combines overnight intermittent PD with a prolonged dwell time during the day. The peritoneal catheter is connected to a cycler machine every evening, and the patient receives three to five exchanges during the night. In the morning, the patient caps off the catheter after infusing 1.5 to 2.5 L of fresh dialysate. This dialysate remains in the abdominal cavity until the tubing is reattached to the cycler machine at bedtime.

BOX 27-9 Nursing Management for Peritoneal Dialysis

Caring for the Catheter Site

To reduce the risk of peritonitis in the patient using peritoneal dialysis (PD), the patient must use meticulous care to avoid contaminating the catheter, fluid, or tubing and to avoid accidentally disconnecting the catheter from the tubing. Excess manipulation is avoided, and meticulous care of the catheter entry site is provided using a standardized protocol. The patient and other caregivers who are present wear a mask and use strict aseptic technique for preparation of the dialysate and dressing changes.

The nurse uses every opportunity to assess technique of catheter care and correct the patient's technique. Routine catheter site care, recommended daily or three or four times weekly, typically is performed during showering or bathing. The exit site should not be submerged in bath water. The most common cleaning method is soap and water; liquid soap is recommended. During care, the nurse and patient need to make sure that the catheter remains secure to avoid tension and trauma. The patient may wear a gauze or semitransparent dressing over the exit site.

Meeting Psychosocial Needs

In addition to the complications of PD previously described, patients who elect to use continuous ambulatory peritoneal dialysis (CAPD) may experience altered body image because of the abdominal catheter and the bag and tubing. Waist size increases from 1 to 2 in (or more) with fluid in the abdomen. This affects clothing selection and may make the patient feel "fat." Body image may be so altered that patients do not want to look at or care for the catheter for days or weeks. The nurse may arrange for the patient to talk with other patients who have adapted well to CAPD. Although some patients have no psychological problems with the catheter—they think of it as their lifeline and as a life-sustaining device—other patients feel they are doing exchanges all day long and have no free time, particularly in the beginning. They may experience depression because they feel overwhelmed with the responsibility of self-care.

Patients undergoing CAPD also may experience altered sexuality patterns and sexual dysfunction. The patient and partner may be reluctant to engage in sexual activities, partly because of the catheter being psychologically "in the way" of sexual performance. The peritoneal catheter, drainage bag, and about 2 L of dialysate may interfere with the patient's sexual function and body image as well. Although these problems may resolve with time, some problems may warrant special counseling. Questions by the nurse about concerns related to sexuality and sexual function often provide the patient with a welcome opportunity to discuss these issues and provide a first step toward their resolution.

Teaching Patients Self-Care

Patients are taught to perform PD according to their own learning ability and knowledge level and are given only as much information at one time as they can handle without feeling uncomfortable or becoming overwhelmed.

Because protein loss is higher with PD than with hemodialysis, the patient is instructed to eat a well-balanced diet that is high in protein. Also the patient is encouraged to increase his or her daily fiber intake to help prevent constipation, which can impede the flow of dialysate into or out of the peritoneal cavity. Many patients gain 3 to 5 lb within a month of initiating CAPD so they may be asked to limit their carbohydrate intake to avoid excessive weight gain. Usually restrictions on potassium, sodium, and fluids are not needed. Patients commonly lose about 2 to 3 L of fluid over and above the volume of dialysate infused into the abdomen during a 24-hour period, permitting a more normal fluid intake.

Continuing Care

The nurse assesses that strict aseptic technique is being followed. Blood chemistry values are followed closely to make certain the therapy is adequate for the patient. The home care nurse assesses the home environment and suggests modifications to accommodate the equipment and facilities needed to carry out CAPD. Additional assessments include checking for changes related to kidney disease, complications such as peritonitis, and treatment-related problems such as heart failure, inadequate drainage, and weight gain

or loss. The nurse continues to reinforce and clarify teaching about kidney failure and kidney disease while assessing the patient's and family's progress in coping with the procedure.

CCPD has a lower rate of infection than other forms of PD because there are fewer opportunities for contamination with bag changes and tubing disconnections. It also allows the patient to be free from exchanges throughout the day, making it possible to engage more freely in work and activities of daily living.

KIDNEY TRANSPLANTATION

Kidney transplantation has become the treatment of choice for most patients with end-stage kidney failure. Each year, between 17,000 and 18,000 total renal transplants, including combined kidney–pancreas, kidney–liver, and kidney–heart, are performed in the United States (Cohen & Valeri, 2016). Waiting times for transplantation across the country continue to increase; the active waiting list is three times longer than the supply of donor kidneys (USRDS, 2014). The median waiting time for a patient awaiting kidney transplantation is currently 4.3 years (Cohen & Valeri, 2016). Healthy People 2020 calls to increase the proportion of patients with kidney failure who receive a transplant within 3 years. A second goal is to increase the proportion of patients who receive a preemptive transplant at the start of kidney failure. Unfortunately, approximately 10% of newly listed candidates for kidney transplants will die within three years waiting for the organ (Cohen & Valeri, 2016). See Box 27-10 regarding kidney donation.

BOX 27-10 Kidney Donation

An inadequate number of available kidneys remain the greatest limitation to treating patients with end-stage kidney disease successfully. For those interested in donating a kidney, the National Kidney Foundation provides written information describing the organ donation program and a card specifying the organs to be donated in the event of death.

The organ donation card is signed by the donor and two witnesses and should be carried by the donor at all times. Procurement of an adequate number of kidneys for potential recipients is still a major problem despite national legislation that requires relatives of deceased patients or patients declared brain-dead to be asked if they would consider organ donation.

In some states in the United States, drivers can indicate their desire to be organ donors on their driver's license application or renewal.

https://www.google.com/search?q=sample+organ+donation+drivers+license

Patients choose kidney transplantation for various reasons, such as the desire to avoid dialysis or to improve their sense of well-being and the wish to lead a more normal life. Additionally, the cost of maintaining a successful transplantation is one third the cost of dialysis treatment. Patients on dialysis have an adjusted all-cause mortality rate that is 6.5 to 7.4 times higher than that of the general population; the rate is 1.1 to 1.6 times higher for transplant patients (www.kidneyfund.org.).

Kidney transplantation involves transplanting a kidney from a living donor or heartbeat-only donor (one who has been pronounced brain dead but whose cardiopulmonary system is maintained artificially) to a recipient who has end-stage kidney failure (Box 27-10). Kidney transplant donors had traditionally been blood relatives; however, living donor kidney transplant (LDKT) between spouses, friends, and those on organ registries may be performed. The LDKT provides a better quality kidney more quickly than from a heart beat only donor (Skelton et al., 2015). The success rate increases if kidney transplantation from a living donor is performed before dialysis is initiated; this is referred to as *preemptive transplant*.

Depending on the cause and symptoms of kidney failure, occasionally a nephrectomy of the patient's own native kidneys may be performed before transplantation. The transplanted kidney is placed in the patient's iliac fossa anterior to the iliac crest. The renal artery of the donor is anastomosed to the hypogastric, renal, or iliac artery of the recipient. The ureter of the newly transplanted kidney is anastomosed to the ureter of the recipient, and the renal vein is anastomosed to the renal vein of the recipient (Fig. 27-8). The left donor kidney is preferred because the left renal vein is longer than the right (6 to 7 cm vs. 2 to 4 cm).

Medical and Nursing Management

Preoperative Management

Preoperative management goals include bringing the patient's metabolic state to a level as close to normal as possible, making sure that the patient is free of infection, and preparing the patient for surgery and the postoperative course. Preoperatively, immunosuppressant medication is initiated prior to the transplant to prevent rejection of the new kidney.

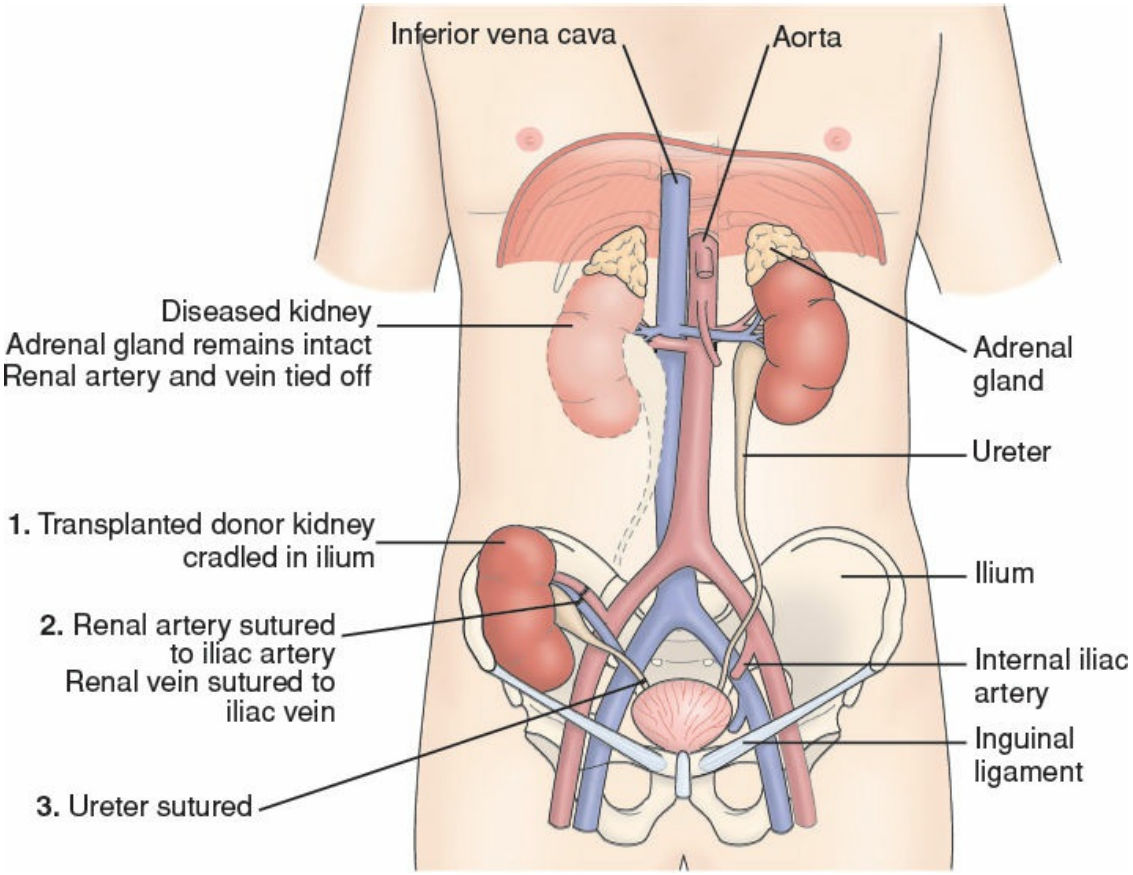

FIGURE 27-8 Kidney transplantation: (*1*) The diseased kidney may be removed and the renal artery and vein tied off. (*2*) The transplanted kidney is placed in the iliac fossa. (*3*) The renal artery of the donated kidney is sutured to the iliac artery, and the renal vein is sutured to the iliac vein. (*4*) The ureter of the donated kidney is sutured to the bladder or to the patient's ureter.

A complete physical examination is performed to detect and treat any conditions that could cause complications after transplantation. Tissue typing, blood typing, and antibody screening are performed to determine compatibility of the tissues and cells of the donor and recipient. Other diagnostic tests must be completed to identify conditions requiring treatment before transplantation. The lower urinary tract is studied to assess bladder neck function and to detect urethral reflux.

The patient must be free of infection and cancers at the time of renal transplantation because medications to prevent transplant rejection suppress the immune response, leaving the patient at risk for infection. Therefore, the patient is evaluated and treated for any infections, including gingival (gum) disease and dental caries.

A psychosocial evaluation is conducted to assess the patient's ability to adjust to the transplant, coping styles, social history, social support available, and financial resources. A history of psychiatric illness is important to obtain because often psychiatric conditions are aggravated by the corticosteroids needed for immunosuppression after transplantation. If a dialysis routine has been established, hemodialysis is performed the day before the scheduled transplantation procedure to optimize the patient's physical status.

The nursing aspects of preoperative care for the patient undergoing renal transplant are similar to those for patients undergoing other types of elective abdominal surgery. Preoperative teaching addresses postoperative pulmonary hygiene, pain management options, dietary restrictions, IV and arterial lines, tubes such as an indwelling catheter and possibly a nasogastric tube, and early ambulation. The patient who receives a kidney from a living-related donor often expresses concern about the donor and how the donor will handle the procedure as well as long-term consequences of donation (Sierverdes et al., 2014).

Most patients have been on dialysis for months or years before transplantation. Many have waited months to years for a kidney transplant and are anxious about the surgery, possible rejection, and the need to return to dialysis. Helping the patient to deal with these concerns is part of the nurse's role in preoperative management as is teaching the patient about what to expect after surgery. A plan of nursing care for a patient undergoing kidney surgery is available online at http://thepoint.lww.com/Honan2e.

Postoperative Management

The goal of care is to maintain homeostasis until the transplanted kidney is functioning well. The patient whose transplanted kidney functions immediately has a more favorable prognosis than does the patient whose transplanted kidney does not.

Antirejection Medication

The survival of a transplanted kidney depends on the ability to prevent the body's immune response to the transplanted kidney. To overcome or minimize the body's defense mechanism, immunosuppressive agents are administered. Corticosteroids are initially part of the immunosuppression regimen but are frequently tapered due to long-term side effects (Wright, 2014). Cyclosporine is available in a microemulsion form (Neoral) that delivers the medication reliably, thus producing a steady-state serum concentration. Tacrolimus (Prograf) is similar to cyclosporine, is about 100 times more potent, and may be more effective in some patients at preventing transplant rejection. Tacrolimus and cyclosporine have received a pregnancy category C designation. This designation means that animal studies have shown an adverse effect and there are no adequate well-controlled studies in pregnant women or no studies have been conducted on animals or humans. Mycophenolate mofetil (CellCept), sirolimus (Rapamune), and antithymocyte globulin (Thymoglobulin), as well as tacrolimus, are used in various combinations to prevent transplant rejection. Treatment with combinations of these new agents has improved survival rates dramatically (Adams & Urban, 2016).

Doses of corticosteroid agents are tapered gradually over a period of several weeks, depending on the patient's immunologic response to the transplant. Corticosteroids may be discontinued, but the nurse reinforces that the patient must take some form of

immunosuppressive therapy for the life of the transplanted kidney (Wright, 2014).

The side effects and risks associated with these medications include nephrotoxicity, hypertension, hyperlipidemia, hirsutism, headache, tremor, and several types of cancers (Adams & Urban, 2016).

Drug Alert!
Long-term use of corticosteroids is associated with hypertension, hyperlipidemia, diabetes, infection, osteoporosis, avascular necrosis, weight gain, cataracts, and mood changes and may contribute to development or worsening of cardiovascular disease (Wright, 2014).

Drug Alert!
Echinacea, often used to treat the common cold and influenza, may interfere with the action of immunosuppressant medications, resulting in subtherapeutic levels (Adams & Urban, 2016).

Assessing the Patient for Transplant Rejection

After kidney transplantation, the nurse assesses the patient for signs and symptoms of transplant rejection: oliguria, edema, fever, increasing BP, weight gain, and swelling or tenderness over the transplanted kidney or graft. Leukocytosis and increasing BUN and creatinine levels should be evaluated. Patients receiving cyclosporine may not exhibit the usual signs and symptoms of acute rejection. In these patients, the only sign may be an asymptomatic rise in the serum creatinine level (a rise of more than 20% is considered acute rejection). Box 27-11 discusses renal transplant rejection and infection.

BOX 27-11 Renal Transplant Rejection and Infection

Renal graft rejection and failure may occur immediately (hyperacute), within the first 2 weeks, or later. Failure is potentially reversible (acute), or the transplanted kidney may steadily lose function after many years (chronic). It is not uncommon for rejection to occur during the first year after transplantation.

Detecting Rejection

Ultrasonography may be used to detect enlargement of the kidney; percutaneous renal biopsy (most reliable) and x-ray techniques are used to evaluate transplant rejection. If the body rejects the transplanted kidney, the patient needs to return to dialysis. The rejected kidney might not be removed, depending on the risk for infection if the kidney is left in place.

Risk for Infection

About 75% of recipients of kidney transplant have at least one episode of infection in the first year after transplantation because of immunosuppressant therapy. Immunosuppressants of the past made the transplant recipient more vulnerable to opportunistic infections (candidiasis, cytomegalovirus, *Pneumocystis* pneumonia) and

infection with other relatively nonpathogenic viruses, fungi, and protozoa, which can be a major hazard. Cyclosporine therapy has reduced the incidence of opportunistic infections because it selectively exerts its effect, sparing T cells that protect the patient from life-threatening infections. In addition, combination immunosuppressant therapy and improved clinical care have produced 1-year patient survival rates approaching 100% and graft survival exceeding 90%. Infections, however, remain a major cause of death at all points in time for recipients of kidney transplant.

Preventing Infection

The patient is monitored closely for infection because of susceptibility to impaired healing and infection related to immunosuppressive therapy and complications of kidney failure. Clinical manifestations of infection include shaking, chills, fever, tachycardia, and tachypnea as well as either an increase or a decrease in WBCs (leukocytosis or leukopenia).

Infection may be introduced through the urinary tract, the respiratory tract, the surgical site, or other sources. Urine cultures are performed frequently because of the high incidence of bacteriuria during early and late stages of transplantation. Any type of wound drainage should be viewed as a potential source of infection because drainage is an excellent culture medium for bacteria. Catheter and drain tips should be cut with sterile scissors, placed in a sterile container, and sent to the laboratory for culture.

The nurse ensures that the patient is protected from exposure to infection by hospital staff, visitors, and other patients with active infections. Careful hand hygiene is imperative for all who come in contact with the patient.

Monitoring Urinary Function

A kidney from a living donor related to the patient usually begins to function immediately after surgery and may produce large quantities of dilute urine. A kidney from a nonliving donor may undergo ATN and, therefore, may not function for 2 or 3 weeks, during which time anuria, oliguria, or polyuria may be present. During this stage, the patient may experience significant changes in fluid and electrolyte status. Therefore, careful monitoring of hourly urine output should be performed. IV fluids are administered on the basis of urine volume and serum electrolyte levels and as prescribed by the provider. Hemodialysis may be necessary postoperatively to maintain homeostasis until the transplanted kidney is functioning well.

Addressing Psychological Concerns

The rejection of a transplanted kidney remains a matter of great concern to the patient, the family, and the health care team. The fears of kidney rejection and the complications of immunosuppressive therapy, which include Cushing syndrome, diabetes, capillary fragility, osteoporosis, glaucoma, cataracts, acne, and nephrotoxicity, place tremendous psychological stresses on the patient. Often anxiety and uncertainty about the future and difficult posttransplantation adjustment are sources of stress for the patient and family.

An important nursing function is the assessment of the patient's stress and coping. The nurse uses each visit with the patient to determine if the patient and family are coping effectively and if the patient is adhering to the prescribed medication regimen. If indicated

or requested, the nurse refers the patient for counseling.

Monitoring and Managing Potential Complications

The patient undergoing kidney transplantation is at risk for the postoperative complications that are associated with any surgical procedure. In addition, the patient's physical condition may be compromised because of the complications associated with longstanding kidney failure and its treatment. Therefore, careful assessment for the complications related to kidney failure and corticosteroid use, such as poor wound healing, is an important aspect of nursing care.

GI ulceration and corticosteroid-induced bleeding may occur. Fungal colonization of the GI tract, especially the mouth and urinary bladder, may occur secondary to corticosteroid and antibiotic therapy. Closely monitoring the patient and notifying the provider about the occurrence of these complications are important nursing interventions. In addition, the patient is monitored closely for adverse effects of corticosteroids or signs of adrenal insufficiency when these medications are discontinued.

Teaching Patients Self-Care

The nurse works closely with the patient and family to be sure that they understand the need for continuing immunosuppressive therapy as prescribed. Additionally, the patient and family are instructed to assess for and report signs and symptoms of transplant rejection, infection, or significant adverse effects of the immunosuppressive regimen. These include decreased urine output; weight gain; malaise; fever; respiratory distress; tenderness over the transplanted kidney; anxiety; depression; changes in eating, drinking, or other habits; and changes in BP. The patient is instructed to inform other health care providers (e.g., dentist) about the kidney transplant and the use of immunosuppressive agents.

Continuing Care

Follow-up care with the transplant team is a lifelong necessity. Individual verbal and written instructions are provided concerning diet, medication, fluids, daily weight, daily measurement of urine, management of intake and output, prevention of infection, resumption of activity, and avoidance of contact sports in which the transplanted kidney may be injured. Cardiovascular disease is the major cause of morbidity and mortality after transplantation, due in part to the increasing age of patients with transplants.

Malignancy develops more frequently in patients receiving long-term immunosuppressive therapy. Posttransplant, patients are at increased risk for various conditions: a "20-fold increase for non-Hodgkin lymphomas, nonmelanoma skin cancers, and Kaposi sarcoma; a 15-fold increase for kidney cancers; a 5-fold increase for melanoma, leukemia, hepatobiliary tumors, cervical tumors, and vulvovaginal tumors; a 3-fold increase for testicular and bladder cancers; and a 2-fold increase for most common tumors (e.g., colon, lung, prostate, stomach, esophagus, pancreas, ovary, and breast)" (Flechner, 2013). The patient is reminded of the importance of health-promotion activities, such as using sunscreen and health screenings, including regular PAP smears, mammogram, colonoscopy, and breast or testicular self-examination as appropriate.

The American Association of Kidney Patients (see Resources) is a nonprofit organization that serves the needs of those with kidney disease. It can provide many helpful suggestions

for patients and family members learning to cope with dialysis and transplantation.

RENAL TRAUMA

The kidneys are protected by the rib cage and musculature of the back posteriorly and by a cushion of abdominal wall and viscera anteriorly. They are highly mobile and are fixed only at the renal pedicle (stem of renal blood vessels and the ureter). With traumatic injury, the kidneys can be thrust against the lower ribs, resulting in contusion and rupture. Renal trauma occurs in approximately 10% of abdominal injuries, and 90% of renal trauma is due to blunt injury (automobile and motorcycle collisions, falls, athletic injuries, assaults) (Coburn, 2013). The nurse should suspect renal injury when the patient presents with blunt abdominal or penetrating flank and back wounds (gunshot wounds, stabbings); nearly all patients with renal gunshot wounds have associated injuries of other internal organs. For renal stab wounds, approximately 60% of have additional intra-abdominal injuries (Coburn, 2013).

Blunt renal trauma is classified into one of four groups, as follows:

- *Contusion:* Bruises or hemorrhages under the renal capsule; capsule and collecting system intact
- *Minor laceration:* Superficial disruption of the cortex; renal medulla and collecting system are not involved
- *Major laceration:* Parenchymal disruption extending into cortex and medulla, possibly involving the collecting system
- *Vascular injury:* Tears of renal artery or vein

The most common renal injuries are contusions, lacerations, ruptures, and renal pedicle injuries or small internal lacerations of the kidney (Fig. 27-9). The kidneys receive half of the blood flow from the abdominal aorta; therefore, even a fairly small renal laceration can produce massive bleeding. The nurse should consider hemorrhage is likely present when gross hematuria or microscopic hematuria occurs. Additional signs of hemorrhage include a decreasing BP, MAP below 65 mm Hg, or tachycardia without a discernible cause, such as pain.

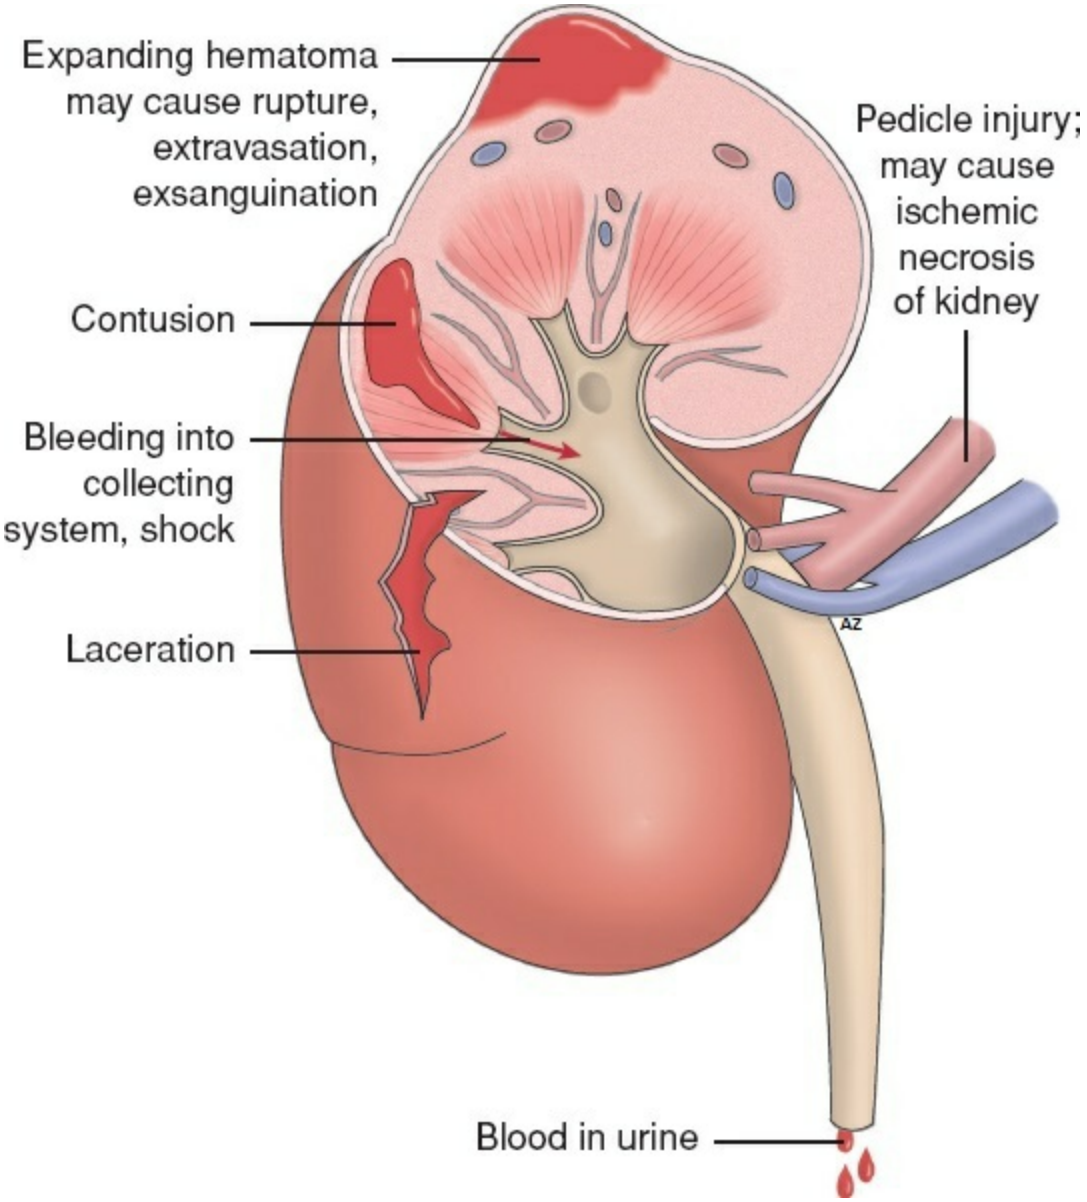

FIGURE 27-9 Types and pathophysiologic effects of renal injuries: contusions, lacerations, rupture, and pedicle injury.

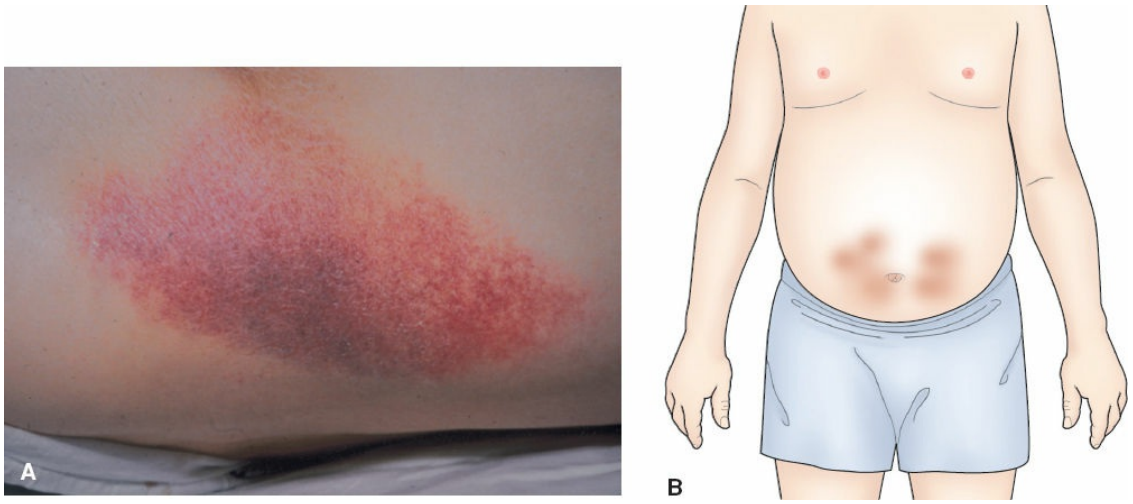

FIGURE 27-10 Ecchymosis with renal trauma. A. Grey–Turner sign. B. Cullen sign. (A from D. Berg,

& K. Worzala. (2006). *Atlas of adult physical diagnosis*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Clinical Manifestations and Assessment

Clinical manifestations of renal injury include pain, renal colic (due to blood clots or fragments obstructing the collecting system), hematuria, mass or swelling in the flank, ecchymosis, and lacerations or wounds of the lateral abdomen and flank. While hematuria is the most common manifestation of renal trauma, there is no relationship between the degree of hematuria and the degree of injury.

The nurse assesses for ecchymosis over the flank (Grey–Turner sign) and periumbilical area (Cullen sign) as well as flank tenderness with palpation and gross hematuria (Fig. 27-10).

Nursing Alert
Grey–Turner sign and Cullen sign are associated with retroperitoneal bleeds.

Microscopic hematuria may be present; therefore, evaluation of hemoglobin and hematocrit is critical. A CT scan of the abdomen may be done to assess penetrating trauma. Free air, injury to the kidney, or a penetrating object is assessed. Any patient with gross hematuria will need to be evaluated, although the nurse should recognize that the amount of hematuria correlates poorly with the magnitude of injury (Coburn, 2013).

Medical and Nursing Management

The goals of management in patients with renal trauma are to control hemorrhage and pain, to prevent infection, and to preserve and restore kidney function. The patient is monitored for oliguria and signs of hemorrhagic shock because a pedicle injury or shattered kidney can lead to rapid exsanguination and death. An expanding hematoma may cause rupture of the kidney capsule. A palpable flank or abdominal mass with local tenderness, swelling, and ecchymosis suggests renal hemorrhage. The area of the original mass can be outlined with a marking pen so that the examiner can evaluate the area for change.

Often renal trauma is associated with other injuries to nearby organs; therefore, the patient is assessed for skin abrasions, lacerations, and entry and exit wounds of the upper abdomen and lower thorax because these may be associated with renal injury. Trauma to the right kidney may be associated with liver injury while trauma to the left kidney may involve injury to the spleen. In rare cases, damage to the adrenal gland may result in adrenal insufficiency and death.

With a contusion of the kidney, healing may take place with conservative measures. If the patient has microscopic hematuria and a normal IV urogram, bed rest will allow the contusion to resolve with time (Coburn, 2013), and outpatient management is possible. If gross hematuria or a minor laceration is present, the patient is hospitalized and kept on bed rest until the hematuria clears. Antimicrobial medications may be prescribed to prevent infection from perirenal hematoma or urinoma (a cyst containing urine). Patients with retroperitoneal hematomas may develop low-grade fever as absorption of the clot takes place.

Nursing Alert

When caring for a trauma patient, if the patient presents with blood at the urethral meatus, an inability to void, and a perineal hematoma, a urethral injury should be suspected. Insertion of a urinary catheter should NOT be undertaken until the patient is evaluated by the provider.

Surgical Management

In renal trauma, any sudden change in the patient's condition suggests hemorrhage and requires rapid surgical intervention within 12 hours to reestablish blood flow to the ischemic kidney (Eswara, 2015). The patient is often in shock and requires aggressive fluid resuscitation. The damaged kidney may have to be removed (nephrectomy).

Early postoperative complications (within 6 months) include rebleeding, formation of a perinephritic abscess, sepsis, urine extravasation, and formation of a fistula. Other complications include formation of stones, infection or abscess, cysts, chronic pyelonephrosis, vascular aneurysms, and loss of kidney function. Hypertension can be a complication of any renal surgery but usually is a late complication of renal injury.

The patient who has undergone surgery is instructed about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the provider, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided. Also guidelines for gradually

increasing activity, lifting, and driving are provided in accordance with the provider's prescription.

Follow-up nursing care includes monitoring the BP to detect hypertension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding. The patient should be advised to schedule periodic follow-up assessments of renal function (creatinine clearance, BUN, and serum creatinine analyses). If a nephrectomy was necessary, the patient is advised to wear medical identification.

Gerontologic Considerations

Care for this population is essentially the same; however, the elderly may have chronic disease processes that must be considered. Older adults often have higher mortality following traumatic injury than do younger adults, including alterations in the cardiac and respiratory systems that reduce physiologic reserve needed to respond to shock and hypoxia.

CHAPTER REVIEW

Critical Thinking Exercises

1. As the primary nurse for a 50-year-old man with kidney failure secondary to poorly controlled diabetes, develop a teaching plan to explain the different types of renal replacement therapies. Include the level of involvement on the part of the patient and family for self-management required for each. How would you modify the approach if the patient is distraught and does not seem to hear what you are saying?

2. A 45-year-old married woman with three teenage children visits the nephrology department to discuss options for dealing with her kidney failure. Her healthy twin sister wants to donate her kidney, and the preliminary reports show that a match is possible. The patient states that she does not want her sister to go through the process of kidney donation if dialysis is possible. Identify the pros and cons of her wishes based on current evidence regarding outcomes of dialysis compared to kidney transplantation.

3. You are treating a 35-year-old woman who is in the emergency department following a motor vehicle crash; she is complaining of severe left-sided flank pain. Identify possible causes of her pain and laboratory tests that would be indicated. What nursing assessment and interventions should you make at this time? What explanations would you give the patient while awaiting the results of laboratory tests?

NCLEX-Style Review Questions

1. The nurse is receiving report on a client with AKI. What should the nurse follow up on first?
   a. Potassium value of 5.0 mEq/L
   b. Patient refused fingerstick blood glucose
   c. Crackles throughout lung fields
   d. Patient reports itching skin

2. When caring for the patient with kidney failure, the nurse teaches the patient to manage his diet by avoiding which foods?
   a. Green leafy vegetables and citrus
   b. Apples and pears

c. Proteins of high biologic value
d. Oat, wheat, and rye-containing products

3. The nurse recognizes the patient comprehends the signs and symptoms of renal transplant rejection when the patient states he will monitor for which of these signs and symptoms? Select all that apply.
a. Thrill and bruit over the fistula
b. Weight gain and fever
c. Palpitations and thirst
d. Flank pain and pyuria
e. Swelling of the ankles and around the eyes

4. When planning care for the patient with kidney trauma, the nurse notifies the physician immediately for which of these findings?
a. Laboratory reports microscopic hematuria
b. Tachycardia and hypotension
c. Patient is upset and crying
d. Scar noted on patient's left flank

5. When caring for the patient with nephrotic syndrome, what is appropriate to include in the patient teaching plan to prevent long-term?
a. Observe for dark urine and clay-colored stool.
b. Void every 2 hours on schedule.
c. Avoid driving at night.
d. Minimize the intake of saturated fat.

CHAPTER 28

Nursing Management: Patients with Urinary Disorders

Susanne A. Quallich • Michelle J. Lajiness

Learning Objectives

After reading this chapter, you will be able to:

1. Identify factors contributing to upper and lower urinary tract infections (UTIs).
2. Describe nursing care of the patient with a UTI.
3. Differentiate between the various adult dysfunctional voiding patterns.
4. Develop a patient education plan for a patient who has mixed (stress and urge) urinary incontinence.
5. Identify potential causes of an obstruction of the urinary tract, and management of the patient with this condition.
6. Develop a teaching plan for the patient undergoing treatment for renal calculi (kidney stones).
7. Discuss the available options for management of urinary cancers.
8. Identify issues relevant to the initial management of trauma to the urinary tract.
9. Identify issues important to patient self-care of urinary diversions.

The urinary system is responsible for providing the route for drainage of urine formed by the kidneys. Nursing requires an understanding of the anatomy, physiology, diagnostic testing, nursing care, and rehabilitation of patients with the multiple processes that interfere with the urinary system. This chapter focuses on the nursing management of patients with common urinary conditions.

INFECTIONS OF THE URINARY TRACT

Urinary tract infections (UTIs) are caused by pathogenic microorganisms in the urinary tract (the normal urinary tract is sterile above the urethra). Lower UTIs include bacterial cystitis (inflammation of the bladder), bacterial prostatitis (inflammation of the prostate), and bacterial urethritis (inflammation of the urethra). Acute or chronic nonbacterial causes of inflammation in any of these areas can be misdiagnosed as bacterial infections. Upper UTIs are much less common and include acute or chronic pyelonephritis (inflammation of the kidney and renal pelvis), interstitial nephritis (inflammation of the spaces between the kidney tubules), and renal abscesses (pus-filled cavity of the kidney) (Fig. 28-1). Upper and

lower UTIs are further classified as uncomplicated or complicated, depending on other patient-related conditions (Box 28-1) (e.g., whether the UTI is recurrent and the duration of the infection). Most uncomplicated UTIs are community-acquired, while complicated UTIs usually occur in people with urologic abnormalities, comorbidities such as diabetes, or recent catheterization.

A UTI is the most common bacterial infection encountered in the ambulatory care setting in the United States (Ferri, 2016), and the second most common reason patients seek health care (Grossman & Porth, 2014). Most cases occur in women; one out of every five women in the United States will develop a UTI sometime during her lifetime, and by the age of 32 years half of all women report having had at least one UTI (Ferri, 2016). The urinary tract is the most common site of nosocomial infection, accounting for greater than 3% of the total number reported by hospitals each year (Centers for Disease Control and Prevention [CDC], 2015). In most of these hospital-acquired UTIs, instrumentation of the urinary tract or catheterization is the precipitating cause.

LOWER URINARY TRACT INFECTIONS

Pathophysiology

For infection to occur, bacteria must gain access to the bladder, attach to and colonize the epithelium of the urinary tract, evade host defense mechanisms, and initiate inflammation. Many UTIs result from fecal organisms that ascend from the perineum to the urethra and the bladder and then adhere to the mucosal surfaces.

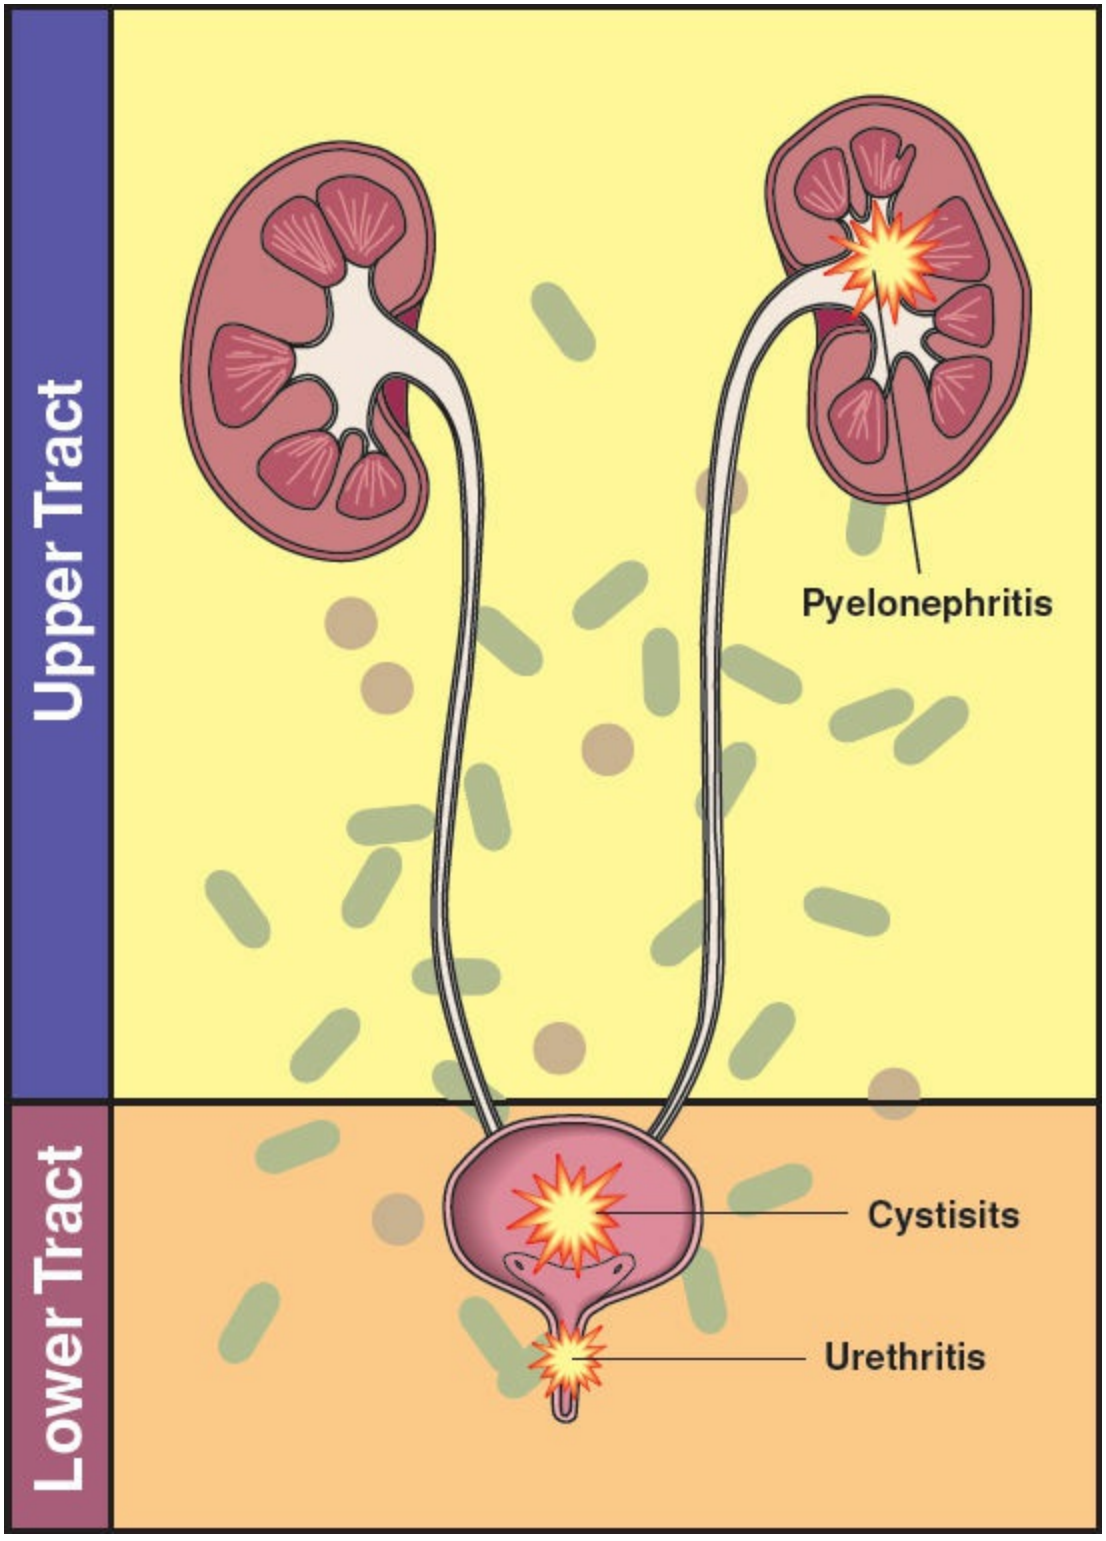

FIGURE 28-1 Urinary Tract Infection. (Courtesy of LifeArt, Lippincott, Wolters Kluwer.)

BOX 28-1 Classifying Urinary Tract Infections

Urinary tract infections (UTIs) are classified by location: the lower urinary tract (which includes the bladder and structures below the bladder) or the upper urinary tract (which includes the kidneys and ureters). They can also be classified as uncomplicated or

complicated UTIs.

Lower UTIs

Cystitis, prostatitis, urethritis

Upper UTIs

Acute pyelonephritis, chronic pyelonephritis, renal abscess, interstitial nephritis, perirenal abscess

Uncomplicated Lower or Upper UTIs

Community-acquired infection; common in young women and not usually recurrent

Complicated Lower or Upper UTIs

Often nosocomial (acquired in the hospital) and related to catheterization; occur in patients with urologic abnormalities, pregnancy, immunosuppression, diabetes mellitus, and obstructions and are often recurrent

Bacterial Invasion of the Urinary Tract

By increasing the normal slow shedding of bladder epithelial cells (resulting in bacteria removal), the bladder can clear even large numbers of bacteria. Glycosaminoglycan (GAG), a hydrophilic protein, normally exerts a nonadherent protective effect against various bacteria by attracting water molecules and forming a water barrier that serves as a defensive layer between the bladder and the urine. GAG may be impaired by certain agents (cyclamate, saccharin, aspartame, and tryptophan metabolites). The normal bacterial flora of the vagina and urethral area also interfere with adherence of *Escherichia coli.*

Reflux

An obstruction to free-flowing urine is a problem known as urethrovesical reflux, which is the reflux of urine from the urethra into the bladder (Fig. 28-2). With coughing, sneezing, or straining, the bladder pressure increases, which may force urine from the bladder into the urethra. When the pressure returns to normal, the urine flows back into the bladder, bringing into the bladder bacteria from the anterior portions of the urethra. Urethrovesical reflux is also caused by dysfunction of the bladder neck or urethra. The urethrovesical angle and urethral closure pressure may be altered with menopause, increasing the incidence of infection in postmenopausal women.

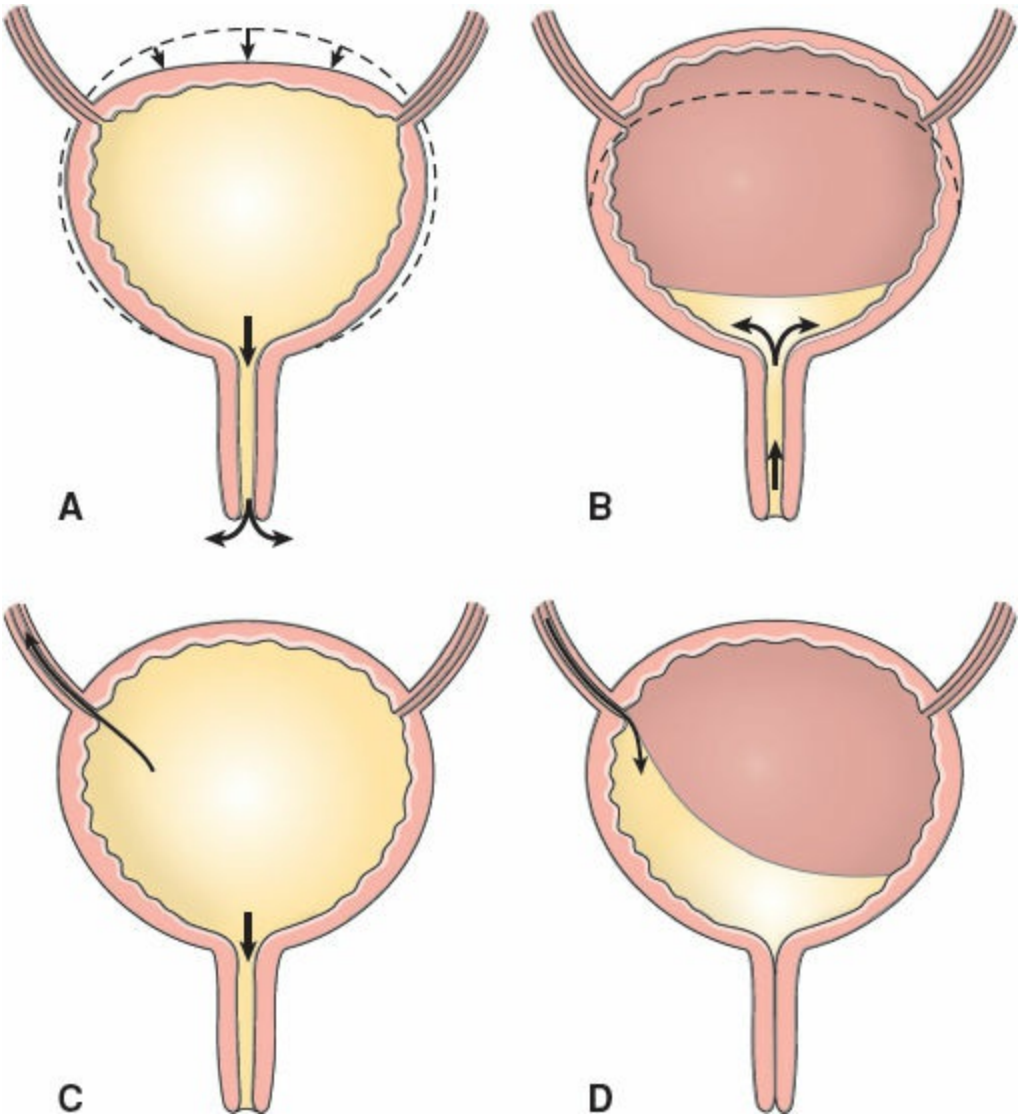

FIGURE 28-2 Mechanisms of urethrovesical and ureterovesical reflux may cause urinary tract infection. Urethrovesical reflux: With coughing and straining, bladder pressure rises, which may force urine from the bladder into the urethra. (A) When bladder pressure returns to normal, the urine flows back to the bladder (B), which introduces bacteria from the urethra to the bladder. Ureterovesical reflux: With failure of the ureterovesical valve, urine moves up the ureters during voiding (C) and flows into the bladder when voiding stops (D). This prevents complete emptying of the bladder. It also leads to urinary stasis and contamination of the ureters with bacteria-laden urine.

Ureterovesical or vesicoureteral reflux refers to the backward flow of urine from the bladder into one or both ureters (see Fig. 28-2). The ureters tunnel into the bladder wall, so that the bladder musculature compresses a small portion of the ureter during normal voiding. When the ureterovesical valve is impaired by congenital causes or ureteral abnormalities, the bacteria may reach the kidneys (Grossman & Porth, 2014).

Uropathogenic Bacteria

Bacteriuria is generally defined as more than 10^5 colonies of bacteria per milliliter of urine, which distinguishes true bacteriuria from contamination, and is a major criterion for infection (Grossman & Porth, 2014). Because urine samples (especially in women) are

commonly contaminated by the bacteria normally present in the urethral area, a bacterial count exceeding 10^5 colonies/mL of clean-catch midstream urine is the measure that distinguishes true bacteriuria from contamination. In men, contamination of the collected urine sample occurs less frequently. If a patient is symptomatic, a smaller number of bacteria (<10,000 colony-forming units [CFU] per milliliter [mL] of midstream urine) is also recognized as an infection (Ferri, 2016). The organisms most frequently responsible for UTIs are those normally found in the lower gastrointestinal (GI) tract. In a large-scale study of the types and prevalence of organisms of patients with UTIs in both the community and hospital, *E. coli* was responsible for 85% of community-acquired and 50% of hospital-acquired infections (Grossman & Porth, 2014; Schaeffer, Matulewicz, & Klumpp, 2016). In women with symptoms of uncomplicated cystitis, 10^2 CFU/mL or more in midstream urine of *E. coli* or *Staphylococcus saprophyticus*is consistent with infection (Nicolle & Norrby, 2016).

Routes of Infection

Bacteria enter the urinary tract in three well-recognized ways: by the transurethral route (ascending infection), through the bloodstream (hematogenous spread), or by means of a fistula (direct extension). The most common route of infection is transurethral, in which bacteria (often from fecal contamination) colonize the periurethral area and subsequently enter the bladder by means of the urethra. In women, the short urethra offers little resistance (Grossman & Porth, 2014). Sexual intercourse or massage of the urethra forces the bacteria up into the bladder, accounting for the increased incidence of UTIs in sexually active women.

BOX 28-2 Risk Factors for Urinary Tract Infection

- Inability or failure to empty the bladder completely
- Obstructed urinary flow:
  - Congenital abnormalities
  - Urethral strictures
  - Contracture of the bladder neck
  - Bladder tumors
  - Calculi (stones) in the ureters or kidneys
  - Compression of the ureters
  - Neurologic abnormalities
- Decreased natural host defenses or immunosuppression
- Instrumentation of the urinary tract (e.g., catheterization, cystoscopic procedures)
- Inflammation or abrasion of the urethral mucosa
- Contributing conditions:
  - Diabetes mellitus (increased urinary glucose levels create an infection-prone environment in the urinary tract)
  - Pregnancy

- Neurologic disorders
- Gout
- Altered states caused by incomplete emptying of the bladder and urinary stasis

Risk Factors

Several mechanisms maintain the sterility of the bladder: the physical barrier of the urethra, urine flow, ureterovesical junction competence, various antibacterial enzymes and antibodies, and antiadherent effects mediated by the mucosal cells of the bladder. Abnormalities or dysfunctions of these mechanisms are contributing risk factors for lower UTIs (Box 28-2).

The American College of Obstetricians and Gynecologists (ACOG) recommends that all pregnant women be screened for asymptomatic bacteriuria, because pregnancy itself is a risk factor for UTIs; the bladder does not empty as well as it normally does.

Clinical Manifestations and Assessment

Signs and Symptoms

A variety of signs and symptoms are associated with UTI but about half of all patients with bacteriuria have no symptoms, and may not need treatment. Signs and symptoms of an uncomplicated lower UTI include dysuria (painful or difficult urination), burning on urination, frequency, urgency, nocturia (excessive urination at night), and incontinence. Suprapubic or pelvic pain, hematuria (bloody urine) and back pain are less common symptoms (Bickley, 2013; Schaeffer et al., 2016). In older people, these symptoms are less common.

Nursing Alert
Elderly patients often lack the typical symptoms of UTI and sepsis. Although frequency, urgency, and dysuria may occur, nonspecific symptoms, such as altered sensorium, lethargy, anorexia, new incontinence, hyperventilation, and low-grade fever, may be the only clues.

Nursing Alert
Often clinicians confuse asymptomatic bacteriuria (ASB, which is bacteria in the urine without any symptoms), with a UTI, resulting in unnecessary antibiotic treatment (Cortes-Penfield, Trautner, & Jump, 2017). The Infectious Diseases Society of America Guidelines for the Diagnosis and Treatment of Asymptomatic Bacteriuria (ASB) in Adults (2016) do not recommend treatment of asymptomatic elderly patients with bacteriuria if the patient is asymptomatic the nurse consider the method of urine collection. For example, a "clean-catch" or mid-stream urine collection in an asymptomatic female should necessitate a repeat sampling to confirm a UTI.

In patients with complicated UTIs, such as those with indwelling catheters, manifestations can range from asymptomatic bacteriuria to gram-negative sepsis with shock. Complicated UTIs often are due to a broader spectrum of organisms, have a lower response rate to treatment, and tend to recur. Many patients with catheter-associated UTIs are asymptomatic and do not need to be treated because administration of antimicrobials to catheterized patients with asymptomatic bacteriuria inevitably results in reinfection with more resistant organisms (Nicolle & Norrby, 2016). However, any patient with a catheter who suddenly develops signs and symptoms of septic shock should be evaluated for bacteremia (the presence of bacteria in blood) from a UTI. The kidneys receive approximately 25% of the cardiac output every minute. When a patient has pyelonephritis, the infection is in the kidney parenchyma and can travel from the kidney into the bloodstream, which is termed *bacteremia. Septicemia* is the clinical syndrome associated with the bacteremia that results in vasodilatation, microvascular permeability, and massive inflammatory response. Nurses should be alert for signs and symptoms of bacteremia from UTI, including hypothermia or hyperthermia, tachycardia, tachypnea, leukocytosis or leukopenia, and greater than 10% immature (band) forms (bands are immature neutrophils

that contain a nucleus, indicating infection). Under normal circumstances only 1% to 3% of neutrophils are band forms. Refer to Chapter 54 for further discussion of sepsis and septic shock.

Diagnostic Tests

Results of various tests such as urine cultures and sensitivities help confirm the diagnosis of UTI. In an uncomplicated UTI, the strain of bacteria determines the antibiotic of choice. Urine cultures are useful for documenting a UTI and can identify the specific organism present. UTI and subsequent sepsis can occur with lower bacterial colony counts. About one third of women with symptoms of acute infections have negative midstream urine culture results and may go untreated if 10^5 CFU/mL is used as the only criterion for infection. The presence of any bacteria in specimens obtained by catheterization (insertion of a tube into the urinary bladder) is considered indicative of infection. If a urine dipstick is used, a positive nitrite and positive leukocyte esterase usually is indicative of UTI in a symptomatic patient (if urine collection was from clean catch or midstream collection or urinary catheterization) (Ferri, 2016).

The following groups of patients may need urine cultures when bacteriuria and symptoms are present:

- All men (because of the likelihood of structural or functional abnormalities)
- Women with a history of compromised immune function or renal problems
- Patients with diabetes mellitus
- Patients who have undergone recent instrumentation (including catheterization) of the urinary tract
- Patients who have been recently hospitalized or who live in long-term care facilities
- Patients with prolonged or persistent symptoms
- Patients with three or more UTIs in the past year
- Pregnant women
- Postmenopausal women
- Sexually active women that use a spermicide for birth control

A multiple-test dipstick often includes testing for white blood cells (WBCs), known as the *leukocyte esterase test*, and nitrite testing (Griess nitrate reduction test). If the leukocyte esterase test is positive, it is assumed that the patient has pyuria (pus in the urine), since esterase is an enzyme released from WBCs; a UTI is suspected and should be treated. The Griess nitrate reduction test is considered positive if bacteria that reduce normal urinary nitrates to nitrites are present. Most Gram-negative bacteria metabolize nitrate to nitrite, however Gram-positive bacteria and fungi do not metabolize nitrate. This rapid (<1 minute) and inexpensive test has a high degree of specificity but is insensitive because it does not detect infections caused by gram-positive organisms (Nicolle & Norby, 2016, page 1874).

Nursing Alert
The nurse is aware that false-positive leukocyte esterase tests can occur if the clean-catch midstream urine collection was not performed correctly or there was

contamination from the vagina in the specimen.

Tests for sexually transmitted infections (STIs) may be performed (see Chapter 35) because acute urethritis caused by sexually transmitted organisms or acute vaginitis infections may be responsible for symptoms similar to those of UTIs.

BOX 28-3 Patient Education

Preventing Recurrent Urinary Tract Infections

Hygiene

- Shower rather than bathe in tub because bacteria in the bath water may enter the urethra.
- After each bowel movement, clean the perineum and urethral meatus from front to back. This will help reduce concentrations of pathogens at the urethral opening and, in women, the vaginal opening.

Fluid Intake

- Drink liberal amounts of fluids daily to flush out bacteria.
- Avoid coffee, tea, colas, alcohol, and other fluids that are urinary tract irritants.

Voiding Habits

- Void every 2–3 hours during the day and completely empty the bladder. This prevents overdistention of the bladder and compromised blood supply to the bladder wall. Both predispose the patient to UTI. Precautions expressly for women include voiding immediately after sexual intercourse.

Therapy

- Take medication *exactly* as prescribed.
- If bacteria continue to appear in the urine, long-term antimicrobial therapy may be required to prevent colonization of the periurethral area and recurrence of infection.
- Special timing of administration may be required.
- If prescribed, test urine for presence of bacteria following manufacturer's and health care provider's instructions.
- Notify the primary health care provider if fever occurs or if signs and symptoms persist.
- Consult the primary health care provider regularly for follow-up.

Imaging studies are rarely indicated for the evaluation of UTIs, except with suspected anatomic issues or if additional pathology, such as renal lithiasis (stone formation or calculi) or fistula (a false track or abnormal passageway), is suspected.

Medical and Nursing Management

Management of UTIs typically involves pharmacologic therapy and patient education. The nurse teaches the patient about medication regimens and infection prevention measures (Box 28-3).

Nursing Alert

Patients who are asymptomatic do not require screening for bacteriuria. It is important to consider that treatment of asymptomatic bacteriuria has not been associated with improved outcomes but is uniformly followed by reinfection with organisms of increasing antimicrobial resistance. There are two exceptions to treatment of asymptomatic bacteriuria: pregnant women or when antimicrobials are given as perioperative prophylaxis before a urologic procedure where trauma to the genitourinary mucosa is anticipated (Nicolle & Norrby, 2016).

Initial Pharmacologic Therapy

The ideal medication for treatment of UTI is an antibacterial agent that eradicates bacteria from the urinary tract with minimal effects on GI and vaginal flora, minimizing the incidence of vaginal yeast infections. (Yeast vaginitis occurs in as many as 25% of patients treated with antimicrobial agents that affect vaginal flora, causes more symptoms, and is more difficult and, thus, more costly to treat than the UTI.) The antibacterial agent should be affordable, have few adverse effects, and produce low resistance in the targeted organisms. Because the organism in initial, uncomplicated UTIs is most likely *E. coli* or other fecal flora, the agent should be effective against these organisms.

Various treatment regimens have been successful in treating uncomplicated lower UTIs in women: single-dose administration, short-course (3 to 4 days) regimens, or 7- to 10-day regimens. The trend is toward a shortened course of antibiotic therapy for uncomplicated UTIs, because most cases are cured after 3 days of treatment (Nicolle & Norrby, 2016). Phenazopyridine, a urinary analgesic, may be prescribed to relieve the discomfort associated with the infection (Karch, 2015). Patients should be informed that their urine will turn dark orange with this medication. Regardless of the regimen prescribed, the patient is instructed to take all the doses prescribed, even if relief of symptoms occurs promptly.

A fluoroquinolone is a routine choice for short-course therapy of uncomplicated, mild to moderate UTIs. There is high patient adherence (95.6%) to the 3-day regimen and a high eradication rate (96.4%) for all pathogens. Before using a fluoroquinolone in patients with complicated UTIs, the causative pathogen should be identified; fluoroquinolone is used only when generic and less costly antibiotics are likely to be ineffective (Vallerand & Sanoski, 2015).

Drug Alert!

Fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture. This risk is further increased in those over age 60, in kidney, heart, and lung transplant recipients, and with use of concomitant steroid therapy. Providers

should advise patients, at the first sign of tendon pain, swelling, or inflammation, to stop taking the fluoroquinolone, to avoid exercise and use of the affected area, and to promptly contact their provider about changing to a nonfluoroquinolone antimicrobial drug (U.S. Food and Drug Administration, 2017).

Nitrofurantoin should not be used in patients with renal insufficiency because it is ineffective at glomerular filtration rates of less than 50 mL/min, and may cause peripheral neuropathy.

In a complicated UTI (i.e., pyelonephritis), the general treatment of choice is usually a cephalosporin or an ampicillin/aminoglycoside combination; ideally, the choice is based on culture results. Patients in institutional settings may require 7 to 10 days of medication for the treatment to be effective. Medications such as ampicillin or amoxicillin can be used, but *E. coli* has developed resistance. Because of this problem of resistance, the fluoroquinolone ciprofloxacin is often used as a first-line agent (Heinz, 2016). Longer medication courses are indicated for men, pregnant women, and women with pyelonephritis and other types of complicated UTIs. Hospitalization and IV antibiotics are occasionally needed.

Long-Term Pharmacologic Therapy

Although brief pharmacologic treatment of UTIs for 3 days is usually adequate in women, infection recurs in about 20% of women treated for uncomplicated UTIs. Infections that recur within 2 weeks of therapy do so because organisms of the original offending strain remain in the vagina. Relapses suggest that the source of bacteriuria may be the upper urinary tract or that initial treatment was inadequate or administered for too short a time. Recurrent infections in men are usually due to persistence of the same organism; further evaluation and treatment are indicated.

If infection recurs after completing antimicrobial therapy, another short course (3 to 4 days) of full-dose antimicrobial therapy, followed by a regular bedtime dose of an antimicrobial agent may be prescribed. In addition, continuous prophylaxis via a 4- to 12-month course of antibiotics may be considered, either nightly or every other night (Heinz, 2016). Long-term use of antimicrobial agents decreases the risk of reinfection and may be indicated in patients with recurrent infections. Choice of antibiotic will be based upon the organism involved, previous UTI strains, and allergic drug history of the patient. Development of microbial resistance to prolonged antibiotic administration is always a concern, therefore the nurse is alert for signs and symptoms of a UTI despite antibiotic therapy.

Reinfection with new bacteria is the reason for more than 90% of recurrent UTIs in women. If the diagnostic evaluation reveals no structural abnormalities in the urinary tract, the woman with recurrent UTIs may be instructed to begin self-treatment when symptoms occur and to contact her health care provider only when symptoms persist, fever occurs, or the number of treatment episodes exceeds three of more episodes in a 6-month period (Ferri, 2016).

If recurrence is caused by persistent bacteria from preceding infections, the cause (i.e., kidney stone, abscess) must be treated. After treatment and sterilization of the urine, low-dose preventive therapy (trimethoprim with or without sulfamethoxazole) each night at bedtime may be prescribed. Finally, for those women who develop UTI after sexual

intercourse, postcoital prophylaxis with low-dose antimicrobials may be prescribed.

The patient is encouraged to drink liberal amounts of fluids (water is the best choice) to promote renal blood flow and to flush the bacteria from the urinary tract. Current evidence about the effectiveness of daily intake of cranberry juice to prevent UTIs has shown that it is no better than placebo for preventing UTIs (Ferri, 2016). However, patients who like cranberry juice can be encouraged to include it in their increased fluid intake that will assist to flush bacteria. Cranberry pill supplement may be recommended, although current evidence is inconclusive regarding its efficacy. It should not be administered to patients on anticoagulants or antiplatelet drugs because of potential to affect coagulation or platelet aggregation. Urinary tract irritants (e.g., coffee, tea, citrus, spices, colas, alcohol) are avoided.

The pain associated with UTI is quickly relieved once effective antimicrobial therapy is initiated. Analgesic agents and the application of heat to the perineum help relieve pain and spasm.

Frequent voiding (every 2 to 3 hours) is encouraged to empty the bladder completely because this can significantly lower urine bacterial counts, reduce urinary stasis, and prevent reinfection.

Gerontologic Considerations

The incidence of bacteriuria in the elderly differs from that in younger adults. Bacteriuria increases with age and disability, and women are affected more frequently than men. UTI is the most common cause of acute bacterial sepsis in patients older than 65 years, in whom gram-negative sepsis carries a mortality rate exceeding 50%. Urologists see many asymptomatic older patients with bacteriuria, and 20% are women older than 65 years. In long-term care facilities, up to 50% of females have asymptomatic bacteriuria (Nicolle & Norrby, 2016). When indwelling catheters are used, the risk for UTI increases dramatically.

In the elderly population at large, structural abnormalities secondary to decreased bladder tone and neurogenic bladder secondary to stroke or autonomic neuropathy of diabetes may prevent complete emptying of the bladder and increase the risk for UTI (Nicolle & Norby, 2016). Elderly women often have incomplete emptying of the bladder and urinary stasis. In the absence of estrogen, postmenopausal women are susceptible to colonization and increased adherence of bacteria to the vagina and urethra. Oral or topical estrogen has been used to restore the glycogen content of vaginal epithelial cells and an acidic pH for some postmenopausal women with recurrent cystitis.

The antibacterial activity of prostatic secretions that protect men from bacterial colonization of the urethra and bladder decreases with aging. Although UTIs are rare in men, the prevalence of infection in men older than 50 years approaches that of women in the same age group. The increase of UTIs in men as they age is due largely to prostatic hyperplasia, strictures of the urethra, and neuropathic bladder. Catheterization may also contribute to the higher incidence of UTI in this group. The incidence of bacteriuria increases in men with confusion, dementia, or bowel or bladder incontinence. The most common cause of recurrent UTIs in elderly males is chronic bacterial prostatitis. In institutionalized elderly patients, such as those in long-term care facilities, infecting pathogens are often resistant to many antibiotics.

Diligent hand hygiene, careful perineal care, and frequent toileting may decrease the incidence of UTIs seen in patients in long-term care facilities. The organisms responsible for UTIs in the institutionalized elderly may differ from those found in patients residing in the community; this may be due to the frequent use of antibiotic agents by patients in long-term care facilities. *E. coli* is the most common organism seen in elderly patients in the community or hospital. However, patients with indwelling catheters are more likely to be infected with *Proteus, Klebsiella, Pseudomonas*, or *Staphylococcus* species. Patients who have been previously treated with antibiotics may be infected with *Enterococcus* species. Controversy continues about the need for treatment of asymptomatic bacteriuria in institutionalized elderly patients, because resulting antibiotic-resistant organisms and sepsis may be greater threats to patients. Treatment regimens are generally the same as those for younger adults, although age-related changes in the intestinal absorption of medications and decreased renal function and hepatic flow may necessitate alterations in dose.

UPPER URINARY TRACT INFECTIONS

Pyelonephritis is a bacterial infection of the renal pelvis, tubules, and interstitial tissue of one or both kidneys. Causes involve either the ascending spread of bacteria from the bladder or proliferation of bacteria from systemic sources reaching the kidney via the bloodstream. It is not uncommon for bacteria that are causing a bladder infection to ascend into the kidney, causing pyelonephritis. An incompetent ureterovesical valve or obstruction occurring in the urinary tract increases the susceptibility of the kidneys to infection (see Fig. 28-1) because static urine provides a good medium for bacterial growth. Bladder tumors, strictures, benign prostatic hyperplasia (BPH), and urinary stones are some potential causes of obstruction that can lead to infections.

Pyelonephritis may be acute or chronic. Acute pyelonephritis is usually manifested by enlarged kidneys with interstitial infiltrations of inflammatory cells. Abscesses may be noted on the renal capsule and at the corticomedullary junction. Atrophy and destruction of tubules and the glomeruli may result. When pyelonephritis becomes chronic, the kidneys become scarred, contracted, nonfunctional, and cause chronic kidney disease that can result in the need for therapies such as transplantation or dialysis.

ACUTE PYELONEPHRITIS

More than 250,000 cases of acute pyelonephritis occur in the United States each year, with 100,000 patients requiring hospitalization.

Clinical Manifestations and Assessment

The patient with acute pyelonephritis is acutely ill with chills, fever, leukocytosis (elevated WBCs), bacteriuria, and pyuria. Low back pain, flank pain (resulting from inflammation and edema of the renal parenchyma), nausea and vomiting, headache, malaise, and painful urination are common findings. Physical examination reveals pain and tenderness in the area of the costovertebral angle (see Chapter 26, Fig. 26-6). In addition, symptoms of lower urinary tract involvement, such as dysuria and frequency, are common. An ultrasound study or a computed tomography (CT) scan may be performed to locate any obstruction in the urinary tract. Relief of obstruction is essential to prevent the complications and eventual kidney damage. Urine culture and sensitivity tests are performed to determine the causative organism so that appropriate antimicrobial agents can be prescribed.

Medical and Nursing Management

Patients with acute uncomplicated pyelonephritis are treated on an outpatient basis if they are not exhibiting dehydration, nausea or vomiting, or symptoms of sepsis. A 2-week course of antibiotics is recommended because renal parenchymal disease is more difficult to eradicate than mucosal bladder infections. Commonly prescribed agents for stable patients who can tolerate oral medications with sensitive pathogens include ciprofloxacin or Levaquin for 10 to 14 days, however recent trials reveal a 7-day course is not inferior to a 14-day course of treatment in women with uncomplicated pyelonephritis (Ferri, 2016). Whereas intravenous (IV) medications are indicated for symptomatic complicated patients, and treatment includes IV Cipro, or Levaquin; piperacillin/tazobactam, carbapenems; aminoglycosides such as gentamicin with or without ampicillin, or a third-generation cephalosporin (Ferri, 2016). Treatment will be based upon urine culture and sensitivity results. These medications must be used with great caution if the patient has renal or liver dysfunction. Pregnant women may be hospitalized for 2 or 3 days of parenteral antibiotic therapy. Oral antibiotic agents may be prescribed once the patient is afebrile and showing clinical improvement. Hydration is essential in all patients with UTIs when there is adequate kidney function; this helps facilitate "flushing" of the urinary tract and reduces pain and discomfort.

A possible issue in acute pyelonephritis treatment is a chronic or recurring symptomless infection persisting for months or years. After the initial antibiotic regimen, the patient may need antibiotic therapy for up to 6 weeks if evidence of a relapse is seen. A follow-up urine culture is obtained 2 weeks after completion of antibiotic therapy to document clearing of the infection.

CHRONIC PYELONEPHRITIS

Repeated bouts of acute pyelonephritis may lead to chronic pyelonephritis.

Clinical Manifestations and Assessment

The patient with chronic pyelonephritis usually has no symptoms of infection unless an acute exacerbation occurs. Noticeable signs and symptoms may include fatigue, headache, poor appetite, polyuria, excessive thirst, and weight loss. Persistent and recurring infection may produce progressive scarring of the kidney resulting in kidney failure (see Chapter 27).

The extent of the disease is assessed by an IV urogram and degree of renal dysfunction via measurements of creatinine clearance, blood urea nitrogen, and creatinine levels. Bacteria, if detected in the urine, are eradicated if possible.

Medical and Nursing Management

Long-term use of prophylactic antimicrobial therapy may help limit recurrence of infections and renal scarring (Kumar, 2015). Impaired renal function alters the excretion of antimicrobial agents and necessitates careful monitoring of renal function, especially if the medications are potentially toxic to the kidneys.

The patient may require hospitalization or may be treated as an outpatient. When the patient requires hospitalization, fluid intake and output are carefully measured and recorded. Unless contraindicated, 3 to 4 L of fluids per day is encouraged to dilute the urine, decrease burning on urination, and prevent dehydration. The nurse assesses the patient's temperature every 4 hours and administers antipyretic and antibiotic agents as prescribed. Symptomatic patients are often more comfortable on bedrest. Patient teaching focuses on prevention of further infection by consuming adequate fluids, emptying the bladder regularly, and performing recommended perineal hygiene. The importance of taking antimicrobial medications exactly as prescribed is stressed, as is the need for keeping follow-up appointments.

Complications

Complications of chronic pyelonephritis include end-stage kidney disease (ESKD) from progressive loss of nephrons secondary to chronic inflammation and scarring.

ADULT VOIDING DYSFUNCTION

Both neurogenic and nonneurogenic disorders can cause adult voiding dysfunction (Table 28-1). The micturition process involves several highly coordinated neurologic responses that mediate bladder function. A functional urinary system allows for appropriate bladder filling and complete bladder emptying (see Chapter 26). If voiding dysfunction goes undetected and untreated, the upper urinary system may be compromised. Chronic incomplete bladder emptying from poor detrusor pressure results in recurrent bladder infection. Incomplete bladder emptying due to bladder outlet obstruction (such as BPH), causing high-pressure detrusor contractions, can result in hydronephrosis from the high detrusor pressure that radiates up the ureters to the renal pelvis.

OVERACTIVE BLADDER

It is estimated that over 33 million Americans have overactive bladder (OAB). OAB is a condition in which a person has urgency, frequency, and nocturia that may or may not be associated with urinary incontinence (Drake, 2016). Normal frequency is seven voids per day and once at night up until the age of 70 years. OAB can have a significant impact on quality-of-life indicators. Treatment for OAB is similar to urge incontinence, discussed later in the chapter.

URINARY INCONTINENCE

More than 17 million adults in the United States are estimated to have urinary incontinence, with most of them experiencing OAB syndrome, making this disorder more prevalent than diabetes or ulcer disease. Despite widespread media coverage, urinary incontinence remains underdiagnosed and underreported. Patients may be too embarrassed to seek help, causing them to ignore or conceal symptoms. Many patients resort to using absorbent pads or other devices without having their condition properly diagnosed and treated. Health care providers must be alert to subtle cues of urinary incontinence and stay informed about current management strategies. Subtle cues include avoidance of social situations, perineal dermatitis, and depression. The costs of care for patients with urinary incontinence include cost of absorbent products, medications, and surgical or nonsurgical treatment modalities, as well as the psychosocial costs of urinary incontinence, including embarrassment, loss of self-esteem, and social isolation.

Risk Factors

Urinary incontinence affects people of all ages but is particularly common among the elderly and can decrease an elderly person's ability to maintain an independent lifestyle. This increases dependence on caregivers and may lead to institutionalization. More than half of all nursing home residents have urinary incontinence. Although urinary incontinence is not a normal consequence of aging, age-related changes in the urinary tract predispose the older person to incontinence.

TABLE 28-1 Conditions Causing Adult Voiding Dysfunction

Condition	Voiding Dysfunction	Treatment
Neurogenic Disorders		
Cerebellar ataxia	Incontinence or dyssynergia	Timed voiding; anticholinergics
Cerebrovascular accident	Retention or incontinence	Anticholinergics; bladder retraining
Dementia	Incontinence	Prompted voiding
Diabetes mellitus	Incontinence and/or incomplete bladder emptying	Timed voiding; electromyelogram (EMG)/biofeedback; pelvic floor nerve stimulation; anticholinergics/ antispasmodics; well-controlled blood glucose levels
Multiple sclerosis	Incontinence or incomplete bladder emptying	Timed voiding; EMG/biofeedback to learn pelvic muscle exercises and urge inhibition; pelvic floor nerve stimulation; antispasmodics
Parkinson disease	Incontinence	Anticholinergics/antispasmodics
Spinal Cord Dysfunction		
Acute injury	Urinary retention	Indwelling catheter
Degenerative disease	Incontinence and/or incomplete bladder emptying	EMG/biofeedback; pelvic floor nerve stimulation; anticholinergics
Nonneurogenic Disorders		
"Bashful bladder"	Inability to initiate voiding in public bathrooms	Relaxation therapy; EMG/biofeedback
Overactive bladder	Urgency, frequency, and/or urge incontinence	EMG/biofeedback; pelvic floor nerve stimulation; anticholinergics
Post general surgery	Acute urine retention	Catheterization
Post-prostatectomy	Incontinence	*Mild:* biofeedback; pelvic floor nerve stimulation *Moderate/severe:* surgery—artificial sphincter
Stress incontinence	Incontinence with cough, laugh, sneeze, position change	*Mild:* biofeedback: periurethral bulking with collagen *Moderate/severe:* surgery

Although it is commonly regarded as a condition that occurs in older multiparous women, it is also seen in young nulliparous women, especially during vigorous high-impact activity. Age, gender, and number of vaginal deliveries are established risk factors (Box 28-4) that explain, in part, the increased incidence in women.

Types of Incontinence

Only with appropriate recognition of the problem, assessment, and referral for diagnostic evaluation and treatment can the outcome of incontinence be determined. All patients with incontinence should be considered for evaluation and treatment. Urinary incontinence may be transient or reversible if the underlying cause is successfully treated and the voiding pattern reverts to normal (Box 28-5).

BOX 28-4 Risk Factors for Urinary Incontinence

- Pregnancy: vaginal delivery, episiotomy
- Menopause
- Genitourinary surgery
- Pelvic muscle weakness
- Incompetent urethra due to trauma or sphincter relaxation
- Immobility
- High-impact exercise
- Diabetes mellitus
- Stroke
- Age-related changes in the urinary tract
- Morbid obesity
- Cognitive disturbances: dementia, Parkinson disease
- Medications: diuretics, sedatives, hypnotics, opioids
- Caregiver or toilet unavailable

BOX 28-5 Causes of Transient Incontinence: DIAPPERS

Delirium

Infection of urinary tract

Atrophic vaginitis, urethritis

Pharmacologic agents (anticholinergics, sedatives, alcohol, analgesics, diuretics, muscle relaxants, adrenergic agents)

Psychological factors (depression, regression)

Excessive urine production (increased intake, diabetes insipidus, diabetic ketoacidosis)

Restricted activity

Stool impaction

Stress incontinence is the involuntary loss of urine through an intact urethra as a result

of sneezing, coughing, or changing position. It predominantly affects women who have had vaginal deliveries and is thought to be the result of decreasing ligament and pelvic floor support (pelvic floor dysfunction) of the urethra and decreasing or absent estrogen levels within the urethral walls and bladder base. In men, stress incontinence is often experienced after a radical prostatectomy for prostate cancer because of the loss of urethral compression that the prostate had supplied before the surgery.

Urge incontinence is the involuntary loss of urine associated with a strong urge to void that cannot be suppressed. The patient is aware of the need to void but is unable to reach a toilet in time. An uninhibited detrusor contraction is the precipitating factor. This can occur in a patient with neurologic dysfunction that impairs inhibition of bladder contraction or in a patient without overt neurologic dysfunction.

Reflex incontinence is the involuntary loss of urine due to hyperreflexia in the absence of normal sensations usually associated with voiding. This commonly occurs in patients with spinal cord injury because they have neither neurologically mediated motor control of the detrusor nor sensory awareness of the need to void (see Chapter 45).

Overflow incontinence is the involuntary loss of urine associated with overdistention of the bladder. Such overdistention results from the bladder's inability to empty normally, despite frequent urine loss. Neurologic abnormalities (e.g., spinal cord lesions), factors that obstruct the outflow of urine (e.g., tumors, strictures, and prostatic hyperplasia), and myogenic abnormalities (problems with bladder contractions) can cause overflow incontinence.

Functional incontinence refers to those instances in which lower urinary tract function is intact but other factors, such as severe cognitive impairment (e.g., Alzheimer dementia), make it difficult for the patient to identify the need to void or physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding.

Iatrogenic incontinence refers to the involuntary loss of urine due to extrinsic medical factors, predominantly medications. One such example is the use of alpha-adrenergic agents to decrease blood pressure. In some people with an intact urinary system, these agents adversely affect the alpha receptors responsible for bladder neck closing pressure; the bladder neck relaxes to the point of incontinence with a minimal increase in intra-abdominal pressure, thus mimicking stress incontinence. As soon as the medication is discontinued, the apparent incontinence resolves.

Some patients have several types of urinary incontinence. This mixed incontinence is usually a combination of stress and urge incontinence (Drake, 2016).

Clinical Manifestations and Assessment

Once incontinence is recognized, a thorough history is necessary. This includes a detailed description of the problem and a history of medication use, noting those associated with urinary incontinence such as loop diuretics, ACE inhibitors, calcium channel blockers, narcotics, sedatives–hypnotics (including alcohol), anticholinergics, and NSAIDs (Resnick, 2016). The patient's voiding history, a diary of fluid intake and output, and bedside tests (e.g., residual urine, stress maneuvers) may be used to help determine the type of urinary incontinence involved. Extensive urodynamic tests may be performed. In addition, urinalysis and urine culture are performed to identify infection.

Medical Management

Management depends on the type of urinary incontinence and its causes. Strategies for promoting urinary continence can be found in Box 28-6. Management of urinary incontinence may be behavioral, pharmacologic, or surgical in nature.

BOX 28-6 Patient Education

Strategies for Promoting Urinary Continence

- Increase your awareness of the amount and timing of all fluid intake.
- Avoid taking diuretics after 4 PM.
- Avoid bladder irritants, such as caffeine, alcohol, and aspartame (NutraSweet).
- Take steps to avoid constipation: Drink adequate fluids, eat a well-balanced diet high in fiber, exercise regularly, and take stool softeners if recommended.
- Void regularly, 5–8 times a day (about every 2–3 hours at first, and increasing duration between voids):
  - First thing in the morning
  - Before each meal
  - Before retiring to bed
  - Once during night if necessary
- Perform all pelvic floor muscle exercises as prescribed, every day.
- Stop smoking (smokers usually cough frequently, which increases incontinence).

Behavioral Therapy

Behavioral therapies are the first choice to decrease or eliminate urinary incontinence and or symptoms of OAB (Box 28-7). In using these techniques, health care professionals help patients avoid potential adverse effects of pharmacologic or surgical interventions.

Pharmacologic Therapy

Pharmacologic therapy works best when used as an adjunct to behavioral interventions. Anticholinergic agents inhibit bladder contraction and are considered first-line medications for urge incontinence. Oxybutynin (Ditropan) is frequently prescribed and has dual actions of relaxing the detrusor muscle and inhibiting bladder contraction. Hormone therapy (e.g., estrogen) taken orally, transdermally, or topically was once the treatment of choice for urinary incontinence in postmenopausal women, however evidence now exists that oral estrogen may worsen incontinence (Resnick, 2016) and is not recommended (Lukacz, 2016). Topical estrogen can be useful for peri- or postmenopausal women with either stress or urgency incontinence and vaginal atrophy which can contribute to incontinence (Lukacz, 2016).

BOX 28-7 Behavioral Interventions for Urinary Incontinence

Behavioral strategies are largely carried out, coordinated, and monitored by the nurse. These interventions may or may not be augmented by the use of medications.

Fluid Management

One of the most common approaches is fluid management because adequate daily fluid intake of approximately 50–60 oz (1,500–1,800 mL), taken as small increments between breakfast and the evening meal, helps to reduce urinary urgency related to concentrated urine production, decreases the risk of urinary tract infection, and maintains bowel functioning. (Constipation, resulting from inadequate daily fluid intake, can increase urinary urgency and/or urine retention.) The best fluid is water. Fluids containing caffeine, carbonation, alcohol, or artificial sweetener should be avoided because they irritate the bladder wall, thus resulting in urinary urgency. Some patients who have coexisting medical diagnoses, such as heart failure or end-stage kidney disease, need to discuss their daily fluid limit with their primary health care provider.

Weight Management

Obesity is associated with OAB and urinary incontinence, thus weight control should be considered as a first-line intervention, particularly when the body mass index (BMI) is greater than 27. Studies reveal that weight loss leads to a significant reduction of the frequency and severity of urge incontinence episodes (Krhut et al., 2016).

Standardized Voiding Frequency

After establishing a patient's natural voiding and urinary incontinence tendencies, voiding on a schedule can be very effective in those with and without cognitive impairment, although patients with cognitive impairment may require assistance with this technique from nursing personnel or family members. The object is to purposely empty the bladder before the bladder reaches the critical volume that would cause an urge or stress incontinence episode. This approach involves the following:

- Timed voiding involves establishing a set voiding frequency (such as every 2 hours if incontinent episodes tend to occur 2 or more hours after voiding). The individual chooses to "void by the clock" at the given interval while awake, rather than wait until a voiding urge occurs.
- Prompted voiding is timed voiding that is carried out by staff or family members when the individual has cognitive difficulties that make it difficult to remember to void at set intervals. The caregiver checks the patient to assess if he or she has remained dry and, if so, assists the patient to use the bathroom while providing positive reinforcement for remaining dry.
- Habit retraining is timed voiding at an interval that is more frequent than the

individual would usually choose. This technique helps to restore the sensation of the need to void in individuals who are experiencing diminished sensation of bladder filling due to various medical conditions such as a mild cerebrovascular accident (CVA).

- Bladder retraining incorporates a timed voiding schedule and urinary urge inhibition exercises to inhibit voiding, or leaking urine, in an attempt to remain dry for a set time. When the first timing interval is easily reached on a consistent basis without urinary urgency or incontinence, a new voiding interval, usually 10–15 minutes beyond the last, is established. Again, the individual practices urge inhibition exercises to delay voiding or avoid incontinence until the next preset interval arrives. When an acceptable voiding interval is reached, the patient continues that timed voiding sequence throughout the day.

Pelvic Muscle Exercise

Pelvic muscle exercise (PME) aims to strengthen the voluntary muscles that assist in bladder and bowel continence in both men and women. Research shows that written and/or verbal instruction alone is usually inadequate to teach an individual how to identify and strengthen the pelvic floor for sufficient bladder and bowel control. Biofeedback-assisted PME uses either electromyography or manometry to help the individual identify the pelvic muscles as he or she attempts to learn which muscle group is involved when performing PME. The biofeedback method also allows assessment of the strength of this muscle area.

PME involves gently tightening the same muscles used to stop flatus or the stream of urine for 5- to 10-second increments, followed by 10-second resting phases. To be effective, these exercises need to be performed 2 or 3 times a day for at least 6 weeks. Depending on the strength of the pelvic musculature when initially evaluated, anywhere from 10 to 30 repetitions of PME are prescribed at each session. Elderly patients may need to exercise for an even longer time to strengthen the pelvic floor muscles. Pelvic muscle exercises are helpful for women with stress, urge, or mixed incontinence and for men who have undergone prostate surgery.

Vaginal Cone Retention Exercises

Vaginal cone retention exercises are an adjunct to the pelvic muscle (Kegel) exercises. Vaginal cones of varying weight are inserted intravaginally twice a day. The patient tries to retain the cone for 15 minutes by contracting the pelvic muscles.

Transvaginal or Transrectal Electrical Stimulation

Commonly used to treat urinary incontinence, electrical stimulation is known to elicit a passive contraction of the pelvic floor musculature, thus re-educating these muscles to provide enhanced levels of continence. This modality is often used with biofeedback-assisted pelvic muscle exercise training and voiding schedules. At high frequencies, it is

effective for stress incontinence. At low frequencies, electrical stimulation can also relieve symptoms of urinary urgency, frequency, and urge incontinence. Intermediate ranges are used for mixed incontinence.

Neuromodulation

Neuromodulation via transvaginal or transrectal nerve stimulation of the pelvic floor inhibits detrusor overactivity and hypersensory bladder signals and strengthens weak sphincter muscles.

Surgical Management

Surgical correction may be indicated in patients who have not achieved continence using behavioral and pharmacologic therapy. Surgical options vary according to the underlying anatomy and the physiologic problem. Most procedures involve lifting and stabilizing the bladder or urethra to restore the normal urethrovesical angle or to lengthen the urethra (Dmochowski, Osborn, & Reynolds, 2016). Urethral slings are currently the procedure of choice for the surgical correction of female stress urinary incontinence. Women with stress incontinence may undergo an anterior vaginal repair, retropubic suspension, or needle suspension to reposition the urethra. Procedures to compress the urethra and increase resistance to urine flow include sling procedures and placement of periurethral bulking agents such as artificial collagen.

Periurethral bulking is a semipermanent procedure in which small amounts of artificial collagen (or other substances) are placed within the walls of the urethra to enhance the closing pressure of the urethra. This procedure takes only 10 to 20 minutes and may be performed under local anesthesia or moderate sedation. A cystoscope is inserted into the urethra, and a small amount of collagen is injected into the urethral wall. The patient is usually discharged home after voiding. More than one collagen bulking session may be necessary if the initial procedure did not halt the stress urinary incontinence. Periurethral bulking with collagen offers an alternative to surgery, as in a frail, elderly person. It is also an option for people who are seeking help with stress urinary incontinence who prefer to avoid surgery and who do not have access to behavioral therapies. Although limited evidence exists to date for the benefit of these agents, because of the low risk of side effects associated with periurethral bulking agents, it is considered an option for those not ready to undergo a more invasive surgical procedure (Dmochowski et al., 2016).

An artificial urinary sphincter can be used to close the urethra and promote continence. Two types of artificial sphincters are a periurethral cuff and a cuff inflation pump. This therapy is approved for men only and is often used after treatment for prostate cancer (Fig. 28-3).

Men with overflow and urge incontinence may undergo a transurethral resection to relieve symptoms of prostatic enlargement.

Nursing Management

Nursing management is based on the premise that incontinence is not inevitable with illness or aging and that it is often reversible and treatable. The nursing interventions are determined by the type of treatment that is undertaken. For behavioral therapy to be effective, the nurse must provide support and encouragement because it is easy for the patient to become discouraged if therapy does not quickly improve the level of continence. Patient teaching is important and should be provided verbally and in writing (see Box 28-6). The patient should be taught to develop and use a log or diary to record timing of pelvic floor muscle exercises, frequency of voiding, any changes in bladder function, and any episodes of incontinence (Drake, 2016; Resnick, 2016).

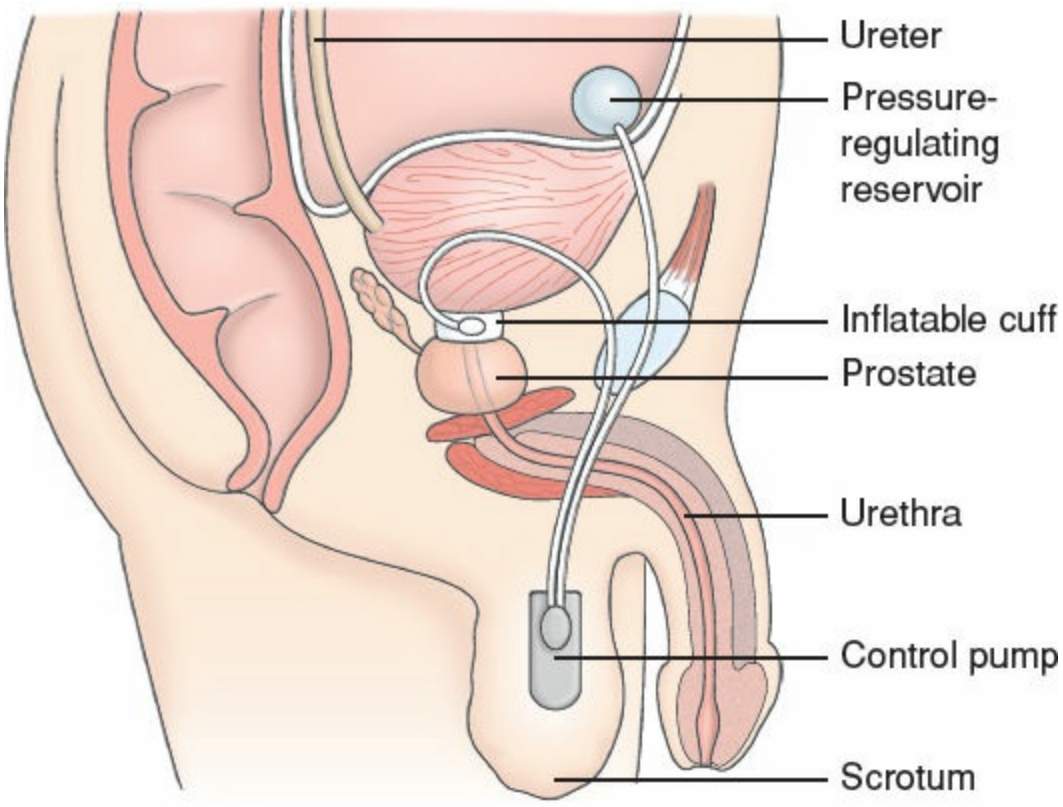

FIGURE 28-3 Male artificial urinary sphincter. An inflatable cuff is inserted surgically around the urethra or neck of the bladder. To empty the bladder, the cuff is deflated by squeezing the control pump located in the scrotum.

If pharmacologic treatment is used, it is important to educate patients who have mixed incontinence (both stress and urge incontinence) that anticholinergic and antispasmodic agents can help decrease urinary urgency and frequency and urge incontinence, but they do not decrease the urinary incontinence related to stress incontinence. If surgical correction is undertaken, the procedure and its desired outcomes are described to the patient and family. Follow-up contact with the patient enables the nurse to answer the patient's questions and to provide reinforcement and encouragement.

Gerontologic Considerations 

Many older people experience transient episodes of incontinence that tend to be abrupt in onset. When this occurs, the nurse should question the patient, as well as the family if possible, about the onset of symptoms and any signs or symptoms of a change in other organ systems. Acute UTI, infection elsewhere in the body, constipation, stool impaction, a change in a chronic disease pattern, such as elevated blood glucose levels in patients with diabetes or decreased estrogen levels in menopausal women, can provoke the onset of urinary incontinence. If the cause is identified and modified or eliminated early at the onset of incontinence, the incontinence itself may be eliminated. Although the bladder of the older person is more vulnerable to altered detrusor activity (bladder capacity does not change, but sensation and contractility decrease), age alone is not a risk factor for urinary incontinence (Resnick, 2016). Decreased bladder muscle tone is a normal age-related change found in the elderly, which can lead to, increased residual urine, and an increase in urgency (Resnick, 2016).

URINARY RETENTION

Urinary retention is the inability to empty the bladder completely during attempts to void. Acute urinary retention in men is frequently associated with obstruction such as BPH or acute prostatitis. Acute retention occurs infrequently in women, with the exception of postoperatively due to anesthesia effects; it can also occur due to organ prolapse. Chronic urine retention often leads to overflow incontinence (from the pressure of the retained urine in the bladder). Residual urine is urine that remains in the bladder after voiding. In a healthy adult younger than 60 years, complete bladder emptying should occur with each voiding. In adults older than 60 years, 50 to 100 mL of residual urine may remain after each voiding because of the decreased contractility of the detrusor muscle.

Urinary retention can occur postoperatively in any patient who received spinal or general anesthesia. General anesthesia reduces bladder muscle innervation and suppresses the urge to void, impeding bladder emptying. A number of medications have been implicated in the development of urinary retention and are briefly discussed below. Other etiologies that should be considered in acute urinary retention are trauma, infection (prostatitis, cystitis), and neurologic and psychiatric disorders.

Pathophysiology

Urinary retention may result from diabetes, prostatic enlargement, urethral pathology (infection, urethral strictures, tumor, calculus), trauma (pelvic injuries), pregnancy, or neurologic or myogenic disorders such as stroke, spinal cord injury, multiple sclerosis (MS), Guillain–Barré syndrome, or Parkinson disease.

Some medications cause urinary retention, either by inhibiting bladder contractility or by increasing bladder outlet resistance, namely anticholinergics and sympathomimetic agents. Medications that cause retention by inhibiting bladder contractility include antispasmodic agents (oxybutynin chloride, belladonna, and opioid suppositories) and tricyclic antidepressant medications (imipramine, doxepin). Medications that cause urine retention by increasing bladder outlet resistance include alpha-adrenergic agents (ephedrine sulfate, pseudoephedrine), beta-adrenergic blockers (propranolol), and estrogens.

Sympathomimetics "mimic" the sympathetic nervous system and therefore have the anticipated result of increasing heart rate and contractility, dilating bronchioles and pupils, and—pertinent to this chapter—relaxing the bladder wall and thus closing the sphincter, affecting urinary retention. Anticholinergics work by blocking the parasympathetic nervous system response, which causes contraction of the bladder and relaxation of the sphincter. Thus since this response is blocked, clinically the effects are similar to the sympathomimetics; hence, both drugs are implicated in urinary retention.

Clinical Manifestations and Assessment

The assessment of a patient for urinary retention is multifaceted because the signs and symptoms may be easily overlooked. The following questions serve as a guide in assessment:

- What was the time of the last voiding, and how much urine was voided?
- Is the patient voiding small amounts of urine frequently?
- Is the patient dribbling urine?
- Does the patient complain of pain or discomfort in the lower abdomen? (Discomfort may be relatively mild if the bladder distends slowly.)
- Is the pelvic area rounded and swollen, indicating urine retention and a distended bladder?
- Does percussion of the suprapubic region elicit dullness, possibly indicating urine retention and a distended bladder?
- Are other indicators of urinary retention present, such as restlessness and agitation?
- Does a postvoid bladder ultrasound test reveal residual urine?

The patient may verbalize an awareness of bladder fullness and a sensation of incomplete bladder emptying. Signs and symptoms of UTI (hematuria, urgency, frequency, nocturia, and dysuria) may be present. A series of urodynamic studies, described in Chapter 26, may be performed to identify the type of bladder dysfunction and to aid in determining appropriate treatment. The patient may complete a voiding diary to provide a written record of the amount of urine voided and the frequency of voiding. Postvoid residual urine may be assessed either using straight catheterization or an ultrasound bladder scanner and is considered diagnostic of urinary retention if there is more than 100 mL of residual urine.

Medical Management

Management strategies are instituted to prevent overdistention of the bladder and to treat infection or correct underlying etiology for the retention. Immediate management involves decompression of the bladder via catheterization, which is discussed later in this chapter.

Nursing Management

Many problems can be prevented with careful assessment and appropriate nursing interventions. The nurse explains why normal voiding is not occurring and monitors urine output closely. The nurse also provides reassurance about the temporary nature of retention and successful management strategies.

In the case of acute urinary retention, decompression with a urethral catheter is commonly required. Nurses need to assess, however, if the patient recently underwent surgery, such as a radical prostatectomy or urethral reconstruction, since catheterization via urethra would be contraindicated. Barring no contraindications to urinary catheterization, the nurse chooses a 14- to 18-French Foley catheter, and if the patient has a past history of prostatic disease a *coude* catheter is recommended to facilitate passage through the posterior urethra. A complication associated with emergent catheterization for urinary retention is hypotension and hematuria.

Promoting Urinary Elimination

Nursing measures to encourage normal voiding patterns include providing privacy, ensuring an environment and a position conducive to voiding, and assisting the patient with the use of the bathroom or bedside commode, rather than a bedpan, to provide a more natural setting for voiding. The male patient may stand beside the bed while using the urinal; most men find this position more comfortable and natural.

Additional measures include applying warmth to relax the sphincters (i.e., sitz baths, warm compresses to the perineum, showers), giving the patient hot tea, and offering encouragement and reassurance. Simple trigger techniques, such as turning on the water faucet while the patient is trying to void, may also be used. After surgery or childbirth, prescribed analgesics should be administered because pain in the perineal area can make voiding difficult.

When the patient cannot void, catheterization is used to prevent overdistention of the bladder (see later discussion of neurogenic bladder and catheterization). Rarely is a suprapubic tube used for BPH. After urinary drainage is restored, bladder retraining is initiated for the patient who cannot void spontaneously.

Promoting Home Care

Modifications to the home environment can provide simple and effective ways to assist in treating urinary incontinence and retention. For example, the patient may need to remove obstacles, such as throw rugs or other objects, to provide easy, safe access to the bathroom. Other modifications that the nurse may recommend include installing support bars in the bathroom; placing a bedside commode, bedpan, or urinal within easy reach; leaving lights on in the bedroom and bathroom; and wearing clothing that is easy to remove quickly.

Complications

Urine retention can lead to chronic infection and, if left unresolved, predispose the patient to renal calculi (urolithiasis or nephrolithiasis), pyelonephritis, and sepsis. Acute or chronic kidney failure may develop secondary to renal obstruction (refer to Chapter 27). If hydronephrosis has occurred due to large volumes of retained urine, renal insufficiency may develop and progress to kidney failure.

NEUROGENIC BLADDER

Neurogenic bladder is a dysfunction that results from a lesion of the nervous system and leads to urinary incontinence. It may be caused by spinal cord injury, spinal tumor, herniated vertebral disk, MS, congenital disorders (spina bifida or myelomeningocele), myogenic disorders, infection, or diabetes mellitus.

Pathophysiology

The two types of neurogenic bladder are spastic (or reflex) bladder and flaccid bladder. Spastic bladder is more common and is caused by any spinal cord lesion above the voiding reflex arc (upper motor neuron lesion). The result is a loss of conscious sensation and cerebral motor control. A spastic bladder empties on reflex, with minimal or no controlling influence to regulate its activity.

Flaccid bladder is caused by a lower motor neuron lesion, commonly resulting from trauma, but increasingly recognized in patients with diabetes mellitus. The bladder continues to fill and becomes greatly distended, and overflow incontinence occurs. The bladder muscle does not contract forcefully at any time. Because sensory loss may accompany a flaccid bladder, the patient feels no discomfort. This can also occur in men with BPH with obstructive component.

Clinical Manifestations and Assessment

Evaluation for neurogenic bladder involves measurement of fluid intake, urine output, and residual urine volume, urinalysis, and assessment of sensory awareness of bladder fullness and degree of motor control. Comprehensive urodynamic studies are also performed.

Medical Management

The problems resulting from neurogenic bladder disorders vary considerably from patient to patient. Several long-term objectives are appropriate for all types of neurogenic bladders:

- Preventing overdistention of the bladder
- Emptying the bladder regularly and completely
- Maintaining urine sterility with no stone formation
- Maintaining adequate bladder capacity with no reflux

Specific interventions include continuous or intermittent self-catheterization (ISC), use of an external condom-type catheter, and encouragement of mobility and ambulation. A liberal fluid intake is encouraged to reduce the urinary bacterial count, reduce stasis, decrease the concentration of calcium in the urine, and minimize the precipitation of urinary crystals and subsequent stone formation.

A bladder retraining program may be effective in treating a spastic bladder or urine retention. Use of a timed voiding schedule may be established. The patient may be taught to "double void": after each voiding, the patient is instructed to remain on the toilet, relax for 1 to 2 minutes, and then attempt to void again in an effort to further empty the bladder.

Pharmacologic Therapy

Alpha blockers were originally developed for hypertension; these drugs block the adrenergic system and help patients with BPH by relaxing smooth muscle tissue found in the prostate and the bladder neck, thereby facilitating urine outflow. The four alpha medications approved by the U.S. Food and Drug Administration (FDA) are: terazosin (Hytrin), doxazosin (Cardura), tamsulosin (Flomax), and alfuzosin (Uroxatral).

Surgical Management

In some cases, surgery may be carried out to correct bladder neck contractures, prostatic obstruction, vesicoureteral reflux, or to perform some type of urinary diversion procedure.

Catheterization

In patients with a urologic disorder or with marginal kidney function, care must be taken to ensure that urinary drainage is adequate and that kidney function is preserved. When urine cannot be eliminated naturally and must be drained artificially, catheters may be inserted directly into the bladder, the ureter, or the renal pelvis. Catheters vary in size, shape, length, material, and configuration. The type of catheter used depends on its purpose, and catheterization is performed to achieve the following:

- Relieve urinary tract obstruction
- Assist with postoperative drainage in urologic and other surgeries
- Provide a means to monitor accurate urine output in critically ill patients
- Promote urinary drainage in patients with neurogenic bladder dysfunction or urine

retention
- Prevent urinary leakage in patients with stage III to IV pressure ulcers (see Chapter 52)

A patient should be catheterized only if necessary, because instrumentation can lead to UTI. Catheters impede most of the natural defenses of the lower urinary tract by obstructing the periurethral ducts, irritating the bladder mucosa, and providing an artificial route for organisms to enter the bladder. Organisms may be introduced from the urethra into the bladder during catheterization, or they may migrate along the epithelial surface of the urethra or external surface of the catheter.

Indwelling Catheters

Approximately 50,000 long-term care patients each year have an indwelling catheter (CDC, 2015). When an indwelling catheter cannot be avoided, a closed drainage system is essential. This drainage system is designed to prevent any disconnections, thereby reducing the risk of contamination. The spout (or drainage port) of any urinary drainage bag can become contaminated when opened to drain the bag. Bacteria enter the urinary drainage bag, multiply rapidly, and then migrate to the drainage tubing, catheter, and bladder. By keeping the drainage bag lower than the patient's bladder and not allowing urine to flow back into the bladder, this risk is minimized.

Triple-lumen catheters are commonly used after transurethral prostate surgery (TURP) (see Chapter 34). This system has a triple-lumen indwelling urethral catheter attached to a closed sterile drainage system. With the triple-lumen catheter, urinary drainage occurs through one channel. The retention balloon of the catheter is inflated with water or air through the second channel, and the bladder is continuously irrigated with sterile irrigating solution through the third channel.

Nursing Alert
After a patient undergoes a TURP, he will have a three-way catheter system in place that fulfills several roles: irrigation, tamponade, drainage, and traction. Precise intake and output records must be maintained, especially if total resection time was greater than 90 minutes. These men are at risk for TUR syndrome, a result of the absorption of irrigation fluid intraoperatively, which can lead to hyponatremia, bradycardia, and confusion.

Accurate intake and output and patient assessment are essential to avoid the complication of hyponatremia and volume overload associated with instillation of large volumes of irrigating solution. Solutions used for urinary irrigation are electrolyte-free, thus hypo-osmotic and in general are glycine, sorbitol, and mannitol. During a TURP, the hypotonic solution can be absorbed into the prostatic veins with resultant volume overload and dilutional hyponatremia. The nurse is alert for signs of fluid overload such as dyspnea, decreasing O_2 saturation, jugular vein distention, development of S_3 gallop, hypertension or hypotension (with the development of congestive heart failure [CHF]), and arrhythmias. Early signs of dilutional hyponatremia are mental status changes, headache, nausea and vomiting, muscle twitching, and respiratory distress. The provider is notified of any change in patient condition. The rate of irrigant infusion is aimed at maintaining clear to pink-colored urine. When clots are present, the rate of infusion is increased to prevent clot retention. Since the draining irrigant and urine are both returning to the urinary drainage

bag, the nurse must keep an accurate record of amount of irrigant solution instilled and subtract the volume of the irrigant from the total drainage amount in the urinary drainage bag, which is recorded as urine. Thus, if 2 L were instilled over the past 4 hours and the urinary drainage bag contained 2,150 mL, the urine output for the past 4 hours is recorded as 150 mL.

Suprapubic Catheters

Suprapubic catheterization allows bladder drainage by inserting a catheter or tube into the bladder through a suprapubic (above the pubis) incision or puncture (Fig. 28-4). The catheter or suprapubic drainage tube is then threaded into the bladder and secured with sutures or tape, and the area around the catheter is covered with a sterile dressing. The catheter is connected to a sterile closed drainage system, and the tubing is secured to prevent tension on the catheter. This may be a temporary or permanent measure to divert the flow of urine from the urethra when the urethral route is impassable (because of injuries, strictures, prostatic obstruction), after gynecologic or other abdominal surgery when bladder dysfunction is likely to occur, and occasionally after pelvic fractures. Suprapubic bladder drainage may be maintained continuously for several weeks.

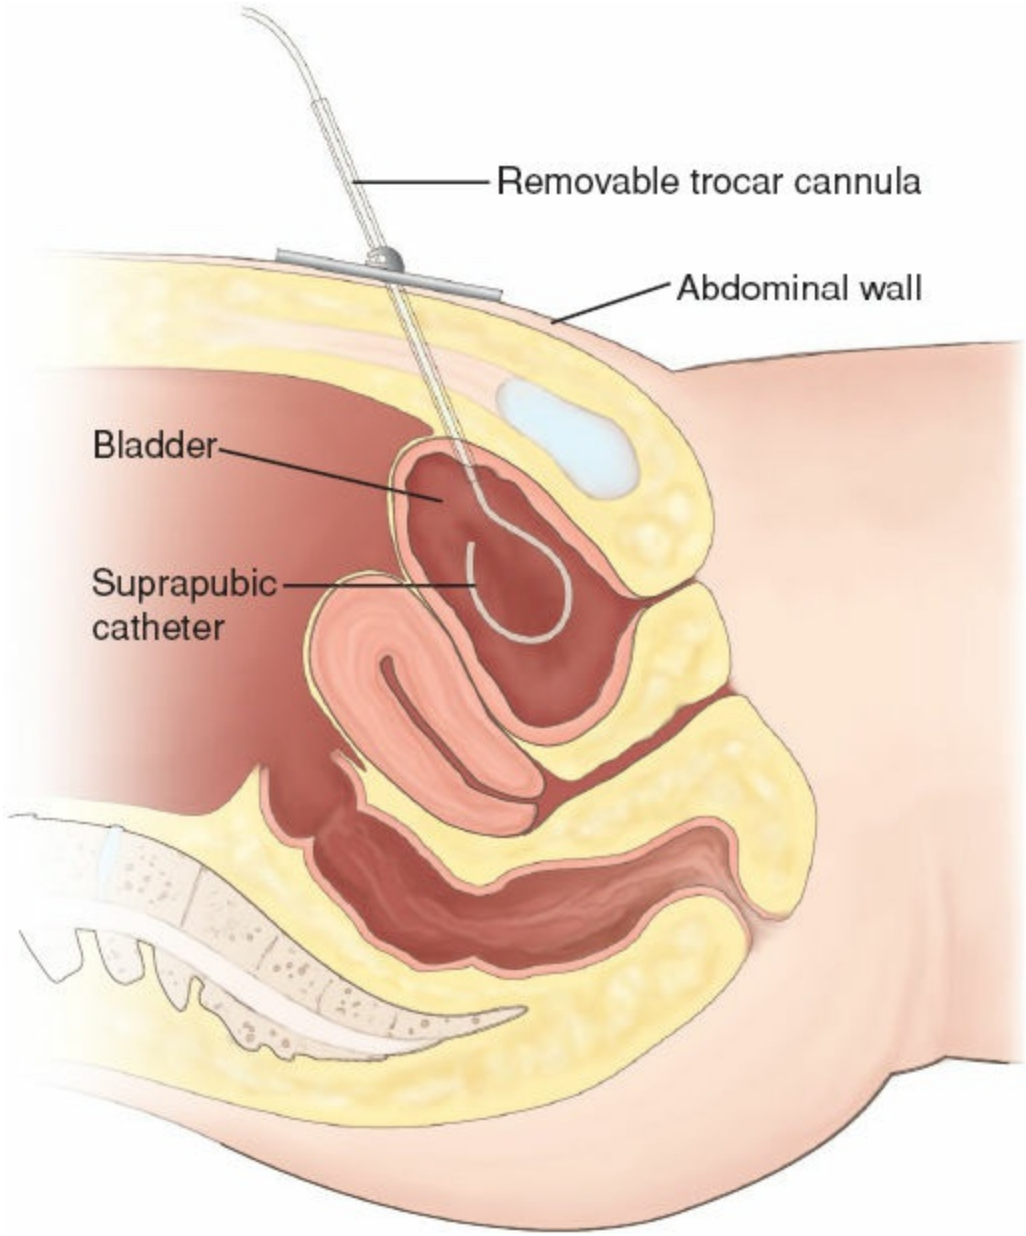

FIGURE 28-4 Suprapubic bladder drainage. A trocar cannula is used to puncture the abdominal and bladder walls. The catheter is threaded through the trocar cannula, which is then removed, leaving the catheter in place. The catheter is secured by tape or sutures to prevent unintentional removal.

Suprapubic drainage offers certain advantages. Patients can usually void sooner after surgery than can those with urethral catheters, and they may be more comfortable. The catheter allows greater mobility, permits measurement of residual urine without urethral instrumentation, and presents less risk of bladder infection. The suprapubic catheter is removed when it is no longer required, and a sterile dressing is placed over the site.

The patient requires liberal amounts of fluid to prevent encrustation around the catheter. Other potential problems include the formation of bladder stones, acute and chronic infections, and problems collecting urine. A wound care specialist/enterostomal therapist, also referred to as a wound-ostomy-continence nurse, may be consulted to assist the patient and family in selecting the most suitable urine collection system and to teach them about its use and care.

Nursing Management During Catheterization

Assessing the Patient and the System

For patients with indwelling catheters, the nurse assesses the drainage system to ensure that it provides adequate urinary drainage. The color, odor, and volume of urine are also monitored. An accurate record of fluid intake and urine output provides essential information about the adequacy of renal function and urinary drainage. The nurse observes the catheter to make sure that it is properly anchored, to prevent pressure on the urethra at the meatus in male patients, and to prevent tension and traction on the tubing in both male and female patients. Care is taken to ensure that the catheter position permits leg movement. In male patients, the drainage tube (not the catheter) is taped laterally to the thigh to prevent pressure on the urethra at the penoscrotal junction, which can eventually lead to formation of a urethrocutaneous fistula. In female patients, the drainage tubing attached to the catheter is taped to the thigh to prevent tension and traction on the bladder.

Patients at high risk for UTI from catheterization need to be identified and monitored carefully. These include women, older adults, and patients who are debilitated, malnourished, chronically ill, immunosuppressed, or have diabetes. The nurse observes these patients for signs and symptoms of UTI that have been discussed previously. The area around the urethral orifice is observed for drainage and excoriation.

The elderly patient with an indwelling catheter or patients with neurologic conditions (MS, stroke, spinal cord injury) may not exhibit the typical signs and symptoms of infection. Any subtle change in physical condition or mental status must be considered a possible indication of infection and promptly investigated because sepsis may occur before the infection is diagnosed. Figure 28-5 summarizes the sequence of events leading to infection and leakage of urine that often follow long-term use of an indwelling catheter in an elderly patient.

Preventing Infection

Certain principles of care are essential to prevent infection in patients with a closed urinary drainage system (Box 28-8). The catheter is a foreign body in the urethra and produces a reaction in the urethral mucosa with some urethral discharge.

Bacteriuria is considered inevitable in patients with indwelling catheters. Continual observation for fever, chills, and other signs and symptoms of systemic infection is necessary; these symptoms are generally treated aggressively.

Minimizing Trauma

Trauma to the urethra during catheterization can be minimized by:

- Using an appropriate-sized catheter
- Lubricating the catheter adequately with a water-soluble lubricant during insertion
- Inserting the catheter far enough into the bladder to prevent trauma to the urethral tissues when the retention balloon of the catheter is inflated

Manipulation of the catheter is the most common cause of trauma to the bladder

mucosa in the catheterized patient. Infection can occur when urine invades the damaged mucosa. Special care should be taken to ensure that any patient who is confused does not remove the catheter with the retention balloon still inflated, because this could cause bleeding and considerable injury to the urethra.

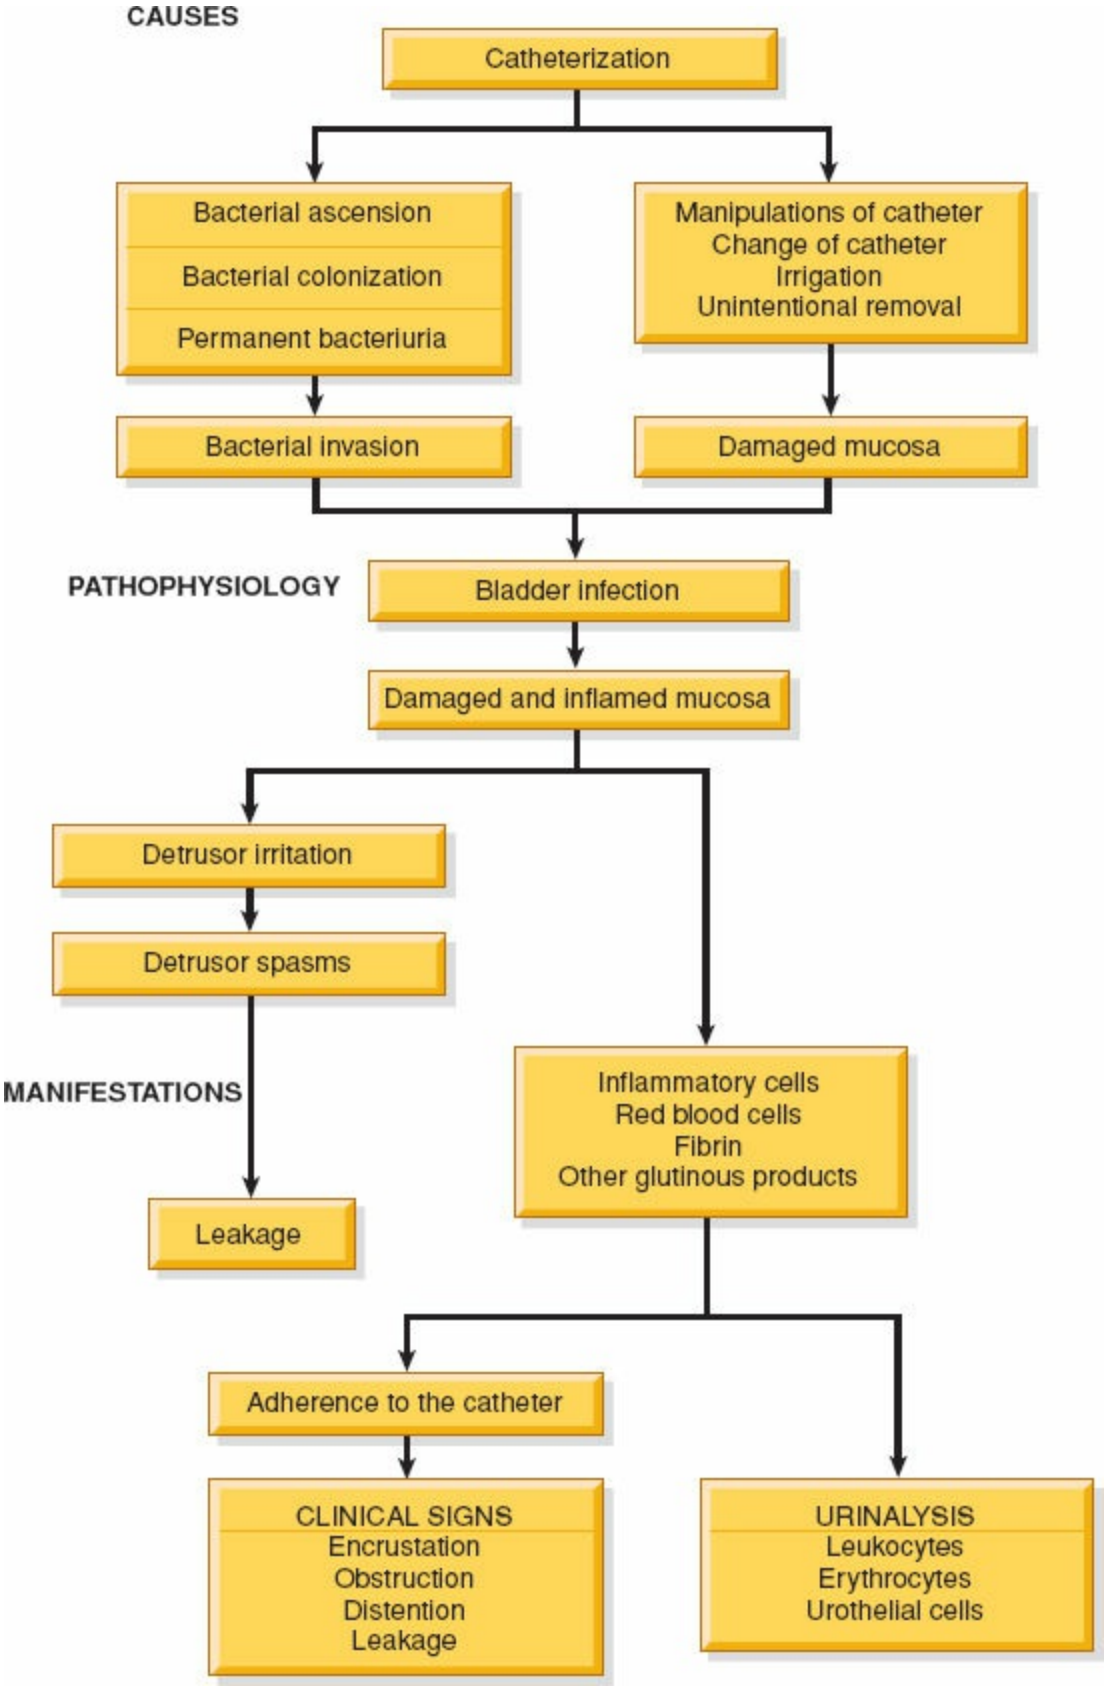

FIGURE 28-5 Pathophysiology and manifestations of bladder infection in long-term catheterized patients.

Retraining the Bladder

When an indwelling urinary catheter is in place, the detrusor muscle does not actively contract the bladder wall to stimulate emptying because urine is continuously draining from the bladder. The detrusor may not immediately respond to bladder filling when the catheter is removed, resulting in either urine retention or urinary incontinence. This condition, known as *postcatheterization detrusor instability*, can be managed with bladder retraining (Box 28-9).

Immediately after the indwelling catheter is removed, the patient is placed on a timed voiding schedule, usually every 2 to 3 hours. After voiding, the bladder is scanned using a portable ultrasonic bladder scanner. If 100 mL or more of urine remains in the bladder, straight catheterization may be performed for complete bladder emptying. After a few days, as the nerve endings in the bladder wall become aware of bladder filling and emptying, bladder function usually returns to normal. If the person has had an indwelling catheter in place for an extended period, bladder retraining will take longer.

BOX 28-8 Preventing Infection in the Catheterized Patient

- Use scrupulous aseptic technique during insertion of the catheter. Use a preassembled, sterile, closed urinary drainage system.
- To prevent contamination of the closed system, *never* disconnect the tubing. The drainage bag must *never* touch the floor. The bag and collecting tubing are changed if contamination occurs, if urine flow becomes obstructed, or if tubing junctions start to leak at the connections.
- If the collection bag *must* be raised above the level of the patient's bladder, clamp the drainage tube. This prevents backflow of contaminated urine into the patient's bladder from the bag.
- Ensure a free flow of urine to prevent infection. Improper drainage occurs when the tubing is kinked or twisted, allowing pools of urine to collect in the tubing loops.
- To reduce the risk of bacterial proliferation, empty the collection bag at least every 8 hours through the drainage spout—more frequently if there is a large volume of urine.
- Avoid contamination of the drainage spout. A receptacle in which to empty the bag is provided for each patient.
- Never irrigate the catheter routinely. If the patient is prone to obstruction from clots or large amounts of sediment, use a three-way system with continuous irrigation.
- Never disconnect the tubing to obtain urine samples, to irrigate the catheter, or to ambulate or transport the patient.
- Never leave the catheter in place longer than is necessary.
- Avoid routine catheter changes. The catheter is changed only to correct problems such as leakage, blockage, or encrustations.
- To remove obvious encrustations from the external catheter surface, the area can be washed gently with soap during the daily bath. Using silicone catheters results in

significantly less crust formation. A liberal fluid intake, within the limits of the patient's cardiac and renal reserve, and an increased urine output must be ensured to flush the catheter and to dilute urinary substances that might form encrustations.

- Avoid unnecessary handling or manipulation of the catheter by the patient or staff.
- Carry out hand hygiene before and after handling the catheter, tubing, or drainage bag.
- Wash the perineal area with soap and water at least twice a day; avoid a to-and-fro motion of the catheter. Vigorous cleansing of the meatus while the catheter is in place is discouraged because the cleansing action can move the catheter back and forth, increasing the risk of infection. Dry the area well, but avoid applying powder because it may irritate the perineum.
- Monitor the patient's voiding when the catheter is removed. The patient must void within 8 hours; if unable to void, the patient may require catheterization with a straight catheter.
- Urine cultures are obtained as prescribed or indicated when monitoring the patient for infection; many catheters have an aspiration (puncture) port from which a specimen can be obtained.

BOX 28-9 Bladder Retraining After Indwelling Catheterization

- Instruct the patient to drink a measured amount of fluid from 8 am to 10 pm to avoid bladder overdistention. Offer no fluids (except sips) after 10 pm.
- At specific times, ask the patient to void by applying pressure over the bladder, tapping the abdomen, or stretching the anal sphincter with a finger to trigger the bladder.
- Immediately after the voiding attempt, assess the postvoid residual (PVR) urine either using straight catheterization or an ultrasound bladder scanner. Residual urine of more than 100 mL is considered diagnostic of urinary retention.
- Measure the volumes of urine voided and obtained by catheterization if indicated.
- Palpate the bladder at repeated intervals to assess for distention. If there is suspicion of urinary retention, percuss the bladder (refer to Chapter 26).
- Instruct the patient who has no voiding sensation to be alert for any signs that indicate a full bladder, such as perspiration, cold hands or feet, or feelings of anxiety.
- Lengthen the intervals between catheterizations as the volume of residual urine decreases. Catheterization is usually discontinued when the volume of residual urine is less than 100 mL.

Assisting with Intermittent Self-Catheterization (ISC)

ISC provides periodic drainage of urine from the bladder. By promoting drainage and eliminating excessive residual urine, intermittent catheterization protects the kidneys, reduces the incidence of UTIs, and improves continence. It is the treatment of choice in patients with spinal cord injury and other neurologic disorders, such as MS, when the ability to empty the bladder is impaired. Self-catheterization promotes independence, results in few complications, and enhances self-esteem and quality of life.

When teaching the patient how to perform self-catheterization, the nurse must use aseptic technique to minimize the risk of cross-contamination. However, the patient may use a "clean" (nonsterile) technique at home, where the risk of cross-contamination is reduced. In teaching the patient, the nurse emphasizes the importance of frequent catheterization and emptying the bladder at the prescribed time. The average daytime clean intermittent catheterization schedule is every 4 to 6 hours and just before bedtime. If the patient is awakened at night with an urge to void, catheterization may be performed after an attempt is made to void normally. Refer to Box 28-10 for details regarding ISC teaching.

BOX 28-10 Patient Education

Intermittent Self-Catheterization[a]

Females:

- Assume a sitting position.
- Use a mirror to help locate the urinary meatus once, and then after that feel for the appropriate location.
- Insert the lubricated catheter 7.5 cm (3 in) into the urethra, in a downward and backward direction until urine begins to flow.
- After removal, discard the catheter.
- Consult a primary health care provider at regular intervals to assess urinary function and to detect complications.

Males:

- Assume a Fowler's or sitting position.
- Lubricate the catheter.
- Retract the foreskin of the penis (if necessary) with one hand.
- Grasp the penis and hold it at a right angle to the body. (This maneuver straightens the urethra and makes it easier to insert the catheter.)
- Insert the catheter 15–25 cm (6–10 in) until urine begins to flow.
- After removal, discard the catheter.
- Consult a primary health care provider at regular intervals to assess urinary function and to detect complications.

[a]If the patient cannot perform intermittent self-catheterization, a family member may be taught to carry out the procedure at regular intervals during the day.

Complications

The most common complication of neurogenic bladder is infection resulting from urinary stasis and catheterization. Long-term complications include urolithiasis (stones in the urinary tract), vesicoureteral reflux, and hydronephrosis, all of which can lead to destruction of the kidney.

UROLITHIASIS AND NEPHROLITHIASIS

Urolithiasis and nephrolithiasis refer to stones (calculi) in the urinary tract and kidney, respectively. Urinary stones are a common condition with almost 2 million outpatient visits for a primary diagnosis of urolithiasis recorded in 2000, and over 80% of these stones will contain calcium, usually as calcium oxalate (Preminger & Curhan, 2016). Additionally, the incidence of asymptomatic renal stones has been reported in approximately 10% of screened populations (Leavitt, de la Rosette, & Hoenig, 2016).

Pathophysiology

Stones are formed in the urinary tract when urinary concentrations of substances such as calcium oxalate, calcium phosphate, and uric acid increase. Referred to as *supersaturation*, this is dependent on the amount of the substance, ionic strength, and pH of the urine (an acid environment promotes calcium excretion). Stones may be found anywhere from the kidney to the bladder (Fig. 28-6) and may vary in size from minute granular deposits, called sand or gravel, to bladder stones as large as an orange.

Stone formation is not clearly understood, and there are a number of theories about their causes and links to systemic conditions such as obesity, hypertension and diabetes. Although it is not clear if stone disease is a direct cause of these disorders or if it is a consequence of the same conditions that lead to these disorders (Pearle et al., 2014, p. 316). Another theory relates to fluid volume status of the patient (stones tend to occur more often in dehydrated patients). Certain factors favor the formation of stones; however, in many patients, no cause may be found.

Risk Factors

Urinary stones occur predominantly in the third to fifth decades of life and affect men more than women (13% in men and 7% in women, annually), although an increased prevalence is observed across all age groups and in both sexes (Ferri, 2016). About half of patients with a single renal stone have another episode within 5 years. Anatomical structure of the upper and lower urinary tract may pose a risk as UTIs (struvite calculi) or stasis is associated with stone formation. Metabolic defects such as hyperparathyroidism and hyperuricemia (gout) are also associated with stone formation. Genetic predisposition, such as familial renal tubule acidosis, is strongly associated with nephrolithiasis. Spring and summer season are associated with a higher incidence of stone formation, most likely due to dehydration.

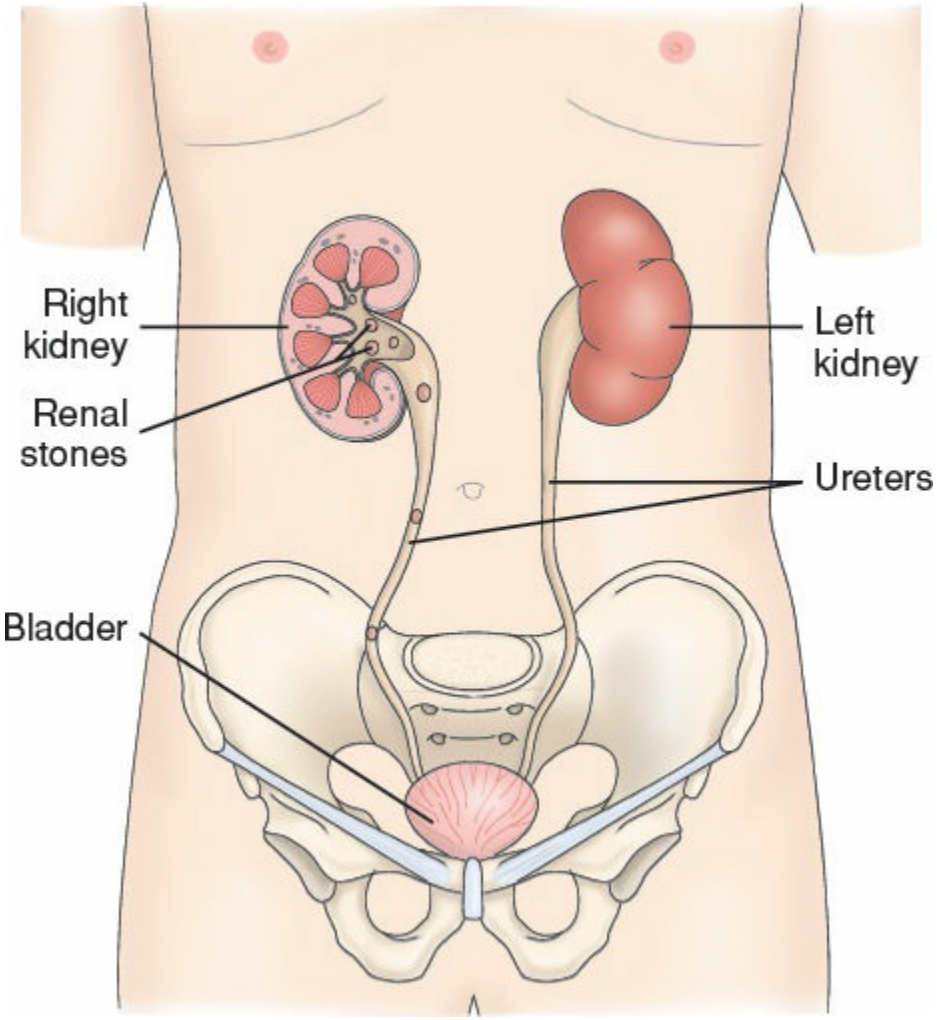

FIGURE 28-6 Examples of potential sites of calculi formation (urolithiasis) in the urinary tract.

Clinical Manifestations and Assessment

Signs and symptoms of stones in the urinary system depend on the presence of obstruction, infection, and edema. When stones block the flow of urine, obstruction develops, producing an increase in hydrostatic pressure and distending the renal pelvis and proximal ureter. Infection (pyelonephritis and UTI with chills, fever, and dysuria) can be a contributing factor with struvite stones (Pearle et al., 2014). Some stones cause few symptoms while slowly destroying the nephrons of the kidney; others cause excruciating pain and discomfort.

Stones in the renal pelvis may be associated with an intense, deep ache in the costovertebral region (see Fig. 26-7). Hematuria is often present; pyuria may also be noted. Pain originating in the renal area radiates anteriorly and downward toward the bladder in the female and toward the testis in the male. If the pain suddenly becomes acute, with tenderness over the costovertebral area, and nausea and vomiting appear, the patient is having an episode of renal colic. Diarrhea and abdominal discomfort may occur. Stones lodged in the ureter (ureteral obstruction) cause ureteral colic: acute, excruciating, colicky, wavelike pain, radiating down the thigh and to the genitalia. Often, the patient has a desire to void, but little urine is passed, and it usually contains blood because of the abrasive action of the stone. In general, the patient spontaneously passes stones 0.5 to 1 cm in diameter. Stones larger than 1 cm in diameter usually must be removed or fragmented so that they can be removed or passed spontaneously. Stones lodged in the bladder usually produce symptoms of irritation and may be associated with UTI and hematuria. If the stone obstructs the bladder neck, urinary retention occurs.

The diagnosis is confirmed by x-rays of the kidneys, ureters, and bladder (KUB) or by ultrasonography, IV urography, or retrograde pyelography. Blood chemistries and a 24-hour urine test for measurement of calcium, uric acid, creatinine, sodium, pH, and total volume are part of the diagnostic workup. Dietary and medication histories and family history of renal stones are obtained to identify factors predisposing the patient to the formation of stones.

When stones are recovered (stones may be freely passed by the patient or removed through special procedures), chemical analysis is carried out to determine their composition. Stone analysis can provide a clear indication of the underlying disorder (Table 28-2, p. 866).

Medical Management

The goals of management are to eradicate the stone, determine the stone type, prevent nephron destruction, control infection, and relieve any obstruction that may be present. The immediate objective of treatment of renal or ureteral colic is to relieve the pain until its cause can be eliminated. Opioid analgesics are administered; nonsteroidal anti-inflammatory drugs (NSAIDs) also have demonstrated efficacy in treating renal stone pain. In addition, NSAIDs also inhibit the synthesis of prostaglandin E, reducing swelling and facilitating passage of the stone. Hot baths or moist heat to the flank areas may also be useful. Fluids are encouraged to increase the hydrostatic pressure behind the stone, assisting it in its downward passage.

Nutritional Therapy

Nutritional therapy plays an important role in preventing renal stones (Pearle et al., 2014). Fluid intake is the mainstay of most medical therapy for renal stones. Unless fluids are contraindicated, patients with renal stones should drink eight to ten 8-oz glasses of water daily or have IV fluids prescribed to keep the urine dilute. A urine output exceeding 2 L a day is advisable.

Procedures for Treatment of Stone Disease

If the stone does not pass spontaneously or if complications occur, common interventions include endoscopic or other procedures—for example, ureteroscopy, extracorporeal shock wave lithotripsy (ESWL), or endourologic (percutaneous) stone removal (Fig. 28-7). Refer to discussion of surgical treatment in Table 28-3 on page 868.

Open surgical removal was the major mode of therapy before the advent of lithotripsy and improved endoscopic techniques. Today, open procedures are performed in only 1% to 2% of patients. Surgical intervention is indicated if the stone does not respond to other forms of treatment, and to correct anatomic abnormalities within the kidney to improve urinary drainage. If the stone is in the kidney, the surgery performed may be a nephrolithotomy (incision into the kidney with removal of the stone) or a nephrectomy, if the kidney is nonfunctional secondary to infection or hydronephrosis. Stones in the kidney pelvis are removed by a pyelolithotomy, those in the ureter by ureterolithotomy, and those in the bladder by cystotomy. If the stone is in the bladder, an instrument may be inserted through the urethra into the bladder, and the stone is crushed in the jaws of this instrument. Such a procedure is called a cystolitholapaxy. Nursing management following kidney surgery is discussed in Chapter 27.

TABLE 28-2 Comparison of Renal Stones

Stone Type	Causes	Treatment
Calcium (~75% of renal stones)	• Hypercalcemia (high serum calcium) and hypercalciuria (high urine calcium) • Hyperparathyroidism • Renal tubular acidosis • Cancers • Granulomatous diseases (e.g., sarcoidosis, tuberculosis), which may cause increased vitamin D production by the granulomatous tissue • Excessive intake of vitamin D • Excessive intake of milk and alkali • Myeloproliferative diseases (leukemia, polycythemia vera, multiple myeloma), which produce an unusual proliferation of blood cells from the bone marrow • Insufficient fluid intake	• If type II absorptive hypercalciuria (half of all patients with calcium stones), restricted calcium intake. • Liberal fluid intake encouraged. • Dietary restriction of protein and sodium. • Medications, such as ammonium chloride, may be used. • Thiazide diuretics may be beneficial in reducing calcium loss in the urine and lowering elevated parathormone levels.
Uric acid (~5–10% of stones) • Gout • Myeloproliferative disorders	• Low-purine diet • Foods high in purine (shellfish, anchovies, asparagus, mushrooms, and organ meats) are avoided. • Allopurinol may be prescribed to reduce serum uric acid levels and urinary uric acid excretion.	• Dietary management is key. • Sustained alkalization of urine with potassium citrate or sodium bicarbonate results in dissolution of existing stones. • Recommended urine output 30 mL/kg/24 hr.
Struvite (~15% of stones)	• Form in persistently alkaline, ammonia-rich urine caused by the presence of urease-splitting bacteria such as *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* or *Mycoplasma* species • Predisposing factors for struvite stones include neurogenic bladder, foreign bodies, and recurrent urinary tract infections (UTIs).	• Fluid intake is increased.
Cystine (1–2% of all stones)	• Occur exclusively in patients with a rare inherited defect in renal absorption of cystine (an amino acid)	• Low-protein diet. • Urine is alkalinized. • Fluid intake is increased.
All stone types	• Infection, urinary stasis, and periods of immobility, all of which slow renal drainage and alter calcium metabolism • Anatomic derangements such as polycystic kidney disease, horseshoe kidneys, chronic strictures, and medullary sponge disease; also inflammatory bowel disease and in ileostomy or bowel resection (patients absorb more oxalate).	• Cessation of medications that cause stones including antacids, acetazolamide, Amphotericin B, vitamin D, loop diuretics, theophylline and high doses of aspirin (Bose, Monk, & Bushinsky, 2016). • A sodium intake of 3–4 g/day is recommended. Table salt and high-sodium foods should be reduced, because sodium competes with calcium for reabsorption in the kidneys. • Avoid intake of oxalate-containing foods (e.g., spinach, strawberries, rhubarb, tea, peanuts, wheat bran). • Drink two glasses of water at bedtime and an additional glass at each nighttime awakening to prevent urine from becoming too concentrated during the night. • Avoid activities leading to sudden increases in environmental temperatures that may cause excessive sweating and dehydration. • Contact your primary health care provider at the first sign of a UTI.

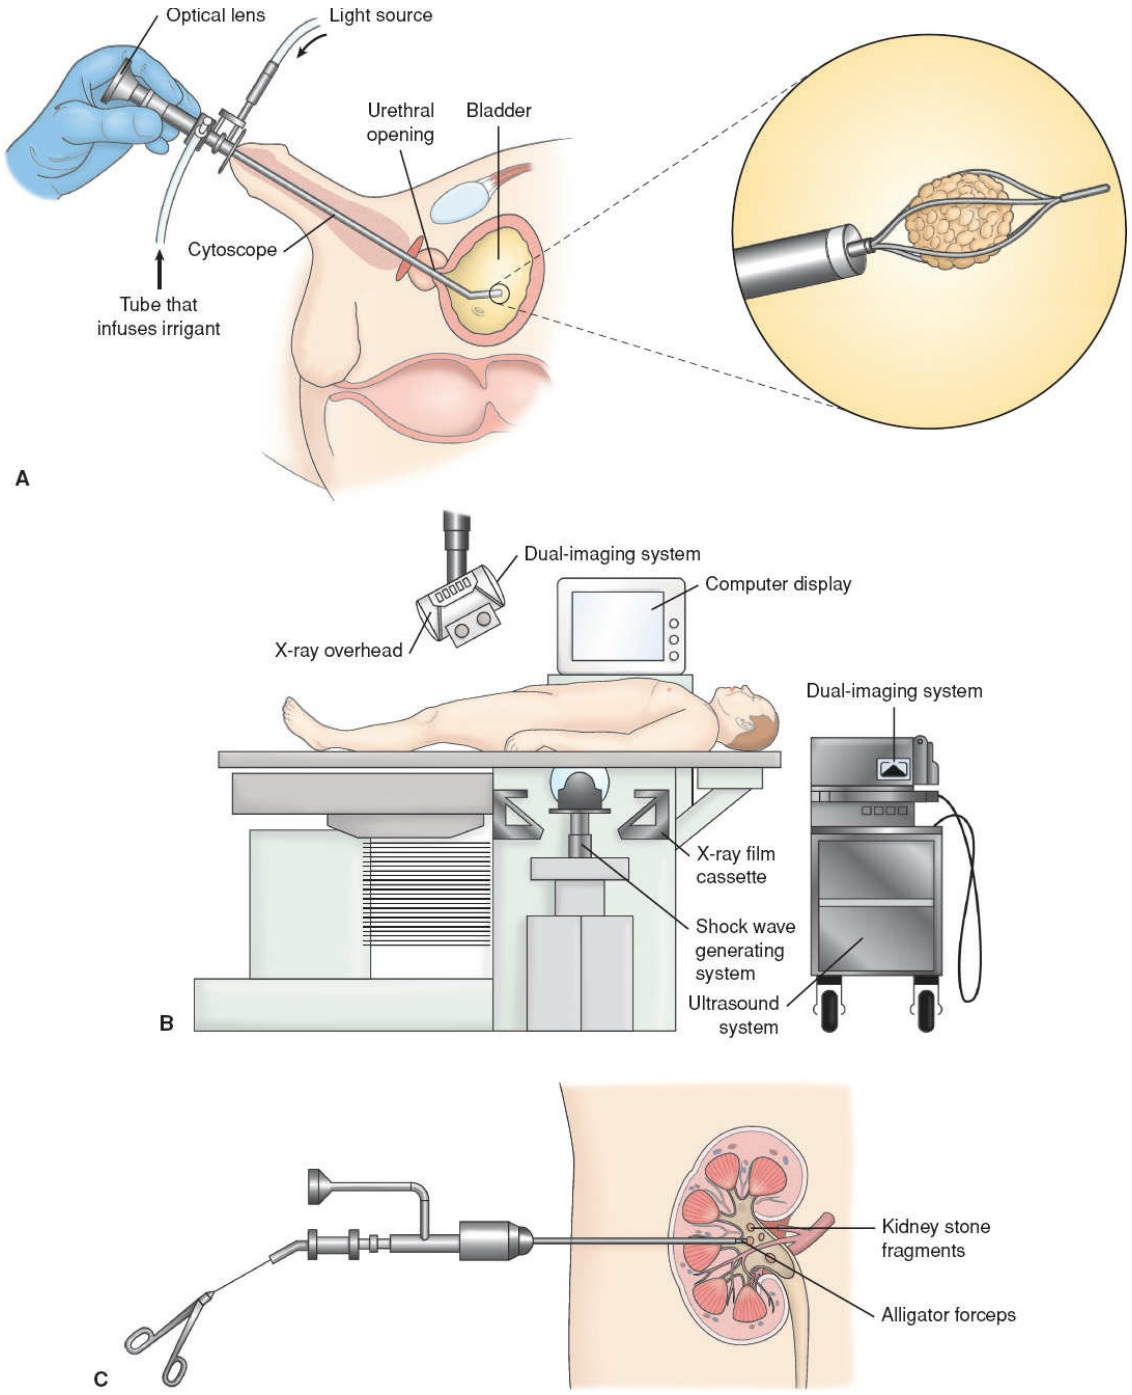

FIGURE 28-7 Methods of treating renal stones. A. During a cystoscopy, which is used for removing small stones located in the ureter close to the bladder, a ureteroscope is inserted into the ureter to visualize the stone. The stone is then fragmented or captured and removed. B. Extracorporeal shock wave lithotripsy (ESWL) may be used for symptomatic, nonpassable upper urinary tract stones. Electromagnetically generated shock waves are focused over the area of the renal stone. The high-energy dry shock waves pass through the skin and fragment the stone. C. Percutaneous nephrolithotomy is used to treat larger stones. A percutaneous tract is formed and a nephroscope is inserted through it. Then the stone is extracted or pulverized.

TABLE 28-3 Surgical Treatment of Renal Stones

Procedure	Description	Postprocedure Care
Ureteroscopy (see Fig. 28-7A)	Access to the stone is accomplished by inserting a ureteroscope into the ureter and then, depending on the size of the stone, either basketing or inserting a laser, electrohydraulic lithotripter, or ultrasound device through the ureteroscope to fragment and remove the stones. A stent may be inserted and left in place for 48 hours or more after the procedure to keep the ureter patent.	***For all procedures:*** • Increase fluid intake to assist in the passage of stone fragments. • Monitor for signs and symptoms that indicate complications, such as fever, decreasing urine output, and pain. ***For all procedures except electrohydraulic lithotripsy:*** • Expect hematuria (it is anticipated in all patients), but it should disappear within 4–5 days.
Extracorporeal shock wave lithotripsy (ESWL) (see Fig. 28-7B)	A high-energy amplitude of pressure, or shock wave, is generated by the abrupt release of energy and transmitted through water and soft tissues; noninvasive procedure used to break up stones in the calyx of the kidney. After the stones are fragmented to the size of grains of sand, the remnants of the stones are spontaneously voided. The patient is observed for obstruction and infection resulting from blockage of the urinary tract by stone fragments.	
Endourologic methods (see Fig. 28-7C) percutaneous nephrostomy; percutaneous nephrolithotomy	A nephroscope is introduced through a percutaneous route into the renal parenchyma. Depending on its size, the stone may be extracted with forceps or by a stone retrieval basket.	
Electrohydraulic lithotripsy	An electrical discharge is used to create a hydraulic shock wave to break up the stone. A probe is passed through the cystoscope, and the tip of the lithotripter is placed near the stone. After the stone is extracted, the percutaneous nephrostomy tube is left in place for a time to ensure that the ureter is not obstructed by edema or blood clots.	

NURSING PROCESS

The Patient with Kidney Stones

ASSESSMENT

The patient with suspected renal stones is assessed for pain and discomfort as well as associated symptoms, such as nausea, vomiting, diarrhea, and abdominal distention. The severity and location of pain are determined, along with any radiation of the pain. Nursing assessment also includes observing for signs and symptoms of UTI and obstruction. The urine is inspected for blood and is strained for stones or gravel. The history focuses on factors that predispose the patient to urinary tract stones or that may have precipitated the current episode of renal or ureteral colic. The patient's knowledge about renal stones and measures to prevent their occurrence or recurrence is also assessed.

DIAGNOSIS

Appropriate nursing diagnoses of the patient with kidney stones may include:

- Acute pain related to inflammation, obstruction, and abrasion of the urinary tract
- Deficient knowledge regarding prevention of recurrence of renal stones
- Deficient knowledge regarding the role of diet in the treatment of renal stones
- Impaired urinary elimination due to presence of renal stones

Potential complications may include the following:

- Infection and urosepsis (from UTI and pyelonephritis)
- Obstruction of the urinary tract by a stone or edema with subsequent acute kidney failure

PLANNING

The major goals for the patient may include relief of pain and discomfort, prevention of recurrence of renal stones, and absence of complications.

NURSING INTERVENTIONS

RELIEVING PAIN

Severe and acute pain is often the presenting symptom of a patient with renal and urinary calculi and requires immediate attention. Opioid analgesic agents (IV or intramuscular) may be prescribed and administered to provide rapid relief along with an IV NSAID. The patient is encouraged and assisted to assume a position of comfort. If activity brings pain relief, the patient is assisted to ambulate. The pain level is monitored closely, and an increase in severity is reported promptly so that relief can be provided and additional treatment initiated.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Increased fluid intake is encouraged to prevent dehydration and increase hydrostatic pressure within the urinary tract to promote passage of the stone. If the patient cannot take adequate fluids orally, IV fluids are prescribed. The total urine output and patterns of voiding are monitored. Ambulation is encouraged as a means of moving the stone through the urinary tract.

All urine is strained because uric acid stones may crumble. Any blood clots passed in the urine should be crushed and the sides of the urinal and bedpan inspected for clinging stones. Because renal stones increase the risk of infection, sepsis, and obstruction of the urinary tract, the patient is instructed to report decreased urine volume and bloody or cloudy urine.

Patients with calculi require frequent nursing observation to detect the spontaneous passage of a stone. The patient is instructed to immediately report any sudden increases in

pain intensity because of the possibility of a stone fragment obstructing a ureter. Vital signs, including temperature, are monitored closely to detect early signs of infection. UTIs may be associated with renal stones due to an obstruction from the stone or from the stone itself. All infections should be treated with the appropriate antibiotic agent before efforts are made to dissolve the stone.

Because the risk of recurring renal stones is high, the nurse provides education about the causes of kidney stones and recommendations to prevent their recurrence (see Table 28-2). The patient is encouraged to follow a regimen to avoid further stone formation, including maintaining a high fluid intake because stones form more readily in concentrated urine. A patient who has shown a tendency to form stones should drink enough fluid to excrete greater than 2,000 mL for the rest of his or her life.

CONTINUING CARE

The patient is monitored closely in follow-up care to ensure that treatment has been effective and that no complications, such as obstruction, infection, renal hematoma, or hypertension, have developed.

The patient's ability to monitor urinary pH and interpret the results is assessed during follow-up visits to the clinic or health care provider's office. Because of the high risk of recurrence, the patient with renal stones needs to understand the signs and symptoms of stone formation, obstruction, and infection, and the importance of reporting these signs promptly. If medications are prescribed for the prevention of stone formation, the actions and importance of the medications are explained to the patient.

EVALUATION

Expected patient outcomes may include:

1. Reports relief of pain
2. States increased knowledge of health-seeking behaviors to prevent recurrence:
   a. Consumes increased fluid intake (at least eight 8-oz glasses of fluid per day)
   b. Participates in appropriate activity
   c. Consumes diet prescribed to reduce dietary factors predisposing to stone formation
   d. Recognizes symptoms (fever, chills, flank pain, hematuria) to be reported to health care provider
   e. Monitors urinary pH as directed
   f. Takes prescribed medication as directed to reduce stone formation
3. Experiences no complications:
   a. Reports no signs or symptoms of infection or urosepsis
   b. Voids 200 to 400 mL per voiding of clear urine without evidence of bleeding
   c. Experiences absence of dysuria, frequency, and hesitancy
   d. Maintains normal body temperature

GENITOURINARY TRAUMA

Various types of injuries of the flank, back, or upper abdomen may result in trauma to the ureters, bladder, or urethra. Renal injury occurs in 8% to 10% of cases of blunt and penetrating trauma, of which approximately 90% result from blunt force and 10% from penetrating injuries (gunshot or stabbing) (Miller & Mirvis, 2015). Approximately 10% of all injuries seen in the emergency department involve the genitourinary system (Runyon, 2014).

Nursing Alert
If a patient is admitted with pelvic fractures, blunt trauma, with trauma related to motor vehicle accidents (MVAs), or with penetrating injuries, or has recently had urethral or bladder neck surgery, do not perform a urinary catheterization unless the provider has evaluated the patient for urethral tear.

Specific Injuries and Clinical Manifestations

Urethral Trauma

Urethral injuries usually occur with blunt trauma to the lower abdomen or pelvic region. Many patients also have associated pelvic fractures. Classic symptoms include blood at the urinary meatus (present in 80% to 90% of patients with urethral injury), penile, scrotal, or perineal, an inability to void, and a distended bladder. The nurse is aware that urinary catheterization is contraindicated if blood is noted at the urinary meatus, until urethral tear has been ruled out.

Ureteral Trauma

Penetrating trauma and unintentional injury during surgery are the major causes of trauma to the ureters. Gunshot wounds account for 95% of ureteral injuries, which may range from contusions to complete transection. Unintentional injury to the ureter may occur during gynecologic or urologic surgery. There are no specific signs or symptoms of ureteral injury; many traumatic injuries are discovered during exploratory surgery. If the ureteral trauma is not detected and urine leakage continues, fistulas can develop. IV urography detects 90% of ureteral injuries and can be performed on the operating table in patients undergoing emergent surgery. Surgical repair with placement of stents (to divert urine away from an anastomosis) is usually necessary.

Bladder Trauma

Injury to the bladder may occur with pelvic fractures and multiple traumas or from a blow to the lower abdomen when the bladder is full (lap belt or steering wheel injuries). Gross hematuria is present in more than 95% of patients with bladder rupture (Biffl, 2015). Blunt trauma may result in contusion, evident as an ecchymosis—a large, discolored bruise resulting from escape of blood into the tissues and involving a segment of the bladder wall —or in rupture of the bladder extraperitoneally, intraperitoneally, or both. Complications from these injuries include hemorrhage, shock, sepsis, and extravasation of blood into the tissues.

Medical Management

The goals of management in patients with genitourinary trauma are to control hemorrhage, pain, and infection and to maintain urinary drainage. Genitourinary trauma is frequently associated with renal trauma. Hematocrit and hemoglobin levels are monitored closely; decreasing values may indicate hemorrhage within the genitourinary system. The patient is also monitored for oliguria, signs of hemorrhagic shock, and signs and symptoms of acute peritonitis.

Surgical Management

Surgery is indicated for hemodynamic instability, ongoing bleeding, or urinary extravasation. However, minimally invasive techniques, such as angiographic embolization for hemorrhage and stenting for urinary extravasation, may allow renal salvage (Biffl, 2015, p. 589). In the case of urethral trauma, unstable patients who need monitoring of urine output may need a suprapubic catheter inserted. The patient is catheterized after urethrography is performed to minimize the risk of urethral disruption and extensive, long-term complications, such as stricture, incontinence, and impotence. Surgical repair may be performed immediately; delayed surgical repair tends to be the favored procedure because it is associated with fewer long-term complications. After surgery, an indwelling urinary catheter may remain in place for up to 1 month.

Nursing Management

The patient with genitourinary trauma should be assessed frequently during the first few days after injury to detect flank and abdominal pain, muscle spasm, and swelling over the flank.

During this time, patients can be instructed about care of the incision and the importance of an adequate fluid intake. In addition, instructions about changes that should be reported to the physician, such as fever, hematuria, flank pain, or any signs and symptoms of decreasing kidney function, are provided. The patient with a ruptured bladder may have gross bleeding for several days after repair. Guidelines for increasing activity gradually, lifting, and driving are also provided in accordance with the physician's prescription.

Follow-up nursing care includes monitoring the blood pressure to detect hypotension and advising the patient to restrict activities for about 1 month after trauma to minimize the incidence of delayed or secondary bleeding.

CANCER OF THE BLADDER

Urinary tract cancers include those of the urinary bladder, kidney and renal pelvis, ureters, and other urinary structures, such as the prostate. Approximately 380,300 cases of bladder cancer are diagnosed annually worldwide; in the United States it is the sixth most common cancer with an estimated 73,510 diagnoses and 13,750 deaths in 2012 (Smith, Balar, Milowsky, & Chen, 2013). Bladder cancer can span the spectrum from non–life-threatening, to invasive tumors that have metastasized at the time of diagnosis. The three types of bladder cancer are transitional cell carcinoma (TCCa) (93%), squamous cell carcinoma (6%), and adenocarcinoma (1%) (Ferri, 2016).

Risk Factors

Bladder cancer has a high worldwide incidence, and when combined with prostatic cancer, is the most common urologic malignancy, accounting for 90% of all tumors seen. Cancers arising from the prostate, colon, and rectum in males and from the lower gynecologic tract in females may metastasize to the bladder. Box 28-11 summarizes risk factors.

BOX 28-11 Risk Factors for Bladder Cancer

- Cigarette smoking: risk proportional to number of packs smoked daily and number of years of smoking (associated with 50% of bladder cancers in the United States)
- Exposure to environmental carcinogens: Dyes, rubber, leather, ink, paint, metals, and petroleum
- Recurrent or chronic bacterial infection of the urinary tract
- Bladder stones
- High urinary pH
- High cholesterol intake
- Pelvic radiation therapy
- Cancers arising from the prostate, colon, and rectum in males
- Diets rich in beef, pork, and animal fat increase risk of bladder cancer (Ferri, 2016)
- Age, incidence increases with age: higher after the age 60 years, uncommon younger than 40 years median age at diagnosis is 73–74 years (Ferri, 2016)

Clinical Manifestations and Assessment

Bladder tumors usually arise at the base of the bladder and involve the ureteral orifices and bladder neck. Painless gross hematuria is the most common symptom of bladder cancer. Infection of the urinary tract is a common complication, producing frequency, urgency, and dysuria. Any alteration in voiding or change in the urine may indicate cancer of the bladder. Pelvic or back pain may occur with metastasis.

The diagnostic evaluation includes cystoscopy (the mainstay of diagnosis), excretory urography, CT, ultrasonography, and bimanual examination with the patient anesthetized. Biopsies of the tumor and adjacent mucosa are the definitive diagnostic procedures. TCCAs and carcinomas in situ shed recognizable cancer cells. Cytologic examination of fresh urine and saline bladder washings provide information about the prognosis and staging, especially for patients at high risk for recurrence of primary bladder tumors (Ferri, 2016).

Although the current diagnostic tools such as cytology and CT have a high detection rate, they are costly. Newer diagnostic tools such as bladder tumor antigens, nuclear matrix proteins, adhesion molecules, cytoskeletal proteins, and growth factors are being studied to support the early detection and diagnosis of bladder cancer. For example, urine telomerase in voided urine or bladder washings determined by the telomeric repeat amplification protocol (TRAP) assay has been reported to accurately detect the presence of bladder tumors in men (Ferri, 2016). It may represent a useful noninvasive diagnostic innovation for bladder cancer detection in high-risk groups such as habitual smokers or in symptomatic patients (Ferri, 2016). To date, no universal screening test has been promoted.

Medical and Nursing Management

Treatment of bladder cancer depends on the grade of the tumor (the degree of cellular differentiation), the stage of tumor growth (the degree of local invasion and the presence or absence of metastasis), and the multicentricity (having many centers) of the tumor. Refer to Chapter 6 for further details on cancer. The patient's age and physical, mental, and emotional status are considered when discussing treatment modalities. Specific nursing care will be dictated by the treatment plan (e.g., relaying instructions with intravesical treatments).

Surgical Management

Transurethral resection or fulguration (cauterization) may be performed for simple papillomas (benign epithelial tumors). These procedures eradicate the tumors through surgical incision or electrical current with the use of instruments inserted through the urethra. After this surgery, intravesical administration of bacille Calmette-Guérin (BCG) may be appropriate. BCG is an attenuated live strain of *Mycobacterium bovis*, the causative agent for tuberculosis. The exact action of BCG is unknown, but it is has shown antitumor activity in multiple cancers, including urothelial carcinoma (Smith et al., 2013).

Management of superficial bladder cancers presents a challenge because there are usually widespread abnormalities in the bladder mucosa. The entire lining of the urinary tract, or urothelium, is at risk because carcinomatous changes can occur in the mucosa of the bladder, renal pelvis, ureter, and urethra. About 25% to 40% of superficial tumors recur after transurethral resection or fulguration. Patients with benign papillomas should undergo cytology and cystoscopy periodically for the rest of their lives.

A simple cystectomy or a radical cystectomy is performed for invasive or multifocal bladder cancer. Radical cystectomy in men involves removal of the bladder, prostate, and seminal vesicles and immediate adjacent perivesical tissues. In women, radical cystectomy involves removal of the bladder, lower ureter, uterus, fallopian tubes, ovaries, anterior vagina, and urethra. Removal of the bladder requires a urinary diversion procedure. Radical cystectomy remains the standard of care for invasive bladder cancer in the United States.

Pharmacologic Therapy

Chemotherapy with a combination of methotrexate, 5-fluorouracil, vinblastine, doxorubicin (Adriamycin), and cisplatin has been effective in producing partial remission of TCCa of the bladder in some patients. Topical chemotherapy (intravesical chemotherapy or instillation of antineoplastic agents into the bladder, resulting in contact of the agent with the bladder wall) is considered when there is a high risk of recurrence, when cancer in situ is present, or when tumor resection has been incomplete, and it delivers a high concentration of medication to the tumor to promote tumor destruction.

BCG is now considered the most effective intravesical agent for recurrent bladder cancer, especially superficial TCCa, because it is an immunotherapeutic agent that enhances the body's immune response to cancer. BCG is particularly effective in the treatment of carcinoma in situ, eradicating it in more than 80% of cases. Once the bladder is full, the patient must retain the intravesical solution for 2 hours before voiding. At the

end of the procedure, the patient is encouraged to void and to drink liberal amounts of fluid to flush the medication from the bladder.

Radiation Therapy

Radiation of the tumor may be performed preoperatively to reduce microextension of the neoplasm and viability of tumor cells, thus reducing the chances that the cancer may recur in the immediate area or spread through the circulatory or lymphatic systems. Radiation therapy is also used in combination with surgery or to control the disease in patients with inoperable tumors.

URINARY DIVERSIONS

Urinary diversion procedures are performed to divert urine from the bladder to a new exit site, usually through a surgically created opening (stoma) in the skin. These procedures are primarily performed when a bladder tumor necessitates cystectomy. Urinary diversion has also been used in managing pelvic malignancy, birth defects, strictures, trauma to the ureters and urethra, neurogenic bladder, chronic infection causing severe ureteral and renal damage, and intractable interstitial cystitis.

Controversy exists about the best method of establishing permanent diversion of the urinary tract. New techniques are frequently introduced in an effort to improve patient outcomes and quality of life. The age of the patient, condition of the bladder, body build, degree of obesity, degree of ureteral dilation, status of renal function, and the patient's learning ability and willingness to participate in postoperative care are all taken into consideration when determining the appropriate surgical procedure. Acceptance of a urinary diversion depends to a large degree on the location or position of the stoma, whether the drainage device (pouch or bag) establishes a watertight seal to the skin, and the patient's ability to manage the pouch and drainage apparatus.

There are two types of urinary diversion. In a cutaneous urinary diversion, urine drains through an opening created in the abdominal wall and skin (Fig. 28-8, p. 873). In a continent urinary diversion, a portion of the intestine is used to create a new reservoir for urine (Fig. 28-9, p. 874).

CUTANEOUS URINARY DIVERSIONS

ILEAL CONDUIT

The ileal conduit, or ileal loop, is the oldest and most common of the urinary diversion procedures in use, because of the low number of complications and surgeons' familiarity with the procedure. The urine is diverted by implanting the ureters into a 12-cm loop of ileum that is led out through the abdominal wall. This loop of ileum is a simple conduit (passageway) for urine from the ureters to the surface. The resected (cut) ends of the remaining intestine are anastomosed (connected) to provide an intact bowel. A loop of the sigmoid colon may also be used. An ileostomy bag is used to collect the urine.

Stents are placed in the ureters to prevent occlusion secondary to postsurgical edema. Bilateral ureteral stents allow urine to drain from the kidney to the stoma and provide a method for accurate measurement of urine output. They may be left in place 10 to 21 days postoperatively. Jackson–Pratt tubes or other types of drains are inserted to prevent the accumulation of fluid in the space created by removal of the bladder.

After surgery, a skin barrier and a transparent, disposable urinary drainage bag are applied around the conduit and connected to drainage. A custom-cut appliance is used until the edema subsides and the stoma shrinks to its final size. The clear bag allows the stoma to be inspected and the patency of the stent and the urine output to be monitored. The ileal bag drains urine (not feces) continuously. The appliance usually remains in place as long as it is watertight; it is changed when necessary to prevent leakage of urine.

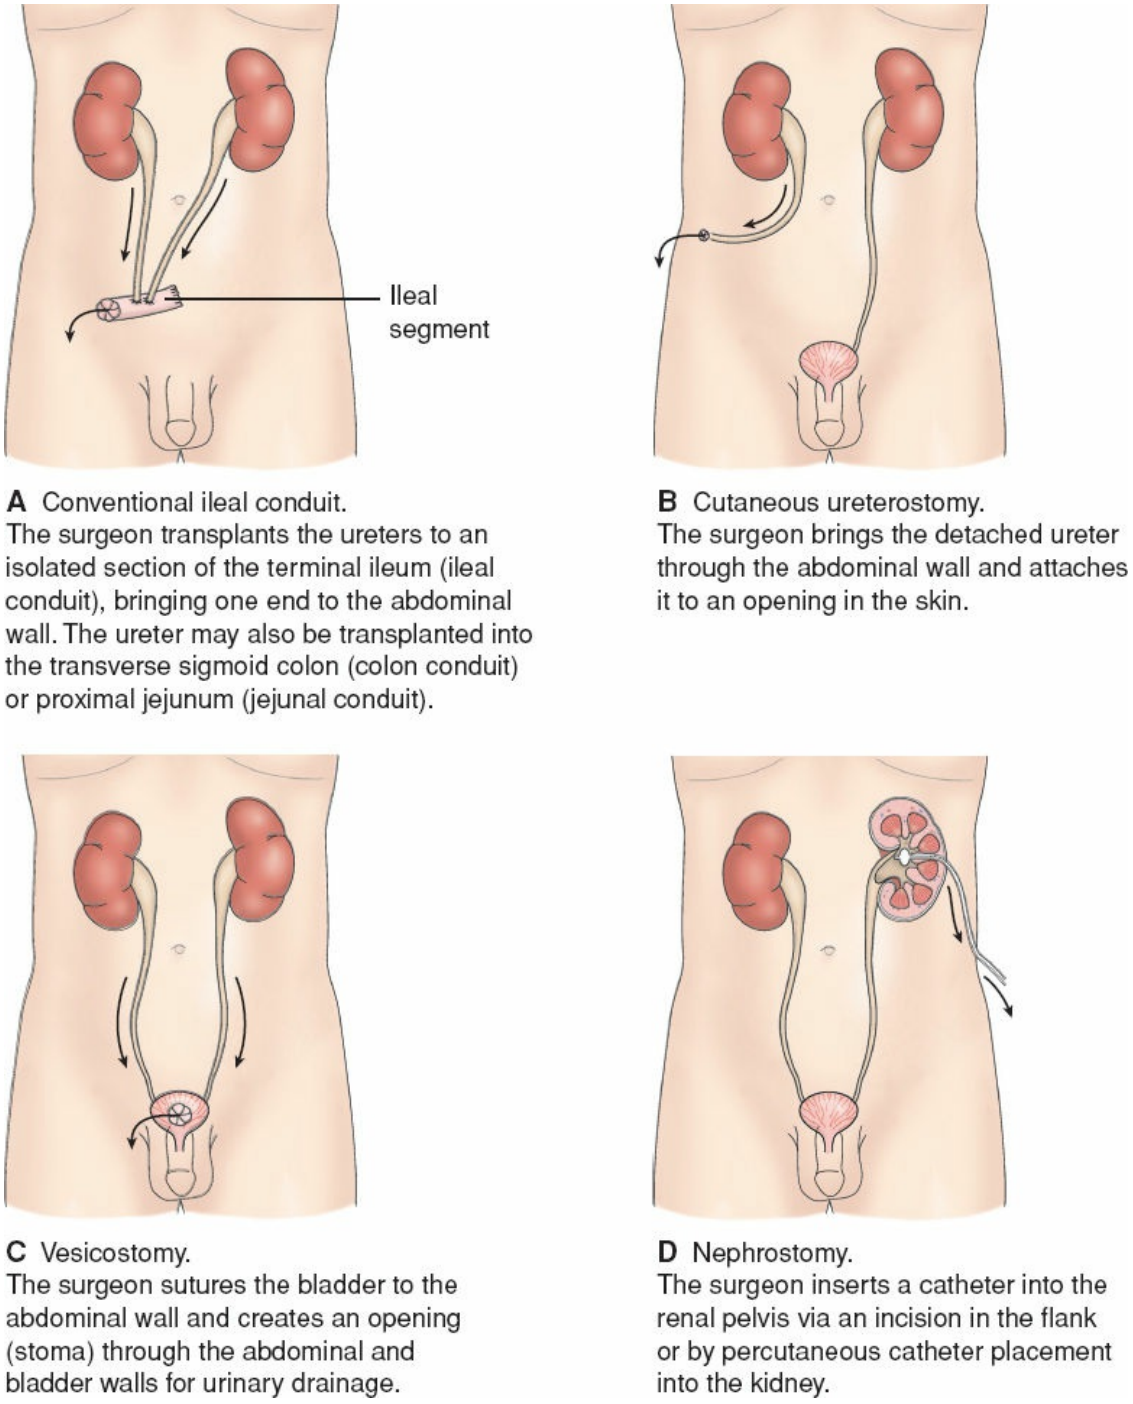
Nursing Alert
The stoma should be pink or red in color. If it appears dusky, the nurse suspects impaired perfusion and alert the surgeon.

Complications

Complications that may follow placement of an ileal conduit include wound infection or wound dehiscence, urinary leakage, ureteral obstruction, hyperchloremic acidosis, small-bowel obstruction, ileus, and gangrene of the stoma. Delayed complications include ureteral obstruction, contraction or narrowing of the stoma (stenosis), renal deterioration due to chronic reflux, pyelonephritis, and renal calculi. Approximately 10% of patients with ileal conduits will demonstrate hyperchloremic acidosis; it can occur both shortly after the procedure or as a longer-term consequence due to retention of urinary ammonium from the mucosa of the colon and loss of bicarbonate.

Stoma Ischemia and Necrosis

The stoma is monitored because ischemia and necrosis of the stoma can result from tension on the mesentery blood vessels, twisting of the bowel segment (conduit) during surgery, or arterial insufficiency. The new stoma must be inspected at least every 4 hours to assess the adequacy of its blood supply. The stoma should be red or pink. If the blood supply to the stoma is compromised, the color changes to purple, brown, or black. These changes are reported immediately to the surgeon. The surgeon or wound care specialist/enterostomal therapist may insert a small, lubricated tube into the stoma and shine a flashlight into the lumen of the tube to assess for superficial ischemia or necrosis. A necrotic stoma requires surgical intervention, but if the ischemia is superficial, the dusky stoma is observed and may slough its outer layer in several days.



A Conventional ileal conduit.
The surgeon transplants the ureters to an isolated section of the terminal ileum (ileal conduit), bringing one end to the abdominal wall. The ureter may also be transplanted into the transverse sigmoid colon (colon conduit) or proximal jejunum (jejunal conduit).

B Cutaneous ureterostomy.
The surgeon brings the detached ureter through the abdominal wall and attaches it to an opening in the skin.

C Vesicostomy.
The surgeon sutures the bladder to the abdominal wall and creates an opening (stoma) through the abdominal and bladder walls for urinary drainage.

D Nephrostomy.
The surgeon inserts a catheter into the renal pelvis via an incision in the flank or by percutaneous catheter placement into the kidney.

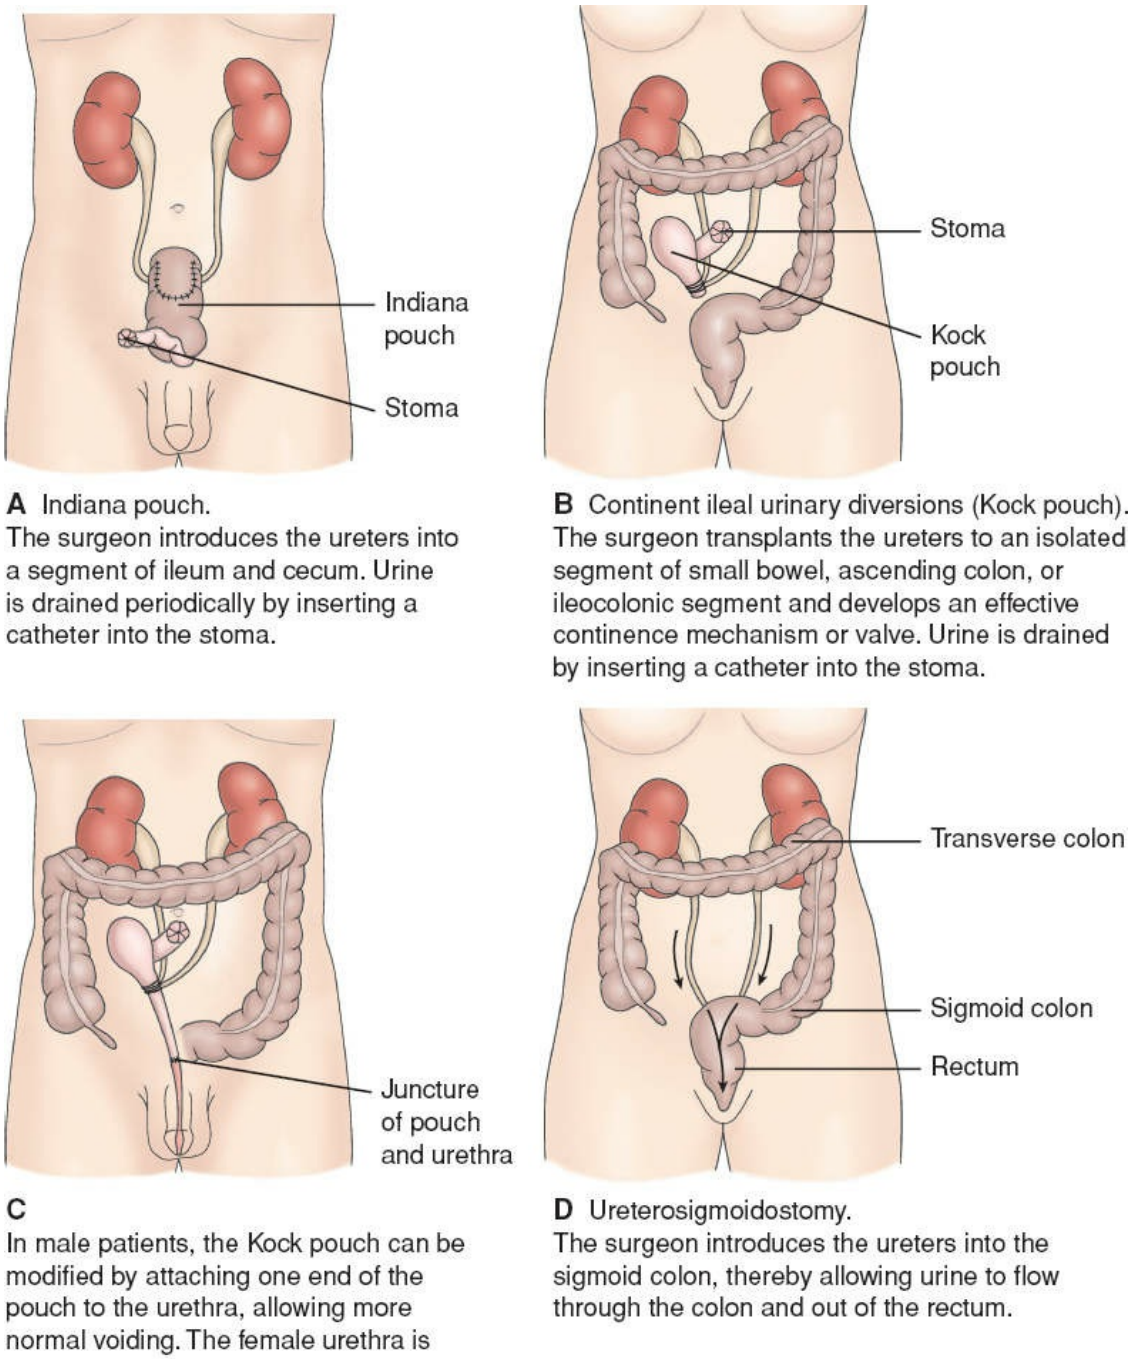
FIGURE 28-8 Types of cutaneous diversions include (A) the conventional ileal conduit, (B) cutaneous ureterostomy, (C) vesicostomy, and (D) nephrostomy.

Stoma Retraction and Separation

Stoma retraction and separation of the mucocutaneous border can occur as a result of trauma or tension on the internal bowel segment used for creation of the stoma. Mucocutaneous separation can occur if the stoma does not heal as a result of accumulation of urine on the stoma and mucocutaneous border. Using a collection drainage pouch with an antireflux valve is helpful because the valve prevents urine from pooling on the stoma and mucocutaneous border. Meticulous skin care to keep the area around the stoma clean and dry promotes healing. If a separation of the mucocutaneous border occurs, surgery is

not usually needed. The separated area is protected by applying karaya powder, stoma adhesive paste, and a properly fitted skin barrier and pouch. By protecting the separation, healing is promoted. If the stoma retracts into the peritoneum, surgical intervention is mandatory.

If surgery is needed to manage these complications, the nurse provides explanations to the patient and family. The need for additional surgery is usually perceived as a setback by the patient and family. Emotional support of the patient and family is provided along with physical preparation of the patient for surgery.



A Indiana pouch.
The surgeon introduces the ureters into a segment of ileum and cecum. Urine is drained periodically by inserting a catheter into the stoma.

B Continent ileal urinary diversions (Kock pouch).
The surgeon transplants the ureters to an isolated segment of small bowel, ascending colon, or ileocolonic segment and develops an effective continence mechanism or valve. Urine is drained by inserting a catheter into the stoma.

C
In male patients, the Kock pouch can be modified by attaching one end of the pouch to the urethra, allowing more normal voiding. The female urethra is too short for this modification.

D Ureterosigmoidostomy.
The surgeon introduces the ureters into the sigmoid colon, thereby allowing urine to flow through the colon and out of the rectum.

FIGURE 28-9 Types of continent urinary diversions include (A) the Indiana pouch, (B) and (C) the Kock pouch, also called a continent ileal diversion, and (D) a ureterosigmoidostomy.

Nursing Management

Teaching Patients Self-Care

A major postoperative objective is to assist the patient to achieve the highest level of independence and self-care possible. The nurse and wound care specialist/enterostomal therapist work closely with the patient and family to instruct and assist them in all phases of managing the ostomy. Adequate supplies and complete instruction are necessary to enable the patient and a family member to develop competence and confidence in their skills. Written and verbal instructions are provided, and the patient is encouraged to contact their provider with follow-up questions. Follow-up telephone calls from the nurse to the patient and family after discharge may provide added support and provide another opportunity to answer their questions. Follow-up visits and reinforcement of correct skin care and appliance management techniques also promote skin integrity. Specific techniques for managing the appliance are described in Box 28-12.

The patient is encouraged to participate in decisions regarding the type of collecting appliance and the time of day to change the appliance. The patient is assisted and encouraged to look at and touch the stoma early to overcome any fears. The patient and family need to know the characteristics of a normal stoma:

- Pink and moist, like the inside of the mouth
- Insensitive to pain because it has no nerve endings
- Vascular and may bleed when cleaned

Additionally, if a segment of the GI tract was used to create the urinary diversion, mucus may be visible in the urine. By learning what is normal, the patient and family become familiar with what signs and symptoms they should report to the health care provider or nurse and what problems they can handle themselves.

BOX 28-12 Patient Education

Using Urinary Diversion Collection Appliances

Applying a Reusable Pouch System

1. Gather all necessary supplies.
2. Prepare new appliance according to the manufacturer's directions: Apply double-faced adhesive disk that has been properly sized to fit the reusable pouch faceplate. Remove paper backing and set pouch aside, or apply thin layer of contact cement to one side of the reusable pouch faceplate. Set pouch aside.
3. Remove soiled pouch gently. Lay aside to clean later.
4. Clean peristomal skin (skin around stoma) with small amount of soap and water. Rinse thoroughly and dry. If a film of soap remains on the skin and the site does not dry, the appliance will not adhere adequately.
5. Inspect peristomal skin for irritation.

6. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry throughout the appliance change.
7. A skin protector wipe or barrier ring may be applied before centering the faceplate opening directly over the stoma.
8. Position appliance over stoma and press gently into place.
9. If desired, use a pouch cover or apply cornstarch under the pouch to prevent perspiration and skin irritation.
10. Clean soiled pouch and prepare for reuse.

Applying a Disposable Pouch System

1. Gather all necessary supplies.
2. Measure stoma and prepare an opening in the skin barrier about 1/8-in larger than the stoma and the same shape as the stoma.
3. Remove paper backing from skin barrier and set aside.
4. Gently remove old appliance and set aside.
5. Clean peristomal skin with warm water and dry thoroughly.
6. Inspect peristomal skin (skin around stoma) for irritation.
7. Use a wick (rolled gauze pad or tampon) over the stoma to absorb urine and keep the skin dry during the appliance change.
8. Center opening of skin barrier over stoma and apply with firm, gentle pressure to attain a watertight seal.
9. If using a two-piece system, snap pouch onto the flanged wafer that adheres to skin.
10. Close drainage tap or spout at bottom of pouch.
11. A pouch cover can be used or cornstarch applied under pouch to prevent perspiration and skin irritation.
12. Apply hypoallergenic tape around the skin barrier in a picture-frame manner.
13. Dispose of soiled appliance.

Information provided to the patient and the extent of involvement in self-care are determined by the patient's physical recovery and ability to accept and acquire the knowledge and skill needed for independence. The patient is given the opportunity to practice and demonstrate the knowledge and skills needed to manage urinary drainage.

Continuing Care

Follow-up care is essential to determine how the patient has adapted to the body image changes and lifestyle adjustments. Visits from a home care nurse are important to assess the patient's adaptation to the home setting and management of the ostomy. Teaching and reinforcement may assist the patient and family to cope with altered urinary function. It is also necessary to assess for long-term complications that may occur, such as pouch leakage or rupture, stone formation, stenosis of the stoma, deterioration in renal function, or incontinence.

Long-term monitoring for anemia is performed to identify vitamin B deficiency, which may occur when a significant portion of the terminal ileum is removed. This may take several years to develop and can be treated with vitamin B injections. The patient and family are informed of the United Ostomy Association and any local ostomy support groups to provide ongoing support, assistance, and education.

CUTANEOUS URETEROSTOMY

A cutaneous ureterostomy (see Fig. 28-8, p. 873), in which the ureters are directed through the abdominal wall and attached to an opening in the skin, is used for selected patients with ureteral obstruction (i.e., advanced pelvic cancer) because it requires less extensive surgery than other urinary diversion procedures. It is also an appropriate procedure for patients who have had previous abdominal irradiation.

A urinary appliance is fitted immediately after surgery. The management of the patient with a cutaneous ureterostomy is similar to the care of the patient with an ileal conduit, although the stomas are usually flush with the skin or retracted.

CONTINENT URINARY DIVERSIONS

CONTINENT ILEAL URINARY RESERVOIR (INDIANA POUCH)

The most common continent urinary diversion is the Indiana pouch, created for the patient whose bladder is removed or no longer functions. The Indiana pouch uses a segment of the ileum and cecum to form the reservoir for urine (see Fig. 28-9A, p. 874). The ureters are tunneled through the muscular bands of the intestinal pouch and anastomosed. The reservoir is made continent by narrowing the efferent portion of the ileum and sewing the terminal ileum to the subcutaneous tissue, forming a continent stoma flush with the skin. The pouch is sewn to the anterior abdominal wall around a cecostomy tube. Urine collects in the pouch until a catheter is inserted and the urine is drained (Skinner & Daneshmand, 2016).

The pouch must be drained at regular intervals by a catheter to prevent absorption of metabolic waste products from the urine, reflux of urine to the ureters, and UTI. Postoperative nursing care of the patient with a continent ileal urinary pouch is similar to nursing care of the patient with an ileal conduit. These patients usually have additional drainage tubes (cecostomy catheter from the pouch, stoma catheter exiting from the stoma, ureteral stents, Penrose drain, as well as a urethral catheter). All drainage tubes must be carefully monitored for patency and amount and type of drainage. In the immediate postoperative period, the cecostomy tube is irrigated two or three times daily to remove mucus and prevent blockage.

Other variations of continent urinary reservoirs include the Kock pouch (U-shaped pouch constructed of ileum, with a nipple-like one-way valve; see Fig. 28-9B,C) and the Charleston pouch (uses the ileum and ascending colon as the pouch, with the appendix and colon junction serving as the one-way valve mechanism).

URETEROSIGMOIDOSTOMY

Ureterosigmoidostomy, another form of continent urinary diversion, is an implantation of the ureters into the sigmoid colon (see Fig. 28-8D). It is usually performed in patients who have had extensive pelvic irradiation, previous small bowel resection, or coexisting small bowel disease.

After surgery, voiding occurs from the rectum (for life), and an adjustment in lifestyle will be necessary because of urinary frequency. Drainage has a consistency equivalent to watery diarrhea, and the patient has some degree of nocturia. Patients usually need to plan activities around the frequent need to urinate, which in turn may affect the patient's social life. However, this provides the advantage of urinary control without having to wear an external appliance.

CHAPTER REVIEW

Critical Thinking Exercises

1. As the head nurse in a long-term care facility, you are approached by the daughter of one of the residents. She requests that her mother, who can ambulate with assistance, undergo bladder retraining in order to increase her level of independence. What should your response be to this request? What is the evidence base that supports your response? Identify the criteria used to evaluate the strength of the evidence.

2. As one of the nurses in a busy urology practice, you are performing telephone triage. A 62-year-old man who underwent a ureteroscopy for stone disease 2 days ago complains of increasing urinary frequency, dysuria, and increasing abdominal pain. Explain the instructions you would provide. What medical and nursing interventions would you anticipate?

NCLEX-Style Review Questions

1. A sexually active, 23-year-old woman presents with a history of three UTIs in the past 12 months. What is the first step in her evaluation?
   a. A urine culture
   b. An intravenous pyelogram to look for an anatomic abnormality
   c. A history and physical examination
   d. A 3-day course of antibiotics
   e. A pregnancy test

2. A 55-year-old woman reports stress incontinence when sneezing and playing tennis. She asks what she can do to prevent this from happening. Which of the following is the nurse's best response?
   a. Start an anticholinergic medication.
   b. Void immediately prior to playing tennis to try and decrease urine loss while playing.
   c. Decrease overall fluid intake so this is unlikely to happen at any time.
   d. Restrict intake of calcium-containing foods.
   e. Choose more supportive undergarments.

3. Mrs. Andersen has an indwelling catheter after an open cholecystectomy. She develops cramping in the suprapubic area and urinary leakage. What is the nurse's first intervention?
   a. Make certain the catheter is not kinked
   b. Evaluate for incisional pain
   c. Explain that her symptoms are due to peristalsis
   d. Irrigate the urinary catheter to assess for blockage of flow
   e. Provide an antispasmodic medication

4. Traci, a 29-year-old married woman, frequently experiences a UTI after sexual intercourse. In addition to instruction regarding voiding after intercourse, her initial

management may include which of the following?

a. A recommendation for abstinence
b. Testing for anatomic abnormalities
c. A prescription for antibiotics to be used post-coitus
d. Boric acid suppositories
e. Wipe the vagina from back to front after voiding

5. When being instructed on methods for managing the mucus in their urinary diversion, patients should be reminded to do which of the following?

a. Increase fiber intake
b. Consume high levels of citrus fruits and juices
c. Increase consumption of cranberry juice
d. Avoid caffeine consumption
e. Increase intake of dairy products

Problems Related to Endocrine Function

A 70-year-old patient with type 1 diabetes is being seen in the endocrinology clinic because of a foot wound that will not heal. The patient states that his blood sugar levels have been ranging from 78 to 350 mg/dL and that he eats "sweets" at every meal. A culture of the wound was sent to the laboratory.

- What questions are pertinent to ask the patient regarding his fluctuating blood sugar levels?
- What teaching areas would you reinforce regarding wound healing in this patient?
- What would help the patient keep an accurate record of his blood sugar times and levels?

CHAPTER 29

Nursing Assessment: Endocrine Function

Gayge J. Maggio

Learning Objectives

After reading this chapter, you will be able to:

1. Identify the major endocrine glands of the body, their anatomic location, and the hormones they secrete.
2. Summarize the major action of the hormones secreted from each of the glands.
3. Describe the negative feedback mechanism and its importance in the regulation of biologic processes.
4. Summarize the role of the hypothalamus and the pituitary in regulation of hormone secretion from the thyroid and the adrenal glands.
5. Name the disorders produced by over- and under-secretion of hormones from the endocrine glands.
6. Describe components of a health history and physical examination of the endocrine system.
7. Identify the diagnostic tests used to assess altered function of the endocrine glands.

Understanding the function of the endocrine glands and the consequences of dysfunction enables the health care professional to anticipate physiologic changes. Symptoms of endocrine disorders usually manifest according to hormone over- or under-secretion. The assessment of the endocrine system is not as straightforward as the other systems because it is difficult to inspect and palpate these glands due to their anatomic location, and patients present with a wide variety of symptoms. The health care professional must understand the function of endocrine hormones and attentively assess a patient's symptoms and diagnostic findings to detect an endocrine disorder.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

Function and Regulation of Hormones

The endocrine system consists of groups of organs involved in regulating metabolism, tissue function, reproduction, growth, and development by synthesizing and releasing specific hormones. The hormones are chemical messengers that, when released, have specific "target" tissue, where the hormone binds and impacts the cells' functions and reactions (Fig. 29-1). The endocrine system maintains optimal internal functional cell integrity, thus its influence impacts almost every cell, organ, and function of the body. The endocrine glands include the pituitary, thyroid, parathyroids, adrenals, pancreatic islets, ovaries, and testes (Fig. 29-2). Endocrine glands secrete their hormones directly into the bloodstream, which differentiates them from exocrine glands, such as sweat glands, which secrete their products through ducts onto epithelial surfaces of the skin, or the salivary glands, which secrete directly into the digestive tract. The endocrine glands are composed of secretory cells arranged in minute clusters known as *acini.* No ducts are present, but the glands have a rich blood supply so the hormones they produce enter the bloodstream rapidly.

The hypothalamus is the link between the nervous system and the endocrine system. The hypothalamus controls the pituitary, which secretes hormones to influence the target glands through the action of the secreting hormones. Table 29-1 lists the major hormones, their target tissue, and some of their properties.

In the healthy physiologic state, hormone concentration in the bloodstream is maintained at a relatively constant level according to need, primarily through a negative feedback mechanism. In a negative feedback loop, when the hormone concentration increases, further production of that hormone is inhibited. When the hormone concentration decreases, the rate of production of that hormone increases. In addition, hormones are regulated by the central nervous system (CNS)—a sympathetic or parasympathetic response can stimulate or suppress hormone production.

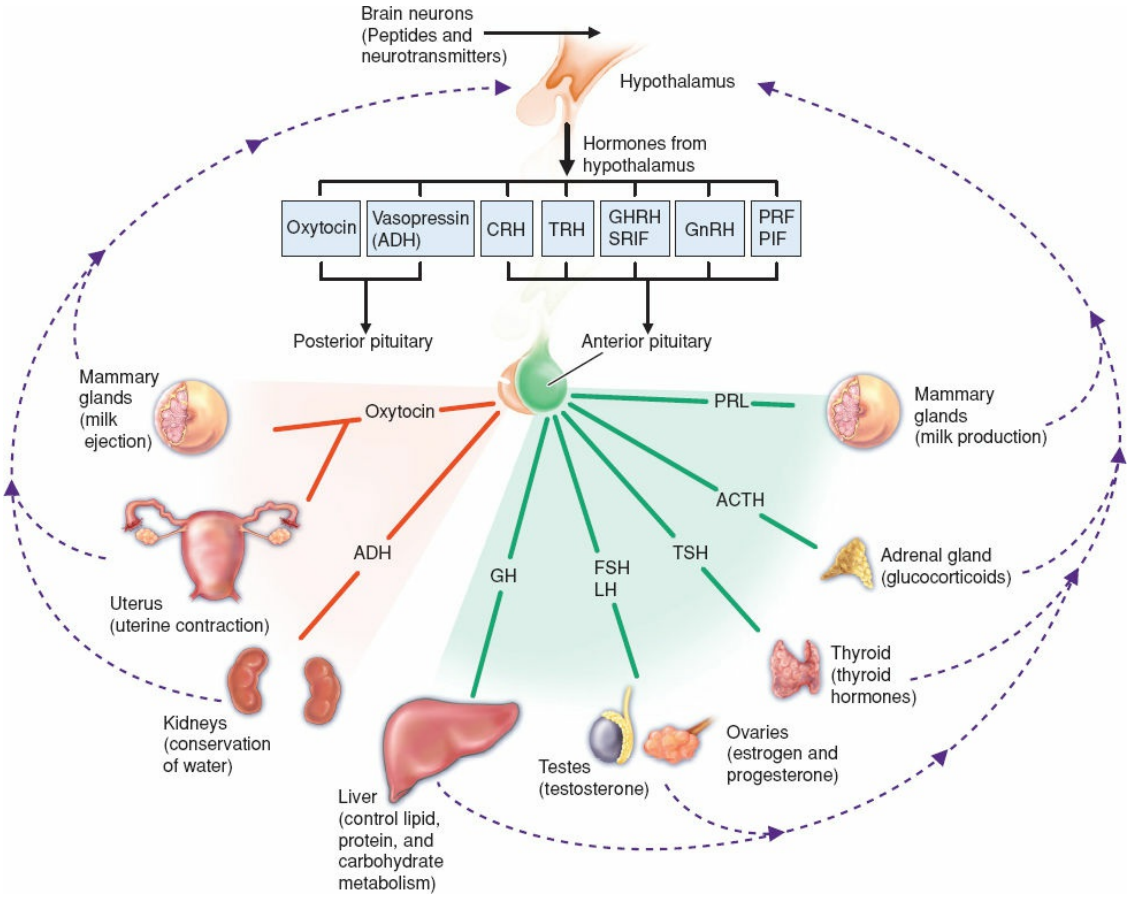

FIGURE 29-1 Hypothalamic and pituitary hormones and their target organs. The hypothalamus produces hormones that act on the anterior pituitary or are stored in the posterior pituitary. The anterior pituitary produces hormones that act on various body tissues and stimulate production of other hormones. T3, triiodothyronine; T4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

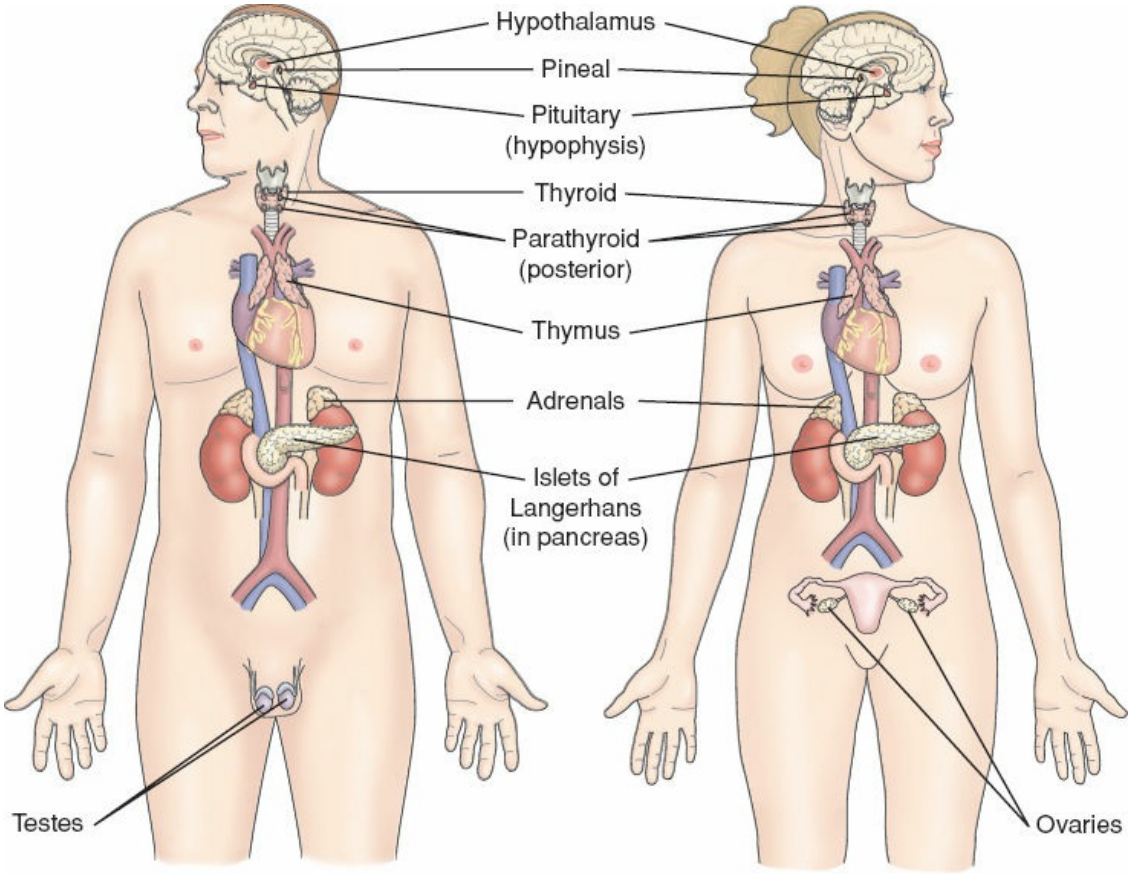

FIGURE 29-2 Major hormone-secreting glands of the endocrine system.

Glands of the Endocrine System

Pituitary Gland

Because the endocrine and nervous systems are so closely associated, they are collectively called the *neuroendocrine system*. The pituitary gland, or hypophysis, is a round structure about 1.27 cm (½ in) in diameter located on the inferior aspect of the brain. Commonly referred to as the *master gland*, the pituitary secretes hormones that control the secretion of additional hormones by other endocrine glands (Fig. 29-3). The pituitary itself is controlled by the hypothalamus, an adjacent area of the brain that is connected to the pituitary by the pituitary stalk. The pituitary gland is divided into the anterior and posterior lobes. The hypothalamus produces and releases factors that act on cells of the pituitary gland: GHRH, gonadotropin-releasing hormone (GnRH), thyrotrophic-releasing hormone (TRH), and corticotrophin-releasing hormone (CRH) act on the anterior pituitary, and oxytocin and vasopressin are produced here before traveling to the posterior pituitary.

Growth Hormone

Growth hormone–releasing hormone (GHRH) from the hypothalamus stimulates cells in the anterior lobe of the pituitary to secrete growth hormone (GH), also known as *somatotropin*. GH impacts all tissues, particularly bone and cartilage (Fig. 29-4). It increases the rate of protein synthesis, stimulating growth of all organs except the brain. It increases mobilization of fatty acids and decreases the rate of carbohydrate metabolism. In addition, it increases muscle mass and stimulates the immune system. GH is considered anti-insulin since it limits insulin's ability to uptake glucose in peripheral tissues and enhances glucose synthesis in the liver.

Anterior Pituitary Gland

The major hormones of the anterior pituitary gland are follicle-stimulating hormone (FSH), luteinizing hormone (LH), prolactin, adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and GH (also referred to as somatotropin). The releasing factors secreted by the hypothalamus, described above, control the secretion of these hormones. These releasing factors reach the anterior pituitary by way of the bloodstream in a special circulation called the *pituitary portal blood system*. Other hormones secreted by the anterior pituitary include melanocyte-stimulating hormone (MSH), which regulates skin pigmentation and beta-lipotropin; the function of lipotropin is poorly understood.

The hormones released by the anterior pituitary enter the general circulation and are transported to their target organs. The main function of FSH, LH, ACTH, and TSH is the release of hormones from other endocrine glands. Prolactin acts directly on the breast to stimulate milk production. Hormones that stimulate other organs and tissues are discussed in conjunction with their target organs later in this chapter.

Posterior Pituitary

Important hormones secreted by the posterior lobe of the pituitary gland (called the

neurohypophysis) include vasopressin, also termed *antidiuretic hormone* or *ADH*, and oxytocin. These hormones are synthesized in the hypothalamus and travel from the hypothalamus to the posterior pituitary gland via nerve tracts. Vasopressin (ADH) release will result in reabsorption of water into the bloodstream rather than excretion by the kidneys; its secretion is stimulated by an increase in blood osmolality (concentrated blood) or by a decrease in blood pressure as additional water is needed to return to the bloodstream. Oxytocin secretion is stimulated during pregnancy and at childbirth. It facilitates milk ejection during lactation and increases the force of uterine contractions during labor and delivery.

Thyroid Gland

TSH (also called *thyrotropin*) acts on the thyroid gland, a butterfly-shaped organ located in the lower neck, anterior to the trachea. It consists of two lateral lobes connected by an isthmus. The gland is about 5 cm long and 3 cm wide and weighs about 30 g. Blood flow to the thyroid is very high (about 5 mL/min per gram of thyroid tissue, approximately five times the blood flow to the liver), reflecting the high metabolic activity of the thyroid gland. The thyroid gland produces three hormones: thyroxine (T_4), triiodothyronine (T_3), and calcitonin. T_4 and T_3 are referred to collectively as *thyroid hormone.* Iodine is essential to the thyroid gland for synthesis of its hormones.

Thyroid Hormone

The primary function of thyroid hormone is to control cellular metabolic activity. T_4, a relatively weak hormone, maintains body metabolism in a steady state. T_3 is about five times as potent as T_4 and has a metabolic action that is more rapid. These hormones accelerate all bodily processes that contribute to oxygen consumption and altering the responsiveness of tissues to other hormones. The thyroid hormones influence cell replication, are important in brain development, and are necessary for normal growth. The thyroid hormones influence every major organ system through their widespread effects on cellular metabolism. The secretion of T_3 and T_4 by the thyroid gland is controlled by TSH from the anterior pituitary gland. TSH controls the rate of release of thyroid hormone. In turn, the level of thyroid hormone in the blood determines the release of TSH. If the concentration of thyroid hormone in the blood decreases, the release of TSH increases, which causes increased output of T_3 and T_4 (this is an example of negative feedback). The term euthyroid refers to thyroid hormone production that is within normal limits. Thyrotropin-releasing hormone (TRH) exerts a modulating influence on the release of TSH from the pituitary. Environmental factors, such as a decrease in temperature, may lead to increased secretion of TRH, resulting in elevated secretion of thyroid hormones. Figure 29-5 shows the hypothalamic–pituitary–thyroid axis, which regulates production of thyroid hormone.

TABLE 29-1 Major Action and Source of Selected Hormones

Source	Hormone	Major Action
Hypothalamus	Releasing and inhibiting hormones	Controls the release of pituitary hormones
	Corticotrophin-releasing hormone (CRH)	ACTH secretion stimulated by CRH
	Thyrotropin-releasing hormone (TRH)	Stimulates the release of TSH
	Growth hormone–releasing hormone (GHRH)	GH secretion stimulated by GHRH
	Gonadotropin-releasing hormone (GnRH)	Stimulates secretion of LH and FSH
	Somatostatin	Inhibits GH and TSH
	Dopamine	Inhibits secretion of prolactin
Anterior pituitary	Growth hormone (GH)	Stimulates growth of bone and muscle, promotes protein synthesis and fat metabolism, decreases carbohydrate metabolism
	Adrenocorticotropic hormone (ACTH)	Stimulates synthesis and secretion of adrenal cortical hormones
	Thyroid-stimulating hormone (TSH)	Stimulates synthesis and secretion of adrenal cortical hormones
	Follicle-stimulating hormone (FSH)	Stimulates synthesis and secretion of thyroid hormone Female: stimulates growth of ovarian follicle, ovulation Male: stimulates sperm production
	Luteinizing hormone (LH)	Female: stimulates development of corpus luteum, release of oocyte, production of estrogen and progesterone Male: stimulates secretion of testosterone, development of interstitial tissue of testes
	Prolactin	Prepares female breast for breast-feeding
Posterior pituitary	Antidiuretic hormone (ADH)	Increases water reabsorption by kidney
	Oxytocin	Stimulates contraction of pregnant uterus, milk ejection from breasts after childbirth
Adrenal cortex	Mineralocorticosteroids, mainly aldosterone	Increases sodium absorption, potassium loss by kidney
	Glucocorticoids, mainly cortisol	Affects metabolism of all nutrients; regulates blood glucose levels, affects growth, has anti-inflammatory action, and decreases effects of stress
	Adrenal androgens, mainly dehydroepiandrosterone (DHEA) and androstenedione	Have minimal intrinsic androgenic activity; they are converted to testosterone and dihydrotestosterone in the periphery
Adrenal medulla	Epinephrine Norepinephrine	Serve as neurotransmitters for the sympathetic nervous system; the flight or fight response specifically increases heart rate, blood flow to skeletal muscle and production of glucose
Thyroid (follicular cells)	Thyroid hormones: triiodothyronine (T_3), thyroxine (T_4)	Increase the metabolic rate; increase protein and bone turnover; increase responsiveness to catecholamines; necessary for fetal and infant growth and development
Thyroid C cells	Calcitonin	Lowers blood calcium and phosphate levels
Parathyroid glands	Parathormone (PTH, parathyroid hormone)	Regulates serum calcium
Pancreatic islet cells	Insulin	Lowers blood glucose by facilitating glucose transport across cell membranes of muscle, liver, and adipose tissue
	Glucagon	Increases blood glucose concentration by stimulation of glycogenolysis and glyconeogenesis
	Somatostatin	Delays intestinal absorption of glucose
Kidney	1,25-Dihydroxyvitamin D	Stimulates calcium absorption from the intestine
	Renin	Activates renin–angiotensin–aldosterone system
	Erythropoietin	Increases red blood cell production
Ovaries	Estrogen	Affects development of female sex organs and secondary sex characteristics
	Progesterone	Influences menstrual cycle; stimulates growth of uterine wall; maintains pregnancy
Testes	Androgens, mainly testosterone	Affect development of male sex organs and secondary sex characteristics; aid in sperm production

Grossman, S., & Porth, C. M. (2014). *Pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

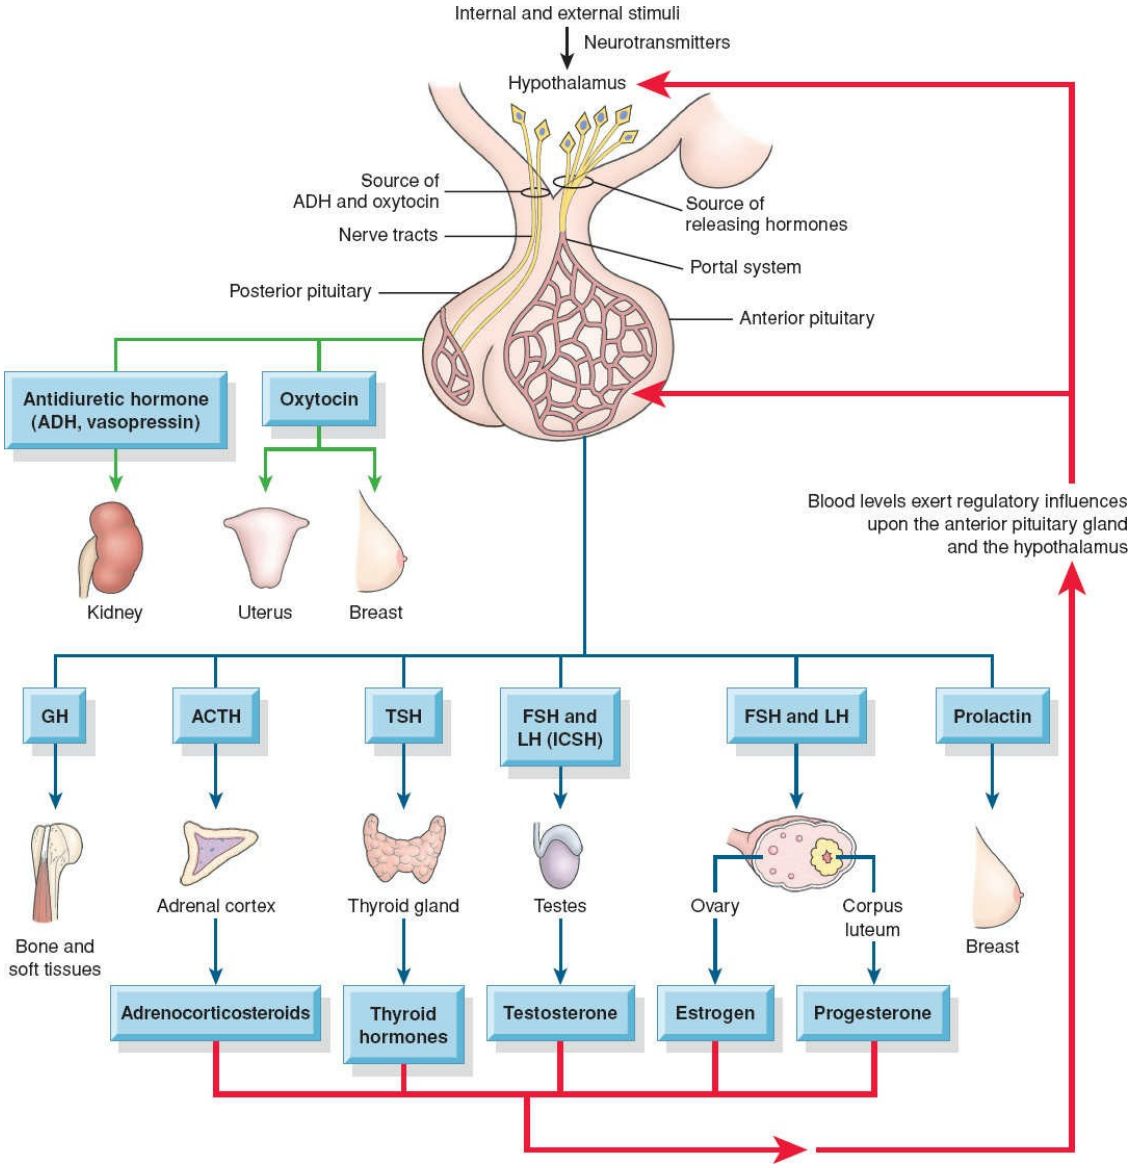

FIGURE 29-3 The pituitary gland, the relationship of the brain to pituitary action, and the hormones secreted by the anterior and posterior pituitary lobes.

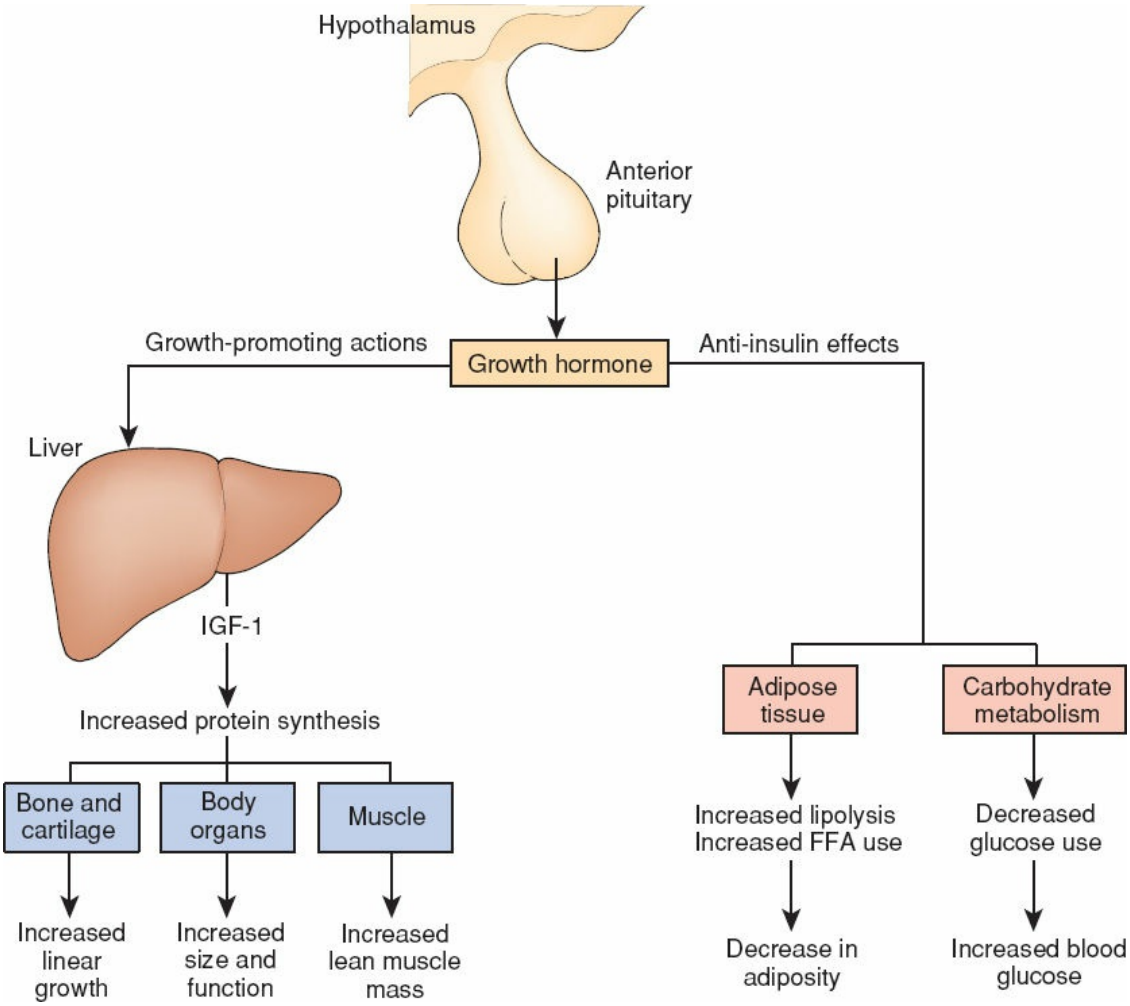

FIGURE 29-4 Feedback mechanism for growth stimulation. Regulation of growth hormone by growth hormone–releasing hormone (GHRH) promotes growth through the action of insulin-like growth factor 1 (IGF-1). Increases in IGF-1 trigger an increase in somatostatin to inhibit growth. Dysregulation can result in gigantism or acromegaly. (Reprinted with permission from Felner, E. I., & Umpierrez, G. E. (2014). *Endocrine pathophysiology*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Parathyroid Glands

The parathyroid glands (normally four in number) are situated in the neck and embedded in the posterior aspect of the thyroid gland (Fig. 29-6). Parathormone (parathyroid hormone), the protein hormone produced by the parathyroid glands, regulates metabolism of calcium and phosphorus. Increased secretion of parathormone results in osteoclast growth and bone resorption. When bone resorption is increased, calcium is released from the bone into the blood, thereby increasing the serum or blood calcium level. Some actions of this hormone are increased by the presence of vitamin D. Parathormone also tends to lower the level of phosphorus in the blood. The serum level of ionized calcium regulates the output of parathormone. Increased serum calcium results in decreased parathormone secretion, another example of a negative feedback system (Fig. 29-7).

Calcitonin

Calcitonin is secreted in response to high plasma levels of calcium, and it reduces the plasma level of calcium by increasing its deposition in bone.

Adrenal Glands

There are two adrenal glands, one attached to the upper portion of each kidney. CRH from the hypothalamus stimulates the pituitary gland to secrete ACTH, which, in turn, stimulates the adrenal cortex to secrete the adrenal hormones (glucocorticoids, mineralocorticoids, and androgens). Increased levels of the adrenal hormones then inhibit the production or secretion of CRH and ACTH. Each adrenal gland is, in reality, two endocrine glands with independent functions. The adrenal medulla at the center of the gland secretes catecholamines, and the outer portion of the gland, the adrenal cortex, secretes glucocorticoids, mineralocorticoids, and sex hormones (Fig. 29-8). The hypothalamic–pituitary–adrenal axis regulates secretion of hormones from the adrenal glands.

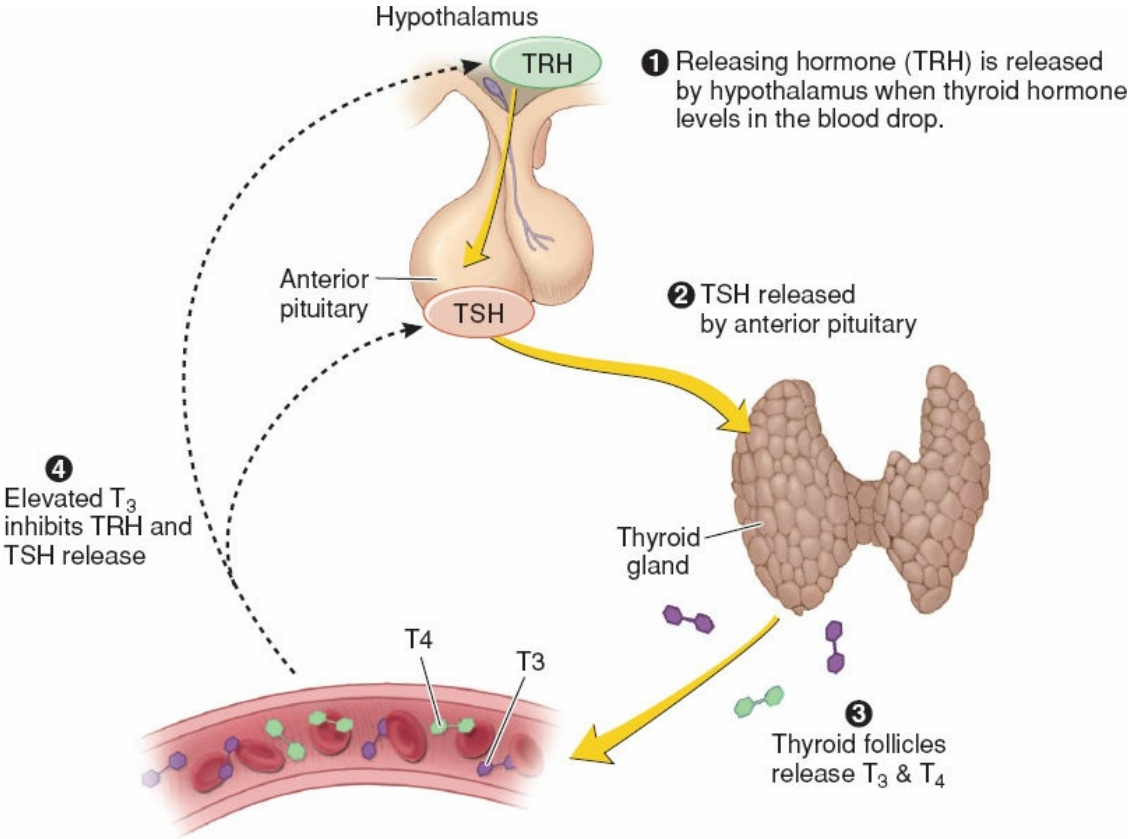

FIGURE 29-5 Thyroid hormone regulation. (1). TRH is secreted by the hypothalamus when thyroid hormone levels in the blood decline. (2). TSH is released by the anterior lobe of the pituitary gland. (3). In response to TSH, the thyroid gland releases thyroid hormones into the bloodstream. Elevated thyroid hormone levels provide the negative feedback signal to the hypothalamus, causing TRH to be reduced. (Reprinted with permission from Wingerd, B. (2014). *The human body*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Adrenal Medulla

The adrenal medulla functions as part of the autonomic nervous system. Stimulation of preganglionic sympathetic nerve fibers, which travel directly to the cells of the adrenal medulla, causes release of the catecholamine hormones epinephrine and norepinephrine. About 90% of the secretion of the human adrenal medulla is epinephrine (also called *adrenaline*). The major effect of epinephrine release is to prepare to meet a challenge (fight-

or-flight response). This causes decreased blood flow to tissues that are not needed in emergency situations, such as the gastrointestinal (GI) tract, and increased blood flow to tissues that are important for effective fight or flight, such as cardiac and skeletal muscle. Catecholamines regulate metabolic pathways to promote catabolism of stored fuels to meet caloric needs from endogenous sources, induce the release of free fatty acids, increase the basal metabolic rate, and elevate the level of blood glucose.

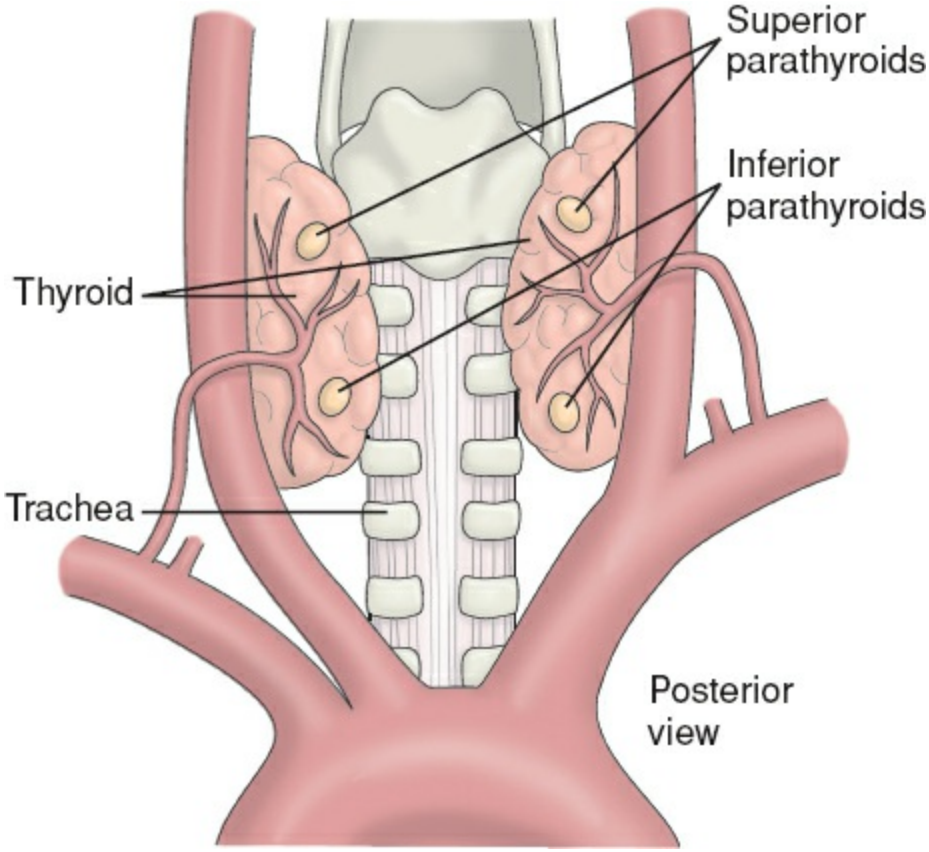

FIGURE 29-6 The parathyroid glands are located behind the thyroid gland. The parathyroids may be embedded in the thyroid tissue.

Adrenal Cortex

A functioning adrenal cortex is necessary for life; adrenocortical secretions make it possible for the body to adapt to stress of all kinds. The adrenal cortex secretes three types of steroid hormones produced by the adrenal cortex: glucocorticoids, the prototype of which is hydrocortisone; mineralocorticoids, mainly aldosterone (important in NA^+/K^+ regulation); and sex hormones, mainly androgens (male sex hormones).

Glucocorticoids. The adrenal cortex secretes glucocorticoids in response to the release of ACTH from the anterior lobe of the pituitary gland. Glucocorticoids have major effects on the metabolism of almost all organs because of their influence on glucose metabolism (elevation of blood glucose levels) as well as their ability to inhibit the inflammatory response to tissue injury and suppress allergic manifestations. Without the adrenal cortex, severe stress would cause peripheral circulatory failure, circulatory shock, and prostration. Survival in the absence of a functioning adrenal cortex is possible only with replacement of

nutritional components, electrolytes, fluids, and appropriate exogenous adrenocortical hormone.

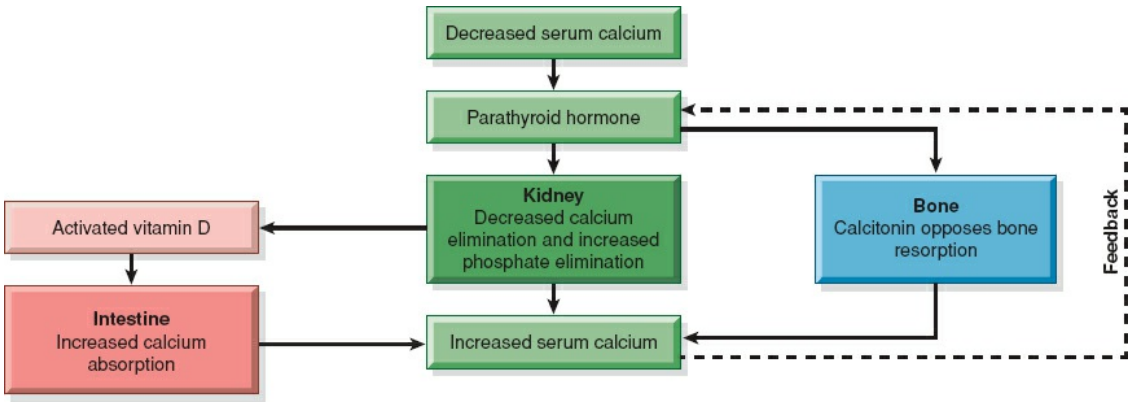

FIGURE 29-7 As extracellular calcium decreases, the parathyroid gland increases secretion of its hormone, P.T.H., which acts on bone tissue to release calcium into the blood. It also acts on the kidneys and intestines to increase the reabsorption of calcium. Calcitonin, which is produced and secreted by the thyroid gland, decreases serum calcium levels by opposing bone resorption. A low calcium level is called hypocalcemia. A high calcium level is called hypercalcemia.

Mineralocorticoids. Mineralocorticoids exert their major effects on electrolyte metabolism. Aldosterone is the primary mineralocorticoid and is the primary hormone for the long-term regulation of sodium balance. It influences fluid balance through the renin–angiotensin–aldosterone system. When sensing decreased perfusion pressure in the body, renin is released from the kidney into the bloodstream. The renin cascade results in an increase in angiotensin II, which stimulates the release of aldosterone and elevates the blood pressure by constricting arterioles. Increased aldosterone levels act principally on the renal tubule to cause increased absorption of sodium ions in exchange for excretion of potassium or hydrogen ions. This tends to restore blood pressure to normal and increases renal excretion of potassium. Therefore, the release of aldosterone also can be increased in the presence of hyperkalemia.

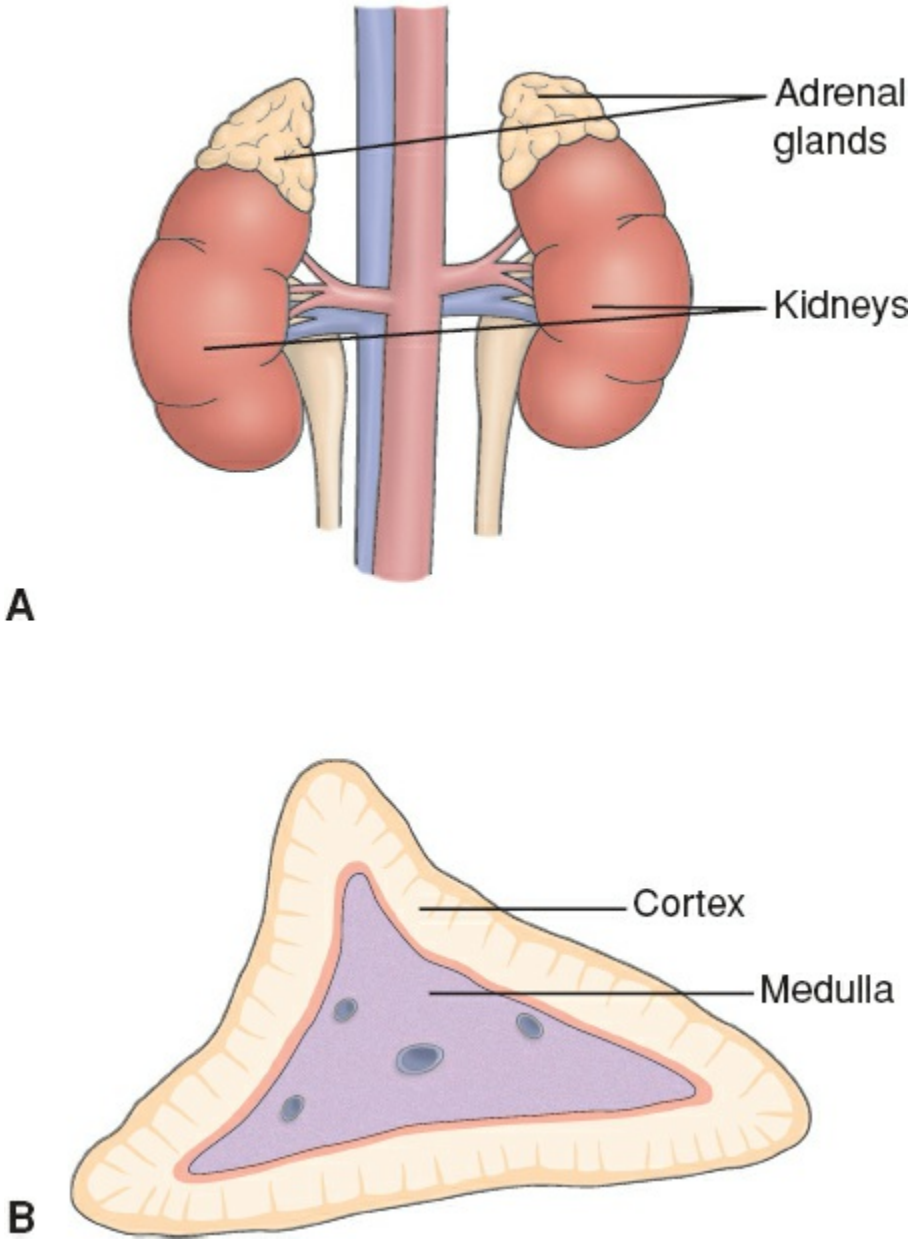

Figure 29-8 A. The adrenal glands sit on top of the kidneys. B. Each gland is composed of an outer cortex and an inner medulla. Each area secretes specific hormones. The adrenal medulla secretes catecholamines—epinephrine and norepinephrine; the adrenal cortex secretes glucocorticoids, mineralocorticoids, and sex hormones.

Sex Hormones. ACTH controls the secretion of adrenal androgens which exert effects similar to those of male sex hormones. The adrenal cortex also may secrete small amounts of some estrogens, or female sex hormones. When secreted in normal amounts, the adrenal androgens appear to have little effect, but when secreted in excess, as in certain inborn enzyme deficiencies, masculinization may result. This is termed the adrenogenital syndrome.

Pancreatic Islets

The pancreas lies transversely in the upper abdomen, with the head of the pancreas resting

at the curve of the duodenum and the body beneath the stomach. The beta cells of the pancreas secrete insulin, which facilitates glucose transport into body cells, thus lowering the blood glucose levels when they are above normal. When blood glucose levels are low, alpha cells of the pancreas secrete the hormone glucagon. It promotes gluconeogenesis to raise the blood glucose level. Because its action is opposite to insulin, it may be termed a *counter-regulatory hormone.* The delta cells of the pancreas secrete somatostatin, which reduces the rate at which food is absorbed from the GI tract. See Chapter 30 for more detailed discussion of insulin.

TABLE 29-2 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes to the Endocrine System

Endocrine Gland	Age-Related Changes	History and Physical Findings
Thyroid	Atrophy and fibrosis of the thyroid gland with decreased activity of the thyroid gland, resulting in decreased basal metabolic rate Reduced uptake of radioactive iodine and decreased secretion and release of thyrotropin Increased nodularity of the thyroid	Cold intolerance Decreased appetite Decreased vital signs
Parathyroid gland	Decreased absorption and activation of vitamin D, which can lead to increased loss of bone minerals and decreased bone mass	Increased risk for fractures
Adrenal gland	Decreased adrenal function; adrenocorticotropic hormone (ACTH) secretion decreases with age with resultant decreased estrogen, progesterone, androgen, and glucocorticoids	Increased incidence of osteoporosis Perineal and vaginal dryness Fragile skin tissue
Pituitary gland	The volume of the pituitary decreases Decreased ACTH, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH)	Decreased muscle mass Decreased strength and energy tolerance Thin and dry skin
Pancreas	Decreased secretion of insulin and decreased sensitivity to circulating insulin, resulting in reduced ability to metabolize glucose	

Adapted from Elipoulos, C. (2013). *Gerontological nursing* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Gerontologic Considerations

As a result of aging, the endocrine glands have decreased ability to secrete hormones, or the target organs lose their ability to respond to the hormones produced by the different glands.

These gerontologic changes are summarized in Table 29-2.

ASSESSMENT OF THE ENDOCRINE SYSTEM

Health History

The nurse assesses the patient's history for the presence of pre-existing endocrine disorders, compliance with medications, and the presence of coexisting medical problems.

Endocrine disorders often manifest with nonspecific, atypical symptoms or common complaints that can be attributed to a variety of disorders. Symptoms include weight gain or loss, constipation or diarrhea, tachycardia or bradycardia, hypotension or hypertension, depression or anxiety, heat or cold intolerance, etc. Additionally, endocrine disease may be masked or associated with other comorbidities. For example, the symptoms of an elderly patient admitted with congestive heart failure (CHF) may be attributed to pre-existing cardiac disease without considering thyroid disease. Because the endocrine system impacts nearly all cells and organs, the nurse must have a suspicion of potential endocrine disorders in all hospitalized patients. Additionally, it is the clustering of signs and symptoms, correlated with the nurse's knowledge of normal physiologic endocrine function, that will alert the nurse to an underlying endocrine disorder. Clinical presentations of endocrine disorders are discussed below according to specific endocrine glands.

Pituitary Dysfunction

Hormonal imbalances of the pituitary involve FSH, LH, ACTH, GH (somatotropin), TSH, MSH, and prolactin from the anterior pituitary as well as ADH and oxytocin from the posterior pituitary.

During the health history, the nurse asks the patient about history of weakness, lethargy, muscular weakness, changes in sexual function (loss of libido) and secondary sex characteristics, as well as any menstrual disturbances in females. In addition, assessment for galactorrhea (spontaneous, inappropriate flow of milk from male or female breast in the absence of pregnancy or breastfeeding) is indicated to assess for prolactinomas (a pituitary tumor causing excessive prolactin). The nurse asks about changes in weight, height, enlargement of peripheral body parts, changes in the texture of the skin or hair, and any changes in urination or body temperature. Owing to the proximity of the pituitary to the optic chiasm, complaints of headaches and visual disturbances are not uncommon and should be evaluated. Neurologic assessment data should consider the patient's level of consciousness, orientation, ability to obey commands, and appropriate response to stimuli. The nurse also inquires about symptoms of hyper/hypotension, heat or cold intolerance, palpitations, tremors, and mood changes.

Growth Hormone Dysfunction

Males and females are affected equally. In adults, assess for bony changes, such as increase in the width and thickness of bones—enlarged hands, feet, sinuses, spine, and mandible (protruding jaw), increase in the size of nose. If there is pressure on the optic nerve, changes in vision and headaches may occur. As GH can cause complications with insulin secretion, including glucose intolerance, leading to diabetes, the blood sugar should be assessed.

Thyroid Gland Dysfunction

During the health history, the nurse asks the patient about changes in weight and appetite, bowel movements, heart rate and respiration, any marked tremors, nervousness, excitability, apprehension or impaired memory, decreased initiative, and slow thought processes. The nurse also asks about changes in the patient's tolerance to heat and cold as well as excessive sweating or feeling very cold, lethargy or apathy, and changes in hair and skin. The presence of exophthalmos, which is an abnormal protrusion of one or both eyeballs that produces a startled expression, also should be assessed (Freedman, 2015).

Parathyroid Dysfunction

During the health history, the nurse considers that hypofunction of the parathyroids is associated with hypocalcemia. Calcium and phosphorus have an inverse relationship, thus when serum calcium levels are low (as a result of parathyroid hyposecretion), phosphate levels rise. If hypofunction is suspected, the nurse assesses for neuromuscular irritability since nerve cells become excited and overstimulate muscle cells in the presence of hypocalcemia. Clinical manifestations include complaints of paresthesias (perioral, extremities) and fasciculations (muscle twitching); therefore, the nurse asks the patient about neuromuscular manifestations. In addition, hypocalcemia has an impact on cardiac function and can prolong the QT interval, causing cardiac arrhythmias, hypotension, and potential cardiac failure. The nurse inquires about complaints of palpitations, shortness of breath, dizziness, and presence of peripheral edema. In addition, since chronic hypocalcemia is associated with cataract formation, the nurse asks about visual changes. The mechanism for the development of cataract may be related to changes in the surface tension of the lens and instability of aqueous humor leading to the development of cataracts in the presence of low calcium.

Hyperfunction of the parathyroids may result in hypercalcemia, as excessive parathyroid hormone causes the release of calcium from bones (Porth, 2015). If hyperfunction of the parathyroid is suspected, the nurse understands that symptoms of hypercalcemia may be vague and include complaints in the following systems: GI (anorexia, nausea, vomiting, bowel hypomotility, and constipation), musculoskeletal (muscle weakness, bone pain), neurologic (fatigue, decreased concentration), or renal (polyuria as hypercalcemia decreases the concentrating ability in the distal tubule). Also the patient may make complaints that are more severe. For example, hyperparathyroidism is associated with an increased incidence of peptic ulcer disease; therefore, the nurse should ask about the presence of melena (dark tarry stools containing decomposing blood). Additionally, the patient is asked about cardiac complaints since hypercalcemia is associated with shortened QT interval, bradycardia, and hypertension. Finally, the formation of stones in one or both kidneys may cause symptoms due to renal calculi, such as back or flank pain, nausea, vomiting, and dysuria.

Adrenal Dysfunction

The nurse asks the patient about symptoms of fluid imbalance (related to aldosterone), symptoms of hyper/hypoglycemia (related to cortisol), and changes in voice, hair, and sexual drive (related to androgens).

To address hypersecretion of the adrenal cortex (known as Cushing disease, covered in Chapter 32), the nurse should inquire about problems with acne or hirsutism (related to hypersecretion of androgens), muscle weakness and paresthesia (hypersecretion of aldosterone), or history of fractures (hypersecretion of cortisol). When considering failure of the adrenal cortex (known as Addison disease, covered in Chapter 32), the nurse asks about symptoms of weakness, fatigue, poor appetite, and weight loss. If a problem with the adrenal medulla is suspected, the nurse assesses the patient's level of stress (related to catecholamines), such as headache, anxiety, nervousness, complaints of a racing heart, and sweating.

Physical Examination

General Appearance

To assess for endocrine dysfunctions, the nurse notes the appearance of facial features, presence of hair, skin condition, and overall proportion. Excessive adrenocortical hormones may cause facial hair in women, "moon face" (swollen and round face), "buffalo hump" (accumulation of fatty deposits at the base of the neck), thinning of the skin, obesity of the trunk and thinness of the extremities, purple striae (stretch marks), and slow healing of minor cuts and bruises. Masculinization in females and truncal obesity may be seen with adrenal hypersecretion as well as a bronze skin color in the creases of the hands or over the metacarpophalangeal (finger) joints, elbows, and knees. This increased pigmentation is associated with excessive MSH.

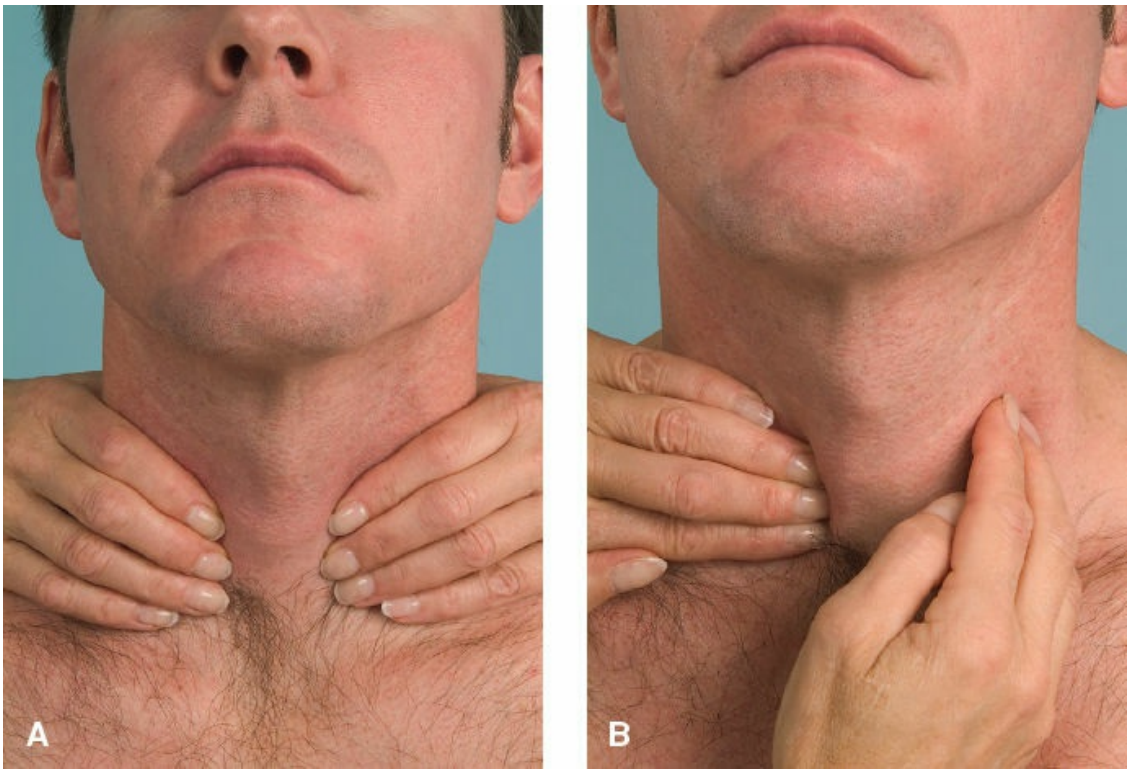

FIGURE 29-9 Palpating the thyroid. A. Posterior approach. B. Anterior approach. (From Rhoads, J. (2006). *Advanced health assessment and diagnostic reasoning*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Vital Signs

The nurse performs a thorough cardiac assessment, including vital signs, noting rate and rhythm of the heart and auscultation of heart sounds. Bradycardia is associated with hypothyroidism; tachycardia is associated with hyperthyroidism. Diabetes insipidus, which causes profound polyuria, may cause clinical signs of volume depletion, such as tachycardia and hypotension.

Parathyroid problems may cause calcium derangements, which profoundly impact the cardiac system. Hypocalcemia decreases myocardial contractility, prolongs the QT interval

(predisposing patients to ventricular arrhythmias), and is associated with hypotension secondary to reduced cardiac output. Hypercalcemia alters myocardial function; causes rhythm disturbances, such as bradycardia, first-, second-, and third-degree heart blocks, and a shortened QT interval; and is associated with hypertension. When a parathyroid problem is suspected, the nurse should assess for pathologic fractures or symptoms due to renal calculi. Assess for neuromuscular irritability (tetany) related to hypocalcemia (refer to Chapter 32 for assessment cues). Pheochromocytoma, a tumor of the adrenal medulla that causes excess secretion of catecholamines, results in episodic severe hypertension and tachycardia.

Thyroid

The nurse inspects and palpates the thyroid gland routinely in all patients. Inspection begins with identification of landmarks. The nurse inspects the lower neck region between the sternocleidomastoid muscles for swelling or asymmetry. The nurse instructs the patient to extend the neck slightly and swallow. Thyroid tissue rises normally with swallowing. The thyroid is palpated for size, shape, consistency, symmetry, and the presence of tenderness. Each of the lobes is palpated in detail. The nurse may examine the thyroid from an anterior or a posterior position (Fig. 29-9). If palpation discloses an enlarged thyroid gland, check for thrills and auscultate both lobes using the bell of the stethoscope to identify any bruits (Box 29-1).

Eyes and Vision

Assess central vision and visual fields. Loss of color discrimination, diplopia (double vision), or blindness in a portion of a field of vision may be related to pressure of a pituitary tumor on the optic chiasm (located anterior to the pituitary stalk). See Chapter 49 for information on assessing vision and extraocular movements (EOM). Exophthalmos or *proptosis* is an anterior bulging of the eyeballs associated with hyperthyroidism.

Diagnostic Evaluation

Diagnostic evaluation is described related to the glands.

Anterior Pituitary Gland Tests

Computed tomography (CT) scan and magnetic resonance imaging (MRI) can be done to identify the presence or extent of tumors. Serum levels of pituitary hormones, along with hormones of target glands, may be indicated to evaluate for increased or decreased activity of each gland. For example, an increased thyrotrophic hormone–releasing factor (TRF), which targets the thyroid, is associated with hyperthyroidism. An increase in ACTH, which targets the adrenal cortex, is found in Cushing disease, whereas a decrease in ACTH will be seen in adrenal insufficiency or Addison disease.

BOX 29-1 Physical Assessment of an Enlarged Thyroid

In Graves disease, hypertrophy (enlarged cells) and hyperplasia (increased number of cells) of the thyroid may cause the gland to grow to two to three times its normal size. If the thyroid is retrosternal, goiters may not be visual so it is important to assess for difficulty in swallowing. When the nurse places the hands on the thyroid, he or she feels increased blood flow to the thyroid (thrills). Often thrills are described as sensation of a purring cat. Auscultation using a stethoscope assesses for a bruit (blowing or whooshing sound), which signifies turbulent blood flow and may be found on one side or on the entire gland.

Posterior Pituitary Gland Tests

Plasma levels of ADH can indicate increased or decreased levels. A fluid deprivation test may be indicated for diabetes insipidus. In this test, plasma and urine osmolality are measured, and these levels may be altered in disease. Refer to Chapter 31 for more details on this test.

Urine osmolality is assessed for syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Because patients with SIADH do not excrete dilute urine, the urine osmolality will be increased. Also serum sodium levels will be recorded as low because of the retention of water. SIADH will be covered in Chapter 32.

Thyroid Gland Tests

Several tests can be performed to test the functioning of the thyroid gland. Serum TSH is the best screening test for thyroid disorders and helps differentiate between disorders of the thyroid gland itself and disorders of the pituitary and hypothalamus. High levels of serum TSH will indicate normal function or hypothyroidism, whereas low values indicate hyperthyroidism. This is an example of the negative feedback system. If the thyroid hormones (T_3 and T_4) are not secreted by the thyroid, TSH is increased to help stimulate

the thyroid to produce these hormones. If T_3 and T_4 are excreted in large amounts, as occurs in hyperthyroidism, TSH is decreased. Also TSH is used to monitor thyroid replacement regimen.

Free T_4 levels measure the unbound thyroxine levels in the blood that is free to enter cells and produce its effects (Porth, 2015). More than 99% of T_3 and T_4 are bound to proteins. Thus, levels of serum-free T_4 will be increased in hyperthyroidism. T_4 decreases in hypothyroidism. Total levels of T_3 or T_4–T_3 increase in hyperthyroidism.

Antithyroid antibodies will be seen in autoimmune thyroid disease, like Hashimoto thyroiditis and Graves disease. A radioactive iodine uptake test also can be done. This indicates the rate of iodine uptake by thyroid gland. It increases in hyperthyroidism and decreases in hypothyroidism. Needle aspiration biopsy can be done to evaluate thyroid cell structure.

Thyroid imaging can be used in the differential diagnosis of masses. Often increased functioning of nodules or "hot" nodules is associated with benign adenomas, whereas "cold" areas refer to decreased functioning. Cancer of the thyroid often manifests as a "cold" area.

Parathyroid Tests

Serum calcium and PTH levels, as well as bone density tests, may be ordered.

In hyperparathyroidism, the serum PTH and calcium will increase, whereas the serum PTH will decrease with hypercalcemia that is related to an etiology other than the parathyroid hypersecretion. Phosphate levels may be decreased but, in general, are in the lower range of normal. Bone density tests may reveal decreased density owing to the increased osteoclast activity.

In hypoparathyroidism, the levels of serum calcium will be lower and phosphate levels elevated.

Adrenal Medulla Tests

With pheochromocytoma, a rare tumor of the adrenal medulla, there will be increased levels of catecholamine and metanephrine in urine and plasma and elevated serum levels of epinephrine and norepinephrine.

A urine vanillylmandelic acid (VMA) level test is performed when pheochromocytoma is suspected. A 24-hour urine specimen will show the level of urine VMA as high as two times the normal level.

Clonidine suppression test, CT, MRI, ultrasound, and scintigraphy are other tests that can be ordered.

Adrenal Cortex Tests

In adrenal insufficiency (Addison disease), the adrenal glands produce too little cortisol, reducing serum cortisol and blood glucose. Reduced levels of aldosterone cause decreased serum sodium and increased potassium levels. A patient with primary adrenal insufficiency will present with a low serum cortisol level and a simultaneously high serum ACTH level. A patient with secondary adrenal insufficiency (pituitary disease) will reveal low serum cortisol and ACTH levels. Refer to Chapter 32 for more details of primary versus secondary

adrenal insufficiency.

To assess for adrenal hypersecretion (Cushing syndrome), a variety of test can evaluate the functioning of the adrenal cortex such as: an overnight dexamethasone suppression test, plasma ACTH, plasma and urinary cortisol, and 24-hour urinary free cortisol level.

CHAPTER REVIEW

Critical Thinking Exercises

1. Explain the mechanism by which the hypothalamic–pituitary–thyroid axis regulates thyroid hormone production.
2. Summarize the functions of the three major types of hormones secreted by the adrenal cortex.

NCLEX-Style Review Questions

1. A client complains of nervousness and palpitations. Upon assessing the patient's heart rate, the nurse notes a heart rate of 120 bpm. Which of the following endocrine disorders is associated with palpitations and increased heart rate?
   a. Hypothyroidism
   b. Hyperthyroidism
   c. SIADH
   d. Hypoparathyroidism
2. While assessing a client with Cushing syndrome, the nurse should expect high blood glucose reading due to increased secretion of which of the following?
   a. The thyroid gland
   b. The parathyroid glands
   c. The adrenal glands
   d. The pituitary gland
3. An elderly woman complaining of weight gain, depression, and lethargy is diagnosed with hypothyroidism, and thyroid replacement is prescribed. During initiation of thyroid replacement therapy for the patient, the priority assessment for the nurse is to evaluate which of the following?
   a. Mental status
   b. Nutritional status
   c. Cardiovascular function
   d. Bowel function
4. A 47-year-old woman presents to her primary care provider complaining of bone pain. Routine laboratory studies reveal a high serum calcium of 12.0 mg/dL and increased PTH levels. Which of the following is the most likely diagnosis?
   a. Graves disease

b. Cushing disease
c. Addison disease
d. Hyperparathyroidism

5. The nurse is assessing a client for acromegaly at the clinic. Besides asking about changes in shoe size and facial features, the nurse should also inquire about changes in which of the following?
a. Hearing
b. Bowel habits
c. Vision
d. Taste of foods

CHAPTER 30

Nursing Management: Diabetes Mellitus

Kathryn W. Tierney

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate between type 1 and type 2 diabetes.
2. Describe etiologic factors associated with diabetes.
3. Relate the clinical manifestations of diabetes to the associated pathophysiologic alterations.
4. Identify the diagnostic and clinical significance of blood glucose test results.
5. Explain the dietary modifications used for management of people with diabetes.
6. Describe the relationships among diet, exercise, and medication for people with diabetes.
7. Develop a plan for teaching insulin self-management.
8. Identify the role of non-insulin antidiabetic agents in diabetic therapy.
9. Differentiate between hyperglycemia with diabetic ketoacidosis and hyperosmolar nonketotic syndrome.
10. Describe management strategies for a person with diabetes to use during "sick days."
11. Describe the major macrovascular, microvascular, and neuropathic complications of diabetes.
12. Use the nursing process as a framework for care of hospitalized patients with diabetes.

Diabetes mellitus is a group of metabolic diseases characterized by elevated levels of glucose in the blood (hyperglycemia). Diabetes is a chronic illness that requires medical care and patient self-management to prevent or decrease the risk of complications (American Diabetes Association [ADA], 2017a). It affects many body systems and has potentially far-reaching and devastating physical, social, and economic consequences. It is a significant risk factor in the development of heart disease and stroke, and it is the leading cause of nontraumatic amputations, blindness in working-age adults, and end-stage kidney disease (ESKD) (Centers for Disease Control and Prevention [CDC], 2014).

The economic cost of diabetes continues to rise because of increasing health care costs and an aging population. Costs related to diabetes are estimated to be $245 billion annually, including direct medical care expenses and indirect costs attributable to disability and premature death (CDC, 2014).

Nursing management of patients with diabetes can involve treatment of a wide variety

of physiologic disorders, depending on the patient's health status and whether the patient is newly diagnosed or seeking care for an unrelated health problem. Because all patients with diabetes must master the concepts and skills necessary for long-term management and avoidance of potential complications of diabetes, patient education is necessary for competent self-care and is an ongoing focus of nursing care.

DIABETES MELLITUS

Diabetes affects more than 29 million people in the United States, or approximately 9.3% of the population (CDC, 2014). Of this number, 21 million are diagnosed with diabetes, and an estimated 8.1 million are undiagnosed. As many as 86 million people are thought to have prediabetes, a condition that puts people at increased risk for the development of diabetes (CDC, 2014). The occurrence of diabetes, especially type 2 diabetes, is increasing in all age groups. Diabetes is especially prevalent in persons over 60 years of age (CDC, 2014).

Classification

The major classifications of diabetes are type 1 diabetes, type 2 diabetes, and gestational diabetes. Other types of diabetes, comprising 1% to 5% of all diagnosed cases, are caused by genetic conditions, surgery, medications, pancreatic disease, and other illnesses (ADA, 2017b).

Table 30-1 summarizes the major classifications of diabetes, current terminology, and major clinical characteristics. This classification system is dynamic in two ways. First, there can be many differences among individuals within each category. Second, except for people with type 1 diabetes, patients may move from one category to another. For example, a woman with gestational diabetes may, after delivery, move into the type 2 category. Also, metabolic processes typically associated with one diagnosis, such as insulin resistance in type 2 diabetes, may be present in other settings, such as type 1 diabetes. Older terms, such as "insulin-dependent diabetes," "non–insulin-dependent diabetes," "juvenile diabetes," "adult-onset diabetes," and others have been eliminated to reduce confusion.

TABLE 30-1 Classification of Diabetes Mellitus and Related Glucose Intolerances

Current Classification	Previous Classifications	Clinical Characteristics and Clinical Implications
Type 1 (5–10% of all diabetes)	Juvenile diabetes Juvenile-onset diabetes Ketosis-prone diabetes Brittle diabetes Insulin-dependent diabetes mellitus (IDDM)	Onset any age, but usually young (under 30 years of age) Usually thin at diagnosis; recent weight loss Etiology includes genetic, immunologic, and environmental factors (e.g., virus) Often have positive islet cell or GAD (glutamic acid decarboxylase) antibodies Little or no endogenous insulin Need insulin to preserve life Ketosis-prone when insulin absent Acute complication of hyperglycemia: diabetic ketoacidosis
Type 2 (90–95% of all diabetes: obese—80% of type 2; nonobese—20% of type 2)	Adult-onset diabetes Maturity-onset diabetes Ketosis-resistant diabetes Stable diabetes Non–insulin-dependent diabetes (NIDDM)	Onset any age, usually over 30 years of age Usually obese at diagnosis Causes include obesity, heredity, and environmental factors No islet cell antibodies Decrease in endogenous insulin, or increased with insulin resistance Most patients can improve blood glucose through weight loss if obese Oral antidiabetic agents may improve blood glucose levels if dietary modification and exercise are unsuccessful May need insulin on a short- or long-term basis to prevent hyperglycemia Ketosis uncommon, except in stress or infection Acute complication: hyperglycemic hyperosmolar nonketotic syndrome

Diabetes mellitus associated with other conditions or syndromes	Secondary diabetes	Accompanied by conditions known or suspected to cause the disease: pancreatic diseases, hormonal abnormalities, medications such as corticosteroids and estrogen-containing preparations Depending on the ability of the pancreas to produce insulin, the patient may require treatment with insulin
Gestational diabetes	Gestational diabetes	Onset during pregnancy, usually in the second or third trimester Due to hormones secreted by the placenta, which inhibit the action of insulin Above-normal risk for perinatal complications, especially macrosomia (abnormally large babies) Treated with diet and, if needed, insulin to strictly maintain normal blood glucose levels Occurs in about 2–5% of all pregnancies Glucose intolerance transitory but may recur: • In subsequent pregnancies • 30–40% will develop overt diabetes (usually type 2) within 10 years (especially if obese) • Risk factors include obesity, over 30 years of age, family history of diabetes, previous macrosomia (over 9 lb) All pregnant women between 24 and 28 weeks of gestation should be screened with oral glucose tolerance test
Impaired glucose tolerance	Borderline diabetes Latent diabetes Chemical diabetes Subclinical diabetes Asymptomatic diabetes	Oral glucose tolerance test value between 140 mg/dL (7.7 mmol/L) and 200 mg/dL (11 mmol/L) Impaired fasting glucose is defined as a fasting plasma glucose between 110 mg/dL (6 mmol/L) and 126 mg/dL (7 mmol/L) 29% eventually develop diabetes Above-normal susceptibility to atherosclerotic disease Renal and retinal complications usually not significant May be obese or nonobese Should be screened for diabetes periodically
Prediabetes	Previous abnormality of glucose tolerance (PrevAGT)	Current normal glucose metabolism Previous history of hyperglycemia (e.g., during pregnancy or illness) Periodic blood glucose screening after age 40 if there is a family history of diabetes or if symptomatic Encourage ideal body weight, because loss of 10–15 lb may improve glycemic control
Prediabetes	Potential abnormality of glucose tolerance (PotAGT)	No history of glucose intolerance Increased risk of diabetes if: • Positive family history • Obesity • Mother of babies over 9 lb at birth • Member of certain Native American tribes (e.g., Pima) with high prevalence of diabetes Screening and weight advice as in PrevAGT

Pathophysiology

Insulin is a hormone produced by the pancreas that controls blood glucose levels by regulating the production, use, and storage of glucose. It is secreted by beta cells, in the islets of Langerhans of the pancreas. In patients with diabetes, cells may respond inadequately to insulin or the pancreas may decrease insulin secretion or stop insulin production completely. Insulin is an anabolic, or storage hormone. When a person eats a meal, insulin secretion increases and moves glucose from the blood into muscle, liver, and fat cells. Once inside the cells, insulin functions in the following ways:

- Transports and metabolizes glucose for energy
- Stimulates storage of glucose as glycogen in the liver and muscle cells
- Signals liver cells to stop the release of glucose
- Enhances storage of dietary fat in adipose tissue
- Accelerates transport of amino acids into cells
- Facilitates the transport of potassium into the cells
- Inhibits the breakdown of stored glucose, protein, and fat (Porth, 2015)

During fasting periods, for example, between meals and overnight, the pancreas continuously releases a small amount of "basal" insulin. If the blood sugar becomes too low, another pancreatic hormone, *glucagon*, is secreted by the alpha cells of the islets of Langerhans. Glucagon stimulates the liver to release stored glucose, thereby increasing the blood sugar. In short, insulin promotes hypoglycemia; glucagon promotes hyperglycemia. They work in tandem to maintain a constant level of glucose in the blood.

Nursing Alert

Approximately 50% of the total insulin secreted daily by the pancreas is secreted under basal conditions, and the remainder is in response to meals. The estimated secretion rate of basal insulin in the average adult (assume a weight of 70 kg) ranges from 18 to 32 units/24 hours (0.7 to 1.3 mg) (Kahn et al., 2005). Minutes after eating, the serum insulin level rises, peaking in 3 to 5 minutes and returning to baseline within 2 to 3 hours (Porth, 2015). To attain glycemic control, nurses may be required to manage insulin drips based upon the secretion rate of basal insulin.

The liver assists with glucose control by storing glucose in the form of glycogen. As the level of glucose in the blood begins to drop, the liver produces glucose through the breakdown of glycogen (glycogenolysis). After 8 to 12 hours without food, the liver forms glucose from the breakdown of noncarbohydrate substances, including amino acids (gluconeogenesis).

Type 1 Diabetes

Type 1 diabetes affects approximately 5% to 10% of people with the disease. It is often

characterized by an acute onset and most commonly affects children and young adults, although it can occur at any age (ADA, 2017b). Type 1 diabetes is characterized by destruction of the pancreatic beta cells. The diagnosis is further defined as type 1a, or immune-mediated diabetes, and type 1b, or idiopathic (Porth, 2015). The etiology of type 1a diabetes is primarily autoimmune. Autoimmune diseases are caused by abnormal immune responses in which antibodies are directed against normal tissues of the body, responding to those tissues as if they were foreign. Immune destruction of the beta cells, caused by autoantibodies against islet cells and insulin, is associated with certain types of human leukocyte antigen (HLA). It is believed that destruction by the immune system of the beta cells is initiated by a combination of genetic, immunologic, and environmental factors, such as viruses or toxins. The risk of developing type 1 diabetes is three to five times higher in people with certain types of HLA. People do not inherit type 1 diabetes itself, but rather they may have a genetic predisposition, or tendency, toward development of the disease.

Type 1b diabetes represents beta cell failure without an immune-mediated etiology. Whereas there is genetic susceptibility in type 1a diabetes, those with type 1b diabetes have a very strong hereditary component (Porth, 2015).

Regardless of the specific cause, beta cell destruction results in decreased insulin production, unchecked glucose production by the liver, and hyperglycemia. In addition, glucose derived from food cannot be stored in the liver but instead remains in the blood and contributes to postprandial (after meals) hyperglycemia. If the concentration of glucose in the blood exceeds the renal threshold for glucose, usually 180 to 200 mg/dL, the kidneys cannot reabsorb all of the filtered glucose; glucose then appears in the urine (glycosuria). Glucose is an osmotic agent; water follows it. As the glucose is excreted in the urine, it is accompanied by excessive loss of fluids and electrolytes. This is termed *osmotic diuresis.*

Because insulin normally inhibits glycogenolysis (breakdown of stored glucose) and gluconeogenesis (production of new glucose from amino acids and other substrates), these processes occur unrestrained in people with insulin deficiency and contribute further to hyperglycemia. In addition, fat breakdown occurs, resulting in an increased production of ketones, which are organic acids. If excessive amounts of ketones are present in the blood, ketoacidosis develops.

Glucose levels can be measured in several ways, including serum levels, capillary glucose, glycated hemoglobin (A1c), and continuous glucose sensing. Serum levels are measured by laboratory testing after a venous blood draw. Capillary glucose is measured using blood from a fingerstick that is placed on a glucose test strip. This type of testing is available to patients at home and is used most frequently to determine glucose levels day to day. The hemoglobin A1c is a measure of average glucose levels over a period of 2 to 3 months. Because it is an average, it does not give any information regarding patterns of blood sugar or periods of hyper or hypoglycemia, but it is useful to track overall control over time. Continuous glucose monitors (CGM) measure subcutaneous glucose levels and provide real-time data on glucose levels and direction and rate of change. Each of these methods of measuring glucose control has pros and cons as well as situations in which they are not as accurate.

Type 2 Diabetes

Type 2 diabetes affects approximately 90% to 95% of people with the disease. Although type 2 diabetes is commonly associated with older age and obesity, its incidence is increasing in younger people because of the growing epidemic of obesity in children, adolescents, and young adults (CDC, 2014). The two main problems related to insulin in type 2 diabetes are insulin resistance and impaired insulin secretion. *Insulin resistance* refers to decreased tissue sensitivity to insulin. Normally, insulin binds to special receptors on cell surfaces and initiates a series of reactions involved in glucose metabolism. In type 2 diabetes, these intracellular reactions are diminished, making insulin less effective in stimulating glucose uptake by the cells and at regulating glucose release by the liver (Fig. 30-1). The exact mechanisms that lead to insulin resistance and impaired insulin secretion in type 2 diabetes are unknown, although increasing age, obesity, and lack of physical exercise as well as genetic factors are thought to play a role (ADA, 2017b).

To overcome insulin resistance and prevent the buildup of glucose in the blood, increased amounts of insulin must be secreted to maintain the glucose level. However, if the beta cells cannot keep up with the increased demand for insulin, the glucose level rises, and type 2 diabetes develops.

Despite the impaired insulin secretion that is characteristic of type 2 diabetes, there is enough insulin present to prevent the breakdown of fat and the accompanying production of ketone acids. Therefore, diabetic ketoacidosis (DKA) does not typically occur in type 2 diabetes. However, uncontrolled type 2 diabetes may lead to *hyperglycemic hyperosmolar nonketotic syndrome* (HHNS), another acute complication of diabetes discussed later in this chapter.

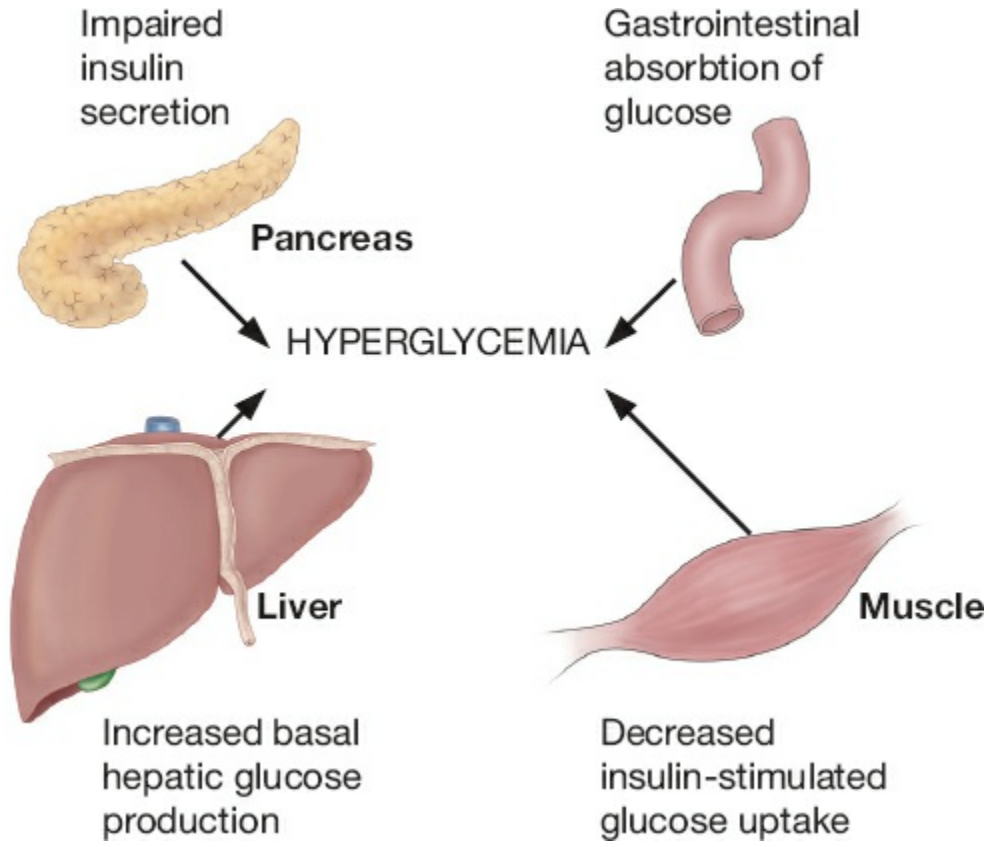

FIGURE 30-1 Pathogenesis of type 2 diabetes.

Because type 2 diabetes is usually associated with slow, progressive glucose intolerance, its onset may go undetected for many years. If the patient experiences symptoms, they are frequently mild and may include fatigue, irritability, increased urination, increased thirst, poor wound healing, frequent infections, or changes in vision.

Many patients with type 2 diabetes are diagnosed as a result of routine laboratory tests or during ophthalmoscopic examinations. One consequence of undetected diabetes is that long-term microvascular (diabetic retinopathy, neuropathy, and nephropathy) and macrovascular complications (peripheral vascular, coronary disease, and stroke) may have developed before the actual diagnosis of diabetes is made (ADA, 2017b).

Gestational Diabetes

Gestational diabetes mellitus (GDM) is any degree of glucose intolerance with onset occurring during pregnancy. Hyperglycemia can develop during pregnancy because of the secretion of placental hormones, which causes insulin resistance. It also can develop when the physiologic stress of pregnancy reveals glucose tolerance abnormalities that were not apparent prior to pregnancy. Gestational diabetes occurs in around 9% of pregnant women (DeSisto, 2014). Having hyperglycemia increases the risk for congenital anomalies and other complications during pregnancy (ADA, 2017h).

Risk assessment for gestational diabetes should be completed during the first prenatal visit. Women at high risk for GDM include those with marked obesity, personal history of GDM, glycosuria, or a strong family history of diabetes. Those at high risk should have their blood glucose tested as soon as possible in the first trimester and retested between 24 and 28 weeks of gestation, if initial glucose was normal. Women at low to moderate risk for gestational diabetes should be tested between 24 and 28 weeks of pregnancy (ADA, 2017b).

Initial management of gestational diabetes includes diet and exercise changes as well as blood glucose monitoring. If hyperglycemia persists despite lifestyle changes, then medication is prescribed. Goals for blood glucose levels during pregnancy are 95 mg/dL or less before meals, less than or equal to 140 mg/dL 1 hour after meals, and less than or equal to 120 mg/dL 2 hours after meals (ADA, 2017h).

After delivery, blood glucose levels in women with GDM usually return to normal. However, women who have had GDM are at risk for developing type 2 diabetes later in life and should be screened at least every 3 years. A woman who has had GDM should be counseled to maintain her ideal body weight and to exercise regularly to reduce her risk for type 2 diabetes.

BOX 30-1 Risk Factors for Diabetes Mellitus

- Family history of diabetes (i.e., parents or siblings with diabetes)
- Obesity (i.e., BMI at least 25 kg/m^2)
- Ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islanders)
- Age 45 years of age or older
- Previously identified impaired glucose tolerance or impaired fasting glucose

- Hypertension (at least 140/90 mm Hg)
- HDL cholesterol level at least 35 mg/dL (0.90 mmol/L) and/or triglyceride level at least 250 mg/dL (2.82 mmol/L)
- History of gestational diabetes or delivery of babies over 9 lb

Adapted from American Diabetes Association. (2015). Standards of medical care in diabetes. Diabetes Care, *30*(S1), S6.

Risk Factors

Because diabetes is sometimes not diagnosed until complications are present, screening is recommended for overweight adults and children with risk factors for type 2 diabetes. Box 30-1 summarizes risk factors for diabetes mellitus.

Because of the increased incidence of type 2 diabetes in children, screening is recommended for at-risk children beginning at 10 years of age (ADA, 2017b).

Ethnic groups and minority populations are disproportionately affected by diabetes. Age-adjusted population differences demonstrate the highest incidence among Native Americans and Alaska Natives (15.9%), followed by blacks (13.2%) and Hispanics (12.8%), compared with 9% for Asian Americans and 7.6% for whites (CDC, 2014). By 2050, nearly half of the population in the United States will be of an ethnicity other than white. Because the racial and ethnic groups noted above are at greater risk for diabetes and because of increasing obesity and inactivity in the general population, the incidence of diabetes is expected to continue to rise well into the 21st century.

Clinical Manifestations and Assessment

Clinical manifestations depend on the patient's level of hyperglycemia. Classic clinical manifestations of all types of diabetes include the "three Ps": polyuria, polydipsia, and polyphagia. Polyuria (increased urination) and polydipsia (increased thirst) occur as a result of the excess loss of fluid associated with osmotic diuresis. Patients may experience polyphagia (increased appetite) resulting from the catabolic state induced by insulin deficiency and the breakdown of proteins and fats. Other symptoms include dehydration, weight loss, fatigue and weakness, vision changes (the accumulation of glucose on the lens causes refractive error but resolves with glucose control, [Crandall & Shamoon, 2016]), tingling or numbness in the hands or feet, dry skin, skin lesions or wounds that are slow to heal, and recurrent infections.

Nursing Alert
Hyperglycemia impairs immune function (decreases white blood cell function), promotes inflammation, increases blood viscosity, favors the growth of yeast organisms, and is associated with changes in the blood vessel walls, resulting in increased risk for infection, microvascular and macrovascular complications, and foot ulcers.

A blood glucose level that is abnormally high is the basic criterion for the diagnosis of diabetes. There are three ways to diagnose diabetes: fasting plasma glucose (FPG) levels of 126 mg/dL or higher, a random plasma glucose level exceeding 200 mg/dL in a patient with classic symptoms of hyperglycemia, or an A1c level of 6.5% or higher (ADA, 2017b). It is recommended that in the absence of overt symptoms of hyperglycemia, the tests should be repeated or two of the three tests should be used simultaneously to confirm the diagnosis (ADA, 2017b). Normal fasting glucose for a nondiabetic is 80 to 90 mg/dL with a range of 70 to 120 mg/dL. Prediabetes is diagnosed when the FPG is 100 to 125 mg/dL. The oral glucose tolerance test (OGTT) is no longer recommended for routine clinical use in nonpregnant adults. See Box 30-2 for ADA diagnostic criteria for diabetes mellitus.

In addition to assessment and diagnostic evaluation to diagnose diabetes, other important components of care include ongoing specialized assessment of patients with known diabetes and evaluation for complications in patients with newly diagnosed diabetes. Parameters that should be assessed regularly are shown in Box 30-3.

BOX 30-2 Criteria for the Diagnosis of Diabetes Mellitus

1. A1c of 6.5% or greater
   or
2. Symptoms of diabetes plus casual plasma glucose concentration equal to or greater than 200 mg/dL (11.1 mmol/L). "Casual" is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
   or

3. Fasting plasma glucose greater than or equal to 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.
   or
4. Two-hour postload glucose equal to or greater than 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The fourth measure is not recommended for routine clinical use.

Gerontologic Considerations 

The overall incidence of diabetes is increasing, with the greatest increase occurring in the aging population (CDC, 2014), necessitating assessment in the elderly. The cause of age-related changes in carbohydrate metabolism is not clear. Possibilities include poor diet, physical inactivity, altered insulin secretion, and insulin resistance.

Elevated levels of blood glucose commonly appear in the fifth decade of life and increase in frequency with advancing age. Almost 27% of people over 65 years of age have diabetes (CDC, 2014). This number is expected to grow (ADA, 2017g). Because people with diabetes are living longer, both type 1 and type 2 diabetes are seen more frequently in the elderly population.

Older patients with diabetes are likely to have coexisting illnesses, such as hypertension, heart disease, stroke, and other health care problems that complicate diabetes management. Normal physiologic changes of aging may mask the symptoms of diabetes, making diagnosis more difficult. Finally, age-related health problems, such as polypharmacy, depression, cognitive impairment, urinary incontinence, falls, and chronic pain increase the risk for complications of diabetes (ADA, 2017f).

Regardless of the type or duration of diabetes, the goals of diabetes treatment may need to be altered when caring for elderly patients. The focus is on quality-of-life issues, such as maintaining independent functioning and promoting general well-being. Although striving for strict control of blood glucose levels may not be safe or appropriate, prolonged hyperglycemia should be avoided. Box 30-4 presents age-related changes that may affect diabetes and its management.

Medical Management

The therapeutic goal for diabetes management is to achieve normal levels of blood glucose (euglycemia) without hypoglycemia while maintaining a high quality of life. Diabetes management has five components:

- Nutrition
- Exercise
- Monitoring
- Medication
- Education

Patients with type 1 diabetes produce little or no insulin and require daily insulin injections to control levels of blood glucose. The primary treatment of type 2 diabetes is decreasing insulin resistance, most commonly with weight loss. Exercise is also important in enhancing the effectiveness of insulin for all patients with diabetes. In patients with type 2 diabetes, non-insulin antidiabetic agents may be added if meal planning, diet therapy, and exercise are not successful in controlling blood glucose levels. If maximum doses of a single category of non-insulin agents fail to reduce glucose to satisfactory levels, additional agents may be used. Insulin may be added to other therapies, or the patient may be changed to insulin therapy entirely. Some patients require insulin on an ongoing basis; others require insulin on a temporary basis during periods of acute physiologic stress, such as illness or surgery. The types and number of agents used initially depend on the severity of the hyperglycemia at the time of diagnosis.

BOX 30-3 Assessing the Patient with Diabetes

History

- Symptoms related to the diagnosis of diabetes:
  Symptoms of hyperglycemia
  Symptoms of hypoglycemia
  Frequency, timing, severity, and resolution
- Results of monitoring of blood glucose
- Status, symptoms, and management of chronic complications of diabetes:
  Eye, kidney, nerve, genitourinary and sexual, bladder, and gastrointestinal
- Cardiac, peripheral vascular, foot complications associated with diabetes:
- Adherence to/ability to follow prescribed dietary management plan
- Adherence to prescribed exercise regimen
- Adherence to/ability to follow prescribed pharmacologic treatment (insulin or oral antidiabetic agents)
- Use of tobacco, alcohol, and prescribed and over-the-counter medications/drugs
- Lifestyle, cultural, psychosocial, and economic factors that may affect diabetes

treatment
- Effects of diabetes or its complications on functional status (e.g., mobility, vision)

Physical Examination

- Blood pressure (sitting and standing to detect orthostatic changes)
- Body mass index (height and weight)
- Fundoscopic examination and visual acuity
- Foot examination (lesions, signs of infection, pulses)
- Skin examination (lesions and insulin-injection sites)
- Neurologic examination:
  Vibratory and sensory examination using monofilament
  Deep tendon reflexes
- Oral examination

Laboratory Examination

- A1c (glycated hemoglobin)
- Fasting lipid profile
- Test for microalbuminuria
- Serum creatinine level
- Urinalysis
- Electrocardiogram

Need for Referrals

- Ophthalmology
- Podiatry
- Dietitian
- Diabetes educator
- Others if indicated

BOX 30-4 Gerontologic Considerations

Age-Related Changes that May Affect Diabetes and Its Management

Sensory Changes
- Decreased vision
- Decreased smell

- Taste changes
- Decreased proprioception
- Diminished thirst

Gastrointestinal Changes
- Dental problems
- Appetite changes
- Delayed gastric emptying
- Decreased bowel motility

Activity/Exercise Pattern Changes
- More sedentary

Kidney Function Changes
- Decreased function
- Decreased drug clearance

Affective/Cognitive Changes
- Medications/meals omitted or taken erratically

Socioeconomic Factors
- Fad diets
- Loneliness/living alone
- Lack of money/lack of support system

Chronic Diseases
- Hypertension
- Arthritis
- Neoplasms
- Acute/chronic infections

Potential Drug Interactions
- Use of another person's medications
- Consulting multiple health providers for different illnesses
- Alcohol use/abuse

Nursing Alert

The stress response results in hyperglycemia because it activates the sympathetic nervous system. The ensuing increase in catecholamines, systemically derived from the adrenal gland or released locally at the level of the liver, increases hepatic

glycogenolysis and the release of large quantities of glucose into the bloodstream while inhibiting the release of insulin. Thus, all patients who are stressed are at risk for hyperglycemia.

Treatment varies because of changes in lifestyle and physical and emotional status as well as because of advances in treatment methods. Therefore, diabetes management involves ongoing assessment and modification of the treatment plan as needed. Although the health care team directs treatment, it is the individual patient who must manage the complex therapeutic regimen. For this reason, education of the patient and family is an essential component of diabetes treatment.

Nutrition

Nutrition is the foundation of diabetes management. Nutrition management alone can be associated with reversal or significant improvement of hyperglycemia in type 2 diabetes. The most important objectives in the dietary management of diabetes are control of total caloric intake to attain or maintain a reasonable body weight, control of blood glucose levels, and normalization of lipids and blood pressure to prevent heart disease. However, achieving these goals is not always easy. Because medical nutrition therapy (nutritional therapy) for diabetes is complex, a registered dietitian who understands diabetes management has the primary responsibility for designing and teaching this aspect of the therapeutic plan. Nurses and other members of the health care team must be knowledgeable about nutrition therapy and supportive of patients who need to implement diet and lifestyle changes. Nutrition management of diabetes includes the following guidelines (ADA, 2017c):

- Promote eating patterns that help improve glucose, blood pressure, and lipid control.
- Tailor therapy to each person's individual cultural and behavioral needs.
- Emphasize the pleasure of eating while changing eating habits.
- Provide practical tools for healthy eating.

For patients who require insulin to help control blood glucose levels, maintaining as much consistency as possible in the amounts of calories and carbohydrates ingested at each meal is essential. In addition, consistency in the approximate time intervals between meals, with the addition of snacks if necessary, helps prevent hypoglycemic reactions and maintain overall control of blood glucose.

For patients who are overweight and obese and have type 2 diabetes, weight loss is an important part of treatment. Weight loss of more than 5% of total weight may improve blood glucose levels (Franz, 2015). Some patients with type 2 diabetes who require insulin or other agents to control blood glucose levels may be able to reduce or eliminate the need for medication through weight loss.

Consistently following a meal plan is one of the most challenging aspects of diabetes management. However, pacing food intake throughout the day and decreasing overall caloric intake places more manageable demands on the pancreas and can lead to weight loss. For obese patients with diabetes who do not take insulin or other agents, consistent meal content or timing is important but not as critical.

Nursing Alert

It is important to assess the patient's blood sugar BEFORE meals when insulin coverage is ordered since the patient's blood sugars will rise after ingesting food.

Meal Planning

For all patients with diabetes, the meal plan must consider the patient's food preferences, lifestyle, usual eating times, and ethnic and cultural background. Advances in diabetes management and insulin therapy allow greater flexibility in the timing and content of meals. This contrasts with the older concept of maintaining a constant dose of insulin, which required patients to adjust their schedule to the actions and duration of the insulin.

When teaching about meal planning, clinical dietitians use various educational tools, materials, and approaches. Initial education addresses the importance of consistent eating habits, the relationship of food and insulin, and the provision of an individualized meal plan. In-depth follow-up education then focuses on management skills, such as eating at restaurants, reading food labels, and adjusting the meal plan for exercise, illness, and special occasions. The nurse plays an important role in communicating pertinent information to the dietitian and reinforcing the patient's understanding.

For some patients, certain aspects of meal planning may be difficult to learn. This may be related to limitations in the patient's intellectual level or to emotional issues, such as difficulty accepting the diagnosis of diabetes or feelings of deprivation. In any case, it helps to emphasize that nutritional management of diabetes provides a new way of thinking about food, rather than a new way of eating. It is also important to simplify information as much as possible and to provide opportunities for the patient to practice and repeat activities and information.

Caloric Requirements and Distribution. Calorie-controlled diets are planned by first calculating a person's energy needs and caloric requirements based on age, gender, height, and weight. Then an activity element is factored in to provide the actual number of calories required for weight maintenance. To promote a 1- to 2-lb weight loss per week, 500 to 1,000 calories are subtracted from the daily total. The calories are distributed into carbohydrates, proteins, and fats, and a meal plan is developed with consideration of the patient's lifestyle and food preferences. Currently, the ADA and the American Dietetic Association recommend that the percentages of carbohydrate, protein, and fat of any diet be tailored specifically to each individual (ADA, 2017c).

Carbohydrates. Carbohydrates are an important source of energy. In general, carbohydrates have the greatest effect on blood glucose levels because they are more quickly digested than other foods and are converted into glucose rapidly.

Sources of carbohydrates include grains, fruits, vegetables, legumes, and milk. The majority of carbohydrate selections in the diabetic diet should come from these sources. Foods containing sucrose (sugar) may be included in the diabetic diet. However, because they are typically high in fat and lack vitamins, minerals, and fiber, sucrose-containing foods and beverages should be limited. All carbohydrates should be eaten in moderation to avoid high postprandial (after meal) levels of blood glucose (ADA, 2017c).

Fats. The current recommendations regarding fat content of the diabetic diet is the same as that for the general population. Increased intake of foods, such as fish, containing long-

chain omega-3 fatty acids is recommended (ADA, 2017c).

Protein. The amount of protein intake in people with diabetes should be tailored to their specific needs. Because protein appears to have minimal effect on glucose level, foods with significant protein content should be avoided for treatment of hypoglycemia (ADA, 2017c).

Food Classification Systems. To teach diet principles and to help patients with meal planning, several systems have been developed in which foods are organized into groups with common characteristics, such as number of calories, composition of foods, or effect on blood glucose levels. Food intake can be managed several ways, including carbohydrate counting, exchange lists, food lists, and calorie counting.

Carbohydrate Intake. Because carbohydrates are the main nutrients in food that influence blood glucose, monitoring carbohydrate intake by carbohydrate counting, exchange lists, or experienced-based estimation can be effective ways to achieve control of blood glucose (ADA, 2017c).

Carbohydrate counting provides flexibility in food choices and can be less complicated to understand than other systems. It also allows for more accurate management with medication and exercise, particularly with insulin. Insulin-to-carbohydrate (I:C) ratios are patient specific and can change over time with changes in weight and other health issues. For example, a patient with an I:C ratio of 1:15 would take 1 unit of insulin for every 15 g of carbohydrate consumed. All food sources of carbohydrates should be considered when developing a diabetic meal plan using carbohydrate counting. Patients who can manage insulin-to-carbohydrate calculations have the potential to enjoy a more flexible lifestyle and more predictable diabetes control.

Exchange lists also are used for the nutritional management of diabetes but have largely been replaced by carbohydrate counting. The Exchange Lists for Meal Planning (ADA, 1995; Oh, Rastogi Kalyani, & Dobs, 2014) consist of six main exchange lists: (1) starch, (2) fruit, (3) milk (4) vegetable, (5) meat, and (6) fat. Foods included on each list, in the amounts specified, contain equal numbers of calories and are approximately equal in grams of protein, fat, and carbohydrate. Meal plans are based on a recommended number of choices from each exchange list. Foods on one list may be interchanged with one another, allowing the patient to choose a variety while maintaining as much consistency as possible in the nutrient content of foods eaten. Table 30-2 presents three sample lunch menus that are interchangeable in terms of carbohydrate, protein, and fat content.

Other Dietary Concerns

Alcohol. Patients with diabetes do not need to give up alcoholic beverages entirely, but they must be aware of the potential adverse effects of alcohol specific to diabetes. Alcohol is absorbed before other nutrients and does not require insulin for absorption. Large amounts can be converted to fats, increasing the risk for DKA. In general, the same precautions regarding the use of alcohol by people without diabetes should be applied to patients with diabetes. Patient teaching about alcohol intake must emphasize moderation in the amount of alcohol consumed. Moderate intake is considered to be one alcoholic beverage per day for women and two per day for men (ADA, 2017c).

A major danger of alcohol consumption by the patient with diabetes is hypoglycemia, especially for patients who take insulin or secretagogues (an agent that stimulates secretion of another substance; in relation to diabetes, secretagogues stimulate insulin secretion). Alcohol may decrease the normal physiologic reactions in the body that produce glucose (gluconeogenesis). Therefore, if a patient with diabetes consumes alcohol on an empty stomach, there is an increased likelihood of hypoglycemia. In addition, excessive alcohol intake may impair the patient's ability to recognize and treat hypoglycemia or to follow a prescribed meal plan to prevent hypoglycemia. To reduce the risk of hypoglycemia, the patient should be cautioned to consume food with alcohol.

TABLE 30-2 Selected Sample Lunch Menus from Exchange Lists

Exchanges	Sample Lunch #1	Sample Lunch #2	Sample Lunch #3
2 starch	2 slices bread	Hamburger bun	1 cup cooked pasta
3 meat	2-oz sliced turkey and 1-oz low-fat cheese	3-oz lean beef patty	3-oz boiled shrimp
1 vegetable	Lettuce, tomato, onion	Green salad	½ cup plum tomatoes
1 fat	1-tsp mayonnaise	1-tbsp salad dressing	1-tsp olive oil
1 fruit	1 medium apple	1¼ cup watermelon	1¼ cup fresh strawberries
"Free" items (optional)	Unsweetened iced tea Mustard, pickle, hot pepper	Diet soda 1-tbsp catsup, pickle, onions	Ice water with lemon Garlic, basil

Sweeteners. There are two main types of sweeteners: nutritive and non-nutritive. Nutritive sweeteners contain calories; non-nutritive sweeteners have few or no calories in the amounts normally used. It is unclear whether the use of non-nutritive sweeteners is acceptable for patients with diabetes. While non-nutritive sweeteners lack calories, which would potentially aid in weight loss and glucose control, recent studies suggest that non-nutritive sweeteners have similar metabolic effects as sugar (Pepino, 2015). Moderation in the amount of any type of sweetener that is used is encouraged to avoid potential adverse effects (Shankar, Ahuja, & Sriram, 2013).

Misleading Food Labels. Food manufacturers are required to include the nutrition content of foods on package labels. Reading food labels is an important skill for patients to learn and use when food shopping.

Foods labeled "sugarless" or "sugar-free" may still provide calories equal to those of the equivalent sugar-containing products if they are made with nutritive sweeteners. Therefore, for weight loss, these products may not always be useful. In addition, patients must not consider them "free" foods to be eaten in unlimited quantity because they can elevate blood glucose levels.

Foods labeled "dietetic" are not necessarily reduced-calorie foods. They may be lower in sodium or have other special dietary uses. Patients are advised that foods labeled "dietetic" still may contain significant amounts of sugar or fat.

Patients also must be taught to read the labels of "health foods"—especially snacks—because they often contain carbohydrates, such as honey, brown sugar, and corn syrup. In addition, these supposedly healthy snacks frequently contain saturated vegetable fats (e.g., coconut or palm oil), hydrogenated vegetable fats, or animal fats, which may be

contraindicated in people with elevated blood lipid levels.

Exercise

Benefits

Exercise is extremely important in diabetes management because of its effects on lowering blood glucose, aiding in weight loss, and reducing cardiovascular risk factors. Exercise lowers blood glucose levels by increasing the uptake of glucose by body muscles and by improving insulin utilization. These effects are useful in patients with diabetes in relation to losing weight, easing stress, and maintaining a feeling of well-being. Exercise also alters blood lipid concentrations, increasing levels of high-density lipoproteins (HDLs) and decreasing levels of total cholesterol and triglycerides. This is especially important for people with diabetes because of their increased risk of cardiovascular disease.

Exercise Precautions

Exercise in the setting of insulin deprivation and acute ketosis can lead to worsening hyperglycemia and ketosis. Patients should monitor urine ketones prior to exercise and should not begin exercising until urine test results are negative for ketones. Hyperglycemia in the absence of ketonuria is not a contraindication for exercise.

Exercising facilitates glucose uptake via intracellular means; therefore, patients also should be instructed to avoid unexpected hypoglycemia. Patients who require insulin or insulin secretagogues should be taught to check a blood glucose level prior to exercising. If the blood glucose is less than 100 mg/dL (5.6 mmol/L), carbohydrate should be consumed prior to starting the exercise (ADA, 2017c). Insulin doses also may need to be altered around the time of exercise to avoid hypoglycemia. The exact change in insulin dose and amount of food needed varies from person to person and should be determined by monitoring blood glucose. Another potential problem for patients who take insulin is hypoglycemia that occurs many hours after exercise. To avoid postexercise hypoglycemia, especially after strenuous or prolonged exercise, the patient may need to eat a snack at the end of the exercise session and at bedtime as well as monitor the blood glucose level more frequently. Other participants or observers should be aware that the person exercising has diabetes, and they should know how to assist if hypoglycemia occurs.

Regular daily exercise, rather than sporadic exercise, should be encouraged. Exercise recommendations must be altered as necessary for patients with diabetic complications, such as retinopathy, autonomic neuropathy, sensorimotor neuropathy, and cardiovascular disease (ADA, 2017c). Increased blood pressure associated with exercise may aggravate diabetic retinopathy and increase the risk of a hemorrhage into the vitreous or retina. Patients with ischemic heart disease risk triggering angina or a myocardial infarction. Avoiding trauma to the lower extremities is especially important in patients with numbness related to neuropathy.

In general, a slow, gradual increase in the exercise period is encouraged. For many patients, walking is a safe and beneficial form of exercise that, other than proper shoes, requires no special equipment and can be performed anywhere. People with diabetes should discuss exercise with their health care providers and undergo medical evaluation before starting an exercise program (ADA, 2017c).

Monitoring Glucose Levels and Ketones

Self-Monitoring of Blood Glucose

Blood glucose monitoring is a cornerstone of diabetes management. Self-monitoring of blood glucose (SMBG) levels by patients has altered diabetes care dramatically. Using frequent SMBG and learning how to respond to the results enable people with diabetes to adjust their treatment regimen to obtain optimal control of blood glucose. This allows for detection and prevention of hypoglycemia and hyperglycemia and plays a crucial role in normalizing blood glucose levels, which, in turn, may reduce the risk of long-term diabetic complications.

SMBG is a key component of treatment for any intensive regimen of insulin therapy and for diabetes management during pregnancy. It is also recommended for patients with unstable diabetes, those with a tendency to develop severe ketosis or hypoglycemia, and for patients who experience hypoglycemia without warning symptoms.

Various methods for SMBG are available. Most involve applying a drop of blood to a special reagent strip and allowing the blood to stay on the strip for the amount of time specified by the manufacturer. Blood glucose meters give a digital readout of the blood glucose value.

Advantages and Disadvantages of SMBG Systems. Methods for SMBG must match the skill level of patients. Factors affecting SMBG performance include visual acuity, fine motor coordination, cognitive ability, comfort with technology and willingness to use it, and cost.

The use of meters to monitor blood glucose is recommended because meters have become much less expensive and less dependent on technique, making the results more accurate. Most insurance companies cover some or all of the costs of meters and strips.

Nurses play an important role in providing initial teaching about techniques for SMBG. Equally important is evaluating the techniques of patients who are experienced in self-monitoring. Patients should be discouraged from purchasing SMBG products from stores or catalogs that do not provide direct education. The accuracy of the meter and strips also should be assessed with control solutions specific to that meter whenever a new vial of strips is used and whenever the validity of the reading is in doubt.

Frequency. For most patients who require insulin, SMBG is recommended two to four times daily, usually before meals and at bedtime. For patients on intensive insulin regimens, such as those on pump therapy or basal-bolus insulin regimens, SMBG is recommended up to 6 to 10 times per day (ADA, 2017d). Patients not receiving insulin may be instructed to assess their blood glucose levels at least two or three times a week, including a 2-hour postprandial test. For all patients, testing is recommended whenever hypoglycemia or hyperglycemia is suspected. Patients should increase the frequency of SMBG with changes in medications, activity, or diet and with stress or illness. Patients are asked to keep a record or logbook of blood glucose levels so that patterns can be detected. SMBG instruction should include parameters for contacting the primary care or endocrine provider.

Continuous Glucose Monitoring System

A continuous glucose monitoring system (CGMS) uses technology capable of monitoring

blood glucose continuously. A sensor capable of measuring glucose in the interstitial fluid is inserted subcutaneously, and the information is transmitted to a receiver or blue-tooth enabled device. The glucose is measured approximately every 3 to 5 minutes, providing real-time information regarding glucose level and rate of change in either direction. Information from the CGMS is especially useful for patients using insulin pumps and intensive insulin regimens in that it can warn the patient of hypoglycemia and hyperglycemia, as well as provide information regarding patterns of diabetes control over specific periods of time. Figure 30-2 shows a CGMS.

Measuring Glycated Hemoglobin

A1c is a blood test that reflects average blood glucose levels over a period of several months (ADA, 2017d). When blood glucose levels are elevated, glucose molecules attach to hemoglobin in red blood cells. The longer the amount of glucose in the blood remains above normal, the more glucose binds to hemoglobin and the higher the glycated hemoglobin level becomes. The glucose remains attached to the hemoglobin for the life of the individual red blood cell, approximately 90 to 120 days. If near-normal blood glucose levels are maintained, with only occasional increases, the overall value will not be elevated greatly. However, if the blood glucose values are consistently high, then the test result also is elevated. If the patient reports mostly normal results of SMBG but the glycated hemoglobin is high, there may be errors in the methods used for glucose monitoring, errors in recording results, or frequent elevations in glucose levels at times during the day when the patient is not usually monitoring blood sugar levels. Normal values differ slightly from test to test and from laboratory to laboratory but typically range from 4% to 6%. Values within the normal range indicate consistently near-normal concentrations of blood glucose, a goal made easier by SMBG.

FIGURE 30-2 MiniMed CGMS System Gold Continuous Glucose Monitoring System (Medtronic, Northridge, CA).

It should be noted that the A1c can be affected by changes in red blood cell turnover and that A1c levels do not correlate with SMBG in some patients. Also, because the A1c represents average glucose levels, it does not provide any information regarding the variability in a particular patient's blood glucose (ADA, 2017d).

Urine Glucose Testing

Before SMBG was available, urine glucose testing was the only way to monitor diabetes on a daily basis. Its advantages are that it is less expensive than SMBG, noninvasive, and painless. However, urine glucose testing is not recommended because the results do not accurately reflect blood glucose level at the time of the test and because the renal threshold for glucose, 180 to 200 mg/dL, is far above target blood glucose levels.

Furthermore, because age and kidney function can affect the renal threshold, it is not an

accurate measure of blood glucose control. Finally, urine testing for glucose cannot detect or measure hypoglycemia.

Testing for Ketones

Ketones (or ketone bodies) are by-products of fat breakdown that accumulate in the blood and urine. Ketones in the urine signal that control of type 1 diabetes is deteriorating and that the risk of DKA is high. When there is little or no effective insulin available, the body starts to break down stored fat for energy. Urine testing is the most common method used for self-testing of ketone bodies by patients. A urine dipstick (Ketostix or Chemstrip uK) is used to detect ketonuria. Other strips are available for measuring both urine glucose and ketones (Keto-Diastix or Chemstrip uGK).

Urine ketone testing should be performed whenever patients with type 1 diabetes have glycosuria, persistently elevated blood glucose levels, or are symptomatic for DKA, as well as during illness and pregnancy.

Pharmacologic Therapy

As previously stated, insulin is secreted by the beta cells of the islets of Langerhans and works to lower the blood glucose level after meals by facilitating the uptake and utilization of glucose by muscle, fat, and liver cells. In the absence of adequate insulin levels or utilization, pharmacologic therapy is essential.

Insulin Therapy

In type 1 diabetes, exogenous insulin must be administered daily for life because the body no longer produces adequate insulin. In type 2 diabetes, insulin may be necessary on a long-term basis to control glucose levels if meal planning and other agents are ineffective. In addition, some patients with type 2 diabetes who usually are controlled by meal planning alone, or by meal planning and an antidiabetic agent, may require insulin temporarily during illness, infection, pregnancy, surgery, or other stressful events.

Sources of Insulin. In the past, all insulins were obtained from pork and beef pancreas. Currently, recombinant DNA technology or genetic engineering is used to create "human" insulin. Human source insulin, which is designed to act more like insulin from the human pancreas, is now standard therapy.

Insulin Preparations. Insulin is available in the following preparations: rapid-acting, short-acting, intermediate-acting, and long-acting. In general, the rapid- and short-acting insulins are expected to cover the increase in glucose levels after meals soon after injection; the intermediate-acting insulins are expected to cover subsequent meals; and the long-acting insulins provide a relatively constant (or basal) level of insulin. Table 30-3 summarizes categories of insulin.

Rapid-acting or "bolus" insulins, such as insulin lispro (Humalog), insulin aspart (NovoLog), and insulin glulisine (Apidra), produce a rapid effect that attempts to mimic the normal physiologic response of the pancreas to food intake. These insulins must be timed to the meal because of their rapid onset. The patient should be instructed to eat within 15 minutes of taking the insulin. The short duration of action of these insulins

usually requires that patients with type 1 diabetes and some patients with type 2 or gestational diabetes receive additional longer-acting insulin to maintain glucose control.

TABLE 30-3 Categories of Subcutaneous Insulin

Time Course	Agent	Onset	Peak	Duration	Indications
Rapid-acting	Lispro (Humalog) Aspart (Novolog) Glulisine (Apidra)	15 minutes 15 minutes 15 minutes	1 h 40–50 minutes 1 hour	3–5 hours 3–5 hours	Used for rapid reduction of glucose level, to treat postprandial hyperglycemia, and/or to prevent nocturnal hypoglycemia "Meal-time insulin"
Short-acting	Regular (Humulin-R, Novolin-R)	½–1 hour	2–3 hours	4–6 hours	Usually administered 20–30 minutes before a meal; may be taken alone or in combination with longer-acting insulin
Intermediate-acting	NPH (Humulin N, Novolin N)	2–4 hours	6–8 hours	12–16 hours	Usually taken after food
Long-acting	Glargine (Lantus, Basaglar) Glargine U-300 (Toujeo) Detemir (Levemir) Degludec (Tresiba)	2 hours	Continuous (no defined onset or peak)	24 hours 42 hours	Used for basal dose

Short-acting insulin, called regular insulin and marked "R" on the vial, is an unmodified clear solution that usually is administered 20 to 30 minutes before a meal. Regular insulin is the only insulin that can be given intravenously and is used to treat DKA. It can be given either alone or in combination with modified longer-acting insulins. Humulin R and Novolin R are examples of regular insulin.

Intermediate-acting insulin is NPH insulin, marked "N" on the vial. Intermediate-acting insulin is cloudy and white in appearance and frequently is used in combination with rapid-acting insulin. To avoid hypoglycemia, it is important that patients eat around the time of the onset and peak of intermediate-acting insulin. Humulin N and Novolin N are examples of NPH insulins.

Basal insulins are long-acting insulins that act consistently over 24 hours. They are given subcutaneously, once a day, and do not have a peak time of effect. Examples of basal insulins are insulin glargine (Lantus), insulin detemir (Levemir), and insulin degludec (Tresiba). Although these insulins are clear and colorless, mixing them with other insulins may cause a dangerous precipitation or diminish the effect of the insulin. Basal insulins can be given once a day and should be given at approximately the same time each day.

Most insulins are considered U-100 insulin, which refers to the concentration of the insulin per volume. In other words, every 1 mL of insulin contains 100 units. This allows for standardization and accuracy in dosing. There are, however, other insulins that are more concentrated for those patients with significant insulin resistance who require larger volumes of insulin each day. Toujeo is insulin glargine U-300. That is, it is modified to be three times more concentrated than U-100 Lantus. Tresiba is available as both U-100 and U-200 concentrations. Humulin R U-500 is five times more concentrated than conventional insulins. A 10-unit dose change in Humulin R U-500 is equivalent to a 50-unit dose change in conventional U-100 insulin. Humalog is also available as U-200 insulin.

Afrezza is the only inhaled insulin approved for use in the United States. This insulin is

used as a pre-meal dose and is delivered through an inhaler device. Afrezza is a rapid-acting or bolus insulin and is available in 4- and 8-unit cartridges. Multiple cartridges can be used consecutively for higher insulin requirements. Patients must undergo spirometry testing prior to using inhaled insulin. Afrezza is contraindicated in patients with chronic lung disease, and only patients who do not smoke or who have not smoked for at least 6 months can use the medication.

Insulin Regimens. Insulin regimens vary from one to four or more injections a day. Usually there is a combination of short-acting insulin and longer-acting insulin in order to more closely approximate insulin secretion in a system without diabetes. The normally functioning pancreas continuously secretes small amounts of insulin during the day and night. In addition, whenever blood glucose increases after ingestion of food, there is a rapid burst of insulin secretion in proportion to the glucose-raising effect of the food. The goal of all but the simplest, one-injection insulin regimens is to mimic this normal pattern of insulin secretion in response to food intake and activity patterns. Table 30-4 illustrates several insulin regimens, including the advantages and disadvantages of each.

TABLE 30-4 Insulin Regimens

Schematic Representation	Description	Advantages	Disadvantages
Normal pancreas 	Release of insulin increases when levels of blood glucose rise and continues at a low, steady rate between meals.		
One injection per day 	Morning or night • Long-acting (basal) insulin	Simple regimen	Afternoon hypoglycemia may result from attempts to control the level of fasting glucose by increasing NPH dose
Two injections per day-mixed 	Before breakfast and dinner: • NPH or • NPH with rapid-acting insulin or • Premixed (rapid-acting insulin) insulin	Simplest regimen that attempts to mimic normal pancreas	Need relatively fixed schedule of meals and exercise Cannot independently adjust NPH or regular insulin if premixed insulin is used
Three or four injections per day 	Rapid-acting insulin before each meal with: • Glargine one or two times per day	More closely mimics normal pancreas than two-injection regimen Each premeal dose of bolus insulin is determined independently More flexibility with meals and exercise	Requires more injections than other regimens Requires multiple blood glucose tests on a daily basis Requires intensive education and follow-up
Insulin pump 	Uses ONLY rapid-acting insulin (lispro, aspart, glulisine) infused at continuous, low rate called *basal rate* (commonly 0.5–1.5 units/hr) and premeal *bolus doses* activated by pump wearer	Most closely mimics normal pancreas Decreases unpredictable peaks of intermediate-acting and long-acting insulins Increases flexibility around meals and exercise	Requires intensive training and frequent follow-up Potential for mechanical problems Requires multiple blood glucose tests on a daily basis Potential increase in expenses (depending on insurance coverage)

BR, breakfast; LU, lunch; DI, dinner; SN, snack. Rapid-acting insulin; lispro, aspart, or glulisine.

The more intensive regimens require significant education and close follow-up by the health care team. There is a greater risk of hypoglycemia with the intensive regimens, but often they are more effective at controlling glucose more closely.

Conventional Insulin Therapy. One approach to insulin use is to simplify the regimen as much as possible, with the goal of avoiding acute complications of diabetes (hypoglycemia and symptomatic hyperglycemia). Conventional insulin therapy typically involves one

injection per day of long-acting insulin, but other insulins, such as short-acting or mixed insulins, can be used depending on the patient's blood glucose pattern.

Intensive Insulin Therapy. A second approach is to use a more complex insulin regimen to achieve levels of blood glucose that are as close to normal as is safe and practical. An intensive insulin therapy regimen involves three to four injections of insulin a day using both long-acting and short-acting insulin or using insulin pump therapy. Although intensive treatment is beneficial in reducing the risk of complications, not all people with diabetes are candidates for this approach to diabetes management.

Nursing Alert
When administering insulin, it is very important to read the label carefully and to be sure that the correct type of insulin is administered. Take care to avoid mistaking Lantus insulin for Lispro insulin (because both begin with "L") or Lantus for regular insulin because both are clear.

Teaching Patients to Self-Administer Insulin. Insulin injections are self-administered into the subcutaneous tissue with the use of insulin-specific syringes. A variety of syringes, insulin pens, and injection-aid devices is available.

Storing Insulin. All insulin, including spare pens and vials not in use, should be refrigerated. Extremes of temperature should be avoided; insulin should not be allowed to freeze and should not be kept in direct sunlight or in high temperatures. The insulin pen or vial in use should be kept at room temperature to reduce local irritation at the injection site, which may occur if cold insulin is injected. Typically, insulin can be kept at room temperature for 1 month, but the patient should consult the package insert for individual instructions for each type of insulin.

Vials of intermediate-acting insulin also should be inspected for flocculation, which is a frosted, whitish coating inside the bottle. If a frosted, adherent coating is present, some of the insulin is bound and should not be used. Pens or vials of insulin that have been open for more than 1 month or those that have passed the expiration date also should be discarded.

Selecting Syringes. Syringes must be matched with the insulin concentration (e.g., U-100). Currently, three sizes of U-100 insulin syringes are available:

- 1-mL syringes that hold 100 units
- 0.5-mL syringes that hold 50 units
- 0.3-mL syringes that hold 30 units

Insulin syringes are disposable and have a 31-gauge needle that is 6 mm, 8 mm, or 12.7 mm long. The smaller syringes are marked in 1-unit increments and may make it easier for patients with visual deficits and those taking very small doses of insulin to get a dose that is more accurate. The 1-mL syringes are marked in 1- and 2-unit increments.

Preparing the Injection: Mixing Insulins. Regular and NPH insulins can be mixed together in the same syringe. Regular insulin must be inspected for clarity and not used unless it is

crystal clear. NPH will be cloudy and should be mixed carefully by rolling the vial gently. The regular insulin is drawn into the syringe first, followed by the NPH. Injecting cloudy insulin into a vial of clear insulin contaminates the entire vial of clear insulin and alters its action.

Patients who have difficulty mixing insulins have two options. They may use premixed insulin in a vial or in a prefilled syringe. A prefilled syringe is shown in Figure 30-3; it is also discussed in detail below. Premixed insulins are available in different ratios of NPH insulin to regular insulin. The ratio of 70/30 (70% NPH and 30% regular insulin in one vial) is most common; this combination is available as Novolin 70/30 (Novo-Nordisk) and Humulin 70/30 (Lilly). Humulin is also available in a 50/50 ratio (Humulin 50/50).

FIGURE 30-3 Prefilled insulin syringe.

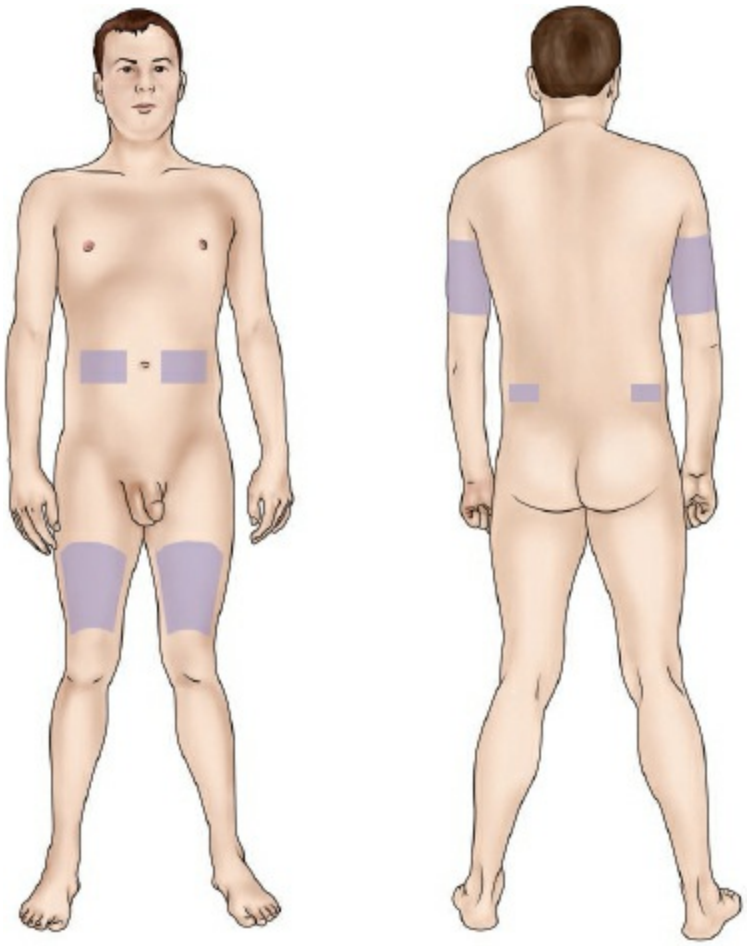

FIGURE 30-4 Suggested areas for insulin injection.

For patients who can inject insulin but who have difficulty drawing up a single or mixed dose, syringes may be prefilled with the help of home care nurses or family and friends. A 3-week supply of insulin syringes may be prepared and kept in the refrigerator. Prefilled syringes should be stored with the needle in an upright position to avoid clogging of the needle. Like insulin in vials, prefilled syringes should be rotated gently between the hands to mix and warm the insulin before injection.

Selecting and Rotating the Injection Site. As shown in Figure 30-4, the four main areas for injection are the abdomen, the posterior surface of the upper arms, the anterior surface of the thighs, and the flank area. Insulin is absorbed faster in some areas of the body than in others. The rate of absorption is greatest in the abdomen and decreases progressively in the arm, thigh, and hip, respectively.

Systematic rotation of injection sites within an anatomic area is recommended to prevent localized changes in fatty tissue (lipodystrophy). To promote consistency in insulin absorption, the patient should be encouraged to use all available injection sites within one area rather than randomly rotating sites from area to area (ADA, 2004d). Another approach to site rotation is always to use the same area at the same time of day. For example, patients may inject morning doses into the abdomen and evening doses into the arms or legs.

Nursing Alert

If the patient plans to exercise, insulin should not be injected into the limb that will be exercised because this can cause faster absorption and may result in hypoglycemia.

Insulin Injection. The injection site is cleansed prior to insertion of the needle. To inject insulin, the skin is gently pinched and the needle inserted at a 90-degree angle. For patients with a lower BMI, a 45-degree angle can be used to avoid inadvertently injecting into muscle. Injection sites should be at least 1 inch apart. An injection that is too deep or too shallow may affect the rate of absorption. Because insulin is injected into subcutaneous tissue, routine aspiration to assess for blood being drawn into the syringe is not necessary. Box 30-5 illustrates patient education for insulin injection. Box 30-6 details how to evaluate the effectiveness of self-injection of insulin education.

Nursing Alert
When administering insulin subcutaneously, the injection site should not be massaged because massaging can interfere with insulin absorption.

Insulin Pens. Insulin pens are prefilled devices for insulin delivery that provide more accurate insulin delivery. Each pen typically holds 300 units of insulin. Rather than having to measure the insulin in a syringe, the pen device allows the patient to select the correct number of units by turning a knob on the end of the pen. A one-time-use pen needle is attached to the pen prior to using and can be discarded the same way as insulin syringes. Insulin pens are generally more convenient than insulin syringes, particularly during travel or eating out. They also are useful for patients with impaired manual dexterity, vision, or cognitive function that makes the use of traditional syringes difficult. Insulin injection technique is the same with the insulin pen as it is for insulin syringe. Insulin pens should not be used for more than one person as blood and other biologic material may transfer into the insulin and cause transmission of blood-borne pathogens between patients.

Selecting Insulin Pen Needles. There are a variety of sizes of pen needles available. In general, all brands are interchangeable and can be used on all insulin pens. Sizes range from 4 mm/32-gauge to 12.7 mm/29-gauge. For most patients, the smaller needles will allow for equivalent glucose control but less pain on injection compared to the larger needles (Bergenstal et al., 2015).

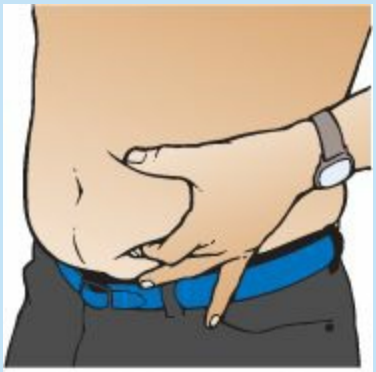
Alternative Methods of Insulin Delivery. Alternative methods of insulin delivery include the use of insulin pumps and jet injectors.

Continuous Subcutaneous Insulin Infusion (CSII): Insulin Pumps. Continuous subcutaneous insulin infusion (CSII), or insulin pump therapy, involves the use of small devices worn externally that more closely mimic the functioning of the normal pancreas. Insulin pumps contain a special syringe, called a reservoir, and are connected to a subcutaneous needle by a thin, narrow-lumen tube with a needle or Teflon catheter attached to the end. The patient inserts the needle or catheter into subcutaneous tissue, usually on the abdomen, and secures it with tape or a transparent dressing. The needle or catheter is changed and the reservoir is refilled at least every 2 to 3 days. Figure 30-5 illustrates CSII equipment.

BOX 30-5 Patient Education

Self-Injection of Insulin

1. With one hand, stabilize the skin by spreading it or pinching up a large area.



Pinching the skin

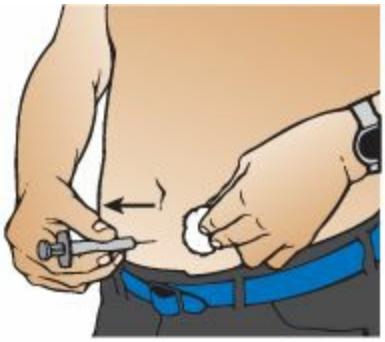
2. Pick up the syringe with the other hand and hold it as you would a pencil. Insert the needle straight into the skin.[a]

Inserting the needle into the skin

3. To inject the insulin, push in the plunger all the way.

Injecting the insulin

4. Pull the needle straight out of the skin. Press a cotton ball over the injection site for several seconds.



Removing the needle and holding cotton ball over site

5. Use a disposable syringe *only once* and discard it into a hard plastic container (with a tight-fitting top), such as an empty bleach or detergent container. Follow state regulations for disposal of syringes and needles.

Disposing of syringe

[a]Some patients may be taught to insert the needle at a 45-degree angle.

In order to more closely approximate the action of a pancreas that is functioning normally, the insulin pump is programmed to deliver rapid-acting insulin in both a basal and bolus manner. The basal rate is infused continuously over 24 hours, though the rate itself can be tailored to the patient's specific needs at specific times of day. For instance, the basal rate is set at a higher rate overnight if the patient has a history of dawn phenomenon (abnormal early-morning increase in blood sugar—usually between 3 and 8 AM) or abnormal nocturnal rise in blood glucose due to release of hormones. Boluses at meals can be calculated by the pump after the patient inputs the blood glucose at the time of the bolus and the amount of carbohydrate that he or she intends to consume. Because the pump is infusing rapid-acting insulin, the patient has increased control over delivery of the insulin and, therefore, has more flexibility regarding meal times, food choices, and exercise timing. The pump can easily be disconnected for limited periods for showering, exercise, or sexual activity.

In general, only rapid-acting insulins, such as lispro, aspart, and glulisine, are used in the insulin pump. In rare cases, Humulin R U-500 insulin may be used for patients who have extreme insulin resistance.

One disadvantage of insulin pumps is that unexpected disruptions in the flow of insulin from the pump may happen if the tubing or needle becomes occluded, if the supply of

insulin runs out, or if the battery is depleted. These occurrences increase the risk of DKA. Another disadvantage is the potential for infection at the sites of needle insertion. Effective patient teaching minimizes these risks. Hypoglycemia also may occur with insulin pump therapy; however, this usually is related to the lowered level of blood glucose achieved by many patients rather than to a specific problem with the pump itself.

BOX 30-6 Outcome Criteria for Determining Effectiveness of Self-Injection of Insulin Education

Equipment

Insulin

1. Identifies information on label of insulin vial or pen:
   - Type (e.g., NPH, regular, 70/30)
   - Species (human, biosynthetic, pork)
   - Manufacturer (Lilly, Novo Nordisk)
   - Concentration (e.g., U-100)
   - Expiration date
2. Checks appearance of insulin:
   - Clear or milky white
   - Checks for flocculation (clumping, frosted appearance)
3. Identifies where to purchase and store insulin:
   - Indicates approximately how long vial or pen will last (1,000 units per bottle U-100 insulin)
   - Indicates how long opened vials or pens can be used

Syringes

1. Identifies concentration (U-100) marking on syringe; U-100 = 100 units per 1 mL.
2. Identifies size of syringe (e.g., 500-unit 100-unit, 50-unit, 30-unit). The most common syringe used for insulin administration is a U-100. However, in the event that very small or large doses of insulin are required, syringe size may be varied. For example, a U-30 syringe = 30 units per mL, allowing for accurate withdrawal of small dosages; however, a U-500 syringe = 500 units per 1 mL, which may be required in patients with insulin resistance.
3. Describes appropriate disposal of used syringe.

Preparation and Administration of Insulin Injection

1. Draws up correct amount and type of insulin
2. Properly mixes two insulins if necessary
3. Inserts needle and injects insulin
4. Describes site rotation:
   - Demonstrates injection with all anatomic areas to be used

- Describes pattern for rotation, such as using abdomen only or using certain areas at the same time of day
- Describes system for remembering site locations, such as horizontal pattern across the abdomen as if drawing a dotted line

Knowledge of Insulin Action

1. Lists prescription:
   - Type and dosage of insulin
   - Timing of insulin injections
2. Describes approximate time course of insulin action:
   - Identifies long- and short-acting insulins by name
   - States approximate time delay until onset of insulin action
   - Identifies need to delay food consumption until 5–15 minutes after injection of rapid-acting insulin (lispro, aspart, glulisine)

Incorporation of Insulin Injections into Daily Schedule

1. States proper order of premeal diabetes activities:
   - May use mnemonic device such as the word "tie," which helps the patient remember the order of activities ("t" = test [blood glucose], "i" = insulin injection, "e" = eat).
   - Describes daily schedule, such as test, insulin, eat before breakfast and dinner; test and eat before lunch and bedtime.
2. Describes information regarding hypoglycemia:
   - Symptoms: shakiness, sweating, nervousness, hunger, weakness
   - Causes: too much insulin, too much exercise, not enough food
   - Treatment: 15-g concentrated carbohydrate, such as two or three glucose tablets, 1 tube glucose gel, or ½ cup of juice
   - After initial treatment, follow with snack that includes starch and protein, such as cheese and crackers, milk and crackers, half sandwich
3. Describes information regarding prevention of hypoglycemia:
   - Avoids delays in meal timing
   - Eats a meal or snack approximately every 4–5 hours (while awake)
   - Does not skip meals
   - Increases food intake before exercise if blood glucose level is less than 100 mg/dL
   - Checks blood glucose regularly
   - Identifies safe modification of insulin doses consistent with management plan
   - Carries a form of fast-acting sugar at all times
   - Wears a medical identification bracelet
   - Teaches family, friends, coworkers about signs and treatment of hypoglycemia
   - Has family, roommates, traveling companions who learn to use injectable glucagon for severe hypoglycemic reactions

4. Maintains regular follow-up for evaluation of diabetes control:
   - Keeps written record of blood glucose, insulin doses, hypoglycemic reactions, variations in diet
   - Keeps all appointments with health professionals
   - Sees health care provider regularly (usually two to four times per year)
   - States how to contact health care provider in case of emergency
   - States when to call health care provider to report variations in blood glucose levels

FIGURE 30-5 Medtronic (Northridge, CA) insulin pump system.

Candidates for the insulin pump must be willing to assess their blood glucose level several times daily. In addition, they must be psychologically stable and open about having diabetes because the insulin pump is a visible sign to others and a constant reminder to patients that they have diabetes. Most important, patients using insulin pumps must have extensive education in the use of the pump and in self-management of blood glucose and insulin doses.

The newest insulin pumps have increased decision-making capability. They combine continuous glucose sensing with insulin infusions and are able to stop the insulin infusion in the setting of unchecked hypoglycemia. Current research is focused on closed-loop systems that include dual hormone infusions with both insulin and glucagon that have the potential to be able to control blood glucose levels with limited input from the patient.

Jet Injectors. Jet injection devices deliver insulin through the skin under pressure in an extremely fine stream. These devices are more expensive than other methods of insulin administration and require thorough training and supervision when first used. In addition, patients should be cautioned that absorption rates, peak insulin activity, and insulin levels may be different when using a jet injector.

Disposing of Syringes and Needles. Insulin syringes and pens, needles, and lancets should be disposed of according to local regulations. Some areas have special programs for needle disposal to prevent sharps from being discarded in the main waste disposal system. If community disposal programs are unavailable, used sharps should be placed in a puncture-resistant container. The patient should contact local authorities for instructions about proper disposal of filled containers; containers of sharps should never be mixed with containers to be recycled.

Complications of Insulin Therapy. Reactions to insulin therapy and other complications may occur.

Local Allergic Reactions. A local allergic reaction (redness, swelling, tenderness, and induration) may appear at an injection site 1 to 2 hours after insulin administration. These reactions are becoming rare because of the increased use of human insulins.

Systemic Allergic Reactions. Systemic allergic reactions to insulin also are rare. When they do occur, there is an immediate local skin reaction that gradually spreads into generalized urticaria (hives). Treatment is desensitization with the administration of small doses of purified pork or human insulin in gradually increasing amounts. Occasionally, these rare reactions are associated with generalized edema or anaphylaxis.

Insulin Lipodystrophy. Lipodystrophy refers to a localized reaction at the insulin injection site, in the form of either lipoatrophy or lipohypertrophy. Lipoatrophy is loss of subcutaneous fat; it appears as slight dimpling or pitting of subcutaneous fat. Lipohypertrophy is the development of a fibrofatty mass; it appears as raised, hardened tissue. Because injection into a damaged site may delay absorption of insulin, use of these areas should be delayed until the lipodystrophy is resolved. The use of human insulin, site rotation, and administration of insulin at room temperature decreases the risk of lipodystrophy.

Resistance to Injected Insulin. Many patients have some degree of insulin resistance at one time or another for various reasons, the most common being obesity, which can be moderated by weight loss. Clinical insulin resistance has been defined as a daily insulin requirement of 200 units or more. Approaches to increased insulin requirements include using insulin sensitizers or using a more concentrated insulin preparation, such as U-500.

Fasting Hyperglycemia. An elevated level of blood glucose upon arising in the morning or after a period of fasting is caused by an insufficient level of insulin or lack of suppression of glucagon. Particular processes, including dawn phenomenon, the Somogyi effect, or insulin waning, also may be present. The *dawn phenomenon* is characterized by a blood glucose level that is relatively normal until approximately 3 AM, when blood glucose levels begin to

rise. This phenomenon is thought to result from nocturnal surges in growth hormone secretions, which create a greater need for insulin in the early morning hours in patients with type 1 diabetes. The dawn phenomenon must be distinguished from *insulin waning* (the progressive increase in blood glucose from bedtime to morning) and from the *Somogyi effect* (nocturnal hypoglycemia followed by rebound hyperglycemia).

It may be difficult to tell from a patient's history which of the above causes is responsible for morning hyperglycemia. To determine the cause, the patient must be awakened once or twice during the night to test blood glucose levels, or a continuous glucose sensor may be used. Testing at bedtime, at 3 AM, and on awakening or reviewing glucose patterns provided by a glucose sensor provides information that can be used to make adjustments in insulin to avoid morning hyperglycemia. Table 30-5 summarizes the differences among insulin waning, the dawn phenomenon, and the Somogyi effect.

TABLE 30-5 Causes of Morning Hyperglycemia

Characteristic	Treatment
Insulin Waning	
Progressive rise in blood glucose from bedtime to morning	Increase evening (predinner or bedtime) dose of intermediate- or long-acting insulin, or institute a dose of insulin before the evening meal if one is not already part of the treatment regimen.
Dawn Phenomenon	
Relatively normal blood glucose until about 3 AM, when the level begins to rise	Change time of injection of evening intermediate-acting insulin from dinnertime to bedtime.
Somogyi Effect	
Normal or elevated blood glucose at bedtime, a decrease at 2–3 AM to hypoglycemic levels, and a subsequent increase caused by the production of counterregulatory hormones	Decrease evening (predinner or bedtime) dose of intermediate-acting insulin, or increase bedtime snack.

Non-insulin Antidiabetic Agents

Non-insulin antidiabetic agents may be effective for patients with type 2 diabetes who cannot be treated effectively with diet and exercise alone. These agents include biguanides, dipeptidyl peptidase 4 (DPP-4) inhibitors, glucagon-like peptide 1 (GLP-1) analogs, sodium-glucose transporter 2 (SGLT-2) inhibitors, sulfonylureas, alpha-glucosidase inhibitors, nonsulfonylurea insulin secretagogues (meglitinides and phenylalanine derivatives), and thiazolidinediones (glitazones). Sulfonylureas and meglitinides are known as *insulin secretagogues* because their action increases the secretion of insulin by the pancreatic beta cells. Table 30-6 provides a summary of antidiabetic agents with nursing implications.

Patients must understand that antidiabetic agents are prescribed as an addition to, not as a substitute for, diet and exercise. Use of antidiabetic medications may need to be stopped temporarily and insulin prescribed during illness, pregnancy, or hospitalization.

In time, as beta cells continue to decline, non-insulin antidiabetic agents may no longer be adequate in controlling type 2 diabetes. In such cases, the patient is treated with insulin. Approximately half of all patients who initially use non-insulin antidiabetic agents eventually require insulin. Because mechanisms of action vary, use of multiple medications with different actions is common. For some patients with type 2 diabetes, the use of non-insulin agents in combination with insulin is indicated. Mechanisms of action for non-

insulin antidiabetic agents are shown in Figure 30-6.

Biguanides. Metformin, the most commonly used biguanide, produces its antidiabetic effects by decreasing hepatic production of glucose and facilitating the action of insulin on peripheral receptor sites. Biguanides have no effect on pancreatic beta cells. Metformin is contraindicated in patients with kidney impairment and in those at risk for acute kidney dysfunction. Metformin-induced lactic acidosis is a serious complication of biguanide therapy in patients with kidney failure. Metformin should not be administered for 2 days before any diagnostic testing that may require use of a contrast agent, and normal kidney function should be confirmed before the medication is restarted after the procedure.

DPP-4 Inhibitors. The DPP-4 inhibitors act by reducing the activity of the DPP-4 enzyme, whose primary action is to degrade glucagon-like peptide 1 (GLP-1). This prolongs the availability of GLP-1, whose actions are to stimulate insulin production, slow gastric emptying, and suppress glucagon secretion.

GLP-1 Agonists. GLP-1 agonists are a class of medications that work to increase insulin secretion, delay gastric emptying, promote satiety, and suppress glucagon secretion. All GLP-1 medications are injected once daily or once weekly depending on the preparation. Whereas most other non-insulin antidiabetic agents are weight neutral or cause weight gain, GLP-1 agonists promote weight loss. They also are glucose dependent and generally do not cause hypoglycemia unless combined with other medications or insulin. Usually side effects are mild but can include nausea.

SGLT-2 Inhibitors. Sodium glucose co-transporter-2 (SGLT-2) inhibitors are oral medications that work primarily by inhibiting reabsorption of glucose in the proximal renal tubules, which promotes loss of glucose through the urine, thereby reducing blood glucose levels. Weight loss and improved blood pressure also are seen with these medications. Common side effects include increased urinary frequency and genital mycotic infections, and some patients have developed DKA while taking the medication.

TABLE 30-6 Antidiabetic Agents

Generic (Trade) Name	Action/Indications	Side Effects	Implications
Sulfonylureas			
First- and Second-Generation Sulfonylureas	Used in type 2 diabetes to control blood glucose levels Stimulate beta cells of the pancreas to secrete insulin; may improve binding between insulin and insulin receptors or increase the number of insulin receptors	Hypoglycemia Mild GI symptoms Weight gain Drug–drug interactions (nonsteroidal anti-inflammatory drugs, warfarin, sulfonamides) Sulfa allergy	Monitor patient for hypoglycemia Monitor blood glucose and urine ketone levels to assess effectiveness of therapy Patients at high risk for hypoglycemia: advanced age, renal insufficiency When taken with beta-adrenergic blocking agents, may mask usual warning signs and symptoms of hypoglycemia Instruct patients to avoid use of alcohol
Second-Generation Sulfonylureas Glipizide (Glucotrol, Glucatrol XL) Glyburide (Micronase, Glynase, Dia-Beta) Glimepiride (Amaryl)	Have more potent effects than first-generation sulfonylureas May be used in combination with metformin or insulin to improve glucose control	Same as above	Same as above
First-Generation Sulfonylureas Chlorpropamide (Diabinese) Tolazamide (Tolinase) Tolbutamide (Orinase)	Used infrequently in the United States today		
Biguanides			
Metformin (Glucophase, Glucophage XL, Fortamet)	Inhibit production of glucose by the liver Increase body tissues' sensitivity to insulin Decrease hepatic synthesis of cholesterol Used in type 2 diabetes to control blood glucose levels Metformin has been effective in preventing type 2 diabetes related to obesity in young adults	Lactic acidosis Hypoglycemia if metformin is used in combination with insulin or other antidiabetic agents Drug–drug interactions GI disturbances Contraindicated in patients with impaired kidney or liver function, respiratory insufficiency, severe infection, or alcohol abuse	Monitor for lactic acidosis and hypoglycemia Patients taking metformin are at increased risk of acute kidney failure and lactic acidosis with use of iodinated contrast material for diagnostic studies; metformin should be stopped 48 hours prior to and for 48 hours after use of contrast agent or until kidney function is evaluated and normal.
Alpha-Glucosidase Inhibitors			
Acarbose (Precose) Miglitol (Glyset)	Delay absorption of complex carbohydrates in the intestine and slow entry of glucose into systemic circulation Do not increase insulin secretion Used in type 2 diabetes to control blood glucose levels Can be used alone or in combination with sulfonylureas, metformin, or insulin to improve glucose control	Hypoglycemia (risk increased if used with insulin or other antidiabetic agents) GI side effects (abdominal discomfort or distention, diarrhea, flatulence) Drug–drug interactions	Must be taken with first bite of food to be effective Monitor for GI side effects (diarrhea, abdominal distention) Monitor for blood glucose levels to assess effectiveness of therapy Monitor liver function studies every 3 months for 1 year, then periodically afterward Contraindicated in patients with GI or renal dysfunction or cirrhosis

Nonsulfonylurea Insulin Secretagogues			
Repaglinide (Prandin) categorized as a meglitinide Neteglide (Starlix) categorized as a D-phenylalanine derivative	Stimulate rapid and short insulin secretion from the pancreas Used in type 2 diabetes to control blood glucose levels by decreasing postprandial increases in blood glucose Can be used alone or in combination with metformin or thiazolidinediones to improve glucose control	Hypoglycemia/weight gain less likely than with sulfonylureas Drug–drug interactions (with ketoconazole, fluconazole, erythromycin, rifampin, isoniazid)	Monitor blood glucose levels to assess effectiveness of therapy Has rapid action and short half-life Monitor patients with impaired liver function and renal impairment Has no effect on plasma lipids Is taken before each meal
Thiazolidinediones (or Glitazones)			
Pioglitazone (Actos)	Sensitize body tissue to insulin; stimulate insulin receptor sites to lower blood glucose and improve action of insulin May be used alone or in combination with sulfonylurea, metformin, or insulin	Hypoglycemia (risk increased with use of insulin or other antidiabetic agents) Anemia Weight gain, edema Decrease effectiveness of oral contraceptives Possible liver dysfunction Drug–drug interactions Hyperlipidemia (has variable effect on lipids; pioglitazone may be preferred choice in patients with lipid abnormalities) Impaired platelet function	Monitor blood glucose levels to assess effectiveness of therapy Monitor for signs of fluid overload Monitor liver function Arrange dietary teaching to establish weight control program
DPP-4 Inhibitors			
Sitagliptin (Januvia) Saxagliptin (Onglyza) Linagliptin (Tradjenta)	Used in type 2 diabetes to control blood glucose levels Indirectly stimulates release of insulin; prevents secretion of glucagon	Nasopharyngitis Possible acute pancreatitis	Can be used with metformin or sulfonylureas to achieve improved blood glucose control
GLP-1 Agonists			
Exenatide and exenatide extended release (Byetta, Bydureon) Liraglutide (Victoza) Albiglutide (Tanzeum) Dulaglutide (Trulicity)	Simulates release of insulin; prevents secretion of glucagon; slow gastric emptying; promotes weight loss	GI side effects, including nausea and diarrhea Possible acute pancreatitis	Use with caution in patients with gastroparesis
SGLT-2 Inhibitors			
Canagliflozin (Invokana) Dapagliflozin (Farxiga) Empagliflozin (Jardiance)	Promotes insulin-independent renal excretion of glucose	Polyuria; mycotic infection; possible DKA	Helpful in controlling blood pressure and improving weight loss; avoid use in renal insufficiency

Sulfonylureas. The sulfonylureas exert their primary action by stimulating the pancreas directly to secrete insulin. Therefore, a functioning pancreas is necessary for these agents to be effective, and they are not indicated in patients with type 1 diabetes. Sulfonylureas improve insulin action at the cellular level and also may directly decrease glucose production by the liver.

The most common side effect of sulfonylureas is hypoglycemia. Second-generation sulfonylureas (glipizide, glyburide, glimepiride) have fewer side effects and drug interactions than do first-generation sulfonylureas since they are excreted by both the liver and the kidneys, thus making them safer to use in the elderly. However, if renal or hepatic insufficiency is suspected, patients must be monitored for hypoglycemia. Because the second-generation drugs are a safer option, first-generation sulfonylureas are seldom used

today.

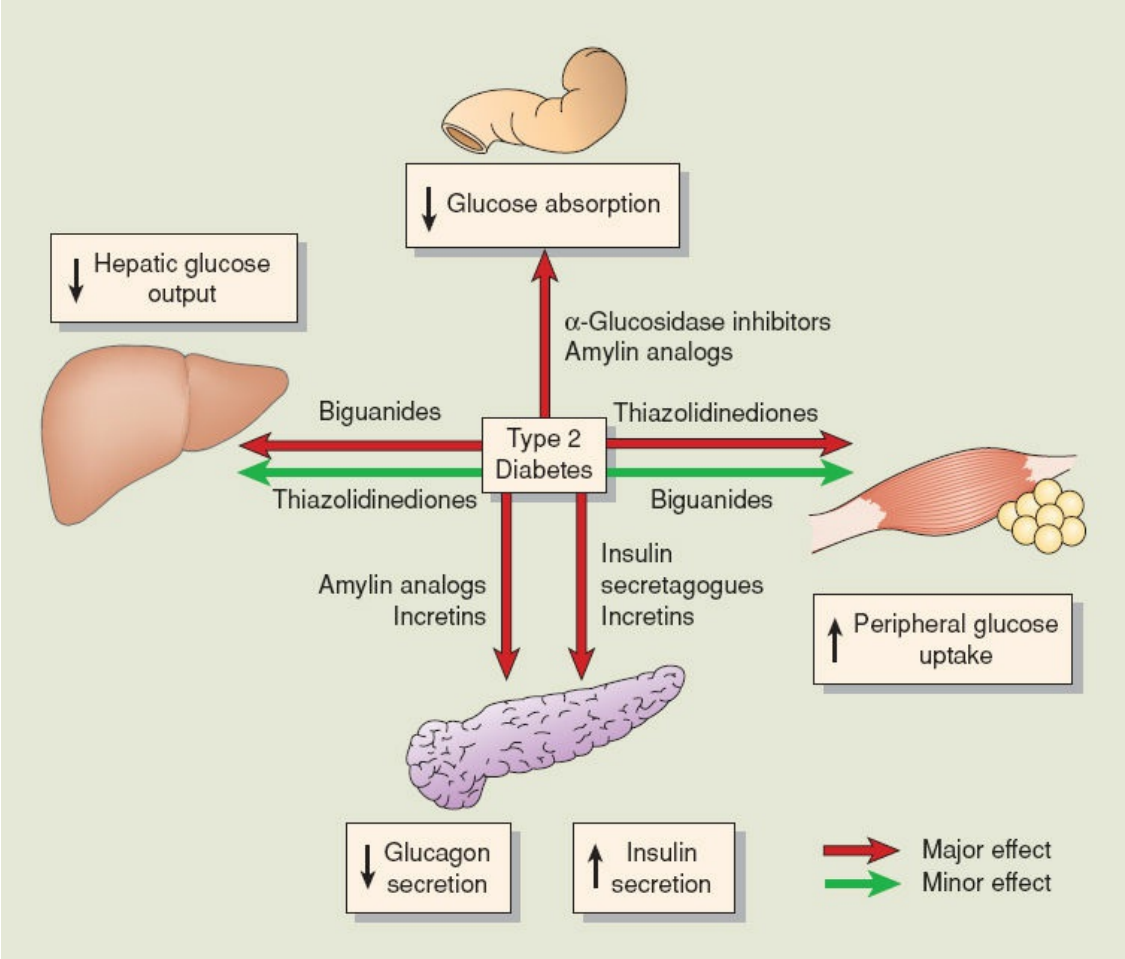


FIGURE 30-6 Sites of action of oral antidiabetic agents.

Nonsulfonylurea Insulin Secretagogues. Repaglinide (Prandin) and naglitinide (Starlix) act similarly to sulfonylureas but have a different chemical structure. Both lower the blood glucose level by stimulating insulin release from the pancreatic beta cells. These drugs have a very rapid onset and a short duration and *must be taken with meals*; they should not be taken if a meal is skipped.

Alpha-Glucosidase Inhibitors. Acarbose (Precose) and miglitol (Glyset) are alpha-glucosidase inhibitors. They work by delaying the absorption of glucose in the intestines, which results in a lower level of postprandial blood glucose. Reduction in plasma glucose results in improved diabetes control and lower A1c levels.

The advantage of alpha-glucosidase inhibitors is that they are not systemically absorbed, making them safer to use. Side effects include diarrhea and flatulence. These effects may be minimized by starting at a very low dose and increasing the dose gradually. Because acarbose and miglitol affect food absorption, they must be taken immediately before a meal, making therapeutic adherence a potential problem.

Thiazolidinediones (TZDs). Pioglitazone (Actos) is an oral antidiabetic medication categorized as a thiazolidinedione (TZD). This class of medication enhances insulin action

at receptor sites without increasing insulin secretion from the beta cells of the pancreas. These medications can be used alone or in combination with other antidiabetic agents. These medications may impair liver function and also may increase the risk of myocardial infarction and congestive heart failure. Liver function studies must be performed at baseline and at frequent intervals throughout treatment.

Other Pharmacologic Therapy

Pramlintide (Symlin) is a synthetic analog of human amylin, a hormone that is secreted by the beta cells of the pancreas. It is used as an adjunct in the treatment of type 1 and type 2 diabetes when insulin alone cannot control blood glucose levels. Pramlintide is used with insulin, not in place of insulin.

Transplantation of Pancreatic Cells

Transplantation of the whole pancreas or a segment of the pancreas is being performed on a limited population, mostly in patients with diabetes who are receiving kidney transplantation simultaneously. The main issue involves weighing the risks of antirejection medications against the advantages of pancreas transplantation.

Nursing Management

Nursing management of patients with diabetes can involve treatment of a wide variety of physiologic disorders, depending on the patient's health status and whether the patient is newly diagnosed or seeking care for an unrelated health problem. Because all patients with diabetes must master the concepts and skills necessary for long-term management and avoidance of potential complications of diabetes, a solid educational foundation is necessary for competent self-care and is an essential component of nursing care.

Diabetes mellitus is a chronic illness that requires a lifetime of special self-management behaviors. Because diet, physical activity, and physical and emotional stress affect diabetic control, patients must learn to balance a multitude of factors. They must learn daily self-care skills to prevent acute fluctuations in blood glucose, and they also must incorporate into their lifestyle many preventive behaviors for avoidance of long-term diabetic complications. Patients must become knowledgeable about nutrition, medication effects and side effects, exercise, disease progression, prevention strategies, blood glucose monitoring techniques, and medication adjustment. In addition, they must learn the skills associated with monitoring and managing diabetes and must incorporate many new activities into daily routines. An understanding of the depth and breadth of knowledge and skills that patients with diabetes must acquire helps nurses provide effective patient education and counseling.

Developing a Diabetic Teaching Plan

Changes in the health care system as a whole have had a major impact on education and training for patients with diabetes. Patients with new-onset type 1 diabetes are hospitalized for much shorter periods or may be managed completely on an outpatient basis. Patients with new-onset type 2 diabetes are rarely hospitalized for initial care. Because many patients with diabetes are admitted to the hospital for reasons other than diabetes or its complications, all nurses play a vital role in identifying patients with diabetes, assessing self-care skills, providing basic education, reinforcing teaching, and referring patients for follow-up care after discharge. Regardless of the setting, all encounters with patients with diabetes are opportunities for reinforcement of self-management skills.

Patients with newly diagnosed diabetes and those who have had diabetes for several years should be assessed for self-care needs. The ADA recommends that teaching include three levels of care. The first, survival skills, provides the patient with basic knowledge and skills for diabetes management. An outline of survival information includes the following:

1. Simple pathophysiology:
    a. Basic definition of diabetes
    b. Normal blood glucose ranges and target blood glucose levels
    c. Effect of insulin and exercise
    d. Effect of food and stress, including illness and infections
    e. Basic treatment approaches
2. Treatment modalities:
    a. Administration of insulin and oral medications

b. Meal planning
c. Monitoring of blood glucose and urine ketones

3. Recognition, treatment, and prevention of acute complications:
   a. Hypoglycemia
   b. Hyperglycemia
4. Practical information:
   a. Where to buy and store insulin, syringes, and supplies for monitoring glucose
   b. When and how to contact the primary care provider

When patients have mastered basic skills and information, they are ready for home management, the second level of teaching. This level involves providing the patient with detailed information, beyond basic survival skills, to foster self-reliance and independence for diabetes management at home.

More advanced patient education includes skills and information to improve lifestyle and individualization of diabetes self-management. The degree of advanced diabetes education provided depends on the patient's interest and ability.

Unfolding Patient Stories: Skyler Hansen • Part 2

Recall from Chapter 3 Skyler Hansen, a high school student recently diagnosed with type 1 diabetes. Outline a diabetes education plan for Skyler and his parents. What are important patient education topics, resources, and methods for the nurse to consider? How would the nurse evaluate whether the patient and his family understand the education provided?

Care for Skyler and other patients in a realistic virtual environment: *vSim* (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

Assessing Readiness to Learn

The nurse must assess the patient's readiness to learn before initiating diabetes education. When patients are first diagnosed with diabetes, or first told of the need for insulin, they often go through various stages of the grieving process. The amount of time it takes for the patient and family members to accept the realities of living with diabetes varies.

Once the patient's questions have been answered and possible misconceptions are corrected, the nurse focuses attention on concrete survival skills. Because of the immediate

need for multiple new skills, teaching is initiated as soon as possible after diagnosis. Nurses whose patients are in the hospital rarely have the luxury of waiting until the patient feels ready to learn; short hospital stays necessitate initiation of survival skill education as early as possible. This gives the patient the opportunity to practice skills with supervision by the nurse before discharge. Follow-up by home health nurses often is necessary for reinforcement of survival skills.

Determining Teaching Methods

Patient teaching must be flexible and planned to meet the needs of the individual patient. Teaching skills and providing information in a logical sequence is not always the most helpful approach for patients. For example, many patients fear self-injection. Before they learn how to prepare insulin, patients should be taught to insert the needle and inject insulin. Once they have actually performed injections, most patients are better prepared to hear and to comprehend other information necessary for insulin administration. Ample opportunity should be provided for patients and families to practice skills under supervision. Refer to Chapter 2 for details on Teaching Techniques and Learning Readiness.

Implementing the Plan

Teaching Experienced Patients

Nurses should continue to assess the skills and self-care behaviors of patients who have had diabetes for many years. Assessment of experienced patients must include direct observation of skills, not just the patient's self-report of self-care behaviors. In addition, these patients must be fully aware of preventive measures related to foot care and eye care as well as management of risk factors.

Teaching Patients Self-Care

Patient teaching and support for diabetes self-management is an important nursing responsibility. Patients who are having difficulty following the diabetes treatment plan must be approached with care and understanding. If problems with glucose control or with the development of preventable complications exist, the nurse should assess the patient to determine possible reasons. Often problems can be corrected simply by providing complete information and ensuring that the patient understands the information. The focus of diabetes education is on patient empowerment, highlighting the knowledge, skills, and attitudes needed to maintain and improve one's health.

If knowledge deficit is not the problem, certain physical or emotional factors may be impairing the patient's ability to perform self-care skills. For example, decreased visual acuity may interfere with the patient's ability to administer insulin accurately, measure the blood glucose level, or inspect the skin and feet. Decreased joint mobility or other disability also may impair a patient's ability to inspect the bottom of the feet. Emotional factors, such as depression or denial of the diagnosis, may impair the patient's ability to carry out multiple daily self-care measures. Sometimes family, personal, or work problems are given priority over diabetes management. It is also important to assess the patient for infection or emotional stress, which can lead to elevated blood glucose levels despite adherence to the treatment regimen.

Providing Continuing Care

Continuing care of patients with diabetes is critical in managing and preventing complications. The degree to which patients interact with health care providers to obtain ongoing care depends on many factors. Age, socioeconomic level, existing complications, type of diabetes, and other health problems all may influence the frequency of follow-up visits. Home health nurses are an excellent resource for ongoing diabetes education, wound care, insulin preparation, or assistance with glucose monitoring. Even patients who achieve excellent glucose control and have no complications should see their primary health care provider at least twice a year for ongoing evaluation. In addition, the nurse should remind the patient about the importance of participating in other health promotion activities, such as immunizations and recommended age-appropriate health screenings. Participation in support groups is encouraged for patients who have had diabetes for many years as well as for those who are newly diagnosed. Those who participate in support groups often have an opportunity to share valuable information and experiences and to learn from others.

ACUTE COMPLICATIONS OF DIABETES

The three major acute complications of diabetes are caused by short-term imbalances in blood glucose levels. They are hypoglycemia, DKA, and HHNS, also called hyperglycemic hyperosmolar syndrome (HHS).

HYPOGLYCEMIA (INSULIN REACTION)

Hypoglycemia (low blood glucose) occurs when the blood glucose falls below the range of 50 to 60 mg/dL.

Pathophysiology

Hypoglycemia is caused primarily by medication, such as insulin or oral hypoglycemic agents. Common factors that affect the action of those medications include inadequate food intake or increased physical activity. Hypoglycemia may occur at any time of the day or night. It often occurs before meals, especially if meals are delayed or snacks are omitted. For example, midmorning hypoglycemia may occur when the morning regular insulin is peaking, while hypoglycemia that occurs in the late afternoon often coincides with the peak of the morning NPH insulin. Nocturnal hypoglycemia may occur because of peaking late afternoon NPH insulin, especially in patients who have not eaten a bedtime snack.

Clinical Manifestations and Assessment

The clinical manifestations of hypoglycemia are grouped into two categories, based on where they are apparent; they are symptoms of the autonomic nervous system (ANS) and of the central nervous system (CNS).

At the onset of hypoglycemia, the parasympathetic system is activated, causing hunger (Porth, 2015). This is followed by activation of the sympathetic nervous system, resulting in a surge of epinephrine and norepinephrine. This causes symptoms, such as diaphoresis, tremor, tachycardia, palpitation, anxiety, and hunger.

In moderate hypoglycemia, the fall in blood glucose level deprives the brain cells of needed fuel for functioning. Signs of impaired function of the CNS may include inability to concentrate, headache, lightheadedness, confusion, memory lapses, numbness of the lips and tongue, slurred speech, impaired coordination, emotional changes, irrational or combative behavior, diplopia (double vision), and drowsiness. Any combination of these symptoms may occur.

In patients with severe cases of hypoglycemia, CNS function is so impaired that the patient needs the assistance of another person for treatment of hypoglycemia. Symptoms may include disoriented behavior, seizures, difficulty arousing from sleep, or loss of consciousness.

Nursing Alert

The brain relies almost entirely on glucose for energy. Since, the brain cannot synthesize or store more than a few minutes' supply of glucose, symptoms of cerebral function deterioration are noted with hypoglycemia (Porth, 2015).

Symptoms of hypoglycemia may occur suddenly and unexpectedly and vary considerably from person to person. To some degree, this may be related to the actual level to which the blood glucose falls or to the rate at which it falls. For example, patients who usually have a blood glucose level in the hyperglycemic range (e.g., 200 mg/dL or greater) may feel hypoglycemic symptoms when the blood glucose falls rapidly to 120 mg/dL or less. This is commonly referred to as *relative hypoglycemia*. Conversely, patients who frequently have a glucose level in the low range of normal (e.g., 80 to 100 mg/dL) may be asymptomatic until the blood glucose falls to less than 50 mg/dL. Some patients who have had diabetes for many years experience hypoglycemic unawareness. This condition occurs when the normal compensatory response to low blood sugar fails to cause symptoms, thus the patient is unaware of the problem and may experience profound hypoglycemia without any warning.

Medical and Nursing Management

Giving Carbohydrates

Immediate treatment must be given when hypoglycemia occurs. The usual recommendation is that 15 to 20 g of a fast-acting concentrated source of glucose be taken orally. Sources of glucose for the treatment of hypoglycemia include:

- Three or four commercially prepared glucose tablets
- 4 to 6 oz of fruit juice or regular soda
- 6 to 10 hard candies
- 2 to 3 teaspoons of sugar or honey

Sugar should *not* be added to juice, even if it is labeled as unsweetened juice. Adding table sugar to fruit juice may cause a sharp increase in the blood glucose level, causing prolonged hyperglycemia.

The blood glucose level should be retested in 15 minutes and retreated with another 15 g of carbohydrate if the patient is still hypoglycemic. If the symptoms persist for longer than 15 minutes after initial treatment, the treatment is repeated even if blood glucose testing is not possible. Once the blood glucose has returned to normal, a snack or meal containing protein and starch (e.g., milk or cheese and crackers) is recommended to prevent recurrent hypoglycemia (ADA, 2017d). It is important that people with diabetes, especially those receiving insulin or oral hypoglycemic agents, have a source of carbohydrate readily available at all times.

Nursing Alert
If a patient with hypoglycemia is unresponsive, a glucagon injection or bolus of IV dextrose according to hospital protocol is administered rather than risking aspiration with carbohydrates by mouth.

Initiating Emergency Measures

For adult patients experiencing hypoglycemia who are unconscious or unable to swallow safely, an injection of glucagon 1 mg can be administered either subcutaneously or intramuscularly. Glucagon is a hormone produced by the alpha cells of the pancreas that stimulates the liver to convert glycogen to glucose. Because of glycogen's short duration of action, the patient should be given both a concentrated source of carbohydrate followed by a snack once he or she regains consciousness. This will prevent recurrence of hypoglycemia and help replenish the glucose stored in the liver.

Glucagon is sold by prescription only and should be part of the emergency supplies available to patients with diabetes who require insulin. Family members, friends, and coworkers should be instructed in the use of glucagon, especially for patients who have little or no warning of hypoglycemic episodes.

Patients who are hospitalized and experience severe hypoglycemia are generally given 25 to 50 mL of 50% dextrose in water ($D_{50}W$) via IV push at a rate of 10 mL/min, but actual amounts are dictated by hospital protocol. This intervention is effective in achieving an

increase in the blood glucose within minutes.

DIABETIC KETOACIDOSIS

DKA is caused by an absence or markedly inadequate amount of insulin. This deficit of insulin results in disorders in the metabolism of carbohydrates, proteins, and fats. The primary clinical features of DKA are hyperglycemia, ketosis, dehydration, electrolyte loss, and metabolic acidosis.

Pathophysiology

Without insulin, the amount of glucose entering the cells is reduced, and production and release of glucose by the liver is increased. Both factors lead to hyperglycemia. In an attempt to rid the body of the excess glucose, the kidneys excrete excess glucose, causing an osmotic diuresis, leading to dehydration and marked loss of electrolytes. The hyperosmolality of the extracellular fluid leads to the stimulation of thirst, resulting in polydipsia and fluid shifting from intracellular to extracellular space. This fluid shifting causes low or normal levels of serum sodium despite water losses with polyuria. This low serum sodium level is referred to as *pseudohyponatremia.*

Another effect of insulin deficiency is the breakdown of fat (lipolysis) into free fatty acids and glycerol. The free fatty acids are converted into ketone bodies by the liver. In DKA, the excessive production of ketone bodies leads to the development of metabolic acidosis. A characteristic response to this acidemia is for the respiratory center to blow off its respiratory acid, leading to rapid deep respirations known as Kussmaul respirations.

Nursing Alert

Since ketones are a volatile acid, as they are exhaled, they may manifest as acetone breath that has a fruity odor similar to overripe apples.

Causes of DKA include insufficient or missed doses of insulin, physical or emotional stress, and illness or infection. An insulin deficit may result from an insufficient dosage of insulin prescribed or from insufficient insulin being administered by the patient. Physical and emotional stress increases the level of the counter regulatory ("stress") hormones—glucagon, epinephrine, norepinephrine, and cortisol—all of which cause an increase in blood glucose. Finally, illness and infection are associated with insulin resistance, which puts the patient at risk for hyperglycemia. If insulin is not increased during times of stress, illness, and infection, hyperglycemia may progress to DKA. For some patients with undiagnosed or untreated type 1 diabetes, DKA is the initial manifestation of diabetes.

Clinical Manifestations and Assessment

Hyperglycemia leads to polyuria, polydipsia, weakness, and malaise. In addition, the patient may experience blurred vision due to osmotic changes on the lens related to hyperglycemia. Clinical manifestations of DKA are depicted in Figure 30-7. Patients with marked intravascular volume depletion may present with orthostatic hypotension; warm, dry skin; decreased skin turgor; flat neck veins; and dry mucous membranes. Volume depletion also may lead to frank hypotension and a weak, rapid pulse.

The ketosis and acidosis of DKA lead to gastrointestinal (GI) symptoms, such as anorexia, nausea, vomiting, and abdominal pain. The patient may have acetone breath (a fruity odor) as well as Kussmaul respirations representing the body's attempt to decrease the acidosis, counteracting the effect of ketone accumulation. Mental status changes in DKA vary widely; the patient may be alert, lethargic, or comatose, usually depending on the severity of the abnormality of plasma osmolality.

Nursing Alert

Ketone bodies are acids that disturb the acid–base balance of the body when they accumulate in excessive amounts. The resulting DKA may cause signs and symptoms, such as abdominal pain, nausea, vomiting, hyperventilation, a fruity breath odor, and, if left untreated, altered level of consciousness, coma, and death. Initiation of insulin treatment, along with fluid and electrolytes as needed, is essential to treat hyperglycemia and DKA and rapidly improves the metabolic abnormalities.

Diagnostic findings include:

- Blood glucose levels greater than 250 mg/dL
- Low serum pH (6.8 to 7.3)
- Low serum bicarbonate (0 to 15 mEq/L)
- Accumulation of serum and urine ketones
- Presence of glucose in the urine
- Abnormal levels of serum electrolytes (sodium, potassium, and chloride)

Pathophysiology Alert

Plasma ketones are used by the body as an energy source when glucose is low or unavailable for cellular metabolism. With the breakdown of stored fat (lipolysis), liberated fatty acids are oxidized to ketone bodies, such as acetone (least abundant of all serum ketones), acetoacetate (a ketoacid), and beta-3-hydroxybutyrate (hydroxy acid). Testing urine for ketones evaluates only acetoacetate and acetone but NOT hydroxybutyrate. Elevated plasma beta-3-hydroxybutyrate is associated with high anion gap metabolic acidosis. Bedside testing or point of care testing (such as glucose finger sticks) for plasma beta-3-hydroxybutyrate is recommended rather than a urine dip test for ketones as a screening for DKA. The technology to do capillary blood testing for beta-3-hydroxybutyrate is currently in development and testing, and nurses can expect this to be available in the future.

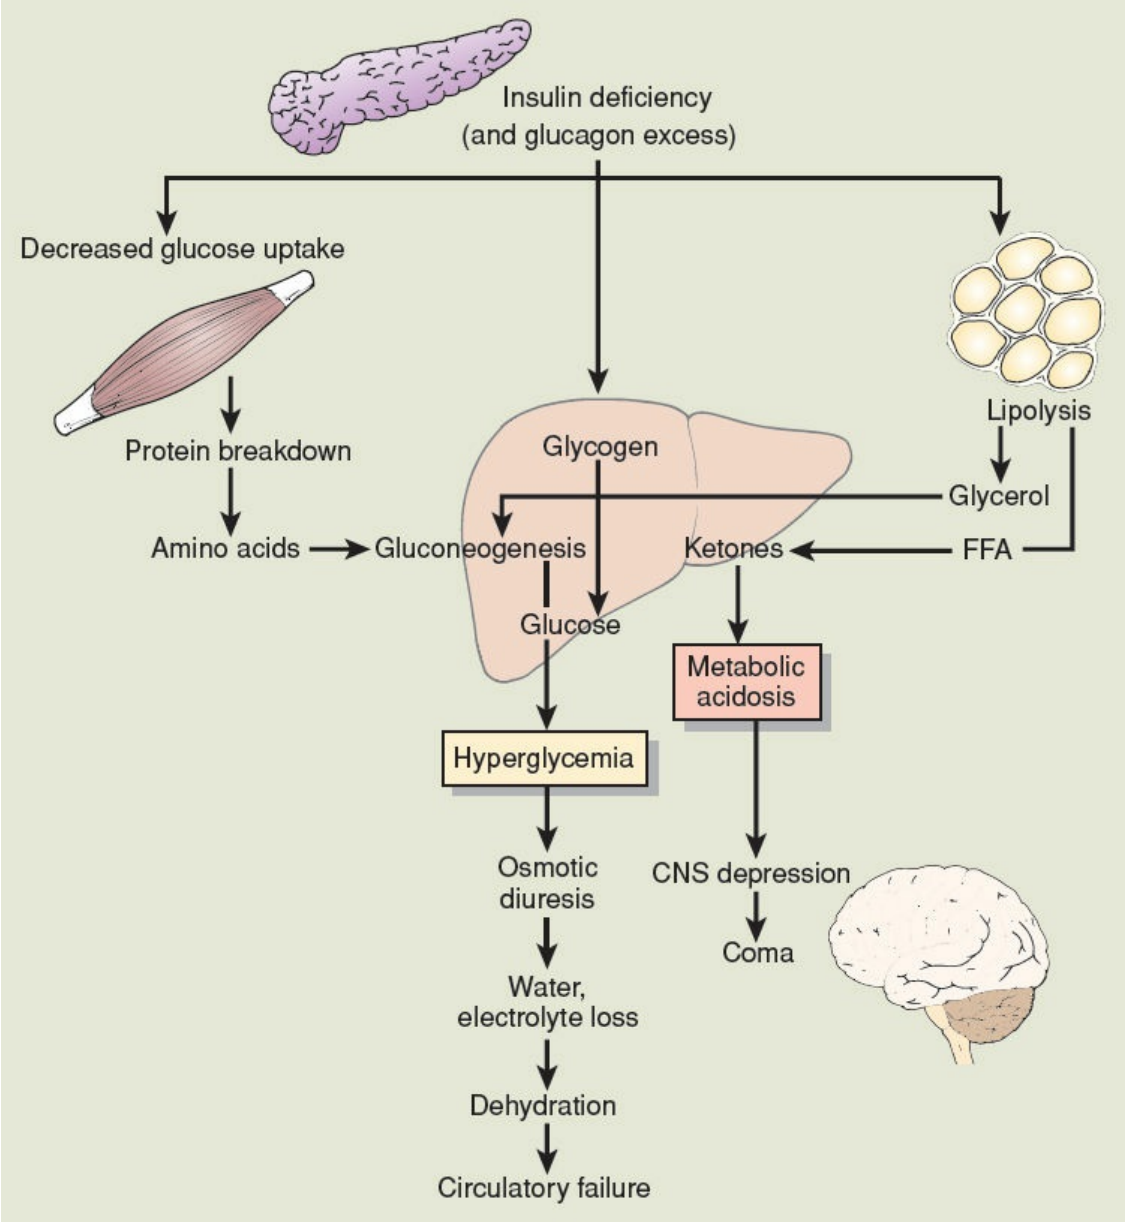

FIGURE 30-7 Mechanisms of diabetic ketoacidosis (DKA). DKA is associated with very low levels of insulin and extremely high levels of glucagon, catecholamines, and other counterregulatory hormones. Increased levels of glucagon and the catecholamines lead to mobilization of substrates for gluconeogenesis and ketogenesis by the liver. Gluconeogenesis in excess of that needed to supply glucose for the brain and other glucose-dependent tissues produces a rise in blood glucose levels. Mobilization of free fatty acids from triglyceride stores in adipose tissue leads to accelerated production of ketones and ketosis. FFA, free fatty acids; CNS, central nervous system. (From Porth, C. M. (2015). *Essentials of pathophysiology* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Prevention

For prevention of DKA related to illness, patients must be taught "sick day" rules for managing their diabetes when ill. Box 30-7 lists sick day rules. The most important concept to teach patients is not to eliminate insulin doses when nausea and vomiting occur. Instead, the patient should take the usual insulin dose, or previously prescribed "sick day" doses, and then attempt to consume frequent small portions of carbohydrates. Drinking fluids every hour is important to prevent dehydration. Blood glucose and urine ketones must be assessed every 3 to 4 hours.

If the patient cannot take fluids without vomiting, or if elevated glucose or ketone levels persist, the patient must contact his or her health care provider. After the acute phase of DKA has been resolved, the patient should be assessed for the underlying cause.

Medical and Nursing Management

In addition to treating hyperglycemia, management of DKA is directed toward correcting dehydration, electrolyte loss, and acidosis.

BOX 30-7 Patient Education

Guidelines to Follow During Periods of Illness ("Sick Day Rules")

- Take insulin or oral antidiabetic agents as usual.
- Test blood glucose and test urine ketones every 3–4 hours.
- Report elevated glucose levels (over 300 mg/dL [16.6 mmol/L] or as otherwise specified) or urine ketones to your health care provider.
- If you take insulin, you may need supplemental doses of regular insulin every 3–4 hours.
- If you cannot follow your usual meal plan, substitute soft foods (e.g., 3 cup regular gelatin, 1 cup cream soup, 2 cup custard, 3 squares graham crackers) six to eight times per day.
- If vomiting, diarrhea, or fever persists, take liquids (e.g., 2 cup regular cola or orange juice, 2 cup broth, 1 cup Gatorade) every 1–2 hours to prevent dehydration and to provide calories.
- Report nausea, vomiting, and diarrhea to your health care provider because extreme fluid loss may be dangerous.
- If you are unable to retain oral fluids, you may require hospitalization to avoid diabetic ketoacidosis and, possibly, coma.

Rehydration

In patients who are dehydrated, rehydration is important for maintaining tissue perfusion. In addition, fluid replacement enhances the excretion of excessive glucose by the kidneys. The patient may need as much as 6 to 9 L of IV fluid to replace fluid losses caused by polyuria, hyperventilation, diarrhea, and vomiting.

Initially, 0.9% sodium chloride (normal saline) is the IV solution selected for patients admitted with DKA. Many protocols call for administration of 1 to 2 L in the first 1 to 2 hours and then 1 L/hour for 3 to 4 hours, depending on the patient's response. The rate of administration varies; however, the ADA suggests a rate of 15 to 20 mL/kg/hr or 1 to 1.5 L during the first hour. Another calculation recommended by Maletkovic and Drexler (2013) is 10 to 15 mL/kg/hr, reducing to a rate of 4 to 14 mL/kg and changing the solution to 0.45% sodium chloride (½ NS) once the patient is euvolemic (has appropriate water balance). The subsequent IV fluid replacement will depend on the sodium level and level of dehydration; typically it will be either normal saline or half-strength normal saline solution. Moderate to high rates of infusion (200 to 500 mL/hr) may continue for several more

hours, depending on the patient's vital signs, physical assessment findings, and urinary output. The nurse follows the institutions protocol regarding IV rate of administration. Administration of IV fluid that is too rapid increases the risk of cerebral edema, and while the patient clinically may present with hypovolemic shock, it is essential to monitor the patient closely to avoid cerebral edema while correcting the fluid volume deficit. When the blood glucose level reaches 250 mg/dL or less, change to IV solutions containing glucose (D_5NS, $D_51/2NS$) to prevent a precipitous decline in the blood glucose level with insulin administration (Gosmanov et al., 2014).

Nursing Alert

The intravenous administration of regular insulin is faster than subcutaneous administration. In general, when regular insulin is administered IV, its half-life is about 9 minutes, and steady state is reached in approximately 45 minutes. Therefore, when monitoring blood glucose levels, the nurse is aware that the IV regular insulin is continuing to exert its action. Once the blood glucose level reaches 250 mg/dL or less, prevention of hypoglycemia necessitates changing the IV solution to one containing glucose. Typically, the initial insulin infusion rate is 0.1 U/kg/hr (Gosmanov et al., 2014).

Monitoring of fluid volume status involves frequent measurements of vital signs; respiratory, cardiac, and neurologic assessment; and evaluation of intake and output. Monitoring for signs of fluid overload is especially important for patients who are older, have renal impairment, or who are at risk for heart failure. Signs include crackles, distended neck veins, edema, weight gain, shortness of breath, orthopnea, paroxysmal nocturnal dyspnea, hypertension, moist mucous membranes, and a full and bounding pulse.

Restoring Electrolytes

Potassium is the major electrolyte of concern during treatment of DKA. The initial plasma concentration of potassium may be low because of renal loss due to osmotic diuresis. Conversely, it may be normal or high because of the shifting of potassium out of the cell to accompany the movement of hydrogen into the cells because of acidemia. If the potassium level is elevated, potassium replacement is withheld until serum levels fall to normal; this prevents the possibility of cardiac arrest from hyperkalemia. The serum level of potassium will decrease with insulin administration as insulin facilitates the movement of potassium intracellularly. Additionally, rehydration leads to increased plasma volume and subsequent decreases in the concentration of serum potassium as well as increased urinary excretion of potassium. It is critical that serum potassium levels be monitored carefully during treatment for DKA.

Nursing Alert

Potassium levels must be assessed prior to starting insulin therapy in the acute care setting. Insulin facilitates movement of potassium into the cell and, therefore, can exacerbate hypokalemia. Potassium must be replaced prior to starting insulin. Every 10 mEq of parenteral potassium should increase the serum level by approximately 0.1 mEq/L. Most protocols require the serum potassium level be greater than 3.3 mEq/L prior to starting

insulin. Cautious but timely potassium replacement is vital to avoid arrhythmias that may occur with hypokalemia. An ECG should be done on admission, and continuous cardiac monitoring is anticipated until the crisis is resolved. To prevent hyperkalemia, urine output is monitored to ensure adequate kidney function before potassium is administered. If the K^+ is higher than 5.3 or the patient is anuric, potassium replacement is withheld. Frequent laboratory measurements of potassium levels are expected.

Nursing Alert
Signs and symptoms of hypokalemia generally are not seen until the serum level is less than 3.0 mEq/L. The most profound effects are on cardiac function and may lead to cardiac arrhythmias, predisposition to digitalis toxicity, and electrocardiographic (ECG) changes, such as prolonged PR interval and the development of a U wave. In addition, patients complain of muscle weakness and fatigue. If the potassium is less than 2.5 mEq/L, muscle weakness and paralysis of the respiratory muscles can occur (Porth, 2015).

Reversing Acidosis

Accumulation of ketone (acetone) bodies occurs as a result of fat breakdown. The acidosis that occurs in DKA is reversed with insulin, which inhibits fat breakdown. Regular insulin is added to a saline solution and infused intravenously at a slow, continuous rate (e.g., 0.1 U/kg/hr) (Gosmanov et al., 2014). Hourly blood glucose values must be measured to avoid precipitous drops in glucose or an inadequate decline. The goal is to decrease the serum glucose level by 50 to 100 mg/dL/hr to prevent complications, such as cerebral edema. When the serum osmolality is decreased too rapidly, fluid shifts into the CNS, causing cerebral edema. Patients may complain of headache and exhibit changes in level of consciousness and cranial nerve function.

To avoid a rapid drop in the level of blood glucose during treatment, normal saline (NS) solutions with higher concentrations of glucose (e.g., D_5NS, D_5.45NS) are administered when blood glucose levels reach 250 mg/dL.

Intravenous regular insulin is the insulin used most commonly to treat DKA (Gosmanov et al., 2014). The nurse must convert hourly rates of insulin infusion (frequently prescribed as "units per hour") to IV drip rates. For example, if 100 units of regular insulin are mixed in 500 mL of 0.9% NS, then 1 unit of insulin equals 5 mL; therefore, an initial insulin infusion rate of 5 units/hr would equal 25 mL/hr. The insulin solution is infused separately from rehydration solutions to allow for the frequent changes in the rate and concentration of the latter.

Insulin is infused continuously until subcutaneous administration of insulin can be resumed. Even if blood glucose levels are decreasing and returning to normal, the insulin drip must not be stopped until subcutaneous insulin therapy has been started. Instead, the rate or concentration of the dextrose infusion can be increased. Usually blood glucose levels are corrected before acidosis is corrected. Therefore, IV insulin must be continued until the serum bicarbonate level improves to at least 15 mEq/L and the anion gap is 12 or less (Gosmanov et al., 2014).

Nursing Alert

To minimize the effect of adsorption of insulin to the IV container or tubing, it is recommended that the nurse "coat the IV line" by flushing the tubing with the insulin solution. When using a standard IV insulin infusion of 100 U of regular human insulin in 100 mL of normal saline, a priming volume of 20 mL is sufficient to saturate the binding sites before connecting it to the patient (Thompson, Vital-Carona, & Faustino, 2012).

HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC SYNDROME

HHNS is a serious life-threatening condition characterized by hyperosmolality (at least 340 mOsm/L) and hyperglycemia (at least 600 mg/dL) with alterations in level of consciousness. Ketosis is minimal or absent. Persistent hyperglycemia causes osmotic diuresis, which results in losses of water and electrolytes. The higher the serum glucose, the more profound the dehydration, and the greater the risk for renal impairment and mental status changes. Table 30-7 compares DKA and HHNS.

TABLE 30-7 Comparison of Diabetic Ketoacidosis (DKA) and Hyperglycemic Hyperosmolar Nonketotic Syndrome (HHNS)

Characteristics	DKA	HHNS
Patients most commonly affected	Can occur in type 1 or type 2 diabetes; more common in type 1 diabetes	Can occur in type 1 or type 2 diabetes; more common in type 2 diabetes, especially elderly patients with type 2 diabetes
Precipitating event	Omission of insulin; physiologic stress (infection, surgery, stroke, MI)	Physiologic stress (infection, surgery, stroke, MI)
Onset	Rapid (less than 24 hours)	Slower (over several days)
Blood glucose levels	Usually over 250 mg/dL (over 13.9 mmol/L)	Usually over 600 mg/dL (over 33.3 mmol/L)
Arterial pH level	Below 7.3	Normal
Serum and urine ketones	Present	Absent
Serum osmolality	300–350 mOsm/L	Greater than 350 mOsm/L
Plasma bicarbonate level	Less than 15 mEq/L	Normal
BUN and creatinine levels	Elevated	Elevated
Mortality rate	Less than 5%	10–40%

MI, myocardial infarction.

Pathophysiology

HHNS occurs most often in older people between 50 and 70 years of age who have no known history of diabetes or who have type 2 diabetes. HHNS often can be traced to a precipitating event, such as infection, acute or chronic illness (e.g., pneumonia, stroke), medications that exacerbate hyperglycemia, or therapeutic procedures, such as surgery or dialysis. The history may include days to weeks of polyuria and polydipsia. What distinguishes HHNS from DKA is that ketosis and acidosis generally do not occur in HHNS, partly because of differences in insulin levels. In DKA, no insulin is present, and this promotes the breakdown of stored glucose, protein, and fat, which leads to the production of ketone bodies and ketoacidosis. In HHNS, the insulin level is too low to prevent hyperglycemia and subsequent osmotic diuresis, but it is high enough to prevent fat breakdown.

Clinical Manifestations and Assessment

The clinical picture of HHNS is one of hypotension, profound dehydration (dry mucous membranes, poor skin turgor), tachycardia, and variable neurologic signs (e.g., alteration of sensorium, seizures, hemiparesis). As HHNS tends to occur in the elderly, many of whom have coexisting cardiac and renal disease, the mortality rate ranges from 10% to 40%, usually related to an underlying illness, the vulnerability of the elderly patient, and the severity of HHNS.

Diagnostic assessment reveals very high blood glucose, usually 600 to 1,200 mg/dL, and high serum osmolality, often exceeding 350 mOsm/kg. Levels of electrolytes and blood urea nitrogen (BUN) are consistent with the clinical picture of profound dehydration. Mental status changes and neurologic deficits are common secondary to cerebral dehydration that results from extreme hyperosmolality. Postural hypotension results from the dehydration.

Medical Management

The overall approach to the treatment of HHNS is similar to that of DKA: replacement of fluids, correction of electrolyte imbalances, and administration of insulin. Because patients with HHNS are typically older, close monitoring of volume and electrolyte status is important for prevention of fluid overload, heart failure, and cardiac dysrhythmias. Fluid treatment is started with 0.9% or 0.45% NS, depending on the patient's sodium level and the severity of volume depletion. Fluid replacement is guided by central venous or hemodynamic pressure monitoring. Potassium is added to IV fluids when urinary output is adequate and is guided by continuous ECG monitoring and frequent laboratory determinations of potassium.

Extremely elevated concentrations of blood glucose decrease as the patient is rehydrated. Insulin plays a less important role in the treatment of HHNS as opposed to DKA because it is not needed for reversal of acidosis, and, therefore, the patient may have lower insulin requirements. Insulin is administered at a continuous low rate to treat hyperglycemia.

As in DKA, replacement IV fluids with dextrose are administered after the glucose level has decreased to the range of 250 to 300 mg/dL (Maletkovic & Drexler, 2013).

Other therapeutic modalities are determined by the underlying illness and the results of continuing clinical and laboratory evaluation. It may take 3 to 5 days for neurologic symptoms to resolve; treatment of HHNS usually continues well after metabolic abnormalities are resolved. After recovery from HHNS, many patients can control their diabetes with diet alone or with diet and oral antidiabetic medications. Insulin may not be needed once the patient has recovered from the acute hyperglycemic episode. Frequent self-blood glucose monitoring (SBGM) is important in preventing recurrence of HHNS.

Nursing Management

Nursing care of patients with HHNS includes close monitoring of vital signs, fluid status, and laboratory values. In addition, strategies are implemented to maintain safety and prevent injury related to changes in the sensorium secondary to HHNS. Fluid status and urine output are monitored closely because of the high risk of kidney failure secondary to severe dehydration. In addition, the nurse must direct care to the condition that may have precipitated the onset of HHNS, such as MI, infection, illness, or extreme stress (burns, trauma, etc.), or consider iatrogenic treatments, such as TPN/PPN, enteral feedings, or sympathomimetics. Because HHNS tends to occur in older patients, the physiologic changes that occur with aging should be noted. Careful assessment of cardiovascular, pulmonary, and renal function throughout the acute and recovery phases of HHNS is important.

LONG-TERM COMPLICATIONS OF DIABETES

Long-term complications, which are becoming more common as people live longer with diabetes, can affect almost every organ system of the body and are a major cause of death and disability. The general categories of long-term diabetic complications are macrovascular disease, microvascular disease, and neuropathy.

The specific causes and pathogenesis of each type of complication are not thoroughly understood. However, it appears that increased levels of blood glucose predispose patients with diabetes to microvascular complications and risk factors contributing to macrovascular complications. Hypertension is most likely another contributing factor, especially in both macrovascular and microvascular diseases.

Long-term complications are seen in both patients with type 1 and type 2 diabetes. Because patients with type 2 diabetes can go undiagnosed for many years, evidence of complications may be present at the time of diagnosis.

MACROVASCULAR COMPLICATIONS

Diabetic macrovascular (macroangiopathy) complications result from changes in medium to large blood vessels. Blood vessel walls thicken, sclerose, and become occluded by plaque that adheres to the vessel walls. Eventually, blood flow is blocked. These atherosclerotic changes tend to occur more often and at an earlier age in patients whose diabetes is poorly controlled. Coronary artery disease, cerebrovascular disease, and peripheral vascular disease are the three main types of macrovascular complications that occur frequently in the diabetic population.

Cardiovascular disease is the major cause of illness and death for people with diabetes (ADA, 2017e). One unique feature of coronary artery disease in patients with diabetes is that typical ischemic symptoms may be absent. Therefore, the patient may not experience the early warning signs of decreased coronary blood flow and may have a "silent" myocardial infarction. This lack of ischemic symptoms may be secondary to autonomic neuropathy. Cardiac disease is discussed in detail in Chapter 14.

Cerebral blood vessels are affected similarly by accelerated atherosclerosis. Occlusive changes or an embolus elsewhere in the vasculature that lodges in a cerebral blood vessel can lead to transient ischemic attacks and strokes. People with diabetes have three times the risk of developing cerebrovascular disease and a greater likelihood of death (Powers, 2016). Recovery from a stroke is likely to be more difficult for patients with elevated blood glucose levels at the time of, and immediately after, a stroke. Because symptoms of cerebrovascular disease may be similar to symptoms of acute diabetic complications (HHNS or hypoglycemia), it is very important to assess the blood glucose level and treat abnormal levels rapidly so that testing and treatment of cerebrovascular disease can be initiated promptly, if indicated.

Atherosclerotic changes in the large blood vessels of the lower extremities are responsible for a two to three times higher incidence of occlusive peripheral arterial disease in people with diabetes. Signs and symptoms of peripheral vascular disease include diminished peripheral pulses and intermittent claudication (pain in the buttock, thigh, or calf during

walking). Severe arterial occlusive disease in the lower extremities is largely responsible for the increased incidence of gangrene and subsequent amputation in patients with diabetes. Refer to Chapter 12 for assessment of ankle-brachial index (ABI).

Medical and Nursing Management

The focus of management is aggressive modification and reduction of risk factors. Diet and exercise are important in managing diabetes, obesity, hypertension, and hyperlipidemia. Smoking cessation is essential. If blood pressure goals are not met within 3 months of lifestyle changes, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are recommended for blood pressure control. Antilipidemic medications (e.g., statins) may be added. Aspirin therapy is recommended as a primary prevention strategy in those patients who have a 10-year risk for cardiovascular disease of at least 10%. Aspirin is not recommended routinely for all patients (ADA, 2017e).

When macrovascular complications do occur, patients may require medication changes or intensification of their regimen to get glucose levels to goal. Target A1c and blood glucose goals are patient-dependent and should be modified to avoid hypoglycemia, with higher A1c targets particularly in those patients who are elderly or have known coronary artery disease.

MICROVASCULAR COMPLICATIONS

Diabetic microvascular disease (microangiopathy) is characterized by thickening of the membrane of the capillary basement. The basement membrane surrounds the endothelial cells of the capillary. Increased blood glucose levels react through a series of biochemical responses to thicken the basement membrane to several times its normal thickness. Two areas affected by these changes are the retina and the kidneys.

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness in the United States among people between 20 and 74 years of age; it occurs in patients with both type 1 and type 2 diabetes. Glaucoma, cataracts, and other disorders of the eye occur earlier and more frequently in people with diabetes (ADA, 2017f). Table 30-8 summarizes the complications of diabetes that affect vision.

Diabetic retinopathy is caused by changes in the small blood vessels in the retina, the area of the eye that receives images and sends information about the images to the brain. The retina is richly supplied with blood vessels of all kinds: small arteries and veins, arterioles, venules, and capillaries. Figure 30-8 shows the difference between a healthy retina and a retina affected by diabetes.

The risk for retinopathy increases with the length of time a person has had diabetes. Chronic hyperglycemia and hypertension also increase the risk for retinopathy (ADA, 2017f). Changes in the microvasculature include microaneurysms, intraretinal hemorrhage, hard exudates, and focal capillary closure.

Retinopathy has three stages: nonproliferative, preproliferative, and proliferative.

- *Stage I:* Nonproliferative retinopathy is characterized by macular edema and occurs in approximately 10% of people with type 1 or type 2 diabetes. It may lead to visual distortion and loss of central vision.
- *Stage II:* Preproliferative retinopathy involves more widespread vascular changes and loss of nerve fibers. Approximately 10% to 50% of patients with preproliferative retinopathy develop proliferative retinopathy in a short time, some within a year.
- *Stage III:* Proliferative retinopathy is characterized by production of new blood vessels and formation of scar tissue. The new vessels are prone to bleeding. Fibrous scar tissue places traction on the retina that may cause hemorrhage or retinal detachment, with subsequent loss of vision.

TABLE 30-8 Ocular Complications of Diabetes

Eye Disorder	Characteristics
Retinopathy	Deterioration of the small blood vessels that nourish the retina
Nonproliferative (Background)	Early-stage, asymptomatic retinopathy. Blood vessels within the retina develop microaneurysms that leak fluid, causing swelling and forming deposits (exudates). In some cases, macular edema causes distorted vision.
Preproliferative	Represents increased destruction of retinal blood vessels
Proliferative	Abnormal growth of new blood vessels on the retina. New vessels rupture, bleeding into the vitreous and blocking light. Ruptured blood vessels in the vitreous form scar tissue, which can pull on and detach the retina.
Cataracts	Opacity of the lens of the eye; cataracts occur at an earlier age in patients with diabetes.
Lens changes	The lens of the eye can swell when blood glucose levels are elevated. For some patients, visual changes related to lens swelling may be the first symptoms of diabetes. It may take up to 2 months of improved blood glucose control before hyperglycemic swelling subsides and vision stabilizes. Therefore, patients are advised not to change eyeglass prescriptions during the 2 months after discovery of hyperglycemia.
Glaucoma	Results from occlusion of the outflow channels by new blood vessels. Glaucoma may occur with slightly higher frequency in the diabetic population.

Clinical Manifestations and Assessment

Retinopathy is a painless process. In nonproliferative and preproliferative retinopathy, blurry vision secondary to macular edema occurs in some patients, although many patients are asymptomatic. Even patients with a significant degree of proliferative retinopathy and some hemorrhaging may not experience major visual changes. Symptoms indicative of hemorrhaging include floaters or cobwebs in the visual field, sudden visual changes including spotty or hazy vision, or complete loss of vision.

Diagnosis of retinopathy is made by direct visualization of the retina through dilated pupils with an ophthalmoscope by an ophthalmologist or optometrist.

Medical Management

The primary focus of the management of retinopathy is prevention through blood glucose control. Other strategies that may slow the progression of diabetic retinopathy include control of hypertension and smoking cessation. Laser photocoagulation in patients with retinopathy is effective at preventing vision loss. Routine screening for diabetic retinopathy allows for earlier access to this important procedure (ADA, 2017f).

Nursing Management

Nursing management of patients with diabetic retinopathy or other eye disorders focuses on patient education about the importance of prevention through regular ophthalmologic examinations and control of blood glucose. The effectiveness of early diagnosis and prompt treatment is emphasized. If vision loss occurs, nursing care also must address the patient's adjustment to impaired vision and use of adaptive devices for diabetes self-care as well as activities of daily living. Nursing care for patients with low vision or loss of vision is discussed in detail in Chapter 49.

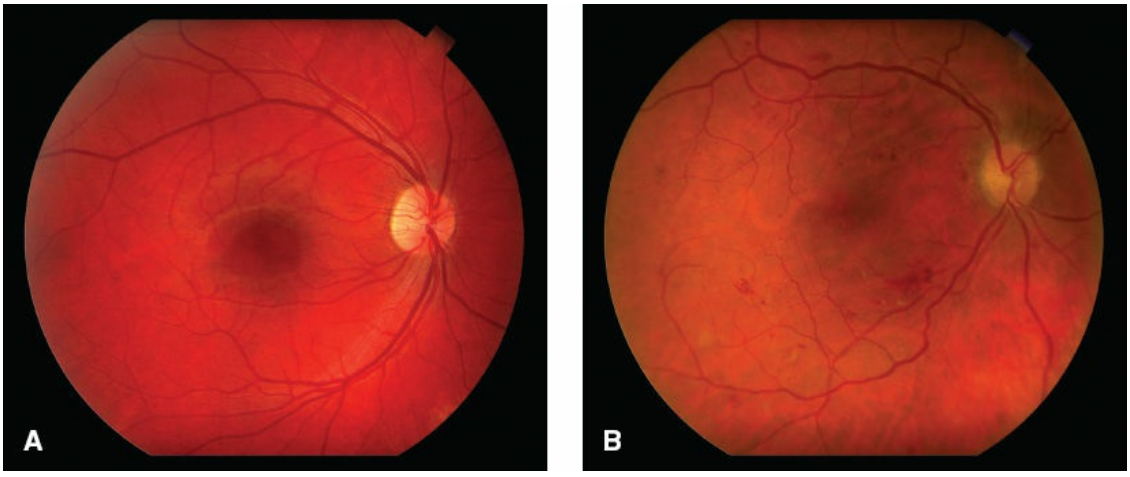

FIGURE 30-8 Diabetic retinopathy. (A) In the fundus photograph of a normal eye, the light circular area over which a number of blood vessels converge is the optic disc, where the optic nerve meets the back of the eye. (B) The fundus photograph of a patient with diabetic retinopathy shows characteristic waxy-looking retinal lesions, microaneurysms of the vessels, and hemorrhages. (Courtesy of American Optometric Association.)

Diabetic Nephropathy

Diabetic nephropathy, or renal disease secondary to microvascular changes in the kidney occurs in 20% to 40% of patients with diabetes and is the single leading cause of End Stage Kidney Disease (ESKD) (ADA 2017f). It is characterized by albuminuria (albumin in the urine), hypertension, and progressive renal insufficiency. Some patients eventually require dialysis or kidney transplantation.

Patients with type 1 diabetes frequently show initial signs of renal disease after 10 to 15 years, while patients with type 2 diabetes may develop renal disease within 10 years after diagnosis. However, because many patients with type 2 diabetes have had diabetes for many years before diagnosis, there can be evidence of nephropathy at the time of diagnosis.

Pathophysiology

If blood glucose levels are elevated consistently for a significant period of time, the kidney's filtration mechanism is stressed, allowing blood proteins to leak into the urine. As a result, the pressure in the blood vessels of the kidney increases. It is thought that this elevated pressure serves as the stimulus for the development of nephropathy.

Clinical Manifestations and Assessment

Most of the signs and symptoms of renal dysfunction in patients with diabetes are similar to those seen in patients without diabetes. For patients with diabetes, as kidney failure progresses, the catabolism (breakdown) of both exogenous and endogenous insulin decreases, causing increased risk for hypoglycemic episodes. Insulin needs change as a result of changes in the catabolism of insulin, changes in diet related to the treatment of nephropathy, and changes in insulin clearance that occur with decreased kidney function. Other medications excreted through the kidney, such as sulfonylureas, may also need to be adjusted to avoid hypoglycemia.

Nephropathy is characterized by the presence of albumin in the urine. Routine urine screening can detect even slight elevations in albumin levels. Albuminuria of ≥30 mg/g is abnormal and signals early nephropathy. People with diabetes should have their urine checked at least annually for the presence of albumin (ADA, 2017f).

Hypertension, whether it is a downstream effect of diabetic nephropathy or a comorbid condition, should be managed aggressively.

Medical Management

In addition to achieving and maintaining near-normal blood glucose levels, management for all patients with diabetes should include careful attention to control of hypertension and promoting smoking cessation to decrease or delay the onset of early albuminuria. Other concerns include prevention or vigorous treatment of urinary tract infections and avoidance of nephrotoxic medications. As kidney function changes, adjustment of medications may be necessary.

For patients who have developed albuminuria, an ACE inhibitor or angiotensin receptor blocker (ARB) should be prescribed. These medications lower blood pressure and reduce

albuminuria, thereby protecting the kidney. This preventive strategy should be part of the standard of care for all people with diabetes. In chronic or end-stage kidney failure, two types of treatment are available: dialysis (hemodialysis or peritoneal dialysis) and kidney transplantation.

Diabetic Neuropathy

Diabetic neuropathy refers to a group of diseases that affect all types of nerves, including peripheral (sensorimotor) and autonomic nerves. The disorders are clinically diverse and depend on the location of the affected nerve cells. They may be focal or diffuse (ADA, 2017f).

The etiology of neuropathy appears to be related to elevated levels of blood glucose over a period of years. The pathogenesis of neuropathy may be attributed to either vascular or metabolic mechanisms, or both. Thickening of the membrane of the capillary basement and closure of capillaries disrupt blood supply to nerves. Also, demyelinization of nerves, which is thought to be related to hyperglycemia, and accumulation of sorbitol in nerve cells slow nerve conduction.

The two most common types of diabetic neuropathy are sensorimotor polyneuropathy and autonomic neuropathy. Sensorimotor polyneuropathy, also called *peripheral neuropathy*, most commonly affects the distal portions of the nerves, especially the nerves of the lower extremities. Mononeuropathies (e.g., cranial neuropathies affecting the oculomotor nerve) affect a single nerve. Autonomic neuropathies cause a variety of clinical manifestations, depending on the area involved.

Peripheral Neuropathy

Clinical Manifestations and Assessment

Initial symptoms of neuropathy may include paresthesias (numbness or tingling) and aching or burning sensations, especially at night. A decrease in proprioception (awareness of posture and movement of the body and of position and weight of objects in relation to the body) and a decreased sensation of light touch may lead to an unsteady gait. Decreased sensations of pain and temperature place patients with neuropathy at increased risk for injury and undetected foot infections. Joint deformities may result from abnormal weight distribution on joints, resulting from lack of proprioception. Sensation can be assessed using a monofilament device (see Fig. 30-9).

FIGURE 30-9 Use of a monofilament in testing for impaired sensation in the foot of a person with diabetes. (From Porth, C. M. (2015). *Pathophysiology* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

On physical examination, there may be a decrease in deep tendon reflexes and vibratory sensation. For patients who have few or no symptoms of neuropathy, these physical findings may be the only indication of neuropathic changes.

Medical and Nursing Management

Pain, particularly of the lower extremities, is a disturbing symptom for many people with neuropathy due to diabetes. The first step in pain management is to achieve optimal control of blood glucose. Pharmacologic treatment of pain may include nonopioid analgesics, opioid analgesics, antidepressants, and antiseizure medications, as well as use of transcutaneous electrical nerve stimulation (TENS).

Autonomic Neuropathies

Neuropathy of the ANS can result in a broad range of dysfunctions affecting many organ systems. Three manifestations of autonomic neuropathy are related to the cardiac, GI, and urogenital systems. Cardiovascular symptoms may range from resting tachycardia, exercise intolerance, and orthostatic hypotension to silent, or painless, myocardial ischemia and infarction.

GI symptoms of early satiety, bloating, nausea, vomiting, and constipation or diarrhea may occur as a result of delayed gastric emptying. Decreased gastric motility may result in poor control of blood glucose caused by delayed absorption of glucose from ingested foods, which leads to increased variability in blood glucose levels and increased risk of hypoglycemia.

Urinary retention, a decreased sensation of bladder fullness, and other urinary symptoms

of neurogenic bladder may result from autonomic neuropathy. The patient with a neurogenic bladder is predisposed to development of urinary tract infections because of the inability to empty the bladder completely. This is especially true of patients with poorly controlled diabetes because hyperglycemia impairs resistance to infection.

Sexual dysfunction, especially erectile dysfunction and ejaculatory changes in men, is a complication of diabetes. Impotence occurs with greater frequency in men with diabetes. Some men with autonomic neuropathy have normal erectile function and can experience orgasm but do not ejaculate normally. The effects of autonomic neuropathy on female sexual functioning include reduced vaginal lubrication, decreased libido, and lack of orgasm. Vaginal infection, which is more common in women with diabetes, may be associated with decreased lubrication, itching, and tenderness.

Medical and Nursing Management

Management strategies depend on symptoms and focus on modification and management of risk factors. Early recognition and appropriate management of neuropathy is important. Effective treatment options for symptomatic diabetic neuropathy are available and may relieve symptoms.

For example, treatment of delayed gastric emptying includes a low-fat diet, frequent small meals, and close monitoring of blood glucose. Metoclopramide is now reserved for the most severe cases of gastroparesis, and treatment duration should be limited (ADA, 2017f). Treatment of diabetic diarrhea may include bulk-forming laxatives or antidiarrheal agents. Constipation is treated with a high-fiber diet and adequate hydration; medications, laxatives, and enemas may be necessary if constipation is severe. Treatment of erectile dysfunction may include medication (e.g., phosphodiesterase type 5 inhibitors) and mechanical devices (ADA, 2017f).

COMPLICATIONS OF THE FEET AND LEGS

Amputation and foot ulcers, consequences of diabetic neuropathy and/or peripheral artery disease, are common and major causes of death and disability in people with diabetes. Early recognition and management of risk factors can prevent or delay these complications of diabetes (ADA, 2017f).

As shown in Figure 30-10, the typical sequence of events in the development of a diabetic foot ulcer begins with a soft tissue injury of the foot, formation of a fissure between the toes or in an area of dry skin, or formation of a callus. Patients with an insensitive foot do not feel injuries, which may be thermal (e.g., from using heating pads, walking barefoot on hot concrete, testing bath water with the foot), chemical (e.g., burning the foot while using caustic agents on calluses, corns, or bunions), or traumatic (e.g., injuring skin while cutting nails, walking with an undetected foreign object in the shoe, or wearing ill-fitting shoes and socks).

FIGURE 30-10 Neuropathic ulcers occur on pressure points in areas with diminished sensation in diabetic polyneuropathy. The ulcer may go unnoticed if pain is absent.

If the patient is not in the habit of thoroughly inspecting both feet on a daily basis, the injury or fissure may go unnoticed until a serious infection has developed. Drainage, swelling, redness of the leg, or gangrene may be the first sign of foot problems that the patient notices. Treatment of foot ulcers typically involves antibiotics and debridement. Controlling glucose levels, which tend to increase when infections occur, is important for promoting wound healing. In addition, smoking cessation should be promoted aggressively. In patients with peripheral vascular disease, foot ulcers may not heal because of the decreased ability of oxygen, nutrients, and antibiotics to reach the injured tissue due to decreased circulation. Amputation may be necessary to prevent the spread of infection.

The risk of amputation and other problems involving the lower extremities is especially high for patients who have had diabetes for more than 10 years, those with poor blood glucose control, and those with peripheral vascular disease and peripheral neuropathy. Foot assessment and foot care instructions are vitally important for patients who are at high risk for foot infections.

Medical and Nursing Management

Teaching patients proper foot care is a nursing intervention that can prevent costly and painful complications that result in disability. Box 30-8 provides foot care tips for patient education. Preventive foot care begins with careful daily assessment of the feet. The feet must be inspected for redness, blisters, fissures, calluses, ulcerations, changes in skin temperature, or development of foot deformities. For patients with visual impairment or decreased joint mobility, use of a mirror or the help of a family member to inspect the bottoms of both feet may be necessary. The interior surfaces of shoes also should be inspected for any rough spots or foreign objects. In addition to daily visual and manual inspection of the feet, the feet should be examined during every health care visit or at least once a year by a health care provider. Patients with diabetes also should undergo neurologic and circulatory evaluation by an experienced examiner. Neurologic examination can be done using a monofilament device, shown in Figure 30-11. Circulation can be assessed by palpating for pulses in the lower extremities or by Doppler ultrasound. Patients with pressure areas, such as calluses, or thick toenails should be treated by a podiatrist.

BOX 30-8 Patient Education

Foot Care Tips

- Take care of your diabetes:
  - Work with your health care team to keep your blood glucose level within a normal range.
- Inspect your feet every day:
  - Look at your bare feet every day for cuts, blisters, red spots, and swelling.
  - Use a mirror to check the bottoms of your feet, or ask a family member for help if you have trouble seeing.
  - Check for changes in temperature.
- Wash your feet every day:
  - Wash your feet in warm, not hot, water.
  - Dry your feet well. Be sure to dry between the toes.
  - Do not soak your feet.
  - Do not check water temperature with your feet; use a thermometer or your elbow.
- Keep the skin soft and smooth:
  - Rub a thin coat of skin lotion over the tops and bottoms of your feet but not between your toes.
  - Have corns and calluses trimmed by a podiatrist.
- Inspect toenails. All diabetic individuals should seek a qualified podiatrist for maintenance of feet and nails.
- Wear shoes and socks at all times:

- Never walk barefoot.
- Wear comfortable closed-toe shoes that fit well and protect your feet.
- Stockings should fit well (without folds, wrinkles, or seams), be comfortable, and be changed daily.
- Feel inside your shoes before putting them on each time to make sure the lining is smooth and there are no objects inside.
- Wear sandals in public showers.

- Protect your feet from hot and cold:
  - Wear shoes at the beach or on hot pavement.
  - Wear socks at night if your feet get cold.
- Keep the blood flowing to your feet:
  - Put your feet up when sitting.
  - Wiggle your toes and move your ankles up and down for 5 minutes, two or three times a day.
  - Do not cross your legs for long periods of time.
  - Do not smoke.
- Check with your health care provider:
  - Have your health care provider check your bare feet and find out whether you are likely to have serious foot problems. Remember that you may not feel the pain of an injury.
  - Call your health care provider right away if there is a cut, sore, blister, or bruise on your foot that does not begin to heal after 1 day.
  - Follow your health care provider's advice about foot care.
  - Do not self-medicate or use home remedies or over-the-counter agents to treat foot problems.

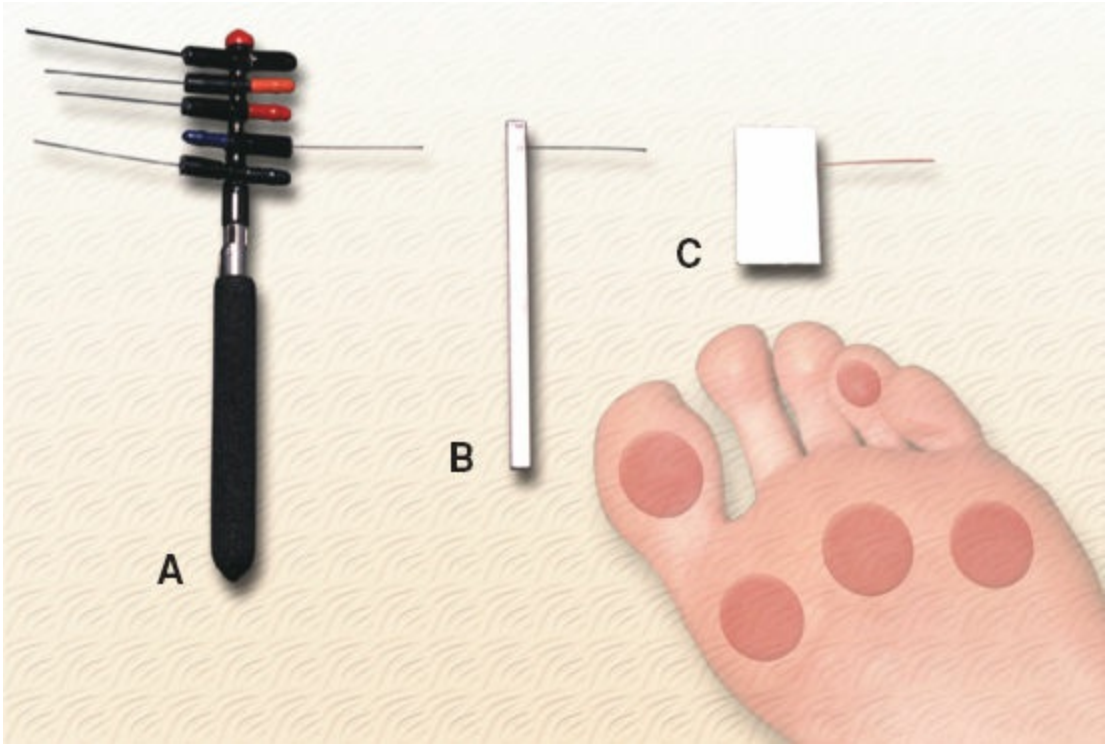

FIGURE 30-11 The monofilament test is used to assess the sensory threshold in patients with diabetes. The test instrument—a monofilament (A, B, and C are examples of monofilaments)—is gently applied to about five pressure points on the foot (as shown in image on left). The examiner applies the monofilament to the test area to determine whether the patient feels the device. (Adapted with permission from Cameron, B. L. (2002). Making diabetes management routine. *American Journal of Nursing*, *102*(2), 26–32.)

Blood glucose control is important for preventing infection and diabetic neuropathy. The patient may be referred by the health provider to a wound care center for management of persistent wounds of the feet or legs.

SPECIAL ISSUES IN DIABETES CARE

Patients with Diabetes Who Are Undergoing Surgery

During periods of physiologic stress, such as surgery, blood glucose levels tend to increase because of changes in stress hormones. If hyperglycemia is not controlled during surgery, the resulting osmotic diuresis may lead to excessive loss of fluids and electrolytes. Patients with type 1 diabetes also are at risk of developing ketoacidosis during periods of stress.

Hypoglycemia is a concern in patients with diabetes who are undergoing surgery. This is a concern especially during the preoperative period if surgery is delayed beyond the morning when the patient received a morning injection of long-acting insulin.

There are various approaches to managing glucose levels during the perioperative period. Frequent monitoring of blood glucose is essential throughout the preoperative and postoperative periods, regardless of the method used for glucose control.

During the postoperative period, patients with diabetes also must be monitored closely for cardiovascular complications because of the increased prevalence of atherosclerosis, wound infection, and skin breakdown.

Patients with Diabetes Who Are Hospitalized

At any one time, 10% to 20% of hospitalized general medical-surgical patients have diabetes. This number may increase as elderly patients make up an increasing proportion of the hospitalized population.

Often, diabetes is not the primary medical diagnosis, yet problems with control of diabetes frequently result from changes in the patient's normal routine or from surgery or illness. Some of the main issues pertinent to nursing care of patients with diabetes who are hospitalized are presented below.

Self-Care Issues

All patients admitted to the hospital must relinquish control of some aspects of their daily care to the hospital staff. For patients with diabetes who are actively involved in diabetes self-management, relinquishing control over meal timing, insulin timing, and insulin dosage can be particularly difficult.

It is important for the nurse to acknowledge the patient's concerns and involve the patient in the plan of care as much as possible. If the patient disagrees with certain aspects of nursing or medical care related to diabetes, the nurse must communicate this to other members of the health care team and, where appropriate, make changes in the plan to meet the patient's needs.

Hyperglycemia During Hospitalization

Hyperglycemia may occur in patients who are hospitalized as a result of the illness that precipitated the hospitalization. Other factors that may contribute to hyperglycemia during hospitalization include:

- Changes in usual treatment regimen
- Use of medications and IV fluids, such as partial parenteral nutrition (PPN) and total parenteral nutrition (TPN), that increase blood sugar
- Inappropriate withholding of insulin or inappropriate use of "sliding scales," or the progressive increase in insulin doses based on predefined blood glucose ranges
- Mismatched timing of meals and insulin

Nursing actions to correct or manage these factors are important for avoiding hyperglycemia.

Hypoglycemia During Hospitalization

Hypoglycemia in hospitalized patients is often the result of too much insulin or delays in eating. Causes of hypoglycemia in hospitalized patients include:

- Overuse of "sliding scale" insulin
- Lack of change in insulin dosage when dietary intake is changed
- Overly vigorous treatment of hyperglycemia

- Delayed meal after insulin administration
- Heart failure or kidney or liver disease

The nurse must assess the pattern of glucose values and avoid giving doses of insulin that repeatedly lead to hypoglycemia. Successive doses of subcutaneous rapid-acting insulin should be administered no more frequently than every 3 to 4 hours. To avoid hypoglycemic reactions caused by delayed food intake, the nurse should arrange for snacks to be given to the patient if meals are postponed because of procedures, physical therapy, or other activities.

Assisting with Hygiene

Nurses caring for patients with diabetes who are hospitalized must focus attention on oral hygiene and skin care. Because these patients are at increased risk for periodontal disease, it is important for the nurse to assist the patient with daily dental care. The patient also may require assistance in keeping the skin clean and dry, especially in the groin and axillary areas and under the breasts, where chafing and fungal infections tend to occur.

For patients who are confined to bed, nursing care must emphasize the prevention of skin breakdown at pressure points. The heels are particularly susceptible to breakdown because of loss of sensation of pain and pressure associated with sensory neuropathy.

Feet should be cleaned, dried, lubricated with lotion, and inspected frequently. If the patient is in the supine position, pressure on the heels can be alleviated by elevating the lower legs on a pillow, with the heels positioned over the edge of the pillow. When the patient is seated in a chair, the feet should be positioned so that pressure is not placed on the heels. If the patient has an ulcer on one foot, it is important to provide preventive care to the unaffected foot as well as to give special care to the affected foot. As always, every opportunity should be taken to teach the patient about diabetes self-management, including daily oral, skin, and foot care.

Managing Stress

Physiologic stress, such as infections and surgery, contributes to hyperglycemia and may precipitate DKA or HHNS. Emotional stress can have a negative impact on diabetes control as well. An increase in stress hormones leads to an increase in glucose levels, especially if intake of food and insulin remains unchanged. In addition, during periods of emotional stress, people with diabetes may alter their usual pattern of meals, exercise, and medication. This can contribute to hyperglycemia or hypoglycemia.

People with diabetes must be made aware of the potential deterioration in diabetic control that can accompany emotional stress. Nursing care must include encouraging the patient to follow the diabetes treatment plan as much as possible during times of stress. In addition, learning strategies for minimizing stress and coping with stress are important aspects of diabetes education.

NURSING PROCESS

The Patient with Diabetes as a Secondary Diagnosis

Patients with diabetes frequently seek medical attention for problems not directly related to control of blood glucose. However, during the course of treatment for the primary medical diagnosis, blood glucose control may worsen. Therefore, it is important for nurses caring for patients with diabetes to focus attention on the diabetes as well as on the primary health issue.

NURSING ASSESSMENT

In addition to nursing assessment for the primary problem, assessment of the patient with diabetes also must focus on hypoglycemia and hyperglycemia, skin assessment, and diabetes self-care skills, including survival skills and measures for prevention of long-term complications. In addition, the nurse should ask about the use of alternative and complementary therapies.

Assessment for hypoglycemia and hyperglycemia involves frequent monitoring of blood glucose, usually before meals and at bedtime, and monitoring for signs and symptoms of hypoglycemia or prolonged hyperglycemia, including DKA or HHNS.

Careful assessment of the skin, especially at pressure points and on the lower extremities, is important. The skin is assessed for dryness, cracks, skin breakdown, and redness. The patient is asked about symptoms of neuropathy, such as tingling and pain or numbness of the feet. Deep tendon reflexes are assessed.

The nurse should assess the patient's diabetes self-care skills as soon as possible to determine whether further diabetes teaching is required. The nurse observes the patient preparing and injecting the insulin, monitoring blood glucose, and performing foot care. The patient's knowledge about diet can be assessed with the help of a dietitian through direct questioning and review of the patient's menu choices. The patient is asked about signs and symptoms, treatment, and prevention of hypoglycemia and hyperglycemia. The patient's knowledge of risk factors for microvascular and macrovascular disease, including hypertension, increased lipids, and smoking, is assessed. In addition, the patient is asked the date of the last eye examination, which included dilation of the pupils. Also it is important to assess the patient's use of preventive health measures, such as an annual influenza vaccination, date of the most recent pneumonia vaccination, as well as current medication regimen.

NURSING DIAGNOSIS

Appropriate nursing diagnoses may include:

- Imbalanced nutrition related to increase in stress hormones secondary to the primary medical problem and imbalances in insulin, food, and physical activity
- Risk for impaired skin integrity related to immobility and decreased sensation
- Deficient knowledge about diabetes self-care skills related to new diagnosis, lack of basic diabetes education, or lack of continuing in-depth diabetes education

Potential complications from inadequate control of blood glucose may include:

- Hyperglycemia, hypoglycemia
- DKA or HHNS

PLANNING AND GOALS

The major goals for the patient may include improved nutritional status, maintenance of skin integrity, and ability to perform basic diabetes self-care skills as well as preventive care for the avoidance of chronic complications of diabetes and absence of complications.

NURSING INTERVENTIONS

IMPROVING NUTRITIONAL STATUS

The patient's food intake is planned with the primary goal of glucose control. The dietary prescription also must consider the primary health problem in addition to lifestyle, cultural background, activity level, and food preferences. Alterations may be required because of the patient's primary health problem. The patient may be NPO in preparation for diagnostic or surgical procedures. Other common alterations for the patient who is hospitalized include special diets, tube feedings, and parenteral fluids. All of these treatments require special consideration for the patient with diabetes. The patient's nutritional intake is monitored carefully along with blood glucose and daily weight.

MAINTAINING SKIN CARE

The skin is assessed daily for dryness or breaks. The feet are cleaned with warm water and soap. Excessive soaking of the feet is avoided. The feet are dried thoroughly, especially between the toes, and lotion is applied to the entire foot, except between the toes. For patients who are confined to bed, the heels are elevated off the bed with a pillow placed under the lower legs and the heels resting over the edge of the pillow. Dermal ulcers are treated as indicated and prescribed. The nurse promotes optimal control of blood glucose in the patient with skin breakdown.

ADDRESSING KNOWLEDGE DEFICITS

Hospital admission of the patient with diabetes provides an ideal opportunity for the nurse to assess the patient's level of knowledge about diabetes and its management. The nurse uses this opportunity to assess the patient's understanding of diabetes management, including blood glucose monitoring, administration of medications, meal planning,

exercise, and strategies to prevent long- and short-term complications of diabetes. The nurse also assesses the adjustment of the patient and family to diabetes and its management and identifies any misconceptions they may have.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Inadequate control of blood glucose levels may hinder recovery from the primary health problem. Blood glucose levels are monitored, and insulin is administered as prescribed. It is important for the nurse to ensure that the prescribed insulin dosage is modified as needed to compensate for changes in the patient's schedule or eating pattern. Treatment is given for hypoglycemia or hyperglycemia. Blood glucose records are assessed for patterns of hypoglycemia and hyperglycemia at the same time of day, and findings are reported to the primary care provider. In the patient with prolonged elevations in blood glucose, laboratory values, and the patient's physical condition are monitored for signs and symptoms of DKA or HHNS.

Development of acute complications of diabetes secondary to inadequate control of blood glucose levels may be associated with other health care problems because of changes in activity level and diet, and physiologic alterations related to the primary health problem itself. Therefore, the patient must be monitored for hyperglycemia and hypoglycemia, and measures must be implemented for their prevention and early treatment.

PROVIDING CONTINUING CARE

A patient who is hospitalized for another health problem may require referral for home care for that problem or if gaps in knowledge about self-care are found. The home care nurse reinforces the teaching provided during hospitalization and assesses the home care environment to determine its adequacy for self-care and safety.

EVALUATION

Expected patient outcomes may include the following:

1. Achieves optimal control of blood glucose:
   a. Avoids extremes of hypoglycemia and hyperglycemia
   b. Takes steps to resolve rapidly any hypoglycemic episodes
2. Maintains skin integrity:
   a. Maintains intact skin without dryness and cracking
   b. Avoids ulcers caused by pressure and neuropathy
3. Demonstrates/verbalizes diabetes survival skills and preventive care
4. Exhibits understanding of treatment modalities:
   a. Demonstrates correct technique for administering insulin or other antidiabetic medications and assessing blood glucose
   b. Demonstrates appropriate knowledge of diet through proper menu selections and identification of pattern used for selecting foods at home

c. Verbalizes signs and symptoms, appropriate treatment, and prevention of hypoglycemia and hyperglycemia

5. Demonstrates proper foot care:
   a. Inspects feet, including inspection for cracks or infections between toes
   b. Washes feet with warm water and soap; dries feet thoroughly
   c. Applies lotion to entire foot, except between toes
   d. Identifies strategies that decrease the risk of foot ulcers, including wearing shoes at all times; using hand or elbow, not foot, to test temperature of bath water; avoiding use of heating pad on feet; avoiding constrictive shoes; wearing new shoes for brief periods only; avoiding home remedies for treatment of corns and calluses; having feet examined at every appointment with the health care provider; and consulting a podiatrist for regular nail care if necessary
6. Takes steps to prevent eye disease:
   a. Verbalizes need for yearly or more frequent thorough eye examinations with pupil dilation by an ophthalmologist
   b. Verbalizes that retinopathy usually does not cause change in vision until serious damage to the retina has occurred
   c. States that early laser treatment along with good control of blood glucose and blood pressure may prevent visual loss from retinopathy
   d. Identifies hypoglycemia and hyperglycemia as two causes of temporary blurred vision
7. States measures to control risk factors:
   a. Smoking cessation
   b. Limitation of fats and cholesterol
   c. Control of hypertension
   d. Exercise
   e. Regular monitoring of kidney function
8. Reports absence of acute complications:
   a. Maintains blood glucose and urine ketones within normal limits
   b. Experiences no signs or symptoms of hypoglycemia or hyperglycemia
   c. Identifies signs and symptoms of hypoglycemia or hyperglycemia
   d. Reports appearance of symptoms so that treatment can be initiated

CHAPTER REVIEW

Critical Thinking Exercises

1. A 65-year-old man with type 2 diabetes is scheduled for surgical repair of an abdominal aortic aneurysm. What modifications in nursing assessment and care before, during, and after surgery are indicated because of the diagnosis of type 2 diabetes? How would these

differ if the patient had type 1 diabetes?

2. You are providing discharge instructions for a patient being discharged from the hospital after coronary artery bypass surgery. The 52-year-old man was overweight before surgery and smoked two packs of cigarettes daily for 20 years. He states that he neglected his health and his type 2 diabetes for two reasons: (1) the stress of his work, and (2) his belief that his diabetes was not serious because he never required insulin. Identify the areas of patient teaching you would provide for this patient and the rationale for each topic as it relates to the complications of diabetes.

3. A 28-year-old patient is newly diagnosed with type 1 diabetes. Identify the major nursing assessment issues and nursing interventions in each of the following situations: (1) the patient is in the first trimester of pregnancy; (2) the patient has a phobia about use of needles; (3) the patient has been blind from birth; and (4) the patient speaks very little English.

4. A 48-year-old woman is brought to the emergency department by her coworkers because she has become drowsy and has had slurred speech for the past hour. Her coworkers report that she lives alone and has no family nearby. They state that they think she has diabetes but can provide no additional information, including the type of diabetes or the name of her health care provider. What would be your initial actions? What assessment data would you obtain initially? What diagnostic tests and treatments would you anticipate? Provide the rationale for those tests and treatments.

5. A 45-year-old man who has three children has had diabetes for 5 years and has not followed the prescribed treatment regimen. He says, "My father and grandfather both died from diabetes. I don't see any point in modifying my life if I'm going to die from diabetes anyway." How would you approach this patient? What resources would you use? How would you alter your approach if your first efforts to convince him of the benefits of treatment were unsuccessful? How would you modify your teaching plan if the patient understands little English?

6. You are caring for a patient with diabetes, for whom self-blood glucose monitoring is recommended. Identify teaching approaches to instruct the patient about blood glucose monitoring. What is the evidence base for the teaching approach or strategy that you selected? What is the strength of the evidence, and what criteria do you use to select the approach? How would you evaluate the effectiveness of your teaching to this patient? Explain how the results of monitoring are used in the management of type 1 and type 2 diabetes.

NCLEX-Style Review Questions

1. Which should be included when teaching a newly diagnosed patient about the dietary management of diabetes?
   a. Food intake should be decreased before exercise.

b. Consistency between food intake and activity is important.
c. Carbohydrates are strictly limited.
d. Insulin and other antidiabetic agents decrease the need for dietary management.

2. A morning dose of NPH insulin is given at 7:30 AM. What is the timeframe in which the nurse can expect it to peak?
a. 11:30 AM and 1:30 PM
b. 1:30 PM and 3:30 PM
c. 3:30 PM and 9:30 PM
d. 5:30 PM and 11:30 PM

3. The nurse would expect that insulin may be substituted for other antidiabetic agents in which of the following patients?
a. In a patient with a history of DM hospitalized for an acute infection
b. In a patient having difficulty with weight management
c. In a patient experiencing hypoglycemia
d. In a patient who is newly diagnosed with borderline hyperglycemia

4. The nurse anticipates that during the initial treatment of diabetic ketoacidosis, the provider will order which solution?
a. D_5W
b. D_5.45% saline
c. Lactated Ringer solution
d. 0.9% saline

5. Which does the nurse recognize as an early indicator of nephropathy?
a. Hematuria
b. Glycosuria
c. Albuminuria
d. Polyuria

CHAPTER 31

Nursing Management: Patients with Endocrine Disorders

Elaine Siow

Learning Objectives

After reading this chapter, you will be able to:

1. Identify the disorders associated with each of the endocrine glands.
2. Describe the underlying pathophysiology of each of the endocrine disorders.
3. Identify the risk factors associated with each of the endocrine disorders.
4. Describe the clinical manifestations and assessment of each of the endocrine disorders.
5. Summarize the medical and nursing management of each of the endocrine disorders.

Disorders of the endocrine system are common and have the potential to affect the function of every organ system in the body, such as growth, development, metabolism, and fluid and electrolyte balances. When considering pathology of the endocrine system, it is helpful to consider that disorders commonly reflect either too little hormone (undersecretion), too much hormone (oversecretion), or tumors. Refer to Table 31-1 for a list of disorders associated with hormone oversecretion and undersecretion (each will be presented in this chapter). Endocrine disorders can occur from a primary condition or from a secondary disorder that resulted in altered endocrine function.

PITUITARY DISORDERS

Oversecretion (hypersecretion) is the most common cause of pituitary disorders. It usually involves hypersecretion of adrenocorticotropic hormone (ACTH) that leads to Cushing syndrome or hypersecretion of growth hormone leading to acromegaly or gigantism. While oversecretion of the pituitary may affect a singular hormone, such as growth hormone, undersecretion (hyposecretion) usually involves all of the anterior pituitary hormones and is termed *panhypopituitarism.* In this condition, the thyroid gland, the adrenal cortex, and the gonads atrophy because of loss of the trophic-stimulating hormones (influencing the activity of a gland). Hypopituitarism can result from destruction of the anterior lobe of the pituitary gland.

Recall that the posterior lobe of the pituitary gland secretes antidiuretic hormone (ADH), also known as *vasopressin*; too little ADH results in diabetes insipidus (DI), while too much ADH leads to syndrome of inappropriate ADH (SIADH).

PITUITARY TUMORS

Pathophysiology

Pituitary tumors are usually benign, although their location and effects on hormone production by target organs can cause life-threatening effects. Although local symptoms, such as headache and visual changes, may be seen as the tumor causes pressure within the brain, systemic effects are varied depending on the over/undersecretion of particular hormones. Prolactinomas are the most common form of pituitary tumor, causing a hypersecretion of prolactin that may lead to amenorrhea (loss of menstruation), galactorrhea (spontaneous, inappropriate flow of milk from male or female breasts in the absence of pregnancy/breastfeeding), and infertility in females. In males, these tumors can cause hypogonadism, decreased libido, and impotence. Because the disorder is not diagnosed early, generally the tumor is large; therefore, visual complaints from pressure on the optic chiasm (Fig. 31-1) and headaches are common findings.

Risk Factors

Multiple endocrine neoplasia, type 1 (MEN1), also known as *Wermer syndrome*, is an autosomal dominant hereditary condition that is strongly associated with developing pituitary tumors (National Cancer Institute, 2015).

TABLE 31-1 Disorders Associated with Hormone Oversecretion and Undersecretion

Hormone	Disorders Caused by Oversecretion	Disorders Caused by Undersecretion
Adrenocorticotropic hormone (ACTH)	Cushing syndrome	Addison disease
Thyroid-stimulating hormone (TSH)	Hyperthyroidism	Hypothyroidism
Growth hormone	In adults: acromegaly In children: gigantism	In children: dwarfism
Antidiuretic hormone (ADH; vasopressin)	Syndrome of inappropriate antidiuretic hormone (SIADH) secretion	Diabetes insipidus
Thyroid hormone	Hyperthyroidism	In children and adults: hypothyroidism or myxedema During fetal and neonatal development: cretinism (stunted body growth and mental development)
Parathormone	Hyperparathyroidism	Hypoparathyroidism
Insulin	Hypoglycemia	Diabetes mellitus

Clinical Manifestations and Assessment

A normal anterior pituitary gland is formed by multiple cell types, including eosinophilic, basophilic, and chromophobic cells. Eosinophilic tumors that develop early in life can result in gigantism, as the epiphyseal plates have not yet fused. The affected person may be more than 7 ft tall and large in all proportions, but the person may be so weak and lethargic that he or she can hardly stand. If the disorder begins during adult life, the excessive skeletal growth occurs only in the feet, the hands, and the superciliary ridge (bony ridge located above the eye sockets); facial features (nose, lips, ears, and forehead) become broader and larger, the tongue enlarges, the space between the teeth increases, and the lower jaw grows, resulting in an underbite and extended lower jaw (Melmed & Synder, 2016), which is called *acromegaly*. Enlargement also can involve all tissues and organs of the body. As an example, because of soft tissue enlargement, carpal tunnel syndrome is noted frequently in patients with acromegaly when carpal tunnel growth compresses on the median nerve. Patients typically suffer from severe headaches and visual disturbances because the growth of tumors exerts pressure on the optic nerves (Porth, 2015). Assessment of central vision and visual fields may indicate loss of color discrimination, diplopia (double vision), or temporal hemianopia (loss of vision of one half of the visual field). These tumors promote protein synthesis, which stimulates the growth of all organs; liver gluconeogenesis, causing hyperglycemia; decalcification of the skeleton; muscular weakness; and endocrine disturbances. Skeletal changes that occur with acromegaly are not reversible, whereas soft tissue changes may be.

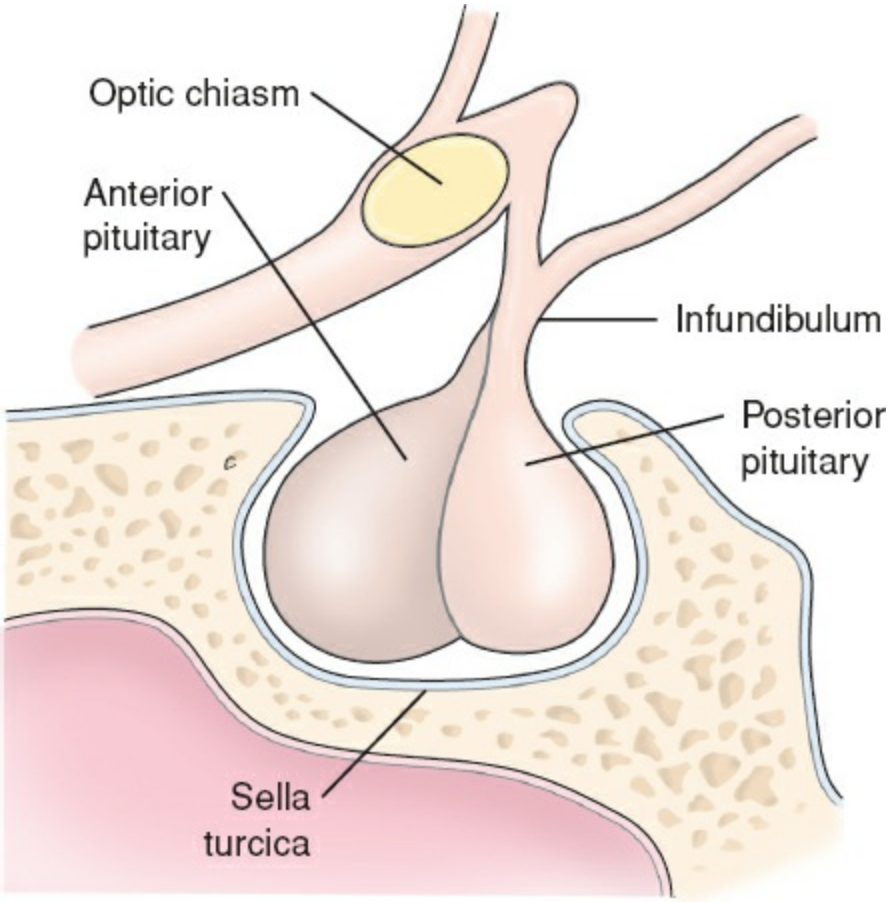

FIGURE 31-1 Relationship of the pituitary gland to the optic chiasm.

Basophilic tumors that give rise to Cushing disease have manifestations that are associated with excessive secretion of ACTH in the pituitary gland. This can lead to masculinization and amenorrhea in females, truncal obesity, hypertension, thin skin, moon face, purple skin striae, and osteoporosis.

Chromophobic tumors represent 90% of pituitary tumors. These tumors usually produce no hormones but destroy the rest of the pituitary gland, causing hypopituitarism. Because the pituitary gland releases growth hormone, thyroid-releasing hormone (TRH), ACTH, luteinizing hormone, follicle-stimulating hormone, and prolactin, signs and symptoms vary depending on the specific hormones that are deficient but may include weight loss; somnolence; fine, scant hair; dry, soft skin; a pasty complexion; short stature; and small bones. Patients also experience headaches, loss of libido, and visual defects progressing to blindness. Other signs and symptoms include polyuria, polyphagia, a lowering of the basal metabolic rate, and a subnormal body temperature.

Diagnosis requires a careful history and physical examination, including assessment of visual acuity and visual fields. Computed tomography (CT) and magnetic resonance imaging (MRI) reveal the presence and extent of pituitary tumors. If other information is inconclusive, serum levels of pituitary hormones may be obtained, along with measurements of hormones of target organs (e.g., thyroid and adrenal) to assist in diagnosis.

Medical Management

Hypophysectomy using a transsphenoidal approach is the treatment of choice for patients with a pituitary tumor, as the approach offers direct access to the sella turcica with minimal risk of trauma and hemorrhage. Tumors within the sella turcica and small adenomas of the pituitary can be removed through a transsphenoidal approach: an incision is made beneath the upper lip (sublabial) or via an endonasal approach, in which entry is gained successively into the nasal cavity, sphenoidal sinus, and sella turcica with minimal risk of trauma and hemorrhage. Microsurgical techniques used in the transsphenoidal approach provide improved illumination, magnification, and visualization so that nearby vital structures can be avoided. The transsphenoidal approach also avoids the risks of craniotomy, and the postoperative discomfort is similar to that of other transnasal surgical procedures.

Preoperatively, the patient undergoes a series of typical baseline endocrine tests, such as measurement of serum prolactin, assessment of hypercortisolism (excessive corticosteroids) for Cushing syndrome, and assessment of hypersecretion of insulin-like growth factor for acromegaly (Woodmansee, Carmichael, Kelly, & Katznelson, 2015). Funduscopic and visual field examination are performed because sometimes the pituitary tumor may create localized pressure on the optic nerve or chiasm. In addition, the nasopharyngeal secretions are cultured to detect a sinus infection, which is a contraindication to using the transsphenoidal approach.

Corticosteroids may be administered before and after surgery because the pituitary is the source of ACTH. In addition, the absence of the pituitary gland can alter the function of many body systems. For instance, cessation of menstruation and infertility can occur after total or near-total ablation of the pituitary gland. Corticosteroid replacement therapy and thyroid hormone replacement is necessary. In addition, prior to surgery, octreotide may be used to shrink the pituitary tumor and inhibit the production or release of growth hormone, improving the patient's clinical condition.

The initial postoperative management focuses on preventing infection and promoting healing because the procedure disrupts the oral and nasal mucous membranes. Antimicrobial agents are continued until removal of the nasal packing. Other medications include corticosteroids, analgesic agents for discomfort, and agents for the control of diabetes insipidus (insufficiency of ADH leading to diabetes insipidus) (Woodmansee et al., 2015).

Nursing Management

Preoperative nursing care of patients undergoing transsphenoidal removal of the pituitary tumor includes teaching deep-breathing exercises before surgery and instructing the patient to avoid vigorous coughing, blowing the nose, sucking through a straw, or sneezing because these actions may place increased pressure at the surgical site and cause a leak of cerebrospinal fluid (CSF). A leak represents a tear in the tough outermost meningeal dura, the membrane that surrounds the brain and spinal cord that contains CSF. If CSF can descend and escape via the nares, so too can bacteria ascend into the meninges. Therefore, the nurse assesses for signs of meningeal irritation, such as nuchal rigidity, temperature elevation, and changes in mental status (see Chapter 46). The nurse teaches patients to avoid activities, such as bending over or straining during urination or defecation, because they can raise intracranial pressure (ICP).

Postoperative nursing care includes monitoring vital signs, such as hemodynamic, cardiac, and respiratory status. The nurse assesses visual acuity and visual fields at regular intervals because of the close anatomic proximity of the pituitary gland to the optic chiasm. One method is to ask the patient to count the number of fingers held up by the nurse. Evidence of decreasing visual acuity may suggest an expanding hematoma. In addition, the nurse raises the head of the bed to 15 to 30 degrees with the patient's head in the midline position to limit neck vein compression, decrease pressure on the sella turcica, and promote cerebral venous drainage (reducing potential for elevated ICP). Measurement of the patient's serum electrolytes and intake and output guide replacement of fluid and electrolytes and assess for diabetes insipidus. The urine-specific gravity is measured after each voiding. The patient's daily weight is monitored to determine fluid status. Usually fluids are given after nausea ceases, after which the patient may be able to progress to a regular diet.

The nurse should check the nasal packing inserted during surgery frequently for blood or CSF drainage (Box 31-1). Often patients are instructed to breathe through their mouth instead of the nose, and oral care should be offered every 4 hours or more frequently as the patient can experience excessive mouth dryness. If a sublabial approach is used, the patient is advised not to brush his or her teeth until the incision above the teeth has been healed. Measures to help patient maintain oral care and moist mucous membranes include offering warm saline mouth rinses, using a mist vaporizer, applying lip balm, and using a room humidifier. Often nasal packing is removed 3 to 4 days postoperatively, and only then can the area around the nares be cleaned with the prescribed solution to remove crusted blood and moisten the mucous membranes (Hickey, 2014). In addition, IV antibiotics are administered as ordered to protect the patient from infection.

BOX 31-1 Focused Assessment

Cerebrospinal Fluid Leak

Be alert for the following signs and symptoms:

- Copious clear drainage from nose or ear.

- Halo ring test: Fluid leaking from the nose or external auditory canal may result in the double ring sign on absorbent tissue, which is a central circle of blood and an outer clear ring of CSF.
- A positive beta-2-transferrin test (a carbohydrate-free isoform of transferrin found in CSF) indicates that CSF fluid is present.

Note: Results of tests for glucose, chloride, and total protein of the fluid are not specific or conclusive for CSF.

From Halpern, C. H., & Grady, M. S. (2015). Chapter 42: Neurosurgery. In F. C. Brunicardi, D. K. Andersen, T. R. Billiar, D. L. Dunn, J. G. Hunter, J. B. Matthews, & R. E. Pollock (Eds.), *Schwartz's principles of surgery* (10th ed.). New York: McGraw Hill Professional.

DIABETES INSIPIDUS

Diabetes insipidus is a disorder of the posterior lobe of the pituitary gland that is characterized by a deficiency of ADH, also known as *vasopressin*. In general, this disorder is characterized by excessive thirst (polydipsia) and large volumes of dilute urine. It is helpful to remember the three D's: Diabetes insipidus, Decreased ADH, and Diuresis. There are three types of diabetes insipidus: neurogenic, nephrogenic, and psychogenic polydipsia.

Pathophysiology

Neurogenic diabetes insipidus is characterized by an acute onset resulting from the destruction of the posterior pituitary gland, resulting in a lack of vasopressin. Nephrogenic diabetes insipidus generally results from drug-related damage to the renal tubules, resulting in the inability to conserve water. Psychogenic diabetes insipidus is caused by excessive water intake.

Risk Factors

Diabetes insipidus may develop as a result of head trauma, brain tumor, surgical ablation, or irradiation of the pituitary. It also may occur with infections of the central nervous system (CNS) (e.g., meningitis, encephalitis, or tuberculosis) or with tumors (e.g., metastatic disease and lymphoma of the breast or lung). Another cause of diabetes insipidus is failure of the renal tubules to respond to ADH. This nephrogenic form of diabetes insipidus may be related to hypokalemia, hypercalcemia, or medications that impair the kidneys' ability to reabsorb water. The incidence of acute diabetes insipidus in patients with a severe head injury is high, especially in penetrating injuries. Independent risk factors for diabetes insipidus include a Glasgow Coma Scale (GCS) of 8 or less, and cerebral edema. See Chapter 45 for details on GSC (Table 45-6). Often acute diabetes insipidus after traumatic brain injury is associated with significantly increased mortality (Hannon et al., 2013).

Clinical Manifestations and Assessment

Without the action of ADH on the distal nephron of the kidney, a patient with ADH likely will have an enormous daily output of very dilute urine (3 to 20 L) with nocturia, frequency, and a specific gravity of 1.001 to 1.005 occurs. Signs and symptoms of fluid volume deficit that occur as patients are unable to compensate for the massive urinary loss include:

- Weight loss
- Poor skin turgor
- Dry mucous membranes
- Increased heart rate
- Hypotension

Due to intense thirst, the patient tends to drink 2 to 20 L of fluid daily and often prefers cold water. The onset of diabetes insipidus may be abrupt or insidious. The disease cannot be controlled by limiting fluid intake because the high-volume loss of urine continues even without fluid replacement. Fluid restriction can cause the patient to experience an insatiable craving for fluid and to develop hypernatremia and severe dehydration.

To diagnose diabetes insipidus, an accurate 24-hour urine collection is obtained to measure for volume and creatinine. A urine volume of less than 2 L/24 hours (without hypernatremia) rules out diabetes insipidus.

If central diabetes insipidus is suspected, a *vasopressin challenge test* may be used (Box 31-2). Desmopressin (DDAVP; desamino-arginine vasopressin) is administered intranasally, subcutaneously, or intravenously (IV) with subsequent measurement of urine volumes, specific gravity, and/or urine osmolality. If diabetes insipidus is secondary to central or neurogenic diabetes insipidus, administration of ADH results in an elevation of urine osmolality by more than 50%. However, if the etiology is nephrogenic, there is a small or no increase in urine osmolality as the kidneys are not responsive to ADH. In addition, levels of serum plasma are obtained to screen for diabetes mellitus (DM) (glucose), dehydration and azotemia (urea nitrogen), hypercalcemia (calcium), hypokalemia (potassium), and hyperuricemia (uric acid).

BOX 31-2 Vasopressin Challenge Test

1. Typically vasopressin test is performed in the morning with the patient having fasted.
2. An IV line has to be inserted to facilitate delivery of medications.
3. Blood samples were obtained to measure serum corticotropin (ACTH) and serum cortisol.
4. The vasopressin test involves administration of intramuscular arginine-vasopressin (AVP; 10 pressor units) or intravenous desmopressin (10 mcg).
5. Before administration of vasopressin, blood samples were obtained 15 minutes before, immediately before, and then afterward at the following intervals: 15, 30, 45,

60, 90, and 120 minutes.

From Lacroix, A., Nieman, L. K., & Martin, K. A. (2013). Vasopressin and desmopressin simulation test. *UpToDate.* Retrieved from http://www.uptodate.com/contents/vasopressin-and-desmopressin-stimulation-test.

TABLE 31-2 Laboratory Tests for Diabetes Insipidus

Test	Normal Values	Critical Values	Nursing Implications
Serum osmolality Urine osmolality Urine-specific gravity	288–291 mOsm/Kg 700–1,400 mOsm/Kg At least 1.015	Over 295 mOsm/kg Under 200 mOsm/kg 1.001–1.005	Patients will not be given fluid intake for 4–18 hours. The nurse will measure hourly urine osmolality, urine-specific gravity, and weigh patient. If patient loses at least 3% of body weight, the nurse will measure serum osmolality.
Plasma sodium	135–145 mEq/L	Over 145 mEq/L	Patient will be monitored for hypernatremia due to hypothalamic lesions, which cause impaired osmotic regulation but intact volume regulation of ADH secretion.
Serum ADH levels	1.3–4.1 pg/mL (values may vary slightly among different laboratories)	Look for low serum ADH levels in diabetes insipidus; e.g., in central diabetes insipidus, look for values below 1.1 pg/mL. High serum ADH levels are seen in nephrogenic diabetes insipidus.	If three successive hourly tests of urine osmolality indicate no change, administer 5 units of vasopressin and measure urine osmolality 1 hour later. Serum ADH is used to determine type of diabetes insipidus; e.g., primary diabetes insipidus ranges from 3 to 7.5 pg/mL, and nephrogenic diabetes insipidus ranges from 12 to 13 pg/mL. The nurse should be aware that serum ADH levels are always interpreted relative to serum osmolality.

Adapted from Williamson, M. A., & Snyder, L. M. (2015). *Wallach's interpretation of diagnostic tests*. Philadelphia, PA: Lippincott Williams & Wilkins.

Other diagnostic procedures include concurrent measurements of plasma levels of ADH and plasma and urine osmolality. Table 31-2 summarizes laboratory findings. A fluid deprivation test may be considered, but it is contraindicated if the patient's serum sodium is elevated. This test involves withholding fluids for 8 to 12 hours or until 3% to 5% of the body weight is lost, and plasma and urine osmolality studies are performed at the beginning and end of the test. Diabetes insipidus is likely if the patient continues to excrete large volumes of urine with low specific gravity and osmolality or experiences weight loss, increasing serum osmolality, and elevated levels of serum sodium. During the deprivation test, ADH or vasopressin can be given subcutaneously as described previously. However, the patient's condition needs to be monitored frequently due to the risk of severe dehydration. The test will be terminated if the patient develops tachycardia, excessive weight loss, or hypotension.

Once the diagnosis is confirmed but the cause (e.g., head injury) is unclear, the patient will be assessed further for presence of tumors that may be causing the disorder.

Pathophysiology Alert

ADH is also known as vasopressin or by its chemical name, arginine vasopressin or AVP. When ADH activity is present, small volumes of concentrated urine are excreted; whereas if ADH is absent, large amounts of diluted urine are excreted. Increased ADH is associated with SIADH while decreased levels are associated with DI (central). Normal levels are below 2.5 pg/mL or below 2.3 pmol/L (Fischbach & Dunning, 2014).

Medical Management

The objectives of medical therapy are to replace ADH (which is usually a long-term therapeutic program), to ensure adequate fluid replacement, and to identify and correct the underlying intracranial pathology.

Desmopressin/DDAVP, a synthetic vasopressin, is used to control fluid balance and prevent dehydration. Desmopressin does not have the vascular effects of natural ADH. Thus, it is particularly valuable due to its longer duration of action and fewer adverse effects compared to other preparations previously used to treat the disease. Desmopressin can be administered orally as tablets or intranasally using a spray or a flexible calibrated plastic tube. Usually one or two administrations daily (every 12 to 24 hours) are needed to control the symptoms. However, sometimes nasal decompression can cause rhinitis or conjunctivitis (Fitzgerald, 2015).

Other medications used to treat patients with diabetes insipidus include intramuscular administration of vasopressin, chlorpropamide (Diabinese), thiazide diuretics (potentiate the action of vasopressin), and/or prostaglandin inhibitors (e.g., ibuprofen, indomethacin, and aspirin). Intramuscular administration of ADH, vasopressin tannate in oil, is used if the intranasal route is not possible. The medication is administered every 24 to 96 hours. The vial of medication should be warmed or shaken vigorously before administration. The injection is administered in the evening so that maximum results are obtained during sleep. Abdominal cramps are a side effect of this medication. Rotation of injection sites is necessary to prevent lipodystrophy. The patient receiving chlorpropamide should be warned of the possibility of hypoglycemic reactions. If the diabetes insipidus is renal in origin, the previously described treatments are ineffective. Thiazide diuretics, mild salt depletion, and prostaglandin inhibitors (ibuprofen, indomethacin, and aspirin) are used to treat the nephrogenic form of diabetes insipidus. There is no effective treatment for psychogenic diabetes insipidus, and sometimes the only help for these patients is to prevent water intoxication by limiting use of drugs that impair free water excretion, such as thiazide diuretics and carbamazepine (Tegretol) (Robertson, 2015).

Nursing Management

The nursing management of the patient with diabetes insipidus includes maintaining adequate fluid volume, monitoring patient's weight, administering vasopressin, monitoring vital signs, and monitoring patient's intake and output. Due to vasoconstrictive properties, vasopressin should be avoided in patients with pre-existing coronary artery disease (CAD) or vascular disease. The patient with possible diabetes insipidus needs support while undergoing studies for a possible cranial lesion. Prior to discharge, the nurse informs the patient and family about follow-up care and emergency measures, provides specific verbal and written instructions, demonstrates how to administer the medications, and observes return demonstrations as appropriate. The nurse should provide instructions on measuring daily weights to determine how much body fluid has been gained or lost. This information will allow the provider to titrate the dosage of vasopressin accordingly to avoid doses that are too high or too low. For instance, high dose of vasopressin will lead to fluid retention and weight gain. On the other hand, insufficient or low dose of vasopressin will lead to excess urine production (polyuria) and weight loss. In addition, the nurse should advise the patient to wear a medical identification bracelet and to carry medication and information about this disorder at all times.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

SIADH is a syndrome characterized by excessive secretion of ADH, causing significant retention of water. As a result, the sodium level becomes dilute, and hyponatremia ensues. It is the most frequently cited cause of euvolemic hyponatremia. In patients hospitalized with hyponatremia, over 50% of cases can be attributed to SIADH (Ferri, 2016a). Table 31-3 details the characteristics of DI versus SIADH.

TABLE 31-3 Differentiating Features of DI versus SIADH

Value	Diabetes Insipidus	SIADH
ADH	⇓	⇑
Serum sodium (Na)	⇑	⇓
Urine output	⇑ urine output	⇓ urine output
Urine osmolality	⇓ (for what would be expected)	⇑ (for what would be expected)
Specific gravity	⇓ <1.005	⇑ >1.030

Pathophysiology

SIADH is a disorder of impaired water excretion caused by the inability to stop the secretion of ADH. As a result, excessive ADH can be secreted from the pituitary gland directly into the bloodstream, or by abnormal synthesis and secretion of vasopressin by tumors. Patients with this disorder cannot excrete diluted urine. They retain water and develop a subsequent sodium deficiency known as dilutional hyponatremia. With too much H_2O in the bloodstream, the kidneys cannot excrete dilute urine, and the water moves from the extracellular compartment to the intracellular region, causing brain cells to swell. This has a significant impact on the CNS (brain and spinal cord) because of brain edema and increased ICP. If the sodium level becomes low enough (approximately 115 mEq/L), seizures may occur.

Risk Factors

SIADH is often of nonendocrine origin. For instance, the syndrome may occur in patients with malignancies, pulmonary disorders, disorders of the nervous system, and medication use. Carcinomas (lung, GI tract [stomach, duodenum, pancreas], GU tract [ureter, bladder, prostate, endometrium], and lymphoma) that synthesize and release ADH can lead to SIADH. SIADH has occurred in patients with pulmonary disease, such as advanced tuberculosis, severe pneumonia, positive-pressure ventilation, and other disorders of the lungs (Porth, 2015). Disorders of the CNS, such as head injury, brain surgery or tumor, vascular (stroke, subdural hematoma, subarachnoid hemorrhage), and infection (brain abscess, meningitis, encephalitis), can produce SIADH by direct stimulation of the pituitary gland. HIV infection is also associated with the development of SIADH and may be related to an underlying infection of the pulmonary (pneumocystic pneumonia) or CNS or malignancy (Porth, 2015). Medications, such as vincristine, phenothiazines, tricyclic antidepressants (SSRIs, tricyclic, MAOI), thiazide diuretics, anticonvulsants, antidiabetic drugs, and nicotine, can cause SIADH, either by directly stimulating the pituitary gland or by increasing the sensitivity of renal tubules to circulating ADH.

Clinical Manifestations and Assessment

The clinical manifestations of SIADH include the following:

- Hyponatremia (sodium below 134 mEq/L),
- Decreased serum osmolality (less than 280 mOsm/kg) with inappropriately increased urine osmolality (greater than 100 mOsm/kg—reveals impaired ability of the kidneys to dilute the urine),
- Urine sodium over 20 mEq/L,
- Low blood urea nitrogen (BUN) (below 10 mg/dL), and
- Hypouricemia (uric acid below 4 mg/dL) (Cho, 2015).

Obtain a detailed history to rule out other causes of hyponatremia, such as heart failure, adrenal insufficiency, and kidney failure. On assessment, patients usually present with normal vital signs, moist mucous membranes, normal skin turgor, and no edema. The reabsorbed water tends to be intracellular rather than interstitial, and, therefore, patients appear euvolemic (normal volume). Patients with SIADH resulting in severe hyponatremia often exhibit more acute symptoms, such as confusion, lethargy, weakness, myoclonus, asterixis, depressed reflexes, generalized seizures, and coma related to ensuing cerebral edema.

Medical Management

Medical management includes identifying and eliminating the underlying cause. Brain and chest imaging may be obtained to identify a potential etiology, such as CNS or lung pathology. Laboratory testing is performed to rule out other cause of hyponatremia, such as infection (white blood cell [WBC] count) or dysfunction of a number of systems: thyroid (thyroid-stimulating hormone [TSH] level), adrenal (cortisol), cardiac (EKG, echocardiogram, brain natriuretic peptide [BNP]), liver (liver function tests), and kidney (BUN and serum creatinine). Elevated plasma arginine vasopressin (AVP) level is expected. Treatment will depend on the speed of onset of the hyponatremia and the clinical presentation. In asymptomatic patients, fluid restriction is the treatment of choice (less than 1 L water per day), whereas in acutely symptomatic patients (profound hyponatremia is present with Na below 120 mEq/L), an IV of 3% sodium chloride (hypertonic saline) will be infused slowly via a central line and IV pump. Diuretics, such as furosemide (Lasix) IV, will prevent extracellular fluid volume expansion by causing diuresis. Because retained water is excreted slowly through the kidneys, the extracellular fluid volume contracts and the serum sodium concentration gradually increases toward normal. It is important not to correct the sodium level too rapidly; the rate of correction aims to increase the serum sodium 8 to 10 mEq/L during the first 24 hours (Ferri, 2016a; Spasovski et al., 2014) since rapid correction can cause demyelination and permanent damage to the CNS.

Nursing Management

Nursing management includes close monitoring of fluid intake and output (fluid restriction is a mainstay of therapy in most patients with SIADH, with a suggested goal intake of less than 800 mL/day), daily weight, urine and blood chemistries, and neurologic status. The sodium level will be evaluated at regular intervals—typically every 4 to 6 hours with any active treatment—until the sodium level stabilizes. The nurse assesses for neurologic signs caused by hyponatremia, such as confusion, seizures, and delirium as well as cardiopulmonary status (hypervolemia, including hypertension, pulmonary crackles, pleural effusions, tachypnea, decreased O_2 saturation, ascites, JVD, and peripheral edema). If ordered, the nurse carefully monitors hypertonic saline administration because a complication of overaggressive treatment with 3% saline is central pontine myelinolysis (CMP) (Box 31-3). Providing supportive measures and explanations of procedures helps the patient with this disorder.

BOX 31-3 Focus on Pathophysiology

Central Pontine Myelinolysis

Central pontine myelinolysis (CMP) is a serious complication that develops after aggressive treatment of hyponatremia. The rapid rise in serum sodium with resultant change in serum osmolality causes water to be pulled from the brain cells. The changes in the brain cell volume (shift in water out of brain cells) causes injury to the myelin sheath (myelin sheath protects the nerves). These changes can result in significant neurologic morbidity and mortality. The most common presentation of CMP is a decreased level of consciousness.

Nursing Alert

As appropriate, use seizure precautions to protect the patient from injury and prevent aspiration. Keep oxygen and suctioning equipment at the bedside. See Box 46-2 on page 1319 for details on seizure precautions. In the event of a seizure, lower the head of the bed and place the patient on his or her side to prevent aspiration and protect the airway.

DISORDERS OF THE THYROID GLAND

The thyroid gland controls cellular metabolic activity, refer to Box 31-4 for symptoms of undersecretion (hypothyroidism) and oversecretion (hyperthyroidism).

HYPOTHYROIDISM

Hypothyroidism results from insufficient levels of thyroid hormone. Thyroid deficiency can affect all body functions, and symptoms range from mild, subclinical forms to myxedema coma, a life-threatening hypothyroidism.

Often patients with hypothyroidism may have *primary* or *thyroidal hypothyroidism*, which refers to dysfunction of the thyroid gland itself. If the cause of the thyroid dysfunction is failure of the pituitary gland, the hypothalamus, or both, then the hypothyroidism is known as *central hypothyroidism.* If the cause is entirely a pituitary disorder, then it may be referred to as *pituitary* or *secondary hypothyroidism.* If the cause is a disorder of the hypothalamus resulting in inadequate secretion of TSH due to decreased stimulation by TRH, then it is referred to as *hypothalamic* or *tertiary hypothyroidism.* If thyroid deficiency is present at birth, then the hypothyroidism is known as *cretinism.* In such instances, the mother also may have thyroid deficiency. See Figure 31-2 and Table 31-4.

BOX 31-4 Focused Assessment

Hyperthyroidism versus Hypothyroidism

Be alert for the following signs and symptoms of hyperthyroidism:

- Weight loss
- Warm, moist, flushed skin
- Tremors, emotionally hyperexcitable
- Tachycardia, irregular pulse
- Heat intolerance, hyperthermia
- Increased GI function
- Thinning of hair
- Exophthalmos (visual protrusion of the eye), corneal ulcerations
- Patients may have a staring gaze, a rim of sclera visible between the upper eyelid and the superior margin of the iris during downward gaze (lid lag)
- Systolic murmur, thrill, bruit

Be alert for the following signs and symptoms of hypothyroidism:

- Weight gain
- Dry skin, nonpitting edema

- Fatigue, mental and physical sluggishness
- Bradycardia
- Cold intolerance
- Constipation
- Coarse hair, loss of eyebrows
- Carpal tunnel syndrome
- Pleural and pericardial effusions

Pathophysiology

In hypothyroidism, the decreased production of thyroxine (T_4) leads to the stimulation of TSH in the pituitary gland. Subsequently, TSH stimulates the secretion of triiodothyronine (T_3) to increase production of T_4, leading to hypertrophy of the thyroid gland. Laboratory findings include decreased T_3 and T_4 and an increased TSH.

Risk Factors

The most common cause of hypothyroidism in adults is autoimmune thyroiditis (Hashimoto disease), in which the immune system attacks the thyroid gland. Hypothyroidism can occur in patients with previous hyperthyroidism treated with radioiodine or antithyroid medications or thyroidectomy. There is an increased incidence of hypothyroidism in patients who have undergone radiation therapy for head and neck cancer. Therefore, thyroid function tests are recommended for all patients who receive such treatment.

Hypothyroidism has been shown to affect women five times more frequently than men and occurs most often in people between 30 and 60 years of age. Additionally, longstanding mild to moderate hypothyroidism often is seen in the elderly. The explanation for the higher prevalence of hypothyroidism among elderly people may be related to alterations in immune function with age. Subclinical disease is common among older women and can be asymptomatic or mistaken for other medical conditions. For instance, subtle symptoms of hypothyroidism, such as fatigue, muscle aches, and mental confusion, may be attributed to the normal aging process by the patient, family, and health care provider. Hence, screening of TSH levels over a 3- to 6-month interval is recommended for nonpregnant adults to confirm or rule out abnormal findings before making a diagnosis or considering any treatment strategies (LeFevre, 2015). Gerontologic considerations are discussed in Box 31-5.

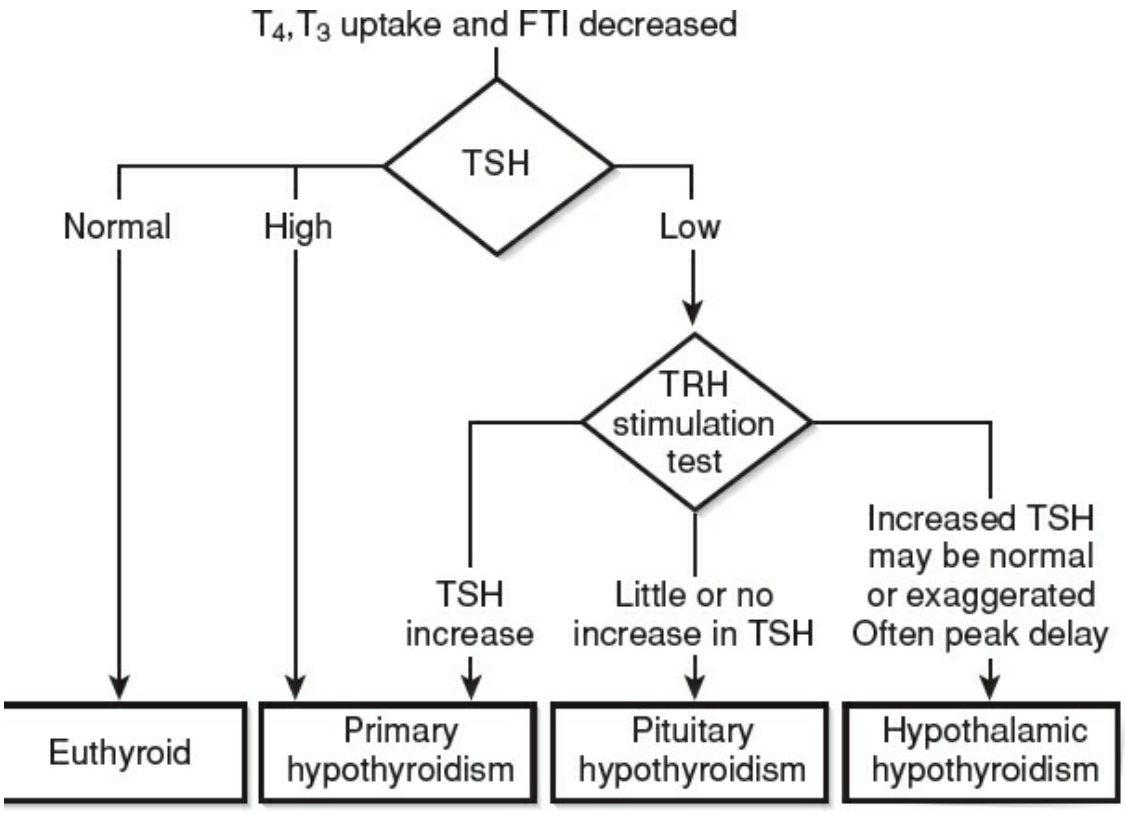

FIGURE 31-2 Algorithm for diagnosis of hypothyroidism. The sensitive thyroid-stimulating hormone (TSH) test is the preferred primary screening test for thyroid disease. Low TSH obviates the need for the thyroid-releasing hormone (TRH) test in most patients. T_4, thyroxine; T_3, triiodothyronine; FTI,

free thyroxine index. (From, Talreia, D. T., Talreia, R. R., & Talreia, R. S. (2005). *Internal medicine peripheral brain*. Philadelphia, PA: Lippincott Williams & Wilkins.)

TABLE 31-4 Varieties of Hypothyroidism and their Causes

Name	Cause
Primary or thyroidal hypothyroidism	Dysfunction of the thyroid gland itself
Central hypothyroidism	Failure of the pituitary gland, the hypothalamus, or both
Pituitary or secondary hypothyroidism	A pituitary disorder
Hypothalamic or tertiary hypothyroidism	Disorder of the hypothalamus resulting in inadequate secretion of TSH due to decreased stimulation by TRH
Cretinism	Thyroid deficiency present at birth, the mother also may have thyroid deficiency

Clinical Manifestations and Assessment

Clinical manifestations of hypothyroidism are divided into early and late symptoms and represent slowing of the metabolic process. The early symptoms of hypothyroidism are nonspecific and can range from fatigue to somnolence, loss of libido to amenorrhea, apathy to mental and physical sluggishness, nonpitting edema to pleural and pericardial effusions. Reports of hair loss, brittle nails, and dry skin are common. The patient frequently complains of constipation. Paresthesia (numbness and tingling of the fingers) and nerve entrapment syndrome have been linked with endocrine disorders, such as hypothyroidism, but the etiology is poorly understood. Also hearing loss may occur.

Late symptoms include slow speech, subdued emotional responses, apathy, absence of sweating, cold intolerance, constipation, thickening of skin (due to accumulation of mucopolysaccharides in subcutaneous tissues), dyspnea, weight gain, thinning of hair, alopecia, and deafness. On assessment, patients usually present with swelling of eyelids, pitting edema, bradycardia, hypotension, and hypothermia. Figure 31-3 illustrates clinical manifestations of hypothyroidism.

Advanced hypothyroidism may produce personality and cognitive changes that are characteristic of dementia. Respiratory manifestations include pleural effusion, respiratory muscle weakness, inadequate ventilation, and sleep apnea.

Severe hypothyroidism is associated with an elevated level of serum cholesterol, atherosclerosis, CAD, poor left ventricular function, and pericardial effusion. In addition, the patient with severe hypothyroidism often presents with subnormal temperature and pulse rate. The patient usually begins to gain weight even without an increase in food intake, although he or she may be cachectic. The hair thins and falls out, and the face becomes expressionless and masklike. The patient often complains of being cold, even in a warm environment.

BOX 31-5 Gerontologic Considerations

Hypothyroidism

The elderly often present with atypical signs and symptoms of hypothyroidism. For instance, the elderly patient may have few or no symptoms until the dysfunction is severe. Depression, apathy, and decreased mobility are major initial symptoms that may be accompanied by significant weight gain despite a poor appetite. In addition, constipation is common and affects one fourth of elderly patients with hypothyroidism. In the elderly patient with mild to moderate hypothyroidism, thyroid hormone replacement must be started with low dosages and increased gradually to prevent serious cardiovascular and neurologic side effects. (Remember “start low and go slow.”) In general, thyroid replacement begins at one fourth to one half the expected dose and is increased in small increments no sooner than 4 to 6 weeks apart. Angina may occur with rapid thyroid replacement in the presence of coronary artery disease secondary to the hypothyroid state or pre-existing atherosclerosis. Heart failure and tachyarrhythmias

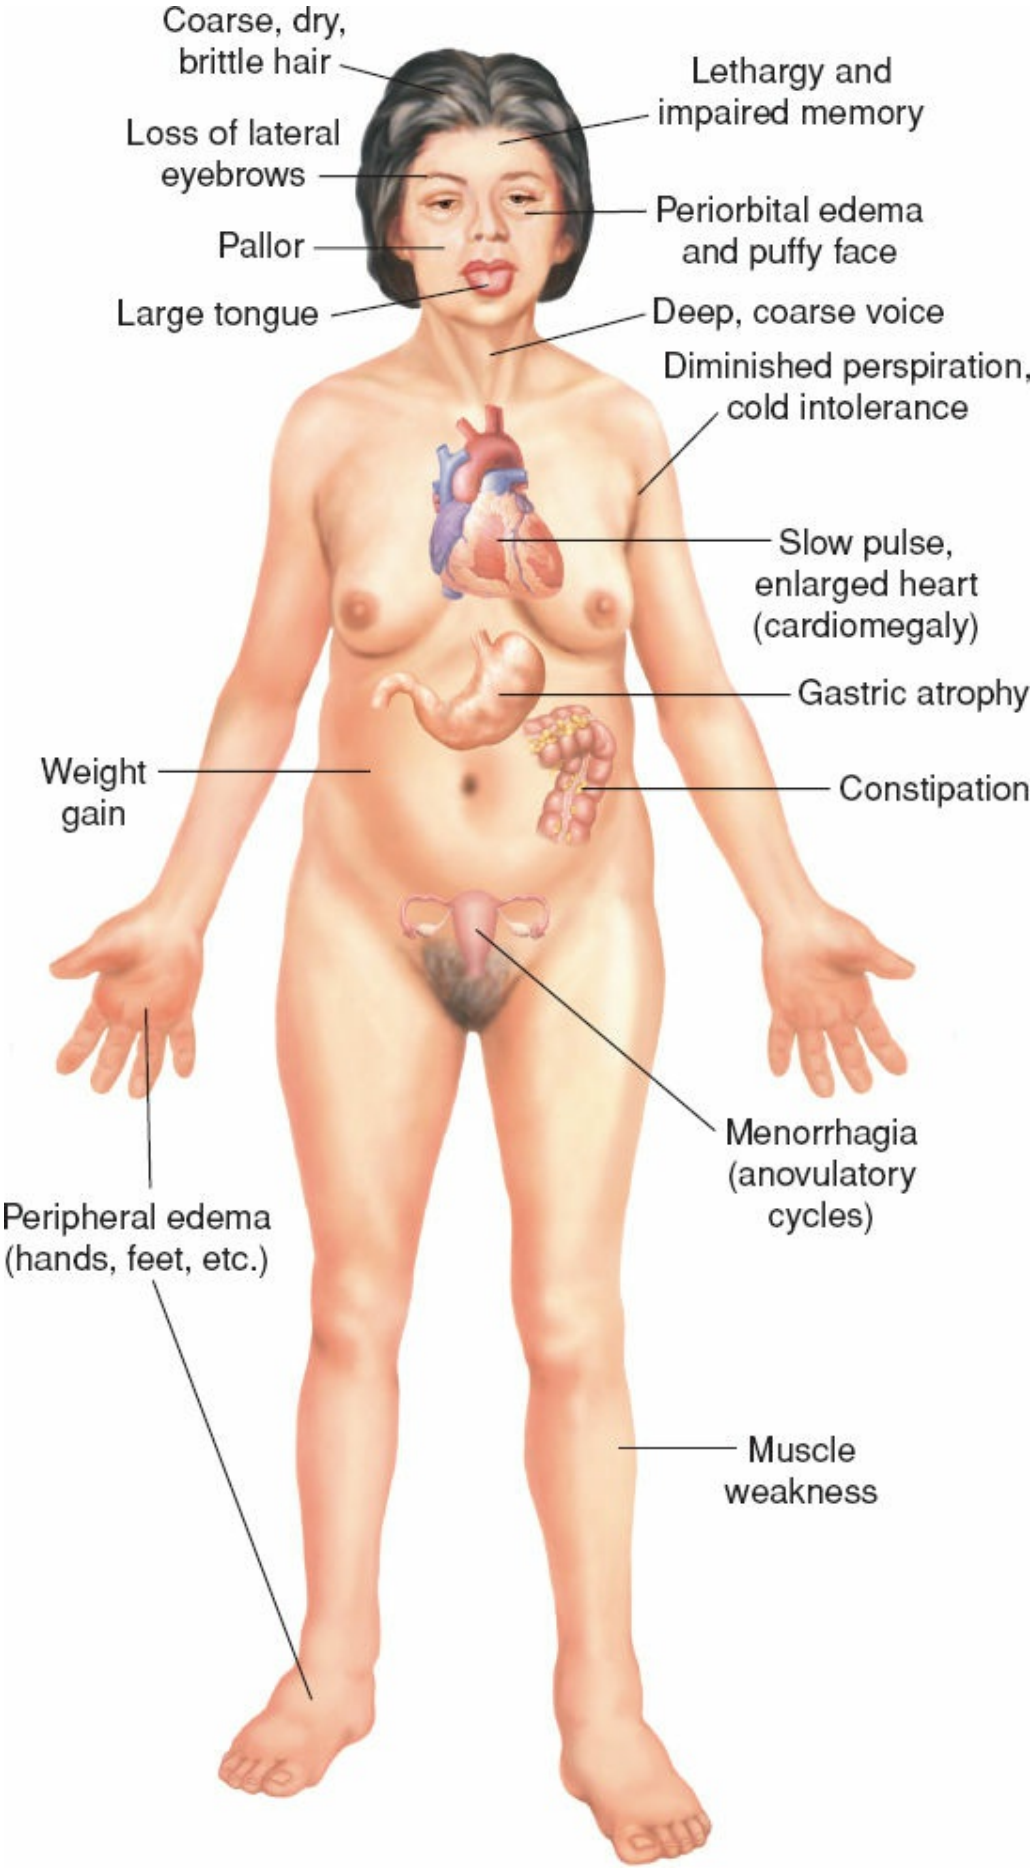
may worsen during the transition from the hypothyroid state to the normal metabolic state. Dementia may become more apparent during early replacement of thyroid hormone in the elderly patient.

Elderly patients with severe hypothyroidism and atherosclerosis may become confused and agitated if their metabolic rate is increased too quickly. Marked clinical improvement follows the administration of hormone replacement; such medication must be continued for life. The elderly patient requires periodic follow-up monitoring of levels of serum TSH. In addition, the elderly should be reminded that failure to comply with current therapy may lead to complications. A careful history can identify the need for further teaching about the importance of safe medication administration.

Complications, such as myxedema and myxedema coma, usually occur exclusively in patients older than 50 years of age. The high mortality rate of myxedema coma mandates immediate IV administration of thyroid hormone as well as supportive care and monitoring for cardiac complications, particularly in patients with ischemic heart disease.

Nursing Alert

The patient with advanced hypothyroidism is profoundly hypothermic (91°F to 95°F) and abnormally sensitive to sedatives, opioids, and anesthetic agents. Therefore, these medications are administered with extreme caution. If these medications are used, closely monitor the patient's vital signs (heart rate, blood pressure, body temperature, and respiration rate).



Coarse, dry, brittle hair
Loss of lateral eyebrows
Pallor
Large tongue
Lethargy and impaired memory
Periorbital edema and puffy face
Deep, coarse voice
Diminished perspiration, cold intolerance
Slow pulse, enlarged heart (cardiomegaly)
Gastric atrophy
Weight gain
Constipation
Menorrhagia (anovulatory cycles)
Peripheral edema (hands, feet, etc.)
Muscle weakness

FIGURE 31-3 Dominant clinical features of hypothyroidism. (From Porth, C. M. (2015). *Essentials of pathophysiology: Concepts of altered health states* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Myxedema coma describes the most extreme, severe stage of hypothyroidism, in which the patient is hypothermic and unconscious. Increasing lethargy may progress to stupor and then to coma. Myxedema leads to the accumulation of mucopolysaccharides in subcutaneous and other interstitial tissues; this causes nonpitting edema and doughy skin. The fluid accumulation causes a characteristic puffy appearance to the face and eyes (periorbital edema). The patient's tongue can be enlarged, and his or her voice becomes hoarse and husky. Sometimes myxedematous fluid can cause pericardial and pleural effusions (Porth, 2015). Myxedema coma may also develop with undiagnosed hypothyroidism and may be precipitated by infection, systemic disease, or the use of sedatives or opioid analgesic agents. The patient's respiratory drive is depressed, resulting in alveolar hypoventilation, progressive carbon dioxide retention, narcosis, and coma. These symptoms, along with cardiovascular collapse and shock, require aggressive and intensive therapy if the patient is to survive. Myxedema coma is a medical emergency; even with early vigorous therapy, mortality rate is high.

Medical Management

Hormone Replacement

The primary objective in the medical management of hypothyroidism is to restore a normal metabolic state by replacing the missing hormone, levothyroxine (thyroxine; T_4). Synthetic levothyroxine (Synthroid or Levothroid) is the preferred preparation for treating hypothyroidism and suppressing nontoxic goiters (enlargements of the thyroid gland). The dosage for hormone replacement is based on the concentration of the patient's serum TSH. If replacement therapy is adequate, the symptoms of myxedema disappear and normal metabolic activity is resumed.

Cardiac Management

The patient who has lived with hypothyroidism for a long period of time is likely to have coronary-related diseases, such as atherosclerosis and CAD. Recall that there is elevated serum cholesterol in hypothyroidism, which is largely accounted for by an increase of LDL-cholesterol, which is a risk factor for coronary heart disease. As long as metabolism is subnormal and the tissues, including the myocardium, require relatively little oxygen, a reduction in blood supply is tolerated without overt symptoms of CAD. When thyroid hormone is administered, the myocardial oxygen demand increases without increasing the myocardial oxygen supply; therefore, patients should be monitored for cardiac complications, such as chest pain and congestive heart failure. Patients also may be treated for angina or arrhythmias due to the release of catecholamines that may be activated during thyroid replacement therapy. In the event of angina or arrhythmias, the nurse should notify the primary care provider immediately and discontinue administration of the thyroid hormone. The thyroid hormone replacement can be resumed at a later time at a lower prescribed starting dosage under the close observation of the prescribing provider and the nurse.

Nursing Management

A plan of nursing care for a patient with hypothyroidism is available online at http://thepoint.lww.com/Honan2e.

Monitoring Physical Status

The nurse closely monitors the patient's vital signs and cognitive level to detect any deterioration of physical and mental status, signs and symptoms indicating that treatment has resulted in a metabolic rate exceeding the ability of the cardiovascular and pulmonary systems to respond, and continued limitations or pleural and pericardial effusions (complications of myxedema). The normal levels of pericardial fluid are from 15 to 50 mL and pleural fluid of less than 10 to 20 mL (Porth, 2015). Table 31-5 discusses pleural and pericardial effusions.

TABLE 31-5 Pericardial and Pleural Effusion

Effusion	Description	Assessment Findings
Pericardial effusion	When fluid accumulates in the pericardium, the intrapericardial pressure increases around the heart, causing a cardiac tamponade. As a result, the ventricles are unable to fill properly, leading to a low stroke volume.	Beck triad: When pericardial effusion increases significantly enough to impair cardiac function, a cardiac tamponade develops (the three **D's**): • **D**istant heart sounds • **D**istention of the jugular veins • **D**ecreased cardiac output
Pleural effusion	Fluid accumulates in the pleural space, causing symptoms of dyspnea, nonproductive cough, and pleuritic chest pain.	The three **D**'s of pleural effusion: • **D**ull to percussion on affected side • **D**ecreased breath sounds on affected side • **D**ecreased respiratory excursion on affected side

Providing Supportive Management

In severe hypothyroidism and myxedema coma, nursing care includes maintaining vital functions, such as managing cardiopulmonary status, hyponatremia, and hypoglycemia (Porth, 2015). Arterial blood gases (ABGs) may be measured to determine retention of carbon dioxide and to guide the use of assisted ventilation to combat hypoventilation. Pulse oximetry also may be helpful in monitoring oxygen saturation levels. The nurse should administer fluids cautiously because of the danger of water intoxication. The patient's blood glucose levels will be monitored closely, especially when on thyroid replacement therapy.

Nursing Alert

Hypoglycemia may be seen with hypothyroidism. The etiology of this finding is associated with a sluggish liver, increasing the patient's susceptibility to low blood sugar. Hyponatremia is associated with approximately 50% of patients with myxedema coma and is thought to be associated with impairment of free water excretion by the kidneys, excess ADH release, or renal impairment (Ross, 2015).

Nursing Alert

If hypoglycemia is evident, concentrated glucose may be prescribed to provide glucose without precipitating fluid overload. Oral antidiabetic agents or insulin may be administered to reduce the effect of hyperglycemia that results from thyroid replacement therapy.

Preventing Medication Interactions

The nurse should take precautions during the course of therapy because of the interaction of thyroid hormones with other medications. Thyroid hormones may increase blood glucose levels, which may necessitate adjustment in the dosage of insulin or oral antidiabetic agents in patients with diabetes. The effects of thyroid hormone may be increased by phenytoin (Dilantin) and by tricyclic antidepressant agents. Thyroid hormones also may increase the pharmacologic effects of digitalis glycosides, anticoagulant agents, and indomethacin, necessitating careful observation and assessment by the nurse for side effects. Also bone loss and osteoporosis may occur with thyroid therapy.

Even in small doses, hypnotic and sedative agents may induce profound somnolence, lasting far longer than anticipated. Furthermore, they are likely to cause respiratory depression, which can easily be fatal because of decreased respiratory reserve and alveolar hypoventilation. If their use is necessary, the dose should be one half or one third of that ordinarily prescribed in patients of similar age and weight with normal thyroid function. If these medications must be used, the patient must be monitored closely for signs of impending narcosis (stupor-like condition) or respiratory failure.

Encouraging Mobility

Encouraging participation in activities within established tolerance can help prevent complications of immobility. The patient with hypothyroidism experiences decreased energy and moderate to severe lethargy. As a result, the risk of complications from immobility increases. The patient's ability to exercise and to participate in activities is further limited by the changes in cardiovascular and pulmonary status that occur secondary to hypothyroidism. The nurse assists the patient with care and hygiene while encouraging the patient to participate within his or her ability.

Promoting Comfort and Safety

The patient often experiences chilling and extreme intolerance to cold, even if the room feels comfortable or hot to others. The nurse provides extra clothing and blankets and protects the patient from drafts. Heating pads and electric blankets should be avoided because of the risk for peripheral vasodilatation, further loss of body heat, and vascular collapse. In addition, the patient is at risk of experiencing burns from these items without being aware of it because of his or her delayed responses and decreased mental status associated with hypothyroidism.

Enhancing Coping Mechanisms

The patient with moderate to severe hypothyroidism may experience severe emotional reactions to changes in appearance and body image and the frequent delay in diagnosis.

The nonspecific, early symptoms may have produced negative reactions by family members and friends, who may have labeled the patient mentally unstable, uncooperative, or unwilling to participate in self-care activities. As hypothyroidism is treated successfully and symptoms subside, the patient may experience depression and guilt as a result of the progression and severity of symptoms that occurred. The nurse informs the patient and family that the symptoms and inability to recognize them are common and are part of the disorder itself. The patient and family may require assistance and counseling to deal with the emotional concerns and reactions that result.

HYPERTHYROIDISM

Hyperthyroidism is the second most prevalent endocrine disorder, after DM.

Pathophysiology

Hyperthyroidism occurs as a result of the overproduction of T_3, T_4, or both from the thyroid gland. Oversecretion of thyroid hormones (hyperthyroidism) is manifested by a greatly increased metabolic rate. Other characteristics of hyperthyroidism result from the increased response to circulating catecholamines (epinephrine and norepinephrine). Refer to Box 31-4. Usually oversecretion of thyroid hormones is associated with an enlarged thyroid gland (goiter).

Graves disease is a common cause of hyperthyroidism. It is an autoimmune disease of the thyroid gland that results in the binding of antibodies to TSH, which causes the overproduction of thyroid hormones T_3 and T_4. Women are eight times more likely to be affected with this disease than men, with an onset usually between 20 and 40 years of age (Fitzgerald, 2015). Symptoms may appear after an emotional shock, stress, or an infection, but the exact significance of these relationships is not understood. Other less common causes of hyperthyroidism include thyroiditis (inflammation of the thyroid), overmedication with synthetic thyroid hormone, and thyroid nodules. Symptoms of hyperthyroidism also may occur with the release of excessive amounts of thyroid hormone as a result of inflammation after irradiation of the thyroid or destruction of thyroid tissue by tumor.

Patients with well-developed hyperthyroidism exhibit a typical group of signs and symptoms associated with hypermetabolism (the basal metabolic rate can increase 60% to 100% above normal when in hyperthyroid state where large amounts of T_4 are present [Porth, 2015]). The course of the disease may be mild, characterized by remissions and exacerbations and terminating with spontaneous recovery in a few months or years. When untreated, the disease may progress relentlessly, leading to emaciation, nervousness, delirium, disorientation, and heart failure. The term thyrotoxicosis refers to *symptomatic* hyperthyroxinemia. While hyperthyroidism is a type of thyrotoxicosis, they are not the same. Although thyrotoxicosis can be caused by hyperthyroidism, other examples of thyrotoxicosis are associated with inflammation of the thyroid gland or ingestion of thyroid hormone. In these circumstances, there is an increased in either release of stored thyroid hormone or ingestion of exogenous hormone but not accelerated synthesis. Finally, a life-threatening complication of hyperthyroidism, in which profound hypermetabolism involves multiple systems, is called *thyrotoxic crisis* or *thyroid storm.*

Clinical Manifestations and Assessment

Patients with hyperthyroidism often present with symptoms of nervousness. Often these patients are emotionally hyperexcitable, irritable, and apprehensive. They cannot sit quietly. Cardiac complaints may include palpitations. Rapid resting pulse rates typically range between 90 and 160 beats per minute. The systolic blood pressure is elevated; and electrocardiogram (ECG) findings may reveal sinus tachycardia or atrial fibrillation. Patients tolerate heat poorly and perspire unusually freely (hyperhydrosis–excessive sweating). The skin appears flushed and feels warm, soft, and moist. The elderly may report dry skin and diffuse pruritus. A fine tremor of the hands and tongue may be observed. Patients typically exhibit exophthalmos (bulging eyes associated with abnormal fluid accumulation behind the eyes), which produces a startled facial expression. Other manifestations include increased dietary intake, progressive weight loss, abnormal muscular fatigability, weakness (e.g., difficulty climbing stairs and rising from a chair), amenorrhea, decreased fertility, and changes in bowel patterns (increased peristalsis). Also osteoporosis and fracture are associated with hyperthyroidism because of increased loss of bone minerals.

On physical assessment, the thyroid gland is enlarged, feels soft, and may pulsate; often a thrill can be palpated, and a bruit is heard over the thyroid arteries. These are signs of increased blood flow through the thyroid gland. If the thyroid becomes hypertrophied, compression may be noted on the trachea or esophagus. Assess for respiratory distress, stridor, or dysphagia. Cardiac effects on the ECG may include sinus tachycardia or arrhythmias. In addition, the physical examination may reveal increased pulse pressure and palpitations. These changes may occur due to the increased sensitivity to catecholamines or to changes in neurotransmitter turnover. Myocardial hypertrophy and heart failure may occur if the hyperthyroidism is severe and untreated. Systolic murmurs may be noted. Cardiac decompensation in the form of heart failure is common, especially in the elderly; note the presence of dyspnea, crackles, peripheral edema, jugular vein distention, and the S_3 heart sound. See Box 31-6 for additional gerontologic considerations. Laboratory findings include a decrease in serum TSH (with primary disease), increased T_3 and T_4, and an increase in radioactive iodine uptake.

BOX 31-6 Gerontologic Considerations

Hyperthyroidism

Hyperthyroidism is less common in the elderly than hypothyroidism. Patients older than 60 years of age account for 10% to 15% of the cases of hyperthyroidism. Clinical manifestations may be as vague as anorexia and weight loss or isolated atrial fibrillation with an absence of ocular signs, making disorders difficult to detect. New or worsening heart failure or angina is more likely to occur in elderly than in younger patients. Patients also may report other cardiovascular symptoms and difficulty climbing stairs or rising from a chair due to muscle weakness.

Spontaneous remission of hyperthyroidism is rare in the elderly. Assessment of TSH

levels are indicated in the elderly who have unexplained physical or mental deterioration. In general, the use of radioactive iodine is recommended for treatment of thyrotoxicosis in the elderly unless an enlarged thyroid gland is pressing on the airway. The hypermetabolic state of thyrotoxicosis must be controlled by antithyroid medications before radioactive iodine is administered because radiation therapy may precipitate thyroid storm by increasing the release of thyroid hormones.

In general, antithyroid medications are not recommended for elderly patients because of the increased incidence of side effects, such as granulocytopenia, and the need for frequent monitoring. The dosage of other medications used to treat other chronic illnesses in elderly patients may need to be modified because of the altered rate of metabolism in hyperthyroidism. In addition, antithyroid medications are considered to be less effective in the treatment of toxic nodular goiter, the most common cause of thyrotoxicosis in the elderly.

Use of beta-adrenergic blocking agents (e.g., propranolol) may be indicated to decrease the cardiovascular and neurologic signs and symptoms of thyrotoxicosis. These agents must be used cautiously in the elderly to minimize adverse effects on cardiac function, such as heart failure.

Medical Management

Appropriate treatment of hyperthyroidism depends on the underlying cause and often consists of a combination of therapies, including radioactive iodine, antithyroid agents, and surgery. Treatment of hyperthyroidism aims to reduce thyroid hyperactivity, relieve symptoms, and prevent complications. The use of radioactive iodine (^{131}I) is the most common form of treatment for Graves disease due to the small risk of developing thyrotoxic crisis (thyroid storm) that can be minimized with 1 month's dosing of antithyroid drugs before radioiodine treatment (Jameson & Weetman, 2015).

Radioisotope Iodine 131 (^{131}I) Therapy

The goal of radioactive iodine therapy (^{131}I) is to destroy the overactive thyroid cells. Almost all the iodine that enters and is retained in the body becomes concentrated in the thyroid gland. Therefore, the radioactive isotope of iodine becomes concentrated in the thyroid gland, where it destroys thyroid cells without jeopardizing other radiosensitive tissues. Over a period of several weeks, thyroid cells exposed to the radioactive iodine are destroyed, resulting in reduction of the hyperthyroid state and, inevitably, hypothyroidism.

The patient is instructed about what to expect with this tasteless, colorless radioiodine, which may be administered by the radiologist. About 95% of patients are cured by one dose of radioactive iodine. The additional 5% of patients require two doses; rarely is a third dose necessary. Radioactive iodine ablation initially causes an acute release of thyroid hormone from the thyroid gland and may cause an increase of symptoms. The patient is observed for signs of thyroid storm (Box 31-7). The use of beta-adrenergic blocking agents, such as propranolol (Inderal), is helpful in controlling these symptoms. Because a higher rate of treatment failure was reported among patients taking Methimazole, it is sometimes discontinued at least 4 days before radioisotope therapy (Fitzgerald, 2015).

After treatment with radioactive iodine, the patient is monitored closely until a euthyroid state is reached. Sometimes the symptoms of hyperthyroidism can persist for 2 to 3 months before radioactive iodine takes effect. Close follow-up is required to evaluate thyroid function because the incidence of hypothyroidism after this form of treatment is very high. Approximately 10% to 20% of patients become hypothyroid within the first year of treatment and another 5% of patients each year thereafter (Jameson & Weetman, 2015). Thus, patients are informed of this possibility before treatment and require close follow-up during the first year and annually for thyroid function tests. When necessary, small doses of thyroid hormone replacement are prescribed with gradual increasing doses over a period of months (up to about 1 year) until the free T_4 and TSH levels stabilize within normal ranges.

Radioactive iodine has been used to treat toxic adenomas, multinodular goiter, and most varieties of thyrotoxicosis (rarely with permanent success); it is preferred for treating patients beyond the childbearing years who have diffuse toxic goiter. Radioiodine treatment is contraindicated during pregnancy for fear of fetal irradiation and risk of fetal/neonatal hyperthyroidism from the mother's TSH-receptor stimulating antibodies, which increases during radioiodine therapy (Ferri, 2016b). Pregnancy should be postponed for at least 6 months after treatment.

BOX 31-7 Thyroid Storm (Thyrotoxic Crisis, Thyrotoxicosis)

Thyroid storm (thyrotoxic crisis) is a form of severe hyperthyroidism, usually of abrupt onset. It is fatal if left untreated, but with proper treatment, the mortality rate is reduced substantially. The patient with thyroid storm or crisis is critically ill and requires astute observation and aggressive and supportive nursing care during and after the acute stage of illness.

Clinical Manifestations

Thyroid storm is characterized by:

- High fever (hyperpyrexia) above 38.5°C (101.3°F)
- Extreme tachycardia (more than 130 bpm)
- Exaggerated symptoms of hyperthyroidism with disturbances of a major system—e.g., GI (weight loss, diarrhea, abdominal pain) or cardiovascular (edema, chest pain, dyspnea, palpitations)
- Altered neurologic or mental state, which frequently appears as delirium, psychosis, somnolence, or coma

Usually life-threatening thyroid storm is precipitated by stress, such as injury, infection, thyroid and nonthyroidal surgery, tooth extraction, insulin reaction, diabetic ketoacidosis, pregnancy, digitalis intoxication, abrupt withdrawal of antithyroid medications, extreme emotional stress, or vigorous palpation of the thyroid. These factors can precipitate thyroid storm in a patient whose hyperthyroidism is partially controlled or completely untreated. Current methods of diagnosis and treatment for hyperthyroidism have greatly decreased the incidence of thyroid storm, making it uncommon today.

Management

Immediate objectives are reduction of body temperature and heart rate and prevention of vascular collapse. Measures to accomplish these objectives include:

- A hypothermia mattress or blanket, ice packs, a cool environment, hydrocortisone, and acetaminophen (Tylenol). Salicylates (e.g., aspirin) are not used because they displace thyroid hormone from binding proteins and worsen the hypermetabolism.
- Humidified oxygen is administered to improve tissue oxygenation and meet the high metabolic demands. ABG levels or pulse oximetry may be used to monitor respiratory status.
- IV fluids containing dextrose are administered to replace liver glycogen stores that have been decreased in the hyperthyroid patient.
- PTU or methimazole is administered to impede formation of thyroid hormone and block conversion of T_4 to T_3, the more active form of thyroid hormone.

- Hydrocortisone is prescribed to treat shock or adrenal insufficiency.
- Iodine is administered to decrease output of T_4 from the thyroid gland. For cardiac problems, such as atrial fibrillation, arrhythmias, and heart failure, sympatholytic agents may be administered. Propranolol, combined with digitalis, has been effective in reducing severe cardiac symptoms.

A major advantage of treatment with radioactive iodine is that it avoids many of the side effects associated with antithyroid medications. However, some patients and their families fear medications that are radioactive. For this reason, patients may elect to take antithyroid medications rather than radioactive iodine.

Antithyroid Drug Therapy

Antithyroid medications are summarized in Table 31-6. The objective of pharmacotherapy is to inhibit one or more stages in thyroid hormone synthesis or hormone release. Antithyroid agents block the utilization of iodine by interfering with the iodination of tyrosine and the coupling of iodotyrosines in the synthesis of thyroid hormones. This prevents the synthesis of thyroid hormone. Most commonly, propylthiouracil (PTU) or methimazole (Tapazole) is used until the patient is euthyroid. These medications block the conversion of T_4 to T_3. T_3 is about four times more potent than T_4.

The therapeutic dose is determined on the basis of clinical criteria, including changes in pulse rate, pulse pressure, body weight, size of the goiter, and results of laboratory studies of thyroid function. Antithyroid medications do not interfere with release or activity of thyroid hormones that were formed previously. As a result, it may take several weeks until relief of symptoms occurs. At that time, the maintenance dose is established, and a gradual withdrawal of the medication over the next several months follows.

Toxic complications of antithyroid medications are relatively uncommon. Nevertheless, the importance of periodic follow-up is emphasized because of medication sensitization, such as fever, rash, urticaria, or even agranulocytosis (a marked decrease in the number of granulocytes) and thrombocytopenia (decreased platelets) may develop. With any sign of infection, especially pharyngitis and fever or the occurrence of mouth ulcers, the patient is advised to notify the provider immediately and undergo hematologic studies. Agranulocytosis, the most serious toxic side effect, occurs in approximately 0.5% of patients. Its incidence is higher in patients older than 40 years of age. It usually occurs within the first 3 months but may occur up to 1 year after therapy is started.

Patients taking antithyroid medications are instructed not to use decongestants for nasal stuffiness because these agents are poorly tolerated. PTU is the treatment of choice during the first trimester of pregnancy, and then Methimazole is administered in the second trimester of pregnancy (Stagnaro-Green, 2015). As thyroid function improves, the dose is tapered as antithyroid medications in late pregnancy can cause fetal hypothyroidism, fetal bradycardia, goiter, and cretinism as well as maternal side effects, such as rash (5%), purities, hepatitis, lupus-like syndrome, drug fever, and bronchospasm (Mandel & Cooper, 2013).

TABLE 31-6 Pharmacologic Agents Used to Treat Hyperthyroidism

Agent	Action	Nursing Considerations
Propylthiouracil (PTU)	Blocks synthesis of hormones (conversion of T_4 to T_3)	Monitor cardiac parameters. Observe for conversion to hypothyroidism. Must be given by mouth. Watch for rash, nausea, vomiting, agranulocytosis, lupus syndrome.
Methimazole	Blocks synthesis of thyroid hormone	More toxic than PTU Watch for rash and other symptoms as for PTU.
Sodium iodide	Suppresses release of thyroid hormone	Given 1 hour after PTU or methimazole. Watch for edema, hemorrhage, GI upset.
Potassium iodide	Suppresses release of thyroid hormone	Discontinue for rash. Watch for signs of toxic iodine levels.
Saturated solution of potassium iodide (SSKI)	Suppresses release of thyroid hormone	Mix with juice or milk. Give by straw to prevent staining of teeth.
Dexamethasone	Suppresses release of thyroid hormone	Monitor input and output. Monitor glucose. May cause hypertension, nausea, vomiting, anorexia, infection.
Beta-blocker (e.g., propranolol)	Beta-adrenergic blocking agent	Monitor cardiac status. Hold for patients with bradycardia or decreased cardiac output. Use with caution in patients with heart failure.

Adapted from Morton, P. G., & Fontaine, D. K. (2013). *Essentials of critical care nursing: A holistic approach*. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.

Another goal of therapy is to reduce the amount of thyroid tissue, with resulting decreased production of thyroid hormone. Occasionally thyroid hormone is administered with antithyroid medications to put the thyroid gland at rest. In this approach, hypothyroidism from excess antithyroid medication is avoided, as is stimulation of the thyroid gland by TSH. Levothyroxine sodium (Synthroid) is the most common thyroid hormone preparation used. It takes approximately 10 days of its administration to achieve full effect. Liothyronine sodium (Cytomel) has a more rapid onset, and its action is of short duration.

Adjunctive Therapy

Iodine or iodide compounds, once the only therapy available for patients with hyperthyroidism, are no longer used as the sole method of treatment. Such compounds decrease the release of thyroid hormones from the thyroid gland and reduce the vascularity and size of the thyroid. Compounds, such as potassium iodide (KI), Lugol's solution, and saturated solution of potassium iodide (SSKI), may be used in combination with antithyroid agents or beta-adrenergic blockers to prepare the patient with hyperthyroidism for surgery. These agents reduce the activity of the thyroid hormone and the vascularity of the thyroid gland, making the surgical procedure safer. Solutions of iodine and iodide compounds are more palatable in milk or fruit juice and are administered through a straw to prevent staining of the teeth. These compounds reduce the metabolic rate more rapidly than antithyroid medications, but their action does not last as long. Beta-adrenergic blocking agents are important in controlling the effects of hyperthyroidism on the sympathetic nervous system. For example, propranolol generally is used to control nervousness, tachycardia, tremor, anxiety, and heat intolerance. The patient continues

taking propranolol until the free T_4 is within the normal range and the TSH level approaches normal.

Thyroidectomy

Thyroidectomy, the surgical removal of most of the thyroid gland, was once the primary method of controlling hyperthyroidism (Fig. 31-4). The surgical removal of about five sixths of the thyroid tissue (subtotal thyroidectomy) reliably results in a prolonged remission in most patients with exophthalmic goiter. Presently, the surgical option is reserved only for special circumstances, such as for patients with nodular goiters with suspicion of malignancy, pregnant women with thyrotoxicosis not controlled with low doses of thioureas, women who desire to become pregnant in the future (Fitzgerald, 2015), and patients who are allergic to or unable to take antithyroid medications. Surgery for the treatment of hyperthyroidism is performed soon after the thyroid function has returned to normal (4 to 6 weeks).

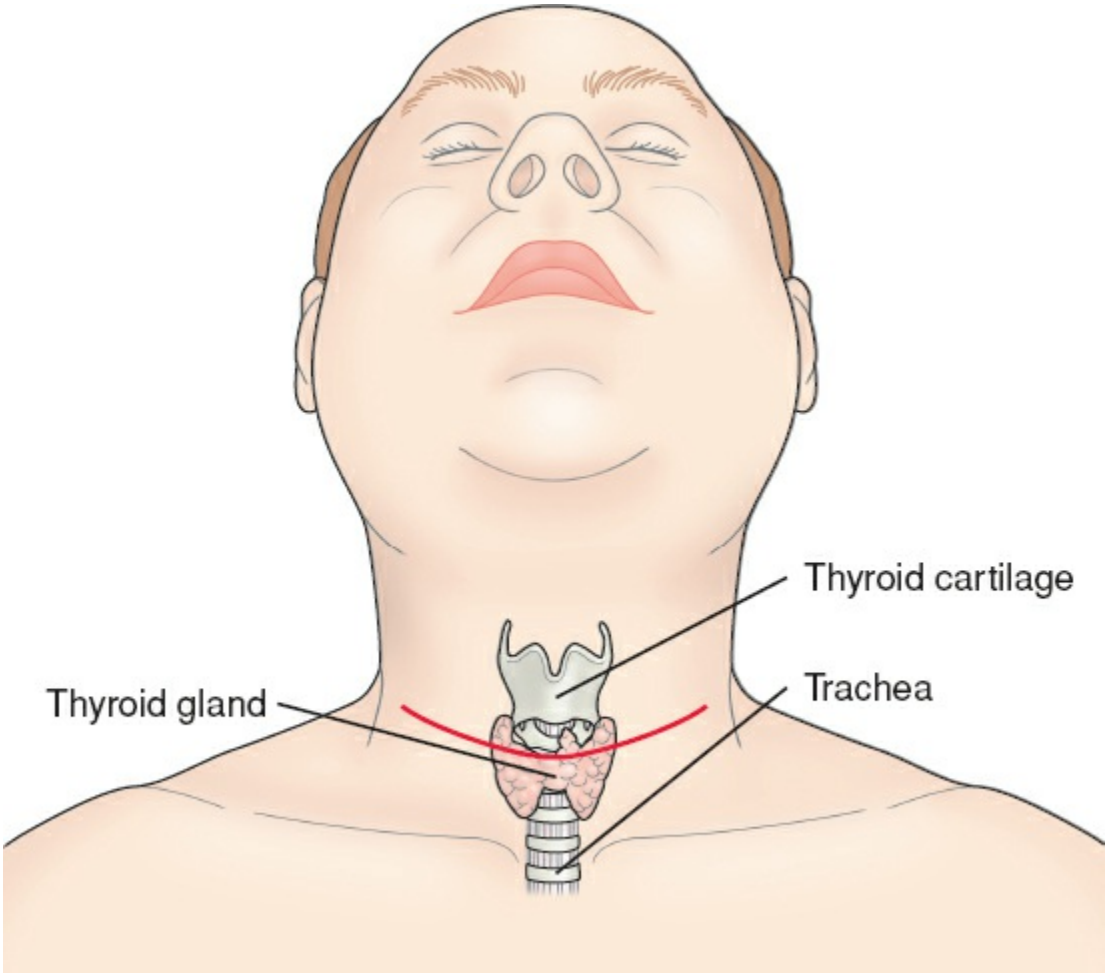


FIGURE 31-4 Thyroidectomy incision.

Preoperatively, PTU is administered until signs of hyperthyroidism have disappeared. A beta-adrenergic blocking agent (propranolol) may be used to reduce the heart rate and other signs and symptoms of hyperthyroidism; however, this does not create a euthyroid state. Iodine (Lugol's solution or KI) may be prescribed in an effort to reduce blood loss;

however, the effectiveness of this treatment is unknown.

NURSING PROCESS

The Patient with Hyperthyroidism

ASSESSMENT

The patient history assessment focuses on symptoms related to accelerated or exaggerated metabolism. These include reports of irritability, increased emotional reaction, and changes in the patient's interactions with family, friends, and co-workers. Additional symptoms include anxiety, sleep disturbances, apathy, and lethargy. The family can provide useful information about the recent changes in the patient's emotional status.

The history-taking also includes probing for other stressors and the patient's ability to cope with stress. The nurse assesses the nutritional status of the patient by obtaining the typical dietary habits of patient and recording the height and weight of the patient. In addition, the nurse assesses for symptoms related to excessive nervous system output and changes in vision and appearance of the eyes. Periodically, the nurse should assess and monitor the patient's cardiac status, including heart rate, heart sounds, blood pressure, and peripheral pulses.

DIAGNOSIS

Appropriate nursing diagnoses may include:

- Altered nutrition, less than body requirements, related to exaggerated metabolic rate, excessive appetite, and increased gastrointestinal (GI) activity
- Ineffective coping related to irritability, hyperexcitability, apprehension, and emotional instability
- Low self-esteem related to changes in appearance, excessive appetite, and weight loss
- Altered body temperature related to hypermetabolic status
- Discomfort related to eye changes secondary to hyperthyroidism

Potential complications may include the following:

- Thyrotoxicosis or thyroid storm
- Hypothyroidism

PLANNING

The goals for the patient may be improved nutritional status, improved coping ability, improved self-esteem, maintenance of normal body temperature, and absence of complications.

NURSING INTERVENTIONS

IMPROVING NUTRITIONAL STATUS

Hyperthyroidism affects all body systems, including the GI system. The appetite is increased but may be satisfied by several well-balanced meals of small size, up to six meals a day. Foods and fluids are selected to replace fluid lost through diarrhea and diaphoresis and to control the diarrhea that results from increased peristalsis. Rapid movement of food through the GI tract may result in nutritional imbalance and further weight loss. The nurse should monitor fluid and electrolytes to assess for unusual loss due to increased GI motility. To reduce diarrhea, highly seasoned foods and stimulants such as coffee, tea, cola, and alcohol are discouraged. The nurse encourages high-calorie, high-protein foods. A quiet atmosphere during mealtime may aid digestion. The nurse records weight (500 mL = 1 lb), dietary intake, and input/output (I&O) to monitor nutritional status.

ENHANCING COPING MEASURES

The patient with hyperthyroidism needs reassurance that the emotional reactions being experienced are a result of the disorder and that, with effective treatment, those symptoms will be controlled. Because of the negative effect these symptoms have on family and friends, they too need reassurance that the symptoms are expected to disappear with treatment. It is important to use a calm, unhurried approach with the patient and to minimize stressful experiences. For instance, the patient should not be placed in a room with other patients who are very ill or talkative. The nurse introduces relaxing activities, such as listening to soft music, or keeps the room quiet. The nurse minimizes noises, such as loud music, conversation, and equipment alarms, as much as possible. If thyroidectomy is planned, the patient needs to know that pharmacologic therapy is necessary to prepare the thyroid gland for surgical treatment. The nurse reminds the patient to take the medications as prescribed. Because of hyperexcitability and shortened attention span, the patient may require repetition of this information and written instructions.

IMPROVING SELF-ESTEEM

The patient with hyperthyroidism is likely to experience changes in appearance, appetite, and weight. These factors, along with the patient's inability to cope well with family and the illness, may result in loss of self-esteem. The nurse must convey an understanding of the patient's concern about these problems and assist the patient in developing effective coping strategies. The patient and family need to know that these changes are a result of the thyroid dysfunction and are, in fact, out of the patient's control.

If changes in appearance are very disturbing to the patient, mirrors may be covered or

removed. In addition, the nurse reminds family members and personnel to avoid bringing these changes to the patient's attention. The nurse explains to the patient and family that these physical changes are expected to disappear with effective treatment.

MAINTAINING NORMAL BODY TEMPERATURE

It is important for the patient to maintain a normal body temperature. The patient with hyperthyroidism frequently finds a normal room temperature too warm because of an exaggerated metabolic rate and increased heat production. To ensure a normal body temperature, the nurse maintains the environment at a cool, comfortable temperature and changes bedding and clothing as needed. Instructions to the patient and family emphasize that cool baths and cool or cold fluids may provide relief. However, shivering is to be avoided as it increases metabolic energy expenditure. The nurse explains the reason for the patient's discomfort and the importance of providing a cool environment to the family and staff.

PROVIDING EYE CARE

Relief of symptoms related to excessive output by the nervous system and changes in vision and appearance of the eyes is indicated when necessary. For instance, if the patient experiences eye changes secondary to hyperthyroidism, eye care and protection may be necessary. The patient may need instructions about instillation of eye drops or ointment prescribed to soothe the eyes and protect the exposed cornea.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Thyrotoxicosis or Thyroid Storm. The nurse closely monitors the patient with hyperthyroidism for signs and symptoms that may be indicative of thyroid storm. The nurse assesses cardiac and respiratory functions by obtaining vital signs and cardiac output, and monitoring ECG, ABGs, and pulse oximetry. Assessment continues after treatment is initiated because of the potential effects of treatment on cardiac function. Oxygen is administered to prevent hypoxia, to improve tissue oxygenation, and to meet the high metabolic demands. IV fluids may be necessary to maintain levels of blood glucose and to replace lost fluids. Antithyroid medications (e.g., PTU or methimazole) may be prescribed to reduce thyroid hormone levels. In addition, propranolol and digitalis may be prescribed to treat cardiac symptoms. If shock develops, treatment strategies must be implemented.

Hypothyroidism. Hypothyroidism is likely to occur with any of the treatments used for hyperthyroidism; periodically monitor the patient for signs and symptoms of hypothyroidism. In addition, as part of the teaching for the patient and family, include instructions on the importance of continuing therapy indefinitely after discharge and a discussion of the consequences of failing to take medication.

EVALUATION

Expected patient outcomes may include the following:

1. Demonstrates improvement in nutritional status:
   a. Reports adequate dietary intake and decreased hunger
   b. Identifies high-calorie, high-protein foods; identifies foods to be avoided
   c. Avoids use of alcohol and other stimulants
   d. Reports decreased episodes of diarrhea
2. Demonstrates effective coping methods in dealing with family, friends, and coworkers:
   a. Explains reasons for irritability and emotional instability
   b. Avoids stressful situations, events, and people
   c. Participates in relaxing, nonstressful activities
3. Achieves increased self-esteem:
   a. Verbalizes feelings about self and illness
   b. Describes feelings of frustration and loss of control
   c. Describes reasons for increased appetite
4. Maintains normal body temperature
5. Experiences relief of symptoms
6. Absence of complications:
   a. Has levels of serum thyroid hormone and TSH within normal limits
   b. Identifies signs and symptoms of thyroid storm and hypothyroidism
   c. Vital signs, ECG, ABGs, and pulse oximetry are within normal limits
   d. States importance of regular follow-up and lifelong maintenance of prescribed therapy

THYROIDITIS

Thyroiditis refers to the inflammation of the thyroid gland that may result in abnormalities in its functioning. The clinical classification of thyroiditis is based on the onset and duration of the disease, resulting from causes that are acute, subacute, or chronic. Thyroiditis can result in the swelling of the thyroid gland, manifesting symptoms in the form of acute and subacute thyroiditis. The chronic form of thyroiditis often presents with painless enlargement of the thyroid gland.

Pathophysiology

Acute thyroiditis is a rare disorder caused by infection of the thyroid gland by bacteria, fungi, mycobacteria, or parasites. The most common cause of acute thyroiditis is *Staphylococcus aureus* and other staphylococci. Chronic thyroiditis occurs frequently in women between 30 and 50 years of age. It has been termed as *Hashimoto disease* or *chronic lymphocytic thyroiditis*. The diagnosis is based on the histologic appearance of the inflamed gland. Cell-mediated immunity may play a significant role in the pathogenesis of chronic thyroiditis, and there may be a genetic predisposition to it. If left untreated, the disease runs a slow, progressive course, eventually leading to hypothyroidism.

Clinical Manifestations and Assessment

In acute thyroiditis, often pharyngitis or pharyngeal pain is present. Physical examination may reveal warmth, erythema (redness), and tenderness over the thyroid gland. The condition manifests as a painful swelling in the anterior neck that lasts between 1 and 2 months and then disappears spontaneously without residual effect. It often follows a respiratory infection. The thyroid enlarges symmetrically and may be painful. The overlying skin is often red and warm. Swallowing may be difficult and uncomfortable. Irritability, nervousness, insomnia, weight loss, chills, fever, and manifestations of hyperthyroidism are common. In contrast to acute thyroiditis, the chronic forms are not accompanied by pain, pressure symptoms, or fever, and thyroid activity is normal or low rather than increased. The most common presentation in a patient suspected to have chronic thyroiditis is a palpable, enlarged, and painless firm mass over the thyroid gland. In addition, patients are likely to present with symptoms of hypothyroidism (Fitzgerald, 2015).

Medical Management

The medical management of acute thyroiditis includes antimicrobial agents and fluid replacement. Surgical incision and drainage may be needed if an abscess is present. In subacute thyroiditis, the treatment aims to control the inflammation. Nonsteroidal anti-inflammatory drugs are commonly used to relieve neck pain. Acetylsalicylic acid (aspirin) is avoided if symptoms of hyperthyroidism occur because aspirin displaces thyroid hormone from its binding sites and increases the amount of circulating hormone. Beta-adrenergic blocking agents (e.g., propranolol) may be used to control symptoms of hyperthyroidism. Antithyroid agents that block the synthesis of T_3 and T_4 are not effective in thyroiditis because the associated thyrotoxicosis results from the release of stored thyroid hormones rather than from their increased synthesis. In more severe cases, oral corticosteroids may be prescribed to reduce swelling and relieve pain. In some cases, temporary hypothyroidism may develop and may necessitate thyroid hormone therapy.

In chronic thyroiditis, the objective of the treatment is to reduce the size of the thyroid gland and prevent hypothyroidism. Thyroid hormone therapy is prescribed to reduce thyroid activity and the production of thyroglobulin. If hypothyroid symptoms are present, thyroid hormone therapy is prescribed. Surgery may be required if pressure symptoms persist.

Nursing Management

The nursing management of patients with thyroiditis includes educating patients about their condition, specifically on pain management and the use of medications. Most patients who present with thyroiditis are given patient education on how to manage the symptoms of the disease and usually do not require in-patient admission.

THYROID TUMOR AND CANCER

Classification of tumors of the thyroid gland includes benign or malignant, presence or absence of associated thyrotoxicosis, and diffuse or irregular quality of the glandular enlargement. A goiter is present if the enlargement is sufficient to cause a visible swelling in the neck. All grades of goiter may occur, from barely visible to those producing disfigurement. The histopathology differs depending on the etiology of goiter. For instance, some are symmetric and diffuse; others are nodular. Often toxic goiters are accompanied by hyperthyroidism. Nontoxic goiters, on the other hand, are associated with a euthyroid (normal) state that does not result from an inflammatory or neoplastic cause.

Thyroid cancer is less prevalent than other forms of cancer; only about 1 in 20 thyroid nodules is cancerous. According to the American Cancer Society, an estimated 62,450 new cases of thyroid cancer are diagnosed each year, 47,230 in women and 15,220 in men. About 1,080 women and 870 men die annually from this malignancy (American Cancer Society, 2015a). Exposure to radiation of the head, neck, or chest in childhood increases the risk for thyroid carcinoma (American Cancer Society, 2015b).

Pathophysiology

The most common type of goiter, a simple or colloid goiter, often is encountered in geographic regions where there is lack of iodine (e.g., the Great Lakes areas of the United States). If too little iodine exists, the level of T_4 will decrease, causing the stimulation of TSH from the anterior pituitary. This stimulation causes the enlargement of the thyroid. Simple goiter also may be caused by an intake of large quantities of goitrogenic substances in patients with unusually susceptible glands. These substances include excessive amounts of iodine or lithium, often used in the treatment of bipolar disorders. Too much iodine can cause enlargement of the thyroid, resulting in the development of excess secretion of thyroid hormone. Keep in mind that many patients receive IV iodine in the hospital as a result of diagnostic studies that require contrast, such as cardiac catheterization and CT scans.

Simple goiter represents a compensatory hypertrophy of the thyroid gland, caused by stimulation by the pituitary gland. Such goiters usually cause no symptoms, except for the swelling in the neck, which may result in tracheal compression when excessive. Many goiters of this type recede after the iodine imbalance is corrected. Supplementary iodine, such as SSKI, is prescribed to suppress the pituitary's thyroid-stimulating activity.

Some thyroid glands are nodular because of areas of hyperplasia (overgrowth). No symptoms may arise unless these nodules increase in size and descend into the thorax, where symptoms of local pressure may manifest. Some nodules become malignant, and some are associated with a hyperthyroid state. The patient with many thyroid nodules eventually may require surgery.

Clinical Manifestations and Assessment

Most patients with simple goiters are asymptomatic and may complain of pressure in the neck. On assessment, the patient may present with a soft, diffusely enlarged nodule over the neck. As the goiter progresses, the patient may experience symptoms, such as difficulty breathing and swallowing. Patients usually present in euthyroid state with normal levels of TSH and T_4.

On the other hand, lesions that are single, hard, and fixed on palpation or associated with cervical lymphadenopathy suggest malignancy. Although thyroid function tests may be helpful in evaluating thyroid nodules and masses, the results are rarely conclusive. Fine-needle biopsy (FNB) of the thyroid gland often is used to establish the diagnosis of thyroid cancer. The purpose of the biopsy is to differentiate cancerous thyroid nodules from noncancerous nodules and to stage the cancer if detected. The procedure is safe and usually requires only a local anesthetic. Another type of aspiration or biopsy uses a large-bore needle rather than the fine needle. This method often is used to detect rapid-growing tumors or when the results of the FNB are inconclusive. Other diagnostic studies include ultrasound, MRI, CT, thyroid scans, radioactive iodine uptake studies, and thyroid suppression tests.

Medical Management

Most patients with small, simple goiters and euthyroid states do not require treatment. Patients with large goiters generally receive exogenous thyroid hormones and iodine to reduce thyroid growth. Surgery is not required unless the goiter continues to grow (1) despite pharmacologic treatment, (2) causing airway difficulties, and (3) leading to suspected malignancy.

Surgical removal, however, is the treatment of choice for thyroid cancers. Total or near-total thyroidectomy is performed if possible. Patients whose thyroid cancer is detected early and who are appropriately treated usually do very well. Patients who have had papillary cancer, the most common and least aggressive tumor, have a 10-year survival rate of 97% (Fitzgerald, 2015). Mortality rates associated with follicular thyroid cancer are less favorable due to more patients presenting with later stages of the disease (Jameson & Weetman, 2015). Hence, continuing thyroid hormone therapy and periodic follow-up with diagnostic testing are important to ensure the patient's well-being.

A modified neck dissection or more extensive radical neck dissection is performed if there is lymph node involvement. Efforts are made to spare parathyroid tissue to reduce the risk of postoperative hypocalcemia with resultant tetany. Ablation procedures are carried out with radioactive iodine to eradicate residual thyroid tissue if the tumor is radiosensitive.

Postoperatively, the patient is instructed to take exogenous thyroid hormone to prevent hypothyroidism. If the remaining thyroid tissue is inadequate to produce sufficient thyroid hormone, thyroxine is required permanently. Free T_4, TSH, and levels of serum calcium and phosphorus are monitored to determine whether the thyroid hormone supplementation is adequate and to note whether calcium balance is maintained. Although local and systemic reactions to radiation may occur and may include neutropenia or thrombocytopenia, these complications are rare when radioactive iodine is used. Patients who undergo surgery that is combined with radioactive iodine have a higher survival rate than do those who undergo surgery alone (Jameson & Weetman, 2015).

Posthospitalization follow-up includes clinical assessment for recurrence of nodules or masses in the neck and signs of hoarseness, dysphagia, or dyspnea. Total-body scans are performed 2 to 4 months after surgery to detect residual thyroid tissue or metastatic disease. Thyroid hormones are stopped for about 6 weeks before the tests. Care must be taken to avoid iodine-containing foods and contrast agents. A repeat scan is performed 1 year after the initial surgery. If measurements are stable, a final scan is obtained in 3 to 5 years.

Nursing Management

Providing Preoperative Teaching

Preoperative patient education is important to gain the patient's confidence and reduce anxiety. The nurse instructs the patient about the importance of eating a diet high in carbohydrates and proteins. A high daily caloric intake is necessary because of the increased metabolic activity and rapid depletion of glycogen reserves. Supplementary vitamins, particularly thiamine and ascorbic acid, may be prescribed. The nurse advises the patient to avoid tea, coffee, cola, and other stimulants. The nurse explains the purpose of preoperative tests and what preoperative preparations to expect. In addition, special efforts are made to ensure a good night's rest before surgery, although many patients are admitted to the hospital on the day of surgery. Preoperative teaching includes demonstrating to the patient how to support the neck with the hands after surgery to prevent stress on the incision. This involves raising the elbows and placing the hands behind the neck to provide support and reduce strain and tension on the neck muscles and the surgical incision.

Assessing the Postoperative Patient

Postoperatively, the nurse periodically assesses the surgical dressings and reinforces them if necessary. The nurse observes the sides and the back of the neck as well as the anterior dressing for bleeding. In addition to monitoring the pulse and blood pressure for any indication of internal bleeding, it is important to be alert for complaints of a sensation of pressure or fullness at the incision site, frequent swallowing, or choking. Such symptoms may indicate subcutaneous hemorrhage and hematoma formation. In addition, the nurse notes vocal changes or hoarseness, as this may indicate injury to the laryngeal nerve or laryngeal edema, which may develop postoperatively. If drains are inserted intraoperatively, the nurse records the color, amount, and consistency of the drainage and maintains function of the device.

Maintaining the Airway

Respiratory difficulties can occur as a result of edema of the glottis, hematoma formation, or injury to the recurrent laryngeal nerve. This complication requires insertion of an airway. It is vital to have a tracheostomy set by the bedside at all times because, in the event of significant edema, placement of an endotracheal tube is unlikely because of narrowing of the airway. If the respiratory distress is caused by hematoma, a surgical evacuation is required.

Managing Pain

The nurse assesses the intensity of pain and administers analgesic agents as prescribed. The nurse should anticipate apprehension in the patient and inform the patient that oxygen will assist breathing. When moving and turning the patient, the nurse must carefully support the patient's head and avoid tension on the sutures. The most comfortable patient position is the semi-Fowler position, with the head elevated and supported by pillows.

Administering Hydration Therapy

IV fluids are administered during the immediate postoperative period. Nurses can anticipate that when PO fluids are allowed, patients report little difficulty in swallowing. Serving small amounts of cold fluids and ice is recommended.

Managing Safety

The nurse advises the patient to talk as little as possible to reduce edema to the vocal cords. Items that are needed frequently are kept within easy reach so the patient does not need to turn the head to reach for them. An overbed table provides easy access to items, such as tissues, a water pitcher and glass, and a small emesis basin. It is also convenient to use this table when vapor-mist inhalations are prescribed for the relief of excessive mucus accumulation.

Encouraging Nutrition and Physical Activity

The patient is permitted to get out of bed as soon as possible but must support his or her neck to reduce strain on the neck muscles. The nurse encourages the patient to eat soft foods. A well-balanced diet high in calories and protein may be prescribed to promote weight gain.

Providing Postoperative Patient Education

Patient teaching emphasizes the importance of taking prescribed medications, discusses postoperative appointment(s), describes suture removal, and provides postoperative recommendations for follow-up. Usually the patient is discharged from the hospital on the day of surgery or soon afterward if the postoperative course is uncomplicated. Also the patient who is undergoing radiation therapy is instructed in how to assess and manage side effects of treatment.

Managing Post-Thyroidectomy Complications

Hemorrhage, hematoma formation, edema of the glottis, and injury to the recurrent laryngeal nerve are complications discussed above. Recall that parathyroid hormone regulates the level of calcium within the blood. Sometimes the parathyroid glands are removed during thyroid surgery, resulting in altered calcium metabolism. As the blood calcium level falls (hypocalcemia), hyperirritability of the nerves occurs, with spasms of the hands and feet and muscle twitching. This group of symptoms is termed *tetany.* Ensure adequate opening of the airway because laryngospasm, although rare, may occur and obstruct the airway. *Usually* tetany is treated with IV calcium gluconate. Hypocalcemia is temporary after thyroidectomy unless all parathyroid tissue was removed.

DISORDERS OF THE PARATHYROID GLANDS

HYPERPARATHYROIDISM

Pathophysiology

Hyperparathyroidism is characterized by having excess parathormone (PTH), leading to a markedly increased level of serum calcium that can present as a potentially life-threatening situation.

Nursing Alert
Hypercalcemia is a total calcium concentration greater than 10.5 mg/dL; hypocalcemia is a total calcium concentration of less than 8.5 mg/dL.

The actions of PTH are increased by the presence of vitamin D. The serum level of ionized calcium regulates the output of parathormone (Fig. 31-5). Increased serum calcium leads to a decreased secretion of parathormone, thus creating a negative feedback system. When the product of serum calcium and serum phosphorus rises, calcium phosphate may precipitate and calcify in various organs of the body, such as the kidneys.

Risk Factors

About 100,000 new cases of hyperparathyroidism are detected each year in the United States. The incidence of this disorder increases 10-fold between 15 and 65 years of age. Primary hyperparathyroidism (tumor or hyperplasia of the parathyroids) occurs two to four times more often in women than in men and is most common in people between 60 and 70 years of age. Secondary hyperparathyroidism is seen most often in patients with chronic kidney failure (Box 31-8).

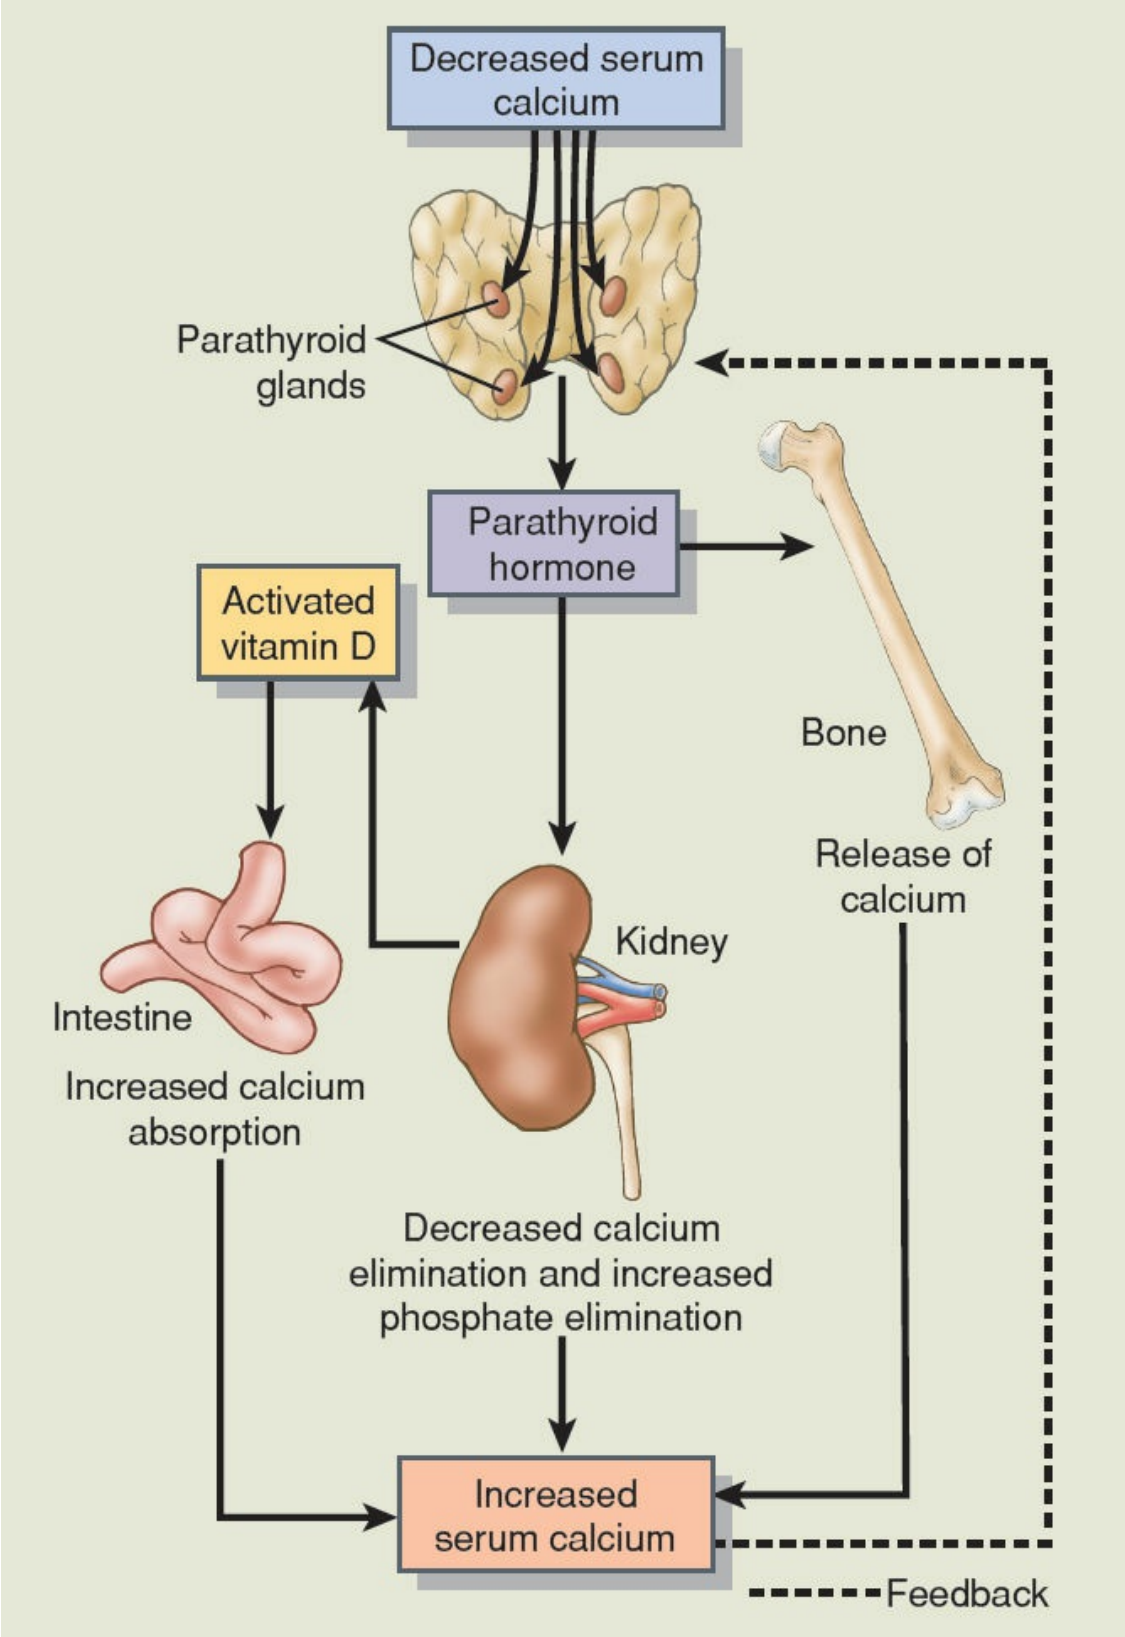

FIGURE 31-5 Regulation of serum calcium concentration by parathyroid hormone. (From Porth, C. M. (2015). *Essentials of pathophysiology: Concepts of altered health states* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

BOX 31-8 Focus on Pathophysiology

Kidney Failure and Secondary Hyperparathyroidism

Phosphate excretion becomes impaired when kidney function deteriorates, resulting in an elevated level of serum phosphate. There is an inverse relationship between calcium and phosphorus: as the level of serum phosphate rises, the level of serum calcium falls.

This hypocalcemia stimulates PTH release with resultant increase in calcium release from the bone. In kidney failure, the kidneys' ability to synthesize vitamin D becomes impaired, which leads to decreased intestinal absorption of calcium. Hypocalcemia in this situation will stimulate the release of PTH, leading to hyperparathyroidism.

Clinical Manifestations and Assessment

Half of the people diagnosed with hyperparathyroidism are asymptomatic. Most cases were detected by high levels of serum calcium during routine blood tests. Secondary hyperparathyroidism manifests signs and symptoms similar to those of primary hyperparathyroidism.

The patient may experience signs and symptoms resulting from involvement of several body systems; Box 31-9 summarizes symptoms of hypercalcemia. Apathy, fatigue, muscle weakness, nausea, vomiting, and constipation may occur due to the increased concentration of calcium in the blood. The direct effect of calcium on the brain and nervous system can cause psychological manifestations, such as irritability, neurosis, or psychoses. Cardiac responses to elevated serum calcium levels include increased cardiac contractility and the development of ventricular arrhythmias. It is important for the nurse to assess patients on digitalis as this drug accentuates the cardiac response of hypercalcemia.

The formation of stones in one or both kidneys, related to the increased urinary excretion of calcium and phosphorus, occurs in 55% of patients with primary hyperparathyroidism. Renal damage results from the precipitation of calcium phosphate in the renal pelvis and parenchyma, which causes renal calculi (kidney stones), obstruction, pyelonephritis, and kidney failure.

BOX 31-9 Focused Assessment

Hypercalcemia

Be alert for the following signs and symptoms:

- Stones: Kidney
- Bones: Bone pain, osteoporosis, pathologic fractures
- Abdominal Moans: Nausea, vomiting, and abdominal pains (hypercalcemia can lead to development of peptic ulcer and acute pancreatitis)
- Psychic Groans: Mental irritability, neurosis, confusion

Musculoskeletal symptoms accompanying hyperparathyroidism—such as skeleton pain and tenderness, especially of the back and joints, pain on weight bearing, pathologic fractures, deformities, and shortening of body stature—may be caused by demineralization of the bones or by bone tumors composed of benign giant cells, resulting from overgrowth of osteoclasts. Oversecretion of PTH causes excessive osteoclast growth, which, in turn, promotes bone resorption. The resultant loss of calcium from the bone or demineralization causes kyphosis, compression fractures, and bony cysts that produce fragile bones, increasing the risk for fracture. Hypercalcemia may stimulate gastric secretions, causing an increased incidence of peptic ulcer and abdominal pain. Pancreatitis may develop as a result of stones in the pancreatic ducts.

Primary hyperparathyroidism is diagnosed by persistent elevation of serum calcium levels and an elevated concentration of PTH. Radioimmunoassay for PTH is sensitive and

differentiates primary hyperparathyroidism from other causes of hypercalcemia in more than 90% of patients with elevated serum calcium levels. An elevated serum calcium level alone is a nonspecific finding because serum levels may be altered by diet, medications, and kidney disease and bone changes. Bone changes on x-ray or bone scans indicates advanced disease. The double-antibody parathyroid hormone test distinguishes between primary hyperparathyroidism and malignancy as a cause of hypercalcemia. Ultrasound, MRI, thallium scan, and FNB evaluate the parathyroid functions and localize parathyroid cysts, adenomas, or hyperplasia.

Medical and Nursing Management

The recommended treatment of primary hyperparathyroidism is the surgical removal of abnormal parathyroid tissue (parathyroidectomy). In some patients who are without symptoms and have serum calcium concentrations that are only mildly elevated and normal kidney function, surgery may be delayed, and the patient is monitored closely for worsening of hypercalcemia, bone deterioration, renal impairment, or the development of kidney stones. Nursing management involves providing hydration, encouraging mobility, administering nutrition and medications, providing emotional support, and observing for and managing hypercalcemic crisis.

Providing Hydration Therapy

Patients with hyperparathyroidism are at risk for renal calculi because kidney involvement is possible. Strict intake and output measurements are monitored in hospitalized patients. The nurse encourages a daily fluid intake of 2,000 mL or more (unless contraindicated) to help prevent calculus formation. Cranberry juice or cranberry extract tablets are suggested as alternatives because it may lower the urinary pH. The nurse instructs the patient to report symptoms of renal calculi, such as abdominal pain and hematuria. Thiazide diuretics are avoided because they decrease the renal excretion of calcium and further elevate levels of serum calcium. Because of the risk for hypercalcemic crisis, the nurse should instruct the patient to avoid dehydration and to seek immediate attention if conditions that commonly produce dehydration (e.g., vomiting and diarrhea) occur.

Encouraging Mobility

The nurse encourages the patient to ambulate using a walker. For those with limited mobility, use a rocking chair because bones that are subjected to normal stress give up less calcium. Bedrest increases calcium excretion and the risk for renal calculi. Oral phosphates lower the serum calcium level in some patients; however, long-term use is not recommended due to the risk of ectopic calcium phosphate deposition into the soft tissues.

Administering Nutrition and Medication

Dietary calcium will be restricted or increased depending on the patient's serum calcium level. If the patient has a coexisting peptic ulcer, prescribed antacids and protein feedings are necessary. Measures to prevent constipation (a common occurrence postoperatively) include offering prune juice or stool softeners (e.g., Colace or Senna) and increasing physical activity and fluid intake.

Providing Emotional Support

The insidious and chronic onset of hyperparathyroidism together with diverse and vague symptoms may lead to depression and frustration. The family may have considered the patient's illness to be psychosomatic. Increasing awareness of the course of the disorder with patient education may help the patient and family deal with their reactions and feelings.

Managing Hypercalcemic Crisis

Acute hypercalcemic crisis can occur with extreme elevation of serum calcium levels. Serum calcium levels of greater than 15 mg/dL (3.7 mmol/L) result in neurologic, cardiovascular, and renal symptoms that can be life-threatening. Treatment involves rehydration with large volumes of IV fluids to keep urine output above 100 mL/hr (normal saline expands volume and inhibits calcium resorption), diuretic agents (to promote renal excretion of excess calcium), and phosphate therapy (to correct hypophosphatemia and decrease serum calcium levels by promoting calcium deposition in bone and reducing the GI absorption of calcium). Cytotoxic agents (e.g., mithramycin), calcitonin, and dialysis may be used in emergency situations to decrease serum calcium levels quickly. Effective results occur within 24 hours but last only about 1 to 2 weeks. A combination of calcitonin and corticosteroids has been administered in emergencies to reduce the serum calcium level by increasing calcium deposition in bone. Other agents that may be administered to decrease serum calcium levels include bisphosphonates (e.g., etidronate [Didronel], pamidronate [Aredia]). Refer to Chapter 6 for more details on hypercalcemia.

Careful assessment and care are required to minimize complications and reverse the life-threatening hypercalcemia. Particular attention to cardiac function is advised since often death from hypercalcemic crisis is caused by cardiac arrest (Porth, 2015). Medications are administered with care, and attention is given to fluid and electrolyte balance. Supportive measures are necessary for the patient and family.

HYPOPARATHYROIDISM

Pathophysiology

Hypoparathyroidism results from hyposecretion of the parathyroid glands, leading to low levels of PTH that eventually results in hypocalcemia and hyperphosphatemia. In the absence of PTH, there is increased blood phosphate (hyperphosphatemia) and a resultant decreased level of blood calcium (hypocalcemia) due to the inverse relationship between serum phosphorus and calcium described in Box 31-8. Without PTH, there is also decreased intestinal absorption of dietary calcium as well as decreased resorption of calcium from bone and through the renal tubules, causing hypocalcemia.

The most common cause of hypoparathyroidism is from surgical removal of parathyroid gland tissue during thyroidectomy, parathyroidectomy, or radical neck dissection. These small glands are easily overlooked and can be removed inadvertently during thyroid surgery.

Hypoparathyroidism also may occur in patients who have undergone a subtotal resection or total parathyroidectomy with parathyroid autotransplantation. Other risk factors include genetic predisposition, exposure to radiation, and magnesium depletion (hypomagnesemia: less than 0.4 mmol/L; less than 0.8 mEq/L) (Jameson & Weetman, 2015).

Clinical Manifestations and Assessment

Hypocalcemia causes irritability of the neuromuscular system and contributes to the chief symptom of hypoparathyroidism, tetany. Tetany is a general muscle hypertonia, with tremor and spasmodic or uncoordinated contractions occurring with or without efforts to make voluntary movements. Symptoms of latent tetany are numbness, tingling, and cramps in the extremities, and the patient complains of stiffness in the hands and feet. In overt tetany, the signs include bronchospasm, laryngeal spasm, carpopedal spasm (flexion of the elbows and wrists and extension of the carpophalangeal joints and dorsiflexion of the feet), dysphagia, photophobia, cardiac arrhythmias, and seizures. Other symptoms include anxiety, irritability, depression, and even delirium. ECG changes, such as prolonged QT intervals, and hypotension also may occur.

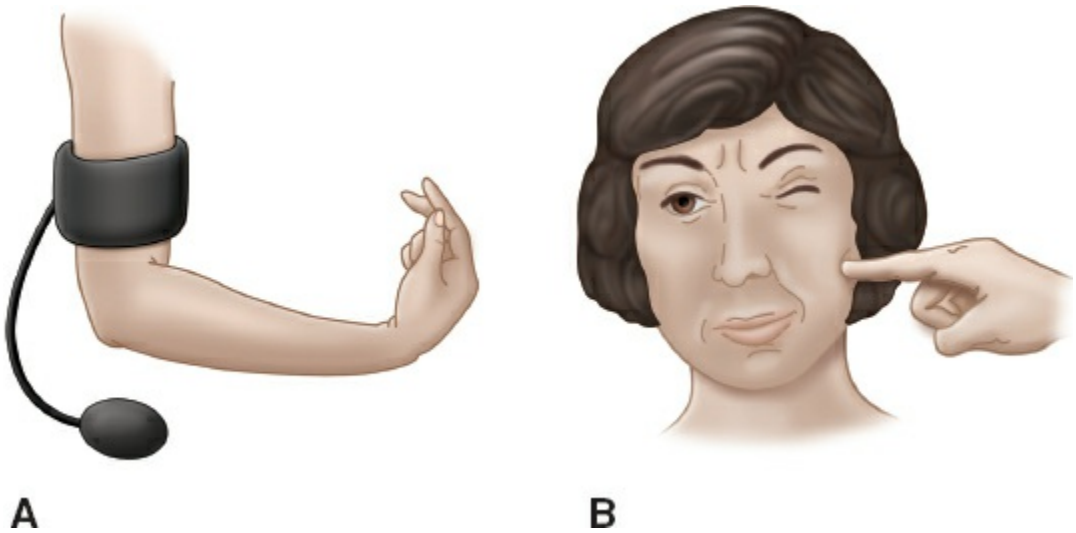

FIGURE 31-6 Tetany is caused by tonic spasm of the intrinsic hand muscles. Evaluate the patient for Trousseau sign (A) or Chvostek sign (B).

A positive Trousseau sign or a positive Chvostek sign on physical assessment suggests latent tetany (Fig. 31-6). Trousseau sign is positive when carpopedal spasm is induced by occluding the blood flow to the arm for 3 minutes with a blood pressure cuff. Chvostek sign is positive when a sharp tapping over the facial nerve just in front of the parotid gland and anterior to the ear causes spasm or twitching of the mouth, nose, and eye.

The diagnosis of hypoparathyroidism often is difficult because of the vague symptoms, such as aches and pains. Therefore, laboratory studies are especially helpful. Tetany develops at serum calcium levels of 5 to 6 mg/dL (1.2 to 1.5 mmol/L) or lower. Serum phosphate levels are increased, and x-rays of bone show increased density. Calcification is detected on x-rays of the subcutaneous or paraspinal basal ganglia of the brain.

Medical Management

The goal is to increase the serum calcium level to 8 to 9 mg/dL (2.0 to 2.25 mmol/L) and to eliminate the symptoms of hypoparathyroidism and hypocalcemia. When hypocalcemia and tetany occur after a thyroidectomy, the immediate treatment is administration of IV 10% calcium gluconate. If this does not decrease neuromuscular irritability and seizure activity immediately, sedative agents, such as pentobarbital, may be administered. Parenteral PTH can be administered to treat acute hypoparathyroidism with tetany. The patient receiving PTH is monitored closely for allergic reactions and changes in serum calcium levels.

Treatment for chronic hypoparathyroidism is determined after serum calcium levels are obtained. A diet high in calcium and low in phosphorus is prescribed (Box 31-10). Oral calcium salts, such as calcium gluconate, may be used to supplement the diet. Aluminum hydroxide gel or aluminum carbonate (Gelusil, Amphojel) may be used after meals to bind phosphate and promote its excretion through the GI tract. Other variable dosages of a vitamin D preparation—dihydrotachysterol (AT 10 or Hytakerol), ergocalciferol (vitamin D), or cholecalciferol (vitamin D)—are usually required and enhance calcium absorption from the GI tract.

BOX 31-10

Nutrition Alert 

Hypoparathyroidism

Patients with hypoparathyroidism are prescribed a diet high in calcium and low in phosphorus. The following foods are recommended:

- Rice milk or nondairy creamer
- Refined white bread
- Green beans, broccoli, cucumbers
- Fish

The following foods are restricted:

- Egg yolks
- Milk and milk products (although high in calcium, these are restricted because they also contain high levels of phosphorus)
- Spinach (contains oxalate that forms insoluble calcium substances)

If the patient develops respiratory distress resulting from neuromuscular irritability, the patient may require tracheostomy or mechanical ventilation along with bronchodilating medications.

Nursing Management

Nursing management of the patient with acute hypoparathyroidism includes the care of patients who have undergone thyroidectomy, parathyroidectomy, or radical neck dissection. Care is directed toward detecting early signs of hypocalcemia and anticipating signs of tetany, seizures, and respiratory difficulties. To anticipate emergencies, calcium gluconate should be kept at the bedside in a locked container or in a place where it is readily available along with equipment necessary for IV administration. Calcium gluconate is administered slowly in patients who have a current cardiac disorder, such as arrhythmias, and in patients who are currently receiving digitalis.

The patient requires continuous cardiac monitoring and careful assessment because calcium and digitalis increase systolic contraction and also potentiate each other, which can produce potentially fatal arrhythmias.

Patient education about medications and diet therapy is essential. The patient needs to know the reason for high calcium and low phosphate intake and the symptoms of hypocalcemia and hypercalcemia. In addition, the nurse teaches the patient to contact the primary care provider if these symptoms occur.

DISORDERS OF THE ADRENAL GLANDS

PHEOCHROMOCYTOMA

Pheochromocytoma is a rare disease, found in two to four new cases per million annually (Fitzgerald, 2015). Although around 0.1% of patients with high blood pressure have this tumor, it can cause severe hypertensive crisis (Neumann, 2015).

Pathophysiology

Pheochromocytoma begins with benign growth of a tumor inside the adrenal medulla and usually secretes epinephrine and norepinephrine (Fitzgerald, 2015). In 90% of patients, the tumor arises in the medulla but can arise in other extra-adrenal chromaffin tissue located in or near the aorta, ovaries, spleen, or other organs. This clinical syndrome is characterized by a massive release of catecholamines that causes severe hypertension. The release may be paroxysmal rather than continuous, causing intermittent episodes of headaches, tremor, nervousness, and marked variability in blood pressure (Porth, 2015).

Risk Factors

Around 30% of patients with pheochromocytoma have a positive family history that makes them prone to developing the tumor (Fitzgerald, 2015). In most cases, 10% of the tumors are bilateral, and 10% are malignant. Although rare, there has been evidence that multiple endocrine neoplasia type 2 (MEN-2) may predispose one to having pheochromocytoma (Neumann, 2015). MEN type 2 is a rare inherited disease that leads to overactivity and enlargement of the endocrine glands (e.g., overproduction of adrenaline in the adrenal glands). Because of the risk of pheochromocytoma in family members of affected people, the patient's family members should be alerted and examined for pheochromocytoma.

Clinical Manifestations and Assessment

The nature and severity of symptoms of functioning tumors of the adrenal medulla depend on the relative proportions of epinephrine and norepinephrine secretion (Table 31-7). Typical presentation of a patient with pheochromocytoma includes the five H's:

- Hypertension (severe),
- Headache,
- Hyperhydrosis (excessive sweating),
- Hypermetabolism, and
- Hyperglycemia (conversion of liver and muscle glycogen to glucose due to epinephrine secretion).

Other symptoms may include tremor, flushing, and anxiety. Approximately 8% of patients are completely asymptomatic. Paroxysmal symptoms of pheochromocytoma usually develop in the fifth decade of life.

Table 31-7Laboratory Tests for Epinephrine and Norepinephrine

Test	Normal Values	Critical Values	Nursing Implications
Plasma level of epinephrine Plasma level of norepinephrine	100 pg/mL (590 pmol/L) Less than 100–550 pg/mL (590–3,240 pmol/L)	Greater than 400 pg/mL (2,180 pmol/L) diagnostic of pheochromocytoma Greater than 2,000 pg/mL (11,800 pmol/L) diagnostic of pheochromocytoma	The nurse should ensure that patients should not be on epinephrine drugs, such as nose drops and cough mixtures, and norepinephrine drugs, such as Levophed, because these drugs may lead to false increases in levels of plasma epinephrine and norepinephrine. In addition, the patient's blood should be drawn in a nonstressful environment.

Typically, pheochromocytoma is characterized by acute, unpredictable attacks lasting seconds or several hours. The attacks can be triggered by events, such as use of intravenous contrast dyes or glucagon injection, needle biopsy of the mass, anesthesia, or surgical procedures, exercise, bending, lifting, emotional stress, and drugs (e.g., MAO inhibitors, caffeine, nicotine, decongestions, and amphetamines) (Fitzgerald, 2015). Symptoms usually begin abruptly and subside slowly. During these attacks, the patient is extremely anxious, tremulous, and weak. The patient may experience headache, vertigo, blurring of vision, tinnitus, air hunger, and dyspnea. Other symptoms include polyuria, nausea, vomiting, diarrhea, abdominal pain, and a feeling of impending doom. Headache is the most common symptom and can be quite severe (Porth, 2015). Blood pressures exceeding 250/150 mm Hg have been recorded. Such elevations in blood pressure are life-threatening and can cause severe complications, such as cardiac arrhythmias, dissecting aneurysm, stroke, and acute kidney failure. Postural hypotension (decrease in systolic blood pressure, lightheadedness, dizziness on standing) occurs in 70% of patients with untreated pheochromocytoma.

Diagnostic measurements of urine and plasma levels of catecholamine and their metabolites (metanephrine [MN], vanillylmandelic acid [VMA]) are the most direct and conclusive tests for overactivity of the adrenal medulla. CT and MRI studies detect tumors

and possible metastases. A negative test result for catecholamines virtually excludes pheochromocytoma; however, increased levels of at least one catecholamine or MN can occur in 10% of patients with essential hypertension. In most cases, pheochromocytoma can be diagnosed or confirmed based on a properly collected 24-hour urine sample of free catecholamine, MN, and VMA; levels as high as twice the normal level may be found. The use of combined serum and urine tests increases the diagnostic accuracy of testing. A number of medications and foods, such as coffee and tea (including decaffeinated varieties), bananas, chocolate, vanilla, and aspirin, may alter the results of these tests. Therefore, the patient must be given instructions to avoid such items.

The total concentration of plasma catecholamine (epinephrine and norepinephrine) is measured with the patient supine and at rest for 30 minutes. To prevent elevation of catecholamine levels resulting from the stress of venipuncture, a butterfly needle, scalp vein needle, or venous catheter may be inserted 30 minutes before the blood specimen is obtained. Factors that may elevate catecholamine concentrations must be controlled to obtain valid results; these factors include the dietary items noted earlier, use of tobacco, emotional and physical stress, and use of many prescription and over-the-counter medications (e.g., amphetamines, nose drops or sprays, decongestant agents, bronchodilators).

Medical Management

Although uncommon, other conditions may be associated with this tumor, including cardiac complications, hypotension, shock, and sudden death. Once pheochromocytoma is diagnosed, the main goal of surgical treatment is the removal of primary tumors and, if possible, the resection of local and distant metastases (Parenti et al., 2012). A laparoscopic removal of the tumor is often the treatment of choice, but open laparotomy is required if tumors are large and invasive in nature (Fitzgerald, 2015).

The patient will be admitted to the intensive care unit for close monitoring (especially ECG) and careful administration of alpha-adrenergic blocking agents (e.g., phentolamine [Regitine]) or smooth muscle relaxants (e.g., sodium nitroprusside [Nipride]) to lower the blood pressure quickly. Phenoxybenzamine (Dibenzyline), a long-acting alpha blocker, may be used after the blood pressure is stable to prepare the patient for surgery. Calcium-channel blockers, such as nifedipine (Procardia) usually are well tolerated by patients and have reduced requirements for perioperative fluids. Although the use of calcium-channel blockers in the management of patients with catecholamine-secreting tumors does not prevent hemodynamic changes, their use was found to be associated with low morbidity and mortality (Lebuffe et al., 2005). However, using calcium-channel blockers alone is not recommended unless patients have very mild preoperative hypertension or have severe orthostatic hypotension (Lenders et al., 2014). Usually calcium-channel blockers are co-administered with alpha-adrenergic blocking agents. Beta-adrenergic blocking agents, such as propranolol (Inderal), may be used in patients with cardiac arrhythmias and in those not responsive to alpha blockers. Alpha-adrenergic and beta-adrenergic blocking agents must be used with caution because patients with pheochromocytoma may have increased sensitivity to them. Catecholamine synthesis inhibitors, such as alpha-methyl-*p*-tyrosine (metyrosine), also may be used preoperatively if adrenergic blocking agents do not reduce the effects of catecholamines. Insulin may be required to maintain normal serum glucose levels.

Nursing Management

The nursing management of the patient includes close monitoring of the patient's vital signs (especially heart rate and blood pressure) for several days in the intensive care unit. Most importantly, the nurse monitors the patient closely for excessive rapid decrease in blood pressure that may cause underperfusion to the vital organs (e.g., brain and kidneys). Other management includes monitoring of patient's mental status, acute ECG changes, arterial pressures, fluid and electrolyte balance, and blood glucose levels. Several IV lines are inserted for administration of fluids and medications. Despite large doses of medications used to lower the blood pressure, some patients may continue to be hypertensive. This is due to the effect of poor elasticity of the damaged blood vessels from chronic hypertension.

During the phases of care, the nurse informs the patient about the importance of follow-up monitoring to ensure that pheochromocytoma does not recur undetected. For instance, due to the risk for recurrence of hypertension, periodic checkups are required, especially in young patients and in those whose families have a history of pheochromocytoma. The patient is scheduled for periodic follow-up appointments to observe for return of normal blood pressure and plasma and urine levels of catecholamines.

ADDISON DISEASE

Addison disease, or primary adrenocortical insufficiency, occurs when adrenal cortex function is inadequate to meet the patient's need for cortical hormones. The three adrenal corticosteroids are glucocorticoids (primarily cortisol, which decreases inflammatory reaction, decreases WBC migration to inflamed area, increases fat metabolism, and raises serum glucose), mineralocorticoids (primarily aldosterone, which causes sodium reabsorption and, with it, water, along with renal excretion of potassium), and androgens (sex hormones).

Pathophysiology

A primary adrenal insufficiency originates in the adrenal glands themselves and is likely associated with autoimmune or idiopathic atrophy of the adrenal cortex when cell-mediated immune mechanisms result in decreased production of adrenocortical hormones (e.g. cortisol and aldosterone). While primary adrenal insufficiency is an uncommon disorder, autoimmunity is responsible for about 80% of spontaneous cases in the United States (Fitzgerald, 2015). In contrast, secondary adrenal insufficiency can be due to either a lack of pituitary ACTH secretion, or Hypothalamic corticotropin-releasing hormone (CRH) dysfunction. This causes a resultant decrease production of cortisol but not aldosterone. ACTH only minimally influences aldosterone secretion, as it is secreted primarily in response to the presence of angiotensin II in the bloodstream.

Risk Factors

The risk factors for Addison disease include surgical removal of both adrenal glands and infection of the adrenal glands. Tuberculosis, cytomegalovirus, and bacterial infections (such as Neisseria meningitidis) are common infections that destroy adrenal gland tissue (National Institute of Diabetes and Digestive and Kidney Disease [NIDDK], 2014). Although autoimmune destruction has replaced tuberculosis as the principal cause of Addison disease, tuberculosis should be considered in the diagnostic workup because of its increasing incidence. Inadequate secretion of ACTH from the pituitary gland results in secondary adrenal insufficiency because of decreased stimulation of the adrenal cortex. Symptoms of adrenocortical insufficiency also may result from the sudden cessation of exogenous adrenocortical hormonal therapy, which suppresses the body's normal response to stress and interferes with normal feedback mechanisms. Hence, corticosteroids should never be stopped abruptly. Daily administration of corticosteroids has the potential to suppress function of the adrenal cortex. It has been shown that a patient who is acutely ill receiving more than 30 mg/day of hydrocortisone, 7.5 mg/day of prednisolone, or 0.75 mg/day of dexamethasone for more than 3 weeks can experience suppression of adrenal cortex function (Cooper & Stewart, 2003).

Clinical Manifestations and Assessment

Addison disease is characterized by muscle weakness, anorexia, GI symptoms, fatigue, emaciation, skin pigmentation changes (Box 31-11), and hypotension as well as low blood glucose, low serum sodium, and high serum potassium levels. Depression, emotional lability, apathy, and confusion are present in 60% to 80% of patients. With decreased glucocorticoids, mineralocorticoids, and androgens, there is a stimulation of the anterior pituitary to increase ACTH. This releases the melanocyte hormone, which results in a bronze-pigmented rash (Fig. 31-7). Figure 31-7 details the clinical manifestations of Addison disease and diagram specifies the relationship of signs and symptoms to specific hormone deficiency.

In severe cases, the disturbance of the metabolism of sodium and potassium may be marked by depletion of sodium and water and severe chronic dehydration. Addisonian crisis is an acute life-threatening event that develops with disease progression. Acute hypotension is characterized by cyanosis and the classic signs of circulatory shock: pallor, apprehension, rapid and weak pulse, rapid respirations, and low blood pressure. In addition, the patient may complain of headache, nausea, abdominal pain, and diarrhea and may show signs of confusion and restlessness. Even slight overexertion, exposure to cold, acute infection, or a decrease in salt intake may lead to circulatory collapse, shock, and death if untreated. The stress of surgery or dehydration resulting from preparation for diagnostic tests may precipitate an addisonian or hypotensive crisis.

BOX 31-11 Focused Assessment

Skin Changes in Addison Disease

Be alert for the following signs and symptoms:

- Skin pigmentation changes of bronzed or suntanned appearance (seen in primary Addison disease because the persistently low levels of cortisol cause hypersecretion of ACTH from the pituitary gland; increased melanin synthesis is associated with an increase in ACTH, thus hyperpigmentation occurs)
- Increased pigmentation at skin creases, pressure points (knuckles, elbows, knees) and buccal mucosa

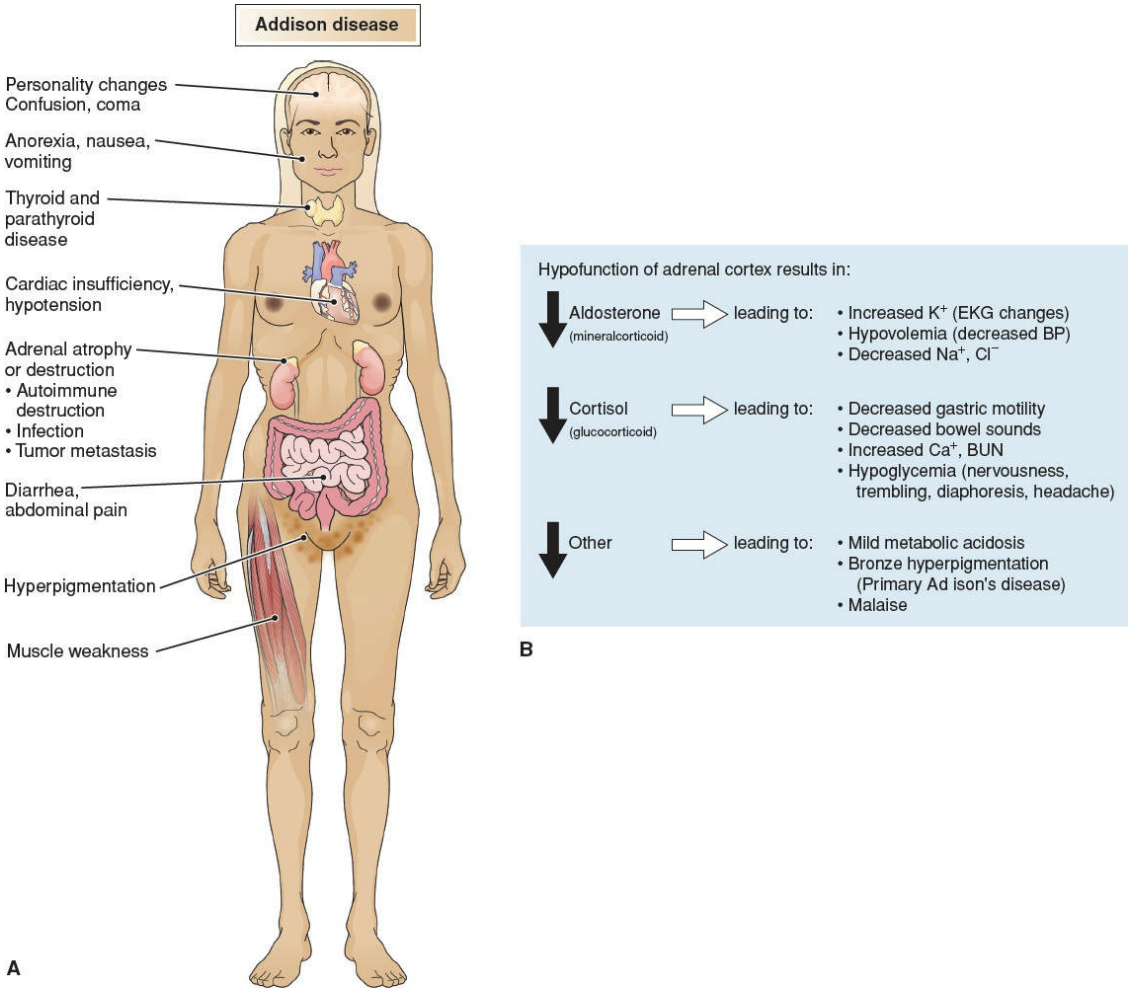

FIGURE 31-7 (A) Clinical manifestations of Addison disease. (From Porth, C. M. (2015). *Essentials of pathophysiology: Concepts of altered health states* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.) (B) Chart detailing the signs and symptoms of Addison disease and relationship to specific hormone deficiencies. (Reprinted with permission from Diepenbrock, N. H. (2015). *Quick reference to critical care* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Symptoms of secondary adrenal insufficiency are the same as those for primary adrenal insufficiency with a few exceptions, most notably the lack of hyperpigmentation, as ACTH secretion is not increased. In addition, symptoms are due to glucocorticoid rather than mineralocorticoid deficiency. Therefore, signs of hypoglycemia are present, while signs of hyperkalemia are not because of the continued presence of aldosterone.

The diagnosis is confirmed by laboratory test results. Combined measurements of early-morning serum cortisol and plasma ACTH are performed to differentiate patients with primary adrenal insufficiency from those with secondary adrenal insufficiency.

Patients with primary insufficiency have a plasma ACTH level that is greatly increased (over 22.0 pmol/L) and a serum cortisol concentration lower than the normal range (less than 165 nmol/L) or in the low-normal range. Other laboratory findings include decreased levels of blood glucose (hypoglycemia) and sodium (hyponatremia), an increased concentration of serum potassium (hyperkalemia), and an increased WBC count (leukocytosis). If the adrenal cortex is destroyed, baseline cortisol values become low, and ACTH administration fails to cause the normal increase in plasma cortisol and urinary 17-hydroxycorticosteroids. Secondary adrenal insufficiency is characterized by low pituitary

dysfunction. The adrenal gland is a healthy, but it is not being stimulated properly by the pituitary. In this situation, low levels of adrenocortical hormones in the blood or urine and decreased serum cortisol levels are seen. A normal response to repeated doses of exogenous ACTH is seen (adrenal gland is normal), but no response occurs after the administration of metyrapone, which stimulates endogenous ACTH.

Medical Management

Immediate treatment is directed toward combating circulatory shock: restoring blood circulation, administering fluids and corticosteroids, monitoring vital signs, and placing the patient in a recumbent position with the legs elevated. Corticosteroid use is discussed in Box 31-12 and Table 31-8. Hydrocortisone (Solu-Cortef) is administered intravenously, followed by 5% dextrose in normal saline. Oral hydrocortisone replacement is resumed once intravenous infusion is discontinued. Vasopressor amines may be required if hypotension persists. Broad-spectrum antibiotics may be administered if infection has precipitated adrenal crisis in a patient with chronic adrenal insufficiency. In addition, the patient is assessed closely to identify other factors, stressors, or illnesses that led to the acute episode.

Nursing Management

Restoring Fluid Status

Along with dietitian referral, the nurse encourages the patient to consume foods and fluids that assist in restoring and maintaining fluid and electrolyte balance and teaches the patient to select foods that are high in sodium during GI disturbances and in very hot weather. The nurse instructs the patient and family to administer hormone replacement as prescribed and to modify the dosage during illness and other stressful situations. Written and verbal instructions are provided about the administration of mineralocorticoid (Florinef) or corticosteroid (prednisone).

Prior to fluid replacement therapy, the nurse monitors the patient for any signs and symptoms of fluid imbalances by monitoring the blood pressure and pulse rate as the patient moves from a lying to a standing position. A decrease in systolic pressure (20 mm Hg or more) indicates fluid volume deficit, as evidenced by the patient's narrowed pulse pressure, delayed capillary filling, and flat neck veins. The nurse monitors the patient for manifestations of hypovolemic shock: hypotension, rapid weak pulse, rapid respiratory rate, pallor, and extreme weakness. Other key considerations include checking for weight loss, measuring intake and output, assessing for muscle weakness and fatigue, and investigating any illness or stress that may have precipitated the acute crisis.

Reducing Stress

Until the patient's condition is stabilized, unnecessary activity and stress that could precipitate another hypotensive episode are avoided. The nurse assesses for signs of infection or the presence of other stressors. Even minor events or stressors may be excessive in patients with adrenal insufficiency. During the acute crisis, the nurse maintains a quiet, nonstressful environment and performs all activities (e.g., bathing, turning) for the patient. Maintaining communication and explaining all procedures to the patient and family can help reduce their anxiety. During stressful procedures or significant illnesses, additional supplementary therapy or higher doses of glucocorticoids are required to prevent an addisonian crisis.

Maintaining Self-Care

Because of the need for lifelong replacement of adrenal cortex hormones to prevent addisonian crises, the patient and family members receive explicit verbal and written instructions about the rationale for replacement therapy and proper dosage. In addition, they learn about how to modify the medication dosage and increase salt intake in times of illness, very hot weather, and other stressful situations. The patient also learns how to modify diet and fluid intake to help maintain fluid and electrolyte balance.

The patient and family are prescribed preloaded, single-injection syringes of corticosteroid for use in emergencies. Specific instructions on how and when to use the injection also are provided. It is important to instruct the patient to inform other health care providers, such as dentists, about the use of corticosteroids, to wear a medical alert bracelet, and to carry information at all times about the need for corticosteroids. The

patient and family need to know the signs of excessive or insufficient hormone replacement. The development of edema or weight gain may signify the dose is too high; postural hypotension and weight loss frequently signify the dose is too low.

BOX 31-12 Using Corticosteroids in the Treatment of Adrenal Disease

Synthetic corticosteroids are administered for a variety of clinical conditions, including adrenal insufficiency, suppressing inflammation and autoimmune reactions, controlling allergic reactions, and reducing the rejection process in transplantation. Choices for corticosteroids include: prednisone, methylprednisolone, and dexamethasone which are all synthetic compositions of cortisol (hydrocortisone). The dosage of corticosteroids is determined by the nature and chronicity of the illness as well as the patient's other medical conditions. Side effects include the development of diabetes mellitus, osteoporosis, peptic ulcer, increased protein breakdown resulting in muscle wasting and poor wound healing, and redistribution of body fat. Therefore, the adverse effects of corticosteroids must be weighed against the benefits to the patient's current condition.

Depending on the severity of disease, corticosteroids may be used for a period of time and gradually reduced or tapered as the symptoms subside so as to avoid undesirable effects, such as adrenal suppression. Traditionally, adrenal suppression was anticipated in individuals who received more than 30 mg of hydrocortisone or its equipotent dosage of 7.5 mg of prednisolone per day (the average daily equivalent output of the adrenal glands) for more than 3 weeks. However, this practice has been questioned since doses of exogenous glucocorticoids do not correlate directly with endogenous production.

Once the primary disorder is resolved, corticosteroid dosages are tapered to allow the return of normal adrenal function and to prevent steroid-induced adrenal insufficiency. However, up to 1 year or longer after use of corticosteroids, the patient still may be at risk for adrenal insufficiency in times of stress. If surgery is necessary, the patient is likely to require IV corticosteroids during and after surgery to reduce the risk for acute adrenal crisis. The nurse plays an important role in providing education about the dosage, taper schedule, and side effects of corticosteroids. Table 31-7 provides an overview of the effects of corticosteroid therapy and their nursing implications.

In keeping with the natural secretion of cortisol, the best time of day for the total corticosteroid dose is in the early morning, between 7 and 8 AM. The half-life of synthetic steroids is approximately 8 hours. Therefore, if a large-dose therapy is administered at 8 AM (when the adrenal gland is most active), maximal suppression of the adrenal gland occurs. The adrenal suppressive effect can last for 12 to 24 hours. If symptoms of the disorder being treated are suppressed, alternate-day therapy may be helpful in reducing pituitary–adrenal suppression in patients requiring prolonged therapy. Since large amounts of glucocorticoids administered exogenously in the blood inhibit the release of ACTH and endogenous glucocorticoids, atrophy of the adrenal cortex can develop with long-term use. If exogenous glucocorticoid administration is

discontinued suddenly, adrenal insufficiency can occur due to the inability of the atrophied cortex to respond adequately.

Although the synthetic corticosteroids are safe for some patients because of relative freedom from mineralocorticoid activity, most natural and synthetic corticosteroids produce similar kinds of side effects. Mineralocorticoids have major effects on electrolyte metabolism, acting principally on the renal tubular and GI epithelium to cause increased absorption of sodium ions in exchange for excretion of potassium or hydrogen ions. ACTH only minimally influences aldosterone secretion. It is primarily secreted in response to the presence of angiotensin II in the bloodstream. Angiotensin II is a substance that elevates the blood pressure by constricting arterioles. Its concentration is increased when renin is released from the kidney in response to decreased perfusion pressure. The resultant increased levels of aldosterone promote sodium reabsorption by the kidney and the GI tract, which tends to restore blood pressure to normal. The release of aldosterone also is increased by hyperkalemia.

Monitoring and Managing Addisonian Crisis

Physical and psychological stressors must be avoided since the patient with Addison disease is at risk for an addisonian crisis, which presents as complete circulatory collapse and shock. Triggers include exposure to cold, overexertion, infection, and emotional distress. The patient with an addisonian crisis requires immediate treatment with IV administration of fluid, glucose, and electrolytes, especially sodium; replacement of missing steroid hormones; and vasopressors. Additionally, the patient must avoid exertion; therefore, the nurse must anticipate the patient's needs and take measures to meet them. Careful monitoring of symptoms, vital signs, weight, and status of fluids and electrolytes is essential to assess the patient's progress and return to a precrisis state. To reduce the risk of future episodes of an addisonian crisis, efforts are made to identify and reduce the factors that may have led to the crisis.

CUSHING SYNDROME/DISEASE

Pathophysiology

Cushing syndrome, or hypercortisolism, is a disorder characterized by high levels of serum cortisol—too much ACTH is at work in the body. Three important causes of Cushing syndrome are:

- A pituitary tumor that overproduces ACTH, termed Cushing disease
- An adrenal tumor that overproduces ACTH, termed Cushing syndrome
- Long-term glucocorticoid pharmacologic therapy, termed iatrogenic

TABLE 31-8 Side Effects of Corticosteroid Therapy and Implications for Nursing Practice

Side Effects	Collaborative Interventions
Cardiovascular Effects	
Hypertension Thrombophlebitis Thromboembolism Accelerated atherosclerosis	Monitor for elevated blood pressure. Assess for signs and symptoms of deep venous thrombosis (DVT): redness, warmth, tenderness, and unilateral edema of an extremity. Remind the patient to avoid positions and situations that restrict blood flow (e.g., crossing legs, prolonged sitting in same position, use of knee highs or girdles). Encourage foot and leg exercises when recumbent. Encourage low sodium intake. Encourage limited intake of fat.
Immunologic Effects	
Increased risk of infection and masking of signs of infection	Assess for subtle signs of infection and inflammation. Encourage the patient to avoid exposure to others with upper respiratory infection. Monitor the patient for fungal infections. Encourage handwashing.
Ophthalmologic Changes	
Glaucoma Corneal lesions	Encourage frequent eye examinations. Refer the patient to an ophthalmologist if changes are detected in visual acuity.
Musculoskeletal Effects	
Muscle wasting Poor wound healing Osteoporosis with vertebral compression fractures, pathologic fractures of long bones, aseptic necrosis of head of the femur	Encourage high intake of protein and vitamin C or supplementation of protein and vitamin C, if indicated. Encourage a diet high in calcium and vitamin D or supplementation of calcium and vitamin D, if indicated. Take measures to avoid falls and other trauma. Use caution in moving and turning patient. Encourage postmenopausal women on corticosteroids to consider bone mineral density testing and treatment, if indicated. Instruct the patient to rise slowly from the bed or chair to avoid falling.
Metabolic Effects	
Alterations in glucose metabolism Steroid withdrawal syndrome	Monitor blood glucose levels at periodic intervals. Instruct the patient about medications, diet, and exercise prescribed to control blood glucose level. Report signs of adrenal insufficiency. Administer corticosteroids and mineralocorticoids as prescribed. Monitor fluid and electrolyte balance. Administer fluids and electrolytes as prescribed. Instruct the patient about the importance of taking corticosteroids as prescribed without stopping therapy abruptly. Encourage the patient to obtain and wear a medical identification bracelet. Advise the patient to notify all health care providers (e.g., dentist) about the need for corticosteroid therapy.
Changes in Appearance	
Moon face Weight gain Acne	Encourage a low-calorie, low-sodium diet. Assure the patient that most changes in appearance are temporary and will disappear if and when corticosteroid therapy is no longer necessary.

Pathophysiology

Cushing syndrome is commonly caused by chronic use of synthetic corticosteroid medications and infrequently is due to excessive production of corticosteroid secondary to hyperplasia or tumor of the adrenal cortex. Overproduction of endogenous corticosteroids may be caused by several mechanisms, including a tumor of the pituitary gland that produces ACTH and stimulates the adrenal cortex to increase its hormone secretion despite production of adequate amounts (as noted earlier, technically termed *Cushing disease*). Primary hyperplasia of the adrenal glands in the absence of a pituitary tumor is less common. Another less common cause of Cushing syndrome is the ectopic production of ACTH by malignancies; bronchogenic carcinoma is the most common type of these malignancies. Regardless of the cause, the normal feedback mechanisms that control the function of the adrenal cortex become ineffective, and the usual diurnal pattern of cortisol is lost.

Risk Factors

The chronic use of corticosteroids is a common risk factor of developing Cushing syndrome. Females are three times more likely than males to develop Cushing syndrome, and the median age of onset or diagnosis was 41.4 years of age (Lacroix, Feelders, Stratakis, & Nieman, 2015). Other less common risk factors that may result in Cushing syndrome include primary hyperplasia of the adrenal glands in the absence of a pituitary tumor and ectopic production of ACTH by malignancies.

Clinical Manifestations and Assessment

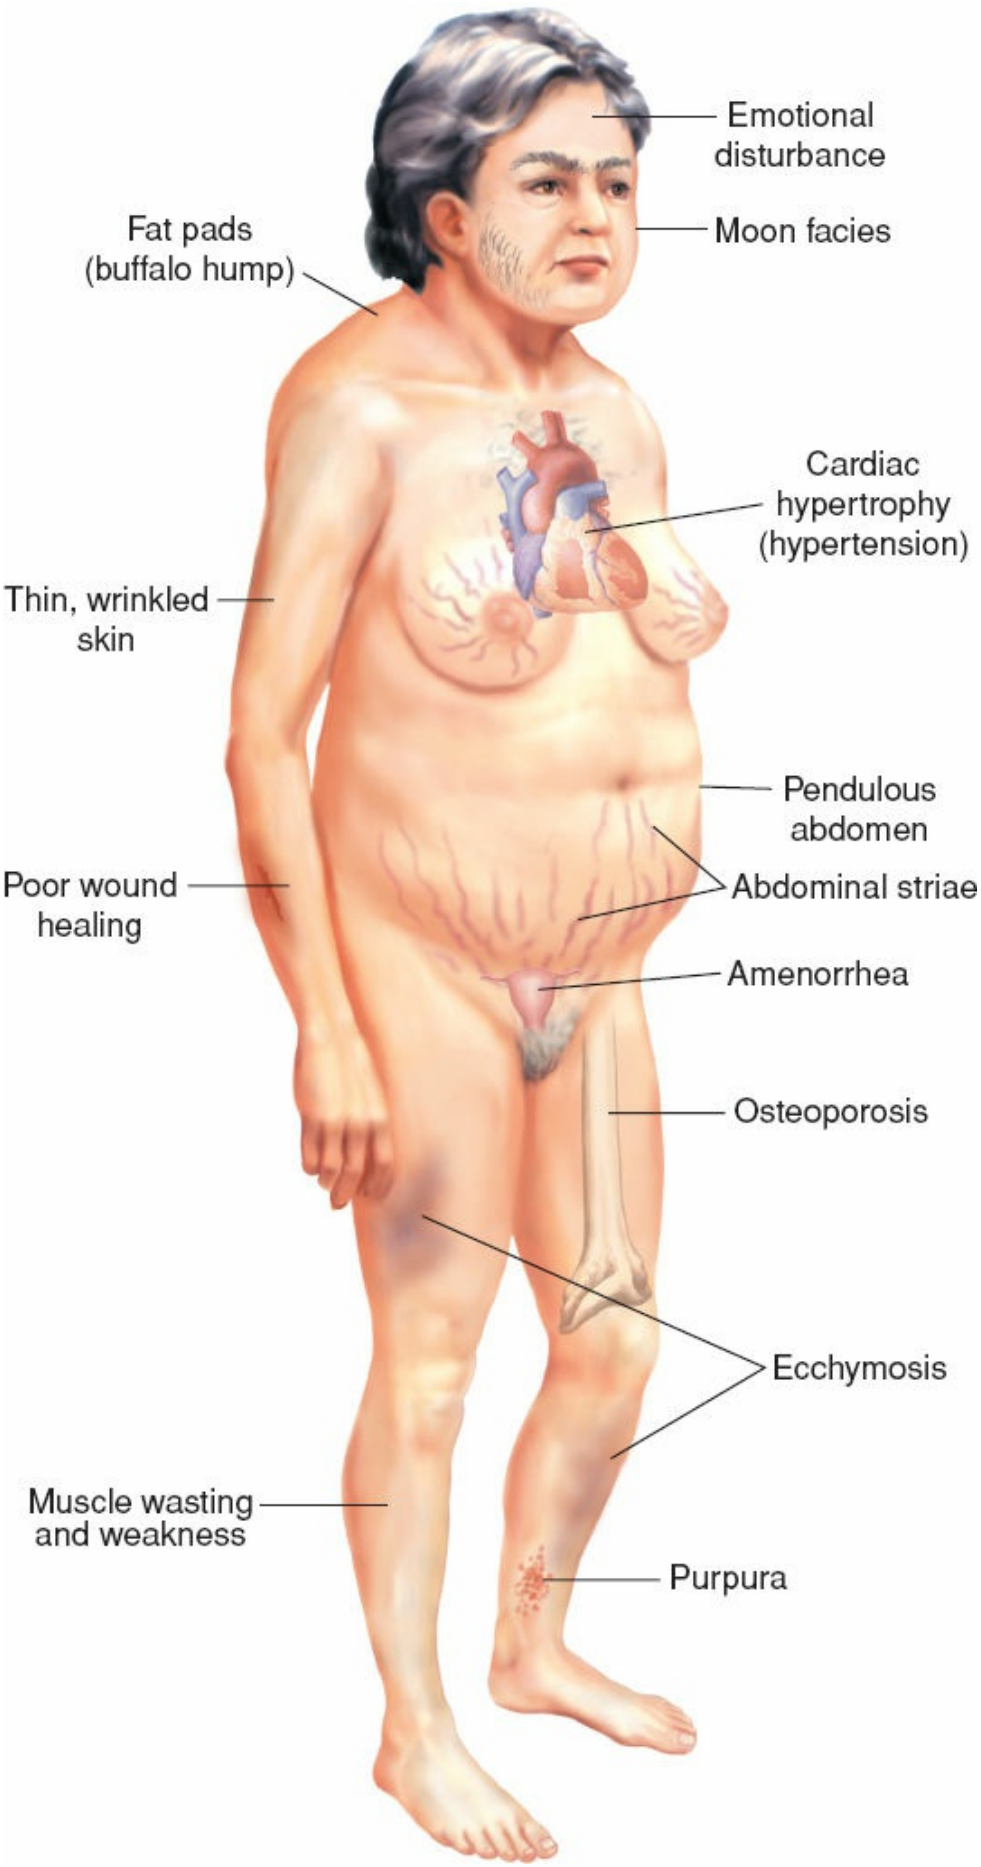
The signs and symptoms of Cushing syndrome are primarily due to oversecretion of glucocorticoids and androgens (sex hormones), although mineralocorticoid secretion also may play a role. Overproduction of the adrenal cortical hormone leads to an arrest of height, obesity, musculoskeletal changes, and glucose intolerance. Altered fat metabolism results in a classic picture of Cushing syndrome in the adult: central-type obesity, a protruding abdomen, a fatty "buffalo hump" in the neck and supraclavicular areas, and a round "moon-faced" appearance (Fig. 31-8). The skin is thin, fragile, and easily traumatized; ecchymoses (bruises) and purple striae develop (secondary to stretching of the weakened skin). The patient complains of weakness and lassitude. Sleep is disturbed due to altered diurnal secretion of cortisol.

Muscle weakness, wasting, and thin extremities are caused by protein wasting. Excessive catabolism of bone protein can result in osteoporosis. Kyphosis, backache, and compression fractures of the vertebrae may result.

Retention of sodium and water occurs as a result of increased mineralocorticoid activity, producing hypertension, hypokalemia, and heart failure. Hyperglycemia or overt diabetes may develop. The patient may report weight gain, increased susceptibility to infection, and slow healing of minor cuts.

In females of all ages, virilization may occur as a result of excess androgens. Virilization is characterized by the appearance of masculine traits and the recession of feminine traits. There is an excessive growth of hair on the face (hirsutism), the breasts atrophy, menses cease, the clitoris enlarges, and the voice deepens. Libido is lost in men and women.

Changes occur in mood and mental activity, and psychosis may develop. Distress and depression are common and are increased by the severity of the physical changes that occur with this syndrome. If Cushing disease is a consequence of a pituitary tumor, visual disturbances may occur because of pressure of the growing tumor on the optic chiasm.



Emotional disturbance
Moon facies
Fat pads (buffalo hump)
Cardiac hypertrophy (hypertension)
Thin, wrinkled skin
Pendulous abdomen
Abdominal striae
Poor wound healing
Amenorrhea
Osteoporosis
Ecchymosis
Muscle wasting and weakness
Purpura

FIGURE 31-8 Major clinical manifestations of Cushing syndrome. (From Porth, C. M. (2015). *Essentials of pathophysiology: Concepts of altered health states* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

The initial diagnostic assessment involves:

i. urine free cortisol (2 measurements),
ii. late night salivary cortisol (2 measurements), and
iii. dexamethasone suppression test: 1 mg overnight or 2 mg over 2 days (Nieman et al., 2008).

The 1 mg overnight dexamethasone suppression test is widely used and the most sensitive screening for the diagnosis of pituitary and adrenal causes of Cushing disease (Porth, 2015). In general, 1 mg of dexamethasone is administered orally at 11:00 PM, and a plasma cortisol level is obtained at 8:00 AM the next morning. Suppression of cortisol to less than 5 mg/dL indicates that the hypothalamic–pituitary–adrenal axis is functioning properly. Stress, obesity, depression, and medications, such as antiseizure agents, estrogen (during pregnancy or as oral medications), and rifampin, can falsely elevate cortisol levels. Studies have shown that nighttime salivary cortisol levels show promise in screening effectively for Cushing syndrome. Although not a routine diagnostic test in the United States, salivary cortisol concentrations are shown to be reflective of active free cortisol in plasma. Usually a saliva sample is collected on two separate evenings either by passive drooling into a plastic tube or by chewing a piece of cotton salivette for 1 to 2 minutes (Nieman et al., 2008). Saliva samples can be obtained easily in a nonstressful environment (e.g., at home); the test is relatively safe and easy to administer, with a sensitivity of 92% to 100% and a specificity of 93% to 100% (Carroll, Raff, & Findling, 2008).

Indicators of Cushing syndrome include an increase in levels of serum sodium (hypernatremia) and blood glucose (hyperglycemia), a decrease in serum potassium (hypokalemia), a reduction in the number of blood eosinophils, and disappearance of lymphoid tissue. Measurements are obtained of plasma and urinary cortisol levels. Several blood samples may be collected to determine whether the normal diurnal variation in plasma levels is present; frequently this variation is absent in adrenal dysfunction. If several blood samples are required, they must be collected at the times specified, and the time of collection must be noted on the requisition slip.

Radioimmunoassay measurement of plasma ACTH is used together with the high-dose suppression test to distinguish pituitary tumors from ectopic sites of ACTH production. Elevation of ACTH and cortisol indicates pituitary or hypothalamic disease. Low ACTH with high cortisol level indicates adrenal disease. CT, ultrasound, or MRI is performed to localize adrenal tissue and detect tumors of adrenal gland.

Medical Management

Treatment is directed at the pituitary gland if Cushing's is caused by pituitary tumors rather than tumors of the adrenal cortex. Successful surgical removal of the tumor by transsphenoidal hypophysectomy is the treatment of choice, and it has early postoperative remission rates between 67% and 95% (Pendharkar, Sussman, Ho, Hayden Gephart, & Katznelson, 2015). In addition, radiation of the pituitary gland has been successful, but it may take several months for control of the symptoms. Adrenalectomy is the treatment of choice in patients with primary adrenal hypertrophy or when other therapies have failed.

Postoperatively, symptoms of adrenal insufficiency may begin to appear 12 to 48 hours after surgery because of the reduction of high levels of circulating adrenal hormones. Temporary replacement therapy with hydrocortisone may be necessary for several months, until the adrenal glands begin to respond normally to the body's needs. If both adrenal glands have been removed (bilateral adrenalectomy), patients should be educated that a lifetime replacement of adrenal cortex hormones is necessary, and they should be taught how to identify signs of acute addisonian crisis.

Adrenal enzyme inhibitors, such as metyrapone, aminoglutethimide, mitotane, and ketoconazole, are used to reduce hyperadrenalism if the syndrome is caused by ectopic ACTH secretion by a tumor that cannot be eradicated. Close monitoring is necessary because symptoms of inadequate adrenal function may result due to possible side effects of these medications.

If Cushing syndrome is a result of the administration of corticosteroids, an attempt is made to reduce or taper the medication to the minimum dosage needed to treat the underlying disease process (e.g., autoimmune, allergic disease, or rejection of transplanted organ). Frequently, alternate-day therapy decreases the symptoms of Cushing syndrome and allows recovery of the adrenal glands' responsiveness to ACTH.

Nursing Management

Decreasing Risk of Injury

Establishing a protective environment helps prevent falls, fractures, and other injuries to bones and soft tissues. The patient who is very weak may require assistance in ambulating to avoid falling or bumping into sharp corners of furniture. Foods high in protein, calcium, and vitamin D are recommended to minimize muscle wasting and osteoporosis. Referral to a dietitian may assist the patient in selecting appropriate foods that are also low in sodium and calories.

Decreasing Risk of Infection

The patient should avoid unnecessary exposure to others with infections. The nurse frequently assesses the patient for subtle signs of infection because the anti-inflammatory effects of corticosteroids may mask the common signs of inflammation and infection.

Encouraging Rest and Activity

Weakness, fatigue, and muscle wasting make it difficult for the patient with Cushing syndrome to carry out normal activities; however, the nurse encourages moderate activity to prevent complications of immobility and promote increased self-esteem. Insomnia often contributes to the patient's fatigue. It is important to help the patient plan and space rest periods throughout the day. Efforts are made to promote a relaxing, quiet environment for rest and sleep.

Promoting Skin Integrity

Proper skin care is necessary to avoid traumatizing the patient's fragile skin. The nurse avoids use of adhesive tape because it can irritate and tear the fragile skin when the tape is removed. The nurse frequently assesses the skin and bony prominences and encourages and assists the patient to change positions frequently to prevent skin breakdown.

Improving Body Image

If the cause of Cushing syndrome can be treated successfully, the major physical changes disappear in time. The patient may benefit from discussion of the effect the changes have had on his or her self-concept and relationships with others. Weight gain and edema may be modified by recommending a low-carbohydrate, low-sodium, and high-protein diet.

Improving Thought Processes

Explanations to the patient and family members about the cause of emotional instability are important in helping them cope with the mood swings, irritability, and depression that may occur. Psychotic behavior may occur in a few patients and should be reported. The nurse encourages the patient and family members to verbalize their feelings and concerns.

Monitoring and Managing Addisonian Crisis

The patient with Cushing syndrome whose symptoms are treated by the withdrawal of corticosteroids, by adrenalectomy, or by removal of a pituitary tumor is at risk for adrenal hypofunction and addisonian crisis. If high levels of circulating adrenal hormones have suppressed the function of the adrenal cortex, atrophy of the adrenal cortex is likely. If the level of circulating hormones is decreased rapidly because of surgery or abrupt cessation of corticosteroid agents, manifestations of adrenal hypofunction and addisonian crisis may develop. The nurse monitors the patient closely for hypotension, rapid weak pulse, rapid respiratory rate, pallor, and extreme weakness. Efforts are made to identify factors that may have led to the crisis. The patient may require IV administration of fluid, electrolytes, and corticosteroids before, during, and after treatment or surgery. The nurse assesses the status of fluid and electrolytes by monitoring laboratory values and daily weights. Retention of sodium and water may result in the development of edema and hypertension; therefore, assessment of vital signs and fluid volume excess is warranted. In addition, observe for signs and symptoms of hypokalemia (K^+ below 3.5 mEq/L), which can have a profound impact on cardiac and neurologic function. Blood glucose monitoring should be followed closely because of the increased risk for glucose intolerance and hyperglycemia with Cushing syndrome and hypoglycemia if the patient is now at risk for adrenal hypofunction due to interventions to treat Cushing syndrome. If addisonian crisis occurs, the patient is treated for circulatory collapse and shock.

Teaching Self-Care Measures

Upon discharge, the patient and family should understand that stopping the use of the corticosteroid abruptly and without medical supervision is likely to result in acute adrenal insufficiency as well as reappearance of the underlying symptoms of the chronic disease. The nurse emphasizes the need to ensure an adequate supply of the corticosteroid because running out of the medication or skipping doses can precipitate adrenal insufficiency and addisonian crisis. The need for dietary modifications is stressed; the nurse reminds the patient and family that it is important to ensure adequate calcium intake without increasing the risks for hypertension, hyperglycemia, and weight gain. The patient and family may be taught to monitor blood pressure, blood glucose levels, and weight. Wearing a medical alert bracelet and notifying health care providers (e.g., dentist) of the patient's condition are important.

PRIMARY ALDOSTERONISM

Pathophysiology

Primary aldosteronism, also known as *Conn syndrome*, is a condition in which the adrenal cortex produces too much aldosterone because of hyperplasia or tumor. The principal action of aldosterone is to conserve body sodium, thus excessive aldosterone will result in increased renal reabsorption of sodium and an increase in extracellular fluids and blood pressure.

Secondary hyperaldosteronism also can occur from a nonadrenal cause of elevated aldosterone and/or nonsuppressed plasma renin activity, such as renal artery stenosis, renin-secreting tumors, kidney disease, and malignant hypertension.

Risk Factors

Excessive production of aldosterone occurs in some patients with functioning tumors of the adrenal gland. The peak incidence is between 30 and 60 years of age (Fitzgerald, 2015). Other risk factors for primary aldosteronism include unilateral or bilateral adrenal hyperplasia (caused by overactivity of one or both adrenal glands), familial hyperaldosteronism, and aldosterone-producing adrenal adenoma (Fitzgerald, 2015).

Clinical Manifestations and Assessment

Patients with hyperaldosteronism exhibit a profound decline in the serum levels of potassium (hypokalemia) and hydrogen ions (alkalosis, leading to tetany) as demonstrated by an increase in pH and serum bicarbonate concentration. The serum sodium level is normal or typically elevated depending on the amount of water reabsorbed with the sodium or water loss in the urine. Hypertension is the most prominent and almost universal sign of aldosteronism and accounts for 10% of cases of hypertension (Piaditis, Markou, Papanastasiou, Androulakis, & Kaltsas, 2015).

Hypokalemia leads to muscle weakness, cramping, and fatigue as well as an inability on the part of the kidneys to acidify or concentrate the urine, leading to polyuria. Serum sodium becomes abnormally concentrated, contributing to excessive thirst (polydipsia) and arterial hypertension. A secondary increase in blood volume and possible direct effects of aldosterone on nerve receptors, such as the carotid sinus, result in hypertension.

Hypokalemic alkalosis may decrease the level of ionized serum calcium and predispose the patient to tetany and paresthesia. Glucose intolerance may occur because hypokalemia interferes with insulin secretion from the pancreas.

In addition to a high or normal serum sodium level and a low serum potassium level, diagnostic studies indicate high serum aldosterone and low serum renin levels. The measurement of the aldosterone excretion rate after salt loading is a useful diagnostic test for hyperaldosteronism. The renin–aldosterone stimulation test and bilateral adrenal venous sampling are useful in differentiating the cause of primary aldosteronism. Antihypertensive medication may be discontinued up to 2 weeks before testing.

Medical Management

Treatment of primary aldosteronism usually involves surgical removal of the adrenal tumor through adrenalectomy. Adrenalectomy is performed through an incision in the flank or the abdomen using laparoscopic techniques. In general, postoperative care resembles that for other abdominal surgeries. The patient is susceptible to fluctuations in adrenocortical hormones and requires administration of corticosteroids, fluids, and other agents to maintain blood pressure and prevent acute complications. If the adrenalectomy is bilateral, lifetime replacement of corticosteroids will be necessary. If one adrenal gland is removed, the replacement therapy may be only temporary because of the suppression of the remaining adrenal gland by high levels of adrenal hormones. A normal level of serum glucose is maintained with insulin, IV fluids, and dietary modifications. Hypokalemia resolves for all patients after surgery, but hypertension may persist. Spironolactone (potassium-sparing diuretic) and Eplerenone may be prescribed to control hypertension and minimize hypokalemia.

Nursing Management

The nursing management during the postoperative period includes frequent assessment of vital signs to detect early signs and symptoms of adrenal insufficiency and crisis or hemorrhage. Explaining all treatments and procedures, providing comfort measures, and providing rest periods can reduce the patient's stress and anxiety level.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 65-year-old woman has just been diagnosed with thyroid cancer. She is scheduled for a total thyroidectomy in 1 week. What preoperative and postoperative nursing care is necessary for her recovery? What long-term follow-up would you anticipate, and what issues should you discuss with the patient and her family?

2. A 70-year-old man has a diagnosis of bronchogenic carcinoma. He is being evaluated for possible SIADH. The patient and his family are asking for explanations about the syndrome and about methods of managing it. What nursing interventions and patient and family teaching are warranted when caring for this patient? Compare and contrast the clinical picture and symptoms of SIADH with those of diabetes insipidus.

3. A 14-year-old girl was diagnosed recently with Addison disease. The patient is overly concerned that she will not be able to lead a normal life as a result of this disease. What advice/patient education should the nurse give to the patient? Describe and provide rationale on how each piece of advice will benefit the patient.

NCLEX-Style Review Questions

1. Upon evaluation of the patient's laboratory data and clinical signs and symptoms, the nurse suspects that the patient may have pheochromocytoma. Which of the following is directly related with pheochromocytoma? Select all that apply.
   a. Severe headache; pain score of 9 out of 10
   b. Perspiration
   c. Blood pressure 80/90 mm Hg
   d. Pallor
   e. Lethargy

2. A 70-year-old female patient is admitted to the unit with enlargement of thyroid gland, hypertension, high TSH levels, and bulging eyes. What nursing intervention is most appropriate for this patient?
   a. Providing a blanket
   b. Instilling eye ointment

c. Providing a warm bath
d. Keep room temperature comfortable at 85°F

3. A patient presented to the unit with an ADH-secreting tumor. Upon diagnostic and physical evaluation, the nurse suspects the patient is experiencing SIADH. Which of the following is a clinical manifestation of SIADH? Select all that apply.
   a. Hyponatremia
   b. Hypernatremia
   c. Increased serum osmolality
   d. Reduced serum osmolality
   e. Dry mucous membranes
   f. Low urine output

4. The nursing management of a patient who underwent transsphenoidal removal of a pituitary tumor yesterday includes which of the following actions? Select all that apply.
   a. Maintaining oral care
   b. Removing nasal pack to check for bleeding and CSF leak
   c. Giving fluid after nausea, and then slowly progressing to normal diet
   d. Raising the head of the bed to promote drainage
   e. Brush teeth to prevent bacterial overgrowth with hard toothbrush

5. A 55-year-old female presents to the clinic with complaints of fatigue and tiredness. The nurse notices that the patient's skin is thin, fragile, and easily traumatized. Ecchymosis and purple striae are noted over the thighs and abdomen. She presents with a slight kyphosis and a protruding abdomen. Which of the following methods of management might be appropriate for her?
   a. Increase dose of corticosteroids
   b. Unilateral or bilateral adrenalectomy
   c. Increase dose of Spironolactone
   d. Diet that is high in carbohydrates and low in protein

Problems Related to Reproductive Function

A 40-year-old mother of three children has been diagnosed with squamous cell carcinoma of the cervix following an abnormal Pap smear and colposcopy. She is being seen in the gynecologist office for follow-up treatment. She is very worried about her prognosis.

- Discuss risk factors associated with this type of cancer.
- What clinical manifestations may this patient have had prior to this diagnosis?
- What is the purpose of a colposcopy?
- Discuss medical management of cervical cancer.

CHAPTER 32

Nursing Assessment: Female and Male Reproductive Function

Jennifer L. Mosher • Susanne A. Quallich

Learning Objectives

After reading this chapter, you will be able to:

1. Describe female reproductive function.
2. Discuss components of female reproductive assessment.
3. Identify the diagnostic examinations and tests used to determine alteration in female reproductive function and breast disorders.
4. Describe structures and function of the male reproductive system.
5. Discuss nursing assessment of the male reproductive system and identify diagnostic tests that complement assessment.

FEMALE REPRODUCTIVE SYSTEM

Statistically women utilize the health care system more often than do men (Blackwell, Lucas, & Clarke, 2014), often seeking health care during the changes involving the reproductive system from the onset of menarche to menopause. An understanding of the normal anatomy and physiology of the female reproductive system is a necessary and important function of the nurse. It is integral to recognizing the complex issues that can occur within the female reproductive system.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

Anatomy of the Female Reproductive System

The female reproductive system consists of the external and internal genital structures as well as the mammary glands located in the female breast. Hormonal influences on the female reproductive system are driven by the hypothalamus and pituitary gland. These influences cause the cyclical changes throughout the reproductive life of women, and the cessation of the changes results in menopause.

External Genitalia

The external genital structures, referred to as the vulva, consist of the mons pubis; labia majora; labia minora; clitoris; and the vestibule of the vagina, which contains the hymen, the urethral and vaginal orifice, and the paraurethral (Skene) and Bartholin glands (Fig. 32-1). The mons pubis is the fatty tissue at the junction of the thighs and torso, while the labia majora are two thick folds of tissue that form the outer border of the vulva. Both are covered by pubic hair after puberty. The upper portions of the labia minora unite anteriorly to form a partial covering for the clitoris, a highly sensitive organ composed of erectile tissue. The labia minora are thinner folds of tissue internal to the majora that cover the urethral meatus and vaginal introitus. The urethral meatus lies below and posterior to the clitoris, and the vaginal introitus lies just posterior to the urethral meatus. The mucus-secreting structures that are set in the wall of the urethra are termed *Skene glands*. The Bartholin glands, bean-sized structures that also secrete mucus, lie on each side of the vaginal orifice. The area between the vagina and rectum is called the perineum.

Internal Reproductive Structures

The internal structures of the female reproductive system are the vagina, uterus, ovaries, and fallopian tubes (Fig. 32-2).

The vagina is a canal that is lined with a mucous membrane and that extends from the vulva to the cervix. The upper part of the vagina, the fornix, surrounds the cervix (the inferior part of the uterus).

The uterus is a pear-shaped, muscular organ, which can vary in size depending on parity (number of viable births) and uterine abnormalities (e.g., fibroids). The uterus lies posterior to the bladder and is held in position by several ligaments. The uterus consists of the cervix, which projects into the vagina, and the fundus or body. The triangular inner portion of the fundus narrows to a small canal in the cervix that has constrictions at each end, referred to as the *external os* and *internal os.* The upper lateral parts of the uterus are called the *cornua.* From here, the oviducts, or fallopian tubes, extend outward to meet the ovaries.

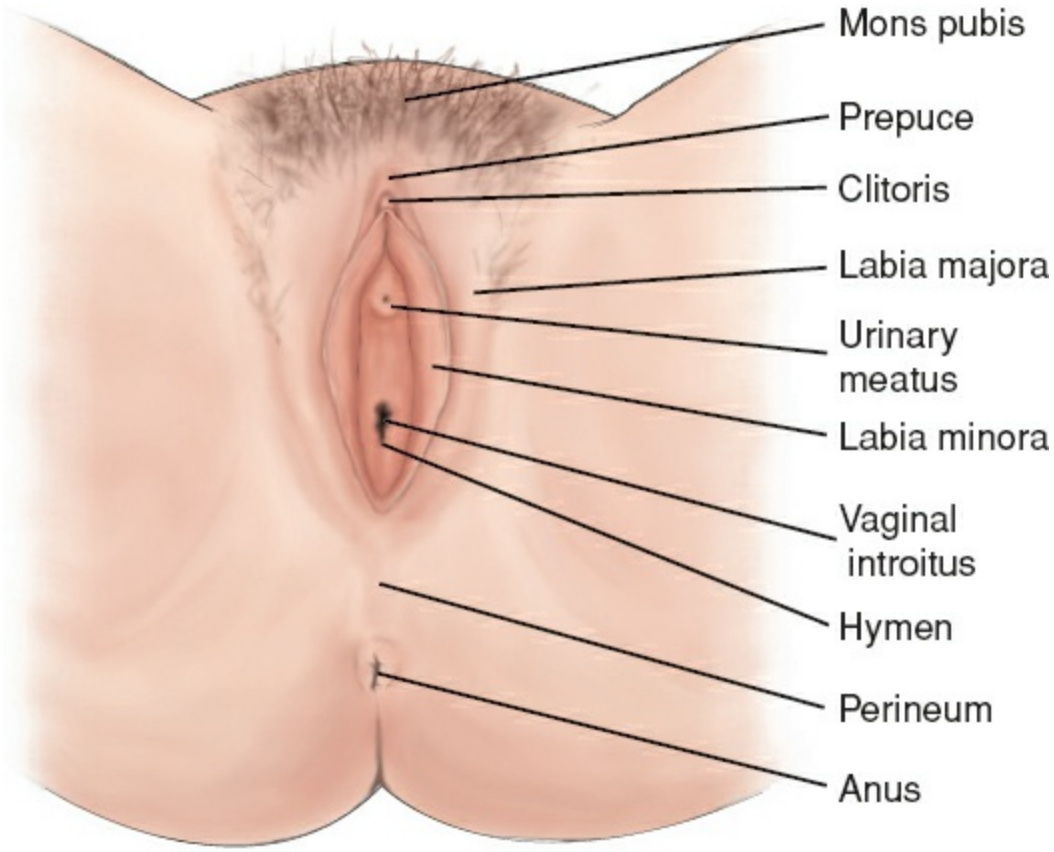

FIGURE 32-1 External female genitalia.

The ovaries lie behind and below the fallopian tubes. They are oval bodies about 3 cm long. When a girl is born, her ovaries contain thousands of tiny egg cells or *ova*. The ovaries and the fallopian tubes together are referred to as the adnexa.

Breasts

The breasts lie over the pectoralis muscle from the sternum to the midaxillary line. An area of breast tissue, called the *tail of Spence*, extends into the axilla. Cooper's ligaments support the breast on the chest wall. During puberty, estrogen and other hormones in the female body stimulate breast development. This development usually occurs from 10 to 16 years of age, although the range can vary from 9 to 18 years of age.

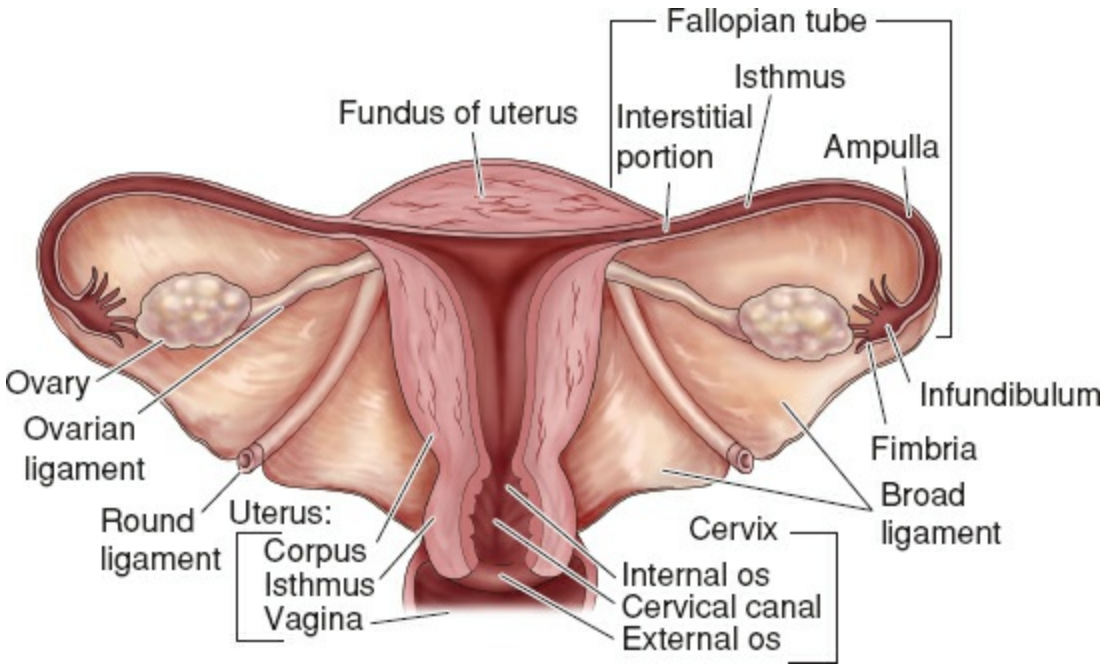

FIGURE 32-2 Internal female reproductive structures.

Each fully developed breast (Fig. 32-3) is made up of glandular lobules and ducts bound and separated by fibrous tissue and fat. Approximately 15 to 20 lobules are grouped together to form cone-shaped lobes. Fibrous tissue surrounds the lobes and ducts. Fatty tissue fills the spaces between lobes and ducts and gives the breast a soft texture. During lactation, milk is produced in the lobules and is carried through the ducts to the nipple.

Function of the Female Reproductive System

The main function of the female reproductive system is to prepare the woman's body each month to be ready to accept a fertilized egg and to provide a nourishing environment for growth of a fetus. The monthly changes in the woman of reproductive age—the menstrual cycle—is a complex process involving the reproductive and endocrine systems. In the United States, the average age at menarche (the start of menstruation in females) is 12.8 years of age, with an age range between 8 and 18 years of age. Genetics is the most important factor in determining the age at which menarche starts, but geographic location, nutrition, weight, general health, cultural and social practices, the girl's educational level, attitude, family environment, and beliefs are also important. The cycle length can vary from 21 to 35 days, but the average length is 28 days (Ricci, 2013).

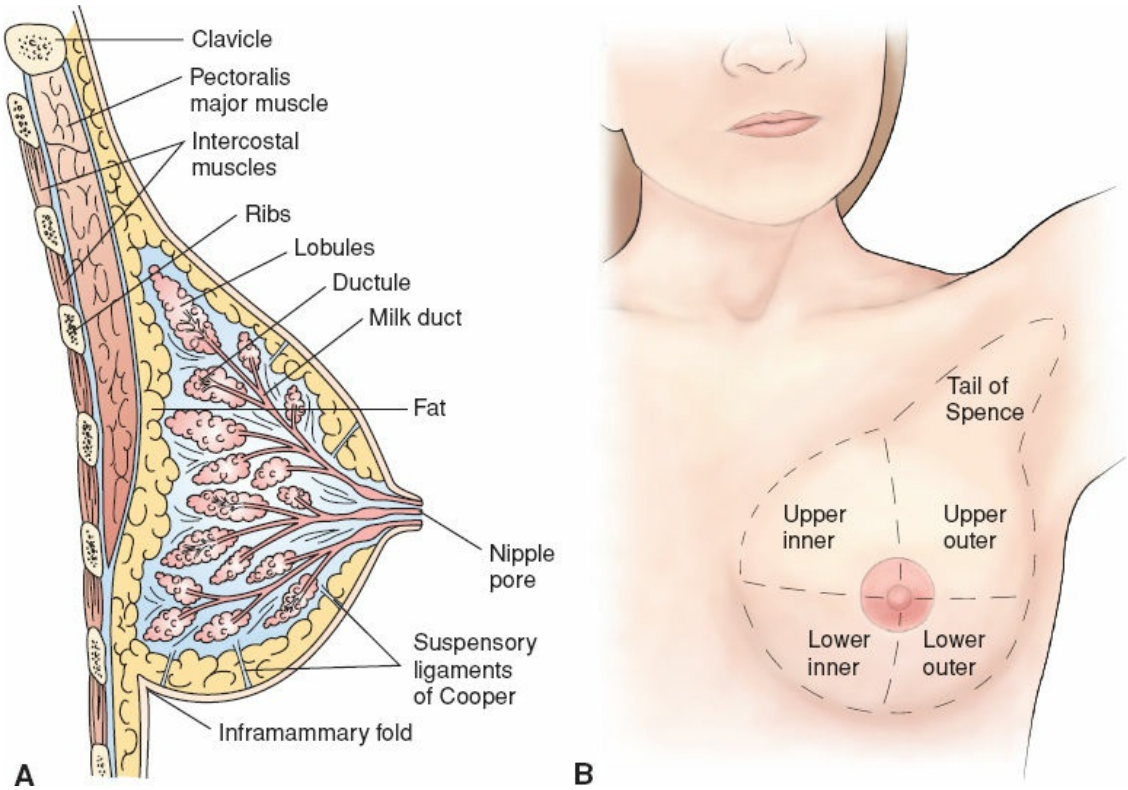

FIGURE 32-3 A. Anatomy of the breast. B. Areas of breast, including the tail of Spence.

The woman's reproductive cycle consists of a complex series of interactions among the hypothalamic–pituitary system, the ovarian system, the endometrial system, and the various hormones secreted by each of those systems.

The Menstrual Cycle

Estrogen and progesterone are two hormones integral to proper functioning of the female reproductive system. The ovaries produce several types of estrogen as well as progesterone. Estrogen is responsible for development and maintenance of the female reproductive organs, secondary sex characteristics of the adult female, breast development, and the monthly uterine changes associated with menstruation. Progesterone plays a role in

regulating uterine changes during the menstrual cycle, preparing the endometrium (via the corpus luteum) for implantation of a fertilized ovum, and maintaining (via the placenta) a normal pregnancy. Together, progesterone and estrogen help prepare the breasts for lactation. Androgens are hormones that are produced by the ovaries and the adrenals in small amounts; they influence early follicular development (Nathan, 2013) as well as the female libido (Pluchino et al., 2013).

The female pituitary gland releases the gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH is responsible primarily for stimulating the ovaries to secrete estrogen and triggering follicles in the ovary to mature into eggs, while LH is responsible primarily for stimulating progesterone production as well as encouraging the release of mature eggs through the midcycle surge of LH. Feedback mechanisms help to regulate secretion of FSH and LH. Elevated estrogen levels in the blood inhibit FSH secretion but promote LH secretion. Release of FSH and LH also is influenced by gonadotropin-releasing hormone (GnRH), which is secreted from the hypothalamus.

This complex feedback system results in the cyclic changes in the uterine endometrium and ovaries as well as the process of menstruation (Table 32-1).

In the beginning of the menstrual cycle, low estrogen levels signal the hypothalamus to release FSH and begin follicular maturation. Maturing follicles release estrogen, which stimulates the release of LH. This surge of LH encourages ovulation, which is the release of the mature egg from the ovary. Ovulation generally occurs mid-way (14 days) through a typical 28-day menstrual cycle. The egg is released into the fallopian tubes, where it awaits fertilization. If fertilization does not occur, hormone levels decrease and the menstrual phase of the cycle begins.

Nursing Alert
Some women can feel a pain on one side of the abdomen around the time the egg is released. This midcycle pain is called mittelschmerz (Ricci, 2013).

Menstruation is the cyclic shedding of the uterine lining that occurs when pregnancy has not been established. This menstrual flow is discharged through the cervix and into the vagina, and it usually lasts an average of 3 to 7 days. The amount of menstrual flow varies but averages 1 oz or a range of approximately 2/3 to 2-2/3 oz in volume per cycle. The beginning of the menstrual flow marks the end of one menstrual cycle and the start of a new one (Ricci, 2013).

Nursing Alert
Regardless of cycle length, ovulation typically occurs 14 days prior to menses (Costanzo, 2014).

Perimenopause

Perimenopause is a transitional time late in a woman's reproductive life before the final menstrual period. Menopause is defined retrospectively by 12 months of amenorrhea and loss of ovarian follicular activity. The mean duration of perimenopause is 5 years, but symptoms may begin 8 years or more before the final menstrual period. The average age at onset of menstrual irregularity is 47.5 years of age. Hallmark symptoms include irregular

menstrual bleeding in addition to hot flashes and night sweats, which are referred to as *vasomotor symptoms*. Women who are perimenopausal also may experience mood changes, sleep disturbances, and sexual dysfunction. Although women who are perimenopausal have declining estrogen levels, they may continue to have unpredictable ovulatory cycles, increasing their risk for unintended pregnancy. Forty-eight percent of all pregnancies in women in their 40s are unplanned, making this the second most common age cohort for unplanned pregnancies. Perimenopause marks a transition between the reproductive years and menopause. Women who are perimenopausal often benefit from information about the subtle physiologic changes they are experiencing. Perimenopause has been described as an opportune time for teaching women about strategies for health promotion and disease prevention. Awareness of the hormonal changes associated with perimenopause helps with the recognition and management of symptoms, including menstrual cycle irregularity, VMS, mood and sleep disorders, and sexual dysfunction. For many patients, hormonal contraception (with appropriate counseling) treats these symptoms and prevents the real risk for pregnancy (McNamara, Batur, & DeSapri, 2015).

TABLE 32-1 Hormonal Influences and Menstrual Cycle

(Times approximate) Phase	Menstrual	Follicular	Ovulation	Luteal	Premenstrual
Days	1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 1 2				
	Ovary				
	Degenerating corpus luteum; beginning follicular development	Growth and maturation of follicle	Ovulation	Active corpus luteum	Degenerating corpus luteum

	None	Low	Low	Increasing	Decreasing
	FSH Production				
	Increasing	High, then decreasing	Low	Low	Increasing
	LH Production				
	Low	Low, then increasing	High	High	Decreasing
	Endometrium				
	Degeneration and shedding of superficial layer. Coiled arteries dilate and then constrict again.	Reorganization and proliferation of superficial layer	Continued growth	Active secretion and glandular dilation; highly vascular; edematous	Vasoconstriction of coiled arteries; beginning degeneration

Menopause

Menopause marks the end of a woman's reproductive capacity and generally occurs between 45 and 52 years of age. With menopause, the ovaries are no longer active and the reproductive organs become smaller. Menopause is not a pathologic phenomenon but a normal part of aging and maturation. In addition to the effects of reduced estrogen on the reproductive system, neuroendocrinologic, biochemical, and metabolic changes related to

aging occur throughout the woman's body (Table 32-2). Early menopause may occur if the ovaries are surgically removed, are destroyed by radiation or chemotherapy, or because of an unknown etiology. Menopause offers a unique opportunity for dialogue between women and their health care providers to evaluate and improve health-related practices. By considering a woman's concerns, values, and preferences, nurses have the potential to enhance a woman's sense of well-being, not only at menopause but for the rest of their lives (Shifren & Gass, 2014). Box 32-1 discusses nursing care of patients experiencing menopause.

ASSESSMENT

Nurses obtaining health history information and performing physical assessments are in ideal positions to discuss women's general health issues, health promotion, and health-related concerns. Relevant topics include fitness, nutrition, cardiovascular risks, health screening, sexuality, menopause, abuse, health risk behaviors, and immunizations. Recommendations for health screening are summarized in Table 32-3. Many problems can be corrected if treated early, while allowing them to go untreated may result in serious health problems.

Although sexuality and sexual function are discussed more often with gynecologic or women's health care providers, any nurse caring for women should consider these issues part of a routine health assessment.

Health History

In addition to obtaining a general health history, information related to past illnesses and experiences specific to women's health are necessary. In addition to basic information related to medical and surgical history, data should be collected about the following:

TABLE 32-2 GERONTOLOGIC CONSIDERATIONS /Age-Related Changes in the Female Reproductive System

Structural Change	Functional Change	History and Physical Findings
Cessation of ovarian function and decreased estrogen production; thinning of urinary and genital tracts; thinning of pubic hair and shrinking of labia	Decreased ovulation Onset of menopause Vasomotor instability and hormonal fluctuations Decreased bone formation Decreased vaginal lubrication Increased vaginal pH	Decreased/loss of ability to conceive; increased infertility Irregular menses with eventual cessation of menses Hot flashes or flushing; night sweats, sleep disturbances; mood swings; fatigue Bone loss and increased risk for osteoporosis and osteoporotic fractures; loss of height Dyspareunia, resulting in lack of interest in sex Increased risk for urinary tract infection Increased incidence of inflammation (atrophic vaginitis) with discharge, itching, and vulvar burning
Relaxation of pelvic musculature	Prolapse of uterus, cystocele, rectocele	Dyspareunia, incontinence, feelings of perineal pressure

BOX 32-1 Management During Menopause

Clinical Manifestations and Assessment

Long before menopause occurs, hormonal changes contribute to common symptoms of menopause, including irregular menses, breast tenderness, mood changes, hot flashes, and night sweats. Thought to be due to hormonal changes, hot flashes denote vasomotor instability and vary in intensity from a barely perceptible warm feeling to a sensation of extreme warmth accompanied by profuse sweating, causing discomfort, sleep disturbances, and subsequent fatigue. Also osteoporosis can be a manifestation of menopause.

Reduced estrogen levels affect the entire genitourinary system. Changes in the vulvovaginal area include gradual thinning of pubic hair and a shrinking of the labia. Vaginal secretions decrease, and women may report dyspareunia (discomfort during intercourse). The vaginal pH increases during menopause, predisposing women to bacterial infections and atrophic vaginitis. Some women report fatigue, forgetfulness, weight gain, irritability, feeling "blue," and feelings of panic. Menopausal complaints need to be evaluated carefully because they also may indicate other disorders.

Women's reactions and feelings related to loss of reproductive capacity may vary.

Some women may experience role confusion, whereas others experience a sense of sexual and personal freedom. Each woman's experience must be considered on an individual basis, and nurses need to be sensitive to all possibilities.

Medical Management

Women approaching menopause often have many concerns about their health. Some have concerns based on a family history of heart disease, osteoporosis, or cancer. Each woman needs to be as knowledgeable as possible about her options and should be encouraged to discuss her concerns with her primary health care provider in order to make an informed decision about managing menopausal symptoms and maintaining her health. Postmenopausal bleeding, or bleeding 1 year after menses cease at menopause, must be investigated as a malignant condition must be considered until proved otherwise.

Seventy-five percent of women who are menopausal experience vasomotor symptoms, such as hot flashes and night sweats. Eighty percent of these women will endure these symptoms for longer than 1 year and 50% for longer than 5 years. Hormone therapy (HT) is first-line treatment. Current recommendations are that HT use should be limited to the lowest effective dose for the shortest treatment duration and that ongoing use should be re-evaluated periodically (Washington & Zacur, 2015).

HT has risks as well as benefits. Extended follow-up data from the Women's Health Initiative (WHI) trials do not support the use of HT for chronic disease prevention (Boardman, 2014). The U.S. Preventive Services Task Force (USPSTF) has found convincing evidence to support combined estrogen/progestin therapy in the reduction of risk for fractures in women who are postmenopausal. However, evidence also indicates an association with moderate harms, including an increase in instances of stroke, dementia, gallbladder disease, deep venous thrombosis (DVT), pulmonary embolism, and a small increase in breast cancer deaths. Combined therapy does not have a beneficial effect on coronary heart disease (CHD) and probably increases the risk of its occurrence. The USPSTF has concluded with high certainty that the chronic disease prevention benefits of combined estrogen and progestin do not outweigh the harms in most women who are postmenopausal (Moyer, 2013).

There are several different treatment methods for those women who do elect to take HT. Both estrogen and progestin pills are prescribed for women who still have a uterus. Progestin prevents proliferation of the uterine lining and hyperplasia, which are factors that increase the risk for uterine cancer. Women without a uterus can take estrogen without progestin (unopposed estrogen).

Patches are another option. Estrogen patches are replaced once or twice weekly but will require a progestin pill along with them if the woman still has a uterus. Another type of patch provides both estrogen and progestin treatment. Vaginal symptoms can be treated with an estrogen cream or suppository, or an estradiol vaginal ring may be used for vaginal dryness or atrophic vaginitis. The selective estrogen receptor modulator, ospemifene, is another option for women with moderate to severe dyspareunia (painful

intercourse).

HT is contraindicated in women with a history of breast cancer, vascular thrombosis, impaired liver function, some cases of uterine cancer, and undiagnosed abnormal vaginal bleeding. Because HT increases the risk for thromboembolic phenomena, women who elect to take HT must be taught the signs and symptoms of DVT and pulmonary embolism (i.e., unilateral leg redness, tenderness, and edema; chest pain, and sudden onset shortness of breath) and told to report these signs and symptoms immediately.

Alternatives to HT for vasomotor symptoms are for women who cannot tolerate or who have contraindications to estrogen use. Selective serotonin and norepinephrine reuptake inhibitors (SSRIs, SNRIs) may reduce hot flashes by up to 61%. Behavioral modifications also have been recommended in the reduction of hot flashes. These include the use of a fan or drinking cool beverages; relaxation techniques, such as slow breathing and yoga; and exercise. Alternate treatment options for vaginal symptoms include moisturizers and lubricants to relieve symptoms of vaginal dryness and dyspareunia (Washington & Zacur, 2015).

Although the results of the WHI study may make the decision about use of HT easy for some women, it remains a difficult decision for those who could benefit from it because of the disruptive symptoms of menopause and evidence of bone loss. HT may be useful for women for short periods of time when no other therapy has been able to reduce their vasomotor symptoms. Women often seek information about alternative therapies to the use of HT, but often these therapies are not regulated or research-proven methods and must be used with caution. Assessment of patients who are menopausal should address their use of complementary and alternative therapies and supplements.

The decisions women make related to the use of HT must be individualized and based on each woman's current health, risk factors, family history, and severity of symptoms.

Nursing Management

Nurses can encourage women to view menopause as a natural change resulting in freedom from symptoms related to menses and pregnancy. Measures should be taken to promote general health. The nurse can explain to the patient that cessation of menses is normal and rarely is accompanied by illness. Many symptoms can even be controlled with lifestyle factors. The current expected lifespan after menopause for the average woman is 30 to 35 years, and women retain their usual response to sex long after menopause. The individual woman's evaluation of herself and her worth, now and in the future, is likely to affect her emotional reaction to menopause. Patient teaching and counseling regarding healthy lifestyles, health promotion, and health screening are of paramount importance.

- Menstrual history (including menarche, length of cycles, length and amount of flow, presence of cramps or pain, bleeding between periods or after intercourse, bleeding after menopause), pain with menses, pain with intercourse, pelvic pain
- Sexual history, including past and present contraceptive use
- Pregnancy history (number of pregnancies, outcomes of pregnancies)
- Exposure to medications (diethylstilbestrol [DES], immunosuppressive agents, others) and present medication use (vitamins, prescriptions, herbs)
- History of vaginal discharge and odor or itching
- History of problems with urinary function, including frequency, urgency, and incontinence
- History of bowel problems
- History of sexually transmitted diseases (STDs) and methods of treatment
- History of fertility treatments or hormone therapy
- History of breast health, including family history of breast disease
- History of sexual or physical abuse
- History of surgery or other procedures on structures within the reproductive tract (including female genital mutilation [FGM] or female circumcision)
- History of chronic illness or disability that may affect health status, reproductive health, need for health screening, or access to health care
- Psychosocial information (availability of resources and support)

Sexual History

Incorporation of the sexual history into the general health history can provide the opportunity to clarify myths and explore areas of concern that the patient may not have felt comfortable discussing in the past. The nurse can begin by explaining the purpose of obtaining a sexual history. History-taking includes gathering data about present and past sexual activity, sexual orientation, and possible sexual dysfunction. Sexual problems may be related to medication, life changes, disability, or the onset of physical or emotional illness. By initiating an assessment about sexual concerns, the nurse can provide a safe environment for discussing sensitive topics as well as validation that these topics are appropriate for discussion.

TABLE 32-3 Summary of Health Screening and Counseling Issues for Women[a]

Component	Screening and Counseling		
	Ages 19–39	Ages 40–64	Ages 65+
Sexuality and reproductive issues	Annual pelvic examination Annual clinical breast examination Contraceptive options High-risk sexual behaviors	Annual pelvic examination Annual clinical breast examination Contraceptive options High-risk sexual behaviors Menopausal concerns	Annual pelvic examination Annual clinical breast examination High-risk sexual behaviors
Health and risk behaviors	Hygiene Injury prevention Nutrition Exercise patterns Risk for domestic abuse Use of tobacco, drugs, and alcohol Life stresses Immunizations	Hygiene Bone loss and injury prevention Nutrition Exercise patterns Risk for domestic abuse Use of tobacco, drugs, and alcohol Life stresses Immunizations	Hygiene Injury prevention Nutrition Exercise patterns Risk for domestic abuse Use of tobacco, drugs, and alcohol Life stresses Immunizations
Diagnostic testing	Pap smear[b] Screening for sexually transmitted diseases (STD) as indicated	Pap smear Mammography[c] Cholesterol and lipid profile Colorectal cancer screening Bone mineral density testing Thyroid-stimulating hormone testing Hearing and eye examinations	Pap smear Mammography Cholesterol and lipid profile Colorectal cancer screening Bone mineral density testing Thyroid-stimulating hormone testing Hearing and eye examinations

[a]Each individual's risks (family history, personal history) influence the need for specific assessments and their frequency.
[b]Recommendations state that cytology screening (Pap smear) should not start before 21 years of age and should be done every 3 years until 30 years of age, when they can continue with cytology only every 3 years or cytology with HPV testing every 5 years.
[c]Recent recommendations include regular screening with mammography at age 50 and then every 2 years through 74 years of age.
http://www.ahrq.gov/professionals/clinicians-providers/guidelines-recommendations/guide/cpsguide.pdf

Sexually Transmitted Infections

Individual risk for sexually transmitted infections (STIs) can be assessed by determining the number of partners a patient has had in the past year or in her lifetime as well as whether or not she is taking proper protective precautions with her partner(s). Women must understand that certain STIs (e.g., chlamydia and gonorrhea), especially if left untreated, can result in pelvic inflammatory disease, ectopic pregnancy, and infertility (Workowski & Bolan, 2015). (For further details, refer to Chapter 35.)

Female Genital Mutilation

Female genital mutilation (FGM) includes procedures that intentionally alter or cause injury to the female genital organs for nonmedical reasons, including partial or total removal of the external female genitalia. FGM is carried out mostly on young girls sometime between infancy and age 15. There are more than 125 million girls and women alive today who have experienced FGM in the 29 countries in Africa and the Middle East where FGM is concentrated. FGM is carried out mostly by traditional circumcisers, who often play other central roles in communities, such as attending childbirths; however, more than 18% of all FGM is performed by health care providers, and the trend toward medicalization is increasing. The causes of FGM include a mix of cultural, religious, and social factors within families and communities. FGM is a rite of passage to womanhood and is a culturally acceptable practice as it is believed to promote hygiene, protect virginity and family honor, prevent promiscuity, improve female attractiveness and male sexual pleasure, and enhance fertility (World Health Organization [WHO], 2014). There are four

types of FGM (Table 32-4).

From a medical perspective, FGM has no health benefits, and it harms girls and women in many ways. Immediate complications can include severe pain, shock, hemorrhage, tetanus or sepsis, urinary retention, open sores in the genital region, and injury to nearby genital tissue. Long-term consequences can include recurrent infections in the bladder and urinary tract, cysts, infertility, an increased risk of childbirth complications and newborn deaths as well as the need for later surgeries. Women who have undergone FGM may not think of themselves as mutilated. Nurses who care for these women must be sensitive, knowledgeable, culturally competent, and nonjudgmental. Respect for others' health beliefs, practices, and behaviors as well as recognition of the complexity of issues involved is crucial (WHO, 2014).

TABLE 32-4 Types of Female Genital Mutilation (FGM)

Type	Description
Type 1 FGM (Clitoridectomy)	Partial or total removal of the clitoris (a small, sensitive, and erectile part of the female genitals) and, rarely, the prepuce (the fold of skin surrounding the clitoris) as well
Type II FGM (Excision)	Clitoridectomy with partial or total excision of the labia minora, with or without excision of the labia majora
Type III FGM (Infibulation)	Narrowing of the vaginal opening through the creation of a covering seal, formed by cutting and repositioning the inner or outer labia, with or without the removal of the clitoris. Type III is more likely than other types of FGM to result in infertility.
Type IV FGM (Other)	All other harmful procedures to the female genitalia for nonmedical purposes, e.g., pricking, piercing, incising, scraping, and cauterizing the genital area.

Domestic Violence

Domestic violence is a broad term that includes child abuse, elder abuse, and abuse of women and men. Abuse can be emotional, physical, sexual, or economic, and it involves fear of one partner by another and control by threats, intimidation, and physical abuse. Nearly 31% of women report having been the victim of some form of violence from an intimate partner in their lifetime. This estimate is likely underrepresentative of actual rates due to underreporting. Although all women are at potential risk for abuse, factors that elevate risk include young age, substance abuse, marital difficulties, and economic hardships (Moyer, 2013). Violence is rarely a one-time occurrence in a relationship; it usually continues and escalates in severity.

All women should be screened for domestic violence. For women who are not pregnant, screening should occur at routine visits. For women who are pregnant, screening should occur over the course of the pregnancy, including at the first prenatal visit, at least once per trimester, and at the postpartum checkup. Abuse should be considered a factor in the presentation of medical complaints because experiences with abuse may adversely affect health status or the ability to comply with medical recommendations (Moyer, 2013). See Box 32-2.

Incest and Childhood Sexual Abuse

Sexual assault is one of the most underreported crimes (Rape, Abuse, & Incest National Network [RAINN], 2015). Strangers do molest children. But in at least 80% of cases, the perpetrators of sexual abuse are known to the child and often are authority figures that the child trusts (American Academy of Pediatrics, 2015). Victims of sexual assault are more likely to suffer from depression or posttraumatic stress disorder, abuse alcohol or drugs, and contemplate suicide (RAINN, 2015). The nurse should plan to offer support and appropriate referrals to psychologists, community resources, and self-help groups.

Rape and Sexual Assault

In 2013, there were an average of 293,066 victims of rape and sexual assault. That means every 107 seconds, another American was sexually assaulted (RAINN, 2015a,b). Screening for abuse, rape, and violence should be part of routine assessment because women often do not report or seek treatment for assault. Often, the assailant is a partner, husband, or date. Nurses may encounter women with infections or pregnancies related to sexual assault who require support, understanding, and comprehensive care. Women who have experienced rape or sexual abuse may be very anxious about pelvic examinations, labor, pelvic or breast irradiation, or any treatment or examination that involves hands-on treatment or requires removal of clothing.

Physical Assessment

The nurse can use the physical assessment time to educate patients on their reproductive health, including normal physiologic processes, like menstruation and menopause, and to assess possible abnormalities. This section focuses on physical assessment, including gynecologic and breast examinations. Annual breast and pelvic examinations are important for all women 18 years of age or older and for those who are sexually active, regardless of age. Most women have a gynecologic examination as part of their annual physical. The gynecologic portion is often the last portion of the physical examination as care providers tend to move from less sensitive areas to more sensitive ones. This also gives the patient a chance to become comfortable with the examination and her provider.

Pelvic Examination

The pelvic portion of the assessment consists of external and internal inspection and palpation or structures and organs. Gynecologic examinations may be uncomfortable or even distressing for some women. It is important, then, that the nurse employs assessment techniques that help patients feel more comfortable and less vulnerable. Patient education is essential as appropriate and accurate information can help to minimize the fear and negative feelings that some women associate with gynecologic examinations (Box 32-3).

BOX 32-2 GUIDELINES FOR NURSING CARE

Managing Domestic Violence

Equipment

- Appropriate documentation forms
- Camera
- Appropriate patient teaching materials

Procedure

ACTIONS	RATIONALE
1. Reassure the woman that she is not alone.	1. Women often believe that they are alone in experiencing abuse at the hands of their partners.
2. Express your belief that no one should be hurt, that abuse is the fault of the abuser, and that it is against the law.	2. Sharing these beliefs lets the woman know that no one deserves to be abused and that she has not caused the abuse.
3. Assure the woman that her information is confidential, although it does become part of her medical record. *If children are suspected of being abused or are being abused, the law requires that this be reported to the authorities.* Some states require reporting of spousal or partner abuse. Domestic violence agencies and medical and nursing groups disagree with this policy and are trying to have it changed. Serious opposition is based on the fact that reporting does not and cannot currently guarantee a woman's safety and may place her in more danger. It also may interfere with a patient's willingness to discuss her personal life and concerns with care providers. This places a serious barrier in the way of comprehensive nursing care. If nurses are in doubt about laws on reporting abuse, they need to check with their local or state domestic violence agency.	3. Often women are afraid that their information will be reported to the police or protective services and their children may be taken away.
4. Document the woman's statement of abuse, and take photographs of any visible injuries if written formal consent has been obtained. (Emergency departments usually have a camera available if one is not on the nursing unit.)	4. The written statement and photographic proof provide documentation of injuries that may be needed for later legal or criminal proceedings.
5. Provide teaching: • Inform the woman that shelters are available to ensure safety for her and her children. (Lengths of stay in shelters vary by state but often are up to 2 months. Staff often assist with housing, jobs, and the emotional distress that accompanies the break-up of the family.) Provide a list of shelters. • Inform the woman that violence gets worse, not better. • If the woman chooses to go to a shelter, let her make the call. • If the woman chooses to return to the abuser, remain nonjudgmental and provide information that will make her safer than she was before disclosing her situation. • Make sure that the woman has a 24-hour hotline telephone number that provides information and support (Spanish translation and a device for the deaf are also available) as well as contact information for her local police (and a reminder about the availability of 911 service). • Assist her to set up a safety plan in case she decides to return home. (A safety plan is an organized plan for departure with packed bags and important papers hidden in a safe spot.)	5. These options may be life-saving for the woman and her children.

BOX 32-3 Patient Education

Pelvic Examination

A pelvic examination includes assessment of the appearance of the vulva, vagina, and cervix and the size and shape of the uterus and ovaries to ensure reproductive health and absence of illness. The nurse should share the following information with the patient in order to help make the examination proceed more smoothly:

- You may have a feeling of fullness or pressure during the examination, but you should not feel pain. It is important to relax because if you are very tense, you may feel discomfort.
- It is normal to feel uncomfortable and apprehensive.
- A narrow, warmed speculum will be inserted to visualize the cervix.

- A Papanicolaou (Pap) smear will be obtained and should not be uncomfortable.
- You may watch the examination with a mirror if you choose.
- The examination usually takes no longer than 5 minutes.
- Draping will be used to minimize exposure and reduce embarrassment.

Before the examination begins, the patient should be asked to empty her bladder. This can aid the examination as a full bladder can make palpation of pelvic organs difficult for the examiner, which may increase discomfort to the patient.

Positioning

Although several positions may be used for the pelvic examination, the supine lithotomy position is used most commonly. In this position, the patient lies on the table with her feet in stirrups, buttocks at the edge of the table, and thighs spread as widely apart as possible. Supine lithotomy offers several advantages as it is more comfortable for most women and allows better eye contact between patient and examiner. It may also facilitate the bimanual examination as well. However, it may be uncomfortable for some women, and some patients may need to be reminded to keep their legs in the proper position. Sims' position (patient on left side with her right leg bent at a 90-degree angle) may be used with a patient who is unable to maintain the supine lithotomy position due to acute illness or disability. The presence of a disability does not justify skipping any parts of the physical assessment, including the pelvic examination.

Inspection

After the patient is positioned, the examiner inspects the external genitalia. Lesions of any type are evaluated. In the nulliparous woman, the labia minora come together at the opening of the vagina. In a woman who has delivered children vaginally, the labia minora may gape and vaginal tissue may protrude. Structural changes from childbirth include cystocele (bulging of bladder into the vagina), rectocele (bulging of rectum into the vagina), or uterine prolapse (uterus falling out of normal position). The examiner may ask the patient to bear down in order to visualize these changes.

Palpation

Using the fingers of a gloved hand, the examiner gently separates the labia and palpates the lower part of the vagina. In many women who have not had vaginal intercourse, the hymen can be palpated within the vaginal opening. In the sexually active woman, remnants of the hymen may be palpated as a rim of scar tissue. The greater vestibular glands (Bartholin glands) lie between the labia minora and the hymenal ring and should be free of abscess and drainage.

Speculum Examination

The speculum is an instrument used to open the vaginal walls for internal inspection of the vagina and cervix as well as for performance of the Papanicolaou (Pap) smear. Warming the speculum prior to insertion can be more comfortable for the patient. Lubrication of the

outer superior and inferior blade of the plastic vaginal speculum with a small amount of a water-soluble lubricant gel decreases the pain associated with insertion and opening of the vaginal speculum in both premenopausal and postmenopausal women without affecting the quality of the cytology results during the collection of Pap test specimens (Simavli, Kaygusuz, Kinay, & Cukur, 2014). When the speculum is positioned properly, it is opened slowly to visualize the cervix and then tightened to hold it in place for inspection of the cervix (Fig. 32-4). The examiner inspects the cervical surface for any lesions or anomalies. The cervix typically is 2 to 3 cm wide and pink in color with a smooth appearance. Discharge from the cervical os may be cultured to rule out infection or disease.

While withdrawing the speculum, the practitioner inspects the vagina. Vaginal discharge, which may be normal or may result from vaginitis, may be present (Table 32-5). Purulent material appearing at the cervical os is obtained for culture with a sterile applicator. In patients at high risk for infection, routine cultures for gonococcal and chlamydial organisms are recommended.

While the speculum is in place, a Papanicolaou (Pap) smear is obtained (this test is discussed in detail under diagnostic evaluation).

Bimanual Palpation

After the internal inspection, a bimanual examination of the pelvic organs may be conducted. The practitioner inserts two lubricated fingers from one hand into the vagina of the patient while the other hand compresses from the outside to assess the reproductive organs. The practitioner assesses size and position of the uterus and ovarian structures while looking for any tenderness upon movement of the organs. Some mild discomfort is not unusual when palpating the ovaries. Many practitioners also perform a rectal examination at this time.

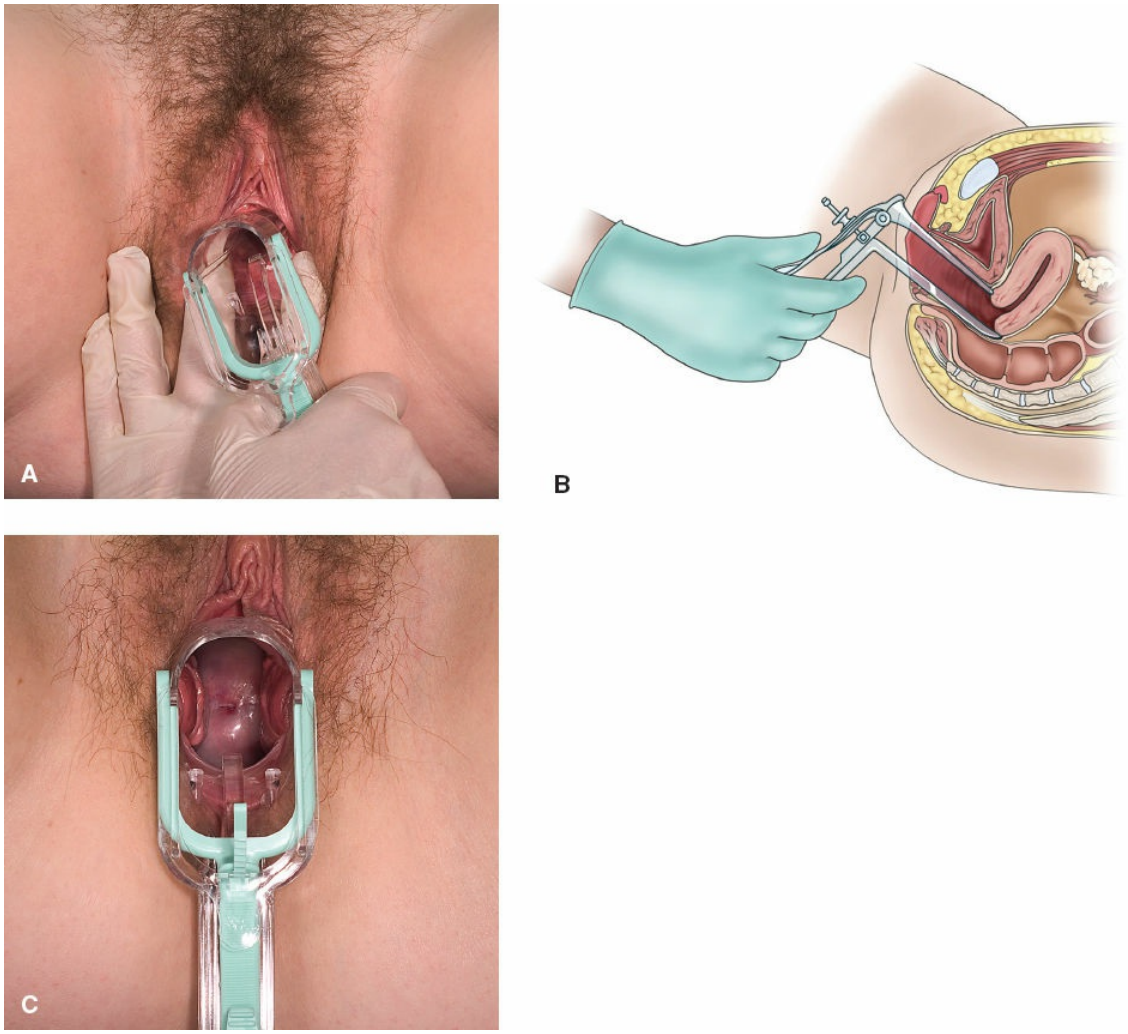

FIGURE 32-4 Technique for speculum examination of the vagina and cervix. (A) The labia are spread apart with a gloved left hand while the speculum is grasped in the right hand and turned counterclockwise before being inserted into the vagina. Once the speculum is inserted, the blades are spread apart (B) to reveal the cervical os (C).

Breast Examination

The American Cancer Society (ACS) recommends that women at average risk for breast cancer undergo a clinical breast examination at least every 3 years while in their 20s and 30s and then annually thereafter (see Chapter 33). In the normal progression of a general physical examination, the breasts would be examined before the genitals as the provider moves from "head to toe." Before the examination, the patient should be asked if she has any known, palpable masses and if there is any associated pain, swelling, redness, nipple discharge, or skin changes.

TABLE 32-5 Vaginal Discharge Characteristics

Cause of Discharge	Symptoms	Odor	Consistency/Color
Physiologic	None	None	Mucus/white
Candida infection	Itching, irritation	Yeast odor or none	Thin to thick, curd-like/white
Bacterial vaginosis	Odor	Fishy, often noticed after intercourse	Thin/grayish or yellow
Trichomonas infection	Irritation, odor	Malodorous	Copious, often frothy/yellow-green
Atrophic	Vulvar or vaginal dryness	Occasional mild malodor	Usually scant and mucoid/may be blood-tinged

Research has not shown a clear benefit of regular physical breast exams done by either a health professional (clinical breast exams) or by the woman herself (breast self-exams). There is very little evidence that these tests help find breast cancer early when women also get screening mammograms. Most often when breast cancer is detected because of symptoms (such as a lump), a woman discovers the symptom during usual activities such as bathing or dressing. Women should be familiar with how their breasts normally look and feel and report any changes to a health care provider right away (ACS, 2017). Breast cancers that are found because they are causing symptoms tend to be larger and more likely to have already spread beyond the breast. In contrast, breast cancers found during screening examinations are more likely to be smaller and still confined to the breast (ACS, 2015).

Inspection

Examination begins with inspection. The patient disrobes to the waist and sits in a comfortable position facing the examiner. The breasts are inspected for size and symmetry. A slight variation in size between the breasts is common and generally normal. Inspect the skin for color, venous pattern, thickening, or edema. Nipple inversion of one or both breasts is not uncommon and is significant only when of recent origin. Ulceration or rashes require evaluation. Then the breasts are inspected while the patient raises both arms overhead and again while she places her hands on her waist, pushing her shoulders in. These movements cause contraction of the pectoral muscles and should not alter the breast contour or nipple direction. Dimpling or retraction observed during these position changes suggests an underlying mass. The nurse observes for deep pin-point dimpling of the skin similar to an orange's skin (termed *peau d'orange*), which is associated with carcinoma. The clavicular and axillary regions are visually inspected before palpation.

Two of the more common issues providers may find affecting the nipple are nipple discharge and fissures.

Nipple Discharge. Nipple discharge in a woman who is not lactating may be related to many causes (Table 32-6), although any discharge that is spontaneous, persistent, or unilateral is of concern. Clear discharge on expression is usually normal, while green discharge could indicate an infection. Bloody discharge does not always indicate malignancy. Tumors of the pituitary or thyroid gland or brain, encephalitis (a brain infection), and head injuries also can cause a nipple discharge. Oral contraceptives, pregnancy, hypertension, chlorpromazine-type medications, and frequent breast stimulation may be contributing factors. Among women who have an abnormal discharge, benign conditions are much more common than breast cancer; in fact, breast cancer is the

cause in fewer than 12% of cases (Patel, Falcon, & Drukteinis, 2014).

TABLE 32-6 Nipple Discharge and Associated Causes

Description of Discharge	Associated Conditions
Clear discharge	Galactorrhea, blunt injury, fibrocystic changes
Bloody discharge	Noncancerous breast tumor (intraductal papilloma), breast cancer (less common), blunt injury, a blocked duct (mammary duct ectasia)
Greenish discharge	Fibroadenoma (a noncancerous solid lump), galactorrhea, a blocked duct (mammary duct ectasia)
Pus discharge	Breast infection, abscess
Milky discharge	Galactorrhea (in women who are not breastfeeding)

A discharge from one breast is likely to be caused by a problem with that breast, such as a noncancerous or cancerous breast tumor. A discharge from both breasts is more likely to be caused by a problem outside the breast, such as an imbalance of hormones made by the pituitary or thyroid gland, or by drugs. If a nipple discharge persists for more than one menstrual cycle or seems unusual to the woman, she should seek evaluation. Postmenopausal women who have a nipple discharge should seek evaluation promptly.

Fissure. A fissure is a longitudinal ulcer that may develop in breastfeeding women. Improper infant positioning may irritate the nipple and may form a painful, raw area, which can be a site of infection. Comfort care measures include daily washing with water, massage with breast milk or lanolin, and exposure to air.

Nursing Alert
Very small erosions (1 to 2 mm) of the nipple epithelium may be the only manifestation of Paget carcinoma (a rare type of breast cancer that occurs in the ducts adjacent to the nipple and areola and spreads to the skin of the nipple and the areola) (Karam, 2013). It accounts for only 1% of breast cancers and may be associated with ductal carcinoma in situ (DCIS) (Karam, 2013). See Chapter 33 for more information.

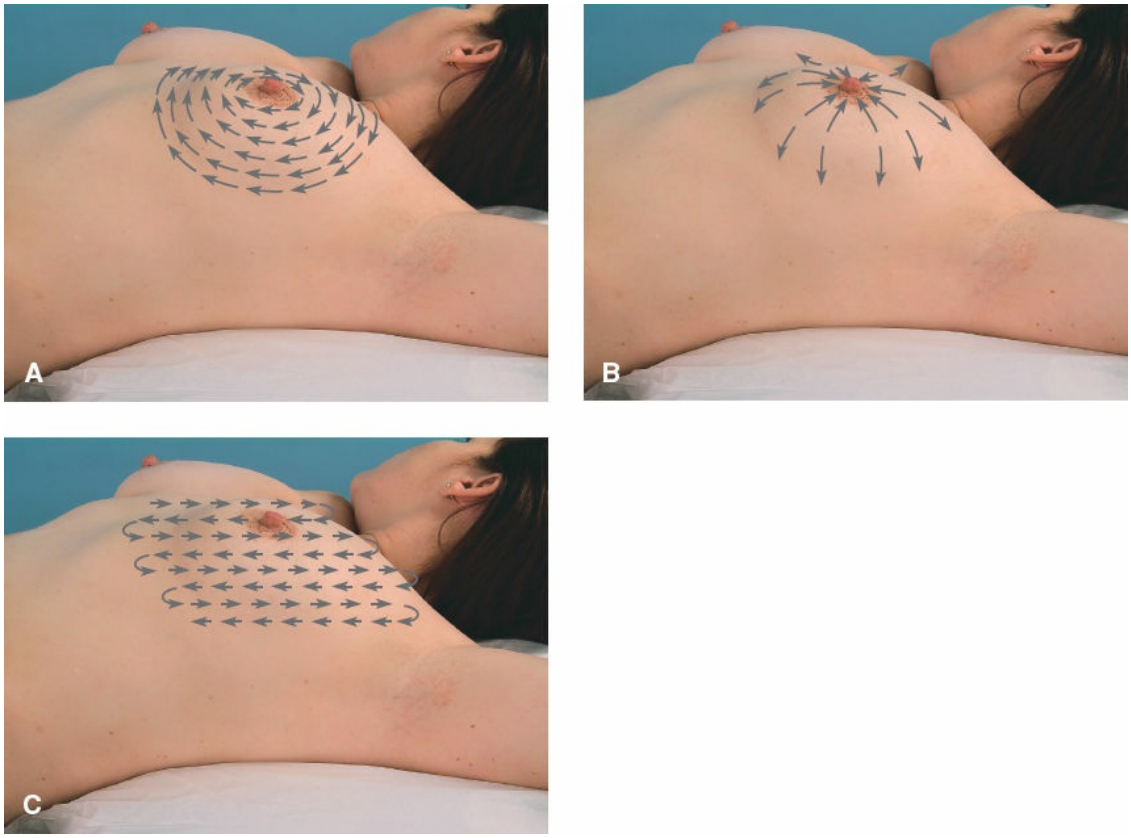

FIGURE 32-5 Breast examination with the woman in a supine position. The entire surface of the breast is palpated from the outer edge of the breast to the nipple; palpation patterns are circular or clockwise, wedge, and vertical strip.

Palpation

Both breasts are palpated with the patient sitting up (upright) and lying down (supine). The entire surface of the breasts and axillary tails are palpated systematically in dime-sized circles, from the outer limits of the breast toward the nipple in a clockwise direction (Fig. 32-5). If a mass is detected, it is described by its location (e.g., left breast, 2 cm from the nipple at 2 o'clock position). Size, shape, consistency, border delineation, and mobility are included in the description. Different phases of the menstrual cycle cause changes in the breast tissue.

Special Considerations in Health Assessment

Cultural Considerations

The health care system is an area in which cultural divisions are notable. Cultural views and beliefs differ, and traditional cultural beliefs can affect women's health care encounters. A nurse who is culturally competent is able to deliver services that are respectful of and responsive to the health beliefs, practices, and cultural and linguistic needs of diverse patients. Cultural competency is critical to reducing health disparities and improving access to high-quality health care, health care that is respectful of and responsive to the needs of diverse patients (National Institutes of Health [NIH], 2015). Refer to Chapter 2 for further details on cultural competency. The nurse should refrain from making assumptions about patients from any ethnic group. Instead, the nurse should feel comfortable asking the patient questions about how she perceives her health care and what she needs in order to make her feel comfortable and confident in the health care setting. A number of social, cultural, and gender-related obstacles can prevent a woman from realizing her preferences (Lewis, Doshi, de Leon, & Refaat, 2014). Knowledge of various cultures can help nurses adapt to the multiple personal preferences and cultural perspectives of patients whose ethnicity, race, age, sex, sexual orientation, religion, language, and/or socioeconomic status differ from their own. Effective communication and positive relationships are essential to developing collaborative culturally competent care and shared decision-making that result in women's greater understanding of their health care plans, satisfaction, and improved health outcomes (Jesse & Kirkpatrick, 2013).

Women with Disabilities

About 27 million women in the United States have disabilities—and the number is growing. More than 50% of women older than 65 years of age are living with a disability. Women with disabilities may need special care to address their individual needs. In addition, they need the same general health care as women without disabilities, and they also may need additional care to address their specific needs. However, research has shown that many women with disabilities may not receive regular health screenings within recommended guidelines (Centers for Disease Control and Prevention [CDC], 2014a). Nurses assessing women with disabilities may require additional time to complete an assessment (Box 32-4) in a sensitive and unhurried manner.

BOX 32-4 Assessment of Women with Disabilities

Health History

Address questions directly to the woman herself rather than to people accompanying her. Ask about:

- Self-care limitations resulting from her disability (ability to feed and dress herself, use of assistive devices, transportation requirements, other assistance needed)
- Sensory limitations (lack of sensation, low vision, deaf or hard of hearing)

- Accessibility issues (ability to get to health care provider, transfer to examination table, accessibility of office/clinic of health care provider, previous experiences with health care providers, health screening practices, her understanding of physical examination)
- Cognitive or developmental changes that affect understanding
- Limitations secondary to disability that affect general health issues and reproductive health and health care
- Sexual function and concerns (those of all women and those who may be affected by the presence of a disabling condition)
- Menstrual history and menstrual hygiene practices
- Physical, sexual, or psychological abuse (including abuse by care providers; abuse by neglect or withholding or withdrawing assistive devices or personal health care)
- Presence of secondary disabilities (i.e., those resulting from the patient's primary disability: pressure ulcers, spasticity, osteoporosis, etc.)
- Health concerns related to aging with a disability

Physical Assessment

Provide instructions directly to the woman herself rather than to people accompanying her; provide written or audiotaped instructions.

Ask the woman what assistance she needs for the physical examination, and provide assistance if needed:

- Undressing and dressing
- Providing a urine specimen
- Standing on scale to be weighed (provide alternative means of obtaining weight if she is unable to stand on scale)
- Moving on and off the examination table
- Assuming, changing, and maintaining positions

Consider the fatigue experienced by the woman during a lengthy examination and allow her time to rest.

Provide assistive devices and other aids/methods needed to allow adequate communication with the patient (interpreters, signers, large-print written materials).

Complete the examination as it would be indicated for any other woman; having a disability is *never* justification for omitting parts of the physical examination, including the pelvic examination.

Breast cancer is a major public health concern for all women, including women with disabilities. Women who have disabilities less likely to have had a mammogram compared to able-bodied women and are significantly less likely to have been screened within the recommended guidelines women (CDC, 2014b). Studies also show higher rates of death related to breast cancer among women with a disability, even when diagnosed at the same

stage as women without a disability. Having regular mammograms can lower the risk of dying from breast cancer (CDC, 2014a). Reminding women of the need for recommended and regular checkups, clinical breast examinations, and mammograms is an important part of nursing care.

Gerontologic Considerations

Women represent the majority of the population 65 years of age and over. On average, women live 6 to 8 years longer than men and, therefore, encounter and live with more physical and medical limitations with aging (Lewis et al., 2014). Elderly women are more likely to place value on screening services, such as mammography, instead of preventative health care counseling regarding things like the effects of diet and exercise on longevity. While diagnostic screening measures are appropriate, preventative health issues may be more likely to positively impact quality and longevity of life in the elderly woman and, therefore, may be appropriate for the practitioner to discuss with elderly patient (McNamara & Walsh, 2015). However, nurses should encourage all aging women to undergo an annual gynecologic examination, and they should use this time to educate and reassure their aging patients.

Caring for older women with gynecologic concerns requires the nurse to be prepared for a wide spectrum of issues. A clinical approach to older women goes beyond a traditional history and physical examination; nurses need to include functional, social, and psychosocial elements that affect the older woman's well-being and quality of life (Johnson & Reuben, 2014). The optimal treatment modality for the elderly patient should not be based on age alone. Many older women, regardless of advancing chronologic age, remain in excellent health. Therefore, the woman's treatment preferences must play a role in the decision-making process, and this should include making her aware of preventative health activities that may be just as important to her continued health as diagnostic procedures (Chang & Williams, 2014).

Abnormal gynecologic findings in the elderly woman include perineal pruritus, which may indicate a disease process, and vulvar dystrophy, characterized by thickened or whitish discoloration of tissue. With relaxing pelvic musculature, uterine prolapse and relaxation of the vaginal walls can occur. Performance of Kegel exercises to strengthen the pelvic floor is frequently recommended. Refer to Chapter 33, Box 33-9 for details regarding Kegel exercises.

Diagnostic Evaluation

Papanicolaou (Pap) Cytologic Test for Cervical Cancer

Often cervical cancer can be found early, and sometimes even prevented entirely, by having regular Pap tests. If detected early, cervical cancer is one of the most successfully treatable cancers. Deaths from cervical cancer are higher in populations around the world where women do not have routine screening for cervical cancer. In fact, cervical cancer is the major cause of cancer deaths in many women in developing countries. Usually these women are diagnosed with late-stage cancers rather than precancers or early cancers. In the United States, however, the death rate from cervical cancer has declined by more than 50% over the last 30 years. This is thought to be mainly related to the effectiveness of Pap test screening (ACS, 2014). Incorporation of the Pap test into routine well-woman care has decreased the incidence of cervical cancer to levels lower than that of breast or ovarian cancer.

During the Pap test, a sample of cells and mucus is lightly scraped or brushed from the cervix. If the cervix has been removed, the cells will be sampled from the upper part of the vagina, known as the vaginal cuff. This test should not be performed when a patient is menstruating as blood can interfere with interpretation. Although the Pap test is an excellent screening system, it is not a diagnostic test; both false-positive and false-negative results may occur. The Bethesda Classification system has been developed to promote consistency in reporting Pap results.

Nursing Alert

To make a Pap test as accurate as possible, patients are informed to:

- *Try not to schedule an appointment for a time during your menstrual period. The best time is at least 5 days after your menstrual period stops.*
- *Don't use tampons; birth-control foams or jellies; other vaginal creams, moisturizers, or lubricants; or vaginal medicines for 2 to 3 days before the test.*
- *Don't douche for 2 to 3 days before the test.*
- *Don't have sexual intercourse for 2 days before the test (ACS, 2014).*

Although patients may assume (incorrectly) that an abnormal Pap smear signifies cancer, this is not generally the case. It simply means just that, it is abnormal: Under the microscope, the appearance of a few cells differs in some way from the classic appearance of healthy, intact cervical cells. The difference could be due to local irritation, a non-HPV infection, a low-risk or high-risk HPV type, or even a mistake in the preparation of the cell sample (National Cervical Cancer Coalition, 2015). Abnormal Pap results require prompt notification and follow-up as abnormalities detected in a Pap test may signify cellular changes that may lead to cancer if left untreated (Box 32-5). Factors associated with poor adherence to recommendations or lack of follow-up include young age, nonwhite race/ethnicity, less than high school education, lack of health insurance, less knowledge about HPV, and physiologic distress (Fish et al., 2013). The nurse should provide simple and clear explanations as well as emotional support designed to meet the needs of the specific patients that may encourage appropriate and timely follow-up. The message should

be persuasive enough to convince women of the importance of follow-up while at the same time minimizing anxiety and distress (Box 32-6).

BOX 32-5 Follow-up According to Pap Test Results

- 21–29 years of age:
  - HPV testing should not be used for screening in this age group. It is done as secondary testing for management decisions.
  - HPV-positive ASC-US: Repeat cytology in 12 months.
  - Cytology of LSIL: Repeat cytology in 12 months.
  - Cytology more severe than LSIL: Colposcopy is recommended.
  - Cytology negative or HPV-Negative ASC-US: Rescreen with cytology in 3 years.
- 30–65 years of age:
  - HPV and cytology "co-testing" every 5 years (preferred screening) results
    - HPV-positive ASC-US or cytology of LSIL or more severe: Colposcopy is recommended.
    - HPV-positive, cytology negative:
      - Option 1: 12-month follow-up with co-testing.
      - Option 2: Test for HPV16 or HPV16/18 genotypes.
        - If HPV16 or HPV16/18 positive: Refer for colposcopy.
        - If HPV16 or HPV16/18 negative: 12-month follow-up with co-testing.
    - Co-test negative or HPV-negative ASC-US: Rescreen with co-testing in 5 years.
  - Cytology alone every 3 years (acceptable screening) results
    - HPV-positive ASC-US or cytology of LSIL or more severe: Colposcopy is recommended.
    - Cytology negative or HPV-negative ASC-US: Rescreen with cytology in 3 years
- Over 65 years of age:
  - No screening following adequate negative prior screening.
  - Women with a history of CIN2 or more severe diagnosis should continue routine screening for at least 20 years.
- After hysterectomy:
  - No screening. This applies to women without a cervix and without history of CIN2 or a more severe diagnosis in the past 20 years or cervical cancer ever.

CIN, cervical intraepithelial neoplasia; LSIL, low-grade squamous intraepithelial lesions; ASC-US, atypical squamous cells of undetermined significance; HPV, human papillomavirus.
Adapted from American Society for Colposcopy and Cervical Pathology. (2013). *Algorithms: Updated consensus guidelines for managing abnormal cervical cancer screening tests and cancer precursors* http://www.asccp.org/Portals/9/docs/ASCCP%20Management%20Guidelines_August%202014.pdf

Uterine Diagnostics

Certain uterine conditions, such as dysfunctional uterine bleeding, may require diagnostic testing as well. Diagnostic tests performed on uterine and peritoneal tissues include endometrial (aspiration) biopsy, dilation and curettage (D&C), laparoscopy, hysteroscopy, and endometrial ablation. For information on these procedures, refer to Table 32-7.

Mammography

Mammography is a breast-imaging technique that takes about 20 minutes and is performed in a hospital radiology department or independent imaging center that can detect nonpalpable lesions and assist in diagnosing palpable masses. The breast is mechanically compressed from top to bottom (craniocaudal view) and side to side (mediolateral oblique view) (Fig. 32-6). Although usually two views of each breast are taken for a screening mammogram, for some women, such as those with breast implants or large breasts, additional pictures may be needed. Experiences of slight discomfort are due to the maximum compression necessary for proper visualization. Although mammography may detect a breast tumor before it is clinically palpable (i.e., smaller than 1 cm), mammography has limitations. Overall, screening mammograms do not find about one in five instances of breast cancer. They do not work as well in women with dense breasts since dense breasts can hide a tumor. Dense breasts are more common in younger women, pregnant women, and women who are breastfeeding, but any woman can have dense breasts.

BOX 32-6 Diagnostic Testing Indicated by Abnormal Pap Test Results

Colposcopy

All suspicious Pap smears should be evaluated by colposcopy. Nurse practitioners and gynecologists require special training in this diagnostic technique.

The colposcope is a portable microscope used to visualize the cervix and obtain samples of abnormal tissue for analysis. The examiner applies acetic acid (similar to vinegar) to the cervix to outline suspect areas.

A cervical biopsy or endocervical curettage may be performed during colposcopy. Tissue analysis is used to determine whether abnormal changes have occurred. If these biopsy specimens show premalignant cells, cervical dysplasia, or cervical intraepithelial neoplasia (CIN), the patient usually requires further intervention (cryotherapy, laser therapy, or a cone biopsy).

Cervical Biopsy

Abnormal colposcopy findings indicating the need for biopsy include leukoplakia (white plaque visible before applying acetic acid), acetowhite tissue (white epithelium after applying acetic acid), punctation (dilated capillaries occurring in a dotted or stippled pattern), mosaicism (a tile-like pattern), and atypical vascular patterns.

Biopsy involves taking a sample of tissue from the cervix for further analysis.

Cryotherapy and Laser Therapy

Both are outpatient procedures. Cryotherapy is the freezing of suspect cervical tissue with nitrous oxide. It is good for small areas of mild to moderate dysplasia. It can be used to treat carcinoma in situ of the cervix (stage 0) but not invasive cancer.

Cryotherapy may result in cramping and occasional feelings of faintness (vasovagal response). A watery discharge is normal for a few weeks after the procedure as the cervix heals. It is not precisely controlled so abnormal cells may be left behind.

Laser treatment uses a tiny beam of light to vaporize abnormal cervical cells. The laser beam is directed through a colposcope, is more precise than cryosurgery, and has the benefit of targeting only the diseased cervical tissues. Healing is much faster than with freezing. Not all offices have lasers, thus increasing costs to patient if treatment is carried out in the hospital. This, too, can be used to treat carcinoma in situ of the cervix (stage 0) but not invasive cancer.

Cone Biopsy and Loop Electrosurgical Excision Procedure

If endocervical curettage findings indicate abnormal changes or if the lesion extends into the canal, the patient may undergo a cone biopsy. The cone biopsy can be performed surgically or with a procedure called loop electrosurgical excision procedure (LEEP).

LEEP can be performed in the outpatient setting and has a high success rate in removal of abnormal cervical tissue. The provider uses a fine wire loop with electrical energy flowing through it to remove abnormal cervical tissue. Samples are sent to pathology.

Usually cone biopsy is done in an operating room with a laser or conventional surgical instruments (cold-cone). A cone- or cylinder-shaped piece of the cervix is removed. Also a diagnostic cone may treat the problem.

TABLE 32-7 Uterine Diagnostic Tests

Test	Description
Endometrial (aspiration) biopsy	Method of obtaining endometrial tissue by placing a flexible suction tube through the cervix into the uterus. This tissue sample permits diagnosis of cellular changes in the endometrium. Indicated in cases of midlife irregular bleeding, postmenopausal bleeding, and irregular bleeding while taking hormone therapy or tamoxifen.
Dilation and curettage (D&C)	Can be used as a diagnostic or therapeutic tool. Cervical canal is dilated and the endometrium is scraped. Can be used to gather endometrial tissue for cytologic examination, control abnormal uterine bleeding, and as a therapeutic measure for incomplete miscarriage.
Laparoscopy (pelvic peritoneoscopy)	Involves inserting laparoscope into peritoneal cavity through small incision below the umbilicus to allow visualization of the pelvic structures. Used for diagnostic purposes (e.g., in cases of pelvic pain when no cause can be found) as well as for surgical procedures, including tubal ligation, ovarian biopsy, hysterectomy, and adhesion lysis.
Hysteroscopy (transcervical intrauterine endoscopy)	Allows direct visualization of all parts of the uterine cavity by means of a lighted optical instrument. Under a local anesthetic, the hysteroscope is passed into the cervical canal and advanced 1 or 2 cm under direct vision. Uterine-distending fluid is infused through the instrument to dilate the uterine cavity and enhance visibility.
Endometrial ablation (destruction of the uterine lining)	Performed in cases of severe bleeding not responsive to other therapies. Performed in an outpatient setting under general, regional, or local anesthesia, the uterus is distended with a fluid infusion. Providers use a hysteroscope and resector (cutting loop), roller ball (a barrel-shaped electrode), or laser beam to destroy the lining of the uterus. Hemorrhage, perforation, and burns can occur. This rapid procedure is an alternative to hysterectomy for some patients.
Hysterosalpingography (HSG)	Radiographic study of the uterus and fallopian tubes performed to evaluate infertility or tubal patency and to detect abnormal conditions in the uterine cavity. With the patient in lithotomy position, the cervix is exposed with a speculum. A cannula is inserted into the cervix, and a contrast agent is injected into the uterine cavity and the fallopian tubes. Then x-rays are taken to show the path and the distribution of the contrast agent.
Ultrasonography (ultrasound [US])	Useful adjunct to the physical examination for patients with abnormal pelvic findings. Based on transmission of pulsed ultrasonic sound waves via a transducer that is either placed on the abdomen (abdominal scan) or through a vaginal probe (vaginal US). The entire procedure takes usually less than 10 minutes and involves no ionizing radiation.
Computed tomography (CT)	More effective than US for obese patients or for those with a distended bowel; demonstrates tumor and any extension into the retroperitoneal lymph nodes and skeletal tissue. Does expose the patient to radiation. More costly than US procedures.
Magnetic resonance imaging (MRI)	Produces patterns that are finer and more definitive than other imaging procedures; does not expose patients to radiation. High cost is the major drawback.

Current screening guidelines of the ACS recommend a mammogram every year beginning at 40 years of age. The ACS also has guidelines for older women and women at increased risk of breast cancer. Three other diagnostic tests to detect/view breast masses are ductogram (galactogram), ultrasound (US), and magnetic resonance imaging (MRI) (Table 32-8).

Other Radiologic Tests for Breasts Masses

Ductogram, also called a galactogram, is used sometimes to help find the cause of any worrisome nipple discharge. In this test, a very thin tube is inserted into the opening of a duct in the nipple where the discharge is coming from and a small amount of contrast material is injected. The contrast material outlines the shape of the duct on x-ray and can show whether there is a mass inside the duct.

Ultrasound (US), also known as sonography, uses sound waves to look inside a part of the body. This test is painless and has no radiation exposure. Breast US is used most often to evaluate breast problems that are found during a mammogram or physical examination and to guide a needle biopsy of a suspicious mass. In someone with a breast tumor, US also may be used to assess lymph nodes under the arm. Breast US may be helpful to use along with a mammogram when screening a woman with dense breast tissue.

Magnetic resonance imaging (MRI) of the breast is a highly sensitive technology that

uses magnets and radio waves instead of x-rays to produce very detailed, cross-sectional pictures. It is a useful diagnostic adjunct to mammography without exposure to radiation. The procedure cannot always distinguish accurately between malignant and benign breast conditions. This is why MRI is not recommended as a screening test for women at average risk of breast cancer as it would result in unneeded biopsies and other tests in many of these women.

MRI is most useful when assessing for disease that is either multifocal (more than one tumor in the same quadrant of the breast) or multicentric (more than one tumor in different quadrants of the breast), chest wall involvement, tumor recurrence, or response to chemotherapy.

MRI also can identify occult (undetectable) breast cancer and determine the integrity of saline or silicone breast implants.

Disadvantages of MRI include high cost, variations in technique and interpretation, and the potential for patient claustrophobia.

Breast Tissue Analysis

Diagnostic tests performed on breast tissue are described in Table 32-8.

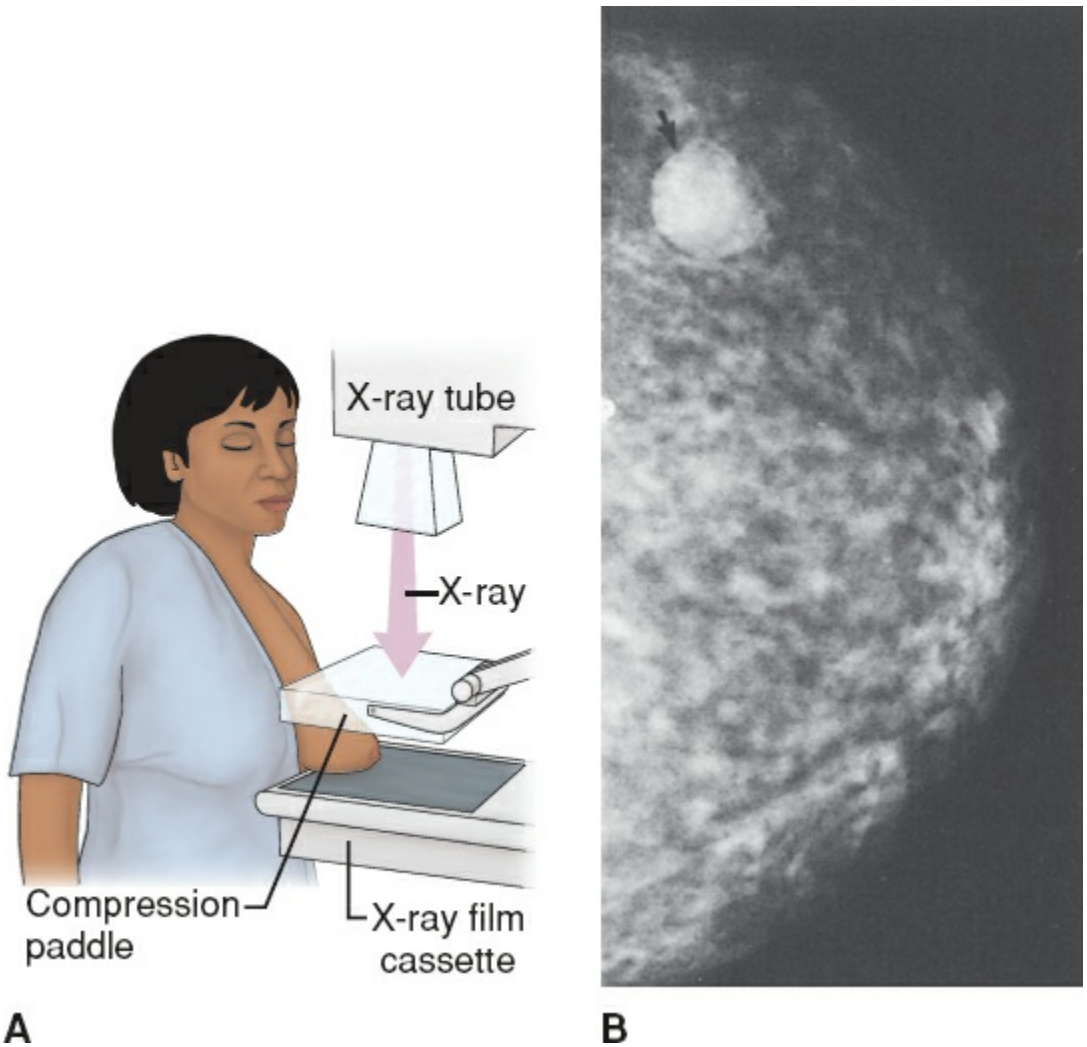

FIGURE 32-6 The mammography procedure (A) relies on x-ray imaging to produce the mammogram (B), which, in this case, reveals a breast lump.

MALE REPRODUCTIVE SYSTEM

In the male, several organs serve as parts of both the urinary tract and the reproductive system. Disorders in the male reproductive organs may interfere with the functions of one or both of these systems. As a result, diseases of the male reproductive system are commonly treated by a urologist.

TABLE 32-8 Procedures for Breast Tissue Analysis

Procedure	Description
Percutaneous biopsy	Samples palpable and nonpalpable lesions via needle or core biopsy that obtains tissue by making a small puncture in the skin. It is less invasive than a surgical biopsy.
Fine-needle aspiration (FNA)	Small-gauge needle with a syringe is inserted into the mass or area of nodularity. Cellular material obtained during the procedure is spread on a glass slide or placed in a preservative and sent for analysis.
Core needle biopsy	Similar to FNA except that a needle with a larger gauge is used (usually 14 gauge). It allows for a more definitive diagnosis than FNA because actual tissue, not just cells, is removed. Often performed for relatively large tumors that are close to the skin surface.
Stereotactic core biopsy	Performed on nonpalpable lesions detected by mammography. After using digital mammography to determine the exact coordinates of the lesion, a core needle is inserted to retrieve samples of the tissue for pathologic examination. Stereotactic biopsy often allows the patient to avoid a surgical biopsy.
Ultrasound-guided core biopsy	Performed on nonpalpable lesions found by ultrasound; does not use radiation and is faster and less expensive than stereotactic core biopsy.
Excisional biopsy (lumpectomy)	Standard procedure for complete pathologic assessment of a palpable breast mass. The entire mass, plus a margin of surrounding tissue, is removed.
Incisional biopsy	Surgical removal of a portion of a mass when complete excision of the area may not be possible or immediately beneficial to the patient. Incisional biopsy is becoming less common as pathologic information can be obtained from core needle biopsy.
Wire needle localization	Technique used to precisely locate nonpalpable masses detected on a mammogram, ultrasound, or MRI that require an excisional biopsy. A long, thin wire is inserted through a needle and guided into the area of abnormality using x-ray or ultrasound. The needle is withdrawn, and the wire is left in place to ensure the precise location.

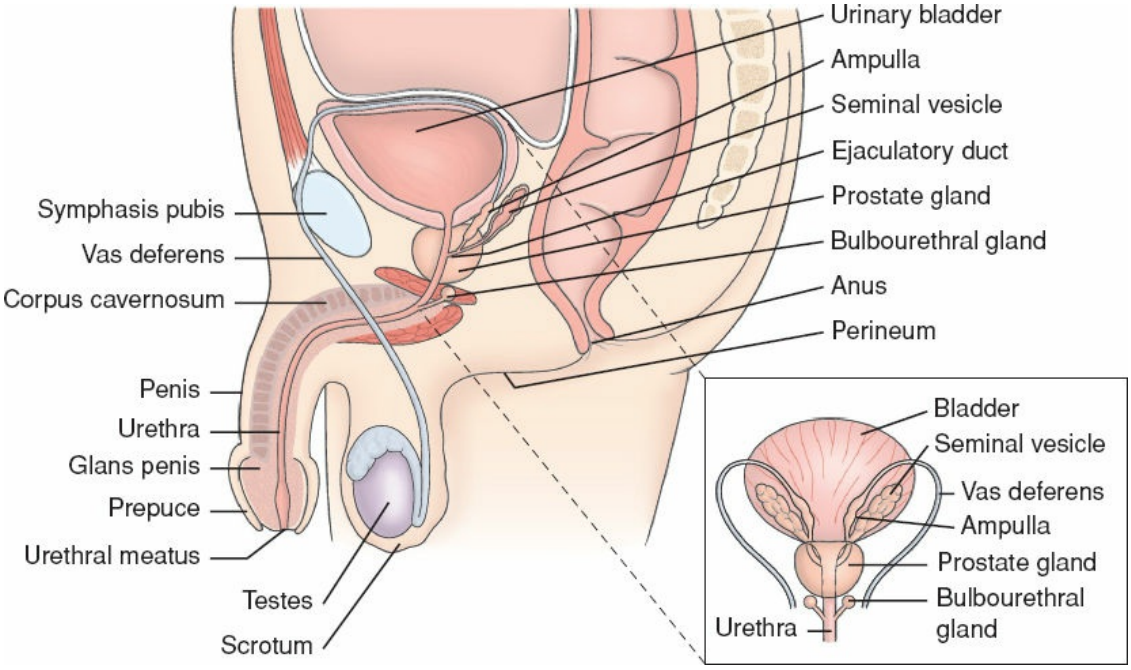

FIGURE 32-7 Structures of the male reproductive system.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The structures in the male reproductive system include the testes, the vas deferens (ductus deferens) and seminal vesicles, the penis, and certain accessory glands, such as the prostate gland and Cowper gland (bulbourethral gland) (Fig. 32-7).

The testes are formed in the embryo, within the abdominal cavity, near the kidney. During the last month of fetal life, the testes descend posterior to the peritoneum, pierce the abdominal wall in the groin, and progress along the inguinal canal into the scrotum. In this descent, they are accompanied by blood vessels, lymphatics, nerves, and ducts, all of which support the tissue and make up the spermatic cord. This cord extends from the internal inguinal ring through the abdominal wall and the inguinal canal to the scrotum. As the testes descend into the scrotum, a tubular extension of peritoneum accompanies them. This tissue is obliterated during fetal development; the only remaining portion is that which covers the testes, the tunica vaginalis.

The testes are encased in the scrotum, which keeps them at a slightly lower temperature than the rest of the body to facilitate spermatogenesis. The testes have a dual function: spermatogenesis (production of sperm) and secretion of the male sex hormone testosterone, which induces and preserves the male sex characteristics. The testes consist of numerous seminiferous tubules in which the spermatozoa form. Collecting tubules transmit the spermatozoa into the epididymis, a hood-like structure lying on the testes and containing winding ducts that lead into the vas deferens. This firm, tubular structure passes upward through the inguinal canal as part of the spermatic cord to enter the abdominal cavity behind the peritoneum. It then extends downward toward the base of the bladder. An outpouching from this structure is the seminal vesicle. The tract is continued as the ejaculatory duct, which passes through the prostate gland to enter the urethra. Secretions from the seminal vesicles join secretions from the prostate and exit the penis during ejaculation.

The penis has a dual function: it is the organ for copulation and for urination. Anatomically, it consists of the glans penis, the body, and the root. The glans penis is the soft, rounded portion at the distal end of the penis. The urethra opens at the tip of the glans. The glans is naturally covered or protected by elongated penile skin—the foreskin—which may be retracted to expose the glans. However, many men have had the foreskin removed (circumcision) as newborns. The body of the penis is composed of erectile tissues containing numerous blood vessels that become distended, leading to an erection during sexual excitement. The urethra, which passes through the penis, extends from the bladder through the prostate to the distal end of the penis, ending at the meatal opening.

The prostate gland lies just below the neck of the bladder. It surrounds the urethra and is traversed by the ejaculatory duct, a continuation of the vas deferens. This gland produces a secretion that is suitable both chemically and physiologically to the needs of the spermatozoa in their passage from the testes. The Cowper gland lies below the prostate, within the posterior aspect of the urethra. This gland empties its secretions into the urethra during ejaculation, providing lubrication.

Gerontologic Considerations

As men age, the prostate gland enlarges, prostate secretion decreases, the scrotum hangs lower, the testes become smaller and less firm, and pubic hair becomes sparser. Changes in gonadal function include a decline in plasma testosterone levels and reduced production of progesterone (Table 32-9). Other potential changes include decreased sexual function, slowed sexual responses, an increased incidence of cancer of the genitourinary tract, and possible urinary incontinence or retention.

Male reproductive capability is maintained with advancing age. Although degenerative changes occur in the seminiferous tubules, spermatogenesis continues. However, libido (sexual desire) and potency decrease (Moskovic, Araujo, Lipshultz, & Khera, 2013).

TABLE 32-9 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Male Reproductive System

Structural Change	Functional Change	History and Physical Findings
Decrease in secretion of sex hormones, especially testosterone Decreased muscle strength and sexual energy Shrinkage and loss of firmness of testes; thickening of seminiferous tubules Enlargement of prostate gland	Changes in sexual response: prolonged time to reach full erection, rapid penile detumescence (decreased rigidity) and prolonged refractory period Possible decline in libido Decrease in number of viable sperm	Smaller testes Erectile dysfunction Weakening of prostatic contractions Hyperplasia of prostate gland Signs and symptoms of obstruction of lower urinary tract (urgency, frequency, nocturia)

Nursing Alert

If the patient is concerned about impotence, the nurse can ask about whether the patient on waking has an early morning erection. If he does, this argues against an organic cause (neurologic, vascular, or endocrinologic) and suggests a functional problem. A thorough history focusing on the onset and progression of symptoms, libido, medications, surgery, and psychosocial issues is important in the evaluation. Screening for depression, hypothyroidism, hypogonadism, and diabetes can be considered (LeBlond, Brown, & DeGowin, 2015).

Hypogonadism occurs in up to one fourth of older men. This decline is more evident in men older than 60 years of age (Moskovic et al., 2013). In older men, the sexual response slows, attaining an erection takes longer, and full erections may not be attained until climax. Sexual function can be affected by several factors, such as:

- Psychological problems,
- Comorbidities (vasculogenic [atherosclerotic disease, occlusions to vasculature after pelvic trauma, liver failure]),
- Neurogenic (spinal cord injury, Parkinson disease, stroke, tumors, trauma),
- Endocrine (hypogonadism, hyper- and hypothyroidism),

- Mixed causation (diabetes, uremia), and
- Medication related (opioids, alcohol, antihypertensive, antidepressants among others) (Mullins, 2013).

Cancers of the kidney, bladder, prostate, and penis all have increased incidence in men older than 50 years of age. Digital rectal examination (DRE) and screening tests for hematuria may uncover a higher percentage of malignancies at earlier stages and lead to lower morbidity associated with treatment as well as a lower mortality rate.

Urinary incontinence or retention in the elderly man may have many causes, including medications and age-related conditions, such as neurologic disease or benign prostatic hyperplasia (BPH). Diagnostic tests are performed to exclude reversible causes of urinary incontinence.

ASSESSMENT

Health History

Male sexuality is a complex phenomenon that is strongly influenced by personal, cultural, and social factors. Sexuality and male reproductive function become concerns in the presence of illness (Davis, Binik, Amsel, & Carrier, 2013). Assessment of male reproductive function begins with an evaluation of urinary function and symptoms. This assessment also includes a focus on sexual function as well as on manifestations of sexual dysfunction.

The patient is asked about his usual state of health and any recent change in general physical and sexual activity. Any symptoms or changes in function are explored fully and described in detail. These symptoms may include those associated with an obstruction caused by an enlarged prostate gland: increased urinary frequency, decreased force of urine stream, or "double" voiding (the patient needs to urinate two or three times over a period of several minutes to completely empty his bladder). The patient also is assessed for dysuria (painful urination) and hematuria (blood in the urine).

Assessment of sexual function is an essential part of every health history. The extent of the history depends on the patient's presenting symptoms and the presence of factors that may affect sexual function: chronic illnesses (e.g., diabetes, multiple sclerosis, stroke, cardiac disease), use of medications that affect sexual function (e.g., many antihypertensive and anticholesterolemic medications, psychotropic agents), stress, and alcohol use.

Often patients are hesitant to initiate a discussion about sexual issues with their health care providers. By initiating an assessment about sexual concerns, the nurse demonstrates that changes in sexual functioning are valid topics for discussion and provides a safe environment for discussing these sensitive topics.

Physical Assessment

Physical assessment includes examination of the penis and scrotum, the DRE, and assessment of the male breasts.

Penis and Scrotal Examination

The male genitalia are inspected for abnormalities and palpated for masses. The scrotum is palpated carefully for nodules, masses, or inflammation. Examination of the scrotum can reveal such disorders as hydrocele (accumulation of serous fluid in the scrotal sac), varicocele (enlargement of the veins of the spermatic cord), or tumor of the testis. The penis is inspected and palpated for ulcerations, plaques, inflammation, and discharge. The testicular examination provides an excellent opportunity to instruct the patient about techniques for testicular self-examination (TSE) and its importance in early detection of testicular cancer (see Chapter 34). TSE could begin during adolescence, although recently this practice has been called into question with recommendations that TSE not be emphasized due to the low incidence of testicular cancer and the high rate of anxiety associated with self-examination (O'Reilly, Le, Sinyavskaya, & Mandel, 2016).

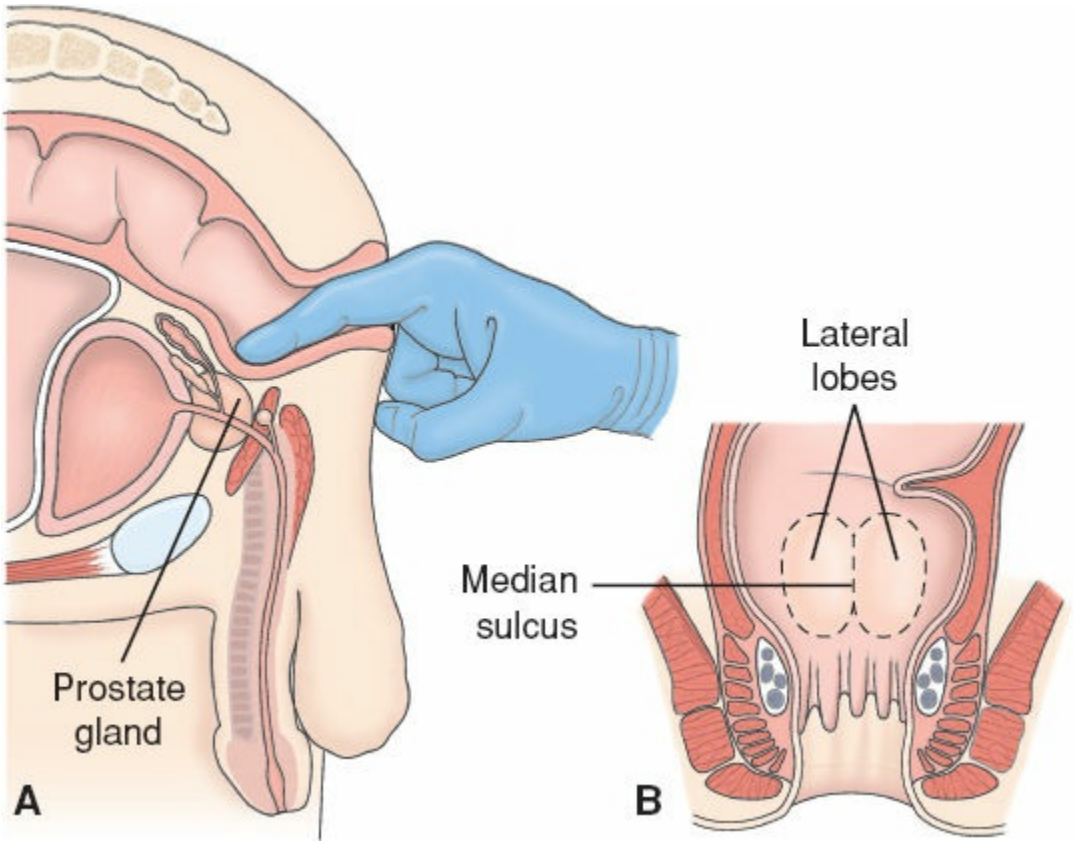

FIGURE 32-8 A. Palpation of the prostate gland during digital rectal examination (DRE) enables the examiner to assess the size, shape, and texture of the gland. B. The prostate is round, with a palpable median sulcus or groove separating the lateral lobes. It should feel rubbery and free of nodules and masses.

Digital Rectal Examination

The DRE is recommended as part of the regular health checkup for every man older than 50 years of age; it is invaluable in screening for cancer of the prostate gland. The DRE enables the examiner to estimate the size, shape, and consistency of the prostate gland (Fig. 32-8). Tenderness of the prostate gland on palpation and the presence and consistency of any nodules are noted. Although this examination may be embarrassing for the patient, it is an important screening tool.

Assessment of the Male Breasts

Breast cancer can occur in men. Examination of the male breasts and axillae should be included in a physical examination. The nipple and areola are inspected for masses and nipple discharge.

Gynecomastia is the firm enlargement of glandular tissue beneath and immediately surrounding the areola of the male. This is different from the enlargement of soft, fatty tissue, which is caused by obesity.

Diagnostic Evaluation

Prostate-Specific Antigen Test

The prostate gland produces a substance known as prostate-specific antigen (PSA). It can be measured in a blood specimen, and levels increase with certain pathologies: prostate cancer, BPH, acute urinary retention, and acute prostatitis are the most common examples. In most laboratories, the range of values generally considered normal is 0.2 to 4.0 ng/mL, with levels greater than 4.0 considered elevated. The use of age-specific reference ranges for populations helps minimize unnecessary biopsies (American Urological Association [AUA], 2013a, 2013b).

Prostate cancer screening with serum PSA testing has become common practice although its overall utility has recently come into question (AUA, 2013a). The AUA recommends a PSA test beginning at 55 years of age, along with DRE, and then screening at 2- to 4-year intervals, although screening needs to be discussed with each man individually, based on his history and risk. Screening should begin at 40 years of age for men at high risk, including those with a family history of prostate cancer (first-degree relative [father, brother, or son] diagnosed with prostate cancer at an early age [under 65 years of age]) and African-American men (AUA, 2013a). Also PSA is useful to monitor patients for recurrence after treatment for cancer of the prostate.

Ultrasonography

Transrectal ultrasound (TRUS) may be offered to patients with abnormalities detected by DRE and in those with elevated PSA levels; a lubricated, condom-covered rectal probe transducer is inserted into the rectum, along the anterior wall. Needle biopsies of the prostate are commonly guided by TRUS.

Prostate Fluid or Tissue Analysis

Specimens of prostate fluid or tissue may be obtained for culture if disease or inflammation of the prostate gland is suspected, but this is uncommonly performed.

Tests of Male Sexual Function

If the patient cannot engage in sexual intercourse to his satisfaction, a detailed history is obtained. A Rigiscan® test may be ordered, or nocturnal penile tumescence tests may be conducted in a sleep laboratory to monitor changes in penile circumference during sleep. The results help identify the cause of erectile dysfunction. Additional tests, including penile Doppler studies or psychological evaluations, also can be part of the diagnostic workup and usually are conducted by a specialized team of health care providers.

CHAPTER REVIEW

Critical Thinking Exercises

1. While you are preparing a male patient to be evaluated by his provider, he confides that his interest in sexual activity and overall energy level have lessened. Explain the information you would provide. What medical and nursing interventions would you anticipate?

2. A 55-year-old woman who is postmenopausal comes to you with concerns regarding vaginal bleeding. She has not had a period in 3 years and is not currently on HR therapy. Vaginal bleeding is noted most significantly after intercourse. What lifestyle questions would you ask this patient? How would you prioritize her plan of care? What types of tests might you order to rule out disease processes?

NCLEX-Style Review Questions

1. A 61-year-old male patient who has been given written information asks why it has been recommended he have a PSA test. What is the nurse's best response?
   a. It will measure his sperm count.
   b. It will measure his response to testosterone replacement.
   c. It is a useful test to screen for cancer of the prostate.
   d. It is a useful test to screen for sexual function.

2. A 21-year-old man asks how long he will continue to produce sperm since he "knows that women can't have babies after they're 43." What is the nurse's best response?
   a. "That is correct; men and women lose their reproductive capacity at roughly the same time."
   b. "Men continue to produce sperm despite advanced age."
   c. "Current literature does not provide this information for men."
   d. "Men stop sperm production at 60 years of age."

3. A 19-year-old girl complains of vaginal irritation. She says she was out for an evening a week ago at a club with friends but doesn't remember leaving the club. She states that she has never been sexually active but is afraid she may have been assaulted. What are the appropriate steps for the nurse to take?
   a. Tell her you are sure nothing bad happened to her if she left willingly with a man. If he was a bad guy, her friends would not have let her leave with him.
   b. Tell her you believe her, this is not her fault, and you want to help her.
   c. Tell her she probably decided to have sex with a man, now she has an STD, and she needs to accept the responsibility for her own actions.
   d. Offer emotional support and referral for counseling, but medical treatment at this time is not necessary as it has been too long since the incident.

4. A 61-year-old male is complaining of erectile dysfunction. The nurse reviews the patient's medical/surgical history. What data in the patient's chart are associated with erectile dysfunction? Select all that apply.
   a. Hypertension

b. Hyperlipidemia
c. GERD
d. Asthma
e. Pelvic fracture 15 years ago
f. Appendectomy
g. ORIF of the left arm

5. A 35-year-old woman has an abnormal Pap test. She will undergo cryotherapy for treatment of moderate dysplasia. What should be included in the teaching plan for this patient?
a. All abnormal cells will be removed.
b. The procedure involves freezing of cervical tissue.
c. Discharge following the procedure is considered abnormal.
d. A tiny beam of light is used to vaporize abnormal cervical cells.

CHAPTER 33

Nursing Management: Patients with Breast and Female Reproductive Disorders

Edith Caroline Smith • Vanessa Pomarico-Denino

Learning Objectives

After reading this chapter, you will be able to:

1. Describe common benign breast problems.
2. Identify risk factors for breast cancer.
3. Identify screening and diagnostic tests used to detect breast disorders.
4. Describe different treatment modalities for breast cancer.
5. Use the nursing process as a framework for care of the patient undergoing breast cancer treatment.
6. Describe the various types of menstrual disorders and their management.
7. Differentiate between bacterial vaginosis and candidiasis.
8. Identify factors associated with pelvic organ prolapse.
9. Understand risk factors for gynecologic cancers.
10. Describe differences between the types of hysterectomies.
11. Identify appropriate care for the transgendered client.

The breast and female reproductive organs play a significant role in normal and abnormal physiology as well as in a woman's sexuality and body image. Disorders of the breast or reproductive system, whether minor or serious, can cause great anxiety. Some disorders require only modest management, while others require significant intervention and may even be life-threatening. All disorders necessitate nurses to have knowledge, understanding, and skill in patient teaching involving all aspects of care, including prevention, etiology, and treatment.

BREAST DISORDERS

Benign Conditions of the Breast

Most benign breast disorders result from normal physiologic processes. They represent a spectrum of conditions that receive clinical attention and may present as imaging abnormalities, palpable lesions, irregularities found on physical examination, or pain. Once a benign diagnosis has been confirmed, treatment typically focuses on symptom management and patient education. Benign epithelial breast lesions are classified in three categories: nonproliferative, proliferative without atypia, and atypical hyperplasia. The latter confers a mild to moderate increase in a patient's risk for developing breast cancer and indicates the need for further evaluation, increased screening recommendations, and a discussion of risk-reduction strategies (Sabel, 2015). The nurse should work as an integral member of the interdisciplinary team to ensure a thorough history and physical examination are completed and that all diagnostic and treatment options are made available to the patient. In addition, the nurse is an invaluable resource and provider of patient education. Table 33-1 compares various types of benign and malignant breast masses.

BREAST PAIN

Mastalgia, or breast pain, is one of the most common breast complaints. Cyclical breast pain, the most common type of breast pain, accounts for nearly 75% of all complaints. It is usually related to hormonal fluctuations during the luteal phase of the menstrual cycle that stimulate the proliferation of normal glandular tissue and subsequently cause pain. Noncyclical pain is far less common, can be constant or intermittent, and does not vary with the menstrual cycle. Women who experience muscle strain or trauma to the breast may experience noncyclical pain. Patients should be reassured that breast pain is rarely indicative of cancer. A patient should seek attention from her health care provider for persistent pain. Elimination of methylxanthines, including caffeine, theophylline, and theobromine may alleviate breast pain. These substances are found in coffee, tea, chocolate, and cola beverages. Lowering dietary fat also may improve cyclic pain, and nonsteroidal anti-inflammatory drugs (NSAIDs) often are initiated. There is some evidence that evening primrose oil, vitamin E, and flaxseed may provide some relief for patients who prefer remedies that are more natural. The attenuated androgen, danazol, may be implemented for severe, persistent pain and is effective due to its ability to suppress pituitary gonadotropins. However, there are significant side effects to this treatment option, and it is not easily tolerated. Because of this, it is rarely used. Similarly, Tamoxifen (a selective estrogen receptor modulator) is an option to treat severe symptoms, but it also carries with it a host of often intolerable side effects, thus it too is not prescribed often. The nurse may recommend that the patient wear a supportive bra both day and night, decrease caffeine intake, and take NSAIDs as needed for breast pain. Oftentimes, this combination of therapies alleviates symptoms significantly (Giuliano & Hurvitz, 2014; Sabel, 2015).

TABLE 33-1 Comparison of Various Breast Masses

The most common breast masses are due to cysts, fibroadenomas, or malignancy. Biopsy is usually needed for confirmation, but the following characteristics are diagnostic clues:

Characteristics	Cysts	Fibroadenomas	Malignancy
			Age	30–55 years of age, regress after menopause except with use of estrogen therapy	Puberty to menopause	At least 30–90+ years of age, most common in postmenopausal years
Number	Single or multiple	Usually single, may be multiple	Usually single
Shape	Round	Round, disk, or lobular	Irregular or stellate
Consistency	Soft to firm, usually elastic	Usually firm	Firm or hard
Mobility	Mobile	Mobile	May be fixed to skin or underlying tissues
Tenderness	Usually tender	Usually nontender	Usually nontender
Retraction signs	Absent	Absent	May be present

BREAST CYSTS

Cysts are the most common nonproliferative breast lesions. They do not increase a woman's risk for developing breast cancer. They are fluid-filled, round or ovoid masses, derived from the terminal duct lobular unit, that develop due to cystic lobular involution (regression of breast lobules). Cysts occur most commonly in women of childbearing age and may be exacerbated during perimenopause when hormonal fluctuations increase. Acute enlargement of cysts, which may occur immediately prior to menses, may cause sudden-onset severe, localized pain.

Simple Cysts

Simple cysts are benign by definition and do not require intervention. On ultrasound, they are well circumscribed, anechoic (low degree of sound reverberation), and have posterior acoustic enhancement and an absence of solid components. Often aspiration is performed to relieve discomfort, but simple, nonpainful cysts identified incidentally on ultrasound do not require intervention.

Complicated Cysts

Complicated cysts meet most, but not all, criteria for simple cysts on ultrasound examination. They may have internal echoes, fluid or debris components, and an imperceptible wall and may lack posterior acoustic enhancement. They are very rarely malignant but should be aspirated to confirm diagnosis or are followed with repeat imaging.

Complex Cysts

Complex cysts have mixed components that are both cystic and solid in nature with a thick wall and/or internal septa (thin wall or partition) and do require core biopsy to rule out malignancy. These lesions are more likely than simple or complicated cysts to be cancerous. The nurse should educate the patient as to the diagnostic workup process and provide support to alleviate anxiety (Athanasiou et al., 2014).

FIBROCYSTIC BREAST CONDITIONS

Often breast pain is attributed to fibrocystic breast changes and may be the patient's presenting complaint. Fibrocystic breast condition also can produce a transient breast mass. Both breast discomfort and breast nodularity are very common and are often a normal response to hormonal changes during the menstrual cycle, with estrogen primarily being the underlying causative factor. Pathologists also may use the term "fibrocystic" in reference to microscopic findings, such as fibrosis, adenosis, papillomatosis, ductal epithelial hyperplasia, and cysts (Giuliano & Hurvitz, 2014).

FIBROADENOMAS

Fibroadenomas are proliferative lesions without atypia (cell abnormalities) in which the underlying etiology is the estrogenic effects on breast tissue. They usually present as firm, round, movable, benign tumors that contain glandular and stromal tissue (connective tissue cells). In many cases, multiple fibroadenomas will occur in the same breast or bilaterally. They can occur from puberty to menopause and are most common from the late teens through the early 30s. Fibroadenomas usually do not require treatment. Diagnosis is best confirmed through a "triple test": clinical examination, imaging, and tissue biopsy. Fibroadenomas larger than 2 cm are more likely to persist and commonly are excised. Fibroadenomas also are sometimes excised when they are painful or when the presence of a palpable mass is too anxiety-provoking for the patient to tolerate. Patients with a negative "triple test" (nonsuspicious clinical examination, benign appearance on imaging, and benign pathology results) do not require treatment but should have short-term interval follow-up with clinical examination and age-appropriate imaging (Giuliano & Hurvitz, 2014; American Cancer Society [ACS], 2015).

ATYPICAL DUCTAL HYPERPLASIA

Atypical ductal hyperplasia (ADH) is usually an incidental finding from biopsy of a radiographic abnormality or palpable mass. It is characterized by an abnormal growth of ductal cells in the breast and the presence of atypia (structural abnormality in a cell) without either the cytologic or architectural criteria necessary for a diagnosis of ductal carcinoma in situ (DCIS). The presence of ADH increases a woman's risk for breast cancer to four to five times that of the general population. Multifocal ADH lesions can present an even higher risk for developing breast cancer (ACS, 2015; Hartmann et al., 2015).

LOBULAR CARCINOMA IN SITU

Lobular carcinoma in situ (LCIS) is characterized by an abnormal proliferation of cells within the breast lobules. LCIS is usually found incidentally from a breast biopsy as it cannot be seen mammographically and may not form a palpable mass. Actually the term is a bit misleading because this condition is not "carcinoma," or cancer. Historically, LCIS was considered a premalignant condition but is now considered more of a marker of increased risk for invasive breast cancer. The subsequent invasive carcinoma can be either ductal or lobular in origin and can develop in either breast. LCIS increases a woman's risk of breast cancer about 7 to 11 times when compared with that of the general population (ACS, 2016). Patients with LCIS should be referred to a breast cancer specialist for full discussion of treatment options due to the significantly higher risk for developing breast cancer. These options include increased surveillance, chemoprevention to reduce the risk of developing breast cancer, and consideration for enrollment in breast cancer prevention trials. Patients also may consider bilateral prophylactic mastectomy dependent upon the level of risk, family history, and other factors (Sabel, 2014; National Comprehensive Cancer Network [NCCN], 2015).

MALIGNANT CONDITIONS OF THE BREAST

Breast cancer occurs when cells in the breast change and grow out of control. Some breast cancers are in situ, meaning confined within the walls of the ducts of the breast, but the majority are invasive or infiltrating. Invasive cancers have extended through the ducts or glandular walls and invaded the surrounding breast tissue. The expected prognosis for invasive breast cancer depends largely on the extent to which it has spread when it is first diagnosed. Breast cancer is the most commonly diagnosed malignancy in women, except for nonmelanoma skin cancer. The ACS estimates that 231,840 new cases of invasive breast cancer were diagnosed in the United States in 2015 as well as an additional estimated 60,290 cases of in situ breast cancer; 39,620 women were expected to die from breast cancer in the United States in 2013. Lung cancer is the only cancer that causes more deaths in women. Although much more rare, males can develop breast cancer. In 2015, it was estimated that 2,350 men were diagnosed with breast cancer, accounting for about 1% of all breast cancer diagnoses. In 2015, there were approximately 2.8 million women living with a history of breast cancer or currently undergoing treatment for the disease (ACS, 2015; Breastcancer.org, 2015).

Risk Factors

The two most significant risk factors for developing breast cancer are being female and growing older. Eighty-five percent of women who develop breast cancer have no risk factors other than age and gender. Whereas most breast cancers are "sporadic," a small percentage (5% to 10%) are due to having an inherited genetic mutation, such as in the *BRCA1* or *BRCA2* genes. Women who carry these mutations have a lifetime risk of 41% to 90% of developing breast cancer (NCCN, 2015). Box 33-1 lists other risk factors for developing breast cancer.

Screening and Prevention

Breast cancer is primarily a disease of early detection, but it also can be one of prevention, especially in high-risk women. Though some risk factors for breast cancer are modifiable, the two greatest risk factors, being female and growing older, are not modifiable. This is why screening mammograms and prompt attention for any breast abnormality are extremely important.

Men can experience breast cancer, as well, with the risk being 1 in 1,000 males, The disease is 100 times more likely to occur in women than in men. Since it is so rare in men, they are not offered routine screening, and male breast cancer is not addressed in detail in this chapter. Any breast mass or abnormality should be evaluated in men, and male BRCA mutation carriers, due to their increased risk of developing breast cancer, are followed with increased breast cancer surveillance. Upon diagnosis, male breast cancer is treated similarly to breast cancer in females (ACS, 2015; NCCN, 2015).

Protective Factors

Women can choose to maximize their overall health by maintaining a normal weight, particularly after menopause, engaging in regular physical activity, and avoiding or limiting alcohol consumption. Women who breastfeed for an extended period of time (for a year or longer) may have some added protection. Women at high risk for breast cancer may be candidates for chemoprevention and opt to take medications such as tamoxifen, raloxifene, or exemestane to reduce their risk (ACS, 2013; NCCN, 2015).

BOX 33-1 Risk Factors for Breast Cancer

- Being a woman
- Increasing age
- Inherited genetic mutation for breast cancer, such as *BRCA1* and/or *BRCA2* or other cancer susceptibility genes
- Family history of breast cancer, particularly with a first-degree relative diagnosed with breast cancer at an early age (under 50 years of age)
- Personal history of breast cancer
- History of benign proliferative breast disease, especially those with atypia
- History of high-dose radiation therapy to the chest, such as patients who have undergone treatment for Hodgkin's disease or non-Hodgkin lymphoma
- Hormonal factors:
  - Early menarche (before 12 years of age)
  - Late menopause (after 55 years of age)
  - Nulliparity or no full-term pregnancies
  - Late age at first full-term pregnancy (after 30 years of age)
  - Recent contraceptive use

- Long-term use of estrogen and progestin (hormone replacement therapy)
- History of ovarian cancer or endometrial cancer
- Obesity, particularly postmenopausal
- Alcohol consumption
- Ashkenazi Jewish ethnicity related to *BRCA1/2* mutation carrier risk

Screening Recommendations

The ACS recommends that women at population risk for breast cancer begin annual screening mammography at age 40. Women also should have a clinical breast examination every 1 to 3 years beginning in their 20s and then annually beginning at 40 years of age, and they should practice breast self-awareness. Women who are at increased risk for breast cancer should talk with their health care provider to establish the optimal age to begin screening as women at high risk often begin clinical breast examinations and breast imaging at younger ages (ACS, 2013; NCCN, 2015).

Prevention Strategies in the High-Risk Patient

By identifying the population of women who are at highest risk for breast cancer, prevention and earlier detection are possible. Women who have risk factors should talk with their health care provider to assess their risk and implement an individualized plan for surveillance and risk reduction. The decision whether or not to undergo genetic testing and the risks and benefits of prevention strategies should be discussed in detail, weighing the potential benefits with the risks of the interventions.

Long-Term Surveillance

Some women at high risk choose a conservative approach, with more frequent or earlier screening and additional imaging modalities, such as magnetic resonance imaging (MRI). More frequent clinical breast examinations and breast self-awareness are emphasized. The NCCN Clinical Practice Guidelines in Oncology offer patient-specific recommendations for screening in this population (2015).

Chemoprevention

Chemoprevention with a variety of medications has demonstrated significant reduction in breast cancer in women at high risk. The National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial showed that treatment with tamoxifen resulted in a 49% decrease in short-term risk for breast cancer in healthy women at increased risk. Raloxifene has also demonstrated effectiveness in risk reduction and has a lower side-effect profile than tamoxifen. Both tamoxifen and raloxifene, which are categorized as selective estrogen receptor modulators (SERMs), are FDA approved for chemoprevention. Another medication, Exemestane, an aromatase inhibitor, also has demonstrated effectiveness in reducing the risk for breast cancer in healthy women who are high risk. Though its use is recognized by the NCCN and the American Society of Clinical Oncology (ASCO), exemestane is not FDA approved for that use (Visvanathan et al., 2013;

Giuliano & Hurvitz, 2014; NCCN, 2015). When considering chemoprevention, the risks and benefits should be weighed carefully by the patient and her health care provider.

Prophylactic Mastectomy

Prophylactic bilateral total mastectomy is an option for carefully selected women with significant breast cancer risk and/or extreme anxiety associated with potential diagnosis. This surgery as a method of breast cancer prevention has demonstrated a significant risk reduction in women who are known to have *BRCA1* or *BRCA2* mutations. The decision to undergo prophylactic mastectomy should be made carefully and with the input of the multidisciplinary team. All breast tissue should be removed, but lymph node dissection is not necessary unless breast cancer is detected upon pathologic examination of the tissue (NCCN, 2015).

Clinical Manifestations

Breast cancers can occur anywhere in the breast but usually are found in the upper outer quadrant, where the most breast tissue is located. In general, the lesions are nontender, tend to be fixed rather than mobile, and may be harder with irregular borders.

With the increased use of screening mammography, more women are being diagnosed early and are seeking treatment for earlier-stage disease. These women often present with no signs or symptoms other than having a mammographic abnormality. Unfortunately, some women seek initial treatment after ignoring symptoms. Oftentimes, those women present with advanced stage disease. Advanced signs may include skin dimpling, nipple retraction, or skin ulceration.

Breast Imaging

Breast imaging includes all of the radiographic imaging modalities used to detect and diagnose breast abnormalities and diseases. Mammography is the most common imaging modality and has improved dramatically over the past several decades. Other common imaging modalities include ultrasound and MRI.

Mammography

Mammography is a specific type of radiographic imaging that utilizes low-dose x-ray for examination of the breasts. Mammography is the best and most universally accepted screening tool available to detect breast cancer at its earliest and most treatable stages, and it is currently the only imaging modality recommended for routine breast cancer screening in the general population.

There are two types of mammograms: screening and diagnostic. Screening mammograms are for routine use at recommended intervals to detect unanticipated breast cancer in asymptomatic women. Screening mammography must be performed on a regular basis in order to reduce breast cancer mortality. Diagnostic mammograms are performed either when a radiographic abnormality is detected on a screening mammogram or when the patient or her caregiver notices a change or a problem in her breast. Also mammography is used to assist in interventional breast procedures, such as stereotactic breast biopsy and needle localization.

Newer, digital mammography techniques provide dramatic improvements in the visualization of lesions for interpreting physicians and greater ease of examination for the patient.

The mammography examination takes only a few minutes and has minimal radiation exposure. During a mammogram, the breast is manually compressed in the mammography unit by a registered mammography technologist in two different views: the craniocaudal view (compression from top to bottom) and the mediolateral oblique view (from side to side). Other views may be obtained when a patient has a palpable or image-detected abnormality requiring more focused or directed examination. The nurse should educate the patient on the importance of regular screening mammography, immediate pursuit of attention upon discovery of any palpable abnormality, and the availability of comfort options, such as disposable foam pads to ease discomfort during compression.

Ultrasound

Ultrasonography (ultrasound) is used as a screening or diagnostic adjunct to mammography. The procedure consists of a thin coating of lubricating jelly spread over the area to be imaged. Then a transducer is placed on the breast. The transducer transmits high-frequency sound waves through the skin toward the area of concern. The sound waves that are reflected back form a two-dimensional image, which is then displayed on a computer screen. No radiation is emitted during the procedure. The technique is used often to determine if a mass is cystic versus solid but cannot rule out malignant lesions definitively. Due to its limited specificity, ultrasound should not be used for routine screening but has recently been advocated as a valuable screening tool in women who have

mammographically dense breasts (ACS, 2015).

Magnetic Resonance Imaging

MRI of the breast produces very detailed cross-sectional images using magnetic fields rather than x-rays. An IV injection of gadolinium, a contrast dye, is given to improve visibility. The patient lies face down and the breast is placed through a depression in the table. A coil is placed around the breast, and the patient is placed inside the MRI machine. The entire procedure takes about 30 to 40 minutes.

MRI is most useful in patients with proven breast cancer, when assessing for multifocal (more than one tumor in the same quadrant of the breast) or multicentric (more than one tumor in different quadrants of the breast), or bilateral disease, chest wall involvement, tumor recurrence, or response to chemotherapy. The procedure also can identify occult (undetectable) breast cancer and determine the integrity of saline or silicone breast implants. It is not recommended for routine screening in the general population, but it is recommended for individuals who have a lifetime risk of greater than 20% to 25% based on predictive models, who have a known or suspected genetic predisposition to breast cancer, or those with other elevating risk factors, such as prior radiation exposure. The risks of false-positive and false-negative examination results should be addressed, and MRI screening should be performed after a detailed discussion with the patient (Giuliano & Hurvitz, 2014).

Some disadvantages of MRI include high cost, variations in technique and interpretation, and the potential for patient claustrophobia. Breast MRI is highly sensitive but has low specificity so the procedure cannot always distinguish between malignant and benign breast conditions accurately. MRI is contraindicated in patients with implantable metal devices, such as aneurysm clips, pacemakers, and ports of tissue expanders, because of the magnetic force acting on metallic objects. Foil-backed medication patches should be removed prior to MRI to avoid burns to the skin (Giuliano & Hurvitz, 2014).

Breast Biopsy

Percutaneous needle biopsy, either by fine-needle aspiration (FNA) or by tissue core biopsy, is the simplest biopsy technique and should always be the first modality considered for breast tissue sampling. This type of biopsy allows for definitive diagnosis with lower morbidity than open surgical biopsy and a lower cost for the procedure. The nurse educates the patient prior to the procedure, answers questions, and offers emotional support.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is a noninvasive biopsy technique that is generally well tolerated by most women. A local anesthetic may or may not be used. For palpable masses, a surgeon performs the procedure. A small-gauge needle (25- or 22-gauge) attached to a syringe is inserted into the mass or area of nodularity. Suction is applied to the syringe, and multiple passes are made through the mass. A simple cyst often disappears on aspiration, and the fluid is usually discarded, though it may be sent for pathologic examination. If no fluid is obtained on aspiration, then any cellular material obtained in the hub of the needle is spread on a glass slide or placed in a preservative and sent to the laboratory for analysis. For nonpalpable masses, the same procedure can be performed by a radiologist or surgeon using ultrasound guidance.

FNA is less expensive than other diagnostic methods, and usually results are available quickly; however, due to risk of a false-negative result, close clinical correlation is necessary (Giuliano & Hurvitz, 2014).

Ultrasound-Guided Breast Biopsy

Ultrasound-guided breast biopsy is a minimally invasive procedure wherein the physician uses the ultrasound to visualize the lesions and guide the needle for sampling (Fig. 33-1). It is the preferred biopsy modality for all lesions visible by ultrasound. For the procedure, the patient lies supine on a table and the physician inserts a needle to obtain specimens after thoroughly cleaning the skin, injecting subcutaneous analgesia such as lidocaine, and making a small nick in the skin. The needle may or may not have vacuum assistance to help obtain adequate specimens. The biopsy needle is typically 12- to 18-gauge without vacuum assistance and 7- to 12-gauge with vacuum assistance. Several tissue samples are obtained and sent to the laboratory for analysis. A small titanium clip should be placed in the biopsy cavity for documentation of correct sampling site, for future mammogram evaluation, and for locating the site should further treatment be warranted.

FIGURE 33-1 Ultrasound-guided breast biopsy. (Courtesy of Mammotome.)

FIGURE 33-2 Stereotactic breast biopsy. (Courtesy of Mammotome.)

Stereotactic Breast Biopsy

Stereotactic core biopsy is another minimally invasive procedure that uses x-ray guidance to obtain breast tissue samples (Fig. 33-2). It is the preferred biopsy modality for microcalcifications and lesions not visible by ultrasound. The patient lies prone on the stereotactic table, and the breast is suspended through an opening and compressed between two x-ray plates. Digital mammography images are obtained, and the exact coordinates of

the lesion to be sampled are located with the aid of a computer. After sterilizing the skin, a local anesthetic is injected into the entry site on the breast. A small nick is made in the skin, a core needle is inserted, and samples of the tissue are taken for pathologic examination. Often, several passes are taken to ensure adequate tissue sampling. Clip placement is necessary for this type of biopsy as well.

Magnetic Resonance Imaging–Guided Breast Biopsy

MRI-guided breast biopsy is logistically similar to stereotactic biopsy and is used increasingly for lesions that cannot be visualized under mammography or ultrasound. Special concern is necessary for equipment safety in the magnetic field, and MRI-specific biopsy equipment is used.

Surgical Biopsy

When minimally invasive breast biopsy is not feasible, an excisional or surgical biopsy may be used to remove an entire lesion and a surrounding margin of breast tissue that appears normal. This type of biopsy also may be referred to as a *lumpectomy*. Depending on the clinical situation, a frozen-section analysis of the specimen may be performed at the time of the biopsy by the pathologist, who does an immediate intraoperative reading and provides a provisional diagnosis. Surgical biopsy is usually performed using local anesthesia and IV sedation and often follows *wire needle localization*, wherein mammography or ultrasonography are used to locate the lesion and place a guidewire through the skin and into the area of suspicion. Then the surgeon may follow the guidewire down to the lesion for precise removal and minimal tissue loss.

The nurse plays an important role in surgical breast biopsy. During the preoperative visit, the nurse assesses the patient for specific educational, physical, or psychosocial needs. The nurse should review medical and psychosocial history and facilitate conversation regarding fears, concerns, and questions. Often patients are worried not only about the procedure but also about the potential implications of the pathology results. The nurse should provide a thorough explanation and written materials to reinforce education.

The patient should discontinue any anticoagulant therapy prior to the procedure. The patient may be instructed not to eat or drink for several hours or after midnight the night before the procedure, depending on the type of biopsy planned. Most breast biopsy procedures today are performed with the use of moderate sedation and local anesthesia.

Immediate postoperative assessment includes monitoring the effects of the anesthesia and inspecting the surgical dressing for any signs of bleeding. Once the sedation has worn off, the nurse reviews the care of the biopsy site, pain management, and activity restrictions with the patient. Prior to discharge from the ambulatory surgical center or the office, the patient must be able to tolerate fluids, ambulate, and void. The patient must have someone to drive her home. Usually the dressing covering the incision is removed after 48 hours, but the Steri-Strips, which are applied directly over the incision, should remain in place for approximately 7 to 10 days. The use of a supportive bra following surgery is encouraged to limit movement of the breast and to reduce discomfort. A follow-up telephone call from the nurse 24 to 48 hours after the procedure can provide the patient with the opportunity to ask any questions and can be a source of great comfort and reassurance.

Most women return to their usual activities the day after the procedure but are

encouraged to avoid jarring or high-impact activities for 1 week to promote healing of the biopsy site. Usually discomfort is minimal, and most women find acetaminophen sufficient for pain relief, although a mild opioid may be prescribed if needed. Follow-up after the biopsy includes a return visit to the surgeon for discussion of the final pathology report and assessment of the healing of the biopsy site.

Staging

There are three primary staging systems for cancer. The most clinically relevant, the American Joint Committee on Cancer (AJCC)'s TNM system classifies tumors using information on the size of the tumor and the extent of spread within the breast (T), involvement in lymph nodes (N), and spread to distant organs (M). Refer to Chapter 6 for more information on staging of cancer. This staging system is used very commonly in clinical settings and assigns a stage of I, II, III, or IV according to the determined T, N, and M classification. Stage I indicates an early-stage breast cancer, and IV indicates the most advanced. The Extent of Disease system used by the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program and the Summary Stage system are other classification systems that are used most often in data reporting and state tumor registries (Le-Petross & Caudle, 2015).

Prognosis

The two most important prognostic factors associated with breast cancer are tumor size and axillary lymph node involvement.

In general, a smaller tumor is associated with a better prognosis. Prognosis also depends on the extent that the breast cancer has spread. Women who are diagnosed at a more advanced stage have a lower 5-year relative survival rate, as do women with larger tumor size at diagnosis. The 5-year relative survival rate for localized disease (stages 0–I) is near or equal to 100%, for regional disease (stages II–III) it is 72% to 93%, and for distant-stage disease (stage IV) it is 22% (ACS, 2015). The most common route of regional spread is to the axillary lymph nodes (Fig. 33-3). Other sites of lymphatic spread include the internal mammary and supraclavicular nodes. Distant metastasis can affect any organ, but the most common sites are bone, lung, liver, pleura, adrenals, skin, and brain. Amplification of certain genes, such as *HER2/neu* (discussed later in this chapter), or excessive amounts of their protein product may represent a poorer prognosis. Box 33-2 lists other prognostic factors.

Types

Ductal Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is characterized by the proliferation of malignant cells inside the milk ducts without invasion into the surrounding tissue. Frequently DCIS is manifested on a mammogram with the appearance of calcifications, and it is considered stage 0 breast cancer. Treatment options include breast-conserving surgery and radiation therapy with or without tamoxifen, total mastectomy with or without tamoxifen, and breast-conserving surgery without radiation therapy (NCI, 2015).

Infiltrating Ductal Carcinoma

Infiltrating ductal carcinoma (IDC), the most common histologic type of breast cancer, accounts for 80% of all cases. The tumors arise from the duct system and invade the surrounding tissues. They often present as a solid mass in the breast.

Infiltrating Lobular Carcinoma

Infiltrating lobular carcinoma (ILC) accounts for approximately 10% of breast cancers and is the second most common type of breast cancer after IDC. These tumors arise from the lobular epithelium and typically occur as an area of ill-defined thickening in the breast. They are often multicentric and can be bilateral.

Medullary Carcinoma of the Breast

Medullary carcinoma is a rare subtype of IDC and accounts for about 5% of breast cancers. It tends to be diagnosed more often in women in their 40s to early 50s. The tumor is usually a soft, fleshy mass that tends to be low grade, and it is not likely to spread outside of the breast tissue. Because of this, the prognosis is often favorable.

Medical and Nursing Management

A multidisciplinary team approach to treatment for breast cancer allows for an individualized plan of care based upon careful consideration of the optimal treatment for the stage and biologic characteristics of the tumor; the patient's personal preference, performance status, and age; and the potential risks and benefits of all treatment options. Treatment decisions should be made by the patient and her physician. Most women who are diagnosed with breast cancer will undergo some type of surgery, and many also will have radiation therapy, chemotherapy, hormone therapy, and/or biologic therapy. The treatment guidelines for breast cancer are available via free registration from the NCCN at nccn.org/professionals/physician_gls/PDF/breast.pdf (NCCN, 2017).

Surgical Management

The primary goal of surgery is to obtain local control of the disease by removing the cancer from the breast and to determine the stage and extent of disease. Because breast cancer is now diagnosable at earlier stages, options for less invasive surgical procedures are available.

Procedures

Lumpectomy. In a lumpectomy, the surgeon removes the cancerous tissue and a border of normal tissue. This usually follows a wire needle localization procedure to mark the tumor or the metallic clip left from the biopsy. Patients who undergo lumpectomy almost always undergo 5 to 7 weeks of radiation therapy afterward. Patients who have a lumpectomy or breast conservation surgery followed by radiation therapy have the same predicted long-term survival as patients who choose to undergo mastectomy (Giuliano & Hurvitz, 2014). Appropriate patient selection is critical when planning surgical intervention. A woman who undergoes lumpectomy also may have regional lymph nodes removed to determine if the cancer has spread beyond the breast.

BOX 33-2 Factors Affecting Prognosis for Breast Cancer

- Age and menopausal status of the patient
- Stage of disease
- Histologic and nuclear grade of the primary tumor
- Estrogen and progesterone receptor status of the primary tumor
- Proliferative capacity of the tumor
- *HER2/neu* gene amplification

From *Breast Cancer Treatment*, NCI. https://www.cancer.gov/types/breast/patient/breast-treatment-pdq

Simple Mastectomy. In a simple or total mastectomy, the entire breast and nipple–areola complex (NAC) are removed, without axillary lymph node dissection (ALND). Total mastectomy may be performed for patients with noninvasive breast cancer, or DCIS, which does not have a tendency to spread to the lymph nodes. It also may be performed prophylactically for patients who are at high risk for breast cancer. Also a total mastectomy may be performed in conjunction with sentinel lymph node biopsy (SLNB) for patients with invasive breast cancer.

BOX 33-3 Patient Education

Hand and Arm Care After Axillary Lymph Node Dissection (ALND)

- Avoid blood pressures, injections, and blood draws in the affected extremity.
- Use sunscreen (at least 15 SPF) for extended exposure to sun.
- Apply insect repellent to avoid insect bites.
- Wear gloves for gardening.
- Use a cooking mitt for removing objects from the oven.
- Avoid cutting the cuticles; push them back during manicures.
- Use an electric razor for shaving the armpit.
- Avoid lifting objects greater than 5–10 lb. Patients should avoid too much increased pressure on the arm (e.g., heavy purse).
- Avoid tight jewelry, clothing, or elastic bandages on the affected arm.
- Avoid chemical hair removers under the affected arm, and avoid nicks and cuts if removing underarm hair.
- If a trauma or break in the skin occurs, wash the area with soap and water, and apply an OTC antibacterial ointment (Bacitracin or Neosporin).
- Observe the area and extremity for 24 hours; if redness, swelling, or a fever occurs, call the surgeon or nurse.

Modified Radical Mastectomy. Modified radical mastectomy is performed to treat invasive breast cancer. The procedure involves removal of the entire breast tissue, including the NAC. In addition, a portion of the axillary lymph nodes are removed (ALND). Box 33-3 discusses hand and arm care after ALND.

If immediate breast reconstruction is desired, the patient is referred to a plastic surgeon prior to the mastectomy so that she has the opportunity to explore all available options. In modified radical mastectomy, the pectoralis major and pectoralis minor muscles are left intact, unlike in radical mastectomy, in which the muscles are removed.

Radical Mastectomy. Radical mastectomy includes removal of the entire breast and lymph nodes under the arm as well as removal of the underlying pectoralis major and minor muscles. This technique is currently used very rarely due to the proven effectiveness and significantly decreased morbidity associated with less aggressive procedures, such as

modified radical mastectomy, total mastectomy, and lumpectomy.

Newer mastectomy techniques, including skin-sparing and NAC sparing, are gaining popularity as the cosmetic outcome is often favorable compared to traditional mastectomy procedures. However, these techniques are not appropriate for everyone and require a careful evaluation and discussion between the patient and her surgeon.

Breast Conservation Therapy. The goal of breast conservation treatment, including lumpectomy, wide excision, partial or segmental mastectomy, and quadrantectomy (one quarter of the breast tissue removed) is to excise the tumor in the breast completely and obtain clear margins while achieving an acceptable cosmetic result. If the procedure is being performed to treat a noninvasive breast cancer, lymph node removal is not necessary. For an invasive breast cancer, lymph node removal is indicated. The lymph nodes are removed through a separate semicircular incision in the axilla. Breast conservation along with radiation therapy in stage I and stage II breast cancer has demonstrated survival rates equal to that of modified radical mastectomy.

Sentinel Lymph Node Biopsy. SLNB is used for pathologic axillary staging for patients with breast cancer. The sentinel lymph nodes are the first nodes in the lymphatic basin to receive drainage from the primary tumor in the breast and are identified by injecting a radioactive tracer, blue dye, or both around the tumor in the breast. The tracer travels via the lymphatic pathways to the sentinel nodes. The surgeon locates the nodes, excises them, and sends them for pathologic analysis. If cancer cells are present in the sentinel nodes, the likelihood of cancer in other lymph nodes is high so the surgeon performs a complete ALND. If the sentinel lymph nodes are free of cancer, ALND is not necessary. SLNB is considered best practice, and it is the standard of care for staging invasive breast cancer as it is accurate and spares patients considerable morbidity and sequelae associated with complete dissection. Figure 33-3 shows the lymphatic drainage of the breast.

Although SLNB is a less invasive procedure than ALND and results in a shorter recovery period, a patient who has undergone SLNB still may experience complications, such as lymphedema, related to the procedure. The nurse's role is to listen to the patient's concerns, provide emotional support, and refer the patient to appropriate specialists when indicated.

Complications for the Surgical Patient

Lymphedema. Lymphedema results from impaired flow of lymph fluid through the draining lymphatic vessels after lymph node dissection. An accumulation of lymph fluid develops in the surrounding and dependent tissues, leading to swelling, fibrosis of the soft tissues, neurologic complications such as pain and paresthesias, and infection. Continuous assessment and early identification of signs and symptoms of lymphedema should be integral in the care of patients undergoing therapy for breast cancer. Risk for lymphedema depends on the type of therapy received and is more common in patients who undergo ALND. Referral to a lymphedema specialist is key to management of this complication (ACS, 2013).

Nursing Alert

To prevent lymphedema or lymphangitis (infection of the lymph vessels), nurses should place a

sign above the bed of a patient following mastectomy or node dissection not to perform blood pressures, blood draws, injections, or IV insertions on the side where the operation was performed. Lymphatic drainage is altered due to node dissection, causing the potential for fluid to accumulate in the affected extremity. Complications of infiltration, phlebitis, or trauma can result if the affected extremity is used. Some patients will obtain a medical alert bracelet with this warning.

Hematoma and Seroma Formation. Hematoma, a collection of blood inside the surgical cavity, may occur after either mastectomy or breast conservation and usually develops within the first 12 hours after surgery. The nurse assesses for signs and symptoms of hematoma at the surgical site, which may include swelling, tightness, pain, and bruising of the skin. The surgeon should be notified immediately for gross swelling or increased bloody output from the drain, typically a Jackson Pratt. While most hematomas are small and resolve without intervention, some must be evacuated surgically. Refer to Box 33-4 for drain care.

A seroma, a collection of serous fluid, may accumulate under the breast incision after mastectomy or breast conservation or in the axilla. Signs and symptoms include swelling, heaviness, discomfort, and a sloshing of fluid. Seromas may develop temporarily after the drain is removed or if the drain is in place and becomes obstructed. Seromas rarely pose a threat and the surgeon or health care provider may unclog the drain or manually aspirate the fluid with a needle and syringe.

Infection. Infection is a risk after any surgical procedure. This risk may be higher in patients with accompanying conditions, such as diabetes, immune disorders, and advanced age, as well as in those with poor hygiene. Patients are taught to monitor for signs and symptoms of infection, such as redness, warmth around the incision, tenderness, foul-smelling drainage, temperature greater than 100.4°F, and chills and to contact the surgeon or nurse for evaluation should they notice any of these. For more severe infections, treatment consists of oral or IV antibiotics for 1 or 2 weeks.

Nursing management for patients undergoing surgery is discussed in the nursing process section later in this chapter.

Reconstructive Surgery

A variety of reconstructive options is available today for women who desire a correction in the size or the shape of the breast, including reduction mammoplasty, augmentation mammoplasty, and mastopexy (discussed shortly). Several options are also available to reconstruct the breast after a mastectomy.

Reconstructive Surgeries for Lumpectomy. Reconstructive surgeries include reduction mammoplasty, augmentation mammoplasty, and mastopexy.

Usually reduction mammoplasty is performed on women who have large breasts. It is an outpatient procedure that is performed under general anesthesia. Most commonly, an anchor-shaped incision that circles the areola is made, extending downward and following the natural curve of the inframammary fold. Depending on the size of the breast, the nipple may be moved up to a higher position while still attached to the breast tissue, or it may be separated and transplanted to a new location. Drains are placed in the incision and remain

for 2 to 5 days.

Augmentation mammoplasty is performed on women who desire larger or fuller breasts. Usually this procedure is performed by placing a silicone or saline breast implant under the pectoralis muscle. The incision line can be placed in the inframammary fold, in the axilla, or around the areola. The procedure is performed as an outpatient procedure under general anesthesia. A drain is not necessary.

Mastopexy is performed when the patient is content with the size of her breasts but wishes to have the shape improved and a lift performed. The procedure is also an outpatient surgery.

Reconstructive Procedures After Mastectomy. Breast reconstruction can provide a significant psychological benefit for women who are already struggling with the emotional distress of losing a breast. A consultation with a plastic surgeon can help the patient understand procedures for which she is a candidate and the pros and cons of each option. Factors to consider include body size and shape; comorbidities, such as hypertension, diabetes mellitus, or obesity; personal habits, such as smoking; and patient preference. The patient must be informed that although breast reconstruction can provide a good cosmetic result, it will never precisely duplicate the natural breast. Realistic preparation can help the patient avoid unrealistic expectations. Reconstruction is considered an integral component in the surgical treatment of breast cancer and is usually covered by insurance companies.

Many women elect immediate reconstruction at the time of the mastectomy operation. Delayed reconstruction may be preferable to women who are having a difficult time deciding on whether reconstruction is desired at all or if they are unsure as to the type of reconstruction they prefer. In patients with advanced disease, such as in inflammatory breast cancer, treatments should be given without delay so immediate reconstruction is not recommended. Delays in healing after immediate reconstruction may interfere with the initiation of treatment, particularly radiation therapy.

BOX 33-4 Surgical Breast Cancer Patient with a Drainage Device

A drain is placed in the surgical wound at the time of surgery to evacuate drainage from the surgical site. The tubing has multiple perforations on the distal end (in the wound site), and the tubing is attached to a device externally that collects the drainage. Suction is maintained by compression of the device. Usually the drain is sutured to the skin. The typical device used for breast surgery is called a *Jackson Pratt* (JP), a bulb-like device (see the figure below).

The nurse and patient or caregiver are aware that the device must be compressed to maintain suction at the wound bed. If the device is inflated fully, it must be emptied to maintain the vacuum necessary to facilitate drainage away from the wound bed.

The nurse explains the procedure to the patient and/or caregiver, brings a measuring device such as an ounce medicine cup (if limited drainage is expected) or a graduated cylinder, and explains the importance of hand washing before the procedure (maximum capacity of the JP is approximately 100 mL). Nonsterile gloves are donned.

The JP drainage device is unclipped from the patient's gown, and, using sterile technique, the spout plug is opened on the JP bulb. The device will expand fully since the suction has been released (image above reveals fully expanded JP; no vacuum exists). The nurse is careful not to touch the inside of the spout or plug and teaches this to the patient and/or caregiver. The device is emptied by turning the bulb over and squeezing the bulb so that the contents can escape from the device. The amount and appearance of the drainage is recorded. The JP bulb is NEVER squeezed unless the spout plug is released.

An alcohol wipe can be used to clean the spout and plug. Maintaining sterile technique, the JP is compressed completely flat with one hand, and, while compression is maintained, the plug is reattached with the other hand.

The nurse is aware that the system must be airtight to function. If rapid reinflation is noted after plugging the spout, an air leak should be suspected; the nurse attempts to compress and plug the device again and if the device remains inflated, the provider should be notified. The nurse secures the device to the patient's gown, below the

wound (to facilitate drainage) to prevent pulling on the wound site and/or potential dislodgment. The nurse removes and discards gloves and washes hands thoroughly.

If multiple drains are used, they are labeled numerically (1, 2) or alphabetically (a, b), and drainage per drain is recorded as deemed by institutional policy or surgeon protocol.

Depending on surgeon preference and quality of the drainage, the patient may be instructed on how to "milk clots" through the tubing of the drainage device, which requires gentle compression of the tubing between the thumb and index finger while stabilizing the exit site to prevent dislodgment of the tubing with the nondominant hand. Holding the tube securely above the obstruction is necessary to avoid pulling the tube out of the incision. *Note: This is only done depending on surgeon preference.*

The nurse teaches the patient and/or caregiver which observations of the drain site require contacting the physician or nurse (e.g., sudden change in color of drainage, sudden cessation of drainage, signs or symptoms of an infection) as per the surgeon's recommendation.

The nurse reinforces that the drain is typically ready for removal by the surgeon when draining is less than 30 mL for a 24-hour period.

Tissue Expander Followed by Permanent Implant. Breast reconstruction using a tissue expander followed by a permanent implant is commonly used. To accommodate an implant, the skin remaining after a mastectomy and the underlying muscle must be stretched gradually by a process called *tissue expansion.* The surgeon places a balloon-like device through the mastectomy incision underneath the pectoralis muscle. A small amount of saline is injected through a metal port intraoperatively to partially inflate the expander, followed by additional saline injections through the port at weekly intervals until the expander is fully inflated. It remains fully expanded for about 6 weeks to allow the skin to loosen. Then the expander is exchanged for a permanent implant.

Advantages are a shorter operating time and a shorter recuperation period than for autologous (using the patient's own tissue) reconstruction. A disadvantage is a tendency for the implant to feel firm and round, with little natural ptosis, or sag. Women with a small to medium contralateral breast with little ptosis are good candidates for this procedure. Women who have had prior radiation or who have connective tissue disease are not good candidates because of the decreased elasticity of the skin.

The patient may be instructed not to have an MRI while the tissue expander is in place as often the port contains metal. This is not an issue once the permanent implant is in place. Figure 33-4 shows breast reconstruction with a tissue expander.

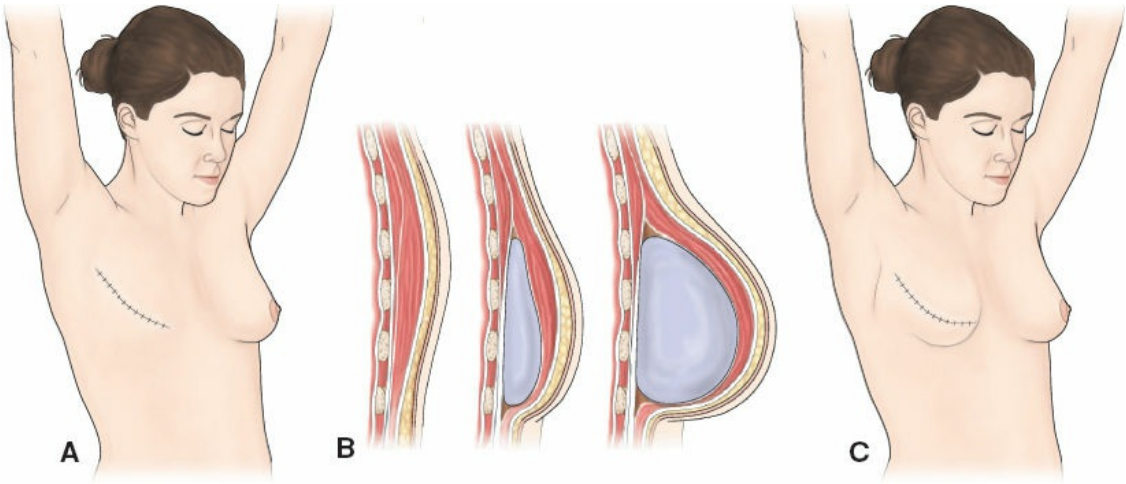

FIGURE 33-4 Breast reconstruction with tissue expander. A. Mastectomy incision line prior to tissue expansion. B. The expander is placed under the pectoralis muscle and is filled gradually with saline solution through a port to stretch the skin enough to accept a permanent implant. C. The breast mound is restored. Although permanent, scars will fade with time. The nipple and areola are reconstructed later. (Adapted from American Society of Plastic and Reconstructive Surgeons. *Breast reconstruction*. Arlington Heights, IL: Author.)

Tissue Transfer Procedures. Autologous reconstruction is the use of the patient's own tissue to create a breast mound. A flap of skin, fat, and muscle with its attached blood supply is rotated to the mastectomy site to create a mound that simulates the breast. Donor sites may include the transverse rectus abdominis myocutaneous (TRAM) flap (Fig. 33-5), gluteal flap, or the latissimus dorsi flap (Fig. 33-6). The results more closely resemble a real breast because the skin and fat from the donor sites are similar in consistency to a natural breast. These procedures are far more complex and involve longer recuperation than a procedure with a tissue expander. The risk for potential complications, such as infection, bleeding, and flap necrosis, is also greater.

The TRAM flap is the tissue transfer procedure that is performed most commonly. This involves completely detaching the skin, fat, muscle, and blood supply from the body and then transplanting them to the mastectomy site using microvascular surgery. Postoperatively, patients who have undergone TRAM procedures often face a lengthy recovery of 8 to 10 weeks and have incisions both at the mastectomy site and at the donor site in the abdomen. The nurse must assess the newly constructed breast site for changes in color, circulation, and temperature because flap loss is a potential complication. Mottling or an obvious decrease in skin temperature is reported to the surgeon immediately. Breathing and leg exercises are essential because the patient is more limited in her activity and is at greater risk for respiratory complications and deep vein thrombosis (DVT). Measures to help the patient reduce tension on the abdominal incision during the first postoperative week include elevating the head of the bed 45 degrees. Once the patient is able to ambulate, she can protect the surgical incision by splinting it and gradually will achieve a more upright position. The patient is instructed to avoid high-impact activities and lifting to prevent stress on the incision.

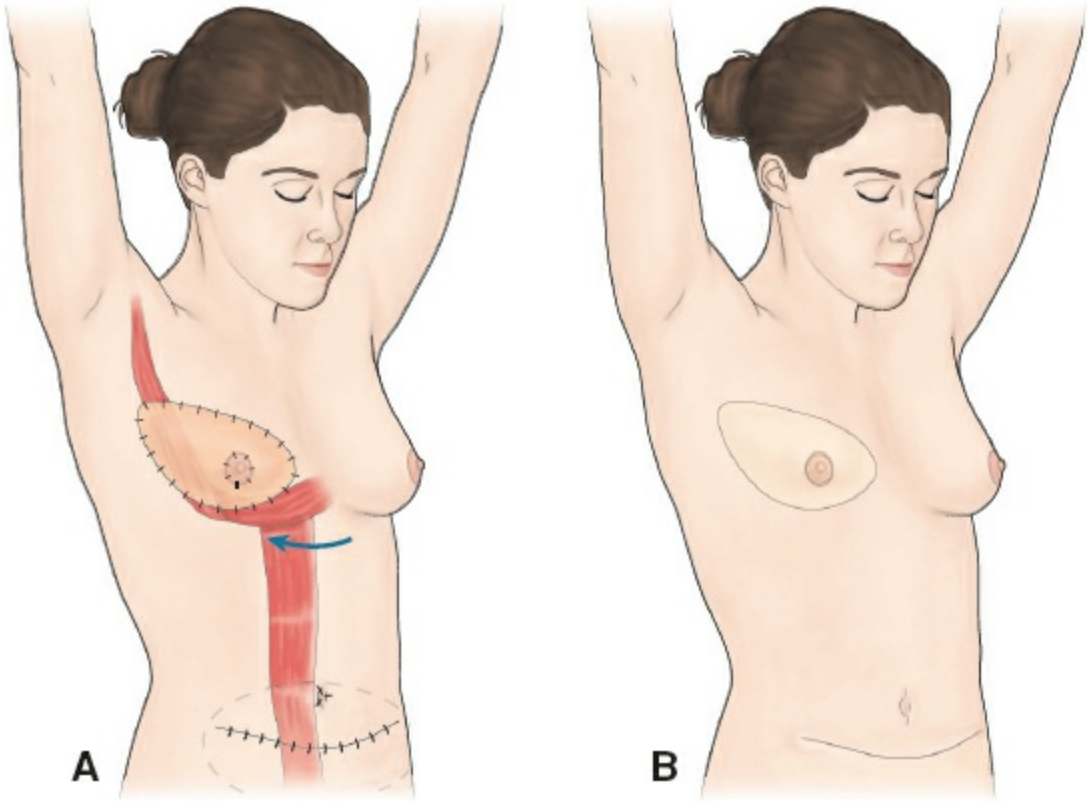

FIGURE 33-5 Breast reconstruction: transverse rectus abdominis myocutaneous (TRAM) flap. A. A breast mound is created by tunneling abdominal skin, fat, and muscle to the mastectomy site. B. Final location of scars. (Adapted from American Society of Plastic and Reconstructive Surgeons. *Breast reconstruction.* Arlington Heights, IL: Author.)

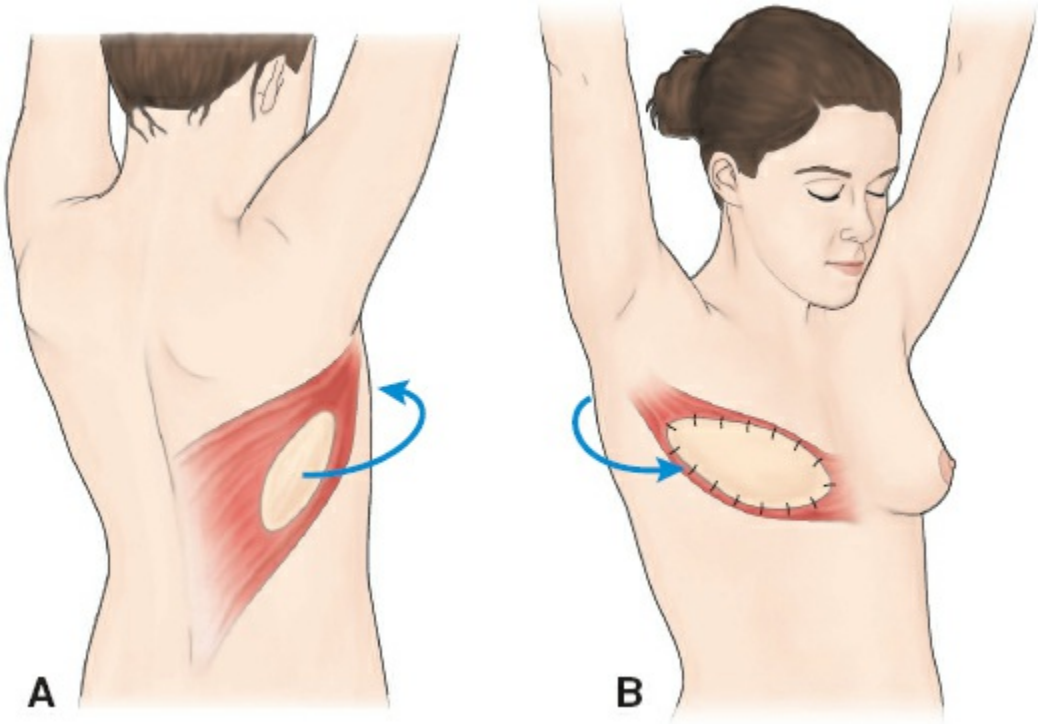

FIGURE 33-6 Breast reconstruction: latissimus dorsi flap. A. The latissimus muscle with an ellipse of skin is rotated from the back to the mastectomy site. B. Because the flap usually is not bulky enough to provide an adequate breast mound, often an implant is also required. (Adapted from American Society

of Plastic and Reconstructive Surgeons. *Breast reconstruction*. Arlington Heights, IL: Author.)

Nipple–Areolar Reconstruction. After the breast mound has been created and the site has healed, some women choose to have nipple–areolar reconstruction. This is a minor surgical procedure carried out either in the physician's office or at an outpatient surgical facility. The most common method of creating a nipple is with the use of local flaps of skin and fat from the center of the new breast mound, which are wrapped around each other to create a projecting nipple. The areola is created using a skin graft. The most common donor site is the upper inner thigh, because this skin has darker pigmentation than the skin on the reconstructed breast. After the nipple graft has healed, micropigmentation or tattooing can be performed to achieve a more natural color. Usually the surgeon can match the reconstructed nipple–areola complex with that of the contralateral breast for an acceptable cosmetic result.

Prosthetics. A breast prosthesis, an external form that simulates the breast, is an option for women who are not candidates for or do not desire breast reconstruction. Prosthetics are available in different shapes, sizes, colors, and materials and can be placed inside a bra.

Prior to discharge from the hospital, the nurse usually provides the patient with a temporary, lightweight, cotton-filled form that can be worn until the surgical incision is well healed. Then the patient can be fitted for a prosthesis. Insurance companies generally cover the cost of the prosthesis and the special bras that hold it in place. A breast prosthesis can provide a psychological benefit and assist the woman in resuming proper posture by balancing the weight of the remaining breast.

Radiation

Patients may undergo radiation therapy to destroy any residual microscopic cancer cells in the breast, the chest wall, axilla, internal mammary, or supraclavicular nodes following surgery.

Breast conservation treatment followed by radiation therapy for stage I and II breast cancer results in a survival rate equal to that of a modified radical mastectomy. If radiation therapy, a component of breast conservation treatment, were contraindicated, then a mastectomy would be indicated. Also radiation treatment is recommended after mastectomy in women whose breast cancer tumors were large (greater than 5 cm) or when the lymph nodes were involved.

Types

Patients may undergo external beam radiation (EBR) therapy or internal radiation, also known as brachytherapy.

External Beam Radiation. EBR typically begins about 6 weeks after breast conservation surgery to allow the surgical site to heal. If systemic chemotherapy is indicated, radiation therapy usually begins after its completion. Before radiation begins, the patient undergoes a planning session called a *simulation*, in which the anatomic areas to be treated are mapped out and then identified with small permanent ink markings. EBR delivers high-energy photons from a linear accelerator and usually is administered to the entire breast region. Each treatment lasts only a few minutes and generally is given 5 days a week for 5 to 7

weeks. In women whose surgery consisted of breast conservation, after completion of radiation to the entire breast, many patients receive a "boost," a dose of radiation to the lumpectomy site where the cancer was removed. If a mastectomy was performed, radiation treatments are targeted at the chest wall. The treatments are not painful.

Accelerated breast irradiation is a newer technique that is gaining favor. It is similar to standard EBR, but it is given at a slightly higher dose over a 3-week period as opposed to 5 to 6 weeks. Breast cancer recurrence rates at 10 years are equal in both groups. Even more accelerated approaches in radiation treatment are being implemented in some settings. These include even larger doses of radiation over a 5-day period as well as intraoperative radiation therapy (IORT), which is single-dose treatment given in the operating room after lumpectomy is performed.

Internal Radiation Therapy. Internal radiation therapy, or brachytherapy, involves inserting a radioactive substance sealed in needles, seeds, catheters, or wires directly into the breast. MammoSite, Savi, Axxent, and Contura are varieties of internal radiation treatment options in which radiation is administered twice a day over a 5-day period.

Some patients receive both internal and external radiation. The type of radiation and the frequency depend on the classification, stage, and location of the tumor (ACS, 2015; Giuliano & Hurvitz, 2014).

Nursing Management of the Patient Undergoing Radiation Therapy

In general, radiation therapy is well tolerated. Acute side effects consist of mild to moderate erythema, breast edema, and fatigue. Occasionally, skin breakdown may occur in the inframammary fold or near the axilla toward the end of treatment. Frequent trips to the radiation oncology unit for treatment can exacerbate fatigue and may be accompanied by depression. The patient needs to be reassured that the fatigue is normal and not a sign of recurrence. Side effects usually resolve within a few weeks to a few months after treatment is completed. Rare long-term effects of radiation therapy include pneumonitis, rib fracture, breast fibrosis, and lymphedema (if radiation treatment also included the axilla).

Self-care instructions for patients receiving radiation are provided to assist in the maintenance of skin integrity during the treatments and for several weeks after completion. They pertain only to the area being treated and not to the rest of the body.

- Use mild soap with minimal rubbing.
- Avoid perfumed soaps or deodorants.
- Use hydrophilic lotions (Lubriderm, Eucerin, Aquaphor) for dryness.
- Use a nondrying, antipruritic soap (Aveeno) if pruritus occurs.
- Avoid tight clothes, underwire bras, excessive temperatures, and ultraviolet light.

Follow-up care includes teaching the patient to minimize sun exposure to the treated area, such as using sunblock with an SPF of 15 or above, and reassuring the patient that minor twinges and shooting pain in the breast are normal after radiation treatment.

Systemic Therapy

Systemic treatment uses anticancer, or antineoplastic, drugs that are given intravenously or orally and travel throughout the body in the bloodstream with the goal of destroying cancer

cells that have escaped the breast and axillary lymph nodes before they metastasize. Chemotherapy and targeted therapy are two types of systemic treatment. Neoadjuvant therapy (drug treatment given prior to surgery) allows for assessment of the tumor's response to the chemical agent and is used to shrink a tumor before surgery. When successful tumor shrinkage occurs, breast conservation surgery without the need for mastectomy can be performed. Adjuvant therapy is administered after surgery and is used to eradicate any residual cancer cells in the body. The type of systemic therapy used depends on the tumor type/grade, size, lymph node status, and angiolymphatic invasion (cancer cells seen in small blood or lymph vessels), as well as the age and performance status of the patient.

For some patients who have metastatic disease, or breast cancer that has traveled beyond the breast and into other organs or parts of the body, surgery may no longer be advisable, and systemic therapy is the primary treatment of choice.

Targeted therapy includes both biologic therapy and endocrine (hormone) therapy.

Biologic Therapy

HER2/neu is a growth-promoting protein that is present in about 15% to 30% of breast cancers and results in faster growth and a higher recurrence rate than in tumors that do not overproduce it. Trastuzumab is a monoclonal antibody that targets this protein and reduces the recurrence rate and mortality in women with both metastatic and early-stage breast cancer. Lapatinib, bevacizumab, and pertuzumab are other biologic therapies that are used to treat advanced breast cancer in appropriate patients.

Endocrine (Hormone) Therapy

Estrogen is a hormone produced in the ovaries that can promote breast cancer growth. Women whose breast cancers have positive hormone receptors may take hormone therapy to block the effects of estrogen on tumor growth. Both premenopausal and postmenopausal women may take tamoxifen if their tumors test positive for hormone receptors. Tamoxifen works by blocking the effects of estrogen on breast tissue. Tamoxifen is recommended for a 5- to 10-year course of therapy after surgery and has demonstrated significant reduction in the recurrence rate and improved survival. Sequelae of tamoxifen include menopausal symptoms, fatigue, mood swings, and an increased risk of endometrial cancer and blood clots.

Aromatase inhibitors, such as letrozole, anastrozole, and exemestane, are another hormone therapy option for postmenopausal women. These drugs work by blocking aromatase, an enzyme whose role is to convert the hormone androstenedione to estrogen in the body after menopause, thus decreasing levels of circulating estrogen. Aromatase inhibitors cannot stop the ovaries from making estrogen so they are not effective in premenopausal women. They are prescribed for a 5-year course of therapy and may be given alone or following a course of tamoxifen. Aromatase inhibitors have a lower side-effect profile than tamoxifen but can cause osteoporosis, bone fractures, and musculoskeletal problems (ACS, 2015). Table 33-2 lists potential adverse effects of different hormonal therapies for breast cancer. Box 33-5 addresses side-effect management of hormonal agents.

Chemotherapy

The indication for chemotherapy depends on the size of the tumor, lymph node involvement, the presence or absence of hormone receptors in the tumor, and the amount of HER2/neu present in the breast cancer cells. Combination chemotherapy, or the use of more than one drug, has proven to be more effective than single-drug regimens. The most common drugs recommended for use in breast cancer are cyclophosphamide, docetaxel, doxorubicin, epirubicin, fluorouracil, and paclitaxel. Most chemotherapy regimens are given in 2- to 3-week cycles for a total of 3 to 6 months of therapy (ACS, 2015).

Nursing Management of the Patient Undergoing Chemotherapy

Common physical side effects of chemotherapy for breast cancer vary with the type of treatment given and may include nausea, vomiting, bone marrow suppression, taste changes, alopecia (hair loss), mucositis (painful inflammation and ulcerations of the mucous membranes in the digestive tract), skin changes, and fatigue. A weight gain of more than 10 lb occurs in about half of all patients; the cause is unknown. Premenopausal women also may experience temporary or permanent amenorrhea (absence of menstrual period) leading to sterility. Nurses play an important role in helping patients manage the physical and psychosocial sequelae of chemotherapy. Instructing the patient about the use of antiemetics and reviewing the optimal dosage schedule can help minimize nausea and vomiting. Measures to ease the symptoms of mucositis may include rinsing with normal saline solution, avoiding hot and spicy foods, and using a soft toothbrush. Some patients may require hematopoietic growth factors to minimize the effects of chemotherapy-induced neutropenia and anemia. Granulocyte colony–stimulating factors (G-CSFs) boost the white blood cell count, helping reduce the incidence of neutropenic fever and infection. Erythropoietin growth factor increases the production of red blood cells, thus decreasing the symptoms of anemia. The nurse instructs the patient and family on proper injection technique of hematopoietic growth factors and about symptoms that require follow-up with their provider.

TABLE 33-2 Adverse Reactions Associated with Adjuvant Hormonal Therapy Used to Treat Breast Cancer

Therapeutic Agent	Adverse Reactions/Side Effects
Selective Estrogen Receptor Modulator	
Tamoxifen	Hot flashes, vaginal dryness/discharge/bleeding, irregular menses, nausea, mood disturbances; increased risk for endometrial cancer; increased risk for thromboembolic events (deep vein thrombosis, pulmonary embolism, superficial phlebitis)
Aromatase Inhibitors	
Anastrozole Letrozole Exemestane	Musculoskeletal symptoms (arthritis, arthralgia [joint pain], myalgia [muscle pain]), increased risk of osteoporosis/fractures, nausea/vomiting, hot flashes, fatigue, mood disturbances

The nurse may assist the patient in finding a wig prior to hair loss to alleviate the stress associated with alopecia. The nurse may provide a list of wig suppliers in the patient's geographic region. Also familiarity with creative ways to use scarves and turbans may help minimize the patient's distress. The patient needs reassurance that new hair will grow back

when treatment is completed, although the color and texture may be different. The ACS offers a program called "Look Good, Feel Better" that provides useful tips for applying cosmetics during chemotherapy.

BOX 33-5 Patient Education

Managing Side Effects of Adjuvant Hormonal Therapy in Breast Cancer

Hot Flashes
- Wear breathable, layered clothing.
- Avoid caffeine and spicy foods.
- Perform breathing exercises (paced respirations).
- Consider medications (vitamin E, antidepressants) or acupuncture.

Vaginal Dryness
- Use vaginal moisturizers for everyday dryness (e.g., Replens, vitamin E suppository).
- Apply vaginal lubrication during intercourse (e.g., Astroglide, K-Y jelly).

Nausea and Vomiting
- Consume a bland diet.
- Try to take medication in the evening.

Musculoskeletal Symptoms
- Take nonsteroidal analgesics as recommended.
- Take warm baths.

Risk of Endometrial Cancer
- Report any irregular bleeding to a gynecologist for evaluation.

Risk for Thromboembolic Events
- Report any redness, swelling, or tenderness in the lower extremities or any unexplained shortness of breath.

Risk for Osteoporosis or Fractures
- Undergo a baseline bone density scan.
- Perform regular weight-bearing exercises.
- Take calcium supplements with vitamin D.
- Take bisphosphonates (e.g., alendronate) or calcitonin as prescribed.

Chemotherapy may negatively affect the patient's self-esteem, sexuality, and sense of well-being. This, combined with the stress of a potentially life-threatening disease, can be overwhelming. Providing support and promoting open communication are important

aspects of nursing care. Referring the patient to the dietitian, social worker, psychiatrist, or spiritual advisor can provide additional support. Numerous community support and advocacy groups are available for patients and their families. Complementary therapies, such as guided imagery, meditation, and relaxation exercises, also can be used in conjunction with conventional treatments. Refer to Chapter 6 for details on cancer care.

Nursing Alert
The nurse recognizes that many patients will experience chemotherapy-induced nausea and vomiting (CINV) which may persist for several days after chemotherapy. For patients at high risk for CINV, antiemetics are given prior to initiation of treatment, and the nurse reviews the discharge medication plan for breakthrough nausea and vomiting. Refer to Chapter 6 for details on CINV.

Treatment for Recurrent or Metastatic Breast Cancer

Breast cancer may recur locally (on the chest wall or in the conserved breast), regionally (in the remaining lymph nodes), or systemically (in distant organs). In metastatic disease, the bone, usually the hips, spine, ribs, or pelvis, is the most common site of spread. Other sites of metastasis include the lungs, liver, pleura, and brain.

The overall prognosis and optimal treatment are determined by a variety of factors, such as the site and extent of recurrence, the time to recurrence from the original diagnosis, history of prior treatments, the patient's performance status, and any existing comorbid conditions. Patients with bone metastases generally have a longer overall survival compared with metastases in visceral organs.

Local recurrence in the absence of systemic disease is treated aggressively with surgery, radiation, and hormonal therapy. Chemotherapy also may be used for tumors that are not hormonally sensitive. Local recurrence may be an indicator that systemic disease will develop in the future, particularly if it occurs within 2 years of the original diagnosis.

Metastatic breast cancer involves control of the disease rather than cure. Treatment includes hormonal therapy, chemotherapy, and targeted therapy. Surgery or radiation may be indicated in select situations. Premenopausal women who have hormonally dependent tumors may eliminate the production of estrogen by the ovaries through oophorectomy or suppression of estrogen synthesis by luteinizing hormone–releasing hormone (LHRH) agonists, such as leuprolide or goserelin.

Patients with advanced breast cancer are monitored closely for signs of disease progression. Baseline studies are obtained at the time of recurrence. These may include complete blood count; comprehensive metabolic panel; tumor markers; bone scan; CT of the chest, abdomen, and pelvis; and MRI of symptomatic areas. Additional x-rays may be performed to evaluate areas of pain or abnormal areas seen on bone scan. These studies are repeated at regular intervals to assess for effectiveness of treatment and to monitor progression of disease.

Nursing Management of the Patient with Recurrent or Metastatic Breast Cancer

Nurses play an important role in not only educating patients and managing their symptoms but also in providing emotional support. Many patients find that recurrence of the disease is more distressing than the initial cancer diagnosis. In addition to coping with further

treatments, they are faced with a greater uncertainty about their future and long-term survival. The nurse can help the patient identify coping strategies and set priorities to optimize quality of life (QOL). Family members and significant others should be included in the treatment plan and follow-up care. Referrals to support groups, psychiatry, social work, and complementary medicine programs, such as guided imagery, meditation, and yoga, should be made as indicated.

Nurses are also key members of the interdisciplinary team providing palliative care. The highest priorities should include alleviating pain and providing comfort measures. A frank discussion with the patient and family regarding their preferences for end-of-life care should occur before the need arises, to ensure a smooth transition without disruption of care. Referrals to hospice and home health care should be initiated as necessary.

Survivorship and Quality of Life

With increased early detection and improved treatment modalities, women with breast cancer have become the largest group of cancer survivors. Sequelae of diagnosis and treatment may affect the patient and her family for an extended period of time. It is important that nurses learn about these long-term effects and intervene appropriately to optimize QOL. The nurse can be pivotal in providing education and support to the patient as she makes very difficult and emotional decisions. The patient should be prepared early for the potential long-term complications of the disease and its treatments so that she can make informed decisions, has realistic expectations, and can be proactive in obtaining the support she needs.

Many breast cancer survivors have difficulty with issues pertaining to sexuality and menopausal symptoms. Estrogen withdrawal due to chemotherapy-induced menopause and hormone therapy can cause a variety of symptoms, including hot flashes, vaginal dryness, urinary tract infections (UTIs), weight gain, decreased sex drive, and increased risk for osteoporosis. Some of these symptoms also can lead to fatigue and sleep disturbances. Hormone replacement therapy (HRT) to alleviate menopausal symptoms is contraindicated in women with breast cancer so women need to rely on alternative remedies. Certain chemotherapeutic agents can cause long-term cardiac effects and impaired cognitive functioning, such as difficulty concentrating. Rare long-term effects of radiation can include pneumonitis and rib fractures. Long-term sequelae after breast surgery may include lymphedema (mainly after ALND), pain, and sensory disturbances.

Nursing Alert

Cardiac function must be assessed in patients undergoing chemotherapy and/or radiation since impaired aortic elasticity and stiffness have been noted in patients with breast cancer undergoing radiation (Kilicaslan et al., 2013), and cardiotoxicity is associated with some chemotherapy agents (Vasiliadis, Kolovou, & Mikhailidis, 2013). The nurse is aware that echocardiography, holter monitoring, cardiac and pulmonary assessments, and laboratory work, such as brain natriuretic peptide (BNP) and troponin levels, may be monitored.

Long-term psychosocial ramifications may include anxiety, depression, uncertainty about the future, and fear of recurrence. Many of these sequelae can affect the patient's partner and children. In the workplace, the patient may suffer from fear of discrimination, concern over coworkers' reactions, fear of losing benefits, and lack of physical stamina. The nurse should facilitate open conversation with the patient about her fears and concerns and provide referrals to support groups and counseling as needed.

NURSING PROCESS

The Patient Undergoing Surgery for Breast Cancer

ASSESSMENT

The health history is a valuable tool to assess the patient's reaction to the diagnosis and her ability to cope with it. Pertinent questions include the following:

- How is the patient responding to the diagnosis?
- What coping mechanisms does she find most helpful?
- What psychological or emotional supports does she have and use?
- Is there a partner, family member, or friend available to assist her in making treatment choices?
- What are her educational needs?
- Is she experiencing any pain or discomfort?

DIAGNOSIS

Major preoperative nursing diagnoses may include the following:

- Deficient knowledge about the planned surgical treatments
- Anxiety related to the diagnosis of cancer
- Fear related to specific treatments and body image changes
- Risk for ineffective coping (individual or family) related to the diagnosis of breast cancer and related treatment options
- Decisional conflict related to treatment options

Major postoperative nursing diagnoses may include the following:

- Pain and discomfort related to surgical procedure
- Disturbed sensory perception related to nerve irritation in affected arm, breast, or chest wall
- Disturbed body image related to loss or alteration of the breast
- Risk for impaired adjustment related to the diagnosis of cancer and surgical treatment
- Self-care deficit related to partial immobility of upper extremity on operative side
- Risk for sexual dysfunction related to loss of body part, change in self-image, and fear of partner's responses
- Deficient knowledge:

- Drain management after breast surgery
- Arm exercises to regain mobility of affected extremity
- Hand and arm care after an ALND

Potential complications may include the following:

- Lymphedema
- Hematoma/seroma formation
- Infection

PLANNING

The major goals may include increased knowledge about the disease and its treatment; reduction of preoperative and postoperative fear, anxiety, and emotional stress; improvement of decision-making ability; pain management; improvement in coping abilities; improvement in sexual function; and the absence of complications.

INTERVENTIONS

Both pre- and postoperative nursing care greatly impact the patient's surgical experience.

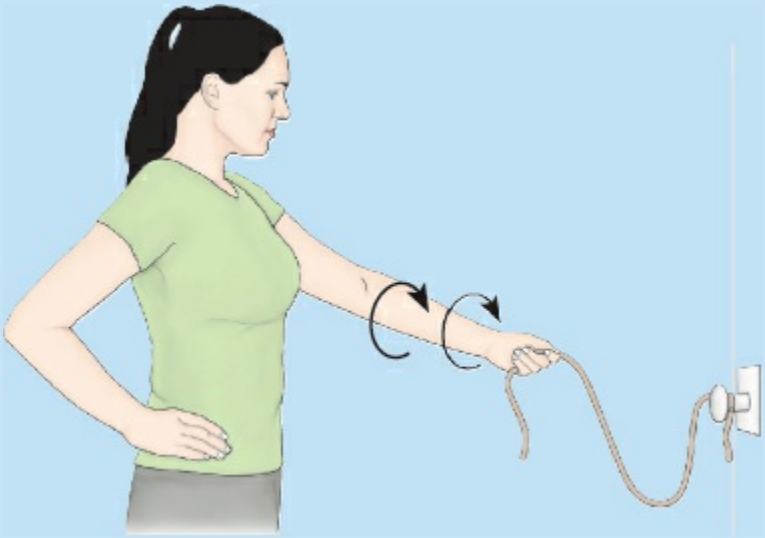
PREOPERATIVE NURSING INTERVENTIONS

Providing Education and Preparation About Surgical Treatments. Patients with newly diagnosed breast cancer are expected to absorb an abundance of new information during a very emotionally difficult time. The nurse plays a key role in reviewing treatment options by reinforcing information provided to the patient and answering any questions. The nurse fully prepares the patient for what to expect before, during, and after surgery. Patients undergoing breast conservation with ALND, or a total or modified radical mastectomy, generally remain in the hospital overnight (or longer if they have immediate reconstruction). Surgical drains will be inserted in the mastectomy incision and in the axilla if the patient undergoes an ALND. The patient should be informed that she will go home with the drain(s) and that complete instructions about drain care will be provided prior to discharge. In addition, the patient should be informed that often she will have decreased arm and shoulder mobility after an ALND and that she will be shown range-of-motion exercises prior to discharge. Refer to Box 33-6 for exercises after breast surgery. The patient also should be reassured that appropriate analgesia and comfort measures will be provided to alleviate any postoperative discomfort.

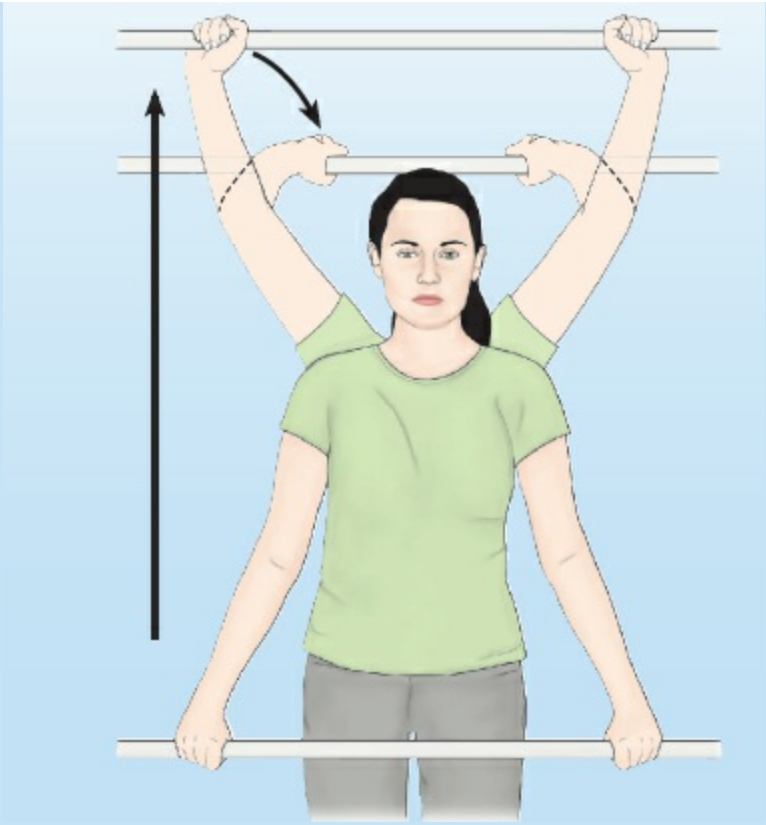
BOX 33-6 Patient Education

Exercise After Breast Surgery

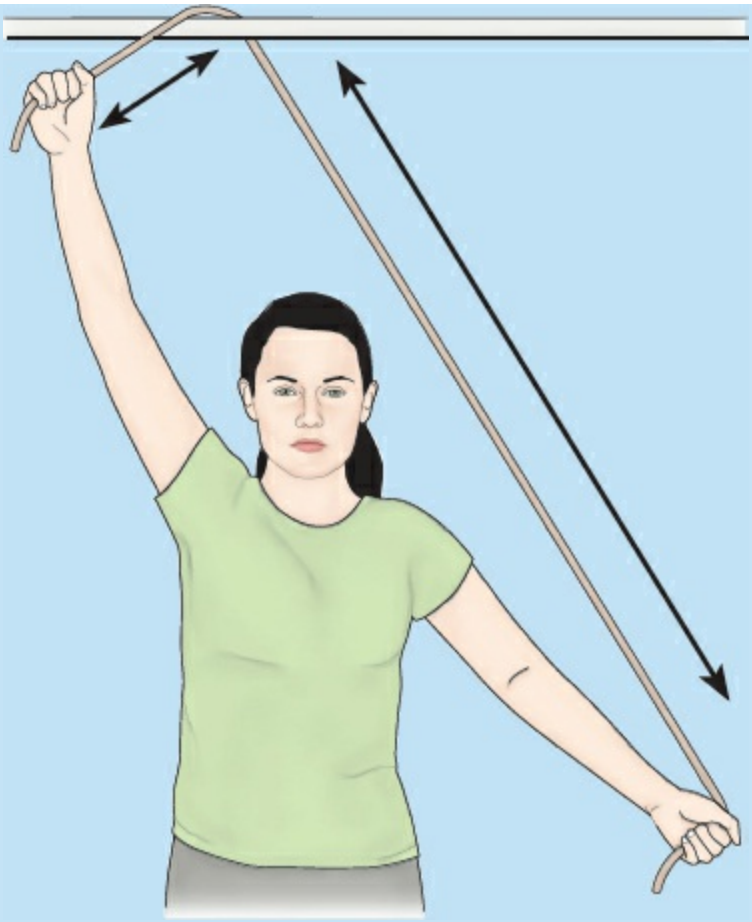
1. *Wall handclimbing*. Stand facing the wall with feet apart and toes as close to the wall as possible. With elbows slightly bent, place the palms of the hand on the wall at shoulder level. By flexing the fingers, work the hands up the wall until arms are fully extended. Then reverse the process, working the hands down to the starting point.



2. *Rope turning*. Tie a light rope to a doorknob. Stand facing the door. Take the free end of the rope in the hand on the side of surgery. Place the other hand on the hip. With the rope-holding arm extended and held away from the body (nearly parallel with the floor), turn the rope, making as wide swings as possible. Begin slowly at first; speed up later.



3. *Rod or broomstick lifting*. Grasp a rod with both hands, held about 2 ft apart. Keeping the arms straight, raise the rod over the head. Bend elbows to lower the rod behind the head. Reverse the maneuver, raising the rod above the head, and then return to the starting position.



4. *Pulley tugging*. Toss a light rope over a shower curtain rod or doorway curtain rod. Stand as nearly under the rope as possible. Grasp an end in each hand. Extend the arms straight and away from the body. Pull the left arm up by tugging down with the right arm, then the right arm up and the left down in a see-sawing motion.

Reducing Fear and Anxiety and Improving Coping Ability. The nurse must help the patient cope with the physical as well as the emotional effects of surgery. Many fears may emerge during the preoperative phase. These can include fear of pain, mutilation (after mastectomy), and loss of sexual attractiveness; concern about inability to care for oneself and one's family; concern about taking time off from work; and coping with an uncertain future. Providing the patient with realistic expectations about the healing process and expected recovery can help alleviate fears. Maintaining open communication and assuring the patient that she can contact the nurse at any time with questions or concerns can be a source of comfort. The patient also should be made aware of available resources at the treatment facility as well as in the breast cancer community, such as social workers, psychiatrists, and support groups. Some women find it helpful and reassuring to talk to a breast cancer survivor who has undergone similar treatments.

Promoting Decision-Making Ability. Choosing the optimal treatment can be very overwhelming for patients. The nurse can be instrumental in ensuring that the patient

and family members truly understand their options and can weigh the risks and benefits of each option. The patient may be presented with the option of having breast conservation treatment followed by radiation or a mastectomy. The nurse can explore the issues with the individual patient by asking questions such as the following:

- How would you feel about losing your breast?
- Are you considering breast reconstruction?
- If you choose to retain your breast, would you consider undergoing radiation treatments 5 days a week for 5 to 6 weeks?

Questions such as these can help the patient focus. Once the patient's decision is made, it is very important to support it.

POSTOPERATIVE NURSING INTERVENTIONS

Relieving Pain and Discomfort. Many patients tolerate the breast surgery quite well and have minimal pain during the postoperative period. Patients who have had more invasive procedures, such as a modified radical mastectomy with immediate reconstruction, may have considerably more pain. All patients are discharged home with analgesic and are encouraged to take it if needed. Sometimes patients complain of a slight increase in pain after the first few days of surgery as they regain sensation around the surgical site and become more active. Patients who report severe pain must be evaluated to rule out any potential complications. Alternative methods of pain management, such as taking warm showers and using distraction methods such as guided imagery, also may be helpful.

Managing Postoperative Sensations. Because nerves in the skin and axilla often are cut or injured during breast surgery, patients experience a variety of sensations, such as tenderness, soreness, numbness, tightness, pulling, and twinges along the chest wall, in the axilla, and along the inside aspect of the upper arm. After mastectomy, some patients experience phantom sensations and report a feeling that the breast and/or nipple are still present. Sensations usually persist for several months and then begin to diminish. Patients should be reassured that this is a normal part of healing and that these sensations are not indicative of a problem.

Promoting Positive Body Image. Patients who have undergone mastectomy often find it very difficult to view the surgical site for the first time. No matter how prepared the patient may think she is, the appearance of an absent breast can be very emotionally distressing. Some patients who have undergone breast conservation treatment may find it difficult to view their surgical incisions, although this is rare. Ideally, the patient sees the incision for the first time when she is with the nurse or another health care provider who is available for support. The nurse first assesses the patient's readiness and provides gentle encouragement and a private setting.

Promoting Positive Adjustment and Coping. Providing ongoing assessment of how the

patient is coping with her diagnosis of breast cancer and her surgical treatment is important in determining her overall adjustment. Assisting the patient in identifying and mobilizing her support systems can be beneficial to her well-being. The patient's spouse or partner may need guidance, support, and education as well. The patient and partner may benefit from a wide network of available community resources, including the Reach to Recovery program of the ACS, advocacy groups, or a spiritual advisor. Encouraging the patient to discuss issues and concerns with other patients who have had breast cancer may help her to understand that her feelings are normal and that other women who have had breast cancer can provide invaluable support and understanding.

The patient also may have considerable anxiety about the treatments that will follow surgery and their implications. Providing her with information about the plan of care and referring her to the appropriate members of the health care team also promote coping during recovery. Some women require additional support to adjust to their diagnosis and the changes that it brings. Box 33-7 lists talking points for patients and partners.

Improving Sexual Function. Once discharged from the hospital, most patients are physically allowed to engage in sexual activity. However, any change in the patient's body image, self-esteem, or the response of her partner may increase her anxiety level and affect sexual function. Some partners may have difficulty looking at the incision, whereas others may be completely unaffected. Encouraging the patient to openly discuss how she feels about herself and about possible reasons for a decrease in libido, such as fatigue, anxiety, and self-consciousness, may help clarify issues for her. Helpful suggestions for the patient may include varying the time of day for sexual activity, such as when the patient is less tired, assuming positions that are more comfortable, and expressing affection using alternative measures such as hugging, kissing, and manual stimulation.

BOX 33-7 Talking with Patients and Partners

For patients in the diagnostic phase: We've talked about your recent breast cancer diagnosis. It's natural for you to be full of feelings, concerns, and fears for yourself and your family. Sometimes it's hard to find someone to speak freely with. Would you like to share what you've been thinking about, feeling, and worrying about recently?

For partners in the diagnostic phase: We've talked about your partner's recent breast cancer diagnosis. It's natural for you to have a lot of feelings, concerns, and fears for your partner, yourself, and your family. Partners often feel that they have to be strong for the patient or for others and that they aren't entitled to express their own concerns. Would you like to share what you've been thinking about, feeling, or worrying about recently?

For patients in the postsurgical phase: Many women who have had breast surgery, especially mastectomy or extensive lumpectomy, are concerned not only with their own loss but also with how their partner will accept it. How have you felt about losing [part of] your breast? How has it changed your body image? Your sense of your sexuality?

Your desire for intimacy?

For partners in the postsurgical phase: Many partners of women who have had breast surgery are concerned, as are the women themselves, about how they'll respond to the loss. How have you felt about your partner's losing [part of] her breast? How has it changed her attractiveness for you? Your sexual feelings toward her? Your desire for intimacy?

For patients in the adjuvant therapy phase: Given the type of therapy (radiation, chemotherapy, hormone therapy) you're going to have, what side effects do you anticipate? What do you know about them? Let's talk about ways to reduce and handle potential side effects.

For partners in the adjuvant therapy phase: Given the type of therapy (radiation, chemotherapy, hormone therapy) your partner is going to have, what side effects do you anticipate? What do you know about them? Let's talk about ways to reduce and handle potential side effects and how it might help you to be familiar with them.

For patients in the ongoing recovery phase: As you plan your return to a full work schedule, what measures—setting priorities, delegating responsibility, managing stress—might help you make the necessary physical and emotional adjustments? What have you learned about balancing work, family, and play in your life?

For partners in the ongoing recovery phase: As your partner plans her return to a full work schedule, what strategies have you thought about using to make your own physical and emotional adjustments so that you don't continue to be overburdened at work and at home?

From Hoskins, C. N., & Haber, J. (2000). Adjusting to breast cancer. American Journal of Nursing, *100*(4), 26–32.

Most patients and their partners adjust with minimal difficulty if they openly discuss their concerns. However, if issues cannot be resolved, a referral may be helpful. The ambulatory care nurse in the outpatient clinic or hospital should inquire whether the patient is having difficulty with sexuality issues because many patients are reluctant or embarrassed to bring it up themselves.

EVALUATION

Expected preoperative patient outcomes may include:

1. Exhibits knowledge about diagnosis and surgical treatment options:
   a. Asks relevant questions about diagnosis and available surgical treatments
   b. States rationale for surgery
   c. Describes advantages and disadvantages of treatment options
2. Verbalizes willingness to deal with anxiety and fears related to the diagnosis and the effects of surgery on self-image and sexual functioning
3. Demonstrates ability to cope with diagnosis and treatment:
   a. Verbalizes feelings appropriately and recognizes normalcy of mood lability

b. Proceeds with treatment in timely fashion
c. Discusses impact of diagnosis and treatment on family and work

4. Demonstrates ability to make decisions regarding treatment options in timely fashion

Expected postoperative patient outcomes may include:

1. Reports that pain has decreased and states that pain and discomfort management strategies are effective
2. Identifies postoperative sensations and recognizes that they are a normal part of healing
3. Exhibits clean, dry, and intact surgical incisions without signs of inflammation or infection
4. Lists the signs and symptoms of infection to be reported to the nurse or surgeon
5. Verbalizes feelings regarding change in body image
6. Discusses meaning of the diagnosis, surgical treatment, and fears appropriately
7. Participates actively in self-care activities:
   a. Performs exercises as prescribed
   b. Participates in self-care activities as prescribed
8. Discusses issues of sexuality and resumption of sexual relations
9. Demonstrates knowledge of postdischarge recommendations and restrictions:
   a. Describes follow-up care and activities
   b. Demonstrates appropriate care of incisions and drainage system
   c. Demonstrates arm exercises and describes exercise regimen and activity limitations during postoperative period
   d. Describes care of affected arm and hand and lists indications to contact the surgeon or nurse
10. Experiences no complications:
    a. Identifies signs and symptoms of reportable complications (e.g., redness, heat, pain, edema)
    b. Explains how to contact appropriate health care providers in case of complications

REPRODUCTIVE DISORDERS

Menstrual Disorders

Menstrual disorders consist of any irregularity within the menstrual cycle. Previous terminology used to describe deviations in uterine bleeding has included: amenorrhea (absence of menses), dysmenorrhea (painful menses), menorrhagia (excessive menstrual bleeding), metrorrhagia (excessive and prolonged menstrual bleeding), irregular bleeding patterns, premenstrual syndrome (PMS), and premenstrual dysphoric disorder (PMDD). Normal menstrual cycles typically occur every 21 to 35 days (Klein & Poth, 2013).

Any menstrual cycle changes should be discussed with the patient's health care provider, so that appropriate diagnosis, management, and treatment can occur.

AMENORRHEA

Amenorrhea is divided into two types: primary, which is the absence of menses until age 16 or absence of secondary sex characteristics and menarche by age 14; and secondary, which is more common and occurs after a regular pattern of menstrual cycles has been established already (Papadakis & McPhee, 2014).

Pathophysiology

Primary amenorrhea is caused by hypothyroidism, Turner syndrome, pituitary disorders, hyperandrogenism, disorders of sexual development, pregnancy, anatomic abnormalities or in utero exposure to DES (diethylstilbestrol) (Klein & Poth, 2013; Papadakis & McPhee, 2014). Those with Turner syndrome have only one normal "X" chromosome and have absence of breast or pubic hair development. DES was a drug given to pregnant women between 1938 and 1970 to help prevent miscarriages. It was discovered later that the drug affected the reproductive organs of the female offspring, causing infertility. These patients will have secondary sex characteristics but incomplete development of reproductive organs (Centers for Disease Control and Prevention [CDC], 2012a).

When menses do not occur for 6 months or more after a regular pattern of cycles has been established, it is considered secondary amenorrhea. Pathologic causes of secondary amenorrhea include eating disorders, pregnancy, excessive weight loss, low body mass index (BMI) of less than 22% of average, excessive exercise, endocrine dysfunction such as polycystic ovarian syndrome (PCOS), hypothalamic or pituitary dysfunction, medications, or anatomical deviations such as cervical stenosis or imperforate hymen (Klein & Poth, 2013; Papadakis & McPhee, 2014).

This type of amenorrhea is common among athletes and those with rapid weight loss due to bariatric surgery or starvation dieting. Amenorrhea also may be caused by hormonal contraceptives, such as oral contraception, Depo-Provera, implanted long-term progesterone contraception, or the presence of a progesterone-only intrauterine device (IUD). Patients with eating disorders are at risk for developing menstrual irregularities due to suppression in the hypothalamic–pituitary–ovarian axis (Snyder, 2014).

Pathophysiology Alert

The female athlete triad is an association between low-energy availability (with or without eating disorders), amenorrhea, and osteoporosis. It is a state of insufficient caloric intake (excessive exercise or reduced energy intake), low estrogen, and elevated cortisol. The elevated cortisol inhibits the release of gonadotropins which results in suppression of ovulation and decreased estrogen production. The negative impact on bone density occurs because of the decreased estrogen availability and suppression of hormones that stimulate bone growth. As a result, amenorrhea, and decreased bone mineral density is seen (Casey & Chen, 2017; Griffin, 2015).

Clinical Manifestations and Assessment

Patients who have an established menstrual cycle pattern will report a history of the absence of menstruation or other symptoms that are associated with the underlying cause of amenorrhea. Those patients 16 years of age who have developed secondary sex characteristics generally will seek medical evaluation if they have not experienced any menstruation as will 14-year-olds who have not developed any secondary sex characteristics. A detailed menstrual history is critical in determining abnormality in menstrual patterns and should be accompanied by pregnancy and sexual histories, contraception use, medications, exercise patterns, and detailed history on any intentional or unintentional changes in weight.

Once pregnancy has been excluded, appropriate labs should include thyroid-stimulating hormone (TSH) and prolactin levels, follicle-stimulating hormone (FSH), luteinizing hormone (LH, also known as lutropin), dehydroepiandrosterone sulfate (DHEAS), and serum testosterone. If the patient is short in stature, genetic testing for Turner syndrome should be considered (Klein & Poth, 2013; Papadakis & McPhee, 2014). Physical examination of the external and internal genitalia by a health care provider will determine any anatomical deviations that may cause obstruction of the vaginal outlet.

Medical and Nursing Management

A withdrawal bleed occurs with the administration of medroxyprogesterone acetate (MPA) (Provera) 10 mg for 7 to 10 days. Depending upon risk factors, an oral contraceptive pill (OCP) then can be initiated to assist with regulation of the menstrual cycle. Alternatively, the patient can be prescribed progesterone the first week of each month or every 3 months for a withdrawal bleed. It is important to instruct the patient that if she has not had a menstrual period for several months, she can expect a heavy flow after taking MPA and may experience severe cramping as a result. Therapies for painful menstruation are listed below.

Also a pelvic ultrasound may be ordered to confirm the absence or presence of a uterus or any other structural abnormalities that may be a contributing factor in amenorrhea (Klein & Poth, 2013).

DYSMENORRHEA

Painful menstruation, or dysmenorrhea, has two classifications: primary and secondary. Primary dysmenorrhea occurs at the onset of menarche and the early following years after establishing a cycle and may become more severe over time (Papadakis & McPhee, 2014). It is considered one of the most common causes of pelvic pain with rates as high as 90% (Osayande & Mehulic, 2014). Approximately 10% to 15% of adolescent females report severe pain from their menstrual cycles, resulting in lost time from work or school (Yu, 2014). Secondary dysmenorrhea begins well after the menstrual cycle has been established and is typically caused by some organic or structural causes (Papadakis & McPhee, 2014).

Pathophysiology

The classic characterization of primary dysmenorrhea is crampy pain in the abdomen and/or lower back just before the onset of bleeding and persisting for the first few days into the menstrual flow. It is due to an excessive production of prostaglandins in the lining of the uterus, which causes contractions of the smooth muscle (Yu, 2014). The onset of primary dysmenorrhea typically occurs 6 to 12 months after the menstrual cycle has been established (Osayande & Mehulic, 2014).

TABLE 33-3 Comparing Primary and Secondary Dysmenorrhea

Aspect	Primary Dysmenorrhea	Secondary Dysmenorrhea
Quality of pain	Sharp, intermittent pain	Recurrent, crampy, suprapubic pain
Timing	Begins with onset of menarche	Symptoms begin earlier in cycle and last longer
Age of onset	Occurs with menarche	Occurs between 30 and 40 years of age
Additional symptoms	Headache, fatigue, backache, dizziness, nausea, diarrhea, and constipation	Change in bowel habits, rectal pressure, painful defecation, dyspareunia

Secondary dysmenorrhea begins well after the onset of menarche, usually after age 20, but can occur as late as the third or fourth decade of life and is suggestive of an underlying pathology, such as endometriosis (most common cause), fibroids (discussed later in this chapter), or a pelvic infection. It may be related to IUDs, congenital anomalies, ovarian cysts, or benign or malignant tumors (Papadakis & McPhee, 2014).

Clinical Manifestations and Assessment

Often primary dysmenorrhea is characterized by sharp, intermittent abdominal pain that is accompanied by headache, fatigue, backache, nausea, diarrhea, or constipation. The gastrointestinal (GI) symptoms are caused by prostaglandins triggering uterine vasoconstriction and prolonged contractions or cramping (Papadakis & McPhee, 2014). Symptoms for secondary dysmenorrhea begin earlier in the cycle and last longer. There is also a change in bowel habits, rectal pressure, and painful defecation due to the influence production of prostaglandins. Table 33-3 compares primary and secondary dysmenorrhea.

Medical Management

Nonsteroidal anti-inflammatories (NSAIDs) and hormonal contraceptives are the mainstay and first-line therapy for treating primary dysmenorrhea due to their antiprostaglandin effect (Osayande & Mehulic, 2014; Papadakis & McPhee, 2014).

Ibuprofen and naproxen are available over the counter (OTC). Other NSAIDs available by prescription include mefenamic acid (Ponstel), prescription-strength ibuprofen and naproxen, and cyclooxygenase (COX)-2 inhibitors (Celebrex). By blocking the production of prostaglandin, pain usually will not occur or will be mild in comparison.

While effective, NSAIDs can have a negative impact on the GI system; therefore, care must be taken to avoid long-term use of these medications. Combined oral contraceptives (COCs) are very beneficial in treatment for this condition as the combined hormones inhibit ovulation as well as decrease uterine flow and thereby decrease uterine contractility (Osayande & Mehulic, 2014). COCs are a good choice for sexually active women who desire birth control as well as relief from dysmenorrhea.

Management of secondary dysmenorrhea is aimed at identification of the causative factor through the use of the appropriate diagnostic tests. The same medications listed above also may be used to alleviate pain.

Nursing Management

Nurses can teach patients how to accurately keep a menstrual diary that will assist in tracking patterns of menstrual discomfort and pain (Fig. 33-7). Advising the patient to take an OTC NSAID 1 to 2 days prior to the onset of menses will help to inhibit prostaglandin production and help to decrease the amount of abdominal pain and cramping. Patients who take proton pump inhibitors (PPIs), which are available OTC or by prescription, need to be instructed on the proper administration of these drugs, which will help to protect the lining of the stomach from the effects of the NSAIDs. It is recommended that PPIs be taken on an empty stomach. The patient should eat something 30 to 60 minutes after taking the PPI to allow the medication to start working. Also, taking the NSAID with food will help to minimize stomach upset.

Nonpharmacologic therapy includes supplementation with magnesium, calcium, and vitamins B and E, but further studies are needed to accurately define appropriate dosages and outcomes (Yu, 2014). Low-level localized heat, such as a heating pad or wrap, for 15 to 20 minutes intermittently can be beneficial in easing uterine contractility. It is important to instruct the patient not to use heat that is too high or for prolonged periods of time due to the risk of burns.

KEY:

Symptoms:

NS, no symptoms
N/V, nausea/vomiting
TS, trouble sleeping
S, sensitive to light, sight, or sound
D, disturbances in sight/vision
B, bleeding: heavy, moderate, light
GI, diarrhea or constipation
BE, binge eating
FC, food cravings
I-irritable
FN-feeling nervous
T-tired
C-abdominal cramping or pain
H-headache
M-mood: depressed, anxious

Intensity:

Mild
Moderate
Severe

Treatment:

M-medicine
BR-bed rest
HCP-contacted health care professional

FIGURE 33-7 Menstrual log.

ABNORMAL UTERINE BLEEDING

Any uterine bleeding that deviates from a patient's usual pattern is considered abnormal uterine bleeding (AUB). This includes bleeding between periods, postmenopausal bleeding, postcoital bleeding, bleeding heavier than usual or for greater length of time, or bleeding between menstrual cycles (American College of Obstetricians and Gynecologists [ACOG],

2013). Approximately 1.4 million women report AUB annually (Carcio & Secor, 2015). The ACOG introduced new terminology recommendations for a universal classification system describing deviations in menstrual bleeding that will lend itself to easier classification. The new classification system is called PALM-COEIN, which is an acronym that refers to polyps, adenomyosis, leiomyoma, malignancies, coagulopathies, ovulatory dysfunction, iatrogenic, not yet classified (ACOG, 2013; Twiss, 2013). This classification system refers to the identification of structural or nonstructural etiologies that contribute to the development of AUB. Despite the new classification recommendations, much of the literature still uses the following terms to describe and categorize abnormal bleeding patterns:

- Any change in a normal menstrual cycle is referred to as *abnormal uterine bleeding* (AUB) (Twiss, 2013).
- Bleeding that occurs at regular intervals but is in excessive amounts and/or duration is known as *menorrhagia* or *heavy menstrual bleeding (HB)*.
- "*Excessive menstrual blood loss* is that which interferes with the woman's physical, emotional, social, and material QOL and can occur alone or in combination with other symptoms" (ACOG, 2013).
- Unpredictable bleeding patterns are considered to be *anovulatory bleeding* (Twiss, 2013).

Bleeding that occurs frequently but irregularly is known as *metrorrhagia*. *Menometrorrhagia* is now the term used to refer to heavy and prolonged menstrual bleeding (HPMB) and is heavy bleeding of prolonged duration occurring at irregular intervals. Any persistent AUB can lead to iron-deficiency anemia if left undiagnosed and untreated. Cycles greater than 35 days are known as oligomenorrhea, and cycles occurring in less than 21 days are known as polymenorrhea.

Causes

Coagulation disorders, such as thrombocytopenia (low platelet count) or Von Willebrand disease (most common inherited bleeding disorder in humans, refer to Chapter 20), are causes of AUB and should be ruled out as an underlying factor. Women who take unopposed estrogen are likely to develop AUB, as well as those with liver diseases that impair fibrinogen synthesis. Certain endocrine disorders, including Cushing syndrome, Addison disease, thyroid disorders, and PCOS; extreme fluctuations in weight; or excessive exercise can cause irregular uterine bleeding. Pregnancy should always be excluded when AUB is present (Papadakis & McPhee, 2014).

Other causes include pelvic infections caused by sexually transmitted infections (STIs; gonorrhea, *Chlamydia*, trichomonas), weight loss or weight gain, recent systemic infections, endometriosis, trauma, benign tumors, or lesions (Papadakis & McPhee, 2014). Refer to Chapter 35 for details on STIs.

Medical and Nursing Management

Nursing care must include vital signs, including orthostatic blood pressures, pulse rate to evaluate for tachycardia or arrhythmias, and a BMI (Carcio & Secor, 2015). Menstrual pad counts assist the health care provider in determining the approximate amount of blood loss through the description of the saturation of sanitary pads or tampons on an hourly basis. Characteristics of the flow, such as the color of blood and presence of clots, are to be noted as well. Physical examination of the genitalia and a Pap smear are performed. It is important that the patient undergo appropriate diagnostic testing to determine underlying pathology of AUB prior to treatment. This may include a pelvic ultrasound and endocrine tests, as described earlier. A CBC with differential, TSH, prothrombin time (PT), and partial prothrombin time (PTT) are indicated in the workup for AUB. Also an iron panel should be included to determine the presence of iron-deficiency anemia (Papadakis & McPhee, 2014). An endometrial biopsy is considered the first-line diagnostic test to rule out endometrial hyperplasia or malignancy in women over 35 years of age or in those under 35 years of age who are morbidly obese or who have chronic anovulation or PCOS (Twiss, 2013).

Once any pathology has been ruled out, it is appropriate for the patient to be treated with hormonal contraception that will regulate the menstrual cycle, decrease bleeding and cramping associated with heavy bleeding, and decrease any incidence of anemia associated with excessive blood loss. Progestin-releasing IUDs reduce blood flow, as does implanted progesterone (Papadakis & McPhee, 2014; Twiss, 2013).

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

PMS is the name given to a cluster of behavioral, emotional, and physical symptoms that typically occur the week prior to menstruation and may continue into the first week of the menstrual cycle (Papadakis & McPhee, 2014). Symptoms usually resolve with the onset of menstrual flow but can persist for the first few days of bleeding. PMDD is a more severe form of PMS and is recognized by diagnostic criteria developed by the American Psychiatric Association (APA), ACOG, and the World Health Organization (WHO). Symptoms must be present consistently during the luteal phase (second half of the menstrual cycle) and have a negative impact to some degree on the woman's life. The severity of the symptoms experienced by the patient and the impact on daily functioning are what delineates PMDD from PMS (Kelderhouse & Taylor, 2013).

It is estimated that approximately 40% of women of reproductive age are affected by symptoms related to menstrual cycle changes that interfere with daily lifestyle and relationships (Papadakis & McPhee, 2014). There is no known cause of PMS/PMDD, although research indicates these symptoms are most likely due to fluctuating levels of estrogen, progesterone, and serotonin.

Clinical Manifestations and Assessment

More than 100 physical and behavioral symptoms are associated with PMS/PMDD and range from mild to severely disabling (Box 33-8).

Symptoms may be misdiagnosed as menopause, anxiety, bipolar disorder, metabolic disorders (such as diabetes), chronic fatigue syndrome, or rheumatologic diseases. It is important that health care providers take a comprehensive, systematic approach to properly diagnosing patients with PMS/PMDD so that appropriate therapy may be initiated. Women may experience some of the symptoms or a constellation of symptoms at any one time during the luteal phase, including breast pain, bloating, ankle swelling, perceived weight gain, food cravings, and functional and cognitive impairments (Papadakis & McPhee, 2014).

BOX 33-8 Focused Assessment

Premenstrual Syndrome

Be alert for the following signs and symptoms:

Physical:

- Weight gain
- Abdominal bloating
- Constipation or diarrhea
- Breast tenderness
- Acne
- Headache
- Heart palpitations

Behavioral:

- Irritability
- Depression
- Mood swings
- Increased appetite
- Overwhelming fatigue
- Insomnia
- Crying spells

Cognitive:

- Decreased concentration
- Paranoia
- Indecision
- Sensitivity to rejection

- Suicidal ideation

Medical Management

Menstrual cycle diaries (see Fig. 33-7) are kept for two to three menstrual cycles (Kelderhouse & Taylor, 2013). The presence or absence of symptoms is to be noted daily, along with the impact of symptoms on daily activities. Providers are able to view trends of symptoms based on these logs that correlate with the menstrual cycle. Nurses can encourage lifestyle changes that will impact the severity of symptoms. These lifestyle changes include regular exercise, which promotes increased circulation of endorphins released from exercise; avoidance of excessive caffeine (coffee, soda, tea, energy drinks, and chocolate) and sodium-rich foods; decreased alcohol intake; and smoking cessation. Randomized trials of patients taking increased complex carbohydrates during the luteal phase have revealed a decrease in the severity of PMS symptoms (Kelderhouse & Taylor, 2013). Low serum calcium can cause muscle irritability; therefore, it is recommended that the patient ensure a daily intake of 1,200 to 1,600 mg of calcium daily.

Use of vitamin B_6 from 50 to 500 mg/day has been met with mixed success. Other nonpharmacologic therapies include oral magnesium, vitamin E supplements, and evening primrose oil. Due to flaws in recent studies of evening primrose oil, results of previous randomized control trials have demonstrated that it does not appear to provide any significant improvement of symptoms (Nevatte et al., 2013).

There are some results on the use of chasteberry for its dopaminergic effects on the emotional and physical symptoms of PMS and PMDD, but the exact mechanism is unknown (Nevatte et al., 2013). For women who do not respond to nonpharmacologic therapy, pharmacologic management is considered. The use of oral contraceptives has proven to be of great benefit for those with physical and emotional symptoms of PMS. Continuous contraception for 3 months' duration or longer often alleviates PMS symptoms (Nevatte et al., 2013; Papadakis & McPhee, 2014).

Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have shown efficacy in mood stabilization. Pulsed or cyclical dosing of SSRIs also can be used during the 2 weeks prior to and including the week of menstrual flow (Papadakis & McPhee, 2014).

Gonadotropin-releasing hormone (GnRH) agonists (Lupron or Depo-Provera) suppress the menstrual cycle, but long-term use can produce consequences of menopause due to the lack of estrogen, which may lead to irreversible osteoporosis. NSAIDs are beneficial for physical symptoms, including headache and dysmenorrhea.

Nursing Management

Nurses must take accurate and detailed health and nutritional histories and screen for symptoms of anxiety and/or depression as well as assess for current or past suicidal and homicidal ideation.

If the nurse recognizes any signs of an inability to manage anger, suicide/homicide ideation, depression, or anxiety, he or she should encourage the patient to seek evaluation by an appropriate health care provider. Nurses also may help patients with stress reduction and management techniques, compliance with medication, and therapeutic lifestyle changes (such as smoking cessation, regular exercise, and eating a low-fat, low-cholesterol, low-sodium diet). Pain management is similar to that discussed under dysmenorrhea (NSAIDs, PPIs, and heat pad use).

VULVOVAGINAL INFECTIONS

Fungal and bacterial infections in the vagina are common, self-limited gynecologic conditions that occur in women of all ages due to a disruption in the normal pH of the vagina (CDC, 2014a). The pH of the vagina is 3.5 to 4.5 and provides the normal environment for *Lactobacillus acidophilus* to exist. This is a healthy bacterium that thrives in the vaginal ecosystem and provides protection against infections by inhibiting growth of anaerobes (Cibulka & Barron, 2013).

Lactobacillus metabolizes glycogen to lactic acid in the vagina and maintains normal vaginal pH. Antibiotics, menopause (or estrogen deficiency), oral contraceptives, spermicides, diabetes, douching, frequent intercourse, and smoking are known to decrease the number of healthy lactobacilli (Miller, 2014).

Without the lactobacillus, there is a proliferation of anaerobic activity, the pH of the vagina is altered, and an overgrowth of bacteria is produced. Table 33-4 summarizes types of vaginal infections and vaginitis. Bacterial vaginosis (BV) and vulvovaginal candidiasis (VVC) are discussed in detail below.

Nurses play a vital role in helping patients to understand the mode of infection, treatment, and self-care modalities. Although not considered STIs, BV and VVC can coexist with STIs; therefore, appropriate screening for these infections is important (Carcio & Secor, 2015). Also it is important to note that the creams and suppositories used in the treatment of VVC and BV have been known to weaken latex condoms, diaphragms, and cervical caps; therefore, caution should be taken to avoid sexual intercourse during treatment.

BACTERIAL VAGINOSIS

The most common vaginal infection is BV or Gardnerella, occurring in approximately 40% to 50% of all cases of vaginitis when there is a decrease in lactobacilli (Cibulka & Barron, 2013; CDC, 2014b, 2015a).

Risk Factors

Risk factors for developing BV include new or multiple sexual partners, douching, an increase in sexual activity, retained foreign body in the vagina (such as a tampon, broken condom, or sex toy) and coexisting STIs (Raphaelidis, 2015). BV also may be present after a menstrual cycle due to the increase in the vaginal pH. If left untreated in patients who are pregnant, BV is a risk factor for premature labor as well as post-abortion endometritis and cuff cellulitis (infection) after hysterectomy.

Clinical Manifestations and Assessment

Approximately 50% of women who have BV are asymptomatic (Carcio & Secor, 2015). Patients with symptomatic BV will report an increased malodorous, vaginal discharge, or leukorrhea that is grayish white in color. Amines commonly found in the vagina become unstable when the pH is altered and release the characteristic "fishy" odor. The odor is generally more noticeable after sexual intercourse, sexual activity, or menses. Unprotected intercourse will produce the malodorous discharge due to the interaction of semen and normal vaginal amines. Sometimes women will report vaginal itching, dysuria, or pelvic pressure similar to that of a UTI due to the localized irritation of the urinary meatus from the discharge (Cibulka & Barron, 2013).

A swab of vaginal discharge taken from the vaginal walls and applied to two glass slides is known as a *wet mount.* One slide has saline added; the other slide has potassium hydroxide (KOH) added and then is viewed under a microscope. The presence of *clue cells* (vaginal epithelial cells that are coated with bacteria) on the saline slide is a hallmark for diagnosing BV. The KOH-prepared slide will release amines and is known as a "whiff test." The presence of a fishy odor on the whiff test suggests BV. Nitrazine paper determines the pH, which will be greater than 4.5 for BV (Carcio & Secor, 2015).

Medical and Nursing Management

The preferred medication for treatment of BV is metronidazole 500 mg twice daily for 7 days. If the patient is noncompliant, a single 2-g dose may be administered, although higher cure rates occur with the 7-day dose (Papadakis & McPhee, 2014). The CDC no longer recommends the single-dose therapy due to its low efficacy (CDC, 2015a). Metronidazole gel 0.75% administered in one 5-g applicator vaginally at bedtime for 7 nights is an alternative and is preferred to avoid any GI upset caused by oral medications. If an allergy to metronidazole exists, alternative therapies are oral clindamycin 300 mg twice daily for 7 days; clindamycin 2% cream, one 5-g application vaginally at bedtime for 7 days; or clindamycin ovules 100 mg intravaginally once at bedtime for 3 days. Tinidazole, a newer-generation medication that is chemically related to metronidazole, was approved in 2007 by the U.S. Food and Drug Administration (FDA) for treatment of BV. Improved patient adherence due to once-a-day dosing and shorter duration of therapy is observed (CDC, 2015a).

TABLE 33-4 Vaginal Infections and Vaginitis

Infection	Cause	Clinical Manifestations	Management Strategies
Candidiasis	*Candida albicans, glabrata,* or *tropicalis*	Inflammation of vaginal epithelium, producing itching, reddish irritation White, cheese-like discharge clinging to epithelium	Eradicate the fungus by administering an antifungal agent. Frequently used brand names of vaginal creams and suppositories are Monistat, Femstat, Terazol, and Gyne-Lotrimin. Review other causative factors (e.g., antibiotic therapy, nylon underwear, tight clothing, pregnancy, oral contraceptives). Assess for diabetes and HIV infection in patients with recurrent infections
Gardnerella-associated bacterial vaginosis	*Gardnerella vaginalis* and vaginal anaerobes	Usually no edema or erythema of vulva or vagina Gray-white to yellow-white discharge clinging to external vulva and vaginal walls	Administer metronidazole (Flagyl) with instructions about avoiding alcohol while taking this medication. If infection is recurrent, may treat partner.
Trichomonas vaginalis vaginitis (STD)	*Trichomonas vaginalis*	Inflammation of vaginal epithelium, producing burning and itching Frothy yellow-white or yellow-green vaginal discharge	Relieve inflammation, restore acidity, and reestablish normal bacterial flora; provide oral metronidazole for patient and partner.
Bartholinitis (infection of greater vestibular gland)	*Escherichia coli* *Trichomonas vaginalis* *Staphylococcus* *Streptococcus* *Gonococcus*	Erythema around vestibular gland Swelling and edema Abscessed vestibular gland	Drain the abscess; provide antibiotic therapy; excise gland of patients with chronic bartholinitis.
Cervicitis: acute and chronic	*Chlamydia* *Gonococcus* *Streptococcus* Many pathogenic bacteria	Profuse purulent discharge Backache Urinary frequency and urgency	Determine the cause: perform cytologic examination of cervical smear and appropriate cultures. Eradicate the gonococcal organism, if present: penicillin (as directed), or spectinomycin or tetracycline if patient is allergic to penicillin. Tetracycline or doxycycline (Vibramycin) to eradicate chlamydia. Eradicate other causes.
Atrophic vaginitis	Lack of estrogen; glycogen deficiency	Discharge and irritation from alkaline pH of vaginal secretions	Provide topical vaginal estrogen therapy; improve nutrition if necessary; relieve dryness through use of moisturizing medications.

It is extremely important that the nurse educate the patient on avoidance of all alcoholic use while taking metronidazole and for 3 days after the last dose due to the disulfiram (Antabuse)-type reaction that is induced; this causes nausea, vomiting, flushing of the skin, chest pain, blurred vision, mental confusion, sweating, breathing difficulty, and anxiety.

VULVOVAGINAL CANDIDIASIS

VVC is caused predominantly by *Candida albicans.* Other nonalbicans species that cause VVC include *C. tropicalis* and *C. glabrata* (Miller, 2014). It is estimated that approximately 25% of all vaginal infections are VVC, but that number is difficult to determine because it is not a reportable condition and because the availability of OTC treatments makes it hard to determine how many women are affected.

Risk Factors

Risk factors include use of broad-spectrum antibiotics (such as penicillins, cephalosporins, and tetracyclines), exogenous hormones, or corticosteroids as well as pregnancy (Papadakis & McPhee, 2014). Other risk factors for VVC include uncontrolled diabetes, obesity, and diets high in sugars or artificial sweeteners (Carcio & Secor, 2015). New sexual partners, contaminated sex toys, or an increase in sexual activity also may change the pH of the vagina, making it more susceptible to infection. Males who are uncircumcised and do not practice good hygiene may harbor yeast and pass on the infection to their partners.

Clinical Manifestations and Assessment

The most common complaint is vulvar pruritus (Miller, 2014). Patients also complain of dysuria related to inflammation of the urinary meatus by means of the vaginal discharge. A urine specimen should be obtained to rule out any other source of infection. Dyspareunia, or pain with intercourse, may also be reported.

VVC differs from BV in that the discharge is generally thick; white; and curd-like, much like the appearance of cottage cheese; and is odorless. It is adherent to the vaginal walls on speculum examination. On physical examination, the external genitalia are erythematous, and adherent white discharge may be noted on the vaginal walls and labia. Diagnosis is established based on a wet mount (a swab of the vaginal discharge on a glass slide that has been mixed with KOH). Under microscopic examination, the presence of hyphae is visible, and Nitrazine will reveal a normal pH of 4.0 to 4.5. If there are clue cells or trichomonads present, it is indicative of a coexisting BV or trichomonas infection (Cibulka & Barron, 2013). A 48-hour culture will diagnose the predominant causative factor definitively.

Medical Management

Many women will self-diagnose and treat based on symptoms with OTC topical preparations containing azole (Monistat or Gyne-Lotrimin). This practice is not encouraged as patients may be self-treating for an infection that may not be VVC or that the yeast will become resistant to the OTC treatment (CDC, 2015). It is important to educate patients to seek evaluation by a health care professional who can diagnose and treat any vaginal infection appropriately.

Topical antifungal agents that are used vaginally offer the most rapid relief. Terconazole (Terazol) cream is available in both 3- and 7-day preparations. This medication covers all three species of yeast, whereas the OTC preparations cover only *C. albicans.* Fluconazole (Diflucan) is a single-dose oral medication that is effective against *Candida*, but there is a delay in symptom relief of up to 3 days. It is, however, an effective treatment, particularly when treating a patient with coexisting BV who is using a vaginal preparation of metronidazole. Oral fluconazole (Diflucan) is a category C drug and should be used with caution during the first trimester of pregnancy. There have been some reports of formation of congenital defects when oral fluconazole is used repeatedly during the first trimester (Cibulka & Barron, 2013).

Nursing Management

The nurse's role in educating a patient with BV or VVC includes assessing for high-risk behaviors, such as multiple sexual partners and unprotected sexual intercourse. If a patient is having recurrent vaginal infections, it is important for the patient to be evaluated by a health care professional to determine the cause.

Recurrent infections can be caused by nonadherence with medication therapy and poor hygiene (Miller, 2014). Also it is important to assess any cross-contamination with sexual toys. Teaching patients and their partners about proper hygiene in addition to sterilization of sex toys can decrease recurrent infections.

If the cause is determined to be from diabetes, the nurse can assist the patient with compliance with dietary guidelines, proper management of blood glucose, and hygienic practices as well as referral to appropriate health care providers for further management.

STRUCTURAL DISORDERS

Physical strain and hormone deficiencies compromise the ability of the pelvic musculature to support pelvic organs. Weakening of this musculature causes pelvic organs to displace downward into the pelvic cavity to varying degrees (Figure 33-8).

PROLAPSE

The pelvic organs are supported by a complex system of ligaments and muscles that are protected by the bony pelvis. The bony pelvis serves as an attachment site for these ligaments and muscles. The uterus is located deep within the bony pelvis but is freely movable during physical examination. A series of muscles known as the pubococcygeal muscles extend from the pubic bone to the coccyx, encompassing the urethra, vagina, anus, and rectum (Carcio & Secor, 2015).

If the muscles and ligaments are weakened, the uterus and bladder prolapse or herniate into the vaginal canal. Patients may or may not be aware of these structural defects until they become symptomatic or are discovered on physical examination. Types of prolapse include:

- *Cystocele:* The herniation of the bladder into the anterior vagina (Fig. 33-8A)
- *Rectocele:* The extrusion of the rectum into the posterior vagina (Fig. 33-8B)
- *Enterocele:* The descent of the small intestine into the vaginal vault (Fig. 33-8C)
- *Uterine prolapse:* Downward descent of the uterus into the vagina (Fig. 33-9)
- *Vault prolapse:* Top of the vagina prolapses after a hysterectomy

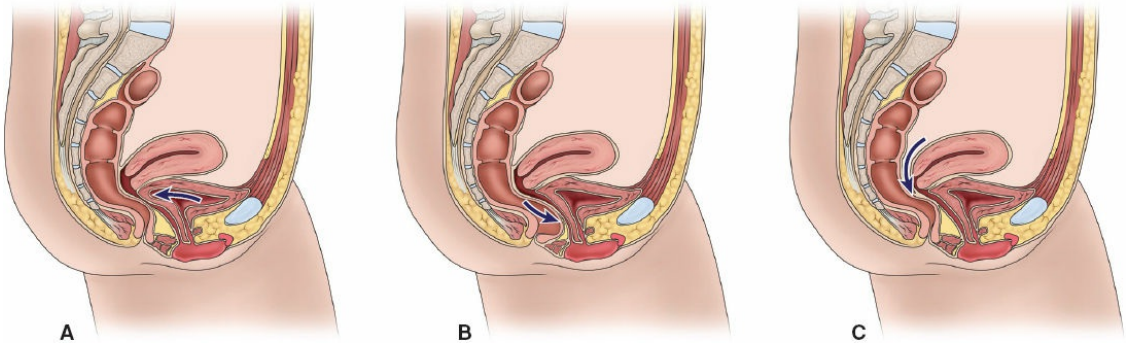

FIGURE 33-8 Diagrammatic representation of the three most common types of pelvic floor relaxation: (A) cystocele, (B) rectocele, and (C) enterocele. *Arrows* depict sites of maximum protrusion.

Pelvic organ prolapse increases with age. More than 225,000 surgical procedures are performed annually to correct these defects (Nygaard et al., 2013). Patients are more likely to develop prolapse once the muscles and ligaments begin to loosen or relax.

Risk Factors

Increased pressure on the abdomen and pelvic floor from pregnancy or obesity causes the ligaments of the pelvic floor to weaken. Direct injury to the levator ani or the stretching of the pudendal nerves during childbirth impairs the elasticity of the pelvic floor muscles (Carcio & Secor, 2015). Women who have more than one vaginal birth are at higher risk for developing prolapse, with risk increasing with each subsequent vaginal delivery (Karatayli et al., 2013). Estrogen helps with maintaining pelvic structure; therefore, patients who are menopausal are more likely to develop a prolapse due to lack of estrogen. Other predisposing factors for developing pelvic organ prolapse include connective tissue disease and neurologic disorders. Increasing strength of the pelvic floor can be correlated to the strengthening effect of exercising the core and abdominal muscles; this can prevent pelvic organs from displacement (Overby, Persons, Carrillo, & Martin, 2014).

Regardless of age, straining from constipation and increased intra-abdominal pressure from coughing are other risk factors for prolapse.

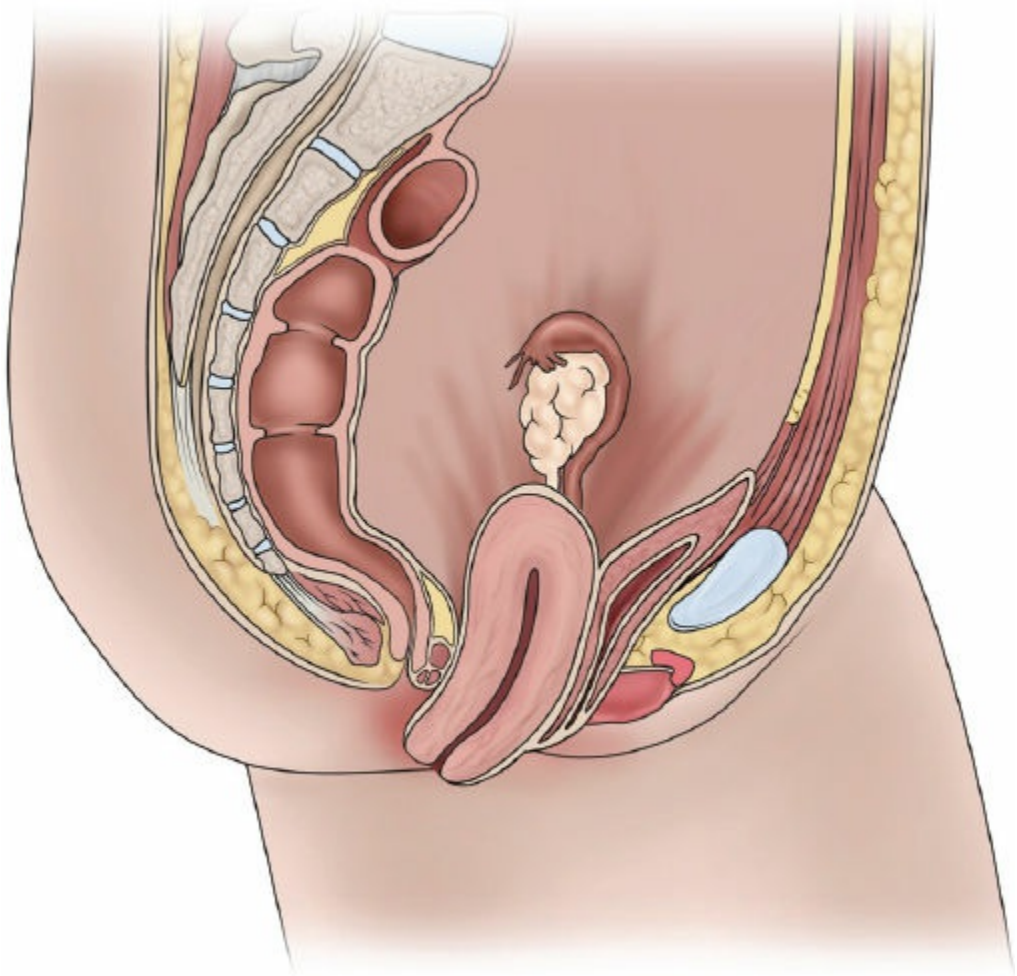

FIGURE 33-9 Complete prolapse of the uterus through the introitus.

Clinical Manifestations and Assessment

Many patients who have a uterine or bladder prolapse will be asymptomatic, while others may seek evaluation by a health care provider because of a noticeable "bulge" in the vaginal area. Back pain in the absence of trauma may be present. Urinary incontinence is a common complaint with a bladder prolapse accompanied by pelvic pressure. Frequently women will complain of a UTI when, in fact, it is the prolapse that is producing the symptoms. Patients also may report difficulty having a bowel movement and often will need to place pressure on their perineal or vaginal areas in order to facilitate a bowel movement. Incomplete rectal evacuation or fecal incontinence may occur as a result of prolapse (Papadakis & McPhee, 2014).

Medical and Nursing Management

Treatment depends upon the severity of the symptoms and degree of prolapse involved. Patients' general state of health and activity is also of concern if considering surgical intervention. Urodynamic testing evaluates bladder function. For mild uterine prolapse, a pessary is the first line of treatment. Pessaries are removable devices made of silicone, latex, plastic, or rubber that are inserted into the vagina to provide support. A variety of styles is available, and they are cost-effective while providing immediate relief of symptoms (Lewthwaite, Staley, Girouard, & Maslow, 2013) (Fig. 33-10).

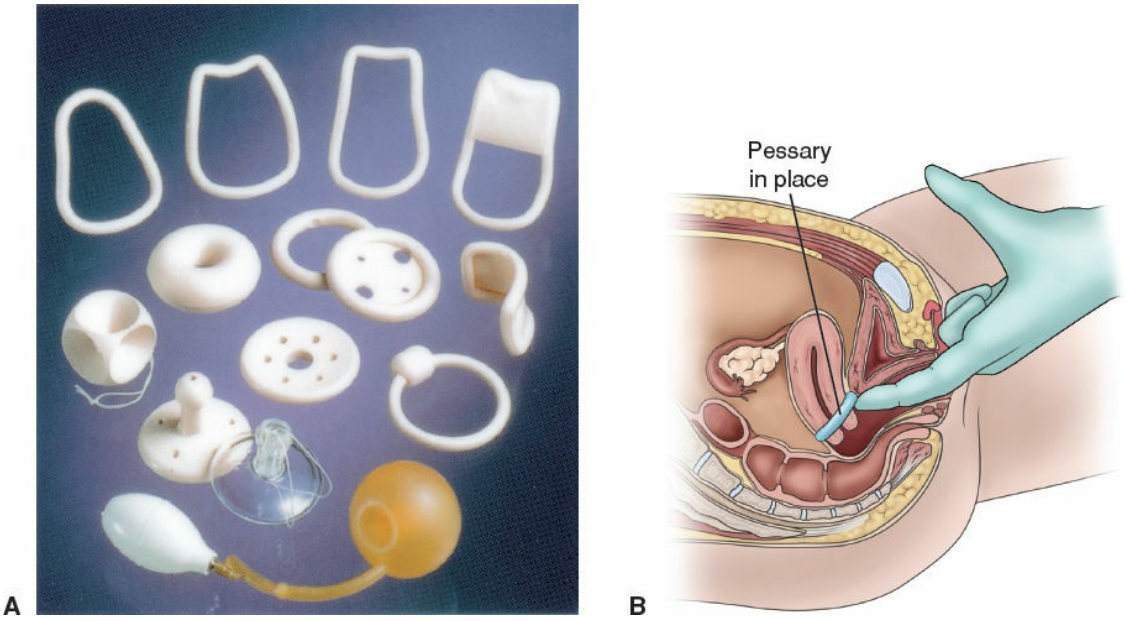

FIGURE 33-10 Examples of pessaries. A. Various shapes and sizes of pessaries available. B. Insertion of one type of pessary.

Pelvic floor rehabilitation or pelvic floor muscle training (PFMT) offers a nonsurgical approach to patients who are motivated to adhere to the exercise schedule (Overby et al., 2014). Kegel exercises are a form of PFMT (Box 33-9). Physical therapists or urogynecologists who are specifically trained in PFMT teach the patient exercises that increase the strength of the pelvic floor muscle. Biofeedback programs feature assisted pelvic floor exercises utilizing a functional electrical stimulator (FES) and are used to help patients contract the appropriate pelvic muscles. Nurses can become trained in PFMT and are able to effectively teach patients about proper use of FES equipment.

Reconstructive pelvic surgery depends upon the impact of the severity of symptoms on the patients' daily living. Sacrospinous fixation, also referred to as an *anterior-posterior repair*, utilizes the surrounding ligaments to tighten and attach lax musculature onto the bony pelvis (van der Ploeg, van der Steen, Rengerink, van der Vaart, & Roovers, 2014). Vaginal hysterectomy is the most common surgical treatment for women beyond childbearing age who have a uterovaginal prolapse (Karatayli et al., 2013). There are some studies that suggest a failure rate 2 to 5 years after surgery for pelvic organ prolapse due to cystocele or rectocele formation (Nygaard et al., 2013).

BOX 33-9 Patient Education

Performing Kegel (Pelvic Muscle) Exercises

Purposes: To strengthen and maintain the tone of the pubococcygeal muscle, which supports the pelvic organs; to reduce or prevent stress incontinence and uterine prolapse; to enhance sensation during sexual intercourse; and to hasten postpartum healing:

1. Become aware of pelvic muscle function by "drawing in" the perivaginal muscles and anal sphincter as if to control urine or defecation, but not contracting the abdominal, buttock, or inner thigh muscles.
2. Sustain contraction of the muscles for up to 10 seconds, followed by at least 10 seconds of relaxation.
3. Perform these exercises 30–80 times a day.

Nurses provide important patient teaching. Educating the patient on weight loss, smoking cessation, and avoiding heavy lifting enables the patient to care for herself. Proper insertion, removal, and cleaning of pessary devices will help the patient to avoid vaginal infections. Nurses can discuss appropriate ways to avoid unnecessary straining and constipation. Anticipatory guidance regarding procedures or surgery will help to alleviate any patient anxiety about the surgical process.

FISTULAS

A fistula is an abnormal, tortuous opening between two internal organs or between an internal hollow organ and the exterior of the body. Fistulas may be simple or complex. Figure 33-11 depicts vaginal fistulas. Rectovaginal fistulas (RVFs) are abnormal openings that occur between the vagina and the rectum, allowing fecal material and flatulence to leak into the vagina, causing fecal incontinence. Anal fistulas generally develop as a result of an anal abscess and may be an indication of some other disorder, such as lymphogranuloma venereum (a sexually transmitted systemic disease that affects the lymph nodes and rectal area, as well as the genitals), rectal tuberculosis, or neoplasm (Papadakis & McPhee, 2014; Nasser, Mendes, Zein, Tanios, & Berjaoui, 2014). Vesicovaginal fistulas occur between the bladder and the vagina and cause urinary incontinence. These conditions occur as a result of congenital anomalies, trauma due to childbirth or surgery, radiation therapy, Crohn disease, diverticular diseases, or neoplasm of the rectum or vagina. Postpartum infections also may result in fistula formation due to third- and fourth-degree perineal tears or tissue breakdown (Brincat, Crosby, McLeod, & Fenner, 2014). This condition causes severe pain and risk for urosepsis due to recurrent UTIs and has social ramifications related to urinary and fecal incontinence (Ma et al., 2015).

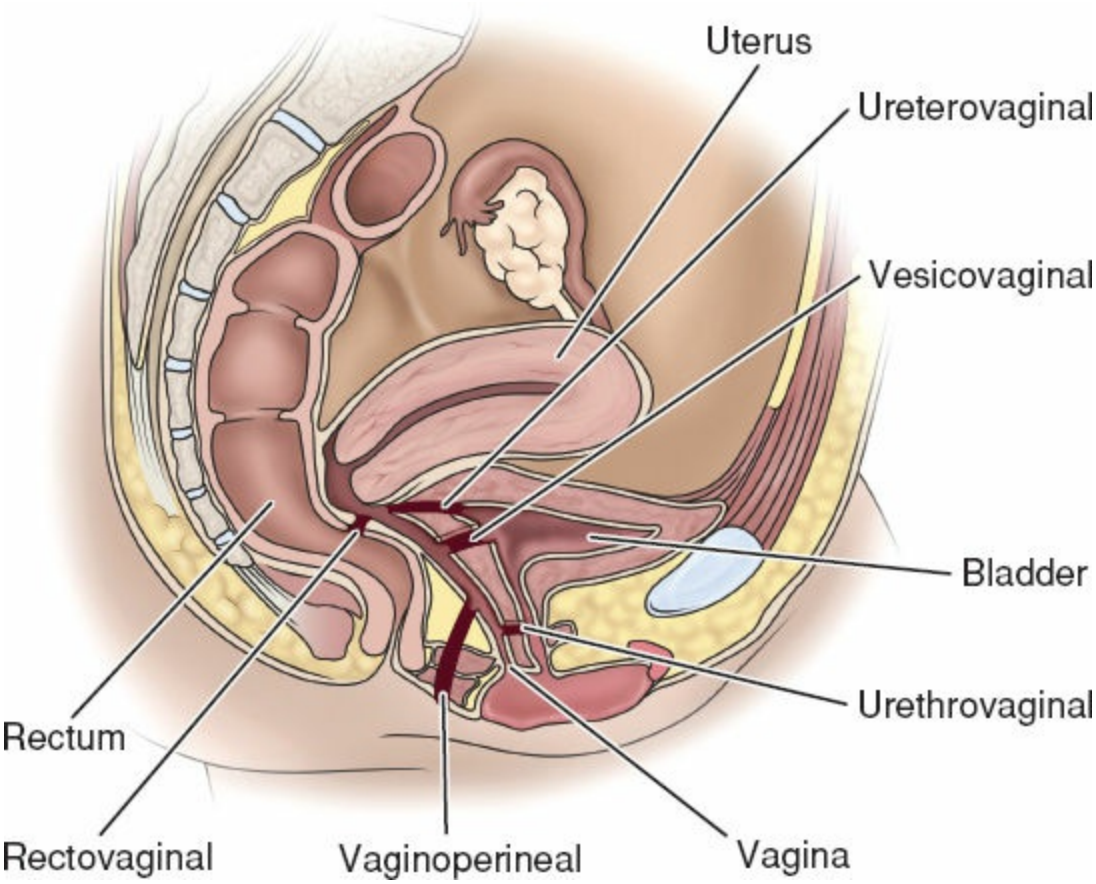

FIGURE 33-11 Common sites for vaginal fistulas: Vesicovaginal, bladder and vagina. Urethrovaginal, urethra and vagina. Vaginoperineal, vagina and perineal area. Ureterovaginal, ureter and vagina. Rectovaginal, rectum and vagina.

Clinical Manifestations and Assessment

Depending upon the type of fistula, symptoms will vary. If caused by an obstetric or surgical complication, fistulas may not be apparent for up to 30 days after the initial injury or may be discovered incidentally during the 6-week postpartum follow-up visit (Ma et al., 2015). Urinary or fecal incontinence are the main reasons why women will seek evaluation by a health care provider. Fecal discharge through the vagina produces a malodorous discharge and may be mistaken for a vaginal infection. An accurate history of onset, timing, and location, along with symptoms the patient is experiencing, is important to help locate the structural abnormality. Physical assessment of the genital area will help to identify the affected area. The fistula may be palpable on digital rectal examination or vaginal examination. A sigmoidoscopy, colonoscopy, small bowel imaging, cystoscopy, or intravenous pyelography will aid in definitive diagnosis.

Medical and Nursing Management

If the fistula is due to Crohn disease or diverticular disease, treatment is aimed at the causative disease and should be followed by a gastroenterologist.

Surgical repair is the only option if the fistula does not heal spontaneously. There is a high rate of recurrence of fistulas in spite of surgical repair. Nurses play an important role in helping the patient to understand the importance of cleanliness and hygiene and to understand the signs and symptoms of recurrent infection or surgical failure to repair the fistula. Regular sitz baths and changing of perineal pads help prevent infection. It is important for the nurse to inspect the patient's skin for any signs of erythema or breakdown.

It is also imperative that nurses assess the impact fistulas play on the patient's psychological state. Many patients suffer from physical and social distress as well as sexual dysfunction as a result of urinary and fecal incontinence due to fistulas (Ma et al., 2015). Assessing the patient's support system as well as appropriate referrals to pain management and surgeons familiar with this type of surgery is imperative.

BENIGN DISORDERS

OVARIAN CYSTS

Ovaries produce estrogen, progesterone, and a small amount of testosterone necessary for female reproductive function as well as formation of oocytes or eggs. Follicles are structures within the ovary containing a single ovum or egg. Follicular growth is stimulated by FSH once a month. After ovulation occurs (release of the egg), the graafian follicle that houses the ovum becomes the corpus luteum. This structure undergoes transformation and regresses with the onset of menses. Ovaries are a common site for cysts to form as a result of hormonal influence on the formation of the graafian follicle and subsequent corpus luteum. When this series of hormonal transitions does not occur, a cyst may develop (Carcio & Secor, 2015). Any graafian follicle that is over 2 cm is considered a cyst. Ovarian cysts are classified as functional or nonfunctional. Statistically, women under age 50 are more likely to have a benign cyst, whereas women over age 50 are more likely to have a cyst that is malignant (McGahan, Corwin, & Gerscovich, 2014).

Types

Functional cysts are also known as *simple cysts* due to their appearance on ultrasound.

These types of cysts rupture and hemorrhage and occasionally cause pain. The condition is self-limiting. Pain that occurs during ovulation, known as mittelschmerz, also produces unilateral ovarian pain and generally is relieved with symptomatic treatment, such as OTC NSAIDs. Ovarian follicles that rupture during ovulation release fluid, cause pain, and may be noted on ultrasound (McGahan et al., 2014).

Nonfunctional cysts, or endometriomas, are also known as "chocolate cysts" due to their characteristic appearance on ultrasound. The cysts develop as a result of sloughed off endometrial tissue that has formed a cystic mass on the ovary; they are brown in appearance. Dermoid cysts are nonfunctional and are comprised of embryonic cells containing hair, teeth, bone, and nails. Since the histologic features and clinical behaviors of dermoid cysts or germ-cell tumors have been well established, there has been little new research performed in this area for the past two decades (Nogales, Dulcey, & Preda, 2014).

Patients with nonfunctional dermoid cysts are diagnosed by pelvic ultrasound after they have had a missed menstrual cycle and have a false-positive pregnancy test. These cysts have characteristic microscopic fat detected within the mass on MRI (McGahan et al., 2014).

Ovaries with multiple cysts due to chronic anovulatory cycles and hyperandrogenism are known as *polycystic ovarian syndrome* (PCOS). PCOS is the most common endocrine disorder that affects approximately 5% to 10% of women of reproductive age (Papadakis & McPhee, 2014). It is a complex disorder of androgen excess, insulin resistance, and an imbalance in the ratios of luteinizing hormone and FSH, causing anovulation (lack of ovulation). Androgen excess coupled with disproportionate amounts of LH and FSH, and decreased sex hormone–binding globulins (SHBG), causes the occurrence of anovulatory cycles. This fluctuation in the normal levels of hormones results in insulin resistance due to the influence of hormone production from the pituitary. Women affected by PCOS are at risk for developing type 2 diabetes, acne, endometrial cancer, hyperlipidemia, obesity, hirsutism, and infertility (Carcio & Secor, 2015; Mahoney, 2014).

Clinical Manifestations and Assessment

Patients experiencing rupture of functional cysts present with a sudden onset of unilateral lower abdominal pain. Nausea and vomiting may be present. Pain typically increases with movement. A typical presentation of PCOS will include a history of irregular menstrual cycles (can be over 35 days per cycle or fewer than eight menses annually). Characteristics of bleeding include heavy flow with increased abdominal cramping and also may include large clots. The patient may be hirsute on the face and chest or between the breasts and demonstrate mild to severe acne. Male pattern baldness or alopecia may be present. Forty to 60% of women with PCOS have central obesity (Mahoney, 2014). Acanthosis nigricans is a hyperpigmentation of the skin around the neck (see Figure 33-12) but also may be noted in the axilla, groin, or the dorsal aspect of hands, and the patient also may have an excessive number of skin tags around the neck, under the arms and breasts, or in the groin (Buttaro et al., 2013). It is commonly associated with insulin resistance. See Figure 33-12. Pelvic ultrasound utilizing color Doppler will reveal follicles varying in size from 2 to 9 mm

or will show an increase in ovarian volume unilaterally (Carcio & Secor, 2015). Patients with unilateral right lower quadrant pain must be evaluated for the potential of appendicitis.

FIGURE 33-12 Acanthosis nigricans. Hyperpigmentation of skin folds, velvety in appearance commonly seen in axilla, groin, and neck. (From *Danforth obstetrics and gynecology*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Medical and Nursing Management

Functional cysts are self-limiting and generally respond to the use of OTC NSAIDs, such as ibuprofen or naproxen. Once a diagnosis of ovarian cysts is made, and depending upon the size of the cyst, hormonal contraception is recommended to induce suppression of FSH. This decreases the incidence of formation of ovarian follicles, limits or halts an increase in the size of any established cysts, and halts the future formation of cysts. If pain persists longer than 48 hours, an exploratory laparoscopy may be performed to rule out the presence of ovarian torsion (twisting of the ovary, primarily affecting the right ovary).

Patients with PCOS require extensive blood work and a transvaginal ultrasound to rule out any other causative factors. Labs include FSH, LH, beta human chorionic gonadotropin (β-hCG), SHBG, free testosterone, prolactin, lipid panel, thyroid studies, and a fasting glucose. A 2-hour glucose tolerance test is useful in determining glucose intolerance. The LH-to-FSH ratio in patients with PCOS is usually greater than 2:1 or 3:1, but a normal ratio is not a diagnosis of exclusion (Buttaro et al., 2013).

It is important that blood work not be performed while the patient is currently taking oral contraceptives as this will alter the accuracy of results and delay diagnosis.

Treatment of PCOS is aimed at the primary concerns (acne, infertility, obesity). Due to the incidence of insulin resistance with PCOS, patients should follow a regular program of exercise and eat a low-fat diet. If, in spite of therapeutic lifestyle changes, the patient is unable to lose weight or ovulate, metformin or Glucophage is initiated to assist with decreasing insulin resistance and allow for spontaneous ovulation. Metformin is an insulin-sensitizing agent that lowers testosterone levels and induces ovulation once hormone levels are balanced. The most common side effect of this medication is transient nausea and diarrhea. Slowly increasing the dosage of metformin and dosing at mealtime will help alleviate these side effects and increase patient compliance. It is estimated that a 1% reduction in BMI has shown a reduction in insulin resistance (Mahoney, 2014). The method of birth control used while on metformin should be discussed with the patient because treatment can restore fertility. Patients with PCOS should be evaluated by a reproductive endocrinologist.

COCs help patients with PCOS regulate menstrual cycles and decrease blood flow with menses and the cramping associated with heavy menses. Additionally, COCs improve SHBG production, which helps bind-free testosterone. This improves acne, hirsutism, and alopecia. Women who do not have regular menstrual cycles are at risk for endometrial cancer due to the prolonged exposure of estrogen and overgrowth of the endometrial lining and, therefore, may need to have an endometrial biopsy if there has not been a menses in 1 year (Valentin, 2014).

Spironolactone is a blood pressure medication that has antiandrogenic effects that is beneficial to those who experience hirsutism (Carcio & Secor, 2015). Because this is a potassium-sparing diuretic, patients with PCOS should have their electrolytes monitored periodically, particularly the potassium level. Two COCs, Yaz and Yasmin, are available that contain *drospirenone*, a newer-generation progesterone that has the same antiandrogenic effects as spironolactone.

Nurses can assist patients with weight loss and exercise guidelines as well as with adherence with medications. It is important to help patients understand the implications of

this disease on QOL and infertility. Nurses play an important role in supporting patients with this disease and recognizing if patients need referral to a dietician or for psychological support.

UTERINE FIBROIDS

Leiomyomas or myomas are common, benign growths of the uterus (Fig. 33-13). Approximately 25% of women over 35 years of have a uterine leiomyomata (Tulandi & As-Asmari, 2015). Risk factors include being African American or being overweight (CDC, 2014d). The high prevalence of uterine fibroids is the cause of high disease burden at the cost of approximately $5.9 to $34.4 billion in the United States annually (Falcone & Parker, 2013; Xuping et al., 2014). Approximately 50% of cases will require surgical intervention. Symptoms largely depend on the size and number of fibroids. The incidence of fibroids increases with age. Box 33-10 describes the types of uterine fibroids.

Clinical Manifestations and Assessment

The majority of women with fibroids are asymptomatic until the fibroid has enlarged and is impeding on other organs. Fibroids cause significant symptoms, including heavy menstrual bleeding, dyspareunia, disabling pelvic pain, rectal pressure, and infertility (Xuping et al., 2014). Diagnosis is made with pelvic ultrasound, which confirms the presence, size, and location of fibroids (Papadakis & McPhee, 2014). Fibroids may be palpated initially on bimanual pelvic examination. Often the uterus is enlarged as a result of the growth.

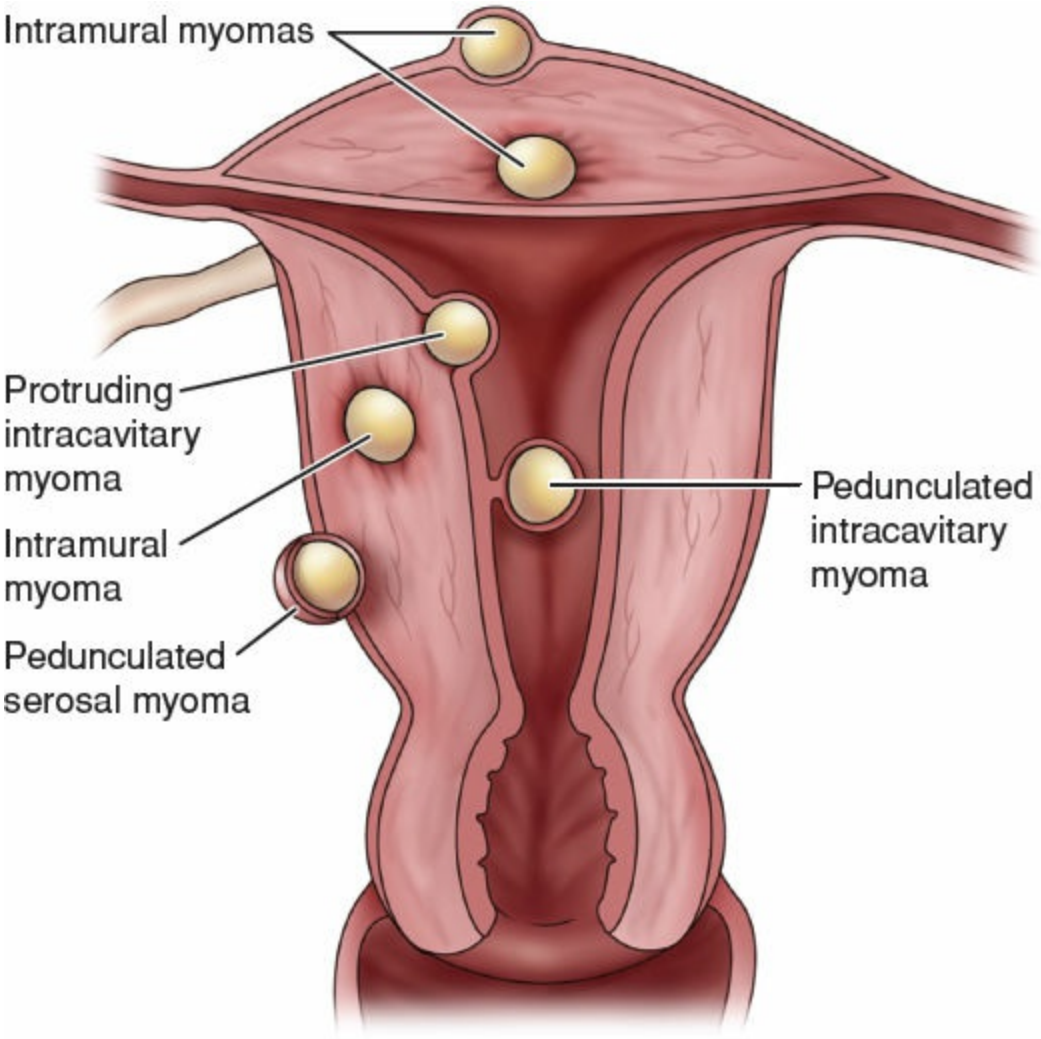

FIGURE 33-13 Myomas (fibroids). Those that impinge on the uterine cavity are called intracavitary myomas.

It is important to rule out pregnancy with a woman who is experiencing these signs and symptoms. There is a risk for miscarriage as the fibroid distorts the uterus impacting on fetal growth. It is estimated that approximately one third of fibroids grow during pregnancy (Lee, Norwitz, & Shaw, 2010).

Medical Management

There are several treatments for fibroids. Medical management is indicated for those women who are considered surgical risks or who decline surgical intervention (Tulandi & Al-Asmari, 2015). GnRH agonists, such as Lupron, are used to decrease the size of the fibroid by effectively suppressing the hormonal production that feeds the fibroid. Hysterectomy is another treatment (see discussion later in the chapter). For patients who have fibroids and want to preserve their fertility, a myomectomy is performed. This is a surgical procedure that removes the fibroid but leaves the uterus intact. Myomectomies can be performed laparoscopically, hysteroscopically (inspection of the uterine cavity by laparoscopy), or via robotic-assisted laparoscopy (Falcone & Parker, 2013).

BOX 33-10 Types of Uterine Fibroids

- *Subserosal fibroids* lie underneath the outermost layer of the uterus and grow toward the pelvic cavity.
- *Intramural fibroids* grow within the wall of the uterine muscle and are the most common type.
- *Submucosal fibroids* grow immediately below the inner uterine surface and into the uterine cavity.
- *Pedunculated fibroids* arise from inside or outside the surface of the uterine muscle and project outward.

Uterine artery embolization (UAE) uses minimally invasive plastic or gelatin particles that are injected into the uterine arteries to occlude blood flow to the fibroid (Ananthakrishnan et al., 2013). The fibroid then shrinks over time. This type of procedure is used only on women who have completed childbearing. Magnetic resonance–guided high-frequency focused ultrasound energy (MRgFUS) uses high-intensity ultrasound with increased temperature to destroy fibroid cells without damaging collateral tissue (Hesley, Gorny, & Woodrum, 2013). In general, this type of procedure is confined to only premenopausal women with symptomatic fibroids. The advantage to this procedure is that patients generally can return to normal activities the day after treatment. Cryoablation, or radiofrequency of individual fibroids, is now FDA approved and is proven safe and effective in reducing the size of fibroids. Cryoablation also has been found to provide a reduction in severity of symptoms 12 months after the procedure without concerns of postembolization syndrome commonly found with patients who have undergone UAE (Chudnoff et al., 2013). Patients typically return to normal activities approximately 5 days postprocedure. Some women undergoing UAE may develop postembolization syndrome: fever, pain, and leukocytosis due to the degenerating fibroid. This is a normal response to treatment, but patients must be monitored for worsening symptoms (Chudnoff et al., 2013).

Nursing Management

Patients experience heightened anxiety when diagnosed with a fibroid. Nurses can reassure patients of the benign nature of fibroids and the potential side effects of medications and surgical procedures. The use of GnRH agonists induces temporary menopause and vasomotor symptoms associated with menopause. The patient may experience hot flashes, sleep disruption, and vaginal dryness as a result of loss of estrogen. These symptoms are reversible once the medication has been discontinued. Due to the high level of bleeding associated with any myomectomy or surgical procedure, all aspirin and aspirin-containing products should be discontinued 3 to 4 weeks before the procedure is performed. Aggressive pain management is advised due to the increased amount of cramping from the infarction of the fibroid. Instructing patients on the patient-controlled analgesia (PCA) pumps and regular administration of NSAIDs and antiemetics will ensure adequate pain control. Patients are coping not only with the physical loss but also the psychological loss of fertility if the patient is not undergoing fertility-sparing surgery so nurses need to address those concerns and offer referrals to therapists if needed.

ENDOMETRIOSIS

Endometriosis is a progressive, benign gynecologic disorder affecting women in their childbearing years and causing chronic inflammation and formation of adhesions. It does not continue after menopause. Approximately 6% to 10% of women suffer from endometriosis, with as high as 80% of these women reporting chronic pelvic pain (Papadakis & McPhee, 2014). This disease may be disabling and chronic. It impacts the woman's sexual relations as well as her physical, social, and psychological well-being.

Pathophysiology

Endometriosis is the presence of endometrial-like tissue that proliferates outside of the uterine cavity, causing persistent pelvic pain and scarring that leads to infertility. The pathophysiology of this disease is largely unknown, but many theories exist (ACOG, 2014). It is thought to be caused by the retrograde flow during menses of endometrial tissue through the fallopian tubes and into the peritoneal cavity, where this tissue seeds, forming adhesions in the pelvic, bladder, and bowel areas. The peritoneal endometrial tissues are influenced by the hormonal changes of the menstrual cycle and, therefore, swell, break down, and bleed; typically, the patient's symptoms worsen during the premenstrual phase. A significant number of women are asymptomatic and may have a normal pelvic examination (Papadakis & McPhee, 2014).

Clinical Manifestations and Assessment

Chronic pelvic pain is the most frequent presentation of endometriosis, but clinical manifestations of the disease are variable in presentation and course of progression (Papadakis & McPhee, 2014). Low back pain, dyspareunia, dysuria, dyschezia (pain with defecation), dysmenorrhea, and menorrhagia are among the common complaints. The level of pain associated with endometriosis is not necessarily correlated with the stage of endometriosis. The cyclical bowel and bladder symptoms of endometriosis are similar to those found in irritable bowel syndrome (IBS) or interstitial cystitis (IC), making it difficult to differentiate among the disorders.

A detailed health history regarding the patient's symptoms in relation to her menstrual cycle will help the health care provider establish a pattern. Any tenderness of the fallopian tubes, ovaries, or uterus on bimanual examination is an indication for further evaluation. The most common finding is tenderness with palpation of the posterior vaginal fornix, but a definitive diagnosis cannot be established without further diagnostic testing. Transvaginal ultrasound visualizes the uterine cavity and endometrium for any adhesions. This examination is unable to visualize smaller lesions; therefore, misdiagnosis may be made. Currently, direct visualization of the adhesions through surgical intervention remains the preferred method for definitive diagnosis (ACOG, 2014).

Medical and Nursing Management

The first line of treatment for endometriosis consists of the use of NSAIDs for pain and COCs to treat the condition. The combined hormones in COCs suppress ovulation and growth of endometrial implants, thereby decreasing inflammation and pain. GnRH agonists (such as Lupron), androgenic agents (Danazol), depot MPA, and levonorgestrel IUD are considered second-line therapy for 3 months (ACOG, 2014). Any of these medications suppresses ovulation and endometrial growth and reduces or eliminates menses, thus alleviating the chance of retrograde flow into the pelvic cavity. Use of continuous contraception provides prolonged suppression of ovulation, inhibiting growth of endometrial tissue. There are no differences in the outcomes of the use of COCs over GnRH, although patients given GnRH agonists have higher incidence of complaints of hot flashes, vaginal dryness, and other vasomotor symptoms associated with menopause. These symptoms are reversible once GnRH therapy has been discontinued.

Surgical intervention is considered the last line of therapy especially if it follows a 24-month use of OCPs (ACOG, 2014). Exploratory laparoscopy with lysis of adhesions is considered the gold standard and temporarily decreases the pain and bleeding associated with endometriosis, although approximately 44% of women will have a recurrence 1 year after surgery (ACOG, 2014). Total abdominal hysterectomy (TAH) remains the definitive therapy for those women who have completed their childbearing and is effective for those women who suffer from debilitating pain (Papadakis & McPhee, 2014).

Complementary and alternative therapies are useful in women who suffer from endometriosis and should be a part of the plan of care for these women. Due to the issues surrounding loss of fertility with this disease, stress management should be included. Yoga may help with stress reduction and also increases core and abdominal strength, which will help patients who undergo surgical intervention to have an easier recovery. Specifically trained physical therapists can help alleviate and manage the symptoms associated with chronic pelvic pain.

Educating the woman affected by endometriosis and her family and support network will help them to understand the significant impact of this disease on the woman and her physical and psychological health. Many women have sought the opinions of multiple medical providers regarding the treatment of endometriosis, and many have had a negative experience or may be in denial of the ramifications of the disease; therefore, establishing trust between the patient and the health care provider is crucial. A collaborative effort among all members of the health care team, including the nurse, health care provider, pharmacist, pain management specialist, and social worker, must exist to help improve the patient's outcome.

MALIGNANT CONDITIONS

CANCER OF THE CERVIX

The most common reproductive cancer among women is cervical cancer; it is the second most common cancer among women. Over 12,000 new cases of cervical cancer were diagnosed in 2011 (the most recent information available), and approximately 4,000 women died of cervical cancer that year (CDC, 2014b). The incidence and mortality of cervical cancer has decreased dramatically over the past 50 years due to the development and subsequent acceptance and use of the Pap smear (Waterman & Voss, 2015).

The most common type of cervical cancer is squamous cell carcinoma (SCC), accounting for approximately 85% of all cervical cancer cases, but the incidence of SCC is decreasing while the incidence of cervical adenocarcinoma is on the rise (Papadakis & McPhee, 2014). Scientists researching triggers to changes in the cervical tissue that lead to cancer have implicated human papilloma virus (HPV) as the most common causative factor in development of cervical cancer (CDC, 2014b). Cervical cancer has a slow progression from certain strains of oncogenic HPV to invasive cervical cancer and may take years to progress. HPV comprises over 100 strains, some of which have oncogenic potential and are known to cause cervical abnormalities. Women are asymptomatic unless they have external genital warts, or condyloma. In general, infection with HPV during a woman's younger years is cleared spontaneously or is suppressed to undetectable levels. The HPV vaccine was developed in 2006, and the quadrivalent vaccine covers four of the oncogenic strains (6, 11, 16, 18) while the bivalent vaccine covers two of the oncogenic strains. This is a primary prevention measure to reduce cervical cancer cases and deaths, but the literature shows that the vaccine continues to be underused (CDC, 2014c).

Screening and Prevention

The Pap smear is a screening tool used to detect any abnormalities of the cervix (Table 33-5). In recent years, liquid-based cytology has been developed to improve specimen adequacy, making it superior to traditional glass slide specimens.

Cytologic screening tests are the most effective preventative measure for screening and diagnosing invasive cervical cancer.

Risk Factors

Lesbian women are at higher risk for HPV and cervical cancer due to misinformation as well as insufficient knowledge and screening. Lesbians are underrepresented in current research due to privacy concerns, lack of inquiries of the part of the health care provider regarding sexual orientation, or fear of repercussions (Waterman & Voss, 2015). Box 33-11 lists other risk factors for cervical cancer.

TABLE 33-5 American Congress of Obstetricians and Gynecologists (ACOG) Cervical Cytology Screening Guidelines

Patient Population	Frequency
21–29 years of age	Every 3 years
30–65 years of age	Every 3 years with HPV cotesting every 5 years
65 years of age and older	Discontinue if no abnormal Pap tests for 10 years and no previous history of moderate–severe dysplasia or cancer
Patients having had a hysterectomy for noncancerous reasons	Discontinue after hysterectomy *unless* patient has had a supracervical hysterectomy, then above guidelines would apply
Patients with high-risk factors: HIV, diethylstilbestrol (DES) exposure, or cervical intraepithelial neoplasm (CIN) 2 or 3	Every 6 months or as directed by health care provider

ACOG. (2013). *Cervical cancer screening*; AP085, January 2013.

Clinical Manifestations and Assessment

Routine screening for cervical cancer increases a woman's chances of being diagnosed at an earlier stage. Advanced disease will manifest itself with irregular vaginal bleeding as well as pelvic pain and pressure. Malodorous vaginal discharge occurs as a result of tumor necrosis. Dyspareunia and rectal pressure also are common as the tumor increases in size and extent, invading surrounding tissue and causing other symptoms to develop. The standard of care for an abnormal Pap test is to follow-up with a colposcopy and directed biopsy. Colposcopy is a high-powered magnification of the cervix, which has had an acetic acid solution applied to it to help differentiate the cervical cells. Biopsies are taken in areas of visible abnormal vascular patterns.

BOX 33-11 Risk Factors for Cervical Cancer

- Intercourse with an uncircumcised male
- Early age of first coitus
- Multiple sexual partners
- High parity
- STIs
- Cigarette smoking
- Exposure to human papillomavirus (HPV)

The squamocolumnar junction of the cervix is rich with squamous cells; this is known as the transformational zone. Cellular abnormalities develop over time, leading to the development of squamous cell dysplasia or cervical intraepithelial neoplasia (CIN) (Papadakis & McPhee, 2014). There are no overt signs or symptoms of CIN, and it is strictly diagnosed via liquid cytology, which provides superior sensitivity to detection of cancer cells. Low-grade lesions correlate with CIN 1, which is mild dysplasia that generally resolves spontaneously without treatment and is monitored through serial cytology to determine any progression to a higher-grade lesion. High-grade lesions are consistent with CIN 2 and CIN 3 and are considered precancerous lesions (Massad et al., 2013). High-grade lesions (severe dysplasia) are more likely to progress to cervical cancer if not treated. Biopsy confirms whether or not the lesion is SCC or adenocarcinoma. Cervical cancer screening should begin at 21 years of age, regardless of sexual debut (ACOG, 2014). Between 21 and 29 years of age, women should have cervical cytology screening without HPV testing every 3 years. All women over 30 years of age should have cervical cytology screening and cotesting for HPV every 3 to 5 years, unless an abnormality is detected. If an abnormal cytology is detected, then appropriate follow-up should occur based on current algorithm guidelines for abnormal cytology. All women 65 years of age and older who have had normal cervical cytology without prior history of CIN should no longer undergo cervical cytology due to the low incidence of disease in this age group (American Society for Colposcopy and Cervical Pathology [ASCCP], 2014).

Delayed diagnosis of cervical cancer will result in a more advanced disease state.

Staging is the next step, once the diagnosis for invasive cervical cancer has been made. Staging is performed on a scale of 0 to IVB. Stage 0 is known as carcinoma in situ (CIS). Stage IVB is consistent with distant metastasis when the disease has spread to the remainder of the reproductive organs, bladder, rectum, liver, and/or lungs. Treatment is dependent upon type of carcinoma and extent of disease. As the tumor size increases, so does the risk of treatment failure. Pelvic ultrasound is an easy and noninvasive way to evaluate any cervical pathology due to its ability to visualize the size and location of a cervical mass. A chest x-ray and abdominal/pelvic imaging, such as CT scan or MRI, are performed to rule out metastasis to other areas of the body.

Medical Management

Abnormal Pap smears that reveal high- or low-grade squamous intraepithelial lesions (HGSIL or LGSIL) are followed up with a colposcopy and cervical biopsy. Once diagnosis has been established, a cervical *conization* or cone biopsy is performed. Cold knife conization and loop electrosurgical excision procedure (LEEP) are other procedures that may be performed to treat HGSIL or LGSIL, which are precursors to cervical cancer. These types of procedures remove cone-shaped wedges high in the cervical canal with enough surrounding tissue to ensure clear margins. This is accomplished using a surgical scalpel, laser, or electrocautery. Prognosis is excellent for patients treated with these types of procedures. Cervical conization alone is adequate for those women who want to preserve childbearing ability (Massad et al., 2013). Invasive cervical cancer is rare under the age of 20, but there has been a documented increased risk for premature births among women who have had excisional cervical procedures for dysplasia prior to conception.

Patients diagnosed with a stage of IB or IIA undergo a radical hysterectomy: removal of the uterus and upper one third of the vagina, including the cervix, but sparing the ovaries. Bilateral pelvic lymph node sampling is also done. Pelvic radiation and chemotherapy may follow depending upon the size and extent of the tumor. Stage IB carries an increased risk of recurrence. Neoadjuvant chemotherapy has demonstrated success in decreasing tumor size and increasing survival when used prior to a radical hysterectomy. Survival rates for patients diagnosed with locally advanced cervical cancer have a higher rate of recurrence than those patients diagnosed with early-stage disease. The survival rate for a patient diagnosed with stage IB is approximately 80% (Straughn & Yashar, 2016).

The HPV vaccine could prevent 95% to 100% of CIN and adenocarcinoma in situ, 99% of genital warts, and 70% of cervical cancer cases worldwide (Papadakis & McPhee, 2014). There are currently two HPV vaccines available: bivalent, which prevents types 16 and 18, and quadrivalent, which prevents types 6, 11, 16, and 18. Routine vaccination should be administered as follows:

- For both males and females at 11 or 12 years of age, and
- For females through 26 years of age and males through 21 years of age who have not been vaccinated previously or who have not completed the 3-dose series (CDC, 2012b).

The HPV vaccines are a series of three vaccines administered at 2 and 6 months after the initial injection. It is important to receive the entire series of three vaccinations. It is recommended that patients remain in the office for at least 15 minutes after administration of the vaccine to ensure there is no reaction.

For women over age 26 years, the best way to prevent cervical cancer is to get routine cervical cancer screening, as recommended.

Nursing Management

Nurses working in a variety of settings have the opportunity to educate women on cervical cancer screenings. Availability of access to care is prevalent with federally funded cervical cancer screening programs through public health departments, hospital-based primary care centers, and community health care clinics. Educating parents and young women about HPV vaccination is important when considering that vaccination is so efficacious. Clinical trials of the vaccine demonstrated a 93% efficacy in prevention of cervical precancers of types 16 and 18 in women who were exposed to HPV. There is a reported 99% antibody response in all studies of the bivalent vaccine 1 month after completion of the series (CDC, 2015b).

If a woman has undergone any cervical biopsy procedures, it is important to instruct her on the importance of pelvic rest (such as abstinence and no vaginal penetration) as well as observing and reporting to her provider if fever, increased bleeding, pelvic pain, or malodorous vaginal discharge is noted. Ensure that the patient has the phone number of her health care provider or local hospital in the event that any of these symptoms occur after her procedure.

CANCER OF THE UTERUS

Cancer of the endometrium or uterus is the most commonly reported female reproductive cancer and comprises approximately 6% of all reproductive cancers in the United States (Park & Nam, 2015). The 5-year survival rate is 67% with localized disease. Usually it is diagnosed early, and better outcomes are reported with surgical intervention. It is rarely diagnosed in women under 40 years of age (CDC, 2014d). Cervical cytology may show atypical endometrial cells but are considered poor predictors of pathology. Endocervical and endometrial sampling is considered the gold standard for diagnosis of this type of cancer (Papadakis & McPhee, 2014).

Most endometrial cancers are considered endometrioid. Less common are the nonendometrioid lesions, including serous, clear cell, and carcinosarcomas. Nonendometrioid cancers are more aggressive, with an increased mortality rate.

Unopposed estrogen causes endometrial hyperplasia, or an overgrowth of the uterine lining. Simple hyperplasia often spontaneously regresses, but complex hyperplasia and atypical hyperplasia are more likely to progress to cancer (ACOG, 2014). The prognosis for type 1 endometrial cancer is good as opposed to type 2, which carries a higher mortality rate. Fertility-sparing progestin therapy is recommended for those who wish to preserve fertility and presumably have type 1 endometrial adenocarcinoma (Park & Nam, 2015). Oral MPA is the most commonly used progestin in this population and should be used for 12 weeks prior to evaluating response to treatment.

Risk Factors

Risk factors are discussed in Box 33-12. Nurses should encourage those with hereditary nonpolyposis colorectal cancer (HNPCC) (Box 33-13) or who are high risk for it to begin annual screening with endometrial biopsies and transvaginal ultrasound beginning at 25 years of age. Some women may reduce their risk of endometrial cancer through the use of OCPs or cyclic progestin therapy (Papadakis & McPhee, 2014).

BOX 33-12 Risk Factors for Endometrial Cancer

- Unopposed estrogen use
- Early onset of menarche (under 12 years of age) or late menopause (over 50 years of age)
- Nulliparous
- Polycystic ovarian syndrome (PCOS)
- Use of tamoxifen
- Obesity
- Diabetes
- Prior pelvic radiation
- Personal or family history of breast, uterine, ovarian, or colon cancer
- Previous history of atypical hyperplasia

Clinical Manifestations and Assessment

Abnormal vaginal bleeding is the most common early symptom of endometrial cancer; 80% of women will present with abnormal vaginal bleeding as their chief complaint (Papadakis & McPhee, 2014). Postmenopausal women also may present with complaints of vaginal bleeding well after menses has ceased. Any unexplained vaginal bleeding or an irregularity in menstrual cycle should be evaluated by a health care professional.

Traditionally diagnosis has been made based on the tissue pathology from a dilation and curettage (D&C); however, endometrial biopsy is the preferred method since it is a simple procedure performed in the health care provider's office and does not involve anesthesia. If the biopsy is inconclusive or suggests endometrial cancer, a D&C is the gold standard. Hysteroscopic-directed biopsy is another alternative that is performed with the insertion of a scope through the cervix and directly into the uterus, allowing for complete visualization of the endometrium. A transvaginal ultrasound may be performed as well as measurements taken of the endometrial thickness. Greater than 16 mm is a predictor of abnormal pathology; in postmenopausal women, greater than 5 mm is considered pathologic (Valentin, 2014).

BOX 33-13 Hereditary Nonpolyposis Colorectal Cancer (HNPCC) Syndrome

Hereditary nonpolyposis colorectal cancer (HNPCC) syndrome increases women's risk of developing ovarian, colon, endometrial, renal, bladder, brain, and stomach cancer.

It is an inherited cancer susceptibility syndrome occurring in approximately 5% of all cancers.

A woman is at higher risk for HNPCC if she has three or more first-degree relatives with colon or endometrial cancer, with at least two of them having been diagnosed with colon cancer at age 50 or younger.

Genetic testing for HNPCC is available and recommended to those at risk.

Nursing Alert

A D&C is brief surgical procedure that can be performed in a medical office or outpatient surgical center in which the cervix is dilated and a special instrument called a curette, or by a suction curettage (also called vacuum aspiration for evacuations for terminations or abortions), is used to scrape the uterine lining. An anesthetic is administered (spinal, general, or local anesthetizing of the cervix) and a sample of the uterine contents may be sent for analysis.

Medical Management

Once the diagnosis has been established, the standard treatment is a TAH with bilateral salpingo-oophorectomy (BSO) (removal of fallopian tubes and ovaries). There is questionable value in pelvic lymph node removal; it is a current source of debate (Valentin, 2014). Type of hysterectomy has little bearing on outcome, although some believe that an open hysterectomy is optimal in visualizing the peritoneum over a laparoscopic-assisted vaginal hysterectomy, in which the peritoneum is not as well visualized; however, this has not been proven in the literature. Laparoscopic vaginal hysterectomy decreases morbidity in women who are morbidly obese or those with high rates of comorbid conditions (ACOG Committee Opinion, 2015). Surgical staging is the most precise method to determine metastasis to surrounding tissues and organs; it involves abdominal and pelvic washings and periaortic lymph node evaluation.

Stage I is curable by surgery alone as it is considered low risk and the disease is confined to the uterus. High-risk stage I and some stage II cancers will require postoperative adjuvant radiation therapy or vaginal brachytherapy as the disease has lymph node involvement, is outside of the uterus, or contains high-risk cell types (papillary or clear cell). Radiation affects the ability of cells to proliferate and decreases growth of cancer cells (ACOG, 2015a). Vaginal brachytherapy consists of the placement of a device containing sealed radioactive material into the vagina postoperatively for 3 to 4 days and then removed. This method is preferred over EBR due to its lessened side effects. It delivers low- or high-dose radiation directly into the tumor. Brachytherapy decreases the incidence of regional recurrence and offers less toxicity than EBR (Klopp et al., 2014). During this time, the patient is on strict bed rest for the entire duration of therapy. Patients are isolated from other patients, and a camera mounted on the wall of the room allows monitoring of the patient while minimizing caregivers' exposure to radiation. Lead absorbs more radiation than any other material; therefore, a portable lead shield is placed at the bedside behind which all caregivers stand to administer medications, change IV bags, or deliver food trays. Nurses wear film badges or dosimeters to measure the amount of radiation exposure.

Patients are kept on a diet of clear liquid or low-residue foods to avoid stool formation. Stool softeners and medications to decrease peristalsis are administered.

Patients with diseases in high-risk stages II and III will receive both radiation and chemotherapy. The role of adjuvant chemotherapy alone or with concurrent radiation is currently under investigation (Papadakis & McPhee, 2014). High-risk features stage IC or poorly differentiated adenocarcinoma, clear cell carcinoma, and papillary serous carcinoma.

Nursing Management

Educating women who have high-risk factors and discussing strategies to reduce risk factors is considered primary prevention. Decreasing obesity and controlling diabetes are two ways to decrease the risk of the development of endometrial cancer.

Nurses can stress the importance of evaluation for any abnormal vaginal bleeding. Use of oral contraceptives as a younger adult also provides some protection against developing endometrial cancer.

Nurses caring for patients receiving brachytherapy must take precautions against occupational exposure to radioactive material. Time, distance, and shielding make up the rules for protecting against unnecessary exposure. A long-handled forceps and lead container are kept in the patient's room after the radioactive material has been placed into the patient. It is imperative that staff never pick up the radioactive source with their bare hands if it becomes displaced from the patient's vagina. The institution's radiation safety team should be notified in the event this occurs. Also patients should be made aware of the side effects of radiation therapy, including radiation enteritis, nausea, loss of appetite, bladder irritation, early menopause, vaginal dryness, and loss of interest in sexual intercourse (Gray & Koh, 2014). Refer to Chapter 6 for more details on radiation therapy.

CANCER OF THE OVARY

Ovarian cancer is referred to as a cancer that "whispers" because its clinical manifestations are not apparent until the tumor has invaded surrounding structures and is causing symptoms. It is the leading cause of death from cancers of the reproductive tract. Approximately 75% of women with ovarian cancer are diagnosed with advanced disease (Papadakis & McPhee, 2014). It carries a high fatality rate due to the aggressiveness of the malignancy. Five-year survivorship rate is not unforeseeable if the cancer is diagnosed at an early stage, but only 20% of women with ovarian cancer are diagnosed at that stage (ACS, 2015). Eighty-five percent of women diagnosed are over 50 years of age; 15% have genetic links, 10% have *BRCA1* and *BRCA2* mutations, and 5% have HNPCC risk factors. See Box 33-14 for additional risk factors. Use of oral contraceptives has been proven to decrease risk of developing ovarian cancer by 50% with long-term protection benefits. Hormonal contraception causes reversible anovulation, thus decreasing the cumulative cycles of the ovary over a woman's lifetime. The longer the duration of use of OCPs means a decrease to the risk of ovarian cancer; every 5 years of use of oral contraceptives equates to a risk reduction of approximately 20% (ACS, 2015).

BOX 33-14 Risk Factors for Cancer of the Ovary

- Age over 40 or postmenopausal
- Nulliparous
- Northern American or Northern European descent
- Personal history of breast, colon, or endometrial cancer
- Obesity (BMI over 30)

- Use of fertility drugs
- Long-term use of hormone replacement therapy (HRT)
- Genetic predisposition; positive family history of ovarian cancer

Cancers of the ovary occur in the epithelial cells lining the ovary. There are several different types of ovarian tumors: those that are germ cell tumors, originating from cells that produce eggs from the ovary; surface cell tumors; and sex cord stromal tumors. Malignant ovarian cells shed from the ovary implant onto the surfaces of the peritoneal cavity. Then these cancerous cells undergo transformation into ovarian surface epithelium (Rooth, 2013). Newer theories point to endometriosis as the predisposing factor for development of ovarian cancer due to damage from inclusion cysts on the ovary or exposure to mullerian factors (specific sensitive tumor marker for ovaries) during menstruation (Tellawi & Morozov, 2014).

Clinical Manifestations and Assessment

Symptoms of ovarian cancer are subtle and start with persistent bloating, early satiety, or a change in bowel or bladder habits. Typically women will complain of weight gain confined to their abdominal area. Due to the close proximity of the ovaries to the intestines, patients will complain of GI symptoms, and, as a result, this cancer carries a high rate of misdiagnosis, with patients commonly receiving treatment for a variety of disorders, including IBS, gastroesophageal reflux (GERD), menopause, or UTIs. Ascites (fluid accumulation in the peritoneal cavity) is considered a late-stage symptom, and prognosis is poor (Rooth, 2013).

No reliable screening tools are available for this disease. Treatment is hindered by late diagnosis, when the disease has already invaded peritoneal tissues and surrounding structures.

Bimanual examinations diagnose approximately one third of ovarian masses. Pelvic ultrasounds and blood tests for CA 125, a tumor marker, are the first diagnostics performed when ruling out an ovarian mass. If either of these tests is suggestive of a tumor, an abdominal and pelvic CT scan is performed. Patients are always referred to an oncologic gynecologist for management of this disease.

Medical Management

Surgical staging identifies tumor histologic grade and volume, which allows for the identification of treatment options and determines the prognosis based on tumor type (Table 33-6). During surgery, the suspicious tissue that is removed and sent to the laboratory for immediate analysis is known as a *frozen section.* If positive, the surgeon then performs extensive cytoreduction surgery or debulking to obtain clean tissue margins. This includes a TAH with BSO, removal of the omentum, peritoneal washings, and partial colectomy if there is any colon involvement (Rooth, 2013).

Stage IA or IB tumors are considered low risk and favorable to treatment, if well- or moderately well-differentiated tumors are confined to the ovary. Absence of tumor on the external surfaces, absence of ascites, and negative peritoneal washings are also favorable signs. Stage IA or IB with poorly differentiated tumors, tumors notable on the external surface of the ovary, ruptured tumor capsule, and positive peritoneal washings all are considered high risk and unfavorable. Advanced stages III and IV require combination chemotherapy after surgical staging has been performed to determine tumor sensitivity to a particular chemotherapeutic agent.

Chemotherapy treats residual tumor and helps to control any metastatic disease. Advance tumors receive chemotherapy first to decrease the size of the tumor; then the patient undergoes surgical debulking to remove as much tumor as possible. First-line chemotherapy consists of platinum and paclitaxel. Seventy-five percent of women respond to initial treatment, but there is an 85% relapse rate with a median survival of 3 years after platinum therapy. Carboplatin and paclitaxel are considered the gold standard for treatment of ovarian cancer. Carboplatin has recently replaced cisplatin due to its ability to be administered on an outpatient basis and its lesser toxicity. Patients undergo two or three cycles to evaluate their response and toxicity before proceeding with further treatment. Carboplatin combined with gemcitabine yields a higher response rate that has a longer median progression-free survival (ACS, 2015). Patients whose tumors are resistant to platinum receive single-agent therapy. A blood test for CA 125 is a sensitive indicator of disease relapse.

TABLE 33-6 Stages of Ovarian Cancer

Stage	Description
Stage I	Tumor confined to ovary
Stage II	Involves one or both ovaries and extends into pelvis
Stage III	Involves one or both ovaries, as well as peritoneal metastasis and/or lymph node involvement
Stage IV	Distant metastasis beyond peritoneal cavity, including the liver

Nursing Management

Education and support begin preoperatively and continue through discharge (Rooth, 2013). Care must be individualized based on the patient's psychological and physical status, stage of illness, and treatment plan. Patients will need anticipatory guidance regarding postoperative infections, pain management, and potential side effects from chemotherapeutic agents. Postoperatively, patients will need to be monitored for signs and symptoms of infection, ileus, DVT, pulmonary embolus (PE), and bleeding. Encouraging the patient in the regular use of incentive spirometry, as well as regular ambulation, will help to decrease the development of DVT and atelectasis.

Emotional support is extremely important as the patient recovers from surgery and has to cope with a diagnosis of cancer. Side effects from chemotherapy should be discussed with the patient and her support system. Hair loss, nutrition, neuropathies, and nausea and vomiting as well as self-image alterations should be addressed regularly with the patient during her preoperative assessment and should be ongoing during her treatment. Refer to Chapter 6 for details on cancer care.

CANCER OF THE VULVA

Vulvar cancer is rare and represents just 5% of all cancers of the female reproductive tract (Rauh-Hain et al., 2014). Its incidence has been increasing slowly since 1973, however, and this is thought to be due to its link with HPV. There is increased evidence of young women with HPV being diagnosed with vulvar intraepithelial neoplasia (VIN), but the disease has a high cure rate after surgical resection and radiotherapy. Women diagnosed with vulvar cancer are usually between 65 and 70 years of age; however, studies now show that age is decreasing to 55 to 60 years of age at diagnosis (Rauh-Hain et al., 2014). Approximately 60% of women will be diagnosed with localized disease (Carcio & Secor, 2015).

The majority (90%) of cases of vulvar cancer is SCC, and approximately 40% to 60% of subtypes are largely due to high-risk strains of HPV (Papadakis & McPhee, 2014). VIN is more complex, deeply invasive, and is considered the precancerous condition of HPV types 16, 18, 31, and 33. Women who have been treated for condyloma, HPV, or abnormal cervical cytology, and those who smoke cigarettes or have an increased number of sexual partners have increased risk of developing cancer of the vulva.

Clinical Manifestations and Assessment

Longstanding external labial itching or burning of the external genitalia are early signs often self-treated by patients with OTC cortisone or anti-itch creams. Only about half of women will present with dyspareunia, vulvar edema, or pain. Later-stage manifestations include ulcerated lesions that are indicative of cancer. Older women are more likely to have advanced disease at the time of diagnosis (Rauh-Hain et al., 2014). Lesions occur in the vulvar area but may extend into the perianal and rectal areas, and lesions occur most commonly in areas that do not have hair. A Keyes punch biopsy or tissue biopsy is the gold standard for diagnosing vulvar cancer.

Medical Management

As with all cancerous lesions, early diagnosis of vulvar cancer is paramount. Vulvar biopsy can be performed in the office if short-term medical therapies have been proven unsuccessful or if there is a high index of suspicion for cancer. Vulvar colposcopy may be performed, but laser ablation or a wide excision of the affected area or a vulvectomy (removal of the vulva) with lymph node sampling for clear margins is dependent upon the size, depth, and focality of lesions. As a result, preservation of the clitoral area may or may not occur (Papadakis & McPhee, 2014). An alternative to surgery for early-stage lesions is the use of imiquimod (Aldara), which is a topical immune-response modifier with antiviral and antitumor properties typically used for the treatment of external genital warts. Depending upon the extent of the vulvectomy, use of chemotherapy, biologics, and radiation treatments also may be indicated. If there is evidence of disease spread to adjacent organs or regional lymph nodes, lymphadenectomy will be performed. There is a statistically significant correlation between extent of reconstructive surgery and disease outcomes, with local reconstructive surgery demonstrating a better prognosis with significant reduction in relapse rate.

Nursing Management

Patients are at higher risk for infection depending upon the size and extent of the surgical site. Monitoring patients postoperatively for wound infections, fever, discharge, and pain is a priority. Avoidance of cross-contamination of body fluids (such as urine or feces) will help to decrease infection. Foley care and assessment of skin are important in identifying any potential site of entry for infection.

Nursing Alert
Catheter-associated urinary tract infection (CAUTI) is one of the most common causes of hospital-acquired infection (HAI); therefore, the nurse plays a key role in detection and prevention of UTIs. The following interventions are recommended:

- *Insert catheters only for appropriate indications, and remove them as soon as possible.*
- *Ensure that only properly trained persons insert and maintain catheters; insert catheters using sterile technique and sterile equipment. Use as small a catheter as possible to minimize urethral trauma.*
- *Maintain a closed drainage system. Empty the collecting bag regularly using a separate collecting container for each patient. Avoid touching the draining spigot to the collecting container.*
- *Maintain unobstructed urine flow (keep the collecting bag below the level of the bladder at all times; do not place the bag on the floor; keep the catheter and collecting tube free from kinking).*
- *Maintain hand hygiene and follow standard (or appropriate isolation) precautions.*
- *If a urine specimen is needed, collect a small sample by aspirating urine from the needleless sampling port with a sterile syringe/cannula adaptor after cleansing the port (Lo et al., 2014; CDC, 2015d).*

Postoperative requirements for prolonged bed rest underscore the importance of assessing the patient for the development of DVT and PE to avoid tension on the surgical site and promote healing. Frequent position changes, and the use of compression stockings and intermittent pneumatic compression boots, along with regular use of incentive spirometry, will aid in avoiding the formation of DVTs and PEs.

Patients who have undergone a vulvectomy may suffer from distorted body images as a result of surgical resection; however, there are gaps in the literature that supports this theory (McCallum et al., 2014). Decreased sensation, vaginal dryness, and dyspareunia all affect a woman's ability to enjoy sexual relations. There is also a risk of pelvic floor dysfunction due to the severing of the delicate nerve supply in the vulvar area. Discussion with the surgeon regarding the extent of surgery will help the nurse to answer any questions the patient may have postoperatively. One of the most frequently reported concerns of patients with gynecologic cancer is the fear of recurrence and difficulty with changes in their sexual health (McCallum et al., 2014). Partner involvement and a social work or mental health referral are beneficial to help patients and their partners understand what to expect after

discharge from the hospital.

HYSTERECTOMY

Surgical removal of the female reproductive organs is performed for a variety of reasons: dysfunctional uterine bleeding, benign or malignant masses, pelvic organ prolapse, pelvic pain, endometriosis, or trauma. Hysterectomies are the most common nonobstetric major surgery performed in the United States. Over 600,000 hysterectomies are performed annually (CDC, 2015e). The majority of hysterectomies are performed for benign uterine disorders that impact the QOL for women suffering from uterine disease or menstrual disorder.

Minimally invasive surgical techniques are now preferred due to reduced blood loss, decreased postoperative complications, and quicker recovery time (Mikhail et al., 2015). Hysterectomies consist of surgical removal of the uterus and fallopian tubes; however, conservation of the ovaries and cervix may be considered depending upon the patient's age and reason for surgery. Bilateral oophorectomy is associated with a decreased risk of breast and ovarian cancer. Fifty percent of women who undergo hysterectomy between 40 and 44 years of age will have both ovaries removed at the time of surgery. That percentage increases to 78% for women between 45 and 64 years of age. Surgical removal of the ovaries results in immediate cessation of production of both estrogen and androgen, causing surgical menopause. Subtotal hysterectomy or sparing of the cervix has no proven benefits (Saccardi et al., 2015). It is important for women to know if they have not had their cervix removed; women with an intact cervix will need to continue to undergo annual Pap smear screening for cervical cancer.

Types

Deciding on whether a TAH versus a total vaginal hysterectomy (TVH) should be performed is largely dependent upon a patient's BMI and other comorbid conditions. TVH allows for less blood loss, quicker recovery, shorter hospital stays, fewer infections, and less pain than the abdominal approach, which requires incisions through the abdominal musculature. TVH and laparoscopic-assisted vaginal hysterectomy (LAVH) can be done in a 1-day surgery center, whereas TAH and radical hysterectomies require a longer hospital stay. The use of laparoscopic and hysteroscopic (inspection of the uterine cavity by endoscopy) approaches are other alternatives to be considered and are dependent upon the surgeons' skill and experience with the equipment, as is robotic-assisted surgery. LAVH seems to be a safe alternative to TAH for patients who are obese (Mikhail et al., 2015). Radical hysterectomies, performed for malignant conditions, consist of the complete removal of all the reproductive organs, including the surrounding tissue margins, the upper one third of the vagina, and pelvic lymph node sampling. The number of hysterectomies performed overall is less now due to the development and use of endometrial ablation, progestin IUDs, and UAE.

Nursing Management

All patients with hysterectomies are surgical patients and, therefore, must be cared for like any other surgical patient. Attention to pain management; postoperative complications, such as DVT, PE, wound infections, and UTIs; and return of bowel function are the primary concerns for nurses. The nurse assesses the patient's lung sounds and encourages regular use of incentive spirometry. The nurse also monitors for return of bowel functions, as an ileus may occur due to manipulation of the bowel during surgery and the effects of anesthesia and analgesia on peristalsis.

Encouraging patients to walk with assistance as soon as the effects from general anesthesia have resolved helps with circulation and prevents formation of blood clots. Many patients undergoing hysterectomy also are dealing with the loss of fertility and, possibly, a cancer diagnosis. The nurse allows patients to verbalize their concerns and feelings and makes referrals to mental health providers if needed.

Discharge planning should include pelvic rest for 4 to 6 weeks and teaching the patient wound care and signs and symptoms of infection. Patients are allowed to shower and should be encouraged to resume regular activity gradually as per the surgeon's recommendation. Patients who have had a TAH generally are not permitted to drive for 4 to 6 weeks. They should avoid any heavy lifting, pushing, or pulling (such as vacuum cleaning) until their surgeon clears them to resume those activities. It is normal for women who have had hysterectomies to have some vaginal discharge. Patients who have undergone TAH normally will have some vaginal bleeding for up to 1 week postoperatively; patients who have undergone TVH and LAVH may have some vaginal discharge consisting of blood and mucus for several weeks postoperatively. Any foul-smelling vaginal discharge, unusual pain, or fever should be reported to the surgeon immediately. If there is evidence of unilateral swelling of the lower extremities, shortness of breath, or any discharge or redness around their incision sites, patients should contact their health care provider.

Unfolding Patient Stories: Doris Bowman • Part 2

Recall from Chapter 6 Doris Bowman, who is undergoing a TAH with BSO. What are potential postoperative complications that the nurse should consider? What assessments and interventions are done by the nurse to monitor for early detection or to prevent these complications? Describe the discharge education provided by the nurse on self-care monitoring required of the patient at home and what should be reported to the

health care provider.

Care for Doris and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

TRANSGENDER HEALTH CARE

Health Care Disparities

There is an increasing awareness of transgender patients and their lack of access to health care. As more people identify as transgender, it is paramount that nurses and health care providers educate themselves in the care of this underserved and sexually marginalized population (Zuzelo, 2014). This patient population is largely uninsured, experiences social stigmatization, and is at higher risk for PCOS, HIV exposure, interpersonal violence, and suicide. Transgender individuals are persons whose gender identity differs from their birth sex or their gender expression is different from what is typically considered to be societal norms. *Gender dysphoria* is a term used to describe the physical and emotional discomfort in one's assigned birth sex (IOM, 2011). If left untreated or if a person was unable to express or live as the gender one identifies with, that could lead to increased depression and, often, suicide. There are a disproportionate number of transgender individuals, especially teens and young adults, who become homeless due to familial isolation, loss of income, and inability to secure employment or housing. They may be placed inappropriately in emergency shelters and become victims of violence.

In 2010, the National Center for Transgender Equality and the National Gay and Lesbian Task Force performed a survey, "National Transgender Discrimination Survey Report on health and health care" (National Center for Transgender Equality, 2010). The results of this survey revealed that 50% of the respondents reported having to teach their health care provider about transgender care. Forty-one percent of transgender individuals reported suicide attempts versus the national average of 1.6%; this population also reported HIV rates that are four times that of the national average. The results also include that a staggering 24% have been discriminated against by a health care provider, and 19% were denied care from a health care provider completely. All patients deserve the same respect regardless of gender identity, preference, or expression.

When an individual identifies as transgender, he or she begins to live socially as a member of the sex identified with, through clothing and perhaps a name change. This is known as "transition." Some will choose to take hormones, such as testosterone or estrogen, for the desired physical effects of the gender they identify with. Many insurance companies deny coverage of hormone therapy for these patients. Others may have gender-affirming surgery, such as chest reconstruction (i.e., bilateral mastectomy), breast implants, orchiectomy, vaginoplasty, or phalloplasty while others may never have surgery at all. Some transgender persons may or may not choose to take hormones. Many patients who are in transition do not qualify for health care insurance, nor will current insurance pay for any procedures related to patients' transitions, mental health therapy, facial-feminization, or gender-affirming surgery. As a result, many patients will purchase hormones via the Internet or from unreliable sources. If patients become hospitalized, they may be anxious that they will not receive their hormones. Frequently they are discriminated against by those in the health care profession due to lack of knowledge, training, or personal bias on the part of the provider. The patient's level of anxiety may be escalated, and he or she may be perceived as a "difficult" patient. A person who has had to turn to prostitution to survive or who has been discriminated against repeatedly throughout life may turn to negative

behaviors in times of crisis. Elder transgender persons are increasingly at risk for death from treatable chronic diseases or cancer due to their fear of stigmatization and previous discrimination or lack of health insurance. End-of-life issues and health care directives become a worrisome issue for elder transgender persons due to the absence of a legal marriage and subsequent legal inability to allow partners to make health care decisions (Kimmel, 2014). Many states that do not recognize same-sex marriage also do not allow partners to make health care decisions so it falls onto the next of kin. This becomes a legal debate especially in the context of end-of-life care especially if the patient does not have a living will or if the patient lives in a state that does not recognize domestic partnerships or same-sex marriages.

These behaviors will dissipate once a relationship of trust with care providers has been formed. It is difficult to find culturally competent and compassionate providers who have experience with transgender clients. The nurse is reminded that Healthy People 2020 states "access to quality health care and related services is important in order to eliminate health disparities and increase the quality and years of healthy life for all persons in the United States" (Healthy People 2020).

Nursing Management

It is important for nurses to be culturally diverse at all levels of practice. Nurses need to understand the specific needs of transgender patients and demonstrate acceptance with increased sensitivity and remain nonjudgmental while delivering care. It is equally as important for nurses to educate other members of the health care team who may not have experience with this population to avoid any compromise in patient care due to bias or ignorance. Any bias or ignorance should not be tolerated by any member of the health care team.

Due to the historically poor treatment of the transgender population by the health care profession, many will seek care only in an emergency and when routine health conditions have exacerbated into a serious condition. It is vital that nurses treat the patient, not the gender, and accept and encourage involvement of the client's domestic partner, significant other, and any other person who is considered family by that patient. Nurses also must be familiar with individual institution policies regarding nonblood relatives as next-of-kin for patients.

Nurses are in a unique position to establish a trusting relationship with patients. It is important to use gender-neutral terms and to ask the patient for the preferred name and pronoun. Other important interventions for this patient population include:

- Assessing the patient for high-risk behaviors, including IV drug abuse, prostitution, or use of hormones obtained via the Internet, on the street, or from the patient's friends.
- Offering to help female-to-male (FTM or transman) patients with their breast binder (if they wear one) after a shower, or assisting with padded bras and undergarments for male-to-female (MTF or transwoman) patients.
- Offering support and reassurance for those undergoing invasive examinations, such as a breast or pelvic examination, as transgender clients have a lot of emotional conflict between their actual body and what they perceive their body to be.

Hysterectomies are routine gynecologic procedures performed for specific medical and surgical needs, as previously discussed in this chapter. In order to be considered a surgical candidate for a hysterectomy, the client will need to undergo a gynecologic examination. It is important to note that almost all transgender patients undergoing this surgery are either nulliparous or have never had vaginal penetration. If the client has been using testosterone, a significant amount of vaginal atrophy will occur. If a client is taking estrogen therapy, penile and scrotal atrophy will be present. A digital rectal examination is still mandatory on any MTF (transwoman) patients over 50 years of age due to the presence of the prostate gland. Any FTM (transman) patient who has not had a hysterectomy or has had a supracervical hysterectomy will need to continue with routine cervical screening. ACOG (2011) recommends routine age-appropriate preventative screenings, including prostate and breast examinations, regardless of gender identity. However, there is varied consensus on whether or not routine cervical cytology should be continued in FTMs (transmen) who take testosterone therapy (ACOG, 2011).

Any transgender patient who has any type of gender-affirming surgery should be treated like any other postoperative patient with the same risk factors.

CHAPTER REVIEW

Critical Thinking Questions

1. A 60-year-old woman has a weak family history of breast cancer, including two great aunts, both postmenopausal at diagnosis. She would like to pursue *BRCA* testing. How would you address this request? What are the implications of genetic testing? What would you need to know about her history to determine the appropriateness of this test?

2. A 72-year-old woman with comorbidities of obesity and diabetes, who lives alone, is scheduled for a modified radical mastectomy for invasive breast cancer. Discuss the postoperative care of this patient, including discharge planning. How would you modify care if she has a severe hearing impairment? How would you modify care if she has been noncompliant with her medical care in the past? What appropriate resources are available for this patient?

3. When visiting the employee health center to obtain her annual influenza vaccine, a 48-year-old woman with a history of breast cancer and previous mastectomy reports that she has been experiencing vague abdominal discomfort, bloating, flatulence, and increased waist size over the last 6 months. Her next annual physical examination is 6 months from now. What additional information is it important to obtain from her? What recommendations for further follow-up and health care would you provide?

4. A 50-year-old woman is scheduled for a total hysterectomy to treat fibroids. She reports that she anticipates severe symptoms of menopause because her mother and grandmother had severe symptoms. She asks you about medications and herbal substances that can prevent or minimize menopausal symptoms without increasing her risk of breast cancer or cardiac disease. What is the strength of evidence about medications, including estrogen, and herbal substances to reduce menopausal symptoms? What criteria would you use to determine the strength of that evidence?

NCLEX-Style Review Questions

1. A patient is concerned with developing breast cancer. The nurse recognizes which as the greatest risk factor for developing breast cancer?
   a. Having a first-degree relative who developed breast cancer
   b. Being female and advancing age
   c. Beginning menses before age 12 and never having children
   d. Smoking and obesity

2. A patient asks the nurse when she should be screened for breast cancer. What is the nurse's best response, based on the American Cancer Society's recommendations for breast cancer screening?
   a. Annual screening mammography beginning at age 40, clinical breast examination

every 3 years beginning at age 20 and annually beginning at age 40, and practicing breast self-awareness

b. Annual screening mammography beginning at age 50, annual clinical breast examination beginning at age 50

c. Screening mammography every other year beginning at age 50, annual clinical breast examination beginning at age 40, monthly breast self-examination

d. Baseline screening mammogram at age 35, annual screening mammography beginning at age 40, breast MRI every 5 years beginning at age 40, annual clinical breast examination beginning at age 20, monthly breast self-examination

3. Which patient would be at highest risk for subsequent development of lymphedema?
   a. A 75-year-old woman with a single focus of biopsy-proven localized ductal carcinoma in situ
   b. A 65-year-old woman with a known benign cyst
   c. A 50-year-old woman with a biopsy-confirmed fibroadenoma
   d. A 62-year-old woman with biopsy-proven invasive ductal carcinoma with palpable axillary lymph nodes and positive node fine-needle aspiration

4. A patient suspects that she may have PMS. The nurse should ask the patient about which symptoms?
   a. Symptoms that occur during the luteal phase of the menstrual cycle
   b. Symptoms that occur during the follicular phase of the menstrual cycle
   c. Symptoms that worsen during menopause
   d. Symptoms that persist throughout the entire menstrual cycle

5. A patient has just been prescribed Lupron for her endometriosis. The nurse should mention which side effects while educating the patient about this drug?
   a. She may experience breakthrough bleeding.
   b. Reversible symptoms of menopause may occur.
   c. The medication will reduce the size of her fibroids.
   d. A form of back-up contraception should be used while taking this drug.

CHAPTER 34

Nursing Management: Patients with Male Reproductive Disorders

Susanne A. Quallich

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss the causes and management of male sexual dysfunction.
2. Compare the types of prostatectomy with regard to advantages and disadvantages.
3. Use the nursing process as a framework for care of the patient undergoing prostatectomy.
4. Describe the various conditions affecting the testes, including pathophysiology, clinical manifestations, and management.
5. Describe the various conditions affecting the penis, including pathophysiology, clinical manifestations, and management.

Disorders of the male reproductive system involve the genitalia and, in some instances, sexuality; as a consequence, the patient may experience anxiety and embarrassment. The effects of trauma, chronic illness, and physical disability on sexual function can be profound. A man's willingness to discuss these issues is influenced directly by his culture, religion, and social community. The nurse must recognize the patient's need for privacy as well as his need for education.

DISORDERS OF MALE SEXUAL FUNCTION

ERECTILE DYSFUNCTION

Erectile dysfunction (ED) is the inability to achieve or maintain an erection sufficient for satisfactory sexual activity. Up to 50% of men 40 years of age and older may report some difficulty with erectile function (Glina, Sharlip, & Hellstrom, 2013).

Pathophysiology

The physiology of erection and ejaculation is complex and involves sympathetic and parasympathetic components. Erection involves the release of nitric oxide into the corpus cavernosum during sexual stimulation; this releases cyclic guanosine monophosphate (cGMP) and causes relaxation of the smooth muscles. This allows flow of blood into the corpus cavernosum, resulting in erection.

ED has both psychogenic and organic causes. Psychogenic causes include anxiety, fatigue, depression, and pressure to perform sexually. Organic causes include occlusive vascular disease, endocrine disease (diabetes, hypogonadism, hyperthyroidism, and hypothyroidism), cirrhosis, chronic kidney failure, postsurgical causes (retroperitoneal surgery), neurologic disorders (neuropathies, parkinsonism, spinal cord injury, and multiple sclerosis), trauma to the pelvic or genital area, alcohol, medications (Box 34-1), and drug abuse.

Clinical Manifestations and Assessment

The diagnosis of ED requires a sexual and medical history; an analysis of presenting symptoms; a physical examination, including a neurologic examination; a detailed assessment of the usage of any medications, alcohol, and drugs; and laboratory studies. Because ED can occur secondary to a variety of disorders and pharmacologic agents, nurses are encouraged to ask the patient questions about erectile function. Numerous tools are available to help nurses introduce the topic of sexual health with their patients. The man may report decreased frequency of erections, inability to achieve a firm erection, or rapid detumescence (subsidence of erection).

Nocturnal penile tumescence tests and Rigiscan® testing are options to evaluate actual erectile function and help to determine whether there is an organic or a psychological cause; these are ordered at the discretion of the provider. Arterial blood flow to the penis can be measured using a Doppler probe. Figure 34-1 describes the evaluation and treatment of ED.

Medical Management

Treatment can be medical, surgical, or both, depending on the cause (Table 34-1). Nonsurgical therapy includes treating associated conditions, such as diabetes, and adjusting antihypertensive agents or other medications. Endocrine therapy may reverse the condition. Patients with ED from psychogenic causes are referred to a sex therapist. Patients with ED secondary to organic causes may be candidates for penile implants.

BOX 34-1 Classes of Medications Associated with Erectile Dysfunction

- Antiadrenergics and antihypertensives
- Anticholinergics and phenothiazines
- Antiseizure agents
- Antifungals
- Antiandrogen medications (prostate cancer treatment)
- Antipsychotics
- Antispasmodics

- Beta blockers
- Calcium-channel blockers
- Carbonic anhydrase inhibitors
- H_2 antagonists
- Thiazide diuretics
- Tricyclic antidepressants

Pharmacologic Therapy

Phosphodiesterase-5 (PDE-5) inhibitors are oral medications that are used to treat ED. Sildenafil citrate (Viagra), the first of these agents, was introduced in 1998 in the United States. Other PDE-5 inhibitors are vardenafil HCl (Levitra), avanafil (Stendra), and tadalafil (Cialis). PDE-5 is an enzyme that destroys cGMP, the nucleotide that causes the cavernosal relaxation necessary for erection to occur. By inhibiting PDE-5, cGMP is allowed to accumulate, thus facilitating relaxation of corporeal smooth muscle in response to sexual stimulation. When these PDE-5 inhibitors are taken about 1 hour before sexual activity, they are effective in producing, with stimulation, an erection that can last 60 to 120 minutes. These medications have side effects and are contraindicated in men who take organic nitrates because together these drugs can cause severe hypotension. Table 34-2 summarizes the dosing and nursing implications of these medications.

Other pharmacologic measures to induce erections include injecting vasoactive agents, such as alprostadil, papaverine, and phentolamine, directly into the penis. Complications

include priapism (a persistent erection of the penis) and development of fibrotic plaques at the injection sites. Alprostadil also is formulated in a gel pellet that can be inserted into the urethra to promote an erection.

Penile Implants

Penile implants are available in two types: the semirigid rod and inflatable. The semirigid rod results in a permanent semierection, but it is not commonly used. The inflatable prosthesis simulates natural erections and natural flaccidity. Complications after implantation include infection and erosion of the prosthesis through the one or both of the corpora cavernosa (see Chapter 32, Fig. 32-7), which may require removal of the implant (Oberlin et al., 2015). Factors to consider in choosing a prosthesis include the expectations of the patient and his partner.

FIGURE 34-1 Evaluation and treatment of men with erectile dysfunction. (From Lue, T. F. (2000). Erectile dysfunction. *New England Journal of Medicine*, *342*(24), 1807. © 2000 Massachusetts Medical Society. All rights reserved. Used with permission.)

TABLE 34-1 Treatments for Erectile Dysfunction

Method	Description	Advantages and Disadvantages	Duration
Pharmacologic therapy • Oral medication (sildenafil citrate [Viagra]; vardenafil HCl [Levitra]; avanafil [Stendra]; tadalafil [Cialis])  Oral medication	Smooth muscle relaxant causing blood to flow into penis	Can cause headache and sinus stuffiness Contraindicated for men taking nitrate medications Used with caution in patients with retinopathy or poor exercise tolerance	Taken orally 1 hour before intercourse Stimulation is required to achieve erection.
• Injection (alprostadil, papaverine, phentolamine)  Penile injection	Smooth muscle relaxant increasing blood to flow into penis	Firm erections are achievable in more than 50% of cases Pain at injection site; plaque formation, risk of priapism	Injection 20 minutes before intercourse Erection can last up to 1 hour.
• Urethral suppository (alprostadil)  Penile suppository	Smooth muscle relaxant increasing blood to flow into penis	May be used twice a day Not recommended with partners who are pregnant or if trying to become pregnant	Inserted 20–30 minutes before intercourse Erection can last up to 1 hour.
Penile implants • Semirigid rod • Inflatable  Penile implant	Surgically implanted into corpus cavernosum	Reliable Requires surgery Healing takes up to 3 weeks Semirigid rod results in permanent semierection	Indefinite—must be deflated manually (inflatable device) Inflatable prosthesis: Saline returns from penile receptacle to reservoir.

Negative-pressure (vacuum) devices  Penile vacuum pump	Induction of erection with vacuum; maintained with constriction band around base of penis	Few side effects Patients may find it cumbersome to use Vasocongestion of penis can cause pain or numbness	To prevent penile injury, constriction band must not be left in place for longer than 1 hour.

TABLE 34-2 Pharmacologic Treatment of Erectile Dysfunction

	Sildenafil Citrate (Viagra)	Vardenafil HCl (Levitra)	Avanavil (Stendra)	Tadalafil (Cialis)
Recommended dose	Dosage range is 25–100 mg, based on individual response. Take only once in 24 hours.	Dosage range is 5–20 mg, based on individual response. Take only once in 24 hours.	Dosage range is 50– 200 mg, based on individual response. Take only once in 24 hours.	Dosage range is 5–20 mg, based on individual response. Take only once in 24 hours. For patients with decreased liver or kidney function, the maximum dose is 10 mg every 48 hours.
When to take	Take the medication 30 minutes to 4 hours before sexual activity. *There must be sexual stimulation to produce an erection.*	Take the medication 1 hour before sexual activity. The peak action occurs in 30–120 minutes. *There must be sexual stimulation to produce an erection.*	Take the medication at least 15 minutes before sexual activity. The peak action occurs in 30–120 minutes. *There must be sexual stimulation to produce an erection.*	Take the medication before sexual activity. Effect peaks at 2–6 hours; effect may last up to 36 hours. *There must be sexual stimulation to produce an erection.*
Side effects	Side effects include headache, flushing, indigestion, nasal congestion, blue vision.	Side effects include headache, flushing, runny nose, indigestion, sinusitis.	Side effects include headache, flushing, runny nose, back pain.	Tadalafil may cause back pain and muscle aches. Tell your provider if you experience any of these side effects.
Note	Patients must be counseled to seek medical attention for erection lasting longer than 4 hours. Patients must be counseled to seek medical attention in the event of a sudden loss of vision in one or both eyes. Taking more than one of these mediations is not advised; combinations have not been evaluated formally for efficacy or safety. These medications can potentiate the effects of nitrates, alpha blockers, antihypertensives, and alcohol.			
Contraindications	Do not take if you are taking nitrate medications, such as nitroglycerine or isosorbide mononitrate. Do not take if you have high uncontrolled blood pressure, coronary artery disease, or have had a heart attack within the past 6 months. Do not take if you have been diagnosed with a cardiac arrhythmia or kidney or liver dysfunction—discuss with your provider to ensure proper dosing.			
Drug interactions	These medications can react with other medications that you may be taking. Provide your provider with a complete list of all prescribed as well as over-the-counter medications that you are using.			

Vacuum Erection Devices

Negative-pressure (vacuum) devices also may be used to induce an erection. A plastic cylinder is placed over the flaccid penis, and negative pressure is applied. When an erection is attained, a constriction band is placed around the base of the penis to maintain the erection.

Nursing Management

Personal satisfaction and the ability to satisfy a partner sexually are common concerns of patients. Men with illnesses and disabilities may need the assistance of a sex therapist to find, implement, and integrate their sexual beliefs and behaviors into a healthy and satisfying lifestyle. The nurse should assess the patient's needs and make appropriate resources available, including information regarding referral to a specialized sex therapist, such as www.aasect.org.

DISORDERS OF EJACULATION

The spectrum of disorders of ejaculation responses ranges from occasional ejaculation through intercourse or self-stimulation to complete inability to ejaculate under any circumstances. For instance, premature ejaculation occurs when a man reaches climax before or shortly after intromission. Treatment modalities depend on the nature and severity of the ejaculation problem. Behavioral therapies may be indicated; these therapies often involve both sexual partners. In some cases, pharmacologic and behavioral therapy together may be effective.

Neurologic disorders (e.g., spinal cord injury, multiple sclerosis, neuropathy secondary to diabetes), surgery (prostatectomy), and medications are the most common causes of inhibited ejaculation. Chemical, vibratory, and electrical methods of stimulation have been used with some success.

CONDITIONS OF THE PROSTATE

PROSTATITIS

Prostatitis is an inflammation of the prostate gland that is caused by infectious agents or other conditions (e.g., urethral stricture, prostatic hyperplasia).

Pathophysiology

Escherichia coli is the organism that is isolated most commonly. Usually microorganisms are carried to the prostate from the urethra. Prostatitis syndromes are classified as acute bacterial (type I), chronic bacterial (type II), chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (type IIIa), inflammatory/chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (type IIIb), and noninflammatory and asymptomatic inflammatory prostatitis (type IV) (National Institute of Health; National Institute of Diabetes and Digestive and Kidney Disease [NIH/NIDDK], 2014).

Clinical Manifestations and Assessment

The diagnosis of prostatitis requires a careful history and physical examination. Symptoms of prostatitis may include perineal discomfort, dysuria, urgency, frequency, and pain with or after ejaculation. Prostatodynia (pain in the prostate) is manifested by pain on voiding or perineal pain without evidence of inflammation or bacterial growth in the prostate fluid.

Acute bacterial prostatitis may produce sudden fever and chills as well as pain in the perineum, rectum, or low back. Urinary symptoms, such as dysuria (painful urination), frequency, urgency, and nocturia (awakening at night to urinate), may occur. Chronic bacterial prostatitis is a major cause of relapsing urinary tract infection (UTI) in men. Symptoms are usually mild, consisting of frequency, dysuria, and, occasionally, urethral discharge. Complications of prostatitis include swelling of the prostate gland, urinary retention, epididymitis, bacteremia, and pyelonephritis (discussed in Chapter 27).

If the patient does not have acute prostatitis, the provider performs a digital rectal examination (DRE) after collection of a urine sample, which commonly reveals many white blood cells. A DRE should not be performed if acute prostatitis is suspected because of the increased risk of causing bacteremia and septicemia.

Medical Management

The goal of therapy for acute bacterial prostatitis is to avoid the complications of abscess formation and septicemia. A complete blood count (CBC) and blood and urine culture may be ordered. A prostate-specific antigen (PSA) test may not be obtained since in many patients the acute inflammatory process causes temporary elevation. However, the PSA test also can provide a means to track the success of treatment as the level should lessen with the use of antibiotics. A broad-spectrum antibiotic, frequently a fluoroquinolone, is administered for 14 to 30 days. Comfort is promoted with analgesic agents, antispasmodic medications, bladder sedatives (to relieve bladder irritability), sitz baths (to relieve pain and spasm), and stool softeners (to prevent pain from straining).

Chronic bacterial prostatitis can be difficult to treat because most antibiotics diffuse poorly from the plasma into the prostatic fluid. Treatment includes alpha-adrenergic blockers to promote relaxation of the bladder and prostate. Antibiotics, such as trimethoprim-sulfamethoxazole or a fluoroquinolone, may be prescribed.

The treatment of nonbacterial prostatitis is directed toward relief of symptoms.

Nursing Management

A patient experiencing symptoms of acute prostatitis may be hospitalized for IV antibiotic therapy. Nursing management includes administration of prescribed antibiotics and provision of comfort measures, including prescribed analgesic agents and sitz baths. In addition, the patient is cautioned to avoid activities that result in repetitive perineal trauma, such as cycling.

Usually the patient with chronic prostatitis is treated on an outpatient basis and needs to be instructed about the importance of continuing antibiotic therapy. The nurse instructs the patient to complete the prescribed course of antibiotics. Hot sitz baths (10 to 20 minutes) may be taken several times daily. Fluids should be encouraged to keep the urine dilute, and the patient should avoid sitting for long periods to minimize discomfort.

BENIGN PROSTATIC HYPERPLASIA

In approximately one half of men 50 years of age and older, the prostate gland enlarges and obstructs the outflow of urine. This enlargement and obstruction, referred to as benign prostatic hyperplasia (BPH), is evident in 80% of men 80 years of age and older.

Pathophysiology

The hypertrophied lobes of the prostate may obstruct the vesical neck or prostatic urethra, causing incomplete emptying of the bladder and urinary retention. As a result, a gradual dilation of the ureters (hydroureter) and kidneys (hydronephrosis) can occur. UTIs may result from urinary stasis since retained urine serves as a medium for infective organisms.

Risk Factors

The cause of BPH is uncertain. Many African-American men develop BPH at a much younger age (40 years of age) than Caucasian men do, whereas Asian men are unlikely to develop BPH (Sotelo, Azhar, & Morales, 2015). Recent studies have identified smoking (both current and former smoking), heavy alcohol consumption, hypertension, heart disease, and diabetes as risk factors associated with BPH (Moyad, 2014). Other studies suggest that dietary factors may affect prostate growth and BPH (Sotelo et al., 2015).

Clinical Manifestations and Assessment

The obstructive and irritating symptoms associated with BPH include increased frequency of urination, nocturia, urgency, hesitancy in starting urination, abdominal straining with urination, a decrease in the volume and force of the urinary stream, interruption of the urinary stream, dribbling, a sensation of incomplete emptying, possible acute urinary retention, and recurrent UTIs.

DRE may reveal a large, rubbery, and nontender prostate gland, although the size of the prostate correlates poorly with symptom report. Diagnostic studies may be indicated to determine the degree to which the prostate is enlarged, the presence of any changes in the bladder wall, and the efficiency of kidney function. These tests may include urinalysis as well as urodynamic studies to assess urine flow and bladder function. Renal function tests, including serum creatinine levels, may be performed to determine whether renal impairment exists.

Medical Management

The treatment plan depends on the severity of the obstruction and the patient's condition. If the patient is admitted on an emergency basis because of urinary retention, an emergency catheterization is performed. The ordinary catheter may be too soft and pliable to advance through the urethra into the bladder. A Coude catheter (45-degree, semirigid curved tip) is recommended to facilitate passage through the prostatic urethra. If a catheter cannot be placed, an incision is made into the bladder (a suprapubic cystostomy) to provide drainage; however, this is rare. Further details are discussed in Chapter 28 under urinary retention.

Pharmacologic Therapy

Pharmacologic treatment for BPH includes use of alpha-adrenergic blockers and 5-alpha-reductase inhibitors. Alpha-adrenergic blockers relax the smooth muscle of the bladder neck and prostate, improve urine flow, and relieve BPH symptoms. 5-alpha-reductase inhibitors interfere with the conversion of testosterone to dihydrotestosterone (DHT), which is associated with prostate growth. Decreased levels of DHT lead to decreased activity of glandular cells and prostate size. Side effects may include gynecomastia, ED, low volume ejaculate, and flushing.

Saw palmetto is an herbal product some men find helpful in addressing symptoms associated with BPH. In theory, it functions by interfering with the conversion of testosterone to DHT. Research has shown that the efficacy of saw palmetto is similar to that of medications such as finasteride, and the herbal product may be better tolerated and less expensive (Katz & Darves-Bornoz, 2014). The lack of standardization of herbal products should be a source of concern for health care professionals (Katz & Darves-Bornoz, 2014; Porth, 2015), and the nurse should warn men that formulations may be different with each purchase.

Other Therapies

Other treatment options for BPH include surgical options, such as transurethral incision of the prostate (TUIP), balloon dilation, transurethral laser resection, transurethral needle ablation, and microwave thermotherapy (Porth, 2015). Surgical approach of choice depends on the size of the gland, the severity of the obstruction, the age of the patient, any comorbidities, and the function of the bladder, and there are potential postoperative management issues (Box 34-3). Stents (devices made of tubular mesh) may be inserted under local or regional anesthesia to maintain patency of the urethra when patients are a poor risk for prostatic surgery. "Watchful waiting" is another option chosen by many, in which patients are monitored periodically for severity of symptoms, physical findings, and laboratory tests and may undergo diagnostic urologic tests.

CANCER OF THE PROSTATE

Prostate cancer is the most common cancer in men other than nonmelanoma skin cancer. It is the second most common cause of cancer death in American men, exceeded only by lung cancer, and is responsible for 10% of cancer-related deaths in men. Among men diagnosed with prostate cancer, 5-year survival is nearly 100%, 99% survive at least 10 years, and 94% survive 15 years (ACS, 2015a, 2015b).

Risk Factors

Prostate cancer is common in the United States and northwestern Europe but is rare in Asia, Africa, Central America, and South America. The worldwide incidence of prostate cancer is highest in African-American men; possible factors that may explain the increased mortality rate in African-American men include their lower level of engagement in the health care system, disparities in health care, and cultural constraints that define masculinity and health (Tanagho & McAninch, 2012). Other risk factors for prostate cancer include increasing age; more than two thirds of cases occur in men older than 65 years of age (ACS, 2015a). A familial predisposition may occur in men who have a father or brother previously diagnosed with prostate cancer, especially if those relatives were diagnosed at a young age. Data suggest that men who consume a diet containing excessive amounts of red meat or high-fat dairy products are at increased risk for prostate cancer (ACS, 2015b).

Clinical Manifestations and Assessment

Cancer of the prostate in its early stages rarely produces symptoms. If the neoplasm is large enough to encroach on the bladder neck, signs and symptoms of urinary obstruction occur (difficulty and frequency of urination, urinary retention, and decreased size and force of the urinary stream). Hematuria may result if the cancer invades the urethra or bladder, or both.

Prostate cancer can metastasize to bone and lymph nodes. Symptoms related to metastases include backache, hip pain, perineal and rectal discomfort, anemia, weight loss, weakness, nausea, and oliguria (less than 400 mL/day). These symptoms may be the first indications of prostate cancer, although due to contemporary US screening practices, it is uncommon for men to present at this advanced stage.

The American Urological Association (AUA) (2013) recommendation states that "the highest-quality evidence for benefit (lower prostate cancer mortality) was found in men ages 55 to 69 screened at 2- to 4-year intervals," and the organization "does not recommend routine screening in men between ages 40 and 54 years at average risk." The AUA also recommends that men be counseled regarding their potential treatment options prior to screening (AUA, 2013).

In direct contrast, the American Cancer Society (2015) does not support routine PSA screening but recommends that "asymptomatic men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about screening for prostate cancer after receiving information about the uncertainties, risks, and potential benefits associated with screening." These tests are recommended for younger men (40 to 45 years of age) if they are at high risk for prostate cancer; namely, African-American men and men who have a first-degree relative (father, brother, or son) diagnosed with prostate cancer at an early age (under 65 years of age) (ACS, 2015b).

The level of PSA in the blood is proportional to the total prostatic mass and does not necessarily indicate malignancy. There are limitations in the relationship among serum PSA, prostate cancer volume, and higher stages of prostate cancer as measured by the Gleason score, which is the system used most often to grade prostate cancer and to guide the physician in determining the most appropriate treatment (Sher & Eastham, 2015). The combination of DRE and PSA testing appears to be a cost-effective method of detecting prostate cancer. If prostate cancer is detected early, the likelihood of cure is high. This is limited by the methods used to identify prostate cancer from abnormal findings on DRE and serum PSA elevations. Both of those tools have issues related to sensitivity and specificity, adding to the continued lack of consensus regarding "best screening" tools.

Routine repeated rectal palpation of the gland (preferably by the same examiner) is important because early cancer may be detected as a nodule within the substance of the gland. The diagnosis of prostate cancer is confirmed by a histologic examination of tissue. Cancer detected when transurethral resection of the prostate (TURP) is performed for benign prostatic enlargement and lower urinary tract symptoms occurs in about one out of 10 cases (Tanagho & McAninch, 2012).

Needle biopsies of the prostate are guided by transrectal ultrasound (TRUS) and may be indicated for men who have elevated PSA levels and abnormal DRE findings. Other tests that may be used to establish the extent of disease include bone scans to detect metastasis to

the bones and computed tomography (CT) scan to identify metastases in the pelvic lymph nodes. Some facilities now offer an MRI/ultrasound fusion biopsy, especially for men with a history of a previous negative ultrasound-guided biopsy and rising PSA. Men who have chosen active surveillance for prostate cancer also may be candidates for this procedure. This new procedure allows the urologist to precisely identify areas of the prostate that should be investigated or biopsied. Patient preparation is the same for a traditional prostate biopsy.

Medical and Nursing Management

Treatment is based on the stage of the disease and the patient's age and symptoms. Review of data from clinical assessment, laboratory and radiology tests, TRUS, and/or biopsy results assists in the treatment decision process.

Surgical Management

Radical prostatectomy is the complete surgical removal of the prostate, seminal vesicles, and, often, the surrounding fat, nerves, lymph nodes, and blood vessels. It is considered the standard first-line treatment for prostate cancer. Although ED commonly follows radical prostatectomy, Da Vinci prostatectomy or robotically assisted laparoscopic radical prostatectomy (RALP) offers advantages of low morbidity and more rapid discharge postprocedure (see below for discussion).

Radiation Therapy

If prostate cancer is detected in its early stage, the treatment may be curative radiation therapy. Two major forms of radiation therapy are used to treat cancer of the prostate: teletherapy (external) and brachytherapy (internal).

Teletherapy (external-beam radiation therapy) involves 6 to 7 weeks of daily (5 days/week) radiation treatments. Current technology sets a dose for the target volume and restricts the dose to adjacent structures. It is thought to be accurate within 1 to 3 mm.

Brachytherapy involves the implantation of interstitial radioactive seeds under anesthesia, via the perineum, into the prostate. Eighty to 100 seeds are placed directly into the prostate, and the patient returns home after the procedure. Exposure of others to radiation is minimal, but the patient should avoid close contact with pregnant women and infants for up to 2 months.

Side effects of teletherapy and brachytherapy include inflammation of the rectum, bowel, and bladder due to their proximity to the prostate and the radiation doses. Men are likely to suffer a decline in erectile function with time. Table 34-3 discusses nursing interventions to minimize side effects. Combination therapy (radiation therapy followed by hormonal therapy) may improve overall survival.

Hormonal Therapy

Hormonal therapy for advanced prostate cancer suppresses androgenic stimuli to the prostate by decreasing the level of circulating plasma testosterone or interrupting the conversion to or binding of DHT. As a result, the prostatic epithelium atrophies. This effect is accomplished either by surgical castration (orchiectomy) or by the administration of medications. Orchiectomy is associated with considerable emotional impact. The most appropriate choice, timing, and actual benefits of hormonal therapy are uncertain.

TABLE 34-3 Management of Radiation-Induced Symptoms

Symptom	Intervention
Cystitis	Maintain hydration. Encourage patient to take prescribed medications (bladder antispasmodics, alpha blockers, analgesics). Avoid known bladder irritants (see Chapter 28).
Diarrhea	Provide low-residue diet. Maintain hydration. Administer antidiarrheals as indicated. Give dietary bulking agents as indicated.
Erectile dysfunction	Assess for level of distress and suggest sexual therapist as appropriate. Provide education regarding appropriate medication.
Proctitis (inflammation of the rectum)	Offer sitz baths. Recommend water-based lubricants. Maintain hydration to avoid constipation. Adjust diet to avoid constipation.

Effective hormonal alternatives to orchiectomy include the nonsteroidal antiandrogen bicalutamide. Newer hormonal therapies include luteinizing hormone–releasing hormone (LHRH) agonists (leuprolide and goserelin) and antiandrogen agents, such as flutamide. LHRH suppresses testicular androgen, while flutamide causes suppression of adrenal androgen. LHRH agonists are used for the following: (1) in the adjuvant and neoadjuvant setting (i.e., before use of hormonal suppressive agents), in combination with radiation therapy; (2) in combination with radical prostatectomy; and (3) in the treatment of recurrence indicated by an elevation in the PSA. Hot flashes can occur with orchiectomy or LHRH-agonist therapy.

Second-Line Medical Treatment

The management of hormone-refractory cancer of the prostate remains somewhat controversial. Administration of second-line hormonal therapy using ketoconazole is an option that lowers testosterone by decreasing both testicular and endocrine production of androgens. There may be benefits in terms of survival with chemotherapy treatment that includes paclitaxel and docetaxel for nonandrogen-dependent prostate cancer.

Other Therapies

Cryosurgery of the prostate is used to ablate prostate cancer in patients who cannot tolerate surgery and in those with recurrent prostate cancer. Transperineal probes are inserted into the prostate under ultrasound guidance to freeze the tissue directly.

Keeping the urethral passage patent may require repeated transurethral (TUR) resections. If this is impractical, catheter drainage is instituted by way of the suprapubic or transurethral route. For men with advanced prostate cancer, palliative measures, such as pain management, complementary and alternative medicine (CAM), and androgen deprivation, can be options. Although cure is unlikely with advanced prostate cancer, many men survive for a long period apparently free of metastatic disease.

Bone lesions resulting from metastasis of prostate cancer can be very painful. Opioid and nonopioid medications are used to control the pain. External-beam radiation therapy can be delivered to skeletal lesions to relieve pain, while radiopharmaceuticals can be injected IV to treat multiple sites of bone metastasis.

More than one third of men with a diagnosis of prostate cancer elect to use some form of CAM. Because of lack of research on many forms of CAM, patients may be forced to rely on anecdotal information or information gained via the Internet to make decisions about its use.

Complications

Each treatment for prostate cancer has some incidence of sexual function issues. With nerve-sparing radical prostatectomy, the likelihood of recovering the ability to have erections is better for men who are younger and in whom both neurovascular bundles (the erectile nerves and blood vessels called neurovascular bundles run along the surface of each side of the prostate) are spared. Hormonal therapy also affects the central nervous system mechanisms that mediate sexual desire and arousability. PDE-5 inhibitors may be effective for treatment of ED in younger men after radical retropubic prostatectomy (discussed shortly), especially if the neurovascular bundles were preserved. They may improve erectile function in men with partial or moderate ED after radiation therapy for localized prostate cancer.

PROSTATE SURGERY

Prostate surgery may be indicated for the patient with BPH or prostate cancer. Prostate surgery should be performed before acute urinary retention develops and damages the upper urinary tract and collecting system or before cancer progresses.

Procedures

Several approaches can be used to remove the hypertrophied portion of the prostate gland: TURP, suprapubic prostatectomy, perineal prostatectomy, retropubic prostatectomy, TUIP, and robotic prostatectomy (Table 34-4). Hyperplastic tissue is removed, leaving behind the capsule of the prostate.

NURSING PROCESS

Patient Undergoing Prostatectomy

ASSESSMENT

The nurse assesses how the underlying disorder (BPH or prostate cancer) has affected the patient's lifestyle. The nurse asks about the patient's family history of cancer and heart or kidney disease, including hypertension. In addition, the nurse observes for weight loss, pallor, ability to get in and out of bed without assistance, and ability to perform activities of daily living (ADL). This information helps determine how soon the patient will be able to return to normal activities after prostatectomy.

DIAGNOSIS

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Preoperative nursing diagnoses:
  - Anxiety related to surgery and its outcome
  - Acute pain related to bladder distention
  - Deficient knowledge about factors related to the disorder and the treatment protocol
- Postoperative nursing diagnoses:
  - Acute pain related to the surgical incision, catheter placement, and bladder spasms
  - Deficient knowledge about postoperative care and management

Based on the assessment data, the potential complications may include the following:

- Hemorrhage and shock
- Infection
- Deep vein thrombosis (DVT)

- Catheter obstruction
- Sexual dysfunction

PLANNING

The major preoperative goals for the patient may include reduced anxiety and learning about his prostate disorder and the perioperative experience. The major postoperative goals may include maintenance of fluid volume balance, relief of pain and discomfort, ability to perform self-care activities, and absence of complications.

PREOPERATIVE NURSING INTERVENTIONS

REDUCING ANXIETY

The nurse must establish communication with the patient to assess his understanding of the diagnosis and of the planned surgical procedure. The nurse clarifies the nature of the surgery and expected postoperative outcomes, familiarizes the patient with the preoperative and postoperative routines, and initiates measures to reduce anxiety. Because the patient may be sensitive and embarrassed discussing problems related to the genitalia and sexuality, the nurse provides privacy and establishes a trusting and professional relationship. The patient is encouraged to verbalize his feelings and concerns.

TABLE 34-4 Surgical Approaches for Treatment of Prostate Disorders

Surgical Approach	Images	Advantages	Disadvantages	Nursing Implications
Transurethral resection of the prostate (TURP) is carried out through endoscopy: the surgical instrument is introduced via the urethra to the prostate, which can then be viewed directly. The gland is removed in small chips with an electrical cutting loop. This procedure may be used for glands of varying size. The procedure is ideal for patients who have small glands and poor surgical risks. Open surgical removal (for prostate cancer; uncommonly used to treat enlarged prostate)		Avoids abdominal incision Safer for patients with surgical risk Shorter hospitalization and recovery periods Lower morbidity rate Causes less pain	Recurrent obstruction, urethral trauma, and stricture may develop. Delayed bleeding may occur. Retrograde ejaculation due to removal of prostatic tissue at the bladder neck, which causes the seminal fluid to flow backward into the bladder.	Monitor for TUR syndrome. Monitor for hemorrhage. Observe for symptoms of urethral stricture (dysuria, straining, weak urinary stream).
Suprapubic approach Suprapubic prostatectomy is one method of removing the gland through an abdominal incision. An incision is made into the bladder, and the prostate gland is removed from above.		Technically simple Offers wide area of exploration Permits exploration for cancerous lymph nodes Allows more complete removal of obstructing gland Permits treatment of associated bladder lesions	Requires surgical approach through the bladder Difficult to control hemorrhage Urine may leak around the suprapubic tube. Recovery may be prolonged and uncomfortable.	Monitor for indications of hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube.
Perineal approach Perineal prostatectomy involves removal of the gland through an incision in the perineum.		Offers direct anatomic approach Permits gravity drainage of catheter Particularly effective for radical cancer therapy Allows hemostasis under direct vision Low mortality rate Low incidence of shock	Higher postoperative incidence of impotence and urinary incontinence Possible damage to rectum and external sphincter Restricted operative field	Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Possible urinary leakage around the wound after the catheter is removed
Retropubic approach Retropubic prostatectomy is more common than the suprapubic approach. A low abdominal incision is made, and the prostate gland can be reached between the pubic arch and the bladder without entering the bladder.		Avoids incision into the bladder Permits surgeon to see and control bleeding Shorter recovery period Less damage to the bladder sphincter	Cannot treat associated bladder disease Increased incidence of hemorrhage from prostatic venous plexus	Monitor for hemorrhage. Anticipate urinary leakage for several days after removing the catheter.
Transurethral incision of the prostate (TUIP) is indicated when the prostate gland is small (30 g or less), and it is an effective treatment for many cases of BPH. An instrument is passed through the urethra. Incisions are made in the prostate and prostate capsule to reduce the prostate's pressure on the urethra and to reduce urethral constriction.		Results comparable to TURP Low incidence of erectile dysfunction and retrograde ejaculation No contracture of the bladder neck Outpatient procedure Low complication rate	Recurrent obstruction and urethral trauma Delayed bleeding	Monitor for hemorrhage.
Robotic prostatectomy (Da Vinci prostatectomy) Laparoscopic prostatectomy provides better visualization of the surgical site and surrounding areas.		Minimally invasive technique Improved patient satisfaction and quality of life Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss Improved magnification of operative field	Technically demanding skill set for surgeon Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation	Observe for symptoms of urethral stricture (dysuria, straining, weak urinary stream). Monitor for hemorrhage and shock. Provide meticulous aseptic care to the area around the suprapubic tube. Avoid using rectal tubes or thermometers and enemas after perineal surgery. Use drainage pads to absorb excess urinary drainage. Anticipate urinary leakage after the catheter is removed.
Postoperative complications depend on the type of prostatectomy performed and may include hemorrhage, clot formation, catheter obstruction, and sexual dysfunction. All prostatectomies carry a risk of impotence because of potential damage to the pudendal nerves. The anatomic changes in the posterior urethra lead to retrograde ejaculation. For the patient with resulting ED that does not resolve, options are available to produce erections sufficient for sexual intercourse: prosthetic penile implants, vacuum devices, and pharmacologic interventions.				

RELIEVING DISCOMFORT

If the patient experiences discomfort before surgery, he is prescribed bed rest, and analgesic agents are administered. If he is hospitalized, the nurse monitors his voiding patterns, watches for bladder distention, and assists with catheterization if indicated. The catheter can help decompress the bladder gradually over several days, especially if the patient is elderly and hypertensive and has diminished kidney function or urinary retention that has existed for many weeks. If the patient cannot tolerate a urinary catheter, he is prepared for a cystostomy (surgical creation of an opening into the bladder, usually with a catheter [e.g., suprapubic tube, see Chapter 28]).

PROVIDING INSTRUCTION

Before surgery, the nurse reviews with the patient the anatomy of the affected structures and their function in relation to the urinary and reproductive systems, using diagrams and other teaching aids if indicated. This instruction often takes place during the preadmission testing visit or in the urologist's office. The nurse explains what will take place as the patient is prepared for surgery (depending on the type of prostatectomy planned). The nurse also describes the type of incision, which varies with the surgery chosen, and informs the patient about the likely type of urinary drainage system and the recovery room procedure. The amount of information given is based on the patient's needs and questions.

PREPARING THE PATIENT

If the patient is scheduled for a prostatectomy, the preoperative preparation described in Chapter 5 is provided.

POSTOPERATIVE NURSING INTERVENTIONS

MAINTAINING FLUID BALANCE

During the postoperative period, the patient is at risk for imbalanced fluid volume due to irrigation of the surgical site during and after surgery. With irrigation of the urinary catheter to prevent its obstruction by blood clots, fluid may be absorbed through the open surgical site and retained, increasing the risk of excessive fluid retention, fluid imbalance, and water intoxication. The patient is observed for signs of fluid volume excess, such as jugular vein distention (JVD), the development of an S_3 gallop, and pulmonary crackles. The urine output and the amount of fluid used for irrigation must be monitored closely to determine whether irrigation fluid is being retained and to ensure adequate urine output. An intake and output record, including the amount of fluid used for irrigation, must be maintained closely. Also the patient is monitored for electrolyte imbalances (e.g., hyponatremia), increasing blood pressure, confusion, and respiratory distress. Refer to Box 34-2 for details on dilutional hyponatremia after a transurethral prostatectomy (TURP). Additionally, since the prostate is a vascular organ, hemorrhage is an immediate danger postoperatively; thus, the nurse monitors the patient

for hypotension, tachycardia, tachypnea, gross hematuria, restlessness, pallor, and decreasing levels of hemoglobin and hematocrit. If deterioration of the patient's condition occurs, the surgeon is notified immediately. The nurse anticipates fluid resuscitation with IV fluids and blood products.

Nursing Alert
In assessing urinary output, the nurse anticipates output at a minimum 0.5 mL/kg/hr; thus, if the patient weighs 70 kg, 35 mL of urine is expected hourly. To calculate the actual urine output, the nurse must consider all irrigating fluids instilled against the total drainage of the urine collection bag. If large amounts of irrigating solutions are required postoperatively, the nurse empties the collection bag frequently to prevent overfilling and creating back pressure within the bladder. Meticulous recording of the urinary output is required.

RELIEVING PAIN

If pain is present, the cause and location are determined, and the severity of pain and discomfort is assessed using a pain scale. The pain may be incisional, referred to the flank area, or caused by bladder spasms. Patients experiencing bladder spasms typically describe the pain as severe cramping and spasmodic in the suprapubic region. They may note a feeling of pressure or fullness in the bladder, and the nurse may encounter leakage from the urethra around the catheter rather than through the catheter.

Nursing Alert
Bladder spasms are associated with irritation to the detrusor muscle, causing spasm of the muscle. If spasms are present, the nurse ensures that the urinary drainage system is patent since obstruction is associated with spasms. In addition, the nurse administers antispasmodic medication as prescribed.

The nurse monitors the drainage tubing and irrigates the system as prescribed to relieve any obstruction that may cause discomfort. Usually, if clots impede urinary drainage, the catheter is irrigated with 50 to 60 mL of irrigating fluid at a time. It is important to make sure that the same amount is recovered in the drainage receptacle. Securing the catheter drainage tubing to the patient's leg or lower abdomen can help decrease tension on the catheter and prevent bladder irritation.

After the patient is ambulatory, he is encouraged to walk but not to sit for prolonged periods because this increases intra-abdominal pressure and the possibility of discomfort and bleeding.

BOX 34-2 Transurethral Resection Syndrome (Symptomatic Dilutional Hyponatremia)

Transurethral resection (TUR) syndrome is a rare (less than 2%) but potentially serious complication of transurethral prostatectomy (TURP). Signs and symptoms are

caused by neurologic, cardiovascular, and electrolyte imbalances associated with absorption of the solution used to irrigate the surgical site during the surgical procedure. Hyponatremia, hypo-osmolality, and hypervolemia are dominant findings. Symptoms usually are associated with a serum sodium level of 125 mEq or less (Duke, 2016). The dilutional hyponatremia leads to cerebral edema; thus, the patient exhibits neurologic symptoms, while the volume overload is noted in symptoms of hypertension; arrhythmias; and full, bounding pulse. Patients with poor left ventricular function may develop pulmonary edema. Given the age of many men undergoing TURP and possible comorbidities of cardiac disease, the nurse is aware that fluctuating intravascular volume and myocardial compromise may result in hypotension. Additionally, if the hyponatremia develops rapidly, with the count dropping to less than 120 mEq/L, negative inotropic effects cause hypotension and electrocardiographic changes of widened QRS complexes and ventricular ectopy (Wieder, 2014).

Signs and Symptoms of TUR Syndrome

- Lethargy and confusion
- Hypertension
- Tachycardia
- Nausea and vomiting
- Visual disturbances, such as flashing lights if glycine is used as an irrigant, as it is a neurotransmitter for the retina (Duke, 2016)
- Headache
- Muscle spasms
- Seizures

Interventions

- During the operative procedure, normal saline cannot be used as it conducts electricity. If the patient displays the aforementioned signs and symptoms, the intraoperative irrigating solution of glycine, sorbitol/mannitol, or water is discontinued and replaced with normal saline.
- Administer diuretics as prescribed to facilitate excretion of absorbed fluid.
- Monitor intake and output.
- Monitor the patient's vital signs and level of consciousness.
- Differentiate the lethargy and confusion of TUR syndrome from postoperative disorientation and hyponatremia.
- Maintain patient safety during times of confusion.
- Assess lung and heart sounds for indications of pulmonary edema, heart failure, or both (fluid already present in profound hyponatremia).

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

After prostatectomy, the patient is monitored for major complications, such as hemorrhage, infection, DVT, catheter obstruction, and sexual dysfunction.

Hemorrhage. The immediate dangers after a prostate surgery are bleeding and hemorrhagic shock. This risk is increased with BPH because a hyperplastic prostate gland is very vascular. Bleeding may result in the formation of clots, which then obstruct urine flow. The drainage normally begins as reddish-pink and then clears to a light pink within 24 hours after surgery. Bright red bleeding with increased viscosity and numerous clots usually indicates arterial bleeding and requires surgical intervention. Venous bleeding, which is dark red in color, may be controlled by the provider via "overinflating" the urinary catheter balloon and applying traction to the catheter so that the balloon holding the urinary catheter in place applies pressure to the prostatic fossa. If, after 20 minutes, the bleeding is not controlled, surgical exploration may be considered. Since bleeding is increased when the patient is in the sitting position, which increases bladder and venous pressure, the patient is encouraged to rest in bed with the head of the bed slightly elevated.

Nursing management includes assistance in implementing strategies to stop the bleeding and to prevent or reverse hemorrhagic shock. If hemorrhagic shock occurs, treatments described in Chapter 54 are initiated.

Nursing interventions include closely monitoring vital signs; administering medications, IV fluids, and blood component therapy as prescribed; maintaining an accurate record of intake and output; and carefully monitoring drainage to ensure adequate urine flow and patency of the drainage system.

Infection. After perineal prostatectomy, the surgeon usually changes the dressing on the first postoperative day. Careful aseptic technique is used because the potential for infection is great. Rectal thermometers, rectal tubes, and enemas are avoided because of the risk of injury and bleeding in the prostatic fossa. Sitz baths are used to promote healing.

UTIs and epididymitis (infection of the epididymis, discussed later in the chapter) are possible complications after prostatectomy, and the patient is assessed for their occurrence. Because the risk for infection continues after discharge from the hospital, the patient and family need to be instructed to monitor for signs and symptoms of infection (fever, chills, sweating, myalgia, dysuria, urinary frequency, and urgency).

Deep Vein Thrombosis. Because patients undergoing prostatectomy have a high incidence of DVT and pulmonary embolism, the provider may prescribe prophylactic low-dose heparin therapy. The nurse assesses the patient frequently after surgery for manifestations of DVT and applies elastic compression stockings as needed. Nursing and medical management of DVT and pulmonary embolism are described in Chapters 10 and 18, respectively.

Obstructed Catheter. After any procedure involving the prostate in which a catheter is placed, the catheter must drain well. An obstructed catheter produces distention of the prostatic capsule and resultant hemorrhage. A diuretic may be prescribed to promote urination and initiate postoperative diuresis, thereby helping to keep the catheter patent. The nurse observes the lower abdomen for increasing distention to ensure that the catheter has not become blocked. On percussion of a patient with a blocked catheter, increased dullness will be noted in the suprapubic region.

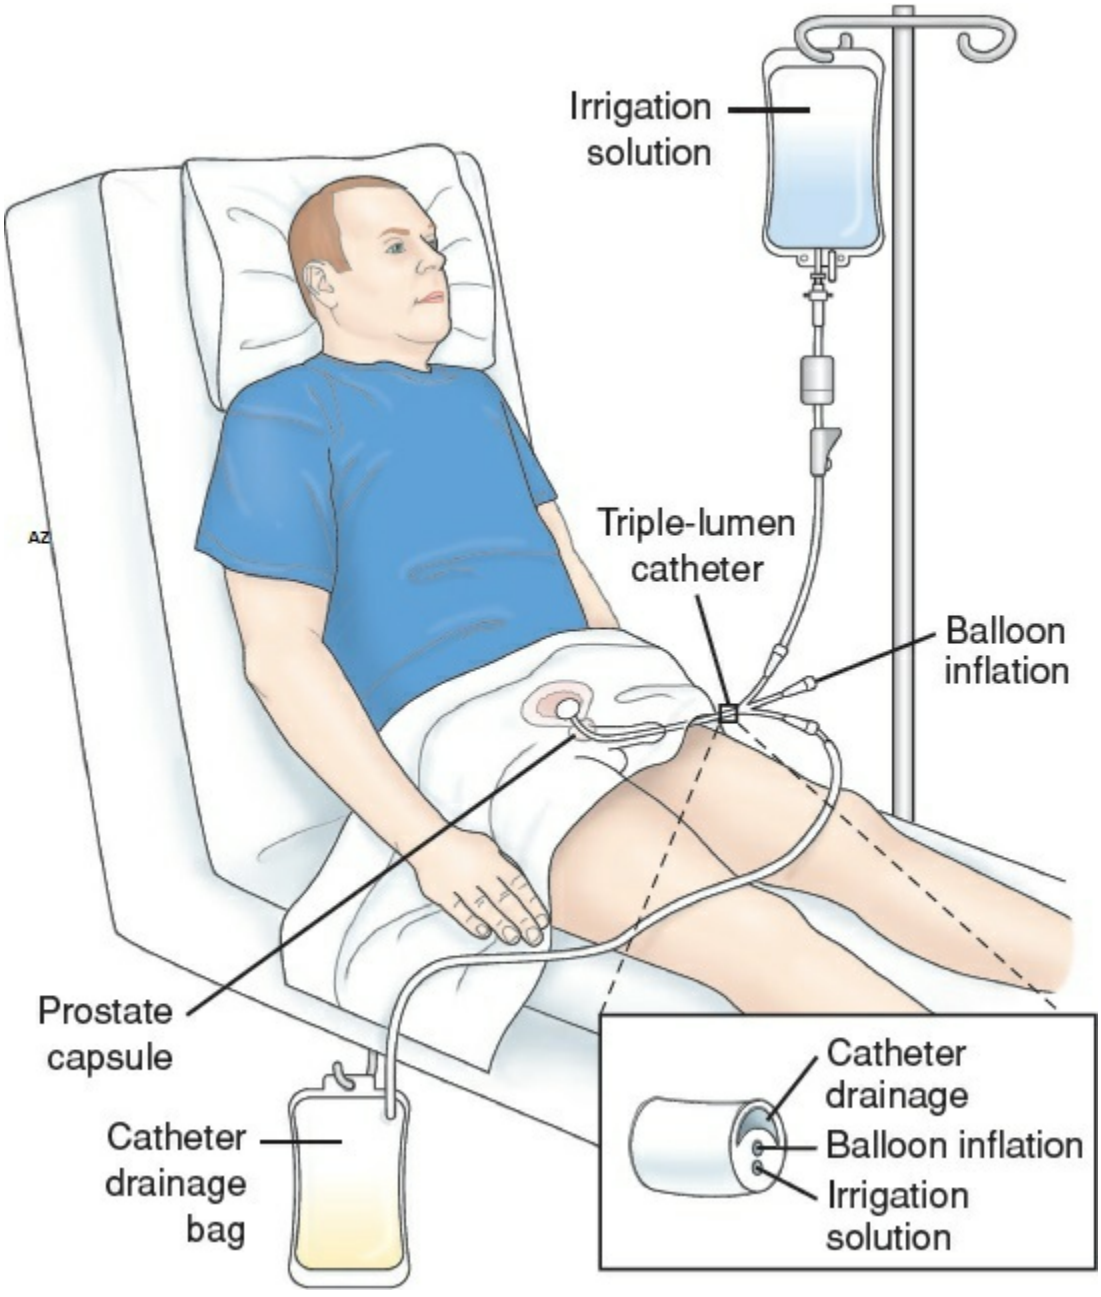

FIGURE 34-2 A three-way system for bladder irrigation.

The drainage bag, dressings, and incisional site are examined for bleeding. The color of the urine is noted and documented; a change in color from pink to amber indicates reduced bleeding. Blood pressure, pulse, and respirations are monitored and compared

with baseline preoperative vital signs to detect hypotension. The nurse also observes the patient for restlessness, diaphoresis, pallor, any drop in blood pressure, and an increasing pulse rate.

Drainage of the bladder may be accomplished by gravity through a closed sterile drainage system. A three-way drainage system is useful in irrigating the bladder and preventing clot formation (Fig. 34-2). Continuous bladder irrigation (CBI) may be used after a TURP to maintain the drainage of the urinary catheter, remove blood clots from the bladder that are the result of the procedure, and cleanse the surgical area to promote healing as well as to prevent potentially obstructing clots. The amount of fluid recovered in the drainage bag must equal the amount of fluid infused. Overdistention of the bladder is avoided because it can induce secondary hemorrhage by stretching the coagulated blood vessels in the prostatic capsule.

To prevent traction on the bladder, the drainage tube (not the catheter) is taped to the shaved inner thigh. If a cystostomy catheter is in place, it is taped to the abdomen.

Sexual Dysfunction. The patient may experience sexual dysfunction related to ED, decreased libido, and fatigue. These issues may become a concern to the patient soon after surgery or in the weeks to months of rehabilitation. Options to restore erectile function may include medications, surgically placed implants, or vacuum devices. The patient should be aware that he may experience fatigue during rehabilitation from surgery, which may decrease his libido and alter his enjoyment of usual activities.

Nursing interventions include assessing for the presence of sexual dysfunction after surgery. Providing a private and confidential environment to discuss issues of sexuality is important. The emotional challenges of prostate surgery and its consequences need to be explored carefully with the patient and his partner.

TEACHING PATIENTS SELF-CARE

The patient undergoing prostatectomy may be discharged within several days. The length of the hospital stay depends on the type of prostatectomy performed. The patient and family require instructions about how to manage the urinary drainage system, how to assess for complications, and how to promote recovery. Verbal and written instructions should be provided, and the patient and family need to know about signs and symptoms that should be reported to the physician (e.g., blood in urine, decreased urine output, fever, change in wound drainage, calf tenderness) (Box 34-3).

After the catheter is removed (usually when the urine appears clear), urine may leak out around the wound for several days. Some urinary incontinence may occur after catheter removal, and the patient is informed that this is likely to subside over time.

BOX 34-3 Patient Education

Self-Care After a Prostatectomy

- Perform Kegel exercises, as they may help with regaining urinary control:

- Tense the perineal muscles by pressing the buttocks together; hold this position; relax. This exercise can be performed 10–20 times each hour while sitting or standing.
- Try to interrupt the urinary stream after starting to void; wait a few seconds and then continue to void.

- While the prostatic fossa heals (6–8 weeks), avoid activities that produce Valsalva effects (straining, heavy lifting) as this may increase venous pressure and produce hematuria.
- Avoid long motor trips and strenuous exercise, which increase the tendency to bleed.
- Note that spicy foods, alcohol, and coffee may cause bladder discomfort.
- Maintain fluid intake to avoid dehydration, which increases the tendency for a blood clot to form and obstruct the flow of urine.
- Report signs of complications, such as bleeding, passage of blood clots, a decrease in the urinary stream, urinary retention, or symptoms of UTI, to the urologist.

CONTINUING CARE

Referral for home care may be indicated if the patient is elderly or has other health problems, if the patient and family cannot provide care in the home, or if the patient lives alone without available supports. The home care nurse assesses the patient's physical status and provides catheter and wound care. The home care nurse encourages the patient to ambulate and to carry out perineal exercises as prescribed. If the prostatectomy was performed to treat prostate cancer, the patient and family also are instructed about the importance of follow-up and monitoring with the urologist.

EVALUATION

Expected postoperative patient outcomes may include the following:

1. Reports relief of discomfort
2. Exhibits fluid and electrolyte balance:
    a. Irrigation fluid and urinary output are within parameters determined by surgeon
    b. Experiences no signs or symptoms of fluid retention
3. Participates in self-care measures:
    a. Increases activity and ambulation daily
    b. Produces urine output within normal ranges and consistent with intake
    c. Performs perineal exercises and interrupts urinary stream to promote bladder control
    d. Avoids straining and lifting heavy objects
4. Is free of complications:
    a. Maintains vital signs within normal limits
    b. Exhibits wound healing without signs of inflammation or hemorrhage
    c. Maintains acceptable level of urinary elimination

d. Maintains optimal drainage of catheter and other drainage tubes
e. Reports understanding of changes in sexual function

CONDITIONS AFFECTING THE TESTES AND ADJACENT STRUCTURES

ORCHITIS AND EPIDIDYMITIS

Orchitis is an inflammation of the testes caused by a variety of factors (bacterial, viral, spirochetal, parasitic, traumatic, chemical, or unknown). Bacterial causes usually spread from an associated epididymitis, which usually descends from an infected prostate or urinary tract. Recommended treatments include rest, elevation of the scrotum, ice packs to reduce scrotal edema, antibiotics, analgesic agents, and anti-inflammatory medications.

Pathophysiology

In men younger than 35 years of age, the major cause of epididymitis or orchitis is *Chlamydia trachomatis*. The infection passes upward through the urethra and the ejaculatory duct and then along the vas deferens to the epididymis, and it can migrate to the testis as well.

Clinical Manifestations and Assessment

The patient complains of unilateral pain and soreness in the inguinal canal along the course of the vas deferens and can develop pain and swelling in the scrotum and the groin. The epididymis becomes swollen and extremely painful. Bacteriuria may be evident, and the patient may experience chills and fever, along with nausea, urinary frequency, urgency, or dysuria. Laboratory assessment includes urinalysis and Gram stain of urethral drainage if there is suspicion of sexually transmitted infection (STI). If the epididymitis is untreated, it can progress to involve the testis.

Medical Management

Treatment of scrotal support, ice, and antibiotic therapy are anticipated on an outpatient basis. If the epididymitis is caused by a chlamydial infection, the patient and his sexual partner must be treated with antibiotics. If no improvement occurs within 2 weeks, an underlying testicular tumor should be considered. An epididymectomy (excision of the epididymis from the testis) may be performed as a last resort for patients who have recurrent, incapacitating episodes of epididymitis or for those with chronic, painful conditions.

Nursing Management

The scrotum is elevated with a scrotal bridge or folded towel to prevent traction on the spermatic cord, to promote venous drainage, and to relieve pain. A folded hand towel is secured under one thigh, allowing the penis and scrotum to be elevated on the midsection of the towel, and then the edge of the towel is secured under opposite thigh. Antimicrobial agents are administered as prescribed until the acute inflammation subsides. Intermittent cold compresses to the scrotum may help ease the pain. Later, local heat or sitz baths may help resolve the inflammation. Analgesic medications are administered for pain relief.

The nurse instructs the patient to avoid straining, lifting, and sexual activity until the infection is resolved. He should continue taking analgesic agents and antibiotics as prescribed and using ice packs if necessary to relieve discomfort. He needs to know that it may take 2 to 3 months for the epididymis to return to normal.

TESTICULAR CANCER

Testicular cancer is the most common cancer in men between 15 and 40 years of age, with the average age at diagnosis of 33 years of age, although it can occur in males of any age. It is a highly treatable and usually curable form of cancer, with a cure rate of greater than 90% for all stages of the disease; in 2015, it was expected that there would be 8,430 cases in the United States (ACS, 2015c).

Classification of Testicular Tumors

The testicles contain several types of cells, each of which may develop into one or more types of cancer. The type of cancer determines the appropriate treatment and affects the prognosis. Testicular cancers are classified as germinal, having their origins within the germ cells of the gonads (testes), or nongerminal (stromal).

Germinal Tumors

More than 90% of all cancers of the testicle are germinal and may be further classified as seminomas or nonseminomas. Seminomas are tumors that develop from the sperm-producing cells of the testes and account for 50% of tumors. Seminomas tend to remain localized, whereas nonseminomatous tumors grow quickly. Nonseminomas tend to develop earlier in life than seminomas, usually occurring in men in their 20s. Many tumors are mixtures of at least two different tumor types.

Nongerminal Tumors

Testicular cancer also may develop in the supportive and hormone-producing tissues, or stroma, of the testicles. The two main types of stromal tumors are Leydig cell tumors and Sertoli cell tumors. These tumors infrequently spread beyond the testicle.

Risk Factors

Risk factors for testicular cancer include undescended testicles (cryptorchidism), a family history of testicular cancer, and cancer of one testicle, which increases the risk in the other testicle. Caucasian-American men have a risk that is five times greater than that of African-American men and more than double the risk of Asian-American men (Wieder, 2014).

Clinical Manifestations and Assessment

The symptoms appear gradually, with a mass or lump on the testicle and usually painless enlargement of the testis. The patient may report heaviness in the scrotum, inguinal area, or lower abdomen. Backache (from retroperitoneal node extension), abdominal pain, weight loss, and general weakness may result from metastasis. Enlargement of the testis without pain is a significant diagnostic finding. Testicular tumors tend to metastasize early, spreading from the testis to the lymph nodes in the retroperitoneum and to the lungs. Monthly testicular self-examinations (TSEs) can detect testicular cancer, but recent recommendations argue against this practice in asymptomatic adolescent and adult males (O'Reilly et al., 2016) due to the low incidence of finding testicular cancer via TSE and the high rate of anxiety associated with self-examination.

Human chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP) are tumor markers that may be elevated. Tumor marker levels in the blood are used for diagnosis, staging, and monitoring the response to treatment. Other diagnostic tests include lactate dehydrogenase (LDH) levels and ultrasound examination to determine the presence and size of the testicular mass.

A CT of the abdomen and pelvis is performed to determine the extent of the disease in the retroperitoneum and pelvis. Also a chest x-ray is performed to assess for lung metastasis. Tissue biopsy is the only definitive way to determine whether cancer is present, and it is performed at the time of surgery rather than as a part of the diagnostic workup, to reduce the risk of promoting spread of the cancer (ACS, 2015c).

Medical Management

Testicular cancer is highly responsive to treatment, with a 5-year survival rate of 95% (National Cancer Institute, 2014). The goals of management are to eradicate the disease and achieve a cure. Treatment selection is based on the cell type and the anatomic extent of the disease. The testis is removed by orchiectomy through an inguinal incision with a high ligation of the spermatic cord. A retroperitoneal lymph node dissection (RPLND) may be performed after orchiectomy if there is evidence of lymph node metastasis. Although libido and climax are usually unimpaired after RPLND, the patient may develop ejaculatory dysfunction. Because men with testicular cancer demonstrate pretreatment subfertility, and treatment of the cancer itself can result in subfertility or infertility, cryopreservation of sperm before treatment should be offered (Yokonishi & Ogawa, 2016).

Seminomatous tumors are more sensitive to radiation therapy, and radiation therapy alone provides excellent results for the majority of patients. Postoperative irradiation of the lymph nodes from the diaphragm to the iliac region is used to treat seminomas. Radiation is delivered only to the affected side; the other testis is shielded from radiation to preserve fertility.

Chemotherapy is reserved for the treatment of stage IIC testicular cancer as well as more advanced stages (ACS, 2015c). Chemotherapy with cisplatin-based regimens results in a high percentage of complete remissions. Even with disseminated testicular cancer, the prognosis is favorable. Follow-up studies may include chest x-rays, hCG levels (a tumor marker with nonseminomatous germ cell tumors), AFP levels (a tumor marker for some men with nonseminomatous germ cell tumors), and LDH levels (an enzyme found in many body tissues, such as heart, skeletal muscle, liver, and kidney, but that also may be elevated in some men with testicular cancer), and serial CT scans to detect recurrent malignancy.

Nursing Management

Nursing management includes assessment of the patient's physical and psychological status and monitoring of the patient for response to and possible effects of surgery, chemotherapy, and radiation therapy (see Chapter 6). Operative care is described in Chapter 5. Because the patient may have difficulty coping with his condition, issues related to body image and sexuality are addressed; he also needs to know that radiation therapy will not necessarily prevent him from fathering children, and unilateral excision of a testis will not necessarily decrease virility.

Banking Sperm

Cryopreserving semen in a sperm bank is an option for men who are about to undergo a procedure or treatment (e.g., radiation therapy to the pelvis, chemotherapy, RPLND) that may affect their fertility. All men undergoing cancer treatment should be offered the opportunity for sperm cryopreservation. This requires visits to the facility, where the sperm is produced by masturbation and collected in a sterile container for storage.

HYDROCELE

A hydrocele is a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord. Hydrocele can be differentiated from a hernia by transillumination; the hydrocele will glow red, whereas dense tissue will not illuminate. Acute hydrocele may occur in association with acute infectious disease of the epididymis or as a result of local injury. Chronic hydrocele has no known cause.

Therapy is not required unless the hydrocele becomes tense or if the scrotal mass becomes large, uncomfortable, or embarrassing. In the surgical treatment of hydrocele, an incision is made through the wall of the scrotum down to the distended tunica vaginalis. The sac is resected and is sutured together to collapse the wall. The patient is advised to wear an athletic supporter postoperatively for comfort and support. The major complication is hematoma.

VARICOCELE

A varicocele is an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis that constitute part of the spermatic cord) and is present in 15% to 20% of men (Fig. 34-3). Varicoceles usually occur in the veins on the upper portion of the left testicle in adults because of the angle in which the left spermatic cord inserts into the left renal vein, while the right spermatic cord enters the inferior vena cava. Varicoceles can be associated with infertility in some men. Few symptoms may be produced by the enlarged spermatic vein, and no treatment is required unless fertility is a concern or there is pain. It is corrected microsurgically by ligation of the external spermatic vein. An ice pack may be applied to the scrotum for the first few hours after surgery to relieve edema. Then the patient wears a scrotal supporter.

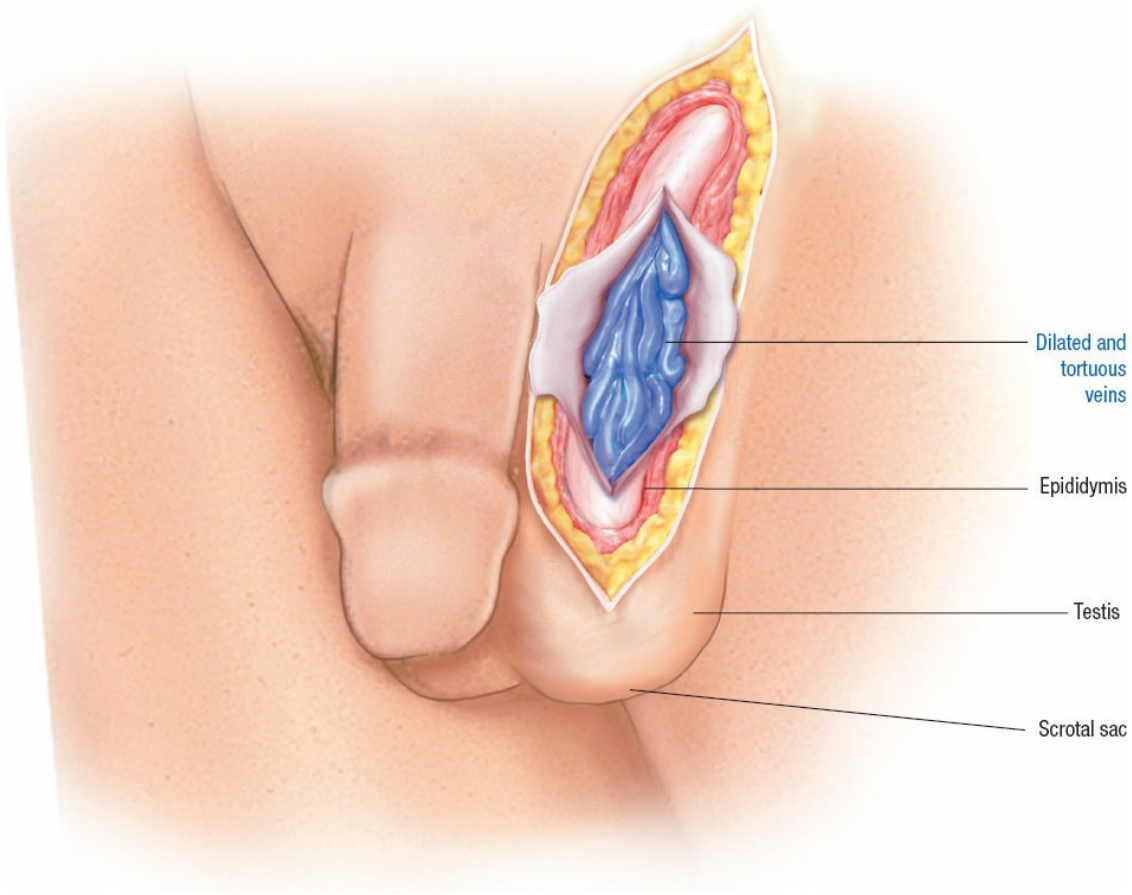

FIGURE 34-3 Varicocele.

CONDITIONS AFFECTING THE PENIS

PHIMOSIS AND PARAPHIMOSIS

Phimosis, a condition in which the foreskin is constricted so that it cannot be retracted over the glans, can occur congenitally or as a result of inflammation and edema. If the preputial area is not cleaned, normal secretions accumulate, causing inflammation (balanitis), which can lead to adhesions and fibrosis. It is seen more commonly in adult men with poorly controlled diabetes and obesity. In elderly men, penile carcinoma may develop. Phimosis is corrected by circumcision or dorsal slit.

Paraphimosis is a condition in which the foreskin is retracted behind the glans and, because of narrowness and subsequent edema, cannot be returned to its usual position covering the glans. It is a true urologic emergency, and patients should be directed to the nearest emergency department for treatment. Initial treatment of paraphimosis involves firmly compressing the glans to reduce its size and then pushing the glans back while simultaneously moving the prepuce forward.

Nursing Alert

To catheterize an uncircumcised male, the nurse retracts the foreskin and uses soap and water to clean away the smegma (whitish sebaceous secretion that collects between the glans penis and foreskin) before beginning the sterile procedure. The glans and foreskin are rinsed thoroughly. The nurse follows institutional protocols for male catheterization. Immediately after catheterization, the foreskin is returned to its normal position to prevent an accumulation of fluid within the glans, which may cause paraphimosis (the inability to retract the foreskin to its natural position because of venous and lymphatic congestion caused by constriction by the foreskin). The provider should be notified immediately if the nurse is unable to retract the foreskin.

PRIAPISM

Priapism is a persistent erection that causes the penis to become large, hard, and painful. It results from either neural or vascular causes, including sickle cell thrombosis, leukemic cell infiltration, and tumor invasion of the penis or its vessels. It may occur with use of medications that affect the central nervous system, antihypertensive agents, antidepressant medications, and substances injected into the penis to treat ED.

Priapism is a true urologic emergency. The goal of therapy is to improve venous drainage of the corpora cavernosa to prevent ischemia, fibrosis, and impotence. The corpora may be irrigated with an anticoagulant, which allows stagnant blood to be aspirated. Shunting procedures to divert the blood from the turgid corpora cavernosa to the venous system or into the corpus spongiosum–glans penis compartment may be attempted.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 58-year-old man with type 2 diabetes has undergone TURP. What immediate postoperative assessment is indicated when he arrives from the postanesthetic care unit and for the first 24 hours after surgery? What discharge teaching and preparation are indicated for this patient?
2. One of your patients, a 32-year-old man with a spinal cord injury, tells you that he has seen an advertisement on television for vardenafil HCl (Levitra). He wishes to try this to improve his erectile function. What is the appropriate teaching for this patient?
3. A 21-year-old college athlete who describes his health as excellent comes to the student health clinic because he noticed a painless walnut-size mass in his testicle when showering. What would be your concerns, and what referrals would be warranted for him? What initial laboratory work would be indicated?

NCLEX-Style Review Questions

1. A 45-year-old man complains of a painless swelling in his scrotum. The nurse assesses the patient for which condition?
   a. Prostatitis
   b. Hydronephrosis
   c. Varicocele
   d. Priapism
   e. Hypospadias
2. A 60-year-old patient is complaining of difficulty sustaining his erections. The nurse is aware that he suffered a myocardial infarction approximately 3 months ago. What teaching is relevant to his concern? Select all that apply.

a. If he increases his physical activity, his function will improve.
b. Function may improve as his medications are adjusted.
c. He should avoid the strain with sexual activity.
d. Men with a heart attack in the preceding 6 months cannot use PDE medications.
e. His complaint is purely psychological.

3. A 55-year-old man has been diagnosed with prostate cancer. On what factors do his treatment options depend? Select all that apply.

a. Staging of the tumor
b. Patient preference
c. Patient diet
d. Patient age
e. Size of his prostate

4. A 50-year-old man is being treated presumptively for acute prostatitis. He asks the nurse why the course of antibiotics is so long. What is the nurse's best response?

a. His infection is resistant to most antibiotics.
b. Most antibiotics diffuse poorly from the plasma into the prostatic fluid.
c. Most of the antibiotic is excreted in the urine, requiring a longer course.
d. His liver is preventing the antibiotic from working effectively.
e. Men of his age need a prolonged antibiotic course.

5. A 58-year-old patient has had a prostatectomy. The nurse is preparing him for discharge. What information is important for the nurse to incorporate in the teaching plan?

a. Do not interrupt the stream after starting to void.
b. Increased activity is permitted.
c. Limit fluid intake to prevent hypervolemia.
d. Note that spicy foods, alcohol, and coffee may cause bladder discomfort.
e. He should expect immediate return of his erectile function.

CHAPTER 35

Nursing Management: Patients with Sexually Transmitted Infections

Christa Palancia Esposito

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate between colonization, infection, and disease.
2. Compare the various types of sexually transmitted infections (STIs) and the signs, symptoms, and treatments of each.
3. Use the nursing process as a framework for care of patients with an STI.
4. Develop a teaching plan for the patient with an STI.

A sexually transmitted infection (STI), also known as a sexually transmitted disease (STD), is an infection acquired through sexual contact with an infected person. STIs are the most common infectious diseases in the United States and are epidemic in most parts of the world. To understand the pathophysiology of STIs, it is important to understand the infectious process.

THE INFECTIOUS PROCESS

An infectious disease is any disease caused by the growth of pathogenic microbes in the body. It may or may not be communicable (i.e., contagious). The nurse plays an important role in infection control and prevention. Educating patients can decrease their risk of becoming infected or decrease the sequelae of infection.

The Chain of Infection

A complete chain of events is necessary for infection to occur. The necessary elements for infection to occur are described in Box 35-1.

Colonization, Infection, and Infectious Disease

Relatively few anatomic sites are sterile (e.g., brain, blood, bone, heart, vascular system). Bacteria found throughout the body usually provide beneficial normal flora to compete with potential pathogens, to facilitate digestion, or to work in other ways symbiotically with the host.

Colonization

The term *colonization* is used to describe microorganisms present without host interference or interaction. Organisms reported in microbiology test results often reflect colonization rather than infection. *Colony count* represents a visual count of microbes present in a sample. In general, clinicians use a colony count of greater than 100,000/mL or 10^5 bacteria/mL to represent an infection. However, astute clinicians also will consider other local and systemic signs of infection at lower colony counts, such as fever, leukocytosis (elevated white blood cells [WBCs]), erythema (redness), purulent exudate, inflammation, warmth, and the like.

Infection

Infection indicates a host interaction with an organism. A patient colonized with *Staphylococcus aureus* may have staphylococci on the skin without any skin interruption or irritation. However, if the patient had an incision, *S. aureus* could enter the wound, be seen as foreign, and result in an immune system reaction of local inflammation and migration of WBCs to the site. Infection may be suggested based on clinical evidence of erythema, heat, and pain as well as laboratory evidence of WBCs on the wound specimen smear.

Infectious Disease

It is important to recognize the difference between infection and infectious disease. While infection merely indicates interaction between the host and the organism, infectious disease is the state in which the infected host displays a decline in wellness due to the infection. When the host interacts immunologically with an organism but remains symptom free, the definition of infectious disease has not been met. The microbiology laboratory report is the primary source of bacterial infection identification and should be viewed as a tool to be used along with clinical indicators to determine whether a patient is colonized, infected, or diseased. Microbiology reports from clinical specimens usually show three components: the smear and stain, the culture and organism identification, and the antimicrobial susceptibility (i.e., sensitivity). As a marker for the likelihood of infection, the smear and stain (referred to as *Gram stain*) generally provide the most helpful information because they describe the mix of cells present at the anatomic site at the time of specimen collection and are a guide to the choice of antibiotic pending the culture results. The Gram stain will classify organisms as either gram-positive or gram-negative. The culture will detail the exact organism(s), while the sensitivity will specify antimicrobials most likely to be effective against the organism(s).

BOX 35-1 Chain of Infection

The chain of infection requires the following elements:

- A causative organism
- A reservoir of available organisms
- A portal or mode of exit from the reservoir
- A mode or route of transmission from reservoir to host
- A susceptible host
- A mode of entry to host

Causative Organism

The types of microorganisms that cause infections are bacteria, rickettsiae (gram-negative bacteria carried by ticks, fleas, and lice), viruses, protozoa, fungi, and helminths (parasitic worms).

Reservoir

Reservoir is the term used for any person, plant, animal, substance, or location that provides nourishment for microorganisms and enables their further dispersal.

Mode of Exit

The organism must have a mode of exit from a reservoir. An infected host must shed organisms to another or to the environment before transmission can occur. Organisms exit through the respiratory tract, the gastrointestinal tract, the genitourinary tract, the skin, or the blood.

Route of Transmission

A route of transmission is necessary and specific to each pathogen in order to connect the infectious source with its new host. Organisms may be transmitted through sexual contact, skin-to-skin contact, percutaneous injection, or through infectious particles carried in the air. A person who carries or transmits an organism but does not have apparent signs and symptoms of infection is called a *carrier.*

Susceptible Host

For infection to occur, the host must be susceptible (not possessing immunity to a particular pathogen). Previous infection or vaccine administration may render the host immune (not susceptible) to further infection with an agent. Although exposure to potentially infectious microorganisms occurs essentially on a constant basis, our elaborate immune systems generally prevent infection from occurring. A person who is immunosuppressed has much greater susceptibility to infection than does a healthy person.

Portal of Entry

A portal of entry is needed for the organism to gain access to the host. For example, airborne *Mycobacterium tuberculosis* does not cause disease when it settles on the skin of an exposed host; the only entry route for *M. tuberculosis* is through the respiratory tract.

SEXUALLY TRANSMITTED INFECTIONS

STIs are acquired through sexual contact with an infected person. Table 35-1 identifies infections that can be classified as STIs and their routes of transmission. Portals of entry of STI-causing microorganisms and sites of infection include the skin and mucosal linings of the urethra, cervix, vagina, rectum, and oropharynx.

Education about prevention of STIs includes information about risk factors and behaviors that can lead to infection. Refer to Box 35-2 for risk factors associated with STIs. The placement of a condom or protective barrier (i.e., dental dam) before any sexual contact is imperative to help prevent the acquisition or transmission of an STI. Refer to Box 35-3 for the application of male condom and Figure 35-1 for the application of a female condom.

TABLE 35-1 Conditions Classified as Sexually Transmitted Diseases (STDs) and Their Routes of Transmission

Disease	Route(s) of Transmission
Chlamydia	Sexual
Gonorrhea	Sexual
Herpes simplex	Sexual, percutaneous, perinatal
Human papillomavirus (HPV)	Sexual, percutaneous
Syphilis	Sexual, perinatal
Trichomoniasis	Sexual

BOX 35-2 Risk Factors for Sexually Transmitted Infections and Diseases

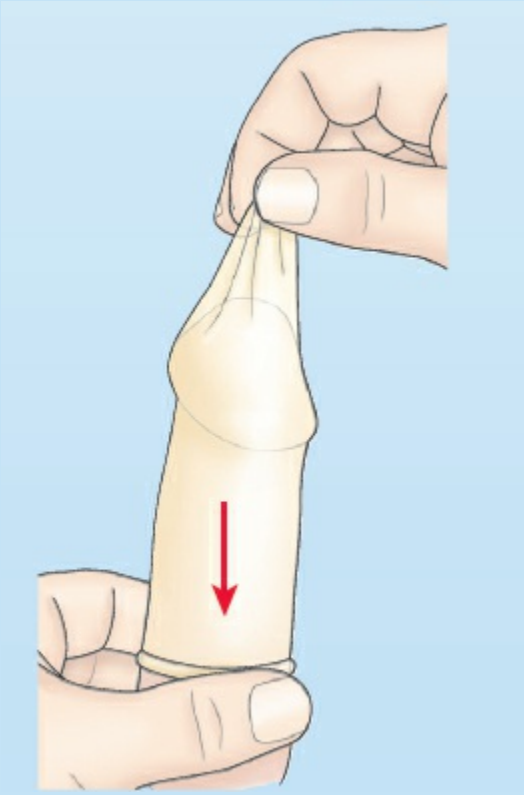
- Having unprotected sex
- Having multiple partners
- Being under 26 years of age
- Starting sex at an early age
- Using alcohol or illegal drugs
- Using IV drugs
- Having a history of STI
- Participating in prostitution
- Using oral contraceptives as only form of contraception

BOX 35-3 Patient Education

Use of Male Condoms

1. Put on a new condom before any kind of sex.
2. Hold the condom by the tip to squeeze out the air.

3. Unroll the condom all the way over the erect penis.



4. Have sex.
5. Hold the condom so it cannot come off the penis.
6. Pull out.
7. Use a new condom if you want to have sex again or if you want to have sex in a different place (e.g., in the anus and then in the vagina).

Keep condoms cool and dry. Never use skin lotions, baby oil, petroleum jelly, or cold cream with condoms. The oil in these products will cause the condom to break. Products made with water (such as K-Y jelly or glycerin) are safer to use.

Nursing Alert
Infection with one STI suggests the possibility of infection with other diseases as well. After one STI is identified, diagnostic evaluation for others should be performed.

SYPHILIS

Pathophysiology

Syphilis is an acute and chronic infectious disease caused by the spirochete *Treponema pallidum.* It is acquired primarily through sexual contact although rarely may be congenital in origin; that is, it is passed from mother to child during pregnancy or childbirth.

Risk Factors

Risk factors include having unprotected sex and being infected with other STIs. The estimated risk of transmission from an individual with primary syphilis to an uninfected individual is 30% per sexual act (Chan & Cu-uvin, 2016).

Clinical Manifestations and Assessment

In the untreated person, the course of syphilis can be divided into three stages: primary, secondary, and tertiary. These stages reflect the time from infection and the clinical manifestations observed in that period and are the basis for treatment decisions.

Primary syphilis occurs 2 to 3 weeks after initial inoculation with the organism. A painless lesion at the site of infection is called a *chancre* (Fig. 35-2). Untreated, these lesions usually resolve spontaneously within about 2 months.

Secondary syphilis occurs when the hematogenous spread of organisms from the original chancre leads to generalized infection. The rash of secondary syphilis occurs about 2 to 8 weeks after the chancre and involves the trunk and the extremities, including the palms of the hands and the soles of the feet. Transmission of the organism can occur through contact with these lesions. Generalized signs of infection may include lymphadenopathy (abnormal enlargement of lymph nodes), arthritis, meningitis (inflammation of the pia mater, arachnoid, and the subarachnoid space), hair loss, fever, malaise, and weight loss. After the secondary stage, there is a period of latency, when the infected person has no signs or symptoms of syphilis. Latency can be interrupted by a recurrence of secondary syphilis.

Tertiary syphilis is the final stage in the natural progression of the disease. It is estimated that between 20% and 40% of those infected do not exhibit signs and symptoms in this final stage. Tertiary syphilis has become uncommon in the era of antibiotics and presents as a slowly progressive inflammatory disease with the potential to affect multiple organs (Cohen, Klausner, Engelman, & Philip, 2013).

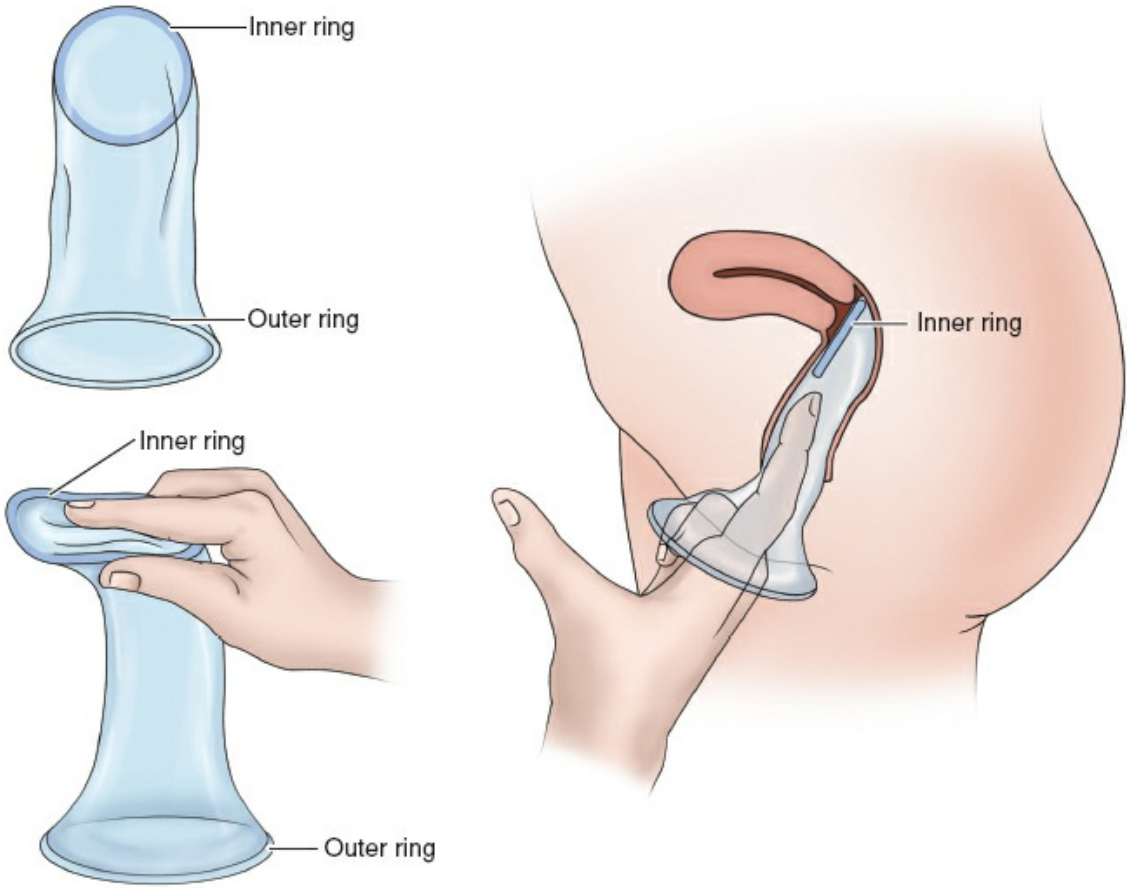


FIGURE 35-1 Female condom. To insert the female condom, hold the inner ring between the thumb and middle finger. Put the index finger on the pouch between the thumb and other fingers and squeeze the ring. Slide the condom into the vagina as far as it will go. The inner ring keeps the condom in place.

The conclusive diagnosis of syphilis can be made by direct identification of the spirochete obtained from the chancre lesions of primary syphilis. Serologic tests used in the diagnosis of secondary and tertiary syphilis require clinical correlation in interpretation. The serologic tests are summarized as follows:

FIGURE 35-2 The first stage of a syphilis infection is the appearance of a chancre, a round, usually solitary, painless sore that appears on the glans penis, the shaft of the penis, or may lie within the urethra. If left untreated, it will heal; however, secondary syphilis will develop. (From Goodheart, H. (2003). *Goodheart's photoguide of common skin disorders.* Philadelphia, PA: Lippincott Williams & Wilkins.)

- Nontreponemal or reagin tests, such as the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin circle card test (RPR-CT), generally are used for screening and diagnosis. After adequate therapy, the test result is expected to decrease quantitatively until it is read as negative, usually about 2 years after therapy is completed.
- Treponemal tests, such as the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination assay test (MHA-TP), are used to verify that the screening test did not represent a false-positive result. Positive results usually are positive for life and, therefore, are not appropriate to determine therapeutic effectiveness.

Medical Management

Administration of antibiotics is the treatment of all stages of syphilis. A single dose of penicillin G benzathine intramuscular injection is the medication of choice for early syphilis or early latent syphilis of less than 1 year's duration. Patients with late latent or latent syphilis of unknown duration should receive three injections at 1-week intervals. Usually patients who are allergic to penicillin are treated with doxycycline or tetracycline (Centers for Disease Control and Prevention [CDC], 2015).

Nursing Management

Nursing interventions include administration of the prescribed antibiotics, referral for further STI testing, and education on the pathophysiology and prevention of transmission of syphilis and all STIs. The nurse advises the patient to get retested at 3 and 12 months after treatment. Syphilis is a reportable communicable disease. The public health department is responsible for identification of sexual contacts, contact notification, and contact screening.

Complications

The most common complications of untreated syphilis manifest as aortitis (inflammation of the aorta) and neurosyphilis and are evidenced by dementia, psychosis, paresis, stroke, or meningitis (Cohen et al., 2013).

CHLAMYDIA TRACHOMATIS AND *NEISSERIA GONORRHOEAE*

Pathophysiology

Chlamydia trachomatis and *Neisseria gonorrhoeae* are the most commonly reported STIs. Coinfection with *Chlamydia* often occurs in patients infected with *N. gonorrhoeae. Chlamydia* and *N. gonorrhoeae* are caused by bacteria that are transmitted during sexual relations or may be transmitted from mother to child during vaginal birth.

Risk Factors

Any sexually active person can be infected with *Chlamydia* or *N. gonorrhoeae*, and the risk increases with the number of sexual partners. The group with the greatest risk for *Chlamydia* infection is young women 24 years of age and younger and may be associated with a cervix that has not matured fully (CDC, 2015). The risk for *N. gonorrhoeae* also includes sexually active young women as well as men who have sex with men.

Clinical Manifestations and Assessment

Both *Chlamydia* and *N. gonorrhoeae* infections frequently do not cause symptoms in women and thus are often referred to as "silent" related to clinical presentation. When symptoms are present, the most frequent finding is mucopurulent cervicitis with exudates in the endocervical canal. Women with gonorrhea also can present with symptoms of urinary tract infection (UTI) or vaginitis.

Although men are more likely than women to have symptoms when infected, infection with *N. gonorrhoeae* and/or *Chlamydia* also can be asymptomatic. When symptoms are present in male patients, the symptoms may include burning during urination and penile discharge. Patients with *N. gonorrhoeae* infection also may report painful swollen testicles.

Assessment includes noting fever, discharge (urethral, vaginal, penis, or rectal), and signs of arthritis. Diagnostic methods available include urine testing or swab specimens of the endocervix, urethra, anal canal, and pharynx. Nucleic acid amplification tests (NAAT) are most sensitive for the detection of chlamydia. The Gram stain best identifies gonorrhea from the male urethra.

Because many chlamydial infections are asymptomatic, the CDC recommends all women younger than 25 years of age who are sexually active be tested routinely for chlamydial infection (CDC, 2015).

Medical Management

Because patients often are infected with both gonorrhea and chlamydia simultaneously, the CDC recommends dual therapy if chlamydia has not been ruled out by NAAT. The CDC-recommended treatment for chlamydia is either doxycycline (Adoxa) or azithromycin (Zithromax), and for gonorrhea ceftriaxone (Rocephin) or cefixime (Suprax) plus azithromycin. Ceftriaxone is the preferred treatment for gonorrhea as cefixime is becoming less effective (CDC, 2015).

Nursing Management

Gonorrhea and chlamydia are reportable communicable diseases. The target group for preventive patient teaching about gonorrhea and chlamydia is the adolescent and young adult population. Along with reinforcing the importance of abstinence, when appropriate, education should address postponing the age of initial sexual exposure, limiting the number of sexual partners, and use of condoms or barrier protection. Moreover, patient counseling includes abstinence for 1 week after treatment in addition to the completion of the partner's treatment. Test of cure is not recommended unless medication compliance is in question; however, the retesting of females 3 months' posttreatment is recommended due to the possibility of reinfection. Education for males includes that they must inform their female partners of infection, and they must provide literature on STIs and the risk of pelvic inflammatory disease (PID) to them.

Complications

In women, PID, ectopic pregnancy, endometritis, and infertility are possible complications of either *N. gonorrhoeae* or *Chlamydia* infection. Figure 35-3 demonstrates how microorganisms spread in pelvic infection.

In men, epididymitis, a painful disease that may lead to infertility, may result from infection with either bacterium. In people of either gender, *N. gonorrhoeae* may cause arthritis or bloodstream infection.

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) infection is the most common STI among young, sexually active people. Millions of Americans are infected with HPV, many unaware they carry the virus. Most sexually active men and women acquire genital HPV infection at some point in their lives (CDC, 2015).

Pathophysiology

The virus affects the skin and mucous membranes through sexual contact (i.e., naked rubbing and vaginal/anal intercourse). At least 40 HPV types can infect the genitalia and perineum, including the skin of the penis, vulva, and anus as well as the linings of the vagina, cervix, and rectum. Certain types of HPV can cause the cells of the cervix to become abnormal, contributing to approximately 70% of cervical cancer cases (refer to Chapter 33 for additional details). Other strains of HPV cause genital warts. The virus can be present in the body for a long period of time before detection or symptoms occur (CDC, 2015). Psychologically, the diagnosis of HPV on a pap can be upsetting to patients. This is particularly stressful and difficult to understand for some women after testing negative for years. Explaining the latency of viruses can facilitate understanding. Often HPV is self-limiting due to an effective immune system response; however, smoking has been associated with increased morbidity. Persistent HPV can lead to cervical cancer but with proper management and patient compliance morbidity and mortality are easily minimized. Therefore, best practice pap follow-up is patient specific. Newer guidelines assist providers on making the determination whether to pap yearly or up to every 3 to 5 years depending on risk factors, history, and age.

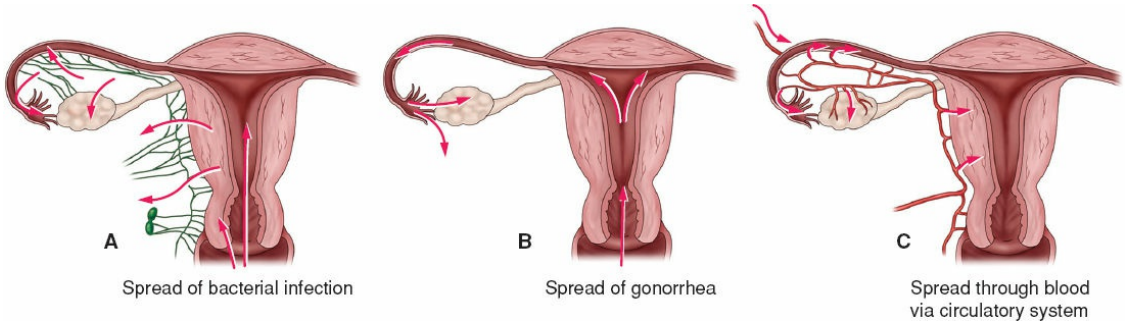

FIGURE 35-3 Pathway by which microorganisms spread in pelvic infections. (A) Bacterial infection spreads up the vagina, into the uterus, and through the lymphatics. (B) Gonorrhea spreads up the vagina, into the uterus, and then to the tubes and ovaries. (C) Bacterial infection can reach the reproductive organs through the bloodstream (hematogenous spread).

Risk Factors

Risk factors include being sexually active, having multiple sex partners, and having sex with a partner who has or has had multiple partners.

Clinical Manifestations and Assessment

More than 100 strains of HPV exist, and infection can be latent (asymptomatic and detected only by DNA hybridization tests for HPV), subclinical (visualized only after application of acetic acid followed by inspection under magnification), or clinical (visible warts).

The most common strains of HPV, 6 and 11, usually cause condylomata (genital warts) on the female and male genitalia and can be found in the mouth. Often these lesions are visible, flesh-colored, flat, verrucous, or papillary.

Some HPV strains (16, 18, 31, 33, and 45) affect the cervix, resulting in abnormal Papanicolaou (Pap) smears and are strongly associated with cervical cancer (CDC, 2015). Thus, the Pap smear is the detection vehicle identifying HPV DNA. Colposcopy-derived biopsies diagnose any cellular changes or dysplasia (changes in cervical cells).

Medical and Nursing Management

Treatment of external genital warts includes topical application of trichloroacetic acid, podophyllin (Podofin), and chemotherapeutic agents as well as injections of interferon administered by a health care provider. Topical agents that can be applied by patients to external lesions include podofilox (Condylox) and imiquimod (Aldara). Electrocautery and laser therapy are alternative therapies that may be indicated for patients with a large number or area of genital warts (CDC, 2015).

Women with HPV should have annual Pap smears because of the potential of HPV to cause dysplasia. Use of condoms can reduce the likelihood of transmission, but transmission also can occur during skin-to-skin contact in areas not covered by condoms.

In many cases, patients are angry about having warts or HPV and do not know who infected them because the incubation period can be long and partners may have no symptoms. Acknowledging the emotional distress that occurs when an STI is diagnosed and providing support and facts are important nursing actions. Likewise, patient education about the likelihood of recurrence in the first 3 months after treatment is encouraged.

Complications

Preventatively, vaccination is recommended for girls and women who are between 11 and 26 years of age, before the onset of sexual activity, against four strains of HPV that account for up to 70% of cervical cancer (CDC, 2015). Also the quadrivalent HPV vaccine should be administered to males who are between 11 and 26 years of age, ideally before the onset of sexual activity, to prevent genital warts. Immunization will not replace other strategies important in the prevention of HPV or the need for cervical cancer screening. Loss of the uterus and death from invasive cancer should be avoidable with proper care and follow-up.

HERPES VIRUS TYPE 2 INFECTION (HERPES GENITALIS, HERPES SIMPLEX VIRUS)

Herpes genitalis is a recurrent, lifelong viral infection that causes herpetic lesions (blisters) on the vulva, vagina, and cervix in females and the penis in males. There are two types of herpes simplex virus (HSV): HSV-1 and HSV-2, which are clinically indistinguishable.

Pathophysiology

HSV-1 is known as the oral type and can be transmitted to the genitalia by oral sex or self-inoculation (i.e., touching a cold sore and then touching the genital area). HSV-2 is always transmitted sexually. Usually the initial infection is very painful and lasts about 1 week, but it also can be asymptomatic. Most HSV infections occur via asymptomatic transmission when neither the carrier nor the recipient manifests lesions (Bernstein et al., 2013).

Recurrences are more common with HSV-2 than HSV-1, are less painful, and usually produce minor itching and burning. Some patients have few or no recurrences, whereas others have frequent bouts. Often recurrences are associated with stress, sunburn, dental work, or inadequate rest or nutrition—all situations that may tax the immune system. When viral replication diminishes, the virus ascends the peripheral sensory nerves and remains inactive in the nerve ganglia. Similar to HPV, HSV can lay dormant without symptoms. Often, HSV is diagnosed through serology testing during STI screening. For many, the diagnosis of HSV comes with emotional distress and sigma necessitating emotional support and reassurance.

Risk Factors

Risk factors include contact with an infected person by the mouth, oropharynx, mucosal surface, vagina, or cervix.

Clinical Manifestations and Assessment

Itching and pain accompany the process as the infected area becomes red and edematous. Primary infection may begin with macules (small flat spots on skin) and papules (small circumscribed elevations) and progress to vesicles (small, serous-filled elevated spots) and ulcers. The vesicular state often appears as a blister, which later coalesces, ulcerates, and encrusts (Fig. 35-4). Influenza-like symptoms may occur 3 or 4 days after the lesions appear. Often inguinal lymphadenopathy (enlarged lymph nodes in the groin), minor temperature elevation, malaise, headache, myalgia (aching muscles), and dysuria (pain on urination) are noted. Pain is evident during the first week and then decreases. The lesions subside in about 2 weeks unless secondary infection occurs.

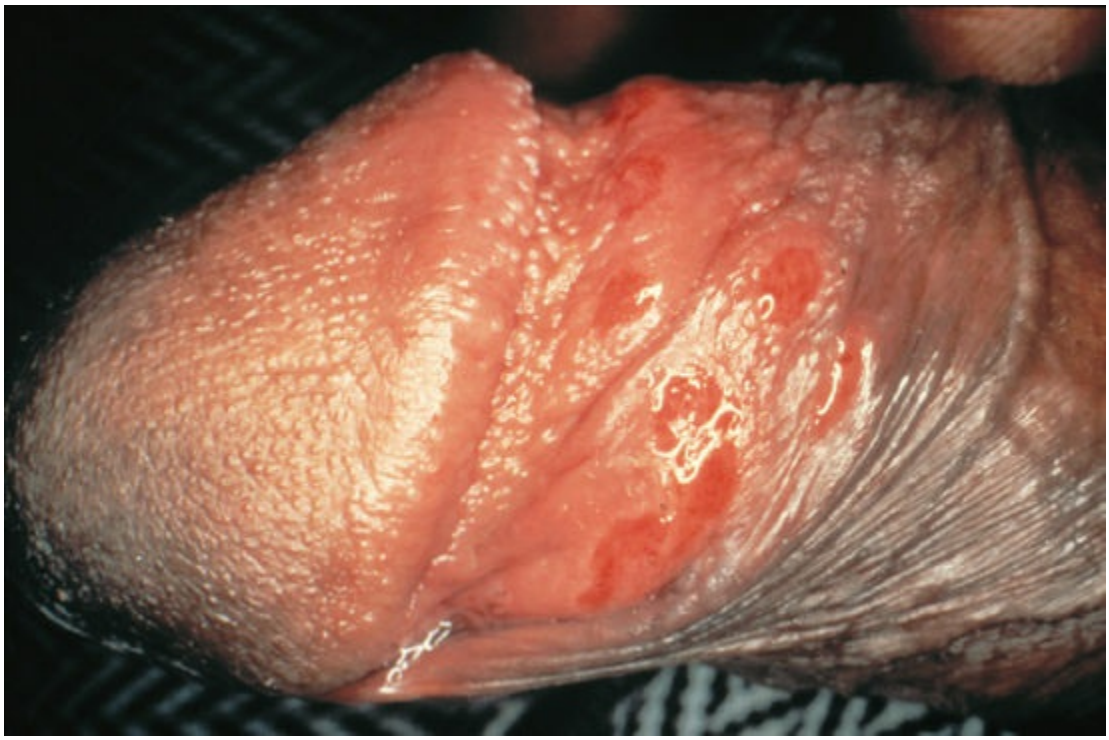

FIGURE 35-4 Herpes simplex may manifest as a painful open ulcer or cluster of superficial vesicles (fluid-filled) with an erythematous base. (From Goodheart, H. (2003). *Goodheart's photoguide of common skin disorders*. Philadelphia, PA: Lippincott Williams & Wilkins.)

The gold standard for HSV diagnosis is a culture of the lesion. Serology may help determine new versus chronic infection when obtained concurrently with positive culture of a lesion.

Medical Management

There is currently no cure for HSV-2 infection, but treatment is aimed at relieving the symptoms. Antiviral dosing varies, depending on primary, recurrent, or suppressive management. Management goals include preventing the spread of infection, making patients comfortable, decreasing potential health risks, and initiating a counseling and education program. The antiviral agents acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir) are recommended to suppress the viral load and decrease recurrence and shedding (CDC, 2015).

Nursing Management

Patient education is paramount in preventing the transmission of HSV. Counseling regarding suppressive therapy should be offered at the initial diagnosis and has been shown to decrease the risk of recurrence by 70 to 80% (Markle, Conti, & Kad, 2013). The nurse informs patients of their potential to transmit the virus without symptoms or lesions. In addition, patients have a potentially legal and moral obligation to disclose their diagnosis to sexual partners. Moreover, the importance of barrier methods to prevent the transmission is imperative. Often emotional support is needed for the patient who is diagnosed with HSV (CDC, 2015), since herpes can be present without symptoms for years.

Concept Mastery Alert

HSV can be transmitted whether lesions are present or not. A client's consistent use of condoms with sexual activity would be a measure to reduce the risk of transmission and recurrences.

Complications

Rarely, complications may arise from extragenital spread of HSV, such as to the buttocks, upper thighs, or even the eyes as a result of touching lesions and then touching other areas. Patients should be advised to wash their hands after contact with lesions. Other potential problems are aseptic meningitis, neonatal transmission, and severe emotional stress related to the diagnosis.

FEMALE REPRODUCTIVE INFECTIONS ASSOCIATED WITH SEXUAL ACTIVITY

PELVIC INFLAMMATORY DISEASE

PID is an inflammatory condition of the pelvic cavity that may begin with cervicitis (inflammation of the uterine cervix) and may involve the uterus (endometritis), fallopian tubes (salpingitis), ovaries (oophoritis), pelvic peritoneum, or pelvic vascular system. Infection may be acute, subacute, recurrent, or chronic and localized or widespread, and infection usually is caused by bacteria but may be attributed to a virus, fungus, or parasite. Gonorrheal and chlamydial organisms are the most likely causes.

Pathophysiology

PID arises from a polymicrobial infection that ascends upward from the vagina and into the uterus, fallopian tubes, and peritoneal cavity. In bacterial infections that occur after childbirth or abortion, pathogens are disseminated directly through the tissues that support the uterus by way of the lymphatics and blood vessels.

In gonorrheal infections, the gonococci pass through the cervical canal and into the uterus, where the environment, especially during menstruation, allows them to multiply rapidly and spread to the fallopian tubes and into the pelvis (see Fig. 35-3B). Usually the infection is bilateral.

Pelvic infection is caused most commonly by sexual transmission but also can occur with invasive procedures, such as endometrial biopsy, surgical abortion, hysteroscopy, or insertion of an intrauterine device (IUD). Bacterial vaginosis (BV), a vaginal infection, may predispose women to pelvic infection.

Figures 35-3 and 35-5 illustrate the path that organisms can travel from the vagina to the sterile peritoneum, resulting in peritonitis (inflammation of the peritoneum).

Risk Factors

Risk factors for PID include early age at first intercourse, multiple sexual partners, frequent intercourse, intercourse without condoms, intercourse with a partner with an STI, and a history of STIs or previous pelvic infection (CDC, 2015).

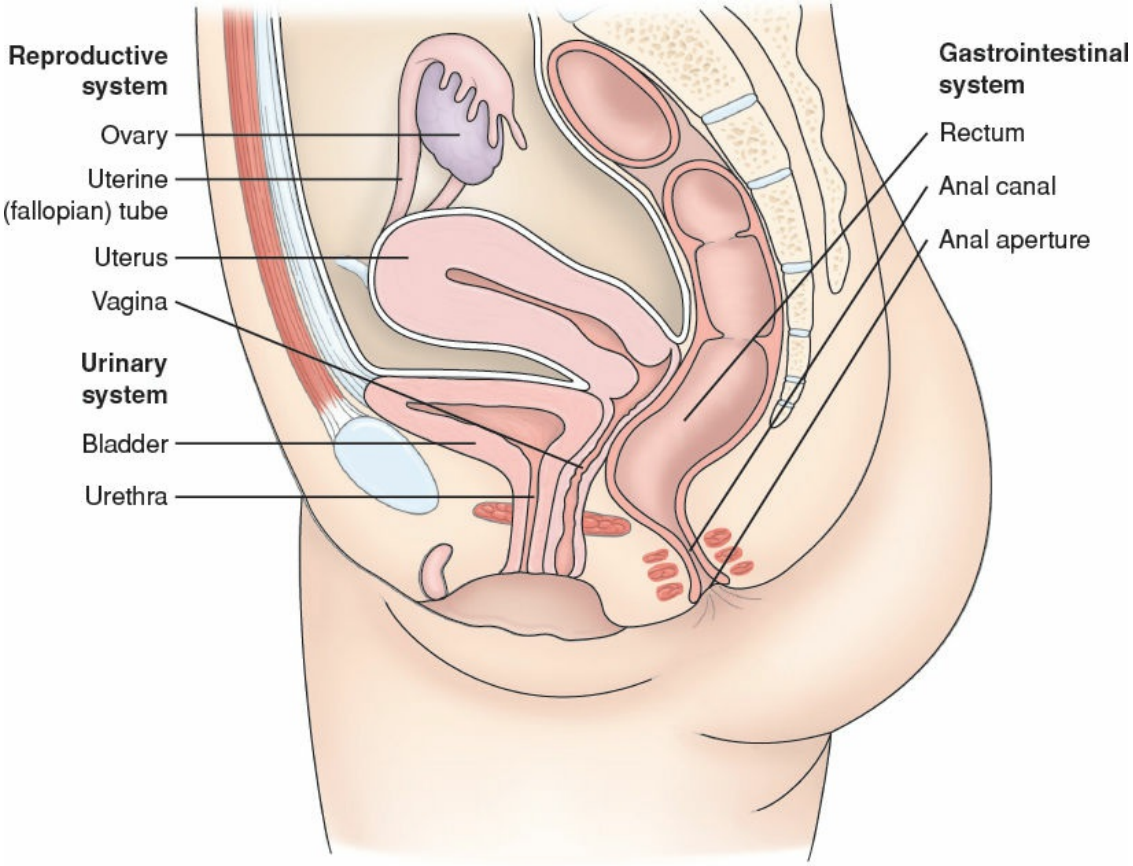

FIGURE 35-5 Female anatomy. Note the relationship of the reproductive organs to the pelvic peritoneum.

Clinical Manifestations and Assessment

Symptoms of pelvic infection usually begin with vaginal discharge, dyspareunia (painful sexual intercourse), lower abdominal pelvic pain, and tenderness that occurs after menses. Pain may increase with voiding or with defecation. The minimal criteria for diagnosis and treatment include one, or more, of the following:

- Uterine tenderness,
- Adnexal tenderness (adnexa are the "appendages" of the uterus, namely the ovaries, fallopian tubes, and ligaments that hold the uterus in place), and
- Cervical motion tenderness.

Other symptoms include fever, general malaise, anorexia, nausea, headache, and, possibly, vomiting (CDC, 2015).

Medical Management

Women with mild infections may be treated as outpatients with ceftriaxone IM and doxycycline with or without metronidazole, but hospitalization may be necessary if a patient is nonresponsive to medication, if a surgical emergency (e.g., appendicitis) or abscess formation is suspected, or if the patient is pregnant and salpingitis (inflammation of the fallopian tubes) is suspected (CDC, 2015; Swygard & Cohen, 2016). Intensive therapy includes bed rest, IV fluids, and IV antibiotic therapy. If the patient has abdominal distention or ileus, nasogastric intubation and suction are initiated. Careful monitoring of vital signs and symptoms assists in evaluating the status of the infection. Treatment of sexual partners is necessary to prevent reinfection.

Nursing Management

A hospitalized patient is maintained on bed rest and usually is placed in the semi-Fowler position to facilitate dependent drainage. The nurse administers analgesic agents as prescribed for pain relief. Heat applied safely to the abdomen also may provide some pain relief and comfort. On an outpatient basis, confirming patient follow-up 3 days after treatment is imperative to assess symptom abatement.

Patient teaching consists of explaining how pelvic infections occur, how they can be controlled and avoided, and their signs and symptoms. All patients who have had PID need to be informed of the signs and symptoms of ectopic pregnancy (pain, abnormal bleeding, delayed menses, faintness, dizziness, and shoulder pain) because they are prone to this complication.

Complications

PID can result in tubo-ovarian abscess, recurrent disease, pelvic or generalized peritonitis, strictures, fallopian tube obstruction, ectopic pregnancy, and infertility. Adhesions are common and often result in chronic pelvic pain. Other complications include bacteremia with septic shock and thrombophlebitis with possible embolization.

BACTERIAL VAGINOSIS (BV)

The vagina is protected against infection by its normally low pH (3.5 to 4.5), which is maintained in part by *Lactobacillus acidophilus*, the dominant bacteria in a healthy vaginal ecosystem. These bacteria suppress the growth of anaerobes and produce lactic acid, maintaining normal pH. Factors that may initiate or predispose a patient to infections include contact with an infected partner and wearing tight, nonabsorbent, and heat- and moisture-retaining clothing. BV and trichomoniasis are two vulvovaginal infections that are sexually associated.

Pathophysiology

BV is caused by an overgrowth of anaerobic bacteria and *Gardnerella vaginalis* normally found in the vagina and an absence of lactobacilli. It is characterized by a fish-like odor that is particularly noticeable after sexual intercourse or during menstruation as a result of an increase in vaginal pH. Usually it is accompanied by a heavier-than-normal discharge.

Risk Factors

Douching after menses, smoking, multiple sex partners, other STIs, and increased sexual activity are risk factors for BV.

Clinical Manifestations and Assessment

BV can occur throughout the menstrual cycle and does not produce local discomfort or pain. Discharge is gray to yellowish white and smoothly coats the vaginal walls. The fish-like odor can be detected before or after adding a drop of potassium hydroxide to a glass slide with a sample of vaginal discharge. Under the microscope, vaginal cells are coated with bacteria and are described as *clue cells.* Usually the pH of the discharge is greater than 4.7 because of the amines that are released from the bacterial overgrowth. Lactobacilli, which serve as a natural host defense, are usually absent.

Medical Management

Metronidazole (Flagyl), administered orally twice a day for 1 week, is effective; a vaginal gel is also available. Also Clindamycin (Cleocin) vaginal cream or ovules (oval suppositories) are effective. BV is not considered an STI exclusively but is associated with sexual activity. Treatment of patients' partners does not seem to be effective, but use of condoms may be helpful.

Nursing Management

Some patients complain of an unpleasant but transient metallic taste when taking metronidazole.

Clindamycin creams are oil-based and will decrease the efficacy of latex condoms. The nurse teaches proper perineal hygiene for prevention (CDC, 2015).

Nursing Alert
Patients taking metronidazole (Flagyl) must be instructed to avoid alcohol during and for 24 hours after treatment to prevent significant gastrointestinal upset (disulfiram-like reaction).

Complications

BV is not considered a serious condition; however, it has been associated with premature labor, endometritis, PID, and recurrent UTI (CDC, 2015).

TRICHOMONIASIS

Pathophysiology

Trichomonas vaginalis (aka "trich") is a flagellated protozoan that causes a common sexually transmitted vaginitis. It may be transmitted by an asymptomatic carrier who harbors the organism in the urogenital tract.

Clinical Manifestations and Assessment

Clinical manifestations include a vaginal discharge that is thin (sometimes frothy), yellow to yellow-green, malodorous, and very irritating. An accompanying vulvitis may result, with vulvovaginal burning and itching. Trich often causes urethritis in men. Diagnosis is made most accurately with NAAT, detecting three to five times more infections than wet mount microscopic analysis (CDC, 2015). Inspection with a speculum often reveals vaginal and cervical erythema (redness) with multiple small petechiae ("strawberry spots"). Testing of a trichomonal discharge demonstrates a pH greater than 4.5.

Medical and Nursing Management

The most effective treatment for trichomoniasis is metronidazole or tinidazole. Both partners receive a one-time loading dose. Test of cure is not needed unless symptoms recur.

Nursing education on abstaining from sexual activity until both partners are treated is imperative.

MALE REPRODUCTIVE INFECTIONS ASSOCIATED WITH SEXUAL ACTIVITY

Several infections affect the male genitourinary tract, including prostatitis (see Chapter 34), epididymitis, and orchitis, often caused by STIs.

Epididymitis usually descends from an infected prostate or urinary tract. The infection passes upward through the urethra, ejaculatory duct, and vas deferens to the epididymis and commonly develops from STIs, such as gonorrhea and chlamydia. In younger men, the major cause of epididymitis is *C. trachomatis* (Stewart, Ubee, & Davies, 2011).

Orchitis is an inflammation of the testes (testicular congestion) that can be caused by a number of factors: bacterial, viral, spirochetal, parasitic, traumatic, chemical, or unknown. Bacterial causes usually spread from an associated epididymitis in men who are sexually active. Causative organisms include *N. gonorrhoeae, C. trachomatis, Escherichia coli, Klebsiella, Pseudomonas aeruginosa, Staphylococcus* species, and *Streptococcus* species. Additionally, a more common cause of isolated orchitis is mumps. When postpubertal men contract mumps, about one in five develop some form of orchitis 4 to 7 days after the jaw and neck swell, and the testes may show some atrophy. Therefore mumps vaccination is recommended for postpubertal men who have not had mumps or previous mumps vaccination in childhood. Further details related to epididymitis and orchitis may be found in Chapter 34.

NURSING PROCESS

The Patient with a Sexually Transmitted Infection

ASSESSMENT

During the physical examination, the examiner looks for rashes, lesions, drainage, discharge, or swelling. Inguinal nodes are palpated to elicit tenderness and to assess swelling (Fig. 35-6). Women are examined for abdominal or uterine tenderness.

DIAGNOSIS

Appropriate nursing diagnoses of the patient with an STI may include:

- Deficient knowledge about the disease and risk for spread of infection and reinfection
- Anxiety related to anticipated stigmatization and to prognosis and complications
- Ineffective health maintenance related to high-risk sexual behaviors

- Risk for infection transmission related to lack of measures for STI prevention
- Risk of infection transmission from mother to child during delivery

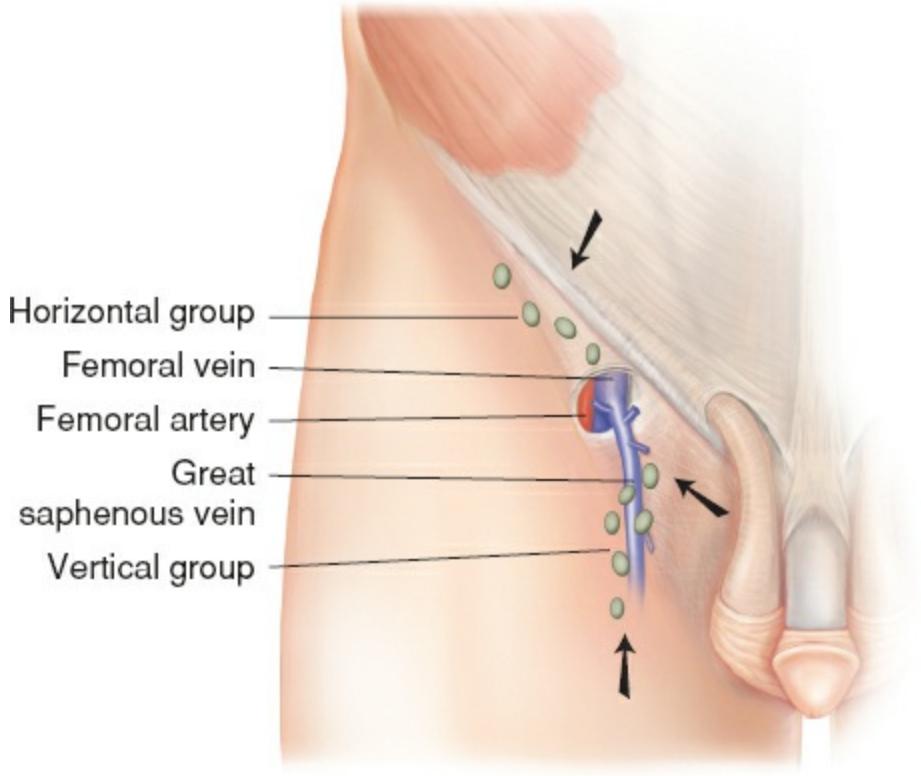

FIGURE 35-6 Superficial inguinal lymph nodes. (Courtesy of Bickley, L. (2013). *Bates' pocket guide to physical examination and history taking*. Philadelphia, PA: Lippincott Wolters Kluwer.)

PLANNING AND GOALS

Major goals are increased patient understanding of the natural history and treatment of the infection, reduced anxiety, increased compliance with therapeutic and preventive goals, and absence of complications.

NURSING INTERVENTIONS

Increasing Knowledge and Preventing Spread of Disease

Often education about STIs and prevention of the spread to others are accomplished simultaneously. Explanation includes covering the causative organism, the usual course of the infection (including the interval of potential communicability to others), and possible complications. The nurse stresses the importance of following therapy as prescribed and the need to report any side effects or progression of symptoms. The nurse emphasizes that the same behaviors that led to infection with one STI increase the risk for any other STI. Methods used to contact sexual partners should be discussed. The patient should understand that until the partner has been treated, continued sexual exposure to the same person may lead to reinfection. The nurse discusses the relative value of condoms in reducing the risk for infection with STIs.

REDUCING ANXIETY

When appropriate, the nurse encourages the patient to discuss anxieties and fear associated with the diagnosis, treatment, or prognosis. Patients may need help in planning discussion with partners. If the patient is especially apprehensive about this aspect, referral to a social worker or other specialist may be appropriate.

INCREASING COMPLIANCE

In group settings or in a one-to-one setting, open discussion about STI information facilitates patient teaching. Discomfort can be reduced by factual explanation of causes, consequences, treatments, and prevention. Patients can obtain more information by accessing the CDC website (see Resources at the end of the chapter).

EVALUATION

Expected patient outcomes may include the following:

1. Understands infection and treatment:
    a. Verbalizes understanding of infectious process
    b. Demonstrates compliance with medications, barriers, and behaviors
2. Absence of complications, such as ectopic pregnancy, infertility, neurosyphilis, gonococcal meningitis/arthritis, and prostatitis

CHAPTER REVIEW

Critical Thinking Exercises

1. During a checkup, a 23-year-old woman tells you that she has a new boyfriend and is not concerned about sexual risks of STIs because she plans on having only oral sex. How would you address the educational needs of this patient? How would your teaching differ if her new partner is a woman?

2. A 28-year-old man is seeking treatment for urinary frequency. He informs you that he believes he has a UTI. When you are obtaining the health history, he reports that he has multiple sexual partners outside his marriage. He has undergone treatment for gonorrhea within the past 6 months. What are your major concerns regarding the patient's complaint of urinary frequency? Describe important aspects that must be addressed when teaching this patient about safer sex. What community resources should you make available to this patient and his wife?

NCLEX-Style Review Questions

1. A 22-year-old woman presents requesting STI testing after a recent encounter ended with a broken condom. She has cervical cultures but declined having blood work done. Which positive test result would lead the nurse to counsel the patient to seek further

blood work related to screening for STIs?

a. Candida yeast
b. Group B *Streptococcus*
c. Trichomoniasis
d. Gardnerella

2. A 16-year-old girl presents with recurrent painful vulvar lesions. The nurse obtains subsequent test results from her pelvic evaluation and confirms the identification of HSV-2. What counseling is most appropriate for this patient?

a. HSV-2 is self-limiting and will go away again on its own, no medication needed.
b. HSV-2 can be transmitted and acquired without obvious symptoms or sores.
c. A blood test can determine if this is a new infection or subsequent outbreak.
d. Stress caused the sores; exercise and stress management will prevent them.

3. A 29-year-old woman presents with pelvic pain, fever, and irregular bleeding. She has been trying to get pregnant and fears she is having a miscarriage. Upon examination, the woman yells when her uterus is palpated bimanually and almost jumps off the table with cervical motion tenderness. The pregnancy test is negative. What nursing intervention is most appropriate for this patient?

a. Administer the antibiotics as prescribed for PID.
b. Reassure her she is not pregnant.
c. Refer her to a fertility specialist.
d. Counsel her on the signs of ectopic pregnancy.

4. A 26-year-old woman recently had a colposcopy that detected cervical dysplasia and HPV types 16 and 18, necessitating the removal of part of her cervix. The patient returns for her postoperative follow-up appointment saying, "I'm glad the cancer thing is over and I don't have to come back again for a long time." Which nursing response is most appropriate?

a. "You are fortunate the cancer was caught early and you healed fast."
b. "You still need to return for frequent Pap smears to monitor your cervix."
c. "Good for you, not smoking helps keep the HPV away for good."
d. "There will be a problem getting pregnant now after your surgery."

5. A 24-year-old man complains about an ulcer on the shaft of his penis along with complaints of fever and enlarged nodes in the inguinal region. He is diagnosed with syphilis and discharged after receiving one dose of penicillin IM. Which comment made by the patient would alert the nurse of the need to review the management plan with this patient?

a. I am aware that all my sexual partners will need to be treated.
b. I know that my blood work (VDRL or RPR titer) may take 12 months to become negative.

c. This disease cannot be cured, and I will likely develop complications.
d. I am aware that I must wear a condom every time I have sex.

Problems Related to Immunologic Function

A 45-year-old patient with a history of leukemia has been diagnosed with secondary gout. She is complaining of pain in the wrist and fingers. She recently had a surgical procedure done and believes this is the cause of her current attack.

- What medications would the nurse expect the health care provider to order for this

patient?

- Discuss the two phases of medical management.
- What are important components of nursing management for this patient?
- List two possible nursing diagnoses for this patient.

CHAPTER 36

Nursing Assessment: Immune Function

Mary E. Bartlett

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss the body's general immune response.
2. Discuss the stages of the immune response.
3. Differentiate between humoral and cellular immune responses.
4. Complete an assessment on the function of the immune system.

The most basic abilities of the human body to protect itself from disease and illness derive from the various components of the immune system. The term *immunity* refers to the body's specific protective response to an invading foreign agent or organism. The immune system functions as the body's defense mechanism against invasion and allows a rapid response to foreign substances in a specific manner. Responses occur at the genetic and cellular levels.

Immune function is affected by a variety of factors, such as central nervous system integrity, emotional status, medications, and the stress of illness, trauma, or surgery. Dysfunctions involving the immune system occur across the lifespan. When the functions of the immune system are diminished or disturbed, autoimmune and other disorders may develop. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the function of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens (Table 36-1).

ANATOMIC AND PHYSIOLOGIC OVERVIEW

One of the most effective defense mechanisms is the body's capacity to equip itself rapidly with weapons (antibodies) individually designed to meet each new invader (antigens). Antibodies react with antigens by:

- Coating antigens' surfaces
- Neutralizing the antigens if they are toxins
- Precipitating the antigens out of solution if they are dissolved

Although this system is normally protective, in some cases, the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity reaction. Before looking at immunity and immune response more closely, it is helpful to understand the basic components of the immune system.

Anatomy of the Immune System

The immune system is composed of an integrated collection of various cell types, each with a designated functional role in defending against infection and invasion by other organisms. Supporting this system are molecules that are responsible for the interactions, modulations, and regulation of the system. These molecules and cells participate in specific interactions with immunogenic epitopes or antigenic determinants, which are substances that, when introduced into the body, stimulate the production of an antibody. These epitopes are present on foreign materials and initiate a series of actions in a host, including the inflammatory response, the lysis of microbial agents, and the disposal of foreign toxins. The major components of the immune system include the bone marrow, the white blood cells (WBCs), the lymphoid tissues (including the thymus gland, the spleen, the lymph nodes, and the tonsils and adenoids), and similar tissues in the gastrointestinal (GI), respiratory, and reproductive systems (Fig. 36-1).

Stem cells (undifferentiated cells) in the bone marrow generate lymphocytes (a type of WBC) (Fig. 36-2). There are two types of lymphocytes: B lymphocytes (B cells), which mature in the bone marrow and enter the circulation as precursors to antibody-secreting cells or memory cells, and T lymphocytes (T cells), which move from the bone marrow to the thymus, where they mature into several kinds of cells with different helper functions (Fig. 36-3).

The thymus is a double-lobed organ found in the upper mediastinum. The spleen is located in the left upper quadrant of the abdomen. It is composed of red pulp (where old and injured red blood cells [RBCs] are destroyed) and white pulp (which contains concentrations of lymphocytes), and it acts like a filter. Lymph nodes are distributed throughout the body and connected by lymph channels and capillaries. The lymph nodes remove foreign material from the lymph system before it enters the bloodstream. The lymph nodes are centers for the proliferation of immune cells.

TABLE 36-1 Immune System Disorders

Disorder	Description
Autoimmunity	Normal protective immune response paradoxically turns against or attacks the body, leading to tissue damage
Hypersensitivity	Body produces inappropriate or exaggerated responses to specific antigens
Gammopathies	Immunoglobulins are overproduced
Immune Deficiencies	
Primary	Deficiency results from improper development of immune cells or tissues; usually congenital or inherited
Secondary	Deficiency results from some interference with an already developed immune system; usually acquired later in life

Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.)

Immune Function

Types of Immunity

There are two general types of immunity: natural (innate) and acquired (adaptive). Natural immunity is a nonspecific immunity present at birth that provides protection against an infectious agent without ever having encountered it before. Acquired or specific immunity develops after birth. Although each type of immunity plays a distinct role in defending the body against harmful pathogens, the various components usually act in an interdependent manner.

Natural Immunity

Natural immunity provides a nonspecific response to any foreign pathogen, regardless of the pathogen's composition. Because of its lack of specificity, natural immunity maintains a broad spectrum of defense against and resistance to infection. The basis of this defense mechanism is the ability to distinguish between "self" and "nonself." Recent research in transplantation medicine demonstrates that this is a very simplistic differentiation. Natural killer (NK) cells also recognize "missing self" or cells that have been transformed or infected by pathogens and no longer present the usual cell membrane markers (Abbas, Lictman, & Pillai, 2016; Paul, 2012). Natural (innate) immunity coordinates the initial response to pathogens through the production of cytokines, which are hormone-like molecules released by cells; they have a profound impact on the growth, development, and activation of immune system cells and the inflammatory response. Natural immunity also responds to pathogens via other effector molecules, which either activate cells for control of the pathogen (by elimination) or promote the development of the acquired immune response. The cells involved in this response include macrophages, dendritic cells, and NK cells. These cells directly recognize and respond to a wide variety of pathogens long before the development of antigen-specific acquired immunity. The early events in this immune response are critical in determining the nature of the adaptive immune response. Innate immune mechanisms can be divided into two stages: immediate (generally occurring within 4 hours) and delayed (occurring between 4 and 96 hours after exposure).

The development of immunity occurs via physical and chemical barriers, inflammatory response, and immune response.

Physical and Chemical Barriers. Activation of the natural immunity response is enhanced by processes inherent in physical and chemical barriers. The processes prevent or delay the entry into the body of various pathogens before infection can develop. Physical surface barriers include intact skin, mucous membranes, and cilia of the respiratory tract, which prevent pathogens from gaining access to the body. The cilia of the respiratory tract, along with coughing and sneezing responses, filter and clear pathogens from the upper respiratory tract before they can invade the body further. Chemical barriers, such as mucus, acidic gastric secretions, enzymes in tears and saliva, and substances in sebaceous and sweat secretions, act in a nonspecific way to destroy invading bacteria and fungi. For example, in addition to dissolving food, hydrochloric acid in the stomach destroys pathogens present in

food or swallowed mucus (Porth, 2015). Viruses are countered by other means, such as interferon (IFN). Interferon, one type of biologic response modifier, is a nonspecific viricidal protein that is naturally produced by the body and is capable of activating other components of the immune system.

Inflammatory Response. The inflammatory response is a major function of the natural immune system that is elicited in response to tissue injury or pathogens. Chemical mediators assist this response by minimizing blood loss, walling off the pathogen, activating phagocytes, and promoting formation of fibrous scar tissue and regeneration of injured tissue. The inflammatory response is facilitated by physical and chemical barriers inherent in the body.

Immune Response. A successful immune response eliminates the responsible antigen. Regulation of the immune response involves balance and counterbalance. Dysfunction of the natural immune system can occur when the immune components are inactivated or when they remain active long after their effects are beneficial. Immunodeficiencies are characterized by inactivation or impairment of immune components (described further in Chapter 37). Disorders with an inflammatory component (e.g., asthma, allergy, arthritis) are characterized by persistent inflammatory responses. In some cases, the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity reaction (Box 36-1). The immune system's recognition of the body's own tissues as "foreign" rather than as self is the basis for many autoimmune disorders (refer to Chapters 38 and 39). Despite the fact that the immune response is critical to the prevention of disease, it must be well controlled to curtail immunopathology. Most microbial infections induce an inflammatory response mediated by T cells and cytokines, which, in excess, can cause tissue damage. Therefore, regulatory mechanisms must be in place to suppress or halt the immune response in order to minimize tissue damage. This is achieved mainly by the production of cytokines and transformation of growth factors that inhibit macrophage activation. In some cases, T-cell activation is so overwhelming that these mechanisms fail, and pathology results. Researchers in gene therapy are attempting to recruit natural components of the immune system to fight cancer through activation of these inhibitory factors (Weiser et al., 2015).

BOX 36-1 Focus on Pathophysiology

Allergic Reaction

An allergic reaction is a manifestation of tissue injury resulting from interaction between an antigen and an antibody. Allergy is an inappropriate and often harmful response of the immune system to substances that are normally harmless. In this case, the inappropriate substance is termed an *allergen*.

Mast cells located in tissues throughout the body can be activated by a variety of stimuli, causing immediate allergic inflammation. The binding of the antigen and antibodies on the mast cells causes the release of mediators that effect blood vessel, smooth muscle, and glandular secretions. The powerful chemical mediators released from the mast cells cause a sequence of physiologic events, resulting in symptoms of

immediate hypersensitivity. There are two types of chemical mediators: primary and secondary. Primary mediators are preformed and are found in mast cells or basophils. Secondary mediators are inactive precursors that are formed or released in response to primary mediators (e.g., leukotrienes, bradykinin, and serotonin).

When in contact with an allergen, the body produces large amounts of IgE, thus causing a hypersensitivity or allergic response (see figure on next page). IgE-producing cells are located in the respiratory and intestinal mucosa. Two or more IgE molecules bind together to an allergen and trigger mast cells or basophils to release chemical mediators, such as histamine and leukotrienes. Maximal intensity of histamine release is reached within about 15 minutes after antigen contact. Effects of histamine release include erythema; localized edema in the form of wheals; pruritus; contraction of bronchial smooth muscle, resulting in wheezing and bronchospasm; dilation of small venules and constriction of larger vessels; and increased secretion of gastric and mucosal cells, resulting in diarrhea. Histamine action results from stimulation of histamine-1 (H_1) and histamine-2 (H_2) receptors found on different types of lymphocytes, particularly T-lymphocyte suppressor cells and basophils. H_1 receptors are found predominantly on bronchiolar and vascular smooth muscle cells; H_2 receptors are found on gastric parietal cells.

Certain medications are categorized by their action at these receptors. Diphenhydramine (Benadryl) is an example of an antihistamine, a medication that displays an affinity for H_1 receptors. Cimetidine (Tagamet) and ranitidine (Zantac) target H_2 receptors to inhibit gastric secretions in cases of peptic ulcer disease.

Leukotrienes, another chemical mediator released by mucosal mast cells, cause smooth muscle contraction, bronchial constriction, mucus secretion in the airways, and the typical wheal-and-flare reaction of the skin. Compared with histamine, leukotrienes are 100 to 1,000 times more potent in causing bronchospasm. Many manifestations of inflammation can be attributed in part to leukotrienes. Medications categorized as leukotriene antagonists or modifiers block the synthesis or action of leukotrienes and prevent the signs and symptoms associated with asthma.

Hypersensitivity

A hypersensitivity reaction is an abnormal, heightened reaction to any type of stimulus. Usually it does not occur with the first exposure to an allergen, but it is a reflection of excessive or atypical immune responses. To promote understanding of the immunopathogenesis of disease, hypersensitivity reactions have been classified into four specific types of reactions: Anaphylactic (type 1) Hypersensitivity, Cytotoxic (type II) Hypersensitivity, Immune Complex (type III) Hypersensitivity, and Delayed-Type (type IV) Hypersensitivity. Most allergies are identified as either type I or type IV hypersensitivity reactions.

Anaphylactic (Type I) Hypersensitivity

The most severe form of hypersensitivity reaction or immune-mediated reaction is

anaphylaxis. An unanticipated severe allergic reaction that is often explosive in onset, anaphylaxis is characterized by edema in many tissues, including the larynx, and often is accompanied by hypotension, bronchospasm, and cardiovascular collapse in severe cases. Mast cells in any organ system may be involved; however, the primary foci are the cardiovascular, skin, respiratory, and gastrointestinal systems (sites where mast cells are abundant) (Schwartz, 2016). Type I or anaphylactic hypersensitivity is an immediate reaction beginning within minutes of exposure to an antigen. This reaction is mediated by IgE antibodies and typically occurs on re-exposure to a specific antigen. If chemical mediators continue to be released, a delayed reaction may occur up to 24 hours after allergen exposure. Refer to Chapter 38 for more details on anaphylaxis.

Cytotoxic (Type II) Hypersensitivity

Type II, or cytotoxic, hypersensitivity occurs when the system mistakenly identifies a normal constituent of the body as foreign. This reaction may be the result of a cross-reacting antibody, possibly leading to damage to cells and tissues. Several disorders are associated with type II hypersensitivity reactions, including myasthenia gravis, in which the body mistakenly generates antibodies against normal nerve ending receptors; or Goodpasture syndrome, in which antibodies are generated against lung and renal tissue, producing lung damage and kidney failure; or they may be associated with drug-induced immune hemolytic anemia, Rh-hemolytic disease of the newborn, and incompatibility reactions in blood transfusions.

Immune Complex (Type III) Hypersensitivity

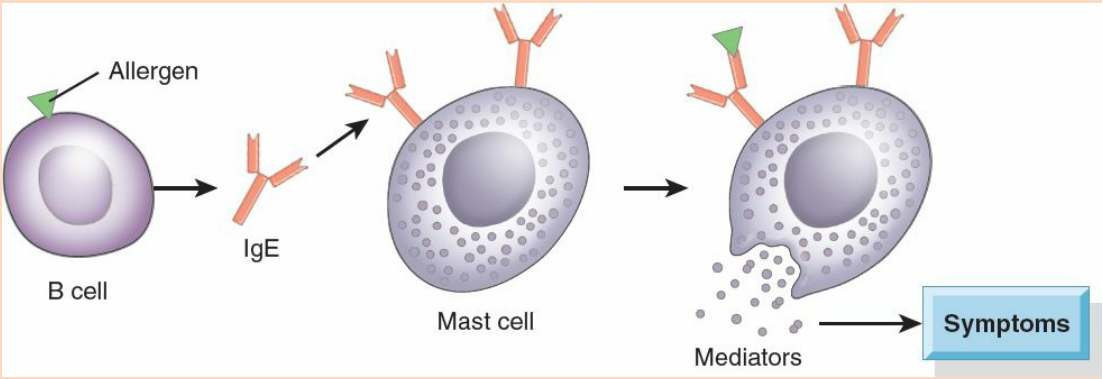
Type III, or immune complex, hypersensitivity involves immune complexes that are formed when antigens bind to antibodies. These complexes are cleared from the circulation by phagocytic action. If these type III complexes are deposited in tissues or vascular endothelium, two factors contribute to injury: the increased amount of circulating complexes and the presence of vasoactive amines. As a result, there is an increase in vascular permeability and tissue injury. The joints and kidneys are particularly susceptible to this type of injury. Type III hypersensitivity is associated with systemic lupus erythematosus, rheumatoid arthritis, certain types of nephritis, and some types of bacterial endocarditis.

Delayed-Type (Type IV) Hypersensitivity

Type IV, or delayed-type hypersensitivity, also known as cellular hypersensitivity, occurs 24–72 hours after exposure to an allergen. It is mediated by sensitized T cells and macrophages. An example of this reaction is the effect of an intradermal injection of tuberculin antigen or purified protein derivative (PPD). Sensitized T cells react with the antigen at or near the injection site. Lymphokines are released and attract, activate, and retain macrophages at the site. These macrophages then release lysozymes, causing tissue damage. Edema and fibrin are responsible for the positive tuberculin reaction.

Another example of a type IV hypersensitivity reaction is contact dermatitis resulting from exposure to allergens, such as cosmetics, adhesive tape, topical agents (e.g.,

povidone-iodine), medication additives, and plant toxins. The most common immune-mediated reaction to local anesthetics is a type IV hypersensitivity reaction. The primary exposure results in sensitization. Re-exposure causes a hypersensitivity reaction with resultant symptoms, such as pruritus, erythema, and raised lesions.



Allergen triggers the B cell to make IgE antibody, which attaches to the mast cell. When that allergen reappears; it binds to the IgE and triggers the mast cell to release its chemicals. (Courtesy of the U.S. Department of Health and Human Services. National Institutes of Health.)

One of the most actively researched areas of immunology involves the inflammatory response and its contribution to chronic conditions, such as diabetes, autoimmune disease, and cancer. Previously, when cells underwent apoptosis (programmed cell death) or phagocytosis (the engulfing of microorganisms or other cells and foreign particles by phagocytes), the death of cells was thought to be a null response that did not contribute to further actions by the immune system. Research into the role of damage-associated molecular pattern molecules (DAMPs) changes this belief and contributes to the evidence that inflammation may be the most important factor of any disease process. DAMPs, also known as alarmins, consist of a wide variety of proteins and other byproducts of cell damage that trigger cascading events in the inflammatory response (Firestein, 2016). As researchers elucidate the contribution of inflammation to chronic disease, further research will determine the role of anti-inflammatory diets and probiotics to counteract these harmful changes.

Acquired Immunity

Acquired immunity—immunologic responses acquired during life but not present at birth—usually develops as a result of exposure to an antigen through immunization (vaccination) or by contracting a disease, both of which generate a protective immune response. Weeks or months after initial exposure to the disease or vaccine, the body produces an immune response that is sufficient to defend against the disease on re-exposure. In contrast to the rapid but nonspecific innate immune response, this form of immunity relies on the recognition of specific foreign antigens. The two components of the immune response are strongly interrelated. Events occurring early in infection dictate the direction of the adaptive response and activate the acquired immune effector mechanisms, which have direct feedback on the cells of the innate (natural) system. The acquired immune response is broadly divided into two mechanisms: the cell-mediated response,

involving T-cell activation, and effector mechanisms, involving B-cell maturation and the production of antibodies. With the combination of innate and acquired immune responses, the body is capable of protecting itself immediately as well as against future challenges to its integrity.

The two types of acquired immunity are known as active and passive. In active acquired immunity, the immunologic defenses are developed by the person's own body. This immunity typically lasts many years or even a lifetime. This response is best demonstrated by the response of the body to immunizations. Exposure to attenuated virus, such as the influenza vaccine, prompts the production of antibodies against influenza. Re-exposure to influenza initiates a cascade of immune responses that are more rapid and capable of controlling the virus. Patients either eliminate the virus from their system or have a milder case of influenza. Passive acquired immunity is temporary immunity transmitted from a source outside the body that has developed immunity through previous disease or immunization. For example, immune globulin or antiserum, obtained from the plasma of people with acquired immunity, is used in emergencies to provide temporary immunity to certain diseases, such as hepatitis, immediately after exposure. Immunity resulting from the transfer of antibodies from the mother to an infant in utero or through breastfeeding is another example of passive immunity. Active and passive acquired immunity involve immunologic responses that are both humoral (antibodies produced by B cells) and cellular (cell-mediated T lymphocytes that attack pathogens).

Response to Invasion

When the body is invaded or attacked by bacteria, viruses, or other pathogens, it has three means of defense:

- The phagocytic immune response
- The humoral or antibody immune response
- The cellular immune response

The first line of defense, the phagocytic immune response, involves the WBCs (granulocytes and macrophages), which have the ability to ingest foreign particles. These cells move to the point of attack, where they engulf and destroy the invading agents. Phagocytes also remove the body's own dying or dead cells. Dying cells in necrotic tissue release substances that trigger an inflammatory response. Apoptosis is the body's way of destroying worn-out cells, such as blood or skin cells, or cells that need to be renewed. The cells that have been damaged by infection or genetic change, or cells that are simply in excess of the body's needs, are targeted for removal and destruction by a subgroup of proteases called *caspase.* Once the process of apoptosis begins, generally it is irreversible (Paul, 2012).

TABLE 36-2 Lymphocytes Involved in Immune Responses

Type of Immune Response	Cell Type	Function
Humoral	B lymphocyte	Produces antibodies or immunoglobulins (IgA, IgD, IgE, IgG, IgM)
Cellular	T lymphocyte	
	Helper T	Attacks foreign pathogens (antigens) directly Initiates and augments inflammatory response
	Helper T_1	Increases activated cytotoxic T cells
	Helper T_2	Increases B-cell antibody production
	Suppressor T	Suppresses the immune response
	Memory T	Remembers contact with an antigen and on subsequent exposures mounts an immune response
	Cytotoxic T (killer T)	Lyses cells infected with virus; plays a role in graft rejection
Nonspecific	Non-T, non–B lymphocyte (L lymphocytes)	Amplify T cell proliferation
	Null cell	Destroys antigens already coated with antibody
	Natural killer (NK) cell (granular lymphocyte)	Defends against microorganisms and some types of malignant cells; produces cytokines

Unlike macrophages, eosinophils are only weakly phagocytic. On activation, eosinophils probably kill parasites by releasing specific chemical mediators into the extracellular fluid. Additionally, eosinophils secrete leukotrienes (discussed later in the chapter), prostaglandins, and various cytokines (Paul, 2012; Salmon, 2016).

A second protective response, the humoral immune response (sometimes called the antibody response), begins with the B lymphocytes, which can transform themselves into plasma cells that manufacture antibodies. These antibodies are highly specific proteins that are transported in the bloodstream and attempt to disable pathogens.

The third mechanism of defense, the cellular immune response, involves the T lymphocytes, which can turn into special cytotoxic (or killer) T cells that can attack the pathogens. Table 36-2 summarizes the types of cells involved in immune response.

Basics of Immune Response

The structural part of the invading or attacking organism that is responsible for stimulating antibody production is called an antigen (or an immunogen). An antigen can be a small patch of proteins on the outer surface of a microorganism. Some antigens are naturally immunogenic or able to stimulate an immune response directly. Most antigens must be coupled with other molecules to stimulate the immune response. A single bacterium or large molecule, such as a diphtheria or tetanus toxin, may have several antigens, or markers, on its surface, thus inducing the body to produce a number of different antibodies. Once produced, an antibody is released into the bloodstream and carried to the attacking organism. There, it combines with the antigen, binding with it like an interlocking piece of a jigsaw puzzle (Fig. 36-4). There are four well-defined stages in an immune response: recognition, proliferation, response, and effector.

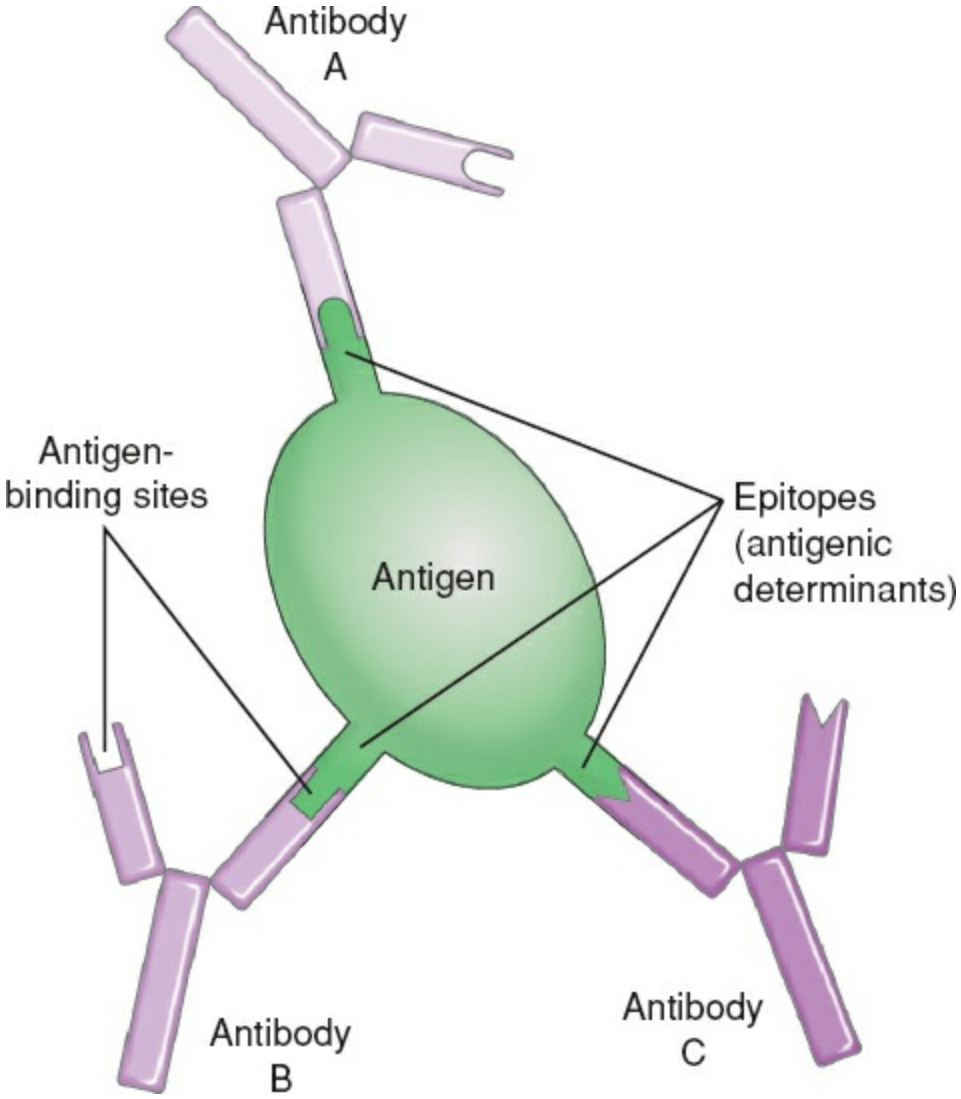


FIGURE 36-4 Complement-mediated immune responses. (From Grossman, S., Porth, C. M., Conelius, J., Gerard, S. O., Moriber, N., O'Shea, E. R., & Wheeler, K. (2014). *Porth's pathophysiology: Concepts of altered health states*. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.)

Recognition Stage. Recognition of antigens as foreign, or nonself, by the immune system is the initiating event in any immune response. The body accomplishes recognition using lymph nodes and lymphocytes for surveillance. Lymph nodes continuously discharge lymphocytes into the bloodstream. These lymphocytes patrol the tissues and vessels that drain the areas served by that node.

The exact way in which circulating lymphocytes recognize antigens on foreign surfaces is through complex rearrangements of genes that produce T-cell antigen receptors (TCR) during cell differentiation and maturation in the thymus. T cells present in primary lymphoid tissue that have not been presented with an antigen are called *naïve* and are capable of responding to a vast array of antigens (Paul, 2012). Macrophages play an important role in helping the circulating lymphocytes process the antigens. Both macrophages and neutrophils have receptors for antibodies and *complement* (a system of proteins found in normal blood plasma that combines with antibodies to destroy pathogens, to be discussed later in this chapter); as a result, they coat microorganisms with

antibodies, complement, or both, enhancing phagocytosis. Then the engulfed microorganisms are subjected to a wide range of toxic intracellular molecules. When foreign materials enter the body, circulating lymphocytes come into physical contact with the surfaces of these materials. Upon contact with the foreign material, naïve lymphocytes, with the help of macrophages, either remove the antigen from the surface or obtain an imprint of its structure, initiating the process of acquired immunity and antigen recognition in preparation for subsequent re-exposure to the antigen (Abbas et al., 2016; Paul, 2012).

Proliferation Stage. The circulating lymphocyte containing the antigenic message returns to the nearest lymph node. Once in the node, the sensitized lymphocyte stimulates some of the resident dormant T and B lymphocytes to enlarge, divide, and proliferate. T lymphocytes differentiate into cytotoxic (or killer) T cells, whereas B lymphocytes produce and release antibodies. Enlargement of the lymph nodes in the neck in conjunction with a sore throat is one example of the inflammatory response during immune activation.

Response Stage. In the response stage, the differentiated lymphocytes function in either a humoral or a cellular capacity. The production of antibodies by the B lymphocytes in response to a specific antigen begins the humoral response. *Humoral* refers to the fact that the antibodies are released into the bloodstream and, therefore, reside in the plasma (fluid fraction of the blood).

With the initial cellular response, the returning sensitized lymphocytes migrate to areas of the lymph node other than those areas containing lymphocytes programmed to become plasma cells. Here, they stimulate the residing lymphocytes to become cells that will attack microbes directly, rather than through the action of antibodies. These transformed lymphocytes are known as *cytotoxic (killer) T cells*. The T stands for *thymus*, signifying that, during embryologic development of the immune system, these T lymphocytes spent time in the thymus of the developing fetus. Viral rather than bacterial antigens induce a cellular response. This response is manifested by the increasing number of T lymphocytes (lymphocytosis) seen on the complete blood counts (CBC) of people with viral illnesses, such as infectious mononucleosis (cellular immunity is discussed in further detail later in this chapter).

Most immune responses to antigens involve both humoral and cellular responses, although one usually predominates. For example, during transplant rejection, the cellular response predominates, whereas in cases of bacterial pneumonias and sepsis, the humoral response plays the dominant protective role (Box 36-2).

Effector Stage. In the effector stage, either the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reaches and connects with the antigen on the surface of the foreign pathogen. The connection initiates a series of events that, in most instances, results in the total destruction of the invading microbes or the complete neutralization of the toxin. The events involve interplay of antibodies (humoral immunity), complement, and action by the cytotoxic T cells (cellular immunity). Figure 36-5 summarizes the stages of the immune response.

BOX 36-2 Examples of Humoral and Cellular Immune Responses

Humoral Responses (B Cells)

- Bacterial phagocytosis and lysis
- Anaphylaxis
- Allergic hay fever and asthma
- Immune complex disease
- Bacterial and some viral infections

Cellular Responses (T Cells)

- Transplant rejection
- Delayed hypersensitivity (tuberculin reaction)
- Graft-versus-host disease
- Tumor surveillance or destruction
- Intracellular infections
- Viral, fungal, and parasitic infections

Humoral Immune Response

The humoral response is characterized by the production of antibodies by B lymphocytes in response to a specific antigen. Although the B lymphocyte is ultimately responsible for the production of antibodies, both the macrophages of natural immunity and the special T-cell lymphocytes of cellular immunity are involved in recognizing the foreign substance and in producing antibodies.

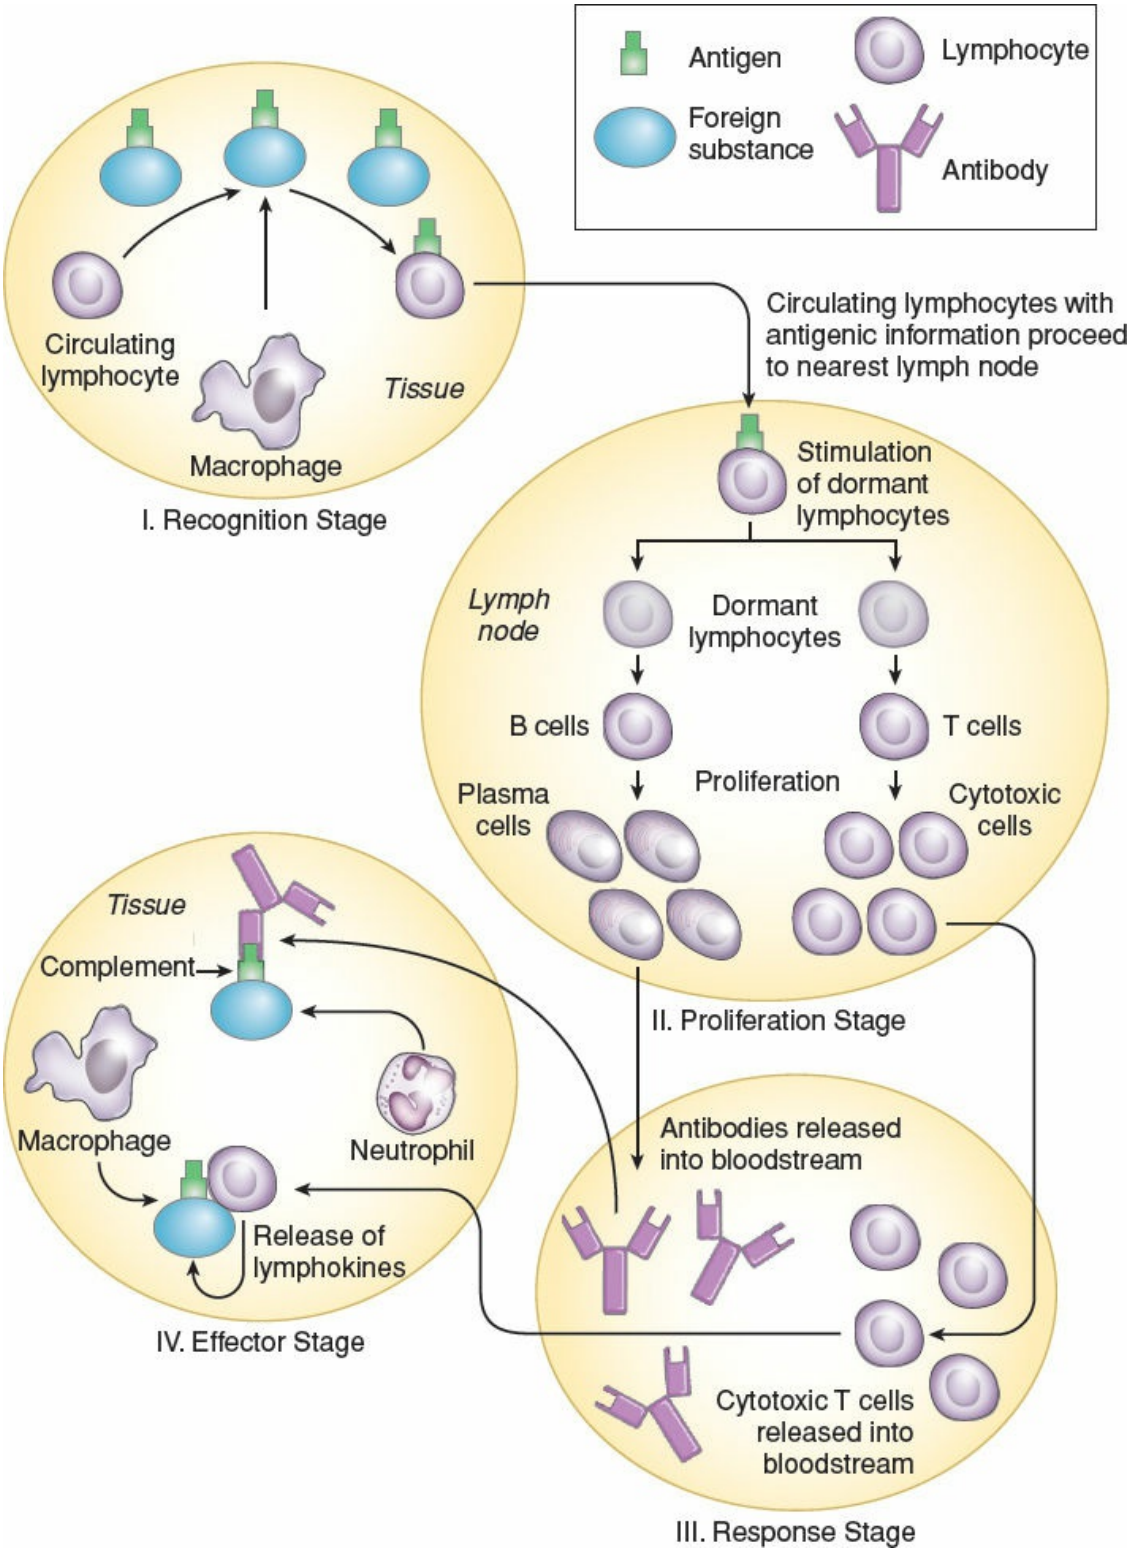

FIGURE 36-5 Stages of the immune response. (I) In the *recognition stage,* antigens are recognized by circulating lymphocytes and macrophages. (II) In the *proliferation stage,* the dormant lymphocytes proliferate and differentiate into cytotoxic (killer) T or B cells responsible for formation and release of antibodies. (III) In the *response stage,* the cytotoxic T cells and the B cells perform cellular and humoral functions, respectively. (IV) In the *effector stage,* antigens are destroyed or neutralized through the action of antibodies, complement, macrophages, and cytotoxic T cells.

Antigen Recognition. B lymphocytes recognize and respond to invading antigens in more

than one way.

The B lymphocytes appear to respond to some antigens by triggering antibody formation directly; however, in response to other antigens, they need the assistance of T cells to trigger antibody formation. The T lymphocytes are part of a surveillance system that is dispersed throughout the body and recycles through the general circulation, tissues, and lymphatic system. With the assistance of macrophages, the T lymphocytes are believed to recognize the antigen of a foreign pathogen. The T lymphocyte picks up the antigenic message, or "blueprint," of the antigen and returns to the nearest lymph node with that message.

B lymphocytes stored in the lymph nodes are subdivided into thousands of clones, each responsive to a single group of antigens having almost identical characteristics. When the antigenic message is carried back to the lymph node, specific clones of the B lymphocyte are stimulated to enlarge, divide, proliferate, and differentiate into plasma cells capable of producing specific antibodies to the antigen. Other B lymphocytes differentiate into B-lymphocyte clones with a memory for the antigen. These memory cells are responsible for the more exaggerated and rapid immune response in a person who is exposed to the same antigen repeatedly.

Role of Antibodies. Antibodies are large proteins called *immunoglobulins* (because they are found in the globulin fraction of the plasma proteins). All immunoglobulins are glycoproteins and contain a certain amount of carbohydrate. Each antibody molecule consists of two subunits, each of which contains a light and a heavy peptide chain. Each subunit has a portion, referred to as the Fab fragment, that serves as a binding site for a specific antigen. The Fab fragment (antibody-binding site) binds to the antigenic determinant, similar to a lock-and-key mechanism. The Fab fragment provides the "lock" portion that is highly specific for an antigen. An additional portion, known as the Fc fragment, which contains the c-terminal and does not contain antigen-binding sites, allows the antibody molecule to take part in the complement system (Frank & Hester, 2014; Paul, 2012).

Antibodies defend against foreign pathogens in several ways, and the type of defense employed depends on the structure and composition of both the antigen and the immunoglobulin. The antibody molecule has at least two combining sites, or Fab fragments. One antibody can act as a cross-link between two antigens, causing them to bind or clump together. This clumping effect, referred to as agglutination, helps clear the body of the pathogen by facilitating phagocytosis. Agglutination is used in several laboratory tests, such as those for syphilis, to recognize and enumerate the presence of antibody–antigen complexes, indicative of infection. Some antibodies assist in removal of offending organisms through opsonization. In this process, the antigen–antibody molecule is coated with a sticky substance that also facilitates phagocytosis.

Antibodies also promote the release of vasoactive substances, such as histamine and slow-reacting substance, two of the chemical mediators of the inflammatory response. Antibodies do not function in isolation; rather, they mobilize other components of the immune system to defend against the pathogen. The typical role of antibodies is to focus components of the natural immune system on the pathogen. This includes activation of both the complement system and phagocytosis (Paul, 2012; Salmon, 2016).

The body can produce five different types of immunoglobulins (Ig). Each of the five

types, or classes, is identified by a specific letter of the alphabet derived from the name of the heavy chain present on the immunoglobulin: IgA for alpha (α), IgD for delta (δ), IgE for epsilon (ε), IgG for gamma (γ), and IgM for mu (μ). Classification is based on the chemical structure and biologic role of the individual immunoglobulin.

Antigen–Antibody Binding. The portion of the antigen involved in binding with the antibody is referred to as the antigenic determinant. The most efficient immunologic responses occur when the antibody and antigen fit like a lock and key (Fig. 36-6). Poor fit can occur with an antibody that was produced in response to a different antigen. This phenomenon is known as *cross-reactivity*. For example, in acute rheumatic fever, the antibody produced against *Streptococcus pyogenes* in the upper respiratory tract may cross-react with the patient's heart tissue, leading to mitral valve abnormalities.

Cellular Immune Response

T lymphocytes are responsible primarily for cellular immunity. Several types of T cells exist, each with designated roles in the defense against bacteria, viruses, fungi, parasites, and malignant cells. T cells attack foreign pathogens directly rather than by producing antibodies. T cells are either naïve—capable of reacting to new antigens—or activated—having the memory of previous antigen exposure (Paul, 2012).

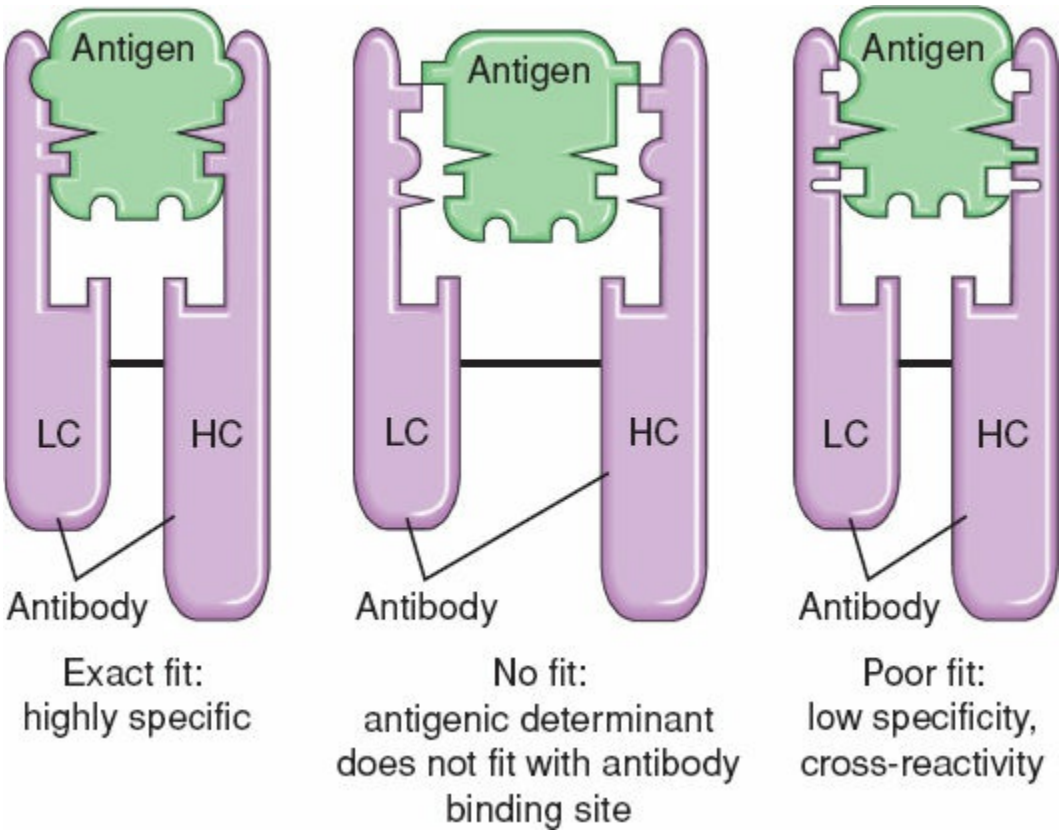

FIGURE 36-6 Antigen–antibody binding. (*Left*) A highly specific antigen–antibody complex. (*Middle*) No match and, therefore, no immune response. (*Right*) Poor fit or match with low specificity; antibody reacts to antigen with similar characteristics, producing cross-reactivity.

Cellular reactions are initiated by the binding of an antigen to an antigen receptor

located on the surface of a naïve T cell. This may occur with or without the assistance of macrophages. The activated T cells then carry the antigenic message, or blueprint, to the lymph nodes, where the production of other T cells is stimulated. Some T cells remain in the lymph nodes and retain a memory for the antigen. Other T cells migrate from the lymph nodes into the general circulatory system and ultimately to the tissues, where they remain until they either come in contact with their respective antigens or die.

Role of T Lymphocytes. T cells include effector T cells, suppressor T cells, and memory T cells. Two major categories of effector T cells exist: helper T cells and cytotoxic T cells. These effector T cells participate in the destruction of foreign organisms. T cells interact closely with B cells, indicating that humoral and cellular immune responses are not separate, unrelated processes but, rather, branches of the immune response that interact.

Helper T cells are activated on recognition of antigens and stimulate the rest of the immune system. When activated, helper T cells secrete cytokines, which attract and activate B cells, cytotoxic T cells, NK cells, macrophages, and other cells of the immune system. Separate subpopulations of helper T cells produce different types of cytokines and determine whether the immune response will be the production of antibodies or a cell-mediated immune response. Helper T cells produce lymphokines, one category of cytokines. These lymphokines activate other T cells (e.g., interleukin-2 [IL-2]), natural and cytotoxic T cells (e.g., IFN-gamma), and other inflammatory cells (e.g., tumor necrosis factor). Helper T cells produce IL-4 and IL-5, lymphokines that activate B cells to grow and differentiate.

Cytotoxic T cells (killer T cells) attack the antigen directly by altering the cell membrane and causing cell lysis (disintegration) and by releasing cytolytic enzymes and cytokines. Lymphokines can recruit, activate, and regulate other lymphocytes and WBCs. These cells then assist in destroying the pathogen. Delayed-type hypersensitivity is an example of an immune reaction that protects the body from antigens through the production and release of lymphokines (see later discussion).

Another type of cell, the suppressor T cell, has the ability to decrease B cell production, thereby keeping the immune response at a level that is compatible with health (e.g., sufficient to fight infection adequately without attacking the body's healthy tissues). Memory cells are responsible for recognizing antigens from previous exposure and mounting an immune response.

Roles of Null Lymphocytes and Natural Killer Cells. Null lymphocytes and NK cells are other lymphocytes that assist in combating organisms. These cells are distinct from B and T cells and lack the usual characteristics of those cells. Null lymphocytes, a subpopulation of lymphocytes, destroy antigens already coated with antibody. These cells have special Fc receptor sites on their surface that allow them to connect with the Fc end of antibodies; this is known as *antibody-dependent, cell-mediated cytotoxicity*.

NK cells, another subpopulation of lymphocytes, defend against microorganisms and some types of malignant cells (Grossman et al., 2014). NK cells are capable of directly killing pathogens and producing cytokines. The helper T cells contribute to the differentiation of null and NK cells.

Complement System

Circulating plasma proteins, known as complement, are made in the liver and other sites and activated when an antibody connects with its antigen. There are more than 35 of these plasma or membrane proteins, and they are an important additional component of the immune system (Paul, 2012). Destruction of an invading or attacking organism or toxin is not achieved merely by the binding of the antibody and antigens; destruction also requires activation of complement, the arrival of killer T cells, or the attraction of macrophages. Complement has three major physiologic functions: defending the body against bacterial infection, bridging natural and acquired immunity, and disposing of immune complexes and the by-products associated with inflammation.

The proteins that comprise complement interact sequentially with one another in a cascading or "falling domino" effect. The complement cascade is important to modifying the effector arm of the immune system. Activation of complement allows for the occurrence of important events, such as removal of infectious agents and initiation of the inflammatory response. These events involve active parts of the pathway that enhance chemotaxis of macrophages and granulocytes, alter blood vessel permeability, change blood vessel diameters, cause cells to lyse, alter blood clotting, and cause other points of modification. These macrophages and granulocytes continue the body's defense by devouring the antibody-coated microbes and by releasing antibacterial products.

Role of Interferons

IFNs are cytokines. They have antiviral and antitumor properties. In addition to responding to viral infection, IFNs are produced by T lymphocytes, B lymphocytes, and macrophages in response to antigens. They modify the immune response by suppressing antibody production and cellular immunity. They also facilitate the cytolytic (cell destruction) role of lymphocytes, macrophages, and NK cells. Research continues on the pathways that IFNs use to transmit signals from cell membranes to the nucleus. IFNs are undergoing extensive testing to evaluate their effectiveness in treating tumors and AIDS (Andzinski et al., 2016).

Advances in Immunology

Genetic Engineering

One of the more remarkable evolving technologies is genetic engineering, which uses recombinant DNA technology. Genetic engineering is used in everything from the production of insulin and human growth hormone to the production of experimental mice. One type of genetic engineering permits scientists to combine genes from one type of organism with genes of a second organism. This type of technology allows cells and microorganisms to manufacture proteins, monokines, and lymphokines that can alter and enhance immune system function. This type of technology also produces genetically modified organisms (GMOs) that have been the source of much controversy in the food industry. The second use of recombinant DNA technology involves gene therapy (Grossman et al., 2014). If a particular gene is abnormal or missing, experimental recombinant DNA technology may be capable of restoring normal gene function. For example, a recombinant gene is inserted onto a virus particle. When the virus particle splices its genes, the virus automatically inserts the missing gene, and theoretically corrects the genetic anomaly. Extensive research into recombinant DNA technology and gene therapy is ongoing; successful models of a recombinant DNA vaccine against tumor cells and angiogenesis have been created in mice (Yin et al., 2015).

Stem Cells

Stem cells are potentially immortal cells that are capable of self-renewal and differentiation; they continually replenish the body's entire supply of both RBCs and WBCs. Some stem cells, described as *totipotent cells*, have tremendous capacity to self-renew and differentiate. Embryonic stem cells, described as *pluripotent*, give rise to numerous cell types that are able to form tissues (Grossman et al., 2014). Research and clinical trials have shown that stem cells can restore an immune system that has been destroyed. Stem cell transplantation therapy has been developed for numerous types of conditions, such as severe combined immunodeficiency (SCID), acute myeloid leukemia, periodontal disease, and other types of cancer (Klein & Nör, 2015). Clinical trials using stem cells as therapy are underway in patients with a variety of disorders having an autoimmune component, including systemic lupus erythematosus (SLE), rheumatoid arthritis, scleroderma, multiple sclerosis, and heart disease, specifically in the repair of endothelial cells (Gurtu & Michelakis, 2015).

Gerontologic Considerations

People at the extremes of the lifespan are more likely than middle-aged adults to develop problems related to the functioning of the immune system (Table 36-3). The greatest impact of aging on the immune system is on cell-mediated immunity; age has a lesser but substantial impact on humoral immunity. The frequency and severity of infections are increased in elderly people, possibly due to a decreased ability to respond adequately to pathogens. Both the production and the function of T and B lymphocytes may be impaired. Responses to antigen stimulation may be altered, with increasing proportions of lymphocytes becoming unresponsive with age. An example of this is the recent development of a vaccine for older patients against herpes zoster and postherpetic neuralgia caused by the varicella virus. The antigen present in this vaccine is 14 times the amount of live attenuated virus present in the varicella vaccine for children (Cohen, 2016). The impact of aging on the immune system can best be summarized as *immunosenescence*, a condition thought to be a result of involution of the thymus (Duggal & Lord, 2013).

ASSESSMENT OF THE IMMUNE SYSTEM

Assessment of the immune system involves nearly every organ system of the body.

Health History

Common Complaints

Accurately assessing a patient's immune system can include consideration of nonspecific signs and symptoms, such as fatigue, impaired wound healing, recurrent infections, weight loss, or lymphadenopathy (Fig. 36-7). Or the signs and symptoms may be more specific, such as a butterfly (malar) rash in SLE; joint deformities in rheumatoid arthritis; thrush in HIV; or erythema, hoarseness, and dyspnea with anaphylactic reaction.

FIGURE 36-7 Lymphadenopathy. An enlarged cervical lymph node. (Courtesy of Gehrig, J. S., *Patient assessment tutorials* (3rd ed.). Lippincott, Wolters, Kluwer.)

Table 36-3 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in Immunologic Function

Body System	Structural and Functional Changes	History and Physical Findings
Immune	Impaired function of B and T lymphocytes Failure of lymphocytes to recognize mutant or abnormal cells Decreased antibody production Failure of immune system to differentiate "self" from "non-self" Suppressed phagocytic immune response	Suppressed responses to pathogenic organisms with increased risk for infection Increased incidence of cancers Anergy (lack of response to antigens applied to the skin [PPD, allergens]) Increased incidence of autoimmune diseases Absence of typical signs and symptoms of infection and inflammation Dissemination of organisms usually destroyed or suppressed by phagocytes (e.g., reactivation or spread of tuberculosis)
Gastrointestinal	Decreased gastric secretions and motility Decreased phagocytosis by the liver's Kupffer cells Altered nutritional intake with inadequate protein intake	Proliferation of intestinal organisms, resulting in gastroenteritis and diarrhea Increased incidence and severity of hepatitis B; increased incidence of liver abscesses Suppressed immune response
Urinary	Decreased kidney function and changes in lower urinary tract function (enlargement of prostate gland, neurogenic bladder) Altered flora in the genitourinary tract	Urinary stasis and increased incidence of UTIs
Pulmonary	Impaired ciliary action due to exposure to smoke and environmental toxins	Impaired clearance of pulmonary secretions; increased incidence of respiratory infections
Integumentary	Thinning of skin with less elasticity; loss of adipose tissue	Increased risk of skin injury, breakdown, and infection
Circulatory	Impaired microcirculation	Stasis and pressure ulcers
Neurologic function	Decreased sensation and slowing of reflexes	Increased risk of injury, skin ulcers, abrasions, and burns

Past History

The nurse asks the patient about childhood and adult immunizations and childhood diseases. Known past or present exposure to tuberculosis is assessed, and the dates and results of any tuberculin tests (PPD or tine test) and chest x-rays are obtained. The nurse elicits information related to any recent exposure to any infections and the exposure dates. It is important for the nurse to assess whether the patient has been exposed to any sexually transmitted infections (STIs) or bloodborne pathogens, such as hepatitis A, B, or C viruses and HIV virus. A history of STIs, such as gonorrhea, syphilis, HPV infection, and chlamydia, can alert the nurse that the patient may have been exposed to HIV infection or to hepatitis. However, the Centers for Disease Control and Prevention (CDC) recommend universal HIV testing of all patients over the age of 13 with risk assessment determining the need for repeat testing. The nurse obtains a history of past and present infections and the dates and types of treatments along with a history of any multiple persistent infections, fevers of unknown origin, lesions or sores, or any type of drainage.

Allergy

The nurse asks the patient about any allergies, including types of allergens (e.g., pollens, dust, plants, cosmetics, food, medications, vaccines, latex), the symptoms experienced, and seasonal variations in occurrence or severity in the symptoms. A history of testing and treatments, including prescribed and over-the-counter medications that the patient has taken or is currently taking for these allergies and the effectiveness of the treatments, is obtained. All medication and food allergies are listed on an allergy alert sticker and placed on the front of the patient's health record or chart to alert others. Continued assessment for potential allergic reactions in the patient is vital.

Autoimmune Disorders

Autoimmune disorders affect people of both genders and of all ages, ethnicities, and social classes. The nurse asks the patient about any autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, or psoriasis. The patient is asked to describe the onset, severity, remissions and exacerbations, functional limitations, treatments that the patient has received or is currently receiving, and the effectiveness of the treatments. Although most specific autoimmune disorders are rare, together they affect approximately 5% of the United States population. The occurrence of different autoimmune diseases within a family strongly suggests a genetic predisposition to more than one autoimmune disease (Paul, 2012).

Neoplastic Disease

If there is a history of cancer in the family, the nurse takes note of the type of cancer, age at onset, and relationship (maternal or paternal) of the patient to the affected family member(s). Dates and results of any cancer screening tests for the patient are obtained. A history of cancer in the patient is also obtained, along with the type of cancer, date of diagnosis, and treatment modalities used. Immunosuppression contributes to the development of cancers; however, cancer itself is immunosuppressive. Hematologic cancers, such as leukemia and lymphoma, are associated with altered production and function of WBCs and lymphocytes (Bierman & Armitage, 2016; Paul, 2012).

The nurse records data about all treatments that the patient has received or is currently receiving, such as radiation or chemotherapy, in the health history. Radiation destroys lymphocytes and decreases the ability to mount an effective immune response. The size and extent of the irradiated area determine the extent of immunosuppression. Whole-body irradiation may leave the patient totally immunosuppressed. Chemotherapy also affects bone marrow function, destroying cells that contribute to an effective immune response and resulting in immunosuppression.

Chronic Illness and Surgery

The nurse notes any history of chronic illness, such as diabetes mellitus, kidney disease, chronic obstructive pulmonary disease (COPD), or fibromyalgia. The onset and severity of illnesses, as well as treatment that the patient is receiving for the illness, are obtained. Chronic illness may contribute to immune system impairments in various ways. Kidney failure is associated with a deficiency in circulating lymphocytes. In addition, immune defenses may be altered by acidosis and uremic toxins. In diabetes, hyperglycemia impairs immune function (decreases the function of WBCs), promotes inflammation, favors the growth of yeast organisms, and is associated with changes in the walls of the blood vessels, resulting in increased risk for infection as well as both microvascular and macrovascular dysfunction. Recurrent respiratory tract infections are associated with COPD as a result of altered inspiratory and expiratory function and ineffective airway clearance.

Special Problems

Conditions such as burns and other forms of injury and infection may contribute to altered immune system function. Major burns cause impaired skin integrity and compromise the body's first line of defense. Loss of large amounts of serum occurs with burn injuries and

depletes the body of essential proteins, including immunoglobulins. The physiologic and psychological stressors associated with surgery or injury stimulate cortisol release from the adrenal cortex; increased serum cortisol also contributes to suppression of normal immune responses.

Social History

Poor nutritional status, poor sleep habits, smoking, excessive consumption of alcohol, illicit drug use, STIs, and occupational or residential exposure to environmental radiation and pollutants have been associated with impaired immune function. The nurse needs to assess all of these factors in a detailed patient history.

Nutrition

The importance of optimal nutrition in enhancing immunity is gaining greater recognition. Inadequate intake of vitamins that are essential for synthesis of both DNA and protein may lead to protein–calorie deficiency and, subsequently, to impaired immune function. Vitamins also help in the regulation of cell proliferation and maturation of immune cells. Excess or deficiency of trace elements (i.e., copper, iron, manganese, selenium, or zinc) in the diet generally suppresses immune function.

Fatty acids are the building blocks that make up the structural components of cell membranes. Lipids are precursors of vitamins A, D, E, and K, as well as cholesterol. Both excess and deficiency of fatty acids have been found to suppress immune function.

Depletion of protein reserves results in atrophy of lymphoid tissues, depression of antibody response, reduction in the number of circulating T cells, and impaired phagocytic function. As a result, susceptibility to infection is greatly increased. During periods of infection or serious illness, nutritional requirements may be altered further, potentially contributing to depletion of stores of protein, fatty acid, vitamin, and trace elements and causing even greater risk of impaired immune response and sepsis. Patients whose nutritional status is compromised have a delayed postoperative recovery and often experience more severe infections and delayed wound healing. The nurse must assess the patient's nutritional status and caloric intake. The nurse is responsible for assuming a proactive role in ensuring the best possible nutritional intake for all patients as a vital step in preventing untoward treatment outcomes.

Box 36-3 discusses the role of probiotics.

Medications and Blood Transfusions

The nurse obtains a list of past and present medications that the patient has used or is using. In large doses, antibiotics, corticosteroids, cytotoxic agents, salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and anesthetics can cause immune suppression (Table 36-4). The overuse of antibiotics, their effect on the intestinal microbiome, and the use of fecal transplants to restore a depleted microbiome are new areas that the nurse may explore with the patient during an assessment of the immune system.

The nurse obtains a history of blood transfusions because previous exposure to foreign antigens through transfusion may be associated with the current abnormal immune function. Additionally, although the risk of HIV transmission through blood transfusion is extremely low in patients who received a transfusion after 1985 (the year that testing of

blood for HIV was initiated in the United States), a small risk remains. The nurse also assesses for signs or symptoms of hepatitis in patients who have received blood products.

BOX 36-3 Nursing Research

Bridging the Gap to Evidence-Based Practice

Probiotics in preventing recurrent urinary tract infections in women: A literature review.

Chisholm, A. H. (2015). Probiotics in preventing recurrent urinary tract infections in women: A literature review. Urologic Nursing, *35*(1), 18–21, 29.

Increasing antibiotic resistance and increasing resistance to commonly used antibiotics makes treatment and prevention of urinary tract infections (UTIs) difficult. The objective of this study was to evaluate the evidence on probiotics in preventing recurrent UTIs in women.

A literature search was conducted to find research articles about the role of probiotics in preventing UTIs in women. The literature provided low to moderate evidence that probiotics are effective in preventing UTIs in women. Conclusions: Level of Evidence —V; this rating refers to evidence that is obtained from systematic reviews of descriptive and qualitative studies (Polit & Beck, 2012).

Purpose
This study employed a literature review to evaluate the evidence on probiotics in preventing recurrent UTIs in women. Given increasing antibiotic resistance to common medications, alternative methods that can prevent UTIs have become increasingly important.

Design
Using several databases, the researcher gathered articles that illustrated the role of probiotics for the prevention of recurrent UTIs in women.

Findings
The literature demonstrated low to moderate evidence that probiotics are effective in the prevention of recurrent UTIs in women. While more research is needed to strengthen the recommendation, the use of probiotics may be a safe alternative for preventing UTIs in women.

Nursing Implications
Lactobacillus probiotics, taken either orally or vaginally, are likely effective in reducing recurrent UTIs in women. Although more research is needed, probiotics should be considered a useful and safe alternative to antibiotics. The review of the research indicates potential benefits to the use of probiotics for several types of disorders. Patient

education focuses on the multitude of strains of probiotics that are commercially available to consumers, from yogurt to nutritional supplements to kombucha and miso. There are no standards developed by the U.S. Food and Drug Administration (FDA) for additions of probiotics to food; nor are there recommended dosages. At this time, the research indicates that probiotics are safe and potentially beneficial for numerous disorders.

Travel and Occupation

Patients who are immunocompromised should be asked about travel history and occupational history to determine exposure to specific pathogens. For example, patients from the Southwest United States are more likely to be infected with certain types of fungi that are more prevalent in the desert.

Psychoneuroimmunologic Factors

The patient assessment also addresses psychoneuroimmunologic factors. The bidirectional pathway between the brain and immune system is referred to as *psychoneuroimmunology*, a field that has been the focus of research and discussion over the last several decades (Haroon, Raison, & Miller, 2012; Pariante, 2015). It is thought that the immune response is regulated and modulated in part by neuroendocrine influences. Lymphocytes and macrophages have receptors that are capable of responding to neurotransmitters and endocrine hormones. Lymphocytes can produce and secrete adrenocorticotropic hormone and endorphin-like compounds. Cells in the brain, especially in the hypothalamus, can recognize prostaglandins, IFNs, and interleukins as well as histamine and serotonin, which are released during the inflammatory process. Like all other biologic systems functioning in the interest of homeostasis, the immune system is integrated with other psychophysiologic processes and is subject to regulation and modulation by the brain.

Conversely, the immune processes can affect neural and endocrine function, including behavior. Growing evidence indicates that a measurable immune system response can be influenced positively by biobehavioral strategies, such as relaxation and imagery techniques, biofeedback, humor, hypnosis, and conditioning. Therefore, the assessment should address the patient's general psychological status and the patient's use of and response to these strategies.

Physical Assessment

Immune dysfunction may have manifestations in various body systems (Box 36-4). In addition to the assessment components described below, the nurse assesses the patient's respiratory, cardiovascular, genitourinary, and neurosensory status for signs and symptoms indicative of immune dysfunction.

TABLE 36-4 Selected Medications and Effects on the Immune System

Drug Classification (and Examples)	Effects on the Immune System
Antibiotics (in large doses)	**Bone marrow suppression**
ceftriaxone (Rocephin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
cefuroxime sodium (Ceftin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
chloramphenicol (Chloromycetin)	Leukopenia, aplastic anemia
dactinomycin (Cosmegen)	Agranulocytosis, neutropenia
fluoroquinolones (Cipro, Levaquin, Tequin)	Hemolytic anemia, methemoglobinemia, eosinophilia, leukopenia, pancytopenia
gentamicin sulfate (Garamycin)	Agranulocytosis, granulocytopenia
macrolides (erythromycin, Zithromax, Biaxin)	Neutropenia, leukopenia
penicillins	Agranulocytosis
streptomycin	Leukopenia, neutropenia, pancytopenia
vancomycin (Vancocin, Vancoled)	Transient leukopenia
Antithyroid drugs	
propylthiouracil (PTU)	Agranulocytosis, leukopenia
Nonsteroidal anti-inflammatory drugs (NSAIDs) (in large doses)	**Inhibit prostaglandin synthesis or release**
aspirin	Agranulocytosis
COX-2 inhibitors (e.g., Celebrex)	Anemia, allergy, no major other adverse effects to the immune system
ibuprofen (Advil, Motrin)	Leukopenia, neutropenia
indomethacin (Indocid, Indocin)	Agranulocytosis, leukopenia
phenylbutazone	Pancytopenia, agranulocytosis, aplastic anemia
Adrenal corticosteroids	**Immunosuppression**
Prednisone	Suppressing or preventing cell-mediated immune reactions reducing leukocyte, monocyte, and eosinophil levels Decreasing immunoglobulin binding to cell surface receptors inhibiting interleukin synthesis
Antineoplastic agents (cytotoxic agents)	**Immunosuppression**
alkylating agents	Leukopenia, bone marrow suppression
cyclophosphamide (Cytoxan)	Leukopenia, neutropenia
mechlorethamine HCl (Mustargen)	Agranulocytosis, neutropenia
cyclosporine	Leukopenia, inhibits T-lymphocyte function
Antimetabolites	**Immunosuppression**
fluorouracil (pyrimidine antagonist)	Leukopenia, eosinophilia
methotrexate (folic acid antagonist)	Leukopenia, aplastic bone marrow
mercaptopurine (6-MP) (purine antagonist)	Leukopenia, pancytopenia

BOX 36-4 Focused Assessment

Immune Dysfunction

Be alert for the following signs and symptoms:

Respiratory System

- Changes in respiratory rate
- Cough (dry or productive)
- Abnormal lung sounds (wheezing, crackles, rhonchi, stridor)
- Rhinitis
- Hyperventilation
- Bronchospasm
- Hypoxemia

Cardiovascular System
- Hypotension
- Tachycardia
- Arrhythmia
- Vasculitis
- Anemia

Gastrointestinal System
- Hepatosplenomegaly
- Colitis
- Vomiting
- Diarrhea

Genitourinary System
- Frequency and burning on urination
- Hematuria
- Discharge

Musculoskeletal System
- Joint mobility, edema, and pain

Skin
- Rashes
- Pruritus
- Lesions
- Dermatitis
- Hematomas or purpura
- Edema, angioedema, or urticaria
- Inflammation
- Flushing
- Discharge

Neurosensory System
- Cognitive dysfunction
- Hearing loss
- Visual changes

- Headaches and migraines
- Ataxia
- Tetany

Assessment of the Skin

The nurse assesses the skin and mucous membranes for color, lesions, dermatitis, purpura (subcutaneous bleeding), urticaria (hives), inflammation (angioedema [Fig. 36-8]), or any discharge. Purpura may indicate life-threatening infections like meningitis; urticaria indicates an acute or chronic response to allergens, pathogens, or autoimmune disorders.

Assessment of Eyes, Ears, Nose, and Throat

The nurse assesses for injected (redness) of the conjunctivae; periorbital tissues may be swollen and darkened with allergic disorders. The nares may show pale and edematous nasal mucous membranes and swollen turbinates. Assess secretions (typically clear) of the nasal passages or in the posterior pharynx. Thick secretions (yellow or green) may suggest infection. Percussion over the maxillary or frontal sinuses may elicit tenderness in acute sinusitis.

Assessment of the Lungs

The nurse inspects the patient for work of breathing, respiratory rate, use of accessory muscles, presence of retractions of bulging at intercostal space and/or supra- and infraclavicular area, and clubbing; the nurse auscultates the lungs for adventitious sounds. Patients with acute asthma may display tachypnea and auditory wheezes, dyspnea, retractions, and use of accessory muscles of respiration.

FIGURE 36-8 Angioedema is a diffuse, nonpitting, tense swelling of the dermis and subcutaneous tissue that can develop rapidly. Although usually allergic in nature and sometimes associated with hives,

angioedema does not itch. (From Neville, B., Damm, D. D., & White, D. K. (1991). *Color atlas of clinical oral pathology*. Philadelphia, PA: Lea & Febiger. Used with permission.)

Assessment for Signs of Infection

The nurse notes any signs of infection (erythema, warmth, tenderness, drainage). The patient's temperature is recorded, and the patient is observed for chills and sweating. Fever often accompanies infection.

Assessment of the Lymph Nodes

The lymph nodes and thyroid are palpated for enlargement. If palpable nodes are detected, their location, size, consistency, and reports of tenderness on palpation are noted. Lymphadenopathy indicates activation of the immune system against pathogens. Generalized lymphadenopathy, which is manifested by swollen lymph nodes in multiple sites, is often one of the first signs of infection with HIV.

Assessment of the Joints

Joints are assessed for tenderness, swelling, increased warmth, and limited range of motion. These findings indicate inflammation and infiltration by leukocytes, including macrophages and cytokines.

Diagnostic Evaluation

The nurse needs to be aware that patients undergoing evaluation for possible immune system disorders experience not only physical pain and discomfort with certain types of diagnostic procedures but also many psychological reactions. For example, patients may fear test results that demonstrate decreased immune function because the diminished immune system can make them more prone to certain infections, cancers, and other disorders. It is the nurse's role to counsel, educate, and support patients throughout the diagnostic process. Further, many patients may be extremely anxious about the results of diagnostic tests and the possible implications of those results for their employment, insurance, and personal relationships. This is an ideal time for the nurse to provide counseling and education, should these interventions be warranted.

Immune Competence Testing

A series of blood and skin tests and a bone marrow biopsy may be performed to evaluate the patient's immune competence. Specific laboratory and diagnostic tests are discussed in greater detail along with individual disease processes in subsequent chapters in this unit. Selected laboratory and diagnostic tests used to evaluate immune competence are summarized in Box 36-5.

Allergy Testing

Diagnostic evaluation of the patient with allergic disorders commonly includes blood tests, smears of body secretions (nasal, conjunctival, or sputum secretions), skin tests (intradermal injections of solutions at several sites that may provoke an allergic response), and the radioallergosorbent test (RAST). Many health organizations recommend that RAST be phased out in favor of more sensitive tests such as fluorescence enzyme-labeled assays.

Results of laboratory blood studies provide supportive data for various diagnostic possibilities; however, they are not the major criteria for the diagnosis of allergic disease.

Nursing Alert
With allergic condition, the WBC count is usually normal, except with infection. Eosinophils, which are granular leukocytes, normally make up 1% to 3% of the total number of WBCs. A level between 5% and 15% is nonspecific but suggests an allergic reaction. Moderate eosinophilia is defined as 15% to 40% eosinophils and is found in patients with allergic disorders; in patients with malignancy, immunodeficiencies, parasitic infections, or congenital heart disease; and in patients receiving peritoneal dialysis. Severe eosinophilia is defined as 50% to 90% eosinophils and is found in patients with the idiopathic hypereosinophilic syndrome.

Skin Tests

If a skin test is indicated, there is a reasonable suspicion that a specific allergen is producing symptoms in an allergic patient. However, several precautionary steps must be observed before skin testing with allergens is performed:

- Testing is not performed during periods of bronchospasm.
- Epicutaneous tests (scratch or prick tests) are performed before other testing methods in an effort to minimize the risk of systemic reaction.
- Emergency equipment must be readily available to treat anaphylaxis.

Methods of skin testing include prick skin tests, scratch tests, and intradermal skin testing. After negative prick or scratch tests, intradermal skin testing is performed with allergens that are suggested by the patient's history to be problematic. The back is the most suitable area of the body for skin testing because it permits the performance of many tests. The multitest applicator is a commercially available device with multiple test heads that allows simultaneous administration of antigens by multiple punctures at different sites. A negative response on a skin test cannot be interpreted as an absence of sensitivity to an allergen. Such a response may occur with insufficient sensitivity of the test or with use of an inappropriate allergen in testing. Therefore, it is essential to observe the patient undergoing skin testing for an allergic reaction, even if the previous response was negative.

The results of skin tests complement the data obtained from the history. They indicate which of several antigens are most likely to provoke symptoms and provide some clue to the intensity of the patient's sensitization. Also the dosage of the antigen (allergen) injected is important. Most patients are hypersensitive to more than one allergen. Under testing conditions, they may not react (although they usually do) to the specific allergens that induce their attacks.

BOX 36-5 Selected Tests for Evaluating Immunologic Status

Various laboratory tests may be performed to assess activity or dysfunction of the immune system. The studies assess leukocytes and lymphocytes, humoral immunity, cellular immunity, phagocytic cell function, complement activity, hypersensitivity reactions, specific antigen–antibodies, or HIV infection.

Leukocyte and Lymphocyte Tests

- White blood cell count and differential
- Bone marrow biopsy

Humoral (Antibody-Mediated) Immunity Tests

- B-cell quantification with monoclonal antibody
- In vivo immunoglobulin synthesis with T-cell subsets
- Specific antibody response
- Total serum globulins and individual immunoglobulins (by electrophoresis, immunoelectrophoresis, single radial immunodiffusion, nephelometry, isohemagglutinin techniques)

Cellular (Cell-Mediated) Immunity Tests

- Total lymphocyte count

- T-cell and T-cell subset quantification with monoclonal antibody
- Delayed hypersensitivity skin test
- Cytokine production
- Lymphocyte response to mitogens, antigens, and allogenic cells
- Helper and suppressor T-cell functions

Phagocytic Cell Function Tests

- Nitroblue tetrazolium reductase assay

Complement Component Tests

- Total serum hemolytic complement
- Individual complement component titrations
- Radial immunodiffusion
- Electroimmunoassay
- Radioimmunoassay
- Immunonephelometric assay
- Immunoelectrophoresis

Hypersensitivity Tests

- Scratch test
- Patch test
- Intradermal test
- Radioallergosorbent test (RAST)
- Immunofluorescence

Specific Antigen–Antibody Tests

- Radioimmunoassay
- Immunofluorescence
- Agglutination
- Complement fixation test

HIV Infection Tests

- Enzyme-linked immunosorbent assay (ELISA)
- P24 antigen test
- Western blot, replaced by the fourth generation antigen/antibody tests
- CD4 and CD8 cell counts
- Polymerase chain reaction (PCR)

Familiarity with and consistent use of a grading system with skin tests are essential. The grading system used should be identified on a skin test sheet for later interpretation. A positive reaction, evidenced by the appearance of an urticarial wheal (round, reddened skin elevation) (Fig. 36-9), localized erythema (diffuse redness) in the area of inoculation or contact, or pseudopodia (irregular projection at the end of a wheal) with associated erythema is considered indicative of sensitivity to the corresponding antigen.

False-negative results may occur because of improper technique, outdated allergen solutions, or prior use of medications that suppress skin reactivity. Corticosteroids and antihistamines, including over-the-counter allergy medications, suppress skin test reactivity and usually are withheld for 48 to 96 hours before testing, depending on the duration of their activity. False-positive results may occur because of improper preparation or administration of allergen solutions.

Interpretation of positive or negative skin tests must be based on the history, physical examination, and other laboratory test results. The following guidelines are used for the interpretation of skin test results:

- Skin tests are more reliable for diagnosing atopic sensitivity in patients with allergic rhinoconjunctivitis (nasal congestion, runny nose, postnasal drip, sneezing, red eyes [conjunctivitis], and itching of the nose or eyes) than in patients with asthma.
- Positive skin tests correlate highly with food allergy.
- The use of skin tests to diagnose immediate hypersensitivity to medications is limited because usually metabolites of medications, not the medications themselves, are responsible for causing hypersensitivity.

In cases of doubt about the validity of the skin tests, an RAST or a provocative challenge test may be performed.

Radioallergosorbent Testing

Radioallergosorbent testing (RAST) is a radioimmunoassay that measures allergen-specific IgE in the patient's blood. In addition to detecting an allergen, RAST indicates the quantity of allergen necessary to evoke an allergic reaction. Values are reported on a scale from 0 to 5. Values of 2 or greater are considered significant. The major advantages of RAST over other tests include decreased risk of systemic reaction, stability of antigens, and lack of dependence on skin reactivity modified by medications. The major disadvantages include limited allergen selection and reduced sensitivity compared with intradermal skin tests, lack of immediate results, and higher cost. RAST is being replaced by the more sensitive fluorescence enzyme-labeled assays such as ImmunoCAP, a quantitative test for IgE proteins.

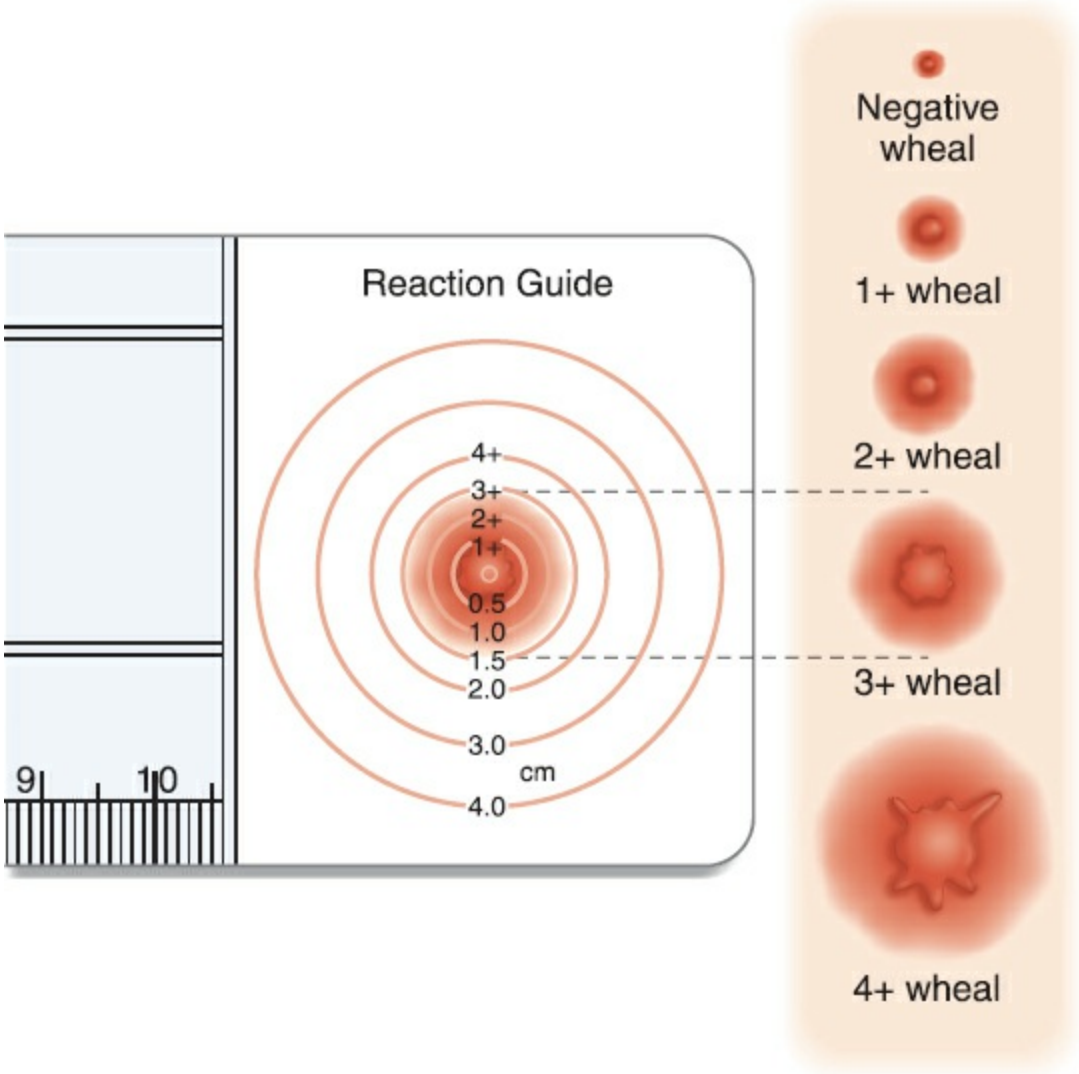

FIGURE 36-9 Interpretation of reactions: Negative = wheal soft with minimal erythema. 1+ = wheal present (5 to 8 mm) with associated erythema. 2+ = wheal (7 to 10 mm) with associated erythema. 3+ = wheal (9 to 15 mm) with slight pseudopodia possible with associated erythema. 4+ = wheal (12 mm+) with pseudopodia and diffuse erythema.

Provocative Testing

Provocative testing involves the direct administration of the suspected allergen to the sensitive tissue, such as the conjunctiva, nasal or bronchial mucosa, or GI tract (by ingestion of the allergen), with observation of target organ response. This type of testing is helpful in identifying clinically significant allergens in patients who have a large number of positive tests. Major disadvantages of this type of testing are the limitation of one antigen per session and the risk of producing severe symptoms, particularly bronchospasm, in patients with asthma.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 36-year-old man was camping and hiking with his partner when he began to run a

high temperature and developed a nonproductive cough. He is diagnosed with *Pneumocystis* pneumonia (PCP) and started on antibiotic therapy. He asks why he has developed this problem. How would you respond? What diagnostic tests would you expect to be ordered? Why?

2. A 68-year-old woman is hospitalized for a kidney transplantation, and immunosuppressant medications are prescribed. Describe the parameters you would use to assess her immune function. How would altered immune function affect the care that you provide?

NCLEX-Style Review Questions

1. In which stage of the immune response does the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reach and connect with the antigen on the surface of the foreign pathogen?
   a. Recognition stage
   b. Proliferation stage
   c. Response stage
   d. Effector stage

2. A patient is exhibiting anaphylaxis after eating shellfish. What type of reaction is the patient experiencing?
   a. Type I
   b. Type II
   c. Type III
   d. Type IV

3. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the functions of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens. Which type of immune system disorder is characterized by an overproduction of immunoglobulins?
   a. Autoimmunity
   b. Gammopathies
   c. Hypersensitivity
   d. Secondary immune deficiency

4. A patient is being seen in the dermatology clinic to have allergy testing performed. What statement is accurate regarding this type of testing?
   a. A positive reaction is evidenced by the appearance of an urticarial wheal.
   b. The arms are the most suitable area of the body for skin testing.
   c. A negative response can be interpreted as an absence of sensitivity to an allergen.
   d. There is no risk of a false-negative result.

5. A patient has requested to be tested for an HIV infection. What test might be performed on this patient?
   a. Bone marrow biopsy
   b. Agglutination
   c. Scratch test
   d. ELISA for specific antibodies

CHAPTER 37

Nursing Management: Patients with Immunodeficiency, HIV Infection, and AIDS

Mary E. Bartlett

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the basic aspects of primary immunodeficiency.
2. Describe the essential aspects of secondary immunodeficiency.
3. Summarize the epidemiology of HIV infection and AIDS.
4. Explain the gerontologic considerations of HIV/AIDS in the United States.
5. Describe the pathophysiology, modes of transmission, and prevention of HIV infection.
6. Explain postexposure prophylaxis for health care workers.
7. Explain pre-exposure prophylaxis for patients at high risk.
8. Summarize the clinical manifestations, assessment, and treatment of patients of HIV infection.
9. Use the nursing process as a framework for care of the patient with AIDS.

Nurses have been at the forefront of caring for patients with human immunodeficiency virus (HIV) even before the cause and infectious nature of the virus was known. Today, nurses work as clinicians, researchers, patient advocates, and educators. Certification for registered nurses and advanced practice nurses is offered through the HIV/AIDS Nursing Certification Board (HANCB). Certification is highly valued and provides formal recognition of HIV/AIDS nursing knowledge. Through the concerted effort of policy makers, researchers, and clinicians developing best practices and strategies, nursing is in a unique position to meet the challenges of HIV care. Because the field of HIV nursing and medicine changes rapidly, readers should refer to the most recent guidelines and recommendations at www.iasusa.org.

Immunodeficiency, or the inability for the body's natural defenses to protect itself from outside pathogens, presents in one of its most complicated forms in patients with the infection that causes acquired immunodeficiency syndrome (AIDS).

PRIMARY AND SECONDARY IMMUNODEFICIENCIES

Immunodeficiencies are classified as either primary or secondary and are further classified by the affected components of the immune system. Primary immunodeficiency diseases are genetic in origin and manifest most commonly in infancy and childhood as abnormally recurrent infections. About 80% of the patients with primary immunodeficiency are less than 20 years of age. Many primary immunodeficiencies may occur alone or as part of a syndrome. More than 250 have been described that affect different components of the immune system. Transmission of these inborn errors is predominantly X-linked; therefore, more than 70% of affected patients are male. Primary immunodeficiencies, classified by the main component of the immune system that is dysregulated, include B lymphocytes (or IgG), T lymphocytes, natural killer (NK) cells, phagocytic cells, or complement proteins. More than 50% of primary immunodeficiency is caused by errors in B lymphocytes, causing decreases in production of immunoglobulin and antibodies. The most common B-cell disorder is selective IgA deficiency (Stiehm, 2014).

In contrast, secondary immunodeficiencies affect the normal immune system of the patient, resulting in increased susceptibility to infection and certain types of cancer. Extrinsic and intrinsic factors, such as nonimmune systemic disorders like HIV infection, immunosuppressive therapy, prolonged illness or hospitalization, and aging, trigger secondary immunodeficiency. These factors cause impaired immune response through loss or destruction of lymphocytes, such as CD4 cell depletion, or decreased production of lymphocytes, as in the effects of irradiation on bone marrow lymphocyte production (Stiehm, 2014). Patients with immunosuppression from secondary immunodeficiencies are referred to as *immunocompromised hosts.* The most common secondary immunodeficiency is AIDS.

HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

The Centers for Disease Control and Prevention (CDC) estimate that more than 1.2 million people are living with HIV/AIDS in the United States. The CDC estimates that there were 44,000 new infections in 2014 with a decline of 19% in new diagnoses since 2005. Worldwide, there were 2 million new cases of HIV in 2014. In 2015, UNAIDS/WHO estimated that 36.9 million people are living with HIV/AIDS in the world, and nearly half of those people have access to highly active antiretroviral (ARV) treatment (HAART). While many advances have been made in the treatment and long-term survival of people living with HIV/AIDS, new infections continue. One in eight people infected with HIV is unaware of the diagnosis; these patients are the ones responsible for transmitting most new infections. The recommendation by the CDC is for universal testing for all people between 13 and 64 years of age to lead to early diagnosis and treatment of people infected with HIV and to slow the rate of new infections in the United States (CDC, 2016a).

Epidemiology

The earliest confirmed case of HIV infection was found in blood drawn from an African man in 1959. Most theories about the origin and spread of AIDS point to a mutated simian immunodeficiency virus (SIV) that crossed species to humans, similar to the changes seen with bird and swine influenza viruses today (AVERT, 2016). An analysis of people with a diagnosis of HIV infection by race/ethnicity and risk factor underscores the disproportionate impact of HIV among communities of color and men who have sex with other men (MSM) of all races. In the United States, new infection rates by race/ethnicity show that nearly half of the cases (49%) are African American. Although African Americans make up only 12% of the population of the 34 states surveyed, their rate of HIV infection is 60% higher than that of Caucasians. While the rate of new diagnosis among African-American women fell by 42% since 2005, new diagnosis among African-American men increased by 22% during that same time period. By transmission category, MSM continues to account for the largest number of diagnoses overall, rising to 67% of newly diagnosed cases (CDC, 2014).

Worldwide, AIDS kills more than 1.1 million people every year, and 75% of those deaths occur in sub-Saharan Africa (UNAIDS, 2015). Since the beginning of the epidemic, 15 million children have been orphaned due to AIDS. In sub-Saharan Africa during 2014, there were 190,000 new infections among children. During that same time period, less than 500 children in Europe and the United States were infected; the difference is related directly to a mother's access to ART during pregnancy (UNAIDS, 2015).

New research finds that many patients live longer due to the use of ARV agents but are increasingly susceptible to age-associated non-AIDS diseases. The mechanism suspected is a chronic inflammatory process caused by HIV or the long-term use of ARV medications. In resource-rich countries, such as the United States, the epidemic has changed to one in which patients who are motivated can achieve long-term, if not lifelong, suppression of the virus with safe and tolerable medications. Patients who access and adhere to therapy rarely suffer AIDS-related complications. More likely, these patients will have many non–AIDS-defining cancers, cardiovascular disease, kidney disease, osteopenia/osteoporosis, liver failure, frailty, and neurologic decline. These normal age-related processes occur sooner and more severely in patients infected with HIV (National Institute on Aging [NIA], 2015).

Gerontologic Considerations 

Of the 47,000 patients newly diagnosed with HIV infections in 2013, more than 18% of these were over 50 years of age. HIV infection in middle-aged and older populations may be underreported and underdiagnosed because health care professionals erroneously believe that older adults are not at risk for HIV infection. In addition, HIV-related dementia in the older adult may mimic Alzheimer disease and may be misdiagnosed.

In fact, several factors put older adults at risk for HIV infection:

- Older adults recently widowed or divorced are dating again and may not be aware of the risks of HIV infection.
- Many older adults are sexually active but do not use condoms, viewing them only as a means of unneeded birth control.
- Older adults may be IV/injection drug users.
- Older adults may have received HIV-infected blood through transfusions before 1985.
- Normal age-related changes include a reduction in immune system function, which puts the older adult at greater risk for infections, cancers, and autoimmune disorders. Many older adults also experience the loss of loved ones, resulting in depression and bereavement, factors that are associated with depressed immune function.

Physical and mental stress of long-term caregiving and the number of comorbidities are significant predictors of the adequacy of social support in older adults with HIV.

Transmission

HIV is a bloodborne, sexually transmissible virus. HIV-1 is transmitted in body fluids containing HIV or infected $CD4^+$ T lymphocytes. These fluids include blood, seminal fluid, vaginal secretions, amniotic fluid, and breast milk. Mother-to-child transmission of HIV-1 may occur in utero or through breastfeeding, but most perinatal infections are thought to occur after exposure during delivery (CDC, 2016a). Inflammation and breaks in the skin or mucosa result in the increased probability of exposure to HIV. HIV is not transmitted through casual contact. Because HIV is harbored within lymphocytes, a type of white blood cell (WBC), any exposure to infected blood results in a significant risk of infection. The amount of virus and infected cells in the body fluid, as well as other host factors, is associated with the risk of new infection after exposure to that fluid.

Transfusion of blood and blood products can transmit HIV to recipients. However, the risk associated with transfusions has been virtually eliminated because of voluntary self-deferral, completion of a detailed health history, extensive testing, heat treatment of clotting factor concentrates, and more effective methods of virus inactivation. Donated blood is tested for antibodies to HIV-1, HIV-2, and p24 antigen (an early marker for HIV infection); in addition, since 1999, nucleic acid amplification testing (NAAT) has been performed (CDC, 2015). However, blood donated during the window period after infection is highly infectious even though it tests negative for HIV antibodies. The window period is the period between initial infection with HIV and development of a positive antibody test for HIV. Development of a positive HIV antibody test generally occurs within 4 weeks and, with few exceptions, by 6 months (Sax, Cohen, & Kuritzkes, 2014).

Until an effective vaccine is developed, preventing HIV by eliminating or reducing risky behaviors is essential (Box 37-1). Primary prevention efforts through effective educational programs are vital for control and prevention. As noted earlier, HIV is not transmitted by casual contact.

Prevention and Education

To reduce further the incidence of HIV infection, the CDC announced a new initiative, Advancing HIV Prevention (AHP), in 2003. This initiative comprises four strategies: making HIV testing a routine part of medical care, implementing new models for diagnosing HIV infections outside medical settings, preventing new infections by working with HIV-infected people and their partners, and further decreasing perinatal transmission of HIV (CDC, 2007).

BOX 37-1 Risk Behaviors Associated with HIV Infection and AIDS

- Sharing injection drug use equipment (aka "works")
- Having sexual relations with infected individuals (both male and female)
- People who received HIV-infected blood or blood products (especially before blood screening was instituted in 1985)
- Infants born to mothers with HIV infection not taking ART medication

BOX 37-2 Health Promotion

Safer Sexual Behaviors

- Encourage patients to be tested for HIV.
- Advise patients to abstain from sharing sexual fluids.
- Advise patients to reduce the number of sexual partners to one.
- Encourage patients to use latex condoms always. If the patient is allergic to latex, polyurethane condoms should be used.
- Advise patients to avoid using cervical caps or diaphragms without using a condom as well.
- Recommend patients always use dental dams for oral–genital or anal stimulation.
- Advise patients to use water-based lubricants to decrease condom breakage.
- Advise patients to avoid anal intercourse because this practice may injure tissues.
- Advise patients to avoid manual–anal intercourse.
- Encourage patients not to ingest urine or semen.
- Educate patients about nonpenetrative sexual activities, such as body massage, social kissing (dry), mutual masturbation, fantasy, and sex films.
- Advise patients to avoid sharing needles, razors, toothbrushes, sex toys, or blood-contaminated articles.
- Encourage patients who are HIV-positive to inform previous, present, and prospective sexual and drug-using partners of their HIV-positive status. If the patient is concerned for his or her safety, advise the patient that many states have anonymous partner notification programs through the public health department to

notify people who have been exposed to HIV.
- Advise HIV-positive patients to avoid donating blood, plasma, body organs, or sperm.

Initiation of effective educational programs educates the public regarding safer sexual practices and decreases the risk of transmitting HIV-1 infection to sexual partners (Box 37-2). Other than abstinence, consistent and correct use of condoms is the only method proven to decrease the risk for sexual transmission of HIV infection (see Chapter 35, Box 35-3, Fig. 35-1). Latex condoms should be used during vaginal or anal intercourse. Nonlatex condoms made of natural materials, such as lambskin, are available for people with latex allergy but will not protect against HIV infection. Condoms made from polyurethane provide comparable protection against STDs and HIV to latex condoms (CDC, 2015). A condom should be used for oral contact with the penis, and a dental dam (a piece of latex used by dentists to isolate a tooth for treatment) should be used for oral contact with the vagina or rectum.

The use of a microbicide, nonoxynol-9 (N-9), was widely advocated to reduce the risk of HIV infection until a clinical trial conducted in almost 1,000 female commercial sex workers in African countries revealed that those who used N-9 intravaginally along with condoms were 50% more likely to be infected with HIV than those who did not use the N-9 gel. Based on these results, it is now recommended that intravaginal application of N-9 not be used as a means of HIV prevention. Further research throughout the world continues to investigate the use of other microbicides, especially since the female sex partner controls its use. The challenge lies in developing a microbicide that is antiviral yet not irritating to the genital mucosa.

Other topics important in preventive education include the importance of avoiding sexual practices that might cut or tear the lining of the rectum, penis, or vagina, and avoiding sexual contact with multiple partners or people who are known to be HIV-positive or IV/injection drug users. In addition, people who are HIV-positive or who use injection drugs should be instructed not to donate blood or share drug equipment with others.

Increasingly, needle exchange programs are available so that IV/injection drug users can obtain sterile drug equipment at no cost. Extensive research has demonstrated that needle exchange programs do not promote increased drug use; in fact, they have been found to decrease the incidence of blood-borne infections in people who use IV/injection drugs (Des Jarlais, Kerr, Carrieri, Feelemyer, & Arasteh, 2016). In the absence of needle exchange programs, IV/injection drug users should be instructed on methods to clean their syringes and advised to avoid sharing cotton and other drug use equipment. Drug users interested in treatment programs should be referred to those programs.

Pre-exposure prophylaxis (PrEP), when taken consistently, has been shown in several clinical trials to reduce the rate of transmission of HIV up to 92%. A combination pill of tenofovir and emtricitabine is taken daily to prevent HIV infection among people whose behavior may increase their risk of exposure through sex or injection drug use. This regimen has shown efficacy and safety for people at substantial risk of acquiring HIV infection. However, people on PrEP must commit to medication adherence and regular follow-up with their health care provider (CDC, 2015).

Nursing Alert

Due to the rapidly changing and evolving guidelines for HIV care, it is essential to access reliable Internet resources. As this book is going to press, clinical evidence demonstrates that durable undetectable viral load translates into effectively no risk of transmission of HIV. This is based on years of cohort studies of serodiscordant couples where the HIV positive partner maintains an undetectable viral load, non-adherence to condom use and no infection of the HIV negative partner. Durably undetectable viral load is defined as at least 6 months of undetectable viral loads after starting medications.

Related Reproductive Education

Because HIV infection in women often occurs during the childbearing years, family planning issues need to be addressed. Attempts to achieve pregnancy by couples in which only one partner has HIV, referred to as serodiscordant, exposes the unaffected partner to the virus. Efforts at artificial insemination using processed semen from an HIV-infected partner are underway. At a fertility clinic in Italy, 3,000 successful pregnancies occurred within serodiscordant couples in whom the male partner was HIV-positive through sperm washing. Women who are HIV-positive and considering pregnancy need to have adequate information about the risks for transmitting HIV infection to their partner and their future children and about the benefits of taking ART agents to reduce perinatal HIV transmission. The desire of women who are HIV-positive to bear children is strong, despite health risks to these women, their children, and society in general (Mabileau et al., 2015). Due to effective ARV medications and universal testing of pregnant women and newborns in the United States, mother-to-child transmission rates have dropped dramatically. Women who are HIV-positive should be instructed not to breastfeed their infants because HIV is transmitted through breast milk. The use of medications coupled with women not breastfeeding has allowed the risk of transmission of HIV from mother to child to drop from 25% to less than 1% in the Western world (Mabileau et al., 2015).

Certain contraceptive methods may pose additional health risks for women. The message to women must be that contraception and prevention of HIV or other sexually transmitted infections (STIs) are two separate considerations. Estrogen and progesterone may increase a woman's risk for HIV infection through changes in the cervical mucosa. In addition, women infected with HIV who use estrogen oral contraceptives have shown increased shedding of HIV in vaginal and cervical secretions putting her partner at increased risk for HIV transmission in serodiscordant couples. The female condom (see Chapter 35, Fig. 35-1) is as effective in preventing pregnancy as other barrier methods, such as the diaphragm and the male condom. Unlike the diaphragm, the female condom also is effective in preventing the transmission of HIV infection and STIs. The female condom has the distinction of being the first barrier method that can be controlled by the woman.

Postexposure Prophylaxis

Standard Precautions

In 1996, the CDC and its Hospital Infection Control Practices Advisory Committee (HICPAC) developed guidelines to reduce the risk for exposure of health care workers to HIV through the development of Standard Precautions. Standard Precautions incorporate the major features of Universal Precautions (designed to reduce the risk of transmission of blood-borne pathogens) and Body Substance Isolation (designed to reduce the risk of transmission of pathogens from moist body substances); these standards are applied to all patients in health care facilities regardless of their diagnosis or presumed infectious status (Box 37-3). Standard Precautions apply to blood; all body fluids, secretions, and excretions (except sweat), regardless of whether they contain visible blood; nonintact skin; and mucous membranes (CDC, 2015). The primary purpose of Standard Precautions is to prevent the transmission of nosocomial infection. The first tier, referred to as Standard Precautions, reduces the risk for exposure from all recognized or unrecognized sources of infections in hospitals. New elements, such as Respiratory Hygiene/Cough etiquette, safe injection practices, and the use of masks during catheter placement, effectively address those specific issues centered on patient protection.

BOX 37-3 Standard Precautions

The following guidelines prevent the transmission of infection during patient care for all patients, regardless of known or unknown infectious status. Barrier protection should be used at all times to prevent contamination of the skin and mucous membrane with blood, body fluids containing visible blood, or other body fluids (cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids, as well as semen and vaginal secretions). Barrier protection should be used with *all* tissues. The type of barrier protection used should be appropriate for the type of procedures being performed and the type of exposure anticipated. Examples of barrier protection include disposable laboratory coats, gloves, and eye and face protection. Private rooms and rooms specially equipped with ventilation systems should be used as indicated.

- Protective body clothing, such as disposable laboratory coats, should be worn whenever there is a potential for splashing of blood or body fluids:
  - Wear a clean, nonsterile gown to protect the skin and prevent soiling of clothing during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.
  - Remove a soiled gown promptly, avoiding contact with clean clothes, and wash hands/perform hand hygiene to prevent the transfer of microorganisms to other patients or environments.
- Gloves are to be worn when there is a potential for hand or skin contact with blood, other potentially infectious material, or items and surfaces contaminated with these materials.

- Clean, nonsterile gloves can be used to protect the nurse's hands.
- Change gloves after contact with materials that may contain a high concentration of microorganisms even when working with the same patient.
- Remove the gloves promptly after use, and wash hands immediately before touching noncontaminated items and environmental surfaces and before going to another patient.

- Face protection (face shield, mask, and eye protection) should be worn during procedures that are likely to generate droplets of blood or body fluid to prevent exposure to mucous membranes of the mouth, nose, and eyes.
- Environmental control includes the following:
  - Ensure that the hospital has adequate procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bed rails, bedside equipment, and other surfaces that are touched frequently.
  - Ensure that procedures are being followed.
  - Advocate for the purchase and correct use of the safest equipment.
- Patient care equipment:
  - Used patient care equipment that is soiled with blood, body fluids, secretions, and excretions should be handled in a manner that prevents exposure of the skin and mucous membrane, contamination of clothing, and transfer of microorganisms to other patients and the environment.
  - Ensure that reusable equipment is not used for the care of another patient until it has been cleaned and reprocessed appropriately.
  - Ensure that single-use items are discarded properly.
  - Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods.
  - Used linen that is soiled with blood, body fluids, secretions, and excretions should be handled, transported, and processed in a manner that prevents exposure of the skin and mucous membrane, contamination of clothing, and transfer of microorganisms to other patients and environments.
- Wash hands thoroughly and immediately if contaminated with blood, body fluids containing visible blood, or other body fluids to which universal precautions apply:
  - Use soap and water or an antimicrobial agent or waterless antiseptic agent.
  - Wash the hands during procedures for the same patient to prevent cross-contamination of different body sites.
  - Wash the hands and other skin surfaces immediately after gloves are removed.
- Avoid accidental injuries that can be caused by needles, scalpel blades, laboratory instruments, and so on when performing procedures, cleaning instruments, handling sharp instruments, disposing of used needles or pipettes, and similar activities. Used needles, disposable syringes, scalpel blades, pipettes, and other sharp items are to be placed in puncture-resistant containers marked with a biohazard symbol for disposal:
  - Use "needleless" systems correctly whenever possible.

- Never recap used needles or otherwise manipulate them by using both hands or use any technique that involves directing the point of the needle toward any part of the body.
- Use either a one-handed scoop technique or a mechanical device designed for holding the needle sheath.
- Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand.
- Place used disposable syringes and needles, scalpel blades, and other sharp items in appropriate puncture-resistant containers as close as practical to the area in which the items were used.
- Place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.

Adapted from Siegel, J. D., Rhinehart, E., Jackson, M., Chiarello, L., & Health Care Infection Control Practices Advisory Committee. (2007). 2007 Guideline for isolation precautions: Preventing transmission of infectious agents in healthcare settings. *American Journal of Infection Control, 35*(10 Suppl 2), S65–164. Accessed from http://www.cdc.gov/ncidod/dhqp/pdf/guidelines/Isolation2007.pdf

Large-scale studies of exposed health care workers continue to be conducted by the CDC and other groups. In November 2000, the Needle-stick Safety and Prevention Act became law, mandating that health care facilities use devices to protect against sharps injuries. A plan of nursing care for a patient with an infectious disease is available online at http://thepoint.lww.com/Honan2e.

Postexposure Prophylaxis for Health Care Providers

Postexposure prophylaxis in response to the exposure of health care personnel to blood or other body fluids reduces the risk for HIV infection. According to the CDC, there have been only 58 confirmed cases of HIV transmission through occupational exposure (CDC, 2014). The CDC recommends that all health care providers who have sustained a significant exposure to HIV be counseled and offered anti-HIV postexposure prophylaxis, if appropriate (Box 37-4). More clinicians are using postexposure prophylaxis for patients exposed to HIV because of high-risk sexual behavior or possible contact through IV/injection drug use. This use of postexposure prophylaxis is controversial because of concern that it may be substituted for safer sex practices and safer IV/injection drug use. Postexposure prophylaxis should not be considered an acceptable method of preventing HIV infection but used for reducing risk after a possible transmission.

The medications recommended for postexposure prophylaxis are those used to treat established HIV infection. Ideally, prophylaxis needs to start immediately after exposure; therapy started more than 72 hours after exposure is thought to offer no benefit due to rapid increases in viral load upon initial infection.

The recommended course of therapy involves taking the prescribed medications for 4 weeks. Those who choose postexposure prophylaxis must be prepared for the side effects of the medications and must be adherent to treatment or face the possible long-term risks due to developing resistance. The cost is also of concern; the average wholesale price of a medication regimen is more than $2,500 (Department of Health and Human Services

[DHHS], 2016), in addition to the costs of testing and counseling. Most health care employers and agencies provide access to treatment and medication through Occupational Health Services.

BOX 37-4 Postexposure Prophylaxis for Health Care Providers

If you sustain a puncture injury, such as a needle stick, take the following actions immediately:

- Wash the area thoroughly with soap and water.
- Alert your supervisor/nursing faculty and initiate the injury-reporting system used in the setting.
- Identify the source patient who may need to be tested for HIV, hepatitis B, and hepatitis C. State laws will determine whether written informed consent must be obtained from the source patient before his or her testing. Rapid testing should be used, if possible, if the HIV status of the source patient is unknown because results can be available within 20 minutes.
- Report as quickly as possible to employee health services, the emergency department, or other designated treatment facility. This visit should be documented in the health care worker's confidential medical record.
- Give consent for baseline testing for HIV, hepatitis B, and hepatitis C. Confidential HIV testing can be performed up to 72 hours after the exposure but should be performed as soon as the health care worker can give informed consent for baseline testing.
- Get postexposure prophylaxis for HIV in accordance with CDC guidelines. Start the prophylaxis medications within 2 hours after exposure. Postexposure prophylaxis must be initiated within 72 hours of exposure to be effective. Make sure that you are being monitored for symptoms of toxicity. Practice safer sex until follow-up testing is complete. Continue the HIV medications for 4 weeks.
- Follow up with postexposure testing at 1 month, 3 months, and 6 months.
- Document the exposure in detail for your own records, as well as for the employer.

Pathophysiology

Because HIV infection is an infectious disease, it is important to understand how HIV integrates itself into a person's immune system and how immunity plays a role in the course of infection. This knowledge is also essential for understanding medication therapy and vaccine development.

Viruses are intracellular parasites. HIV belongs to a group of viruses known as retroviruses. These viruses carry their genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). As shown in Figure 37-1, HIV consists of a viral core containing the viral RNA, surrounded by an envelope consisting of protruding glycoproteins (gp). For HIV to enter the targeted cell, the membrane of the viral envelope must be fused with the plasma membrane of the cell, a process mediated by the envelope glycoproteins of HIV and other coreceptors (National Institutes of Health [NIH], 2016).

All viruses target specific cells. Lymphocytes (type of WBC) consist of three major populations: T cells, B cells, and NK cells. Mature T cells are phenotypically (characteristics of the cells) composed of two major subpopulations, defined by cell surface reciprocal expression of CD4 or CD8. Approximately two thirds of peripheral blood T cells are $CD4^+$, and approximately one third is $CD8^+$. Most people have about 700 to 1,500 $CD4^+$ cells/mm^3, but a count as low as 500 cells/mm^3 can be considered "normal." HIV targets cells with the CD4 glycoprotein expressed on the surface of T lymphocytes, monocytes, dendritic cells, and brain microglia. Monocytes and macrophages serve as long-lived reservoirs of HIV. Most primary clinical isolates of HIV use the chemokine coreceptor CCR5 for cell entry. HIV-1 isolates that appear later in the course of infection often use other chemokine receptors, such as CXCR4, in addition to CCR5 (National Institute of Allergy and Infectious Disease [NIAID], 2016). HIV must attach to both the CD4 and the CCR5 coreceptor binding sites in order to infect $CD4^+$ cells.

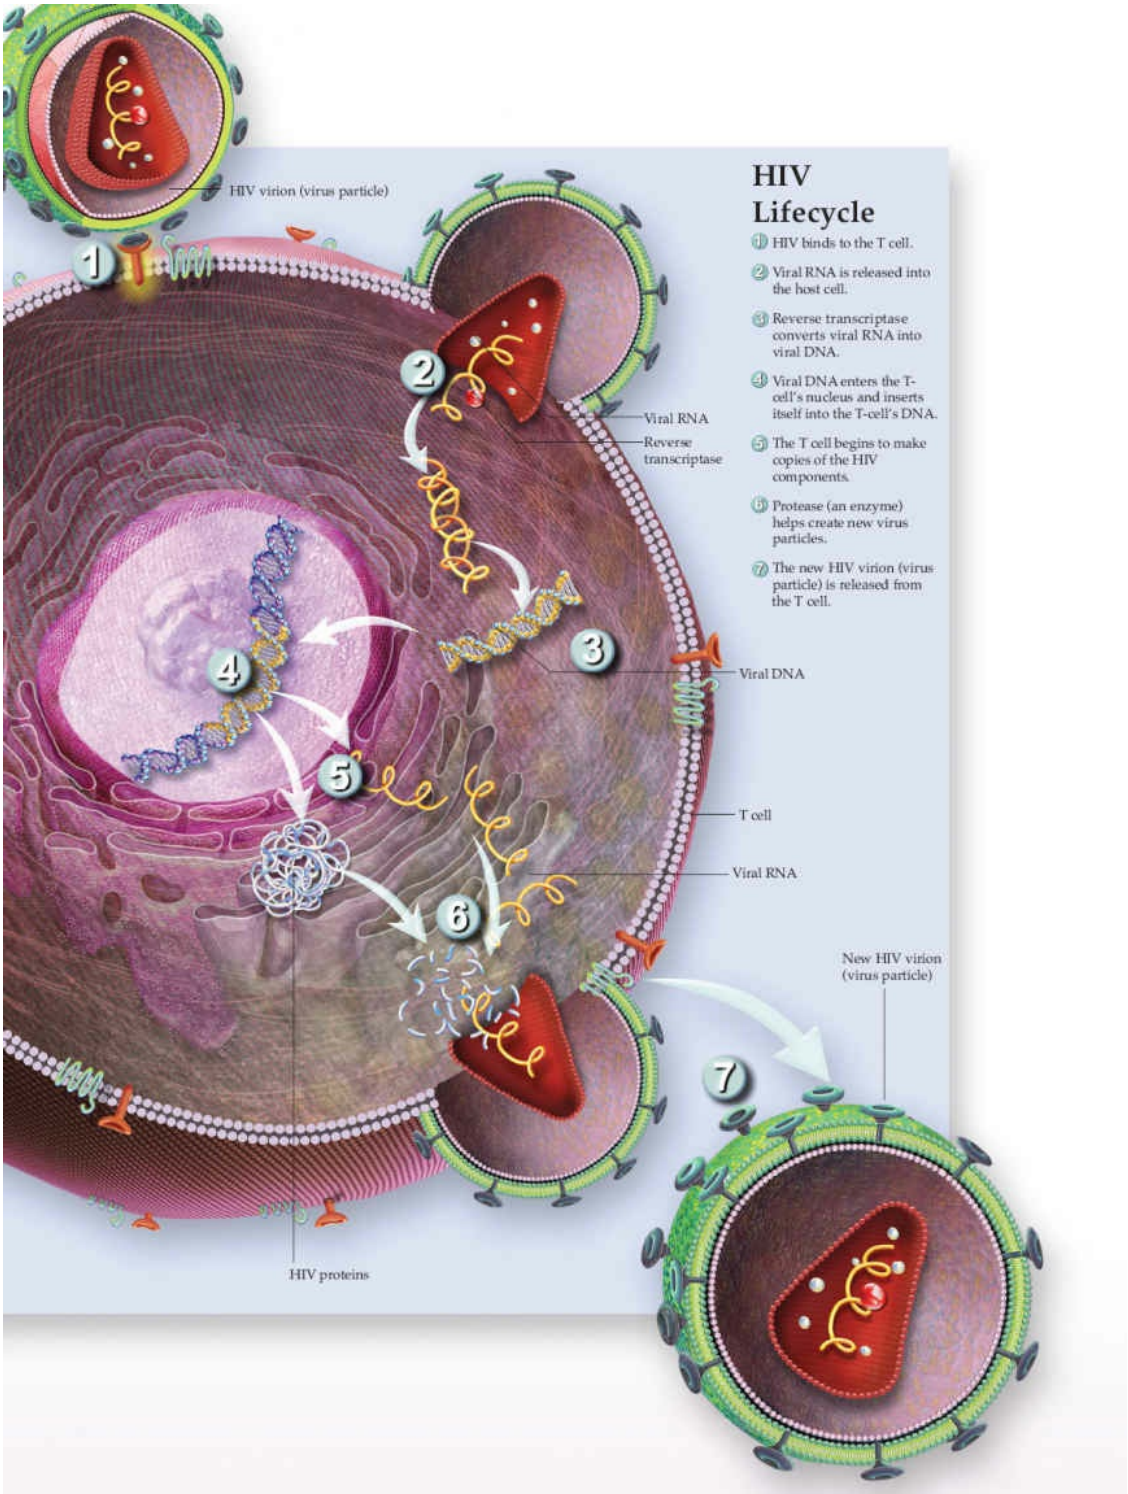

FIGURE 37-1 HIV life cycle. (Courtesy of Anatomical Chart Company.)

A mutation of CCR5 that is common among Caucasians but not other ethnic groups has been identified. About 1% of Caucasians lack functional CCR5 and are highly protected against HIV infection even if exposed (although protection is not absolute); about 18% are not markedly protected against infection but, if infected, demonstrate significantly slower rates of disease progression (Tebas et al., 2014). Reports of a man treated in Berlin, Germany, who received a stem cell transplant for treatment of acute myeloid leukemia from a donor with the Delta 32 mutation at the CCR5 binding site

shows promise for further research for HIV treatment. After total intentional destruction of the patient's bone marrow, a procedure with a 30% mortality rate, this patient has had no detectable virus 20 months after transplant and discontinuation of ARV therapy (Symons et al., 2014).

The HIV life cycle is complex (see Fig. 37-1) and consists of the following:

- The HIV gp120 and gp41 attach to the uninfected $CD4^+$ lymphocyte at the CD4 receptor and one of two coreceptors, fusing with the cell membrane.
- The viral core contents are emptied into the host cell, a process known as *uncoating*.
- HIV enzyme reverse transcriptase converts the viral genetic material from RNA into double-stranded DNA.
- Double-stranded DNA is spliced into the cellular DNA by the action of integrase, another HIV enzyme.
- During transcription, the integrated DNA or provirus makes new viral proteins and viral RNA. Provirus may remain inactive for months to years within the $CD4^+$ cell and other components of the immune system.
- HIV protease cleaves the new proteins (polyproteins).
- The new proteins join the viral RNA into new viral particles.
- New viral particles bud from the cell and start the process all over.

In resting (nondividing) cells, HIV can apparently survive in a latent state as an integrated provirus that produces few or no viral particles. These resting $CD4^+$ T cells as well as monocytes and macrophages can be stimulated to produce new particles if something reactivates them. Activation of the infected cell may be achieved by antigens, mitogens, certain cytokines (tumor necrosis factor-α [TNF] or interleukin-1 [IL-1]), or virus gene products of such viruses as cytomegalovirus (CMV), Epstein–Barr virus, herpes simplex virus, and hepatitis viruses. Consequently, whenever the infected T cell is activated, HIV replication and budding occur, which often destroys the host cell. Then newly formed HIV is released into the blood plasma and infects other $CD4^+$ cells (see Fig. 37-1). If inadequately suppressed, HIV mutates at a relatively constant rate, enabling it to blunt or completely suppress the effects of HIV medications.

TABLE 37-1 Selected Laboratory Tests for Diagnosing and Tracking HIV and Assessing Immune Status

Test	Findings in HIV Infection
Enzyme immunoassay (EIA)	Antibodies are detected, resulting in positive results. May have false-negative results within the window period.
Antigen/antibody	Detects HIV antibodies and p24 antigen; detects early acute infection.
Viral load	Quantifies HIV RNA in the plasma. Monitors efficacy of ART through virologic suppression. Goal is undetectable.
CD4/CD8 ratio	These are markers found on lymphocytes. HIV kills $CD4^+$ cells, which results in a significantly impaired immune system. Used in decision to initiate ART and use of prophylactic medications.

Assessment and Diagnosis

Diagnostic tests are summarized in Table 37-1.

HIV Antibody Tests

Before an HIV antibody test is performed, the meaning of the test and possible test results are explained, and informed consent for the test is obtained from the patient. The CDC recommends universal testing of all patients 13 to 64 years of age through opt-out testing. However, some states still require written informed consent and face-to-face results counseling. Consult state laws about specific requirements related to testing for HIV. When the result of the HIV antibody test is received, it is carefully explained to the patient in private (Box 37-5). All test results are kept confidential. Education and counseling about the test result and about preventing transmission are essential. The patient's psychological response to a seropositive test result may include feelings of panic, depression, and hopelessness. The social and interpersonal consequences of a positive test result can be devastating. The patient may lose his or her sexual partner because of disclosure. The patient may experience discrimination in employment and housing, as well as social ostracism. For these reasons and others, a patient who tests positive may need ongoing counseling, as well as referrals for social, financial, medical, and psychological support services.

BOX 37-5 HIV Test Results: Implications for Patients

Interpretation of Positive Test Results

- Antibodies to HIV are present in the blood (the patient has been infected with the virus, and the body has produced antibodies).
- HIV is active in the body, and the patient can transmit the virus to others.
- Despite HIV infection, the patient does not necessarily have AIDS.
- The patient is not immune to HIV (the antibodies do not indicate immunity).

Interpretation of Negative Test Results

- Antibodies to HIV are not present in the blood at this time, which can mean that the patient has not been infected with HIV or, if infected, the body has not yet produced antibodies (the patient may be in the window period—usually 4 weeks to 6 months).
- The patient should continue taking precautions. The test result does not mean that the patient is immune to the virus, nor does it mean the patient is not infected; it just means that the body may not have produced antibodies yet. Recommend repeat testing if at high risk for HIV.

Patients whose test results are seronegative may develop a false sense of security, possibly resulting in continued high-risk behaviors or feelings that they are immune to the virus. These patients may need ongoing counseling to help modify high-risk behaviors and to encourage returns for repeated testing. Other patients may experience anxiety regarding the uncertainty of their status.

During initial infection with HIV, the immune system responds by producing antibodies against the virus, usually within 4 to 12 weeks after infection. In 1985, the U.S. Food and Drug Administration (FDA) licensed the first HIV-1 antibody assay that used approximately 5 to 7 mL of blood. The enzyme immunoassay (EIA) test, formerly referred to as the enzyme-linked immunosorbent assay (ELISA) test, identifies antibodies directed specifically against HIV. As of 2014, the CDC recommends testing with the newer fourth-generation test for HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen using an immunoassay process. Confirmation testing includes nucleic acid testing (NAT) and no longer utilizes the Western Blot test. This process allows detection of early infections and reduces indeterminate results (CDC, 2014).

Home-based testing for HIV antibodies using a small amount of blood was first proposed in 1985 but was not approved by the FDA until 1995. Although home testing kits are commercially available, they raise concerns because of the lack of counseling and the possibility of inaccurate results, including both false-positive and false-negative results.

Viral Load Tests

Target amplification methods quantify HIV RNA or DNA levels in the plasma and have replaced p24 antigen capture assays. Target amplification methods include reverse transcriptase–polymerase chain reaction (RT-PCR) and nucleic acid sequence–based amplification (NASBA). A widely used viral load test measures plasma HIV RNA levels. Currently, these tests track viral load and response to treatment of HIV infection. RT-PCR is also used to detect HIV in high-risk seronegative people before antibodies are measurable, to confirm a positive EIA result, and to screen neonates. Viral load is a better predictor of the risk for HIV disease progression than the $CD4^+$ count. The lower the viral load, the longer the time to AIDS diagnosis and the longer the survival time. Increased presence of the virus causes lymphoid dysfunction and other inflammatory responses that affect long-term survival (NIA, 2016).

Stages of HIV Disease

The stage of HIV disease is based on clinical history, physical examination, laboratory evidence of immune dysfunction, signs and symptoms, opportunistic infections, and malignancies. The CDC standard case definition of AIDS categorizes HIV infection and AIDS in adults and adolescents based on clinical conditions associated with HIV infection and $CD4^+$ T-cell counts. The classification system groups clinical conditions into one of three categories, denoted A, B, and C. Each category represents clinical progression of HIV infection in the patient, from asymptomatic (category A) to "full blown" AIDS (category C). Although a patient's health and immune status may improve, the CDC classification of the patient's illness does not change. Universal testing coupled with early diagnosis and treatment attempts to intervene in the natural progression of HIV to maintain as functional an immune system as possible.

Primary Infection (Acute HIV Infection, Acute Retroviral Syndrome)

The period from infection with HIV to the development of antibodies to HIV is known as primary infection. This period is characterized by intense viral replication and widespread dissemination of HIV throughout the body. During primary infection, a window period occurs, during which a person with HIV infection tests negative on the HIV antibody blood test. Although antibodies to the HIV envelope glycoproteins typically can be detected in the sera of HIV-infected individuals by 2 to 3 weeks after infection, most of these antibodies lack the ability to inhibit virus infection. By the time neutralizing antibodies can be detected, HIV-1 is firmly established in the host. During this period, there are high levels of viral replication and destruction of $CD4^+$ T cells, resulting in high levels of HIV in the blood and a dramatic drop in $CD4^+$ T-cell counts from the normal range of 500 to 1,500 cells/mm^3 of blood. Detectable levels of virus can occur as early as 72 hours after exposure; this provides the rationale for immediate initiation of prophylaxis.

About 3 weeks into this acute phase, the person may display symptoms similar to mononucleosis, such as fever, enlarged lymph nodes, rash, muscle aches, and headaches. These symptoms resolve within another 1 to 3 weeks as the immune system begins to recuperate. That is, the $CD4^+$ T-cell population responds in ways that cause other immune cells, such as $CD8^+$ lymphocytes, to increase their killing of infected, virus-producing cells. The body produces antibody molecules in an effort to contain the virus; they bind to free HIV particles (outside cells) and assist in their removal. This balance between the amount of HIV in the body and the immune response is referred to as the viral set point; it results in a steady state of infection that can last for years.

Primary HIV infection, the time during which the viral burden set point is achieved, includes the acute symptomatic and early infection phases. During this initial stage, viral replication is associated with dissemination in lymphoid tissue (lymph nodes, spleen, tonsils and adenoids, and the thymus) and a distinct immunologic response. The final level of the viral set point is inversely correlated with disease prognosis; that is, the higher the viral set point, the poorer the prognosis. The primary infection stage is part of CDC category A.

HIV Asymptomatic (CDC Category A: More Than 500 $CD4^+$ T Lymphocytes/mm^3)

When a viral set point is reached, a chronic, clinically asymptomatic state begins. Despite its best efforts, the immune system rarely, if ever, fully eliminates the virus. By about 6 months, the rate of viral replication reaches a lower but relatively steady state that is reflected in the maintenance of viral levels at a set point. This set point varies greatly from patient to patient and dictates the subsequent rate of disease progression; on average, 8 to 10 years pass before a major HIV-related complication develops. In this prolonged, chronic stage, patients feel well and have few if any symptoms. Apparent good health continues because $CD4^+$ T-cell levels remain high enough to preserve defensive responses to other pathogens.

HIV Symptomatic (CDC Category B: 200 to 499 $CD4^+$ T Lymphocytes/mm^3)

Over time, the number of $CD4^+$ T cells gradually falls. Category B consists of symptomatic conditions in HIV-infected patients that are not included in the conditions listed in category C. These conditions also must meet one of the following criteria: (1) the condition

is due to HIV infection or a defect in cellular immunity, or (2) the condition is considered to have a clinical course or to require management that is complicated by HIV infection.

AIDS (CDC Category C: Fewer Than 200 $CD4^+$ T Lymphocytes/mm^3)

When the $CD4^+$ T-cell level drops below 200 cells/mm^3 of blood, the person has AIDS. As levels decrease to fewer than 100 cells/mm^3, the immune system is significantly impaired. Once a patient has had a category C condition, he or she maintains a permanent diagnosis of AIDS even if the immune system recuperates. This classification has implications for entitlements (i.e., disability benefits, housing, and food stamps) because these programs are often linked to an AIDS diagnosis. Although the revised classification system of the CDC emphasizes $CD4^+$ T-cell counts, it allows for the count of $CD4^+$ T-cells to be expressed as a percentage (percentage of $CD4^+$ T cells compared with total lymphocytes). The $CD4^+$ percentage is less subject to variation on repeated measurements than is the absolute $CD4^+$ T-cell count. A $CD4^+$ percentage of less than 14% of the total lymphocytes is consistent with an AIDS diagnosis. The percentage, as compared with the absolute number of $CD4^+$ T cells, becomes particularly important when the patient has a heightened immune response to infections in addition to HIV.

Clinical Manifestations

During the first stage of HIV infection, the patient may be asymptomatic or may exhibit various signs and symptoms. The patient's health history should alert the health care provider about the need for HIV screening based on the patient's sexual practices, IV/injection drug use, and receipt of blood transfusions. Patients who are in later stages of HIV infection may have a variety of symptoms related to their immunosuppressed state. HIV often causes opportunistic infections (OIs). With widespread availability and improved effectiveness of ARVs, clinical occurrence of OIs has plummeted. OIs and other common manifestations are discussed below.

Respiratory Manifestations

Dyspnea (labored breathing), cough, chest pain, and fever are associated with various OIs, such as those caused by *Pneumocystis jiroveci, Mycobacterium avium-intracellulare,* CMV, and *Legionella* species.

Pneumocystic Pneumonia

The most common infection in people with AIDS is *Pneumocystic* pneumonia (PCP). The current guidelines on treatment of OIs (Sax et al., 2014) refer to the causative organism as *P. jiroveci* instead of *P. carinii,* although the infection is still abbreviated as PCP. PCP was one of the first OIs described in association with AIDS, and it is the most common OI resulting in the diagnosis of AIDS. Without prophylactic therapy, 80% of all people infected with HIV will develop PCP.

The clinical presentation of PCP in patients with HIV infection is generally less acute than in people who are immunosuppressed because of other conditions. The time between the onset of symptoms and the actual documentation of disease may be weeks to months. Patients with AIDS initially develop nonspecific signs and symptoms, such as nonproductive cough, fever, chills, dyspnea, and, occasionally, chest pain. PCP may be present despite the absence of crackles. Arterial oxygen concentrations in patients who are breathing room air may be mildly decreased, indicating minimal hypoxemia. Pulse oximetry after exercise, such as walking up and down a flight of stairs is a simple, noninvasive test for outpatient use.

If left untreated, PCP eventually progresses and causes significant pulmonary impairment and respiratory failure. Some patients have a dramatic onset and a fulminating course involving severe hypoxemia, cyanosis, tachypnea, and altered mental status. Respiratory failure can develop within 2 to 3 days after the initial appearance of symptoms.

PCP can be diagnosed definitively by identifying the organism in lung tissue or bronchial secretions. This is accomplished by such procedures as sputum induction, bronchial-alveolar lavage, and transbronchial biopsy (by fiberoptic bronchoscope).

Tuberculosis

Mycobacterium tuberculosis tends to occur in IV/injection drug users and other groups with a pre-existing high prevalence of tuberculosis (TB) infection. TB that occurs late in HIV infection is characterized by the absence of delayed type of hypersensitivity response

mediated by T lymphocytes to the tuberculin skin test. This is known as anergy, and it occurs because the compromised immune system can no longer respond to the TB antigen. For this reason, TB testing is essential upon initial diagnosis of HIV, with appropriate treatment for patients demonstrating latent TB infection. Nurses administer the Mantoux test to determine infection with TB (refer to Chapter 10 for further discussion). In the later stages of HIV infection, TB may be associated with dissemination to extrapulmonary sites, such as the central nervous system (CNS), bone, pericardium, stomach, peritoneum, and scrotum. Multidrug-resistant strains of the bacillus have emerged and often are associated with a lack of adherence to regimens for antituberculosis medication.

Immune reconstitution syndrome (also known as *paradoxical reactions*) seems to occur more often among patients with TB. Patients can experience high fevers, worsening lymphadenopathy, or transient to severe worsening of pulmonary infiltrates and expanding CNS lesions. Reduction of HIV-1 RNA levels and marked increases in $CD4^+$ T-lymphocyte counts have been associated with the occurrence of paradoxical reactions in patients with TB disease or *Mycobacterium avium* complex (MAC). A common mycobacterium, MAC may cause infection in immunosuppressed patients. While affecting the lungs primarily, it can have extrapulmonary impact on the lymph nodes, bones, skin, and other tissues. However, a MAC infection cannot be passed from one person to another. Although the majority of reactions occur within the first few weeks after initiation of ART, some have occurred up to several months after the initiation of TB therapy or ART (Sax et al., 2014).

Gastrointestinal Manifestations

The gastrointestinal (GI) manifestations of AIDS include loss of appetite, nausea, vomiting, oral and esophageal candidiasis, and chronic diarrhea. Diarrhea is a problem in 50% to 90% of all AIDS patients. GI symptoms may be related to the direct effect of HIV on the cells lining the intestines. Some of the enteric pathogens that occur most frequently, identified by stool cultures or intestinal biopsy, are *Cryptosporidium muris, Salmonella* species, *Isospora belli, Giardia lamblia,* CMV, *Clostridium difficile,* and *M. avium-intracellulare.* In patients with AIDS, the effects of diarrhea can be devastating in terms of profound weight loss (more than 10% of body weight), fluid and electrolyte imbalances, perianal skin excoriation, weakness, and inability to perform the usual activities of daily living.

Candidiasis

Candidiasis or *thrush*, a fungal infection, occurs in almost all patients with AIDS and AIDS-related conditions. It commonly precedes other life-threatening infections and is characterized by adherent creamy-white patches in the oral cavity (Fig. 37-2). When left untreated, oral candidiasis progresses to involve the esophagus and stomach. Associated signs and symptoms include difficult, painful swallowing, and retrosternal pain. Some patients also develop ulcerating oral lesions and are particularly susceptible to dissemination of candidiasis to other body systems.

FIGURE 37-2 Oral candidiasis. (From Goodheart, H. P. (2015). *Goodheart's photoguide of common skin disorders* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Wasting Syndrome

Wasting syndrome is part of the category C case definition for AIDS. Diagnostic criteria include profound involuntary weight loss exceeding 10% of baseline body weight and either chronic diarrhea for more than 30 days or chronic weakness and documented intermittent or constant fever in the absence of any concurrent illness that could explain these findings. This protein–energy malnutrition is multifactorial. In some AIDS-associated illnesses, patients experience a hypermetabolic state in which excessive calories are burned and lean body mass is lost. This state is similar to that seen in sepsis or trauma and can lead to organ failure. The distinction between cachexia (wasting) and malnutrition, or between cachexia and simple weight loss, is important because the metabolic derangement seen in wasting syndrome may not be modified by nutritional support alone.

Progressive tissue wasting may occur with only modest GI involvement and without diarrhea. TNF and IL-1 are cytokines that play important roles in AIDS-related wasting syndrome and the inflammatory processes that complicate its course. Both act directly on the hypothalamus to cause anorexia. Cytokine-induced fever accelerates the body's metabolism by 14% for every 1°F increase in temperature. TNF causes inefficient use of lipids by reducing enzymes that are needed for fat metabolism, whereas IL-1 triggers the release of amino acids from muscle tissue. It is believed that infections and sepsis lead to transient increases in TNF, IL-1, and other cell mediators above the chronically elevated levels that often are seen with AIDS (refer to Chapter 54 for discussion of sepsis). These transient increases in TNF and IL-1 trigger muscle wasting. People with AIDS generally experience increased protein metabolism in relation to fat metabolism, which results in

significant decreases in lean body mass due to muscle and protein breakdown. Hypertriglyceridemia, seen in people with AIDS and attributed to chronically elevated cytokine levels, can persist for months without tissue wasting and loss of lean body mass. It is also caused by protease inhibitors (PIs) and increases the risk for pancreatitis.

Oncologic Manifestations

Patients with AIDS have a higher than usual incidence of cancer, possibly related to HIV stimulation of developing cancer cells or to the immune deficiency that allows cancer-causing substances, such as viruses, to transform susceptible cells into malignant cells. Kaposi sarcoma (KS), certain types of B-cell lymphomas, and invasive cervical carcinoma are included in the CDC classification of AIDS-related malignancies. Carcinomas of the skin, stomach, pancreas, rectum, and bladder also occur more frequently than expected in people with AIDS.

Kaposi Sarcoma

KS, the most common HIV-related malignancy, is a disease that involves the endothelial layer of blood and lymphatic vessels. Since the introduction of ARVs, there has been a significant decrease in the incidence of KS. It is associated with transmission of human herpes virus 8 (HHV-8). Acquired KS occurs in patients who are treated with immunosuppressive agents and commonly in patients who have undergone organ transplantation. In such patients, KS usually resolves once the dose of the immunosuppressive medication is decreased or discontinued. In people with AIDS, epidemic KS is seen most often among male homosexuals and bisexuals. Although the histopathology of all forms of KS is virtually identical, the clinical manifestations differ: AIDS-related KS exhibits a more variable and aggressive course, ranging from localized cutaneous lesions to disseminated disease involving multiple organ systems. Cutaneous signs may be the first manifestation of HIV, appearing in more than 90% of HIV-infected patients as the immune functions deteriorate. These skin signs correlate to low $CD4^+$ counts, usually less than 50. Cutaneous lesions can appear anywhere on the body and are brownish pink to deep purple. They may be flat or raised and surrounded by ecchymoses (hemorrhagic patches) and edema (Fig. 37-3). Rapid development of lesions involving large areas of skin is associated with extensive disfigurement. The location and size of some lesions can lead to venous stasis, lymphedema, and pain. Ulcerative lesions disrupt skin integrity and increase discomfort and susceptibility to infection. The most common sites of visceral involvement are the lymph nodes, GI tract, and lungs. Involvement of internal organs may eventually lead to organ failure, hemorrhage, infection, and death.

Proper identification of these lesions is difficult with darkly pigmented skin; biopsy confirms the diagnosis. Prognosis depends on the extent of the tumor, the presence of other symptoms of HIV infection, and the $CD4^+$ count. Death may result from tumor progression.

FIGURE 37-3 Lesions of AIDS-related Kaposi sarcoma. Whereas some patients may have lesions that remain flat, others experience extensively disseminated, raised lesions with edema.

B-Cell Lymphomas

B-cell lymphomas are the second most common malignancy occurring in people with AIDS. Lymphomas associated with AIDS usually differ from those occurring in the general population. Patients with AIDS are typically much younger than the usual population affected by non-Hodgkin lymphoma. In addition, AIDS-related lymphomas tend to develop outside the lymph nodes, most commonly in the brain, bone marrow, and GI tract. These types of lymphomas are characteristically of a higher grade, indicating aggressive growth and resistance to treatment.

The course of AIDS-related lymphomas includes multiple sites of organ involvement and complications related to OIs. Although aggressive combination chemotherapy is frequently successful in the treatment of non-Hodgkin lymphoma in the patient who is HIV-negative, treatment is less successful in people with AIDS because of severe hematologic toxicity and complications of OIs.

Neurologic Manifestations

An estimated 80% of all patients with AIDS experience some form of neurologic involvement during the course of HIV infection. Many neuropathologic disorders are underreported because patients may have neurologic involvement without overt signs or symptoms. Neurologic complications involve central, peripheral, and autonomic functions. HIV-associated neurocognitive disorders (HAND) can affect memory, attention, language, and executive functioning. Neurologic dysfunction results from direct effects of HIV on nervous system tissue, OIs, primary or metastatic neoplasms, cerebrovascular changes, metabolic encephalopathies, or complications secondary to therapy. Immune system response to HIV infection in the CNS includes inflammation, atrophy, demyelination,

degeneration, and necrosis.

HIV Encephalopathy

HIV encephalopathy or HIV-associated dementia (HAD) was formerly referred to as *AIDS dementia complex.* The clinical syndrome is characterized by a progressive decline in cognitive, behavioral, and motor functions. Substantial evidence exists that HIV encephalopathy is a direct result of HIV infection in brain macrophages and microglia. HIV infection is thought to trigger the release of lymphokines and other inflammatory factors that result in cellular dysfunction or interference with neurotransmitter function rather than cellular damage.

Signs and symptoms may be subtle and difficult to distinguish from fatigue, depression, or the adverse effects of treatment for infections and malignancies. Early manifestations include memory deficits, headache, difficulty concentrating, progressive confusion, psychomotor slowing, apathy, and ataxia. Later stages include global cognitive impairments, delay in verbal responses, a vacant stare, spastic paraparesis (a slight weakness or paralysis of both lower extremities), hyperreflexia, psychosis, hallucinations, tremor, incontinence, seizures, mutism, and death.

Confirming the diagnosis of HIV encephalopathy can be difficult. Extensive neurologic evaluation includes a computed tomography (CT) scan, which may indicate diffuse cerebral atrophy and ventricular enlargement. Other tests that may detect abnormalities include magnetic resonance imaging (MRI), analysis of CSF through lumbar puncture, and brain biopsy.

Cytomegalovirus

Retinitis is the most common clinical manifestation of CMV. Before the use of ARVs, 30% of patients experienced CMV retinitis with a high incidence of blindness. The incidence of CMV retinitis has been reduced by 80% with these medications.

Peripheral retinitis might be asymptomatic or present with floaters, scotomata (a loss of vision within the visual field), or reduced visual acuity. CMV retinitis has characteristic fluffy yellow-white retinal lesions with or without intraretinal hemorrhage visualized on funduscopic examination. Blood vessels near the lesions might appear to be sheathed. Patients with $CD4^+$ counts of less than 50 should be examined by an ophthalmologist on a yearly basis (Sax et al., 2014).

Other Neurologic Disorders

Other common infections involving the nervous system include *Toxoplasma gondii, M. tuberculosis*, and syphilis. Additional neurologic manifestations include both central and peripheral neuropathies. Vascular myelopathy is a degenerative disorder that affects the lateral and posterior columns of the spinal cord, resulting in progressive spastic paraparesis, ataxia (inability to coordinate body movements), and incontinence. HIV-related peripheral neuropathy is thought to be a demyelinating disorder. It is associated with pain and numbness in the extremities, weakness, diminished deep tendon reflexes, orthostatic hypotension, and impotence. Peripheral neuropathy is a common adverse effect of many HIV medications.

Depressive Manifestations

The prevalence of depression among people with HIV infection is three times higher than in the HIV-negative population (Mayo, Brouillette, & Fellows, 2016). The causes of depression are multifactorial and may include a history of pre-existing mental illness, neuropsychiatric disturbances, and psychosocial factors. Depression also occurs in people with HIV infection in response to the physical symptoms, including pain and weight loss, as well as isolation. People with HIV/AIDS who are depressed may experience irrational guilt and shame, loss of self-esteem, feelings of helplessness and worthlessness, and suicidal ideation.

Integumentary Manifestations

Cutaneous manifestations are associated with HIV infection and the accompanying OIs and malignancies. KS (described earlier) and OIs, such as herpes zoster and herpes simplex, are associated with painful vesicles that disrupt skin integrity. Molluscum contagiosum is a viral infection characterized by multiple grouped lesions. Seborrheic dermatitis is associated with an indurated, diffuse, scaly rash involving the scalp and face (see Chapter 52). Patients with AIDS also may exhibit a generalized eosinophilic folliculitis associated with dry, flaking skin or atopic dermatitis, such as eczema or psoriasis. Up to 60% of patients treated with trimethoprim-sulfamethoxazole (TMP-SMZ) develop a drug-related rash that is pruritic with pinkish-red macules and papules. Regardless of the origin of these rashes, patients experience discomfort and are at increased risk for additional infection from disrupted skin integrity. See Chapter 51 for how to assess and describe rashes.

Nursing Alert
The viral exanthem associated with acute retroviral syndrome during initial infection with AIDS is one of the few rashes accurately described as maculopapular (flat, erythematous rash on the skin that is covered with small confluent [merging] bumps).

Gynecologic Manifestations

Persistent, recurrent vaginal candidiasis or bacterial vaginosis may be the first sign of HIV infection in women. Past or present genital ulcer disease is a risk factor for the transmission of HIV infection. Women with HIV infection are more susceptible to and have increased rates of incidence and recurrence of genital ulcer disease and venereal warts. Ulcerative STIs, such as chancroid, syphilis, and herpes, are more severe in women with HIV infection. Human papillomavirus (HPV) causes venereal warts and is a risk factor for cervical intraepithelial neoplasia, a cellular change that is frequently a precursor to cervical cancer. Women with HIV are 10 times more likely to develop cervical intraepithelial neoplasia than are those not infected with HIV. HIV-seropositive women with cervical carcinoma present at a more advanced stage of disease and have more persistent and recurrent disease and a shorter interval to recurrence and death than women without HIV infection.

A significant percentage of women who require hospitalization for pelvic inflammatory disease (PID) have HIV infection. Women with HIV are at increased risk for PID, and the

associated inflammation may potentiate the transmission of HIV infection (see Chapter 35 for information related to PID). Moreover, women with HIV infection appear to have a higher incidence of menstrual abnormalities, including amenorrhea or bleeding between periods, than do women without HIV infection.

Immunologic Manifestations

Immune reconstitution inflammatory syndromes (IRIS) have been described for mycobacterial infections, including disease caused by MAC and *M. tuberculosis*, PCP, toxoplasmosis, hepatitis B and hepatitis C, CMV infection, varicella-zoster virus infection, cryptococcal infection, and progressive multifocal leukoencephalopathy. Immune reconstitution syndromes are characterized by fever and worsening of the clinical manifestations of the OI, or the appearance of new manifestations developing weeks after the initiation of ART. It is important to determine the absence or reappearance of the underlying OI, new drug toxicity, or a new OI. If the syndrome represents an immune restoration response, adding nonsteroidal anti-inflammatory agents (NSAIDs) or corticosteroids to alleviate the inflammatory reaction is appropriate. The inflammation might take weeks to months to subside (Sax et al., 2014). The nurse should be alert to signs of immune reconstitution syndrome and advise the patient to seek health care if he or she is feeling sicker with no clear explanation.

Medical and Nursing Management

Treatment Regimen

Protocols on treatment of HIV disease change frequently. The U.S. DHHS periodically convenes a team of HIV specialists from across the country to evaluate the latest evidence and make recommendations that are widely disseminated (DHHS, 2016). In general, ARV medications should be offered to all individuals, regardless of CD4 cell count to reduce the morbidity and mortality of HIV infection (DHHS, 2016). In addition, ARV therapy (ART) is recommended to prevent HIV transmission. Even with these overriding recommendations from DHHS, treatment decisions are individualized based on a number of factors, including $CD4^+$ T-cell count, HIV RNA (viral load), severe symptoms of HIV disease or AIDS, and willingness of the patient to adhere to a lifelong treatment regimen. New HIV medications are easier to take, have fewer adverse reactions, and are effective and potent. Monitoring the DHHS website for updates to the recommendations is essential before caring for patients with HIV/AIDS (DHHS, 2016).

ART may be complex, have major side effects, pose difficulties with regard to adherence, and carry serious potential consequences; these include viral resistance resulting from nonadherence to the medication regimen or suboptimal levels of ARV agents. Adherence to ART facilitates long-term success of initial regimens that are easily tolerated and convenient. Poor adherence allows the development of resistance to ART necessitating the use of less tolerable and more complicated regimens. Patient education about adherence continues to be an essential intervention by nurses. The increasing number of ARV agents (Table 37-2) and the rapid evolution of new information have introduced extraordinary complexity into the treatment of HIV infection in the patient with a resistant virus. The goals of treatment include maximal and sustained suppression of viral load, restoration or preservation of immunologic function, improved quality of life, and reduction of HIV-related morbidity and mortality. The DHHS Guidelines recommend viral load testing at the time of diagnosis of HIV disease and every 3 to 4 months thereafter; $CD4^+$ cell counts should be measured at diagnosis and usually every 3 to 6 months thereafter (DHHS, 2016).

TABLE 37-2 Commonly Used Antiretroviral Agents[a]

Generic Name (Abbreviation) and Trade Names	Food Effect	Adverse Events
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		
emtricitabine (FTC) Emtriva Truvada (FTC + TDF)	Can be taken without regard to meals	Minimal toxicity; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs); combined with tenofovir as part of the PrEP regimen
tenofovir disoproxil fumarate (TDF) Viread Truvada (TDF + FTC)	Can be taken without regard to meals	Asthenia (loss of strength and energy), headache, diarrhea, nausea, vomiting, and flatulence; renal insufficiency; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs)
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
efavirenz (EFV) Sustiva	High-fat/high-caloric meals increase peak plasma concentrations of capsules by 39% and tablets by 79%; take on an empty stomach.	Rash (rare cases of Stevens–Johnson syndrome have been reported); central nervous system symptoms (dizziness, somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired concentration, amnesia, agitation, depersonalization, hallucinations, and euphoria); increased transaminase levels (ALT/AST or liver enzymes); false-positive cannabinoid test; teratogenic
Protease Inhibitors (PIs)		
atazanavir (ATV) Reyataz	Administration with food increases bioavailability. Should be taken with food; avoid taking with antacids.	Indirect hyperbilirubinemia; prolonged PR interval—some patients experienced asymptomatic first-degree AV block; use with caution in patients with underlying conduction defects or on concomitant medications that can cause PR prolongation; hyperglycemia; fat maldistribution, possible increased bleeding episodes in patients with hemophilia
Fusion Inhibitors		
enfuvirtide (T-20) Fuzeon	Injected subcutaneously	Local injection site reactions—almost 100% of patients (pain, erythema, induration, nodules and cysts, pruritus, ecchymosis); increased rate of bacterial pneumonia; hypersensitivity reaction—symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum liver enzymes
CCR5 Antagonists		
maraviroc (MVC) Selzentry	No food effect; take with or without food.	Abdominal pain; cough; dizziness; musculoskeletal symptoms; pyrexia; rash; upper respiratory infections; hepatotoxicity; orthostatic hypotension
Integrase Inhibitors		
raltegravir (RAL) Isentress	Take with or without food.	Nausea, headache; diarrhea; pyrexia; CPK elevation

[a]Regimens should be individualized based on the advantages and disadvantages of each combination, such as pill burden, dosing frequency, toxicities, drug–drug interaction potential, comorbid conditions, and level of plasma HIV-RNA. Complete listing of medications, adverse effects and patient education available at https://aidsinfo.nih.gov/contentfiles/lvguidelines/adultandadolescentgl.pdf
The nurse is advised to refer to pharmacologic resources for additional information.

Medications

More than 28 approved ARV agents, belonging to 6 classes, are available for the design of combination regimens. Effective regimens contain at least three virologically active medications from at least two classes. The six classes currently approved by the FDA are the

- nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs),
- non-nucleoside reverse transcriptase inhibitors (NNRTIs),
- PIs,
- integrase strand transfer inhibitors (INSTIs),
- CCR5 antagonist, and
- fusion inhibitor (see Table 39-2, [DHHS, 2015]).

Each of these medications attacks HIV at different stages of viral replication in the $CD4^+$ lymphocyte.

As new medications are developed and research is completed, the number and types of recommended drug combinations continue to change (DHHS, 2016). In addition, some pharmaceutical companies have combined two to three agents into one tablet or capsule (such as Kaletra, which is a combination of lopinavir and ritonavir) so that a patient may be taking one tablet or capsule that contains two different medications. With a decrease in the number of tablets or capsules that the patient must take ("pill burden"), the patient is more likely to adhere to prescribed regimens and achieve sustained viral suppression. Efforts are underway to develop additional combinations of ARV medications. The first single tablet for once-a-day use was made available in 2006; Atripla combined Sustiva (efavirenz), Emtriva (emtricitabine), and Viread (tenofovir disoproxil fumarate). Today, there are six of these well-tolerated combination pills available. Simplifying treatment regimens and decreasing the number of medications that must be taken each day increase patients' adherence to therapy (DHHS, 2016).

Adherence

It is difficult to predict which patients will adhere to medication regimens. Adherence rates of 95% minimize the risks of developing a resistant virus. Patients should understand that the first regimen prescribed has the best chance for long-term treatment success with minimal impact on daily functioning and prevention of resistance. Individualized plans of care that take into consideration housing and social support issues, in addition to health indicators, are essential. Adherence to the ART plan involves very complex behavior that can change over the duration of the medication regimen. Self-reported adherence measures can distinguish clinically meaningful patterns of medication-taking behaviors; therefore, nurses should ask patients if they are taking their medications as prescribed. Factors associated with nonadherence include active substance abuse, depression, lack of social support, and treatment fatigue. Gender, race, pregnancy, and history of past substance use have not been associated with nonadherence (DHHS, 2016). Box 37-6 summarizes various strategies that health care providers can use to encourage adherence to the treatment regimen. Every health care encounter should be used as an opportunity to briefly review the treatment regimen and identify any new issues.

Patients who elect to interrupt therapy should be counseled that the HIV viral load would increase, usually to pretreatment levels, resulting in an increased risk for transmission to others during risky behaviors, such as unsafe sex and sharing needles. Because of drug toxicities, drug resistance, quality-of-life issues, and the high cost of medications, some patients may choose to take a "drug holiday" or structured treatment interruption. Through an open, honest partnership between the health care provider and the patient, these options can be explored and their effectiveness maximized. Structured intermittent therapy, characterized by alternating short periods on and off medication, appears to be ineffective and may increase mortality.

BOX 37-6 Patient Education

Adhering to the Medication Therapy for HIV

With the advent of one daily pill for treatment for most patients, adherence is significantly simplified. To help ensure adherence with more complicated therapy regimens, you need to be able to:

- Correctly identify each medication, preferably by name.
- State the action of each medication.
- State the correct times that medication is to be taken.
- Identify special guidelines to follow when taking medications (e.g., with meals, on an empty stomach, medications that are not to be taken together).
- Demonstrate methods of tracking and storage of the medication regimen and use reminders such as beepers and/or pillboxes.
- Identify specific laboratory tests, such as viral load, that are necessary to monitor the effectiveness of the medication regimen.
- List expected side effects of each medication.
- Identify side effects reportable to health care providers.
- Explain the importance of and necessity for adherence.
- Demonstrate correct administration of intramuscular, subcutaneous, or IV medications.
- Demonstrate correct use and safe disposal of needles, syringes, and other IV equipment.
- Discuss episodes of nonadherence to the medication regimen.

Evaluation of Therapy

Viral load tests evaluate the results of therapy (DHHS, 2016). Viral load levels should be measured immediately before initiation of ART and again after 2 to 8 weeks. In most patients, adherence to a regimen of potent ARV agents should result in a significant decrease in the viral load by 2 to 8 weeks. The viral load should continue to decline over the following weeks, and, in most individuals, it will drop below detectable levels (currently defined as less than 50 RNA copies/mL) by 16 to 20 weeks. The rate of viral load decline toward undetectable levels is affected by the baseline T-cell count, the initial viral load, the potency of the medication, adherence to the medication regimen, prior exposure to ARV agents, and the presence of any OIs. The confirmed absence of a viral load response in an adherent patient should prompt the health care team to re-evaluate the regimen and check for resistant mutations. The $CD4^+$ count should increase by 100 to 150 cells/mm^3 per year, with an accelerated response in the first 3 months (DHHS, 2016).

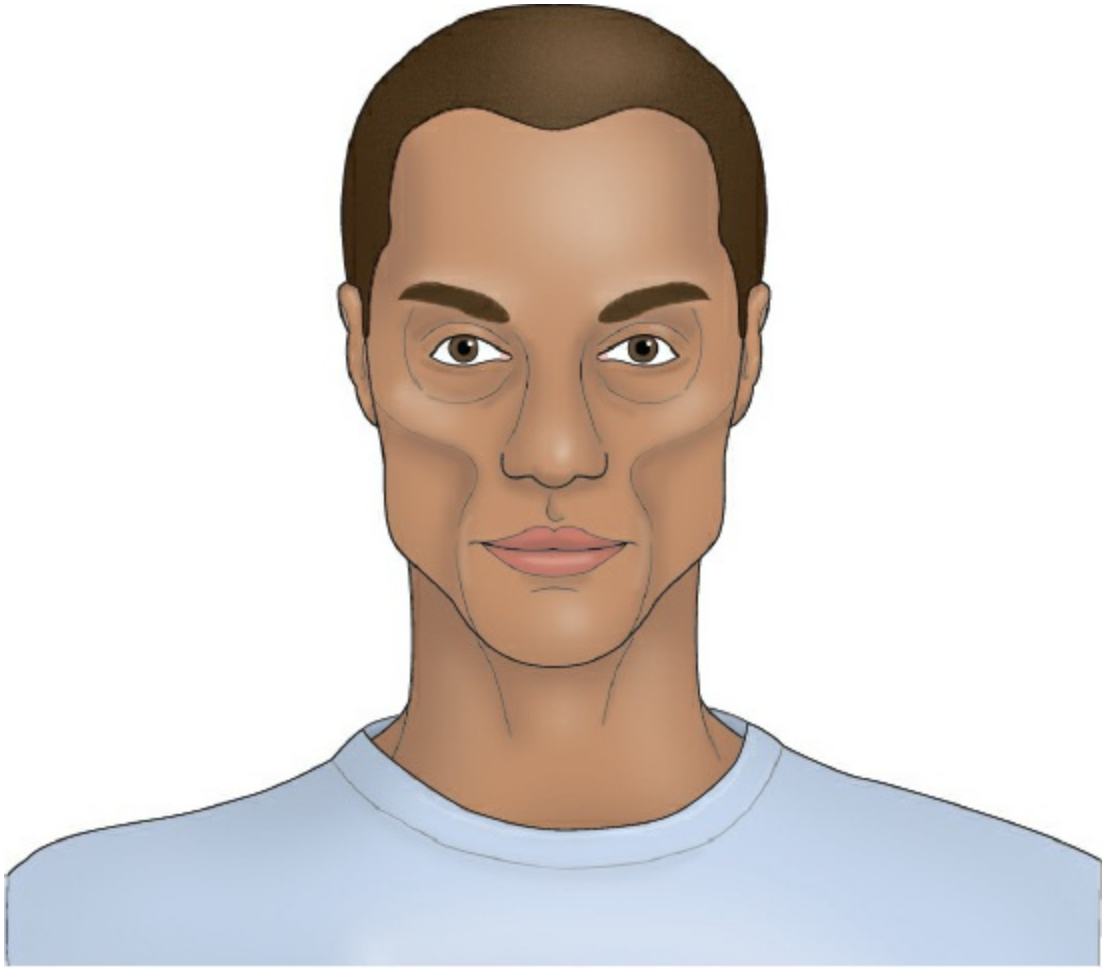

FIGURE 37-4 Facial lipoatrophy.

Side Effects

Many of the ARV agents that prolong life may simultaneously cause lipodystrophy syndrome and place the person at risk for early-onset hypercholesterolemia, heart disease, and diabetes. Fat redistribution syndrome, which consists of lipoatrophy (Fig. 37-4), lipohypertrophy, or both in localized areas, is also known as *lipodystrophy syndrome.* This syndrome is one of the most frequent systemic side effects associated with the use of ARV medications, especially PIs, and affects up to 58% of patients (Sax et al., 2014). Many people who have lipodystrophy experience an increase in fat loss in the legs, arms, face, or a buildup of fat around the abdomen and at the base of the neck, or both. Patients also may experience an increase in breast size. All of these adverse effects can have a profound impact on a patient's psychological well-being due to the increased stress of stigmatization.

Facial wasting, characterized as a sinking of the cheeks, eyes, and temples caused by the loss of fat tissue under the skin, may be treated by injectable fillers such as poly-L-lactic acid (Sculptra).

Drug Resistance

Drug resistance can be broadly defined as the ability of pathogens to withstand the effects of medications that are intended to be toxic to them. Resistance develops because of spontaneous genetic mutation of the pathogens or in response to exposure to the

medication. Factors associated with the development of drug resistance include serial monotherapy (taking one medication at a time), common during early clinical trials, inadequate suppression of virus replication with suboptimal treatment regimens, difficulty with adherence to complex and toxic regimens, and initiation of therapy late in the course of HIV infection. HIV-1 may find refuge beyond physiologic protective adaptations, such as behind the blood–brain barrier, where diminished drug concentrations in the CNS might induce the development of drug-resistant mutants. HIV-1 persists in lymphoid tissue even in people who appear to have responded well to antiviral therapy, another factor that is limiting discovery of a cure or vaccine for HIV.

Resistance testing has a number of limitations and is more helpful in the elimination of ARV agents rather than in deciding which ones should be used. Deciding whether a medication regimen is effective or ineffective is a complex phenomenon. Some patients demonstrate inconsistent results on virologic, immunologic, and clinical parameters. In general, virologic failure occurs first, followed by immunologic failure, and, finally, by clinical progression. These events may be separated by months to years (DHHS, 2015). Genotypic testing allows detection of amino acid mutations that are either proved or suspected to be associated with phenotypic resistance. Phenotypic testing predicts the susceptibility of resistant virus to inhibition by a particular drug (DHHS, 2016).

In addition to resistance testing, several factors must be considered in choosing medications for a new regimen, once the prior regimen has failed. These factors include the patient's treatment history, viral load, and medication tolerance; the likelihood of the patient's adhering to the medication regimen; and concomitant medical conditions or medications. Resistance testing is of greatest value when it is performed before drugs are discontinued or immediately afterward (within 4 weeks). Most HIV providers perform genotype testing during the initial diagnosis stage as some patients with HIV are infected with a resistant virus. Drug resistance testing is not advised for patients with a viral load of less than 1,000 copies/mL because amplification of the virus is unreliable (DHHS, 2016).

Vaccines

Vaccine research for HIV has two potential areas of application: prevention of new infections and therapy for those already infected with HIV (therapeutic vaccine). Since HIV-1 was discovered, researchers have been working to develop a vaccine. A vaccine is a substance that triggers the production of antibodies to destroy the offending organism. Creation of an HIV vaccine is feasible, but researchers have had difficulty finding an adequate animal model in which to test new vaccines. Because HIV can attack the human immune system as either cell-free or cell-associated virus, a vaccine against HIV must be capable of producing both antibodies and cytotoxic lymphocytes.

Treatment of Opportunistic Infections

Pneumocystis Pneumonia

In the past several years, many advances have been made in the treatment of PCP. TMP-SMZ (Bactrim, Septra), the treatment of choice for PCP in patients with AIDS and in immunocompromised patients without HIV infection, is available in both IV and oral preparations. TMP-SMZ is an antibacterial agent used to treat various organisms causing infection. People with HIV infection who have a T-cell count of less than 200 cells/mm^3

should receive chemoprophylaxis against PCP with TMP-SMZ. PCP prophylaxis can be safely discontinued in patients who are responding to highly active ART (HAART) with a sustained increase in T lymphocytes. TMP-SMZ also confers cross-protection against toxoplasmosis and some common respiratory bacterial infections. Patients with AIDS who are treated with TMP-SMZ experience a high incidence of adverse effects, such as fever, rashes, leukopenia (decreased WBC count), thrombocytopenia (decreased platelet count), and kidney dysfunction. Reintroduction of TMP-SMZ using a gradually increasing dose (desensitization) may be successful in up to 70% of patients (DHHS, 2015).

Pentamidine (Pentacarinat, Pentam 300, NebuPent), an antiprotozoal medication, is used as an alternative agent for combating PCP. Avoid intramuscular administration because of the potential for painful formation of a sterile abscess. In addition, IV pentamidine can cause severe hypotension if it is administered too rapidly. Other adverse effects include impaired glucose metabolism leading to the development of diabetes mellitus from damage to the pancreas, kidney damage, liver dysfunction, and neutropenia. Initially, the success of aerosolized pentamidine led to its use as a treatment for mild to moderate PCP. However, it has proved to be less effective and more costly than TMP-SMZ, and early relapses are common. Because of these limitations, aerosolized pentamidine should not be used (DHHS, 2016).

Mycobacterium Avium Complex

Chemoprophylaxis against disseminated MAC disease is indicated for people infected with HIV whose T-cell count is lower than 50 cells/mm^3. Treatment for MAC infections involves use of either clarithromycin (Biaxin) or azithromycin (Zithromax). Secondary prophylaxis for disseminated MAC may be discontinued in patients who have sustained increases in CD4 counts (at least 100 cells/mm^3) in response to HAART, have completed 12 months of MAC therapy, and have no signs or symptoms attributable to MAC. Primary prophylaxis for disseminated MAC may be discontinued in patients who have responded to HAART with CD4 counts of 100 cells/mm^3 or higher for at least 3 months and may be reintroduced if counts decrease to 50 to 100 cells/mm^3 (DHHS, 2016).

Cytomegalovirus Retinitis

Retinitis caused by CMV is a leading cause of blindness in patients with AIDS. Prophylaxis with oral ganciclovir may be considered for people infected with HIV who have CD4$^+$ T-cell counts of less than 50 cells/mm^3. Two antiviral agents, ganciclovir (DHPG, Cytovene, Vitrasert) and foscarnet (Foscavir), offer effective treatment but not a cure for CMV retinitis. Because ganciclovir and foscarnet do not kill the virus but rather control its growth, they must be taken for life. Relapse rates associated with the two agents are similar. Discontinuation of the medication is associated with the relapse of retinitis within 1 month.

A common adverse reaction to ganciclovir is severe neutropenia, which limits the concomitant use of zidovudine (AZT, Retrovir). Intravitreal injections of ganciclovir have been effective for patients who cannot tolerate systemic ganciclovir because of severe neutropenia, infection at the venous access site, or the need to take zidovudine. Zidovudine may be given with foscarnet (Foscavir). Common adverse reactions to foscarnet are nephrotoxicity, including acute kidney failure, and electrolyte imbalances, including

hypocalcemia, hyperphosphatemia, and hypomagnesemia, which can be life-threatening. Other common adverse effects include seizures, GI disturbances, anemia, phlebitis at the infusion site, and low back pain. Possible bone marrow suppression (producing a decrease in WBC and platelet counts), oral candidiasis, and liver and kidney impairments require close patient monitoring.

Other Infections

Oral acyclovir, famciclovir, or valacyclovir may be used to treat infections caused by herpes simplex or herpes zoster. Patients coinfected with HSV and HIV are more likely to transmit and infect others if not treated for herpes. Esophageal or oral candidiasis is treated topically with clotrimazole (Mycelex) oral troches or nystatin suspension. Chronic refractory candidiasis (thrush) or esophageal involvement is treated with ketoconazole (Nizoral) or fluconazole (Diflucan).

Antidiarrheal Therapy

Although many forms of diarrhea respond to treatment, it is not unusual for this condition to recur and become a chronic problem for the patient with HIV. Therapy with octreotide acetate (Sandostatin), a synthetic analog of somatostatin, has been shown to be effective in managing chronic severe diarrhea. High concentrations of somatostatin receptors have been found in the GI tract and in other tissues. Somatostatin inhibits many physiologic functions, including GI motility and intestinal secretion of water and electrolytes.

Chemotherapy

Kaposi Sarcoma

Usually management of KS is difficult because of the variability of symptoms and the organ systems involved. KS is rarely life-threatening except when there is pulmonary or GI involvement. The treatment goals are to reduce symptoms by decreasing the size of the skin lesions, to reduce discomfort associated with edema and ulcerations, and to control symptoms associated with mucosal or visceral involvement. No one treatment has been shown to increase survival. Localized treatment includes surgical excision of the lesions or application of liquid nitrogen to local skin lesions, and injections of intraoral lesions with dilute vinblastine. Injection of intraoral lesions has been associated with local pain and skin irritation. Radiation therapy is effective as a palliative measure to relieve localized pain due to tumor mass (especially in the legs) and for KS lesions that are in sites such as the oral mucosa, conjunctiva, face, and soles of the feet.

Interferon is known for its antiviral and antitumor effects. Patients with cutaneous KS treated with alpha-interferon have experienced tumor regression and improved immune system function. Positive responses have been observed in 30% to 50% of patients, with the best responses seen in those with limited disease and no OIs. Alpha-interferon is administered by the IV, intramuscular, or subcutaneous route. Patients may self-administer interferon at home or receive interferon in an outpatient setting. Rituximab infusions are monoclonal antibodies effective in the treatment of KS and non-Hodgkin lymphoma but may cause a fatal infusion reaction and are administered in the inpatient setting so that the patient can be observed during administration.

Lymphoma

Successful treatment of AIDS-related lymphomas has been limited because of the rapid progression of these malignancies. Combination chemotherapy and radiation therapy regimens may produce an initial response, but it is usually short-lived. Because standard regimens for non-AIDS lymphomas have been ineffective, many clinicians suggest that AIDS-related lymphomas should be studied as a separate group in clinical trials.

Antidepressant Therapy

Treatment for depression in people with HIV infection involves psychotherapy integrated with pharmacotherapy. If depressive symptoms are severe and of sufficient duration, treatment with antidepressants may be initiated. Antidepressants, such as imipramine (Tofranil), desipramine (Norpramin), and fluoxetine (Prozac), may be used because these medications also alleviate the fatigue and lethargy associated with depression. A psychostimulant, such as methylphenidate (Ritalin), may be used in low doses in patients with neuropsychiatric impairment. Electroconvulsive therapy may be an option for patients with severe depression who have not responded to pharmacologic interventions.

Nutrition Therapy

Malnutrition increases the risk for infection and may increase the incidence of OIs. Nutrition therapy should be integrated into the overall management plan and should be tailored to meet the nutritional needs of the patient, whether by oral diet, enteral tube feedings, or parenteral nutritional support, if needed. As with all patients, a healthy diet is essential for the patient with HIV infection. For all patients with AIDS who experience unexplained weight loss, calorie counts should be obtained to evaluate nutritional status and initiate appropriate therapy. The goal is to maintain the ideal weight and, when necessary, to increase weight.

Appetite stimulants have been used successfully in patients with AIDS-related anorexia. Megestrol acetate (Megace), a synthetic oral progesterone preparation used to treat breast cancer, promotes significant weight gain and inhibits cytokine IL-1 synthesis. In patients with HIV infection, it increases body weight primarily by increasing body fat stores. Dronabinol (Marinol), which is a synthetic tetrahydrocannabinol (THC), the active ingredient in marijuana, has been used to relieve nausea and vomiting associated with cancer chemotherapy. Many states now allow the use of medical marijuana for patients who are HIV-positive.

Oral supplements may be used to improve diets that are deficient in calories and protein. Ideally, oral supplements should be lactose-free as many people with HIV infection are lactose intolerant. Parenteral nutrition is the final option because of its prohibitive cost and associated risks, including risk of infections.

Complementary and Alternative Medicine (CAM)

Traditional Western or allopathic medicine focuses on the treatment of disease. These treatments or interventions are taught in medical and nursing schools and are used by health care providers in the care of patients. Complementary and alternative medicine (CAM) is often viewed as consisting of unconventional and unorthodox treatments or

interventions. These modalities and therapies stress the need to treat the whole person, recognizing the interaction of the body, mind, and spirit. People with HIV infection report substantial use of CAM for symptom management. The use of CAM in patients with HIV infection and AIDS often results because of disillusionment with standard medical treatment, which to date has provided no cure. Combined with traditional therapies, CAM may improve the patient's overall well-being. However, there can be adverse drug–drug interactions between certain CAM therapies (e.g., St. John wort) and some ARV medications (DHHS, 2016).

CAM can be divided into four categories:

- Spiritual or psychological therapies, which may include humor, hypnosis, faith healing, guided imagery, and positive affirmations.
- Nutritional therapies, which may include vegetarian or macrobiotic diets or supplements of vitamin C or beta-carotene. Also Chinese herbs are used, in addition to compound Q (a Chinese cucumber extract) and *Momordica charantia* (bitter melon).
- Drug and biologic therapies, including medications and other substances not approved by the FDA. Examples are *N*-acetylcysteine, pentoxifylline (Trental), and 1-chloro-2, 4-dinitrobenzene.
- Treatment with physical forces and devices, which may include acupuncture, acupressure, massage therapy, reflexology, therapeutic touch, and yoga.

Although there is insufficient research on the effects of CAM, a growing body of literature reports benefits for modalities involving nutrition, exercise, psychosocial treatment, and Chinese medicine.

Many patients who use these therapies do not report use of CAM to their health care providers. To obtain a complete health history, the nurse should ask about the patient's use of alternative therapies, including all over-the-counter, nutritional supplements and vitamins. Patients may need to be encouraged to report their use of CAM to their primary health care provider. Problems may arise, for example, when patients are using CAM while participating in clinical drug trials; alternative therapies can have significant adverse side effects, making it difficult to assess the effects of the medications in the clinical trial. The nurse needs to become familiar with the potential adverse side effects of these therapies. The nurse who suspects that CAM is causing a side effect needs to discuss this with the patient, the alternative therapy provider, and the primary health care provider. It is important for the nurse to view CAM with an open mind and to try to understand the importance of this treatment to the patient. This approach will improve communication with the patient and reduce conflict.

NURSING PROCESS
The Patient with AIDS

The nursing care of patients with AIDS is challenging because of the potential for any organ system to be the target of infections or cancer. In addition, this disease is complicated by many emotional, social, and ethical issues.

ASSESSMENT

Nursing assessment includes identification of potential risk factors, including a history of risky sexual practices or IV/injection drug use. The nurse assesses the patient's physical and psychological status and should explore all factors affecting the immune system and its function.

NUTRITIONAL STATUS

The nurse assesses nutritional status by obtaining a dietary history and identifying factors that may interfere with oral intake, such as anorexia, nausea, vomiting, oral pain, or difficulty swallowing. In addition, the nurse evaluates the patient's ability to purchase and prepare food. Weight history (i.e., changes over time); anthropometric measurements; and levels of blood urea nitrogen (BUN), serum protein, albumin, and transferrin provide objective measurements of nutritional status.

Nursing Alert

Transferrin, which is synthesized in the liver, is a transport protein that regulates iron absorption by transporting it from the intestines to the bloodstream; therefore, it may be monitored to evaluate iron saturation of the blood. Low levels of transferrin impair hemoglobin production, resulting in anemia. Transferrin levels also decrease with liver disease and poor protein intake, thus this laboratory test may be ordered to assess liver function and nutritional status. High levels of transferrin are associated with immune function and the ability to deal with infection. Normal transferrin levels for adults are 250 to 425 mg/dL or 2.5 to 4.2 g/L. Decreased transferrin levels are seen in microcytic (small red blood cells) anemia, protein calorie malnutrition, chronic infection, acute liver disease, and nephrotic disease (protein loss in urine) (Minchella et al., 2015).

SKIN INTEGRITY

The nurse inspects the skin and mucous membranes daily for evidence of breakdown, ulceration, or infection. Monitoring the oral cavity for redness, ulcerations, and the presence of creamy-white adherent patches detects candidiasis. Assessment of the perianal

area for excoriation and infection in patients with profuse diarrhea is important. Cultures of wounds may be indicated and performed by the nurse to identify infectious organisms, especially methicillin-resistant *Staphylococcus aureus* (MRSA).

RESPIRATORY STATUS

The nurse assesses respiratory status by monitoring the patient for cough, sputum production (i.e., amount and color), dyspnea on exertion, orthopnea, tachypnea, and chest pain. Auscultation detects the quality of breath sounds. Other measures of pulmonary function include chest x-ray results, arterial blood gas values, pulse oximetry, and pulmonary function tests.

NEUROLOGIC STATUS

The nurse determines neurologic status by assessing level of consciousness; orientation to person, place, and time; and memory lapses. Assessment of mental status as early as possible during initial care provides a baseline. The nurse assesses the patient for sensory deficits (visual changes, headache, or numbness and tingling in the extremities), motor involvement (altered gait, paresis [slight or partial paralysis], or paralysis), and seizure activity.

FLUID AND ELECTROLYTE BALANCE

Fluid and electrolyte status is determined by examining the skin and mucous membranes for turgor and dryness. Dehydration may be indicated by increased thirst, decreased urine output, postural hypotension, weak and rapid pulse, and urine-specific gravity of 1.025 or more. Electrolyte imbalances, such as decreased serum sodium, potassium, calcium, magnesium, and chloride, typically result from profuse diarrhea. The nurse assesses the patient for signs and symptoms of electrolyte deficits, including decreased mental status, muscle twitching, muscle cramps, irregular pulse, nausea, vomiting, and shallow respirations.

KNOWLEDGE LEVEL

The nurse evaluates the patient's level of knowledge about the disease and the modes of disease transmission. In addition, the nurse assesses the level of knowledge of family and friends. The patient's psychological reaction to the diagnosis of HIV infection or AIDS is important to explore. Reactions vary among patients and may include denial, anger, fear, shame, withdrawal from social interactions, and depression. The nurse should identify the patient's resources for support.

DIAGNOSIS

The list of potential nursing diagnoses is extensive because of the complex nature of this disease. However, based on assessment data, major nursing diagnoses for the patient may include the following:

- Impaired skin integrity related to cutaneous manifestations of HIV infection, excoriation, and diarrhea
- Diarrhea related to enteric pathogens, HIV infection, or ARV medications
- Risk for infection related to immunodeficiency
- Activity intolerance related to weakness, fatigue, malnutrition, impaired fluid and electrolyte balance, and hypoxia associated with pulmonary infections
- Disturbed thought processes related to shortened attention span, impaired memory, confusion, and disorientation associated with HIV-related cognitive decline
- Ineffective airway clearance related to PCP, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue
- Pain related to impaired perianal skin integrity secondary to diarrhea, KS, and peripheral neuropathy
- Imbalanced nutrition, less than body requirements, related to decreased oral intake
- Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
- Anticipatory grieving related to changes in lifestyle and roles and unfavorable prognosis
- Deficient knowledge related to HIV infection, means of preventing HIV transmission, and self-care

Based on the assessment data, possible complications may include the following:

- OIs
- Impaired breathing or respiratory failure
- Wasting syndrome and fluid and electrolyte imbalance
- Adverse reaction to medications

PLANNING

Goals for the patient may include achievement and maintenance of skin integrity, resumption of usual bowel patterns, absence of infection, improved activity tolerance, improved thought processes, improved airway clearance, increased comfort, improved nutritional status, increased socialization, expression of grief, increased knowledge regarding disease prevention and self-care, and absence of complications.

NURSING INTERVENTIONS

PROMOTING SKIN INTEGRITY

The nurse routinely assesses the skin and oral mucosa for changes in appearance, location and size of lesions, and evidence of infection and breakdown. The nurse assists immobile patients to change position every 1 to 2 hours. Devices such as alternating-pressure mattresses and low-air-loss beds are used to prevent skin breakdown. Patients should avoid scratching; use nonabrasive, nondrying soaps; and apply nonperfumed skin moisturizers to dry skin surfaces. Regular oral care is also encouraged.

The nurse applies medicated lotions, ointments, and dressings to affected skin surfaces as prescribed. Adhesive tape is avoided. Protect patient's skin from friction and rubbing by keeping bed linens free of wrinkles and avoiding tight or restrictive clothing. The nurse advises patients with foot lesions to wear cotton socks and shoes that do not cause the feet to perspire. Antipruritic, antibiotic, and analgesic agents are administered as prescribed.

The nurse assesses the perianal region frequently for impairment of skin integrity and infection. The patient should keep the area as clean as possible. The perianal area should be cleaned after each bowel movement with nonabrasive soap and water to prevent further excoriation and breakdown of the skin. If the area is very painful, soft cloths or cotton sponges may be less irritating than washcloths. In addition, sitz baths or gentle irrigation may facilitate cleaning and promote comfort. It is important to dry the area thoroughly after cleaning. Topical lotions or ointments may be prescribed to promote healing. If infection is suspected, wounds should be cultured to initiate the appropriate antimicrobial treatment. The nurse assists debilitated patients in maintaining hygienic practices.

PROMOTING USUAL BOWEL PATTERNS

The nurse assesses bowel patterns for diarrhea. The nurse monitors the frequency and consistency of stools and the patient's reports of abdominal pain or cramping associated with bowel movements. Factors that exacerbate frequent diarrhea should be avoided. The nurse measures the quantity and volume of liquid stools to document fluid volume losses and obtains stool cultures to identify pathogenic organisms.

The nurse counsels the patient about ways to decrease diarrhea. Recommendations may include restricting oral intake to rest the bowel during periods of acute inflammation associated with severe enteric infections. As the patient's dietary intake is increased, the patient avoids foods that act as bowel irritants, such as raw fruits and vegetables, popcorn, carbonated beverages, and spicy foods. Small, frequent meals help to prevent abdominal distention. The nurse administers prescribed medications, such as anticholinergics, antispasmodics, or opioids, which decrease diarrhea by decreasing intestinal spasms and motility. Administering antidiarrheal agents on a regular schedule may be more beneficial than administering them on an as-needed basis. Also antibiotics and antifungal agents may be prescribed to combat pathogens identified by stool cultures. The nurse also assesses the self-care strategies being used by the patient to control diarrhea, including the use of probiotics.

PREVENTING INFECTION

The nurse instructs the patient and caregivers to monitor for signs and symptoms of infection: fever; chills; night sweats; cough with or without sputum production; shortness of breath; difficulty breathing; oral pain or difficulty swallowing; creamy-white patches in the oral cavity; unexplained weight loss; swollen lymph nodes; nausea; vomiting; persistent diarrhea; frequency, urgency, or pain on urination; headache; visual changes or memory lapses; redness, swelling, or drainage from skin wounds; and vesicular lesions on

the face, lips, or perianal area. The nurse monitors laboratory test results that indicate infection, such as the WBC count and differential. Culture specimens of wound drainage, skin lesions, urine, stool, sputum, and blood as well as a culture from the patient's mouth are obtained to identify pathogenic organisms and the most appropriate antimicrobial therapy. The nurse instructs the patient to avoid others with active infections, such as upper respiratory infections.

IMPROVING ACTIVITY TOLERANCE

The nurse assesses activity tolerance by monitoring the patient's ability to ambulate and perform activities of daily living. Patients may be unable to maintain their usual levels of activity because of weakness, fatigue, shortness of breath, dizziness, and neurologic involvement. Assistance in planning daily routines that maintain a balance between activity and rest may be necessary. In addition, patients benefit from instructions about energy conservation techniques, such as sitting while washing or while preparing meals. Personal items that are used frequently should be kept within the patient's reach. Measures, such as relaxation and guided imagery, may be beneficial because they decrease anxiety, which contributes to weakness and fatigue.

Collaboration with other members of the health care team may uncover other factors associated with increasing fatigue and strategies to address them. Physical therapists participate in the plan of care of patients with AIDS at long-term care facilities to increase endurance and tolerance for activities of daily learning. If fatigue is related to anemia, administering epoetin alfa (Epogen) as prescribed may relieve fatigue and increase activity tolerance.

MAINTAINING THOUGHT PROCESSES

The nurse assesses the patient for alterations in mental status that may be related to neurologic involvement, metabolic abnormalities, infection, side effects of treatment, and coping mechanisms. Manifestations of neurologic impairment may be difficult to distinguish from psychological reactions to HIV infection, such as anger and depression.

If the patient experiences altered mental or cognitive status, the nurse instructs family members to speak to the patient in simple, clear language and give the patient sufficient time to respond to questions. Family members orient the patient to the daily routine by talking about what is taking place during daily activities. They are encouraged to provide the patient with a regular daily schedule for medication administration, grooming, meal times, bedtimes, and awakening times. Posting the schedule in a prominent area (e.g., on the refrigerator), providing nightlights for the bedroom and bathroom, and planning safe leisure activities allow the patient to maintain a regular routine in a safe manner. The nurse encourages activities that the patient previously enjoyed. These should be easy to accomplish and fairly short in duration. Around-the-clock supervision may be necessary, and strategies can be implemented to prevent the patient from engaging in potentially dangerous activities, such as driving or using the stove. The nurse uses strategies for improving or maintaining functional abilities and for providing a safe environment for

patients with HIV-related cognitive decline.

IMPROVING AIRWAY CLEARANCE

At least daily, the nurse assesses respiratory status, including rate, rhythm, use of accessory muscles, breath sounds, mental status, and skin color. Any cough and the quantity and characteristics of sputum are documented. The nurse obtains sputum specimens for infectious organism analysis as indicated. Pulmonary therapy (coughing, deep breathing, postural drainage, percussion, and vibration) as often as every 2 hours may be required to prevent stasis of secretions and promote airway clearance. Because of weakness and fatigue, many patients require assistance in attaining a position (such as a semi-Fowler position) that facilitates breathing and airway clearance. The nurse evaluates fluid volume status so that adequate hydration can be maintained. Daily intake is 3 L of fluid unless contraindicated because of renal or cardiac disease. Humidified oxygen may be prescribed, and nasopharyngeal or tracheal suctioning, intubation, and mechanical ventilation may be necessary to maintain adequate ventilation.

RELIEVING PAIN AND DISCOMFORT

The nurse assesses the patient for the quality and severity of pain associated with impaired perianal skin integrity, the lesions of KS, and peripheral neuropathy. In addition, the nurse explores the effects of pain on elimination, nutrition, sleep, affect, and communication, along with exacerbating and relieving factors. Cleaning the perianal area, as previously described, can promote comfort. Topical anesthetics or ointments may be prescribed. The nurse increases patient comfort while sitting with the use of soft cushions or foam pads. If necessary, systemic analgesic agents also may be prescribed. Frequently pain from KS is described as a sharp, throbbing pressure and heaviness if lymphedema is present. Pain management may include use of NSAIDs and opioids, plus nonpharmacologic approaches, such as relaxation techniques. When NSAIDs are administered to patients who are receiving zidovudine, the nurse is aware that hepatic and hematologic status is evaluated.

The patient with pain related to peripheral neuropathy frequently describes it as burning, numbness, and “pins and needles.” Pain management approaches may include opioids, tricyclic antidepressants, and elastic compression stockings to equalize pressure. Tricyclic antidepressants potentiate the actions of opioids and can be used to relieve pain without increasing the dose of the opioid. Ongoing assessment by the nurse of the use and potential abuse of opioids is part of the collaborative model of pain management.

IMPROVING NUTRITIONAL STATUS

The nurse assesses nutritional status by monitoring weight, dietary intake and output, and levels of serum albumin, BUN, protein, and transferrin. The patient is assessed for factors that interfere with oral intake, such as anorexia, candidal infection, nausea, pain, weakness, fatigue, and lactose intolerance. Based on the results of assessment, the nurse implements specific measures to facilitate oral intake. A dietitian helps to determine the

patient's nutritional requirements.

Control of nausea and vomiting with antiemetic medications administered on a regular basis may increase the patient's dietary intake. Inadequate food intake resulting from pain caused by oral lesions or a sore throat may be managed by administering prescribed opioids and viscous lidocaine. Additionally, the nurse encourages the patient to eat foods that are easy to swallow and to avoid rough, spicy, or sticky food items and foods that are excessively hot or cold. The patient should perform oral hygiene before and after meals; in the debilitated patient with AIDS, the nurse will assist in these activities. If fatigue and weakness interfere with intake, the nurse encourages the patient to rest before meals. If the patient is hospitalized, meals should be scheduled so that they do not occur immediately after painful or unpleasant procedures. The nurse advises the patient with diarrhea and abdominal cramping to avoid foods that stimulate intestinal motility and abdominal distention, such as fiber-rich foods or lactose, if the patient is intolerant to lactose. The nurse instructs the patient about ways to enhance the nutritional value of meals. Supplements, such as puddings, powders, milkshakes, and Advera (a nutritional product specifically designed for people with HIV infection or AIDS) also may be useful. Patients who cannot maintain their nutritional status through oral intake may require enteral feedings or parenteral nutrition.

DECREASING THE SENSE OF ISOLATION

People with AIDS are at risk for double stigmatization. Judgments about disease acquisition and lifestyle choices isolate many patients who are HIV-positive. Many people with AIDS are young adults at a developmental stage that is usually associated with establishing intimate relationships, personal goals, and career goals, as well as having and raising children. Their focus changes as they are faced with a disease that threatens their quality of life with no cure. In addition, they may be forced to reveal hidden lifestyles or behaviors to family, friends, coworkers, and health care providers. As a result, people with HIV infection may be overwhelmed with emotions such as anxiety, guilt, shame, and fear. They also may be faced with multiple losses, such as loss of financial security, normal roles and functions, self-esteem, privacy, ability to control bodily functions, ability to interact meaningfully with the environment, and sexual functioning, as well as rejection by sexual partners, family, and friends. Some patients may harbor feelings of guilt because of their lifestyle or because they may have infected others in current or previous relationships. Other patients may feel anger toward sexual partners who transmitted the virus to them. Infection control measures used in the hospital or at home may further contribute to the patient's emotional isolation. Any or all of these stressors may cause the patient with AIDS to withdraw both physically and emotionally from social contact.

Nurses are in a key position to provide an atmosphere of acceptance and understanding for people with AIDS and their families and partners. The nurse assesses the patient's usual level of social interaction as early as possible to provide a baseline for monitoring changes in behaviors that suggest social isolation (e.g., decreased interaction with staff or family, hostility, noncompliance). Patients are encouraged to express feelings of isolation

and loneliness with the assurance that these feelings are not unique or abnormal.

Providing information about how to protect themselves and others may help patients avoid social isolation. The nurse reassures patients, family, and friends that AIDS is not spread through casual contact. Patient care conferences that address the psychosocial issues associated with AIDS may help sensitize the health care team to patients' needs.

COPING WITH GRIEF

The nurse helps the patient verbalize feelings and explore and identify resources for support. In addition, the nurse works with the patient to establish mechanisms for coping, especially when the patient is grieving anticipated losses. The patient is encouraged to maintain contact with family, friends, and coworkers and to use local or national AIDS support groups and hotlines. If possible, losses are identified and addressed. The nurse encourages the patient to continue usual activities whenever possible. Consultations with mental health counselors are useful for many patients.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Opportunistic Infections. Patients who are immunosuppressed are at risk for OIs. Therefore, anti-infective agents may be prescribed and laboratory tests obtained to monitor their effect. The nurse should report signs and symptoms of OIs, including fever, malaise, difficulty breathing, nausea or vomiting, diarrhea, difficulty swallowing, and any occurrences of swelling or discharge.

Respiratory Failure. Impaired breathing is a major complication that increases the patient's discomfort and anxiety and may lead to respiratory and cardiac failure. The nurse monitors respiratory rate and pattern and auscultates the lungs for abnormal breath sounds. The patient should report shortness of breath and increasing difficulty in carrying out usual activities. The nurse monitors pulse rate and rhythm, blood pressure, and oxygen saturation. Suctioning, if indicated, and oxygen therapy ensure an adequate airway and prevent hypoxia. Mechanical ventilation may be necessary for the patient who cannot maintain adequate ventilation because of pulmonary infection, fluid and electrolyte imbalance, or respiratory muscle weakness. Arterial blood gas values will be obtained to guide ventilator management. Instruct intubated patients in methods to allow communication with the nurse and others. The patient receiving mechanical ventilation should be assessed regarding coping with the stress associated with intubation and ventilator assistance. The possible need for mechanical ventilation in the future should be discussed early in the course of the disease, when the patient is able to make known his or her preferences about treatment. The use of mechanical ventilation should be consistent with the patient's decisions about end-of-life treatment.

Cachexia and Wasting. Wasting syndrome, and fluid and electrolyte disturbances, including dehydration, are common complications of HIV infection and AIDS. The nurse evaluates the patient's nutritional and electrolyte status by monitoring weight gains

or losses, skin turgor, ferritin (blood cell protein that contains iron) levels, hemoglobin, hematocrit, and electrolyte levels. Fluid and electrolyte status is monitored on an ongoing basis; fluid intake and output and urine-specific gravity may be monitored daily if the patient is hospitalized with complications. The nurse assesses the skin for dryness and adequate turgor. Vital signs are monitored for decreased systolic blood pressure or increased pulse rate on sitting or standing. The nurse documents and reports signs and symptoms of electrolyte disturbances, such as muscle cramping, weakness, irregular pulse, decreased mental status, nausea, and vomiting to the provider. The nurse also monitors serum electrolyte values and reports abnormalities.

The nurse helps the patient select foods that will replenish electrolytes, such as oranges and bananas (potassium) and cheese and soups (sodium). Fluid intake is 3 L or more per day, unless contraindicated, to replace fluid lost with diarrhea, and measures to control diarrhea are initiated. If fluid and electrolyte imbalances persist, the nurse administers IV fluids and electrolytes as prescribed. The nurse also monitors effects of parenteral therapy.

Side Effects of Medications. Adverse reactions are of concern in patients who receive many medications to treat HIV infection or its complications. Many medications can cause severe toxic effects. The nurse provides information about the purpose of the medications, their correct administration, side effects, and strategies to manage or prevent side effects. Patients and their caregivers need to know which signs and symptoms of side effects should be reported immediately to their primary health care provider (see Table 37-2).

In addition to medications used to treat HIV infection, other medications that may be required include opioids, tricyclic antidepressants, and NSAIDs for pain relief; medications for treatment of OIs; antihistamines (diphenhydramine) for relief of pruritus; acetaminophen or aspirin for management of fever; and antiemetic agents for control of nausea and vomiting. Concurrent use of these medications can cause many drug interactions, resulting in hepatic and hematologic abnormalities. Therefore, careful monitoring of laboratory test results is essential.

During each contact with the patient, it is important for the nurse to ask not only about side effects but also about how well the patient is adhering to the medication regimen.

TEACHING PATIENTS SELF-CARE

The nurse instructs patients, families, and friends about the routes of transmission of HIV. As discussed earlier, the nurse discusses precautions the patient can use to avoid transmitting HIV sexually or through sharing of blood. Patients and their families or caregivers must receive instructions about how to prevent disease transmission, including handwashing techniques and methods for safely handling and disposing of items soiled with body fluids. Clear guidelines about avoiding and controlling infection, maintaining regular health care appointments, managing symptoms, and getting adequate nutrition, rest, and exercise are necessary. Emphasize the importance of personal and environmental hygiene. The nurse teaches caregivers the guidelines (Standard Precautions) described in

Box 37-3. Patients and caregivers should clean kitchen and bathroom surfaces regularly with disinfectants to prevent growth of fungi and bacteria. Patients with pets should have another person clean the area soiled by animals, such as birdcages and litter boxes. If this is not possible, patients should use gloves and should wash their hands after they clean the area. Patients should avoid exposure to others who are sick or who have recently received live vaccines. The nurse emphasizes the importance of avoiding smoking, excessive alcohol, and over-the-counter and street drugs. Instruct patients who are HIV-positive or who inject drugs not to donate blood. IV/injection drug users who are unwilling to stop using should avoid sharing drug equipment with others.

The nurse teaches caregivers how to administer medications, including IV preparations, in the home. Often the medication regimens used for patients with HIV infection and AIDS are complex and expensive. If the patient requires enteral or parenteral nutrition, provide instruction to the patient and family about how to administer nutritional therapies at home. Home care nurses provide ongoing teaching and support for the patient and family.

PROVIDING CONTINUING CARE

Many people with AIDS remain in their community and continue their usual daily activities, whereas others can no longer work or maintain their independence. Families or caregivers may need assistance in providing supportive care. Many community-based organizations provide a variety of services for people living with HIV infection and AIDS; nurses can help identify these services.

Nurses may refer patients to community programs that offer a range of services for patients, friends, and families, including help with housekeeping, hygiene, and meals; transportation and shopping; individual and group therapy; support for caregivers; telephone networks for the homebound; and legal and financial assistance. These services are typically provided by both professionals and nonprofessional volunteers. A social worker can identify sources of financial support, if needed.

Home care and hospice nurses are called on to provide physical and emotional support to patients and families as patients with AIDS enter the terminal stages of disease. This support takes on special meaning when people with AIDS lose friends and when family members fear the disease or feel anger concerning the patient's lifestyle. The nurse encourages the patient and family to discuss end-of-life decisions and to ensure that care is consistent with those decisions, all comfort measures are employed, and the patient is treated with dignity at all times.

EVALUATION

Expected patient outcomes may include:

1. Maintains skin integrity
2. Resumes usual bowel habits
3. Experiences no OIs

4. Maintains adequate level of activity tolerance
5. Maintains usual level of thought processes
6. Maintains effective airway clearance
7. Experiences increased sense of comfort and less pain
8. Maintains adequate nutritional status
9. Experiences decreased sense of social isolation
10. Progresses through grieving process
11. Reports increased understanding of AIDS and participates in self-care activities
12. Remains free of complications

A plan of nursing care for a patient with AIDS is available online at http://thepoint.lww.com/Honan2e.

Emotional and Ethical Concerns

Nurses in all settings provide care for patients with HIV infection. In doing so, they encounter not only the physical challenges of this epidemic but also emotional and ethical concerns. The concerns raised by health care professionals involve issues such as fear of infection, responsibility for giving care, values clarification, confidentiality, developmental stages of patients and caregivers, and poor prognostic outcomes.

Many patients with HIV infection have engaged in "stigmatized" behaviors. Because these behaviors challenge some traditional religious and moral values, nurses may feel reluctant to care for these patients. In addition, health care providers still may have fear and anxiety about disease transmission despite education concerning infection control and the low incidence of transmission to health care providers. Nurses are encouraged to examine their personal beliefs and to use the process of values clarification to approach controversial issues. The American Nurses Association's Code of Ethics for Nurses also can be used to help resolve ethical dilemmas that might affect the quality of care given to patients with HIV infection and AIDS (refer to Chapter 1).

Nurses are responsible for protecting the patient's right to privacy by safeguarding confidential information. Inadvertent disclosure of confidential patient information may result in personal, financial, and emotional hardships for the patient. The controversy surrounding confidentiality concerns the circumstances in which information may be disclosed to others. Many patients avoid necessary health care appointments due to confidentiality concerns. Health care team members need accurate patient information to conduct assessment, planning, implementation, and evaluation of patient care. Failure to disclose HIV status could compromise the quality of patient care. Sexual partners of patients who are HIV-infected should know about the potential for infection and the need to engage in safer sex practices as well as the possible need for testing and health care. State health departments offer confidential partner notification services. In situations in which a patient cannot or will not inform others, "duty to warn" regulations vary by state. Nurses are advised to discuss concerns about confidentiality with nurse administrators and to consult professional nursing organizations, such as the Association of Nurses in AIDS Care (ANAC), and legal experts in their state to identify the most appropriate course of action.

AIDS has had a high mortality rate, but advances in ARV and multidrug therapy have demonstrated promise in slowing or controlling disease progression. It is not known whether current treatment regimens will remain effective because viral drug resistance has developed with many medications. However, most experts agree that educated, adherent patients can expect to survive for decades living a life that is relatively complication-free. In spite of these advances, many young and middle-aged adults will experience serious illness and may die during the usual course of the disease process. Unlike cancer or other diseases, AIDS is associated with controversies challenging our legal and political systems as well as religious and personal beliefs. Contributing to this stress is personal fears of contagion or disapproval of the patient's lifestyle and behaviors. Nurses who feel stressed and overburdened may experience physical and mental distress in the form of fatigue, headache, changes in appetite and sleep patterns, helplessness, irritability, apathy, negativity, and anger.

Many strategies have been used by nurses to cope with the stress associated with caring

for patients with AIDS. Education and provision of up-to-date information help to alleviate apprehension and prepare nurses to deliver safe, high-quality patient care. Interdisciplinary meetings allow participants to support one another and provide comprehensive patient care. Staff support groups give nurses an opportunity to solve problems and explore values and feelings about caring for patients with AIDS and their families; the groups also provide a forum for grieving. Other sources of support include nursing administrators, peers, and spiritual advisors.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 43-year-old man who has been injecting drugs for 20 years says that he is not going to stop his use of drugs but wants to reduce his risk for HIV infection. What would you teach him? What types of community agencies could provide resources to this patient?

2. During a code response in the intensive care unit (ICU), a nursing student was inadvertently stuck with a needle used on a homeless patient who has AIDS. The student states that he is not concerned about contracting any diseases as a result. As his clinical instructor or the nurse manager of the ICU, what actions should you take? What reporting and documentation are needed? What testing, treatment, and counseling are indicated for the student?

3. During a home visit to a family in which two adolescents are HIV-positive, you are instructing the adolescents, their siblings, and their parents about strategies to protect the adolescents from other infections and to protect other family members from HIV transmission. What is the evidence for strategies that you plan to discuss with the adolescents and their family members? What is the strength of that evidence, and what criteria would you use to evaluate the strength of the evidence?

NCLEX-Style Review Questions

1. The patient with a $CD4^+$ count of 100 cells/mm^3 and not taking any antiretroviral medications is admitted to the hospital after a motor vehicle accident. In addition, the patient has a productive cough, fever, lymphadenopathy, and a history of night sweats. The patient's purified protein derivative (PPD) test is negative. What is the nurse's best action?
   a. Use Standard Precautions alone because the patient does not have tuberculosis.
   b. Use Airborne Precautions alone because the patient has not started appropriate therapy for HIV.
   c. Use Standard Precautions and Airborne Precautions because the patient has tuberculosis.
   d. Use Standard and Airborne Precautions until the infectious disease providers verify the patient does not have tuberculosis, and then continue using standard precautions.

2. The patient who just tested HIV-positive has persistent lymphadenopathy. The patient asks, "When will I be capable of transmitting the virus to others?" What is the nurse's best response?
   a. At this stage, you can transmit the virus only through donation of blood or blood products.
   b. If your $CD4^+$ T cells drop below 200 cells/mm^3 you would be considered infectious.
   c. You cannot transmit the virus as long as you take your prescribed drugs.
   d. The virus can be transmitted at all stages and categories of HIV infection.

3. Which finding in the patient with HIV disease who started HAART 3 months ago indicates that the treatment is effective? Select all that apply.
   a. Increased CD4 cells
   b. Decreased CD4 cells
   c. Decreased viral load
   d. Increased CD8 cells
   e. Decreased HIV antibody levels

4. The nurse suspects a patient has the early signs of an opportunistic infection with CMV. Which one of the early signs that may be present?
   a. Discolorations of the mucous membranes
   b. Cardiac arrhythmias
   c. Hypotension
   d. Visual disturbances

5. Kaposi sarcoma, once a common manifestation of AIDS before HAART was available, is seldom seen. A patient with AIDS wants to know how Kaposi sarcoma presents. What is the nurse's best response?
   a. Thick, white exudate in the mouth
   b. A purple-red lesion on the body
   c. Weight loss
   d. An increase in respiratory secretions

CHAPTER 38

Nursing Management: Patients with Allergic Disorders

Nicole C. Colline

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the management of patients with allergic disorders.
2. Describe measures to prevent and manage anaphylaxis.
3. Discuss the different allergic disorders according to type.

Autoimmune reactions occur when self-antigens are recognized by the body's normal defense mechanisms as foreign. With the presence of these "foreign" antigens, B cells become hyperactive, and increased amounts of immunoglobulin E (IgE) are produced, thus causing a hypersensitivity or allergic response. *Hypersensitivity* is an amplified or inappropriate response to an antigen (on second exposure, see Pathophysiology), leading to inflammation and destruction of healthy tissue. The cause may result from genetic, hormonal, and environmental factors; many times, the etiology is unclear. The reaction time varies and can be within minutes to hours of exposure or may be delayed. Refer to Chapter 36 for details of types of allergic classifications (Table 36-1). Symptoms will vary depending on the classification and may range from a local reaction to the life-threatening systemic response of anaphylaxis. It is important for nurses to recognize signs and symptoms of allergic reactions, understand the risk factors associated with reaction, and become familiar with treatment management.

There are two types of IgE-mediated allergic reactions: atopic (local) and nonatopic disorders. Although the underlying immunologic reactions of the two types of disorders are the same, the predisposing factors and manifestations are different. The atopic disorders are characterized by a hereditary predisposition and production of a local reaction to IgE antibodies, which manifests in one or more of the following three atopic disorders: allergic rhinitis, asthma, and atopic dermatitis/eczema. The nonatopic disorders (e.g., tetanus vaccine, insect venom, airborne allergens) lack the genetic component and organ specificity of the atopic disorders (Porth, 2015). Latex allergy (see pages 1134–1137) may be a type I or type IV hypersensitivity reaction, although true latex allergy is considered to be a type I hypersensitivity reaction. Contact dermatitis is considered to be a type IV hypersensitivity reaction (Peng & Novak, 2015).

Unfolding Patient Stories: Jennifer Hoffman • Part 2

Recall from Chapter 11 Jennifer Hoffman, who came to the clinic with continued symptoms of asthma. The nurse confirmed that she was following the asthma action plan; however, Jennifer now returns to the clinic with worsening symptoms. What assessment findings would indicate to the nurse that Jennifer is having a hypersensitivity reaction to an allergen(s)? What questions can assist the nurse in identifying the causative agent(s)? What interventions should be implemented when allergen(s) are identified?

Care for Jennifer and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

ANAPHYLAXIS

Anaphylaxis is defined as a severe allergic reaction that is rapid in onset and can cause various systemic reactions, including death (Ferri, 2016). Anaphylaxis is a clinical response to an immediate (type I hypersensitivity) immunologic reaction between a specific antigen and an antibody. The reaction results from a rapid release of IgE-mediated chemicals, which can induce a severe, life-threatening allergic reaction.

Pathophysiology

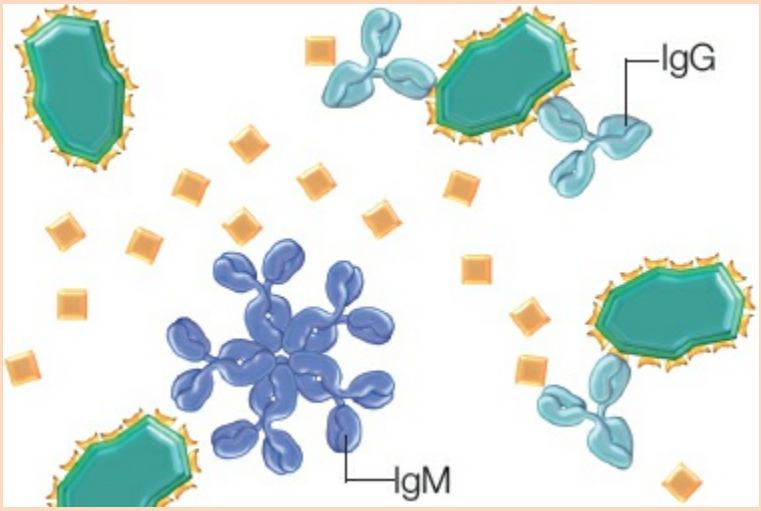
Anaphylaxis occurs when the body's immune system produces specific IgE antibodies toward a substance that is normally nontoxic (e.g., food such as a peanut) (Box 38-1). When the person first ingests the peanut, for example, there are no physical reactions manifested. Instead, antibodies are produced for that specific substance, and then those antibodies are stored in the immune system for future re-exposure. If the substance is ingested again, the body releases excess amounts of the protein histamine. Large amounts of histamine released into the body may cause flushing, urticaria, angioedema, hypotension, and bronchoconstriction (Fig. 38-1). These systemic changes (most commonly in the dermatologic, respiratory, cardiovascular, and gastrointestinal [GI] tracts) characteristically produce clinical manifestations within seconds or minutes after antigen exposure. In severe cases, these symptoms may cause shock. If no medical intervention is sought, death may ensue (Lieberman, 2014).

BOX 38-1 Focus on Pathophysiology

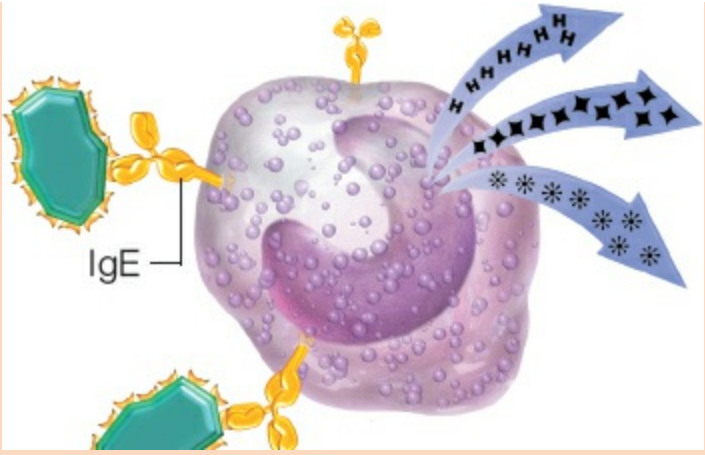
Anaphylaxis

The chain of events for anaphylaxis:

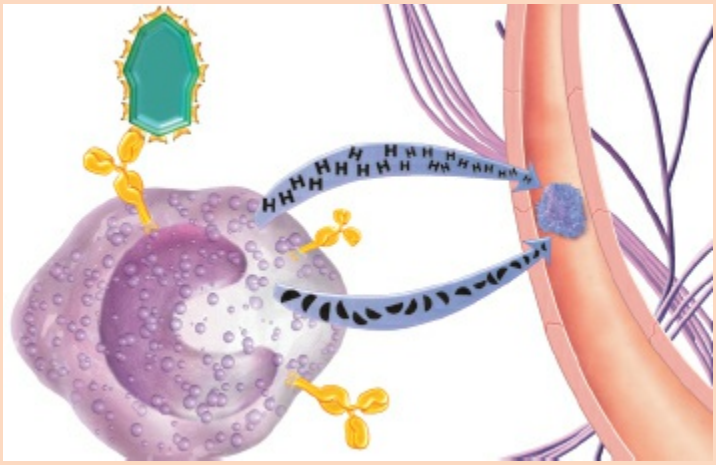
1. Response to antigen. IgM and IgG recognize and bind the antigen.



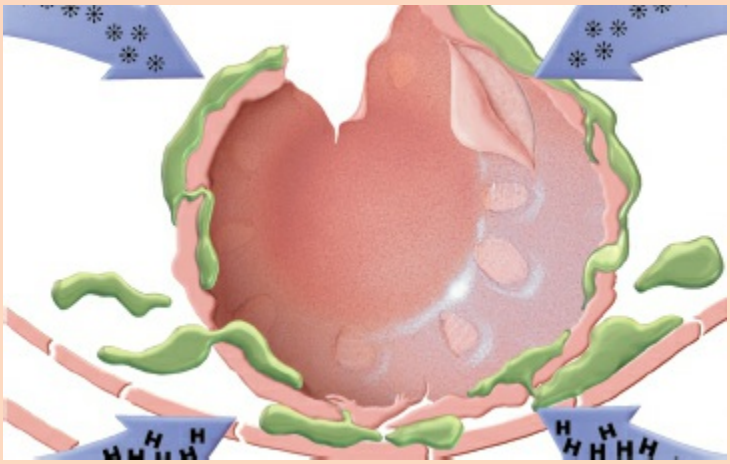
2. Release of chemical mediators. Activated IgE on basophils promotes release of mediators (histamine, serotonin, and leukotrienes).



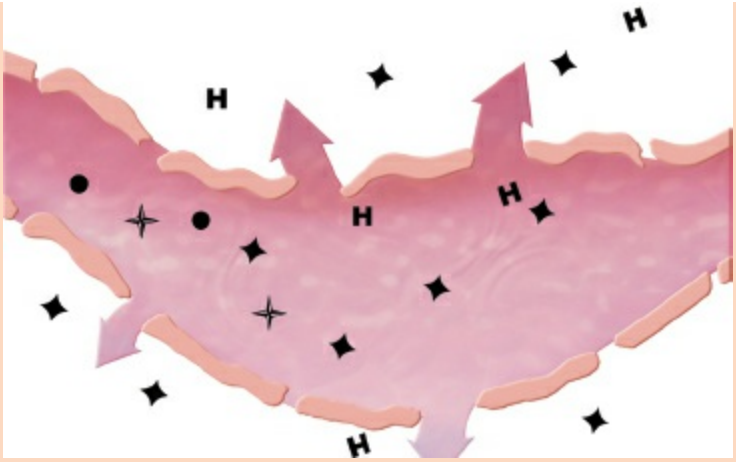
3. Intensified response. Mast cells release more histamine and eosinophil chemotactic factor of anaphylaxis (ECF-A), which create venule-weakening lesions.



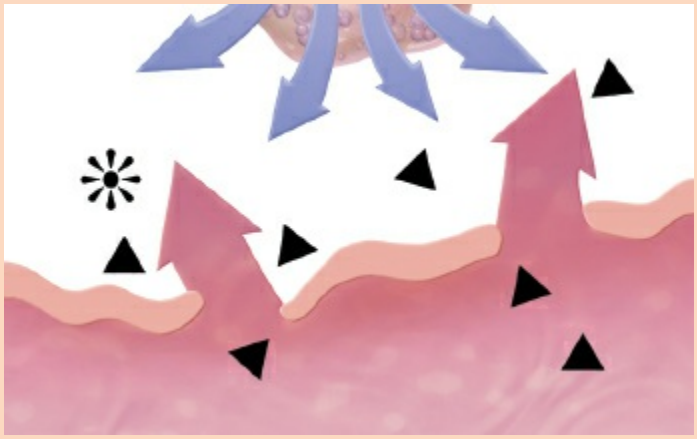
4. Respiratory distress. In the lungs, histamine causes endothelial cell destruction and fluid leakage into the alveoli.



5. Deterioration. Meanwhile, mediators increase vascular permeability, causing fluid to leak from the vessels.



6. Failure of compensatory mechanisms. Endothelial cell damage causes basophils and mast cells to release heparin and mediator-neutralizing substances. However, anaphylaxis is now irreversible.



Adapted from Lippincott. (2010). *Pathophysiology: An incredibly visual! pocket guide*. Philadelphia, PA: Lippincott Williams & Wilkins.

Box 38-2 lists substances that most commonly cause anaphylaxis.

The diagnosis of anaphylaxis is predominantly based on objective findings during clinical examination, despite potential negative laboratory testing (i.e., serum IgE levels or tryptase levels [a protease of human mast cells that has been implicated as a pathologic mediator of numerous allergic and inflammatory conditions]). Some providers continue to utilize prick and intradermal skin testing to assist in diagnosis; however, a positive test result cannot confirm a diagnosis due to asymptomatic sensitization (when the body's cells detect the allergen but re-exposure does not cause physical or immunologic effects). Anaphylaxis continues to be underdiagnosed in the medical community, largely in part from patients not describing all of their symptoms, all the while undermining their expressed symptoms. Another contributing factor to underdiagnosing an acute anaphylactic episode is that medical providers are not well versed in the complexity of anaphylaxis. As the prevalence of anaphylaxis is rising, proper diagnosis and medical management is imperative to save people's lives.

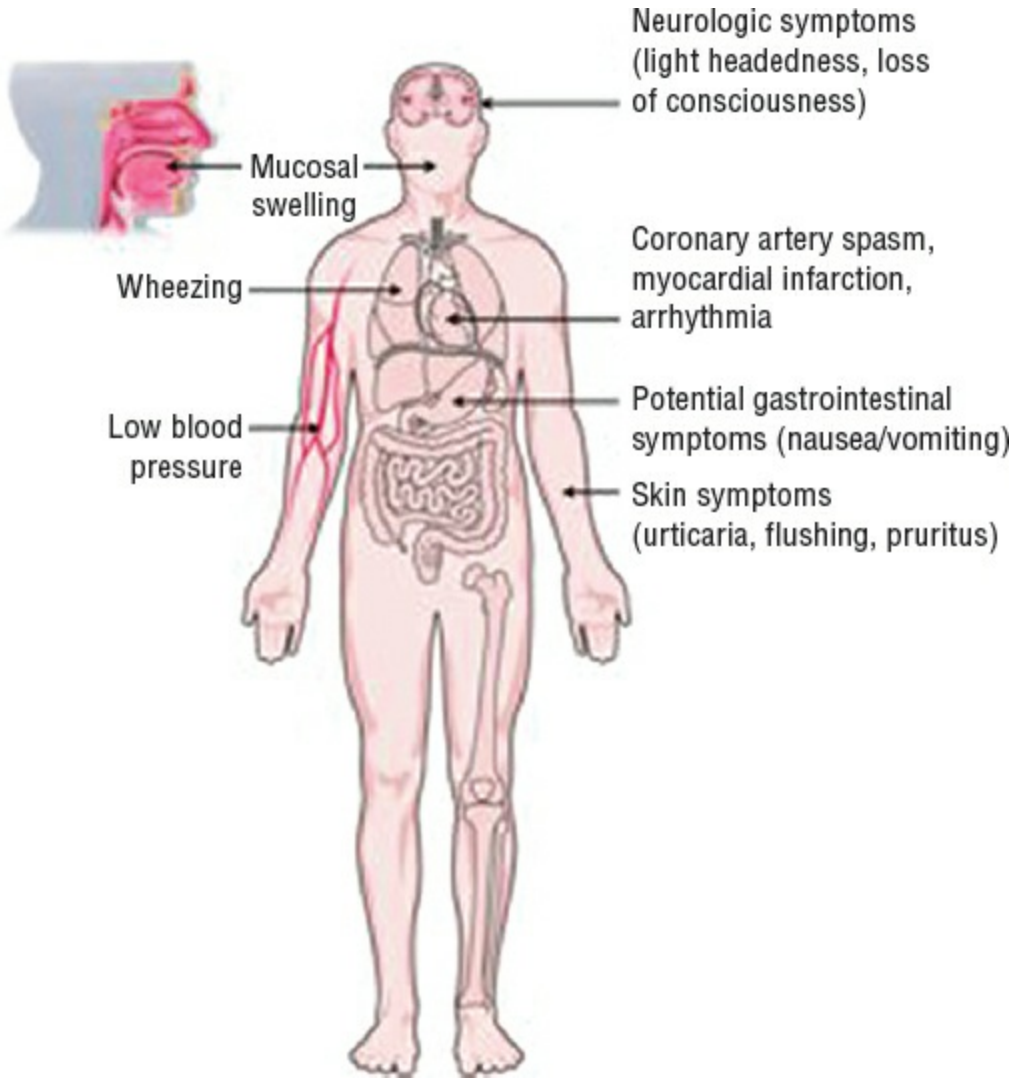


FIGURE 38-1 Anaphylaxis: Systemic symptoms. (Miller, M. D., Chhabra, A. B., Konin, J., & Mistry, D. (2013). *Sports medicine conditions: Return to play: recognition, treatment, planning*. Philadelphia, PA: Lippincott Williams & Wilkins.)

BOX 38-2 Common Causes of Anaphylaxis

Foods

Peanuts, tree nuts (e.g., walnuts, pecans, cashews, almonds), shellfish (e.g., shrimp, lobster, crab), fish, milk, eggs, soy, wheat

Medications

Antibiotics (especially penicillin and sulfa antibiotics), allopurinol, radiocontrast agents, anesthetic agents (lidocaine, procaine), vaccines, hormones (insulin, vasopressin, adrenocorticotropic hormone [ACTH], aspirin, nonsteroidal anti-inflammatory drugs [NSAIDs]).

Other Pharmaceutical/Biologic Agents

Animal serums (tetanus antitoxin, snake venom antitoxin, rabies antitoxin), antigens used in skin testing

Insect Stings

Bees, wasps, hornets, yellow jackets, ants (including fire ants)

Latex

Medical and nonmedical products containing latex

Clinical Manifestations and Assessment

The severity of previous anaphylactic reactions does not determine the severity of subsequent reactions, which could be the same, more, or less severe. The severity depends on the degree of allergy and the dose of allergen (Porth, 2015; Simons, 2010).

Anaphylactic reactions consist of three basic patterns: uniphasic, biphasic, and protracted reactions. Uniphasic reactions occur as an exclusive incident where the patient develops symptoms within 30 minutes of allergen exposure that resolve spontaneously within 1 to 2 hours, either with or without medical treatment. In biphasic responses, the patient will have an initial reaction, followed by subsequent symptoms up to 8 hours after the first reaction. These patients should be managed in the emergency room. Finally, a protracted reaction is just that: a reaction that may last for a prolonged period of time, up to 32 hours, and may include cardiogenic or septic shock and respiratory distress despite medical treatment (Lieberman, 2014).

Mild systemic reactions consist of peripheral tingling and a sensation of warmth, possibly accompanied by a sensation of fullness in the mouth and throat. Nasal congestion, periorbital swelling, pruritus, sneezing, and tearing of the eyes also can be expected.

Moderate systemic reactions may include flushing, warmth, anxiety, and itching in addition to any of the milder symptoms. More serious reactions include bronchospasm and edema of the airways or larynx with dyspnea, cough, and wheezing. Both mild and moderate reactions begin within 2 hours of exposure. Severe systemic reactions, however, have an abrupt onset with the same signs and symptoms described previously. These symptoms progress rapidly to bronchospasm, laryngeal edema, severe dyspnea, cyanosis, and hypotension. Dysphagia (difficulty swallowing), abdominal cramping, vomiting, diarrhea, and seizures also can occur. Cardiac arrest and coma may follow. Monitoring the patient with anaphylaxis includes continual assessment of the patient's respiratory rate and pattern, oxygen saturation, assessing for breathing difficulties or abnormal lung sounds, and monitoring for hemodynamic stability (pulse rate and rhythm, and blood pressure). Table 38-1 summarizes the clinical manifestations of various pathophysiologic changes.

Prevention

Strict avoidance of potential allergens is an important preventive measure for the patient at risk for anaphylaxis. For example, patients at risk for anaphylaxis from insect stings should avoid areas populated by insects and should use appropriate clothing, insect repellent, and caution to avoid further stings.

If avoidance of exposure to allergens is impossible, the patient should be instructed to carry and administer epinephrine to prevent an anaphylactic reaction in the event of exposure to the allergen. People who are sensitive to insect bites and stings, those who have experienced food or medication reactions, and those who have experienced idiopathic or exercise-induced anaphylactic reactions should always carry an emergency kit that contains epinephrine. The EpiPen from Dey Pharmaceuticals (Napa, CA) is a commercially available first-aid device that delivers premeasured doses of 0.3 mg (EpiPen) or 0.15 mg (EpiPen Jr.) of epinephrine (Fig. 38-2). The autoinjection system requires no preparation, and the self-administration technique is uncomplicated. The patient must be given an opportunity to demonstrate the correct technique for use; an EpiPen training device can be used for teaching correct technique. Verbal and written information about the emergency kit, as well as strategies to avoid exposure to threatening allergens, also must be provided. Failure to administer epinephrine promptly and properly has proven to be fatal in severe anaphylactic reactions.

TABLE 38-1 Clinical Manifestations of Anaphylaxis

Change	Signs and Symptoms
Activation of IgE and subsequent release of chemical mediators	Feeling of impending doom or fright
Histamine release	Sweating; sneezing; shortness of breath; nasal pruritus, urticaria, and angioedema (swelling of the deep dermis or subcutaneous or submucosal tissues); nasal mucosal edema; profuse watery rhinorrhea; itching; nasal congestion
Increased vascular permeability, subsequent decrease in peripheral resistance and leakage of plasma fluids	Hypotension, shock, and possible cardiac arrhythmias
Increased capillary permeability and mast cell degranulation	Edema of upper respiratory tract, resulting in hypopharyngeal and laryngeal obstruction
Bronchiole smooth muscle contraction and increased mucus production	Hoarseness, stridor, wheezing, and use of accessory muscles
Smooth muscle contraction of intestines and bladder	Severe stomach cramps, nausea, diarrhea; urinary urgency and incontinence

Screening for allergies before a medication is prescribed or first administered is an important preventive measure. A careful history of any sensitivity to suspected antigens must be obtained before administering any medication, particularly in parenteral form, because this route is associated with the most severe anaphylaxis. Nurses caring for patients in any setting (hospital, home, outpatient diagnostic testing sites, long-term care facilities) must assess patients' risks for anaphylactic reactions. Patients are asked about previous exposure to contrast agents used for diagnostic tests and any allergic reactions as well as reactions to any medications, foods, insect stings, and latex. People who are predisposed to anaphylaxis should wear some form of identification, such as a medical alert bracelet, which

names allergies to medications, food, and other substances.

FIGURE 38-2 The EpiPen. Autoinjectors are commercially available first-aid devices that administer premeasured doses of epinephrine. An EpiPen training device is available for patients to practice correct self-injection technique. (Courtesy of Dey L.P., Napa, CA.)

People who are allergic to insect venom may require venom immunotherapy, which is used as a control measure and not a cure. Immunotherapy administered after an insect sting is very effective in reducing the risk of anaphylaxis from future stings (Schwartz, 2016; Simons, 2010). Insulin-allergic patients with diabetes and those who are allergic to penicillin may require desensitization. Desensitization is based on controlled anaphylaxis, with a gradual release of mediators. Patients who undergo desensitization are cautioned that there should be no lapses in therapy because this may lead to the reappearance of the allergic reaction when the use of the medication is resumed. See further discussion of immunotherapy later in this chapter.

Medical Management

Acute management depends on the severity of the reaction. Initially, respiratory and cardiovascular functions are evaluated. If the patient is in cardiac arrest, cardiopulmonary resuscitation is instituted. Oxygen is provided in high concentrations during cardiopulmonary resuscitation or if the patient is cyanotic, dyspneic, or wheezing. At first response, epinephrine, in a 1:1,000 dilution, is administered subcutaneously in the upper extremity or thigh and may be followed by a continuous IV infusion. Epinephrine is the first-line treatment of anaphylaxis as it is the only medication that may halt cardiac or respiratory arrest, which typically occurs 5 to 30 minutes after exposure to an allergen (Lieberman, 2014). Most adverse events associated with administration of epinephrine (e.g., adrenaline) occur when the dose is excessive or given intravenously. Patients at risk for adverse effects include elderly patients and those with hypertension, arteriopathies (diseases of the arteries), or known ischemic heart disease (Schwartz, 2016; Simons, 2010).

Drug Alert!
To avoid mishaps in dosing, many emergency departments now stock both adult and pediatric EpiPens, which provide the standard adult or pediatric dose (EpiPen, 0.3 mg epinephrine; EpiPen-Jr, 0.15 mg epinephrine) (Schwartz, 2016).

Antihistamines and corticosteroids also may be administered to prevent recurrences of the reaction and to treat urticaria and angioedema, although they are not the first-line treatment. Antihistamines take up to 80 minutes to suppress histamine levels by 50%, and steroids generally work very slowly once administered. IV fluids (e.g., normal saline solution), volume expanders, and vasopressor agents are administered to maintain blood pressure and normal hemodynamic status. In patients with episodes of bronchospasm or a history of bronchial asthma or chronic obstructive pulmonary disease, aminophylline and corticosteroids also may be administered to improve airway patency and function. If hypotension is unresponsive to vasopressors, glucagon may be administered intravenously for its acute inotropic and chronotropic effects (Schwartz, 2016; Simons, 2010). Glucagon stimulates the enzyme adenylate cyclase, and its activation results in the intracellular accumulation of the second messenger cyclic adenosine monophosphate (cAMP). Increased levels of cAMP improve the suppressive actions that epinephrine exerts on the biochemical events responsible for the anaphylactic response.

Patients who have experienced anaphylactic reactions and received epinephrine should be transported to the local emergency department for observation and monitoring because of the risk for a "rebound" reaction usually within 4 to 10 hours after the initial allergic reaction. Patients with severe reactions are monitored closely for 12 to 14 hours in a facility that can provide emergency care, if needed. Because of the potential for recurrence, patients with even mild reactions must be informed about this risk (Lieberman, 2014). Refer to Nursing research brief (Box 38-3) that discusses Emergency Room (ER) management of anaphylaxis.

Nursing Management

If a patient is experiencing an acute allergic response, the nurse's initial action is to assess the patient for signs and symptoms of anaphylaxis. The nurse assesses the airway, breathing pattern, and other vital signs. The patient is observed for signs of increasing edema and respiratory distress. Prompt notification of the provider (or calling 911 if in the community) and preparation for initiation of emergency measures (intubation, administration of emergency medications, insertion of IV lines, fluid administration, oxygen administration) are important to reduce the severity of the reaction and to restore cardiovascular function. The nurse documents the interventions used and the patient's vital signs and response to treatment.

Nursing Alert
In the event of an acute allergic reaction, the nurse recognizes that ET intubation may be difficult or impossible because it can result in increased laryngeal edema, bleeding, and further narrowing of the glottic opening. Fiberoptic ET intubation, needle cricothyrotomy (followed by transtracheal ventilation), or cricothyrotomy may be necessary (Wafer, 2015).

The patient who has recovered from anaphylaxis needs an explanation of what occurred as well as instruction about avoiding future exposure to antigens and how to administer emergency medications to treat anaphylaxis. All patients who have experienced an anaphylactic reaction should receive a prescription for preloaded syringes of epinephrine. The nurse instructs the patient and family in their use and has the patient and family demonstrate correct administration of the medication (Box 38-4).

Long-term preventative measures include proper management of a patients' chronic condition(s), such as asthma, cardiovascular disease, etc., followed by detailed education in regards to treating an acute anaphylactic reaction. All patients are to be informed that anaphylaxis is a potential life-threatening allergy, and immediate treatment can be the difference between life and death.

ALLERGIC RHINITIS

Allergic rhinitis (hay fever, seasonal allergic rhinitis), a type I hypersensitivity reaction and the most common form of chronic respiratory allergic disease, remains the fifth most common chronic disease in the United States. It is one of the most common reasons for visits to primary care practitioners. Symptoms are similar to those of viral rhinitis but usually are more persistent and demonstrate seasonal variation; rhinitis is considered to be the allergic form if the symptoms are caused by an allergen-specific IgE-mediated immunologic response. However, a sizable proportion of patients with rhinitis have mixed rhinitis, or coexisting allergic and nonallergic rhinitis (Seidman et al., 2015).

The proportion of patients with the allergic form of rhinitis is greatest among children yet is on the rise among adults. It often occurs with other conditions, such as allergic conjunctivitis, sinusitis, and asthma. If symptoms are severe, allergic rhinitis may interfere with sleep, leisure, and school or work activities. If left untreated, many complications may result, such as allergic asthma, chronic nasal obstruction, chronic otitis media with hearing loss, anosmia (absence of the sense of smell), and, in children, orofacial dental deformities. Early diagnosis and adequate treatment are essential to relieve current symptoms and reduce comorbidities later in life (Rachelefsky & Farrer, 2013).

BOX 38-3 Nursing Research

Bridging the Gap to Evidence-Based Practice

Caton, E., & Flynn, M. (2013). Management of anaphylaxis in the ED: A clinical audit, International Emergency Nursing, *21*(1), 64–70.

Purpose

The purpose of this paper was to review the existing evidence around the effective diagnosis, emergency treatment, and long-term management of anaphylaxis. It then describes a clinical audit that was carried out in the ED of a large University hospital in the United Kingdom.

Design

A retrospective audit design sampled all patients presenting with anaphylaxis in one calendar year; 146 cases were eligible for inclusion. The audit results showed widespread inconsistencies in the diagnosis and treatment of this patient group.

Findings

Of the 507 patients included in the original sample, a total of 29% (n = 146) of the identified cases met all the inclusion criteria for the audit, and the sample was made up of 92 (63%) women and 54 (37%) men. The median age was 34 years, and those under 40 years old accounted for 60% (n = 88) while 14% (n = 21) were over the age of 70 years. Patients in the range between 80 and 89 years of age were the only ones in which the number of men presenting to the ED was greater than the number of women.

In the majority of patients (66%, n = 96) a diagnosis of allergic reaction was

documented, with anaphylaxis noted as the reason for presentation in 21% (n = 30) of cases. Angioedema was diagnosed in 8% (n = 12), while allergic rash and drug reactions occurred in a further 4% (n = 6) of cases. One patient self-discharged from the ED prior to being seen by a clinician, and a hypersensitivity reaction was recorded in one other patient.

Adrenaline was administered alone or in combination with antihistamine and or hydrocortisone in 43% (n = 63) of patients. The remaining 57% (n = 83) received hydrocortisone and/or antihistamine without adrenaline. The administration of adrenaline was recorded in 21% (n = 31) of patients where the diagnosis was reported as an allergic reaction. In an additional 5% (n = 7) of patients who had not received adrenaline, a diagnosis of anaphylaxis was recorded. A systolic blood pressure of 90 mm Hg or below was evident in 3% (n = 5) of patients who did not have adrenaline administered, one of whom was discharged with a diagnosis of anaphylaxis. There were only two diagnoses, allergic rash and hypersensitivity reaction, in which patients did not require adrenaline.

Of the 146 patients included in the audit, 37 (25%) had been diagnosed previously as having asthma, but adrenaline was administered to only half of them (n = 19). A previous anaphylactic episode had occurred in 50% (n = 73) of patients, but an autoinjector of adrenaline was carried by less than half (n = 34). In addition, the discharge diagnosis recorded in 60% (n = 44) of the patients with a known anaphylactic history was documented as an allergic reaction. In 2% (n = 3) of cases, the patient's anaphylaxis history was unknown.

In 54% (n = 79) of cases, patient care and management involved admission to the ED observation ward, while 9% (n = 13) of patients were admitted directly to specialty wards. Discharge directly from the ED accounted for the remaining 37% (n = 54).

Guidelines recommend that all patients treated for anaphylaxis are referred to an allergy specialist, but in this audit no patient was referred to an allergy specialist from the ED. Of the 73 cases with a previous episode of anaphylaxis only 10 had been referred for consultation with an allergy specialist and a further nine patients had appointments pending. However, the majority of patients reporting a history of anaphylaxis (n = 49) had received no specialist referral. Over half (n = 19) of the 34 patients who carried their own adrenaline had not consulted an allergy specialist previously, and only three patients who were known to be asthmatics had been referred previously.

As a result of admission to an inpatient ward from the ED, referral outcomes on eventual hospital discharge were unknown in 14% (n = 20) of cases, and discharge without any follow-up occurred in 28% (n = 41) of cases.

Nursing Implications

The results of this audit are consistent with the published evidence and suggest there is more work to be done to enhance our understanding of the issues surrounding the ED treatment of anaphylaxis, to deliver the best possible patient care. The findings support

the notion that the lack of an accepted definition of anaphylaxis generates conflict and confusion for ED practitioners. With no definitive diagnostic criteria, the ED clinicians' subjective interpretation of anaphylactic symptoms can result in a huge divergence among evidence-based guidelines, expert recommendations, and clinical practice.

Because allergic rhinitis is induced by airborne pollens or molds, it is activated by the following seasonal occurrences:

- Early spring: Tree pollen (oak, elm, poplar), mold spores
- Early summer: Rose pollen (rose fever), grass pollen (timothy, red-top)
- Early fall: Weed pollen (ragweed), mold spores

Each year, attacks begin and end at about the same time. Airborne mold spores require warm, damp weather. Although there is no rigid seasonal pattern, these spores appear in early spring, are rampant during the summer, and then taper off and disappear by the first frost.

Clinical Manifestations and Assessment

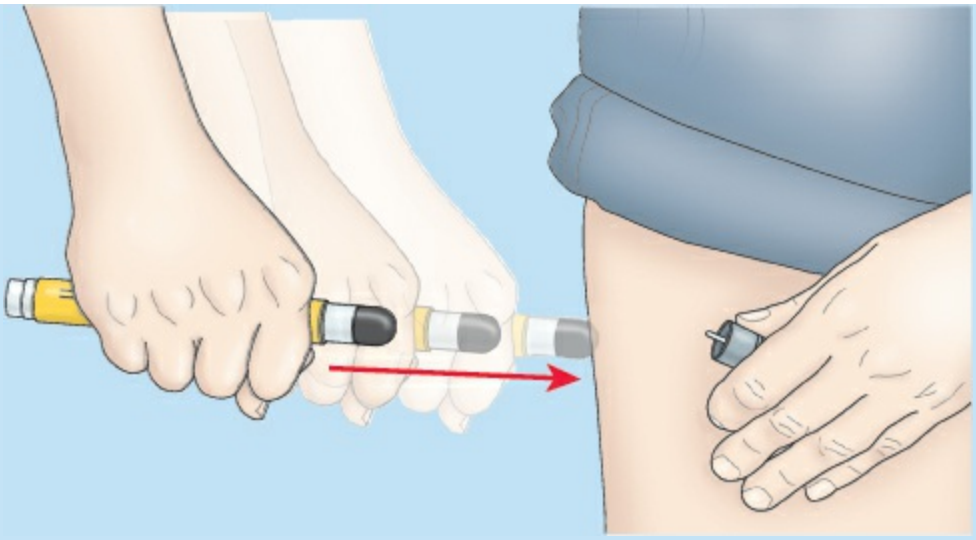
Typical signs and symptoms of allergic rhinitis include sneezing and nasal congestion; clear, watery nasal discharge; itchy eyes and nose; and lacrimation (Ferri, 2016). Drainage of nasal mucus into the pharynx, otherwise known as *postnasal drip*, results in multiple attempts to clear the throat and results in a dry cough, hoarseness, or scratchy throat. Headache, pain over the paranasal sinuses, and epistaxis can accompany allergic rhinitis. The symptoms of this chronic condition depend on environmental exposure and intrinsic host responsiveness. Allergic rhinitis can affect quality of life by also producing fatigue, loss of sleep, poor concentration, and interference with physical activities. Of great concern is the risk of developing persistent asthma and other comorbid conditions (chronic otitis media and sinusitis, obstructive sleep apnea, airway inflammation, etc.) from uncontrolled allergic rhinitis (Seidman et al., 2015).

BOX 38-4 Patient Education

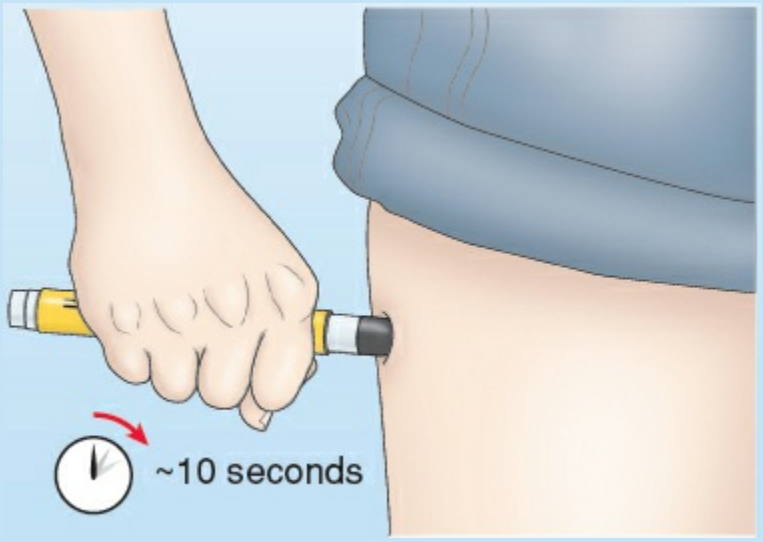
Self-Administration of Epinephrine

1. After removing the EpiPen autoinjector from its carrying tube, grasp the unit with the black tip (injecting end) pointing downward. Form a fist around the unit with the black tip down; with your other hand, remove the gray safety release cap.

2. Hold the black tip near the outer thigh. Swing and jab firmly into the outer thigh until a click is heard with the device perpendicular (90-degree angle) to the thigh.



3. Hold the device firmly against the thigh for approximately 10 seconds.



4. Remove the unit from the thigh, and massage the injection area for 10 seconds. Call 911, and seek immediate medical attention. Carefully place the used EpiPen, needle-end first, into the device storage tube without bending the needle. Screw on the storage tube completely, and take it with you to the hospital emergency room.

Diagnosis of seasonal allergic rhinitis is based on history, physical examination, and diagnostic test results. On objective examination, a patient suffering with allergic rhinitis may appear fatigued (the patient may complain of not feeling well-rested after a full night's sleep); the patient may present with any of the following conditions:

- Allergic "shiners" (gray-black discoloration below lower eye lids that some refer to as "raccoon eyes");
- Puffy eyes;
- Clear or cloudy fluid surrounding the tympanic membranes;

- Nasal congestion or rhinorrhea;
- Marked erythema of palpebral conjunctivae associated with increased tearing;
- Enlarged nasal turbinates that are a pale-bluish color and boggy in texture;
- Enlarged anterior cervical lymph nodes;
- Cobblestoned appearance on the posterior pharynx (due to chronic postnasal drip and nasal congestion); and
- Sinus tenderness on palpation (Seidman et al., 2015).

Diagnostic tests include nasal smears, peripheral blood counts, total serum IgE, epicutaneous and intradermal testing, radioallergosorbent test (RAST), food elimination and challenge, and nasal provocation tests. Results indicative of allergy as the cause of rhinitis include increased levels of IgE and eosinophil and positive reactions on allergen testing. False-positive and false-negative responses to these tests, particularly skin testing and provocation tests, may occur, yet they still are considered a highly effective means of identifying agents that are causative of allergic responses (Kim & Mun, 2010; Van Rooyen, 2014).

It is imperative that patients with allergic rhinitis are diagnosed correctly and their treatment is individualized according to the severity of their disease. Then patients must be able to verbalize understanding of their diagnosis and proper treatment modalities.

Medical Management

The goal of therapy is to provide relief from symptoms and encourage adherence to therapeutic regimens. Therapy may include one or all of the following interventions: avoidance therapy, pharmacotherapy, immunotherapy, and homeopathic modalities. Verbal instructions must be reinforced by written information. Knowledge of general concepts regarding assessment and therapy in allergic diseases is important so that the patient can learn to manage certain conditions as well as prevent severe reactions and illnesses.

Avoidance Therapy

In avoidance therapy, every attempt is made to remove the allergens that act as precipitating factors. Often simple measures and environmental controls are effective in decreasing symptoms. Examples include using air cleaners/purifiers, humidifiers, and dehumidifiers; keeping windows closed during periods of high pollen counts and windy conditions; using air conditioning as much as possible in the warmer months; sleeping with windows closed; removing dust-catching furnishings (carpets, stuffed animals, feather bedding, window coverings); removing pets from the home or bedroom; removing cockroaches by professional extermination followed by regular cleaning of the infested area(s); using pillow and mattress covers that are impermeable to dust mites; washing bedding materials biweekly in hot water (55°C); and maintaining a smoke-free environment (Ferri, 2016). Because multiple allergens are often implicated, multiple measures to avoid exposure to allergens are often necessary. High-efficiency particulate air (HEPA) purifiers and vacuum cleaner filters also may be used to reduce allergens in the environment. The patient is instructed to reduce exposure to people with upper respiratory tract infections. If an upper respiratory infection occurs, the patient is encouraged to take deep breaths and to cough frequently to ensure adequate gas exchange and to prevent atelectasis. The patient is instructed to seek medical attention because the presence of allergy symptoms along with an upper respiratory tract infection may compromise adequate lung function (Seidman et al., 2015).

Research has shown that multiple avoidance strategies tailored to a person's risk factors can reduce the severity of symptoms, the number of work or school days missed because of symptoms, and the number of unscheduled health care visits for treatment. In many cases, it is impossible to avoid exposure to all environmental allergens so pharmacologic therapy or immunotherapy is needed.

Pharmacologic Therapy

Although allergen avoidance is clearly the safest and most effective means of treating symptoms associated with allergic rhinitis, some individuals may require pharmacologic therapy to further suppress the effects of histamine on the body.

Antihistamines

Antihistamines, now classified as H_1-receptor antagonists (or H_1-blockers), are used in the

management of *mild* allergic disorders. H_1-blockers bind selectively to H_1 receptors, preventing the actions of histamines at these sites. They do not prevent the release of histamine but rather protect the surrounding tissue from the effects of the histamine release.

Oral antihistamines, which are readily absorbed, are most effective when given at the first occurrence of symptoms because they prevent the development of new symptoms. The effectiveness of these medications is limited to certain patients with hay fever, vasomotor rhinitis, urticaria (hives), and mild asthma. Examples of antihistamine medications include diphenhydramine (Benadryl), loratadine (Claritin), cetirizine (Zyrtec), levocetirizine (Xyzal), desoloratidine (Clarinex), and fexofenadine (Allegra). Currently, most antihistamines are available over-the-counter in local pharmacies. Refer to Table 38-2 for details.

Patients also need to understand that medications for allergy control should be used only when the allergy is apparent. This is usually on a seasonal basis. Continued use of medications when not required can cause an increased tolerance to the medication, with the result that the medication will not be effective when needed.

Adrenergic Agents

Adrenergic agents, vasoconstrictors of mucosal vessels, are used topically (nasal and ophthalmic formulations) in addition to the oral route. These medications help relieve severity of symptoms by narrowing blood vessels in the nasal passageways, therefore decreasing nasal congestion; however, these medications will not treat the underlying cause of nasal congestion, sinus pressure, etc. The most commonly used oral adrenergic agent is pseudoephedrine hydrochloride (Sudafed). Although considered safe if used as directed, pseudoephedrine hydrochloride has been known to cause some patients to complain of mild shakiness, heart palpitations, and anxiety shortly after ingestion. Pseudoephedrine is to be used cautiously or avoided in patients with underlying cardiac conditions, anxiety disorders, patients who are or plan on becoming pregnant, asthmatics, and those who use herbal supplements on a regular basis. Potential side effects include hypertension, arrhythmias, palpitations, central nervous system stimulation, irritability, tremor, and tachyphylaxis (acceleration of hemodynamic status) (Meltzer, Ratner, & McGraw, 2015).

TABLE 38-2 Selected H_1-Antihistamines

H_1-Antihistamine	Contraindications	Major Side Effects	Nursing Implications and Patient Teaching
First-Generation H_1-Antihistamines (Sedating)			
Diphenhydramine (Benadryl)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, benign prostatic hypertrophy or bladder neck obstruction, elderly patients	Drowsiness, confusion, dizziness, dry mouth, nausea, vomiting, photosensitivity, urinary retention	Administer with food if gastrointestinal upset occurs. Caution patients to avoid alcohol, driving, or engaging in any hazardous activities due to sedative effects of this medication. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Encourage the use of sunscreen and a hat while outdoors. Assess for urinary retention; monitor urinary output.
Chlorpheniramine (Chlor-Trimeton)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, BPH or bladder neck obstruction, elderly patients	Drowsiness, sedation, and dizziness, although less than other sedating agents; confusion, dry mouth, nausea, vomiting, urinary retention, epigastric distress, thickening of bronchial secretions	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Hydroxyzine (Atarax)	Allergy to hydroxyzine or cetirizine (Zyrtec), pregnancy, lactation	Drowsiness, dry mouth, involuntary motor activity, including tremor and seizures	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Instruct patients to report tremors.
Second-Generation H_1-Antihistamines (Nonsedating)			
Cetirizine (Zyrtec)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Lactation	Dry nasal mucosa, thickening of bronchial secretions	Can be taken without regard to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.
Desloratadine (Clarinex)	Allergy to loratadine (Alavert, Claritin) Lactation Use cautiously with kidney or liver impairment or with pregnancy	Somnolence, nervousness, dizziness, fatigue, dry mouth	Can be taken without regard to meals. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.
Loratadine (Alavert, Claritin)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction	Headache, nervousness, dizziness, depression, edema, increased appetite	Instruct patients to take on empty stomach (1 hour before or 2 hours after meals or food). Instruct patients to avoid alcohol and to use caution if driving or performing tasks that require alertness. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend the use of a humidifier.

Fexofenadine (Allegra)	Allergy to any antihistamines Pregnancy Lactation Use with caution with liver or kidney impairment and in elderly patients	Fatigue, drowsiness, GI upset	Should not be administered within 15 minutes of ingestion of antacids. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend the use of a humidifier.
Levocetirizine (Xyzal)	Allergy to any antihistamines; Dosage should be selected with caution in geriatric patients (start low dosage range) because of the greater frequency of decreased liver, kidney, and/or cardiac function and of concomitant disease and drug therapy; not recommended in nursing women Contraindicated in children 6 months to 11 years of age with renal impairment.	Somnolence, nasopharyngitis, fatigue, dry mouth, and pharyngitis	Avoid concomitant use with alcohol or other CNS depressants; Maintain fluid intake of 1500–2000 mL/day to decrease viscosity of secretions. May cause false-negative result in allergy skin testing. May cause transient ↑ in serum bilirubin and transaminases.

The topical route (drops and nasal sprays) causes fewer side effects than oral administration; however, the use of drops (e.g., tetrahydrozoline hydrochloride [Visine]) and sprays (e.g., oxymetazoline hydrochloride [Afrin]) should be limited to a few days to avoid rebound congestion. Adrenergic nasal decongestants are applied topically to the nasal mucosa for the relief of nasal congestion. They activate the alpha-adrenergic receptor sites on the smooth muscle of the nasal mucosal blood vessels, reducing local blood flow, fluid exudation, and mucosal edema. Topical ophthalmic drops are used for symptomatic relief of eye irritations caused by allergies. Common ocular complaints warranting use of ophthalmic drops include tearing, scleral and/or conjunctival erythema, and itching.

Mast Cell Stabilizers

Mast cell stabilizers are used prophylactically (before exposure to allergens) to prevent the onset of symptoms and to treat symptoms once they occur. They are also used therapeutically in chronic allergic rhinitis. Intranasal cromolyn sodium (NasalCrom) is a spray that acts by stabilizing the mast cell membrane, thus reducing the release of histamine and other mediators of the allergic response (Ferri, 2016). This spray is as effective as antihistamines but less effective than intranasal corticosteroids in the treatment of seasonal allergic rhinitis. The patient must be informed that the beneficial effects of the medication may take a week or so to manifest.

Corticosteroids

Intranasal corticosteroids (INCS) are indicated in more severe cases of acute allergic and perennial rhinitis that cannot be controlled by more conventional medications, such as decongestants, antihistamines, and intranasal cromolyn. Examples of these medications include beclomethasone (Beconase, Vancenase), budesonide (Rhinocort), dexamethasone (Decadron Phosphate Turbinaire), flunisolide (Nasalide), fluticasone (Cutivate, Flonase), and triamcinolone (Nasacort). Studies have proven that INCS are the most effective *maintenance* therapy for chronic allergic rhinitis, regardless of the patient's age, sex, race, or gender. These findings are based on their ability to prevent progression to more severe disease, along with their ability to decrease the likelihood of the evolution of a sleep-related breathing disorder or asthma (Rachelefsky & Farrer, 2013).

Because of their anti-inflammatory actions, these medications are equally effective in

preventing or suppressing the major symptoms of allergic rhinitis.

Corticosteroids are administered by metered-spray devices. If the nasal passages are blocked, a topical decongestant may be used to clear the passages before the administration of the INCS. Patients must be aware that full benefit may not be achieved for several days to 2 weeks. Adverse effects of INCS are mild and include drying of the nasal mucosa, potentially causing epistaxis (bloody nose), which is resolved with discontinuing the medication for a few days, as well as burning and itching sensations caused by the vehicle used to administer the medication. Recommended use of this medication is limited to 30 days (Seidman et al., 2015).

Topical nasal medication for moderate to severe seasonal and perennial allergic rhinitis has emerged in the pharmaceutical industry. MP29-02 (Dymista), which consists of azelastine hydrochloride (AZE) and fluticasone propionate (Flonase), has a wider spray angle, lower viscosity, and smaller droplet size. The medicine has a greater ability to retain itself within the nasal cavity mucosa, thus decreasing nasal congestion and allergy symptoms (Rossi et al., 2015).

Immunotherapy

Allergen desensitization (allergen immunotherapy, hyposensitization) is primarily used to treat IgE-mediated diseases by injections of allergen extracts. Immunotherapy involves the administration of gradually increasing quantities of specific allergens to the patient until a dose is reached that is effective in reducing disease severity from natural exposure (Schwartz, 2016). Immunotherapy is treatment in the form of vaccine therapy (better known as "allergy shots") and, if available, sublingual medication. This type of therapy provides an adjunct to symptomatic pharmacologic therapy and can be used when avoidance of allergens is not possible. Goals of immunotherapy include reducing the level of circulating IgE, increasing the level of blocking antibody IgG, and reducing the sensitivity of mediator cells. Immunotherapy has been most effective for ragweed pollen; however, treatment also has been effective for grass, tree pollen, cat dander, and house dust mite allergens. Indications and contraindications for immunotherapy are presented in Box 38-5.

Unlike antiallergy medication, allergen immunotherapy has the potential to alter the allergic disease course after 3 to 5 years of therapy. Because it may prevent progression or development of asthma or multiple or additional allergies, it is also considered to be a potential preventive measure. The patient must understand what to expect and the importance of continuing therapy for several years before immunotherapy is accomplished. Subcutaneous immunotherapy (SCIT) treatment consists of injecting extracts of the allergens that cause symptoms in a particular patient. Injections begin with very small amounts and are increased gradually, usually at weekly intervals, until a maximum tolerated dose is attained. Maintenance booster injections are administered at 2- to 4-week intervals, frequently for a period of several years, before maximum benefit is achieved, although some patients will note early improvement in their symptoms. Long-term benefit seems to be related to the cumulative dose of vaccine given over time, lasting 3 or more years after therapy has stopped (Vadlamudi & Shaker, 2015). Immunotherapy should not be initiated during pregnancy; for patients who have been receiving immunotherapy before pregnancy, the dosage should not be increased during pregnancy provided the patient is tolerating and

benefiting from the injections.

BOX 38-5 Immunotherapy: Indications and Contraindications

Indications

- Allergic rhinitis, conjunctivitis, or allergic asthma
- History of a systemic reaction to *Hymenoptera* and specific IgE antibodies to *Hymenoptera* venom
- Desire to avoid the long-term use, potential adverse effects, or costs of medications
- Lack of control of symptoms by avoidance measures or use of medications

Contraindications

- Use of beta blocker or angiotensin-converting inhibitor therapy, which may mask early signs of anaphylaxis
- Presence of significant pulmonary or cardiac disease or organ failure
- Inability of the patient to recognize or report signs and symptoms of a systemic reaction
- Nonadherence of the patient to other therapeutic regimens and low probability that patient will adhere to immunization schedule (often weekly for an indefinite period)
- Inability to monitor the patient for at least 30 minutes after administration of immunotherapy
- Absence of equipment or adequate personnel to respond to allergic reaction if one occurs

A newer approach evolving in the treatment of allergies is sublingual immunotherapy (SLIT). The U.S. Food and Drug Administration has recently approved SLIT, yet the treatment has not been utilized much due to lack of treatment options for polysensitized patients. Currently, there are sublingual tablets commercially available for grass and ragweed only. From approximately 8 weeks before the onset of the targeted pollen season continuing through the end of the season, an individual would ingest a pill daily. Benefits of SLIT include self-administration at home, no pain during administration, improvement in comorbid conditions (e.g., asthma, conjunctivitis), and reduced risk of anaphylaxis. Adverse effects include potential bad taste and risk of noncompliance as the patient must adhere to taking the medication daily in order for maximum benefits to be achieved (Lin et al., 2013; Vadlamudi & Shaker, 2015).

Concept Mastery Alert

Allergy control by immunotherapy usually requires treatment for 3 to 5 years.

Candidates for SLIT therapy are chosen carefully after analyzing the risk/benefit ratio. Although severe systemic reactions occur in fewer than 1% of patients receiving immunotherapy, the risk for systemic and potentially fatal anaphylaxis does exist. It tends to occur most frequently at the induction or "up-dosing" phase. Therefore, the patient must be monitored after administration of immunotherapy. SLIT is to be administered under supervision by the medical provider in the provider's office. The patient remains in the office or clinic for at least 30 minutes after the injection and is observed for possible systemic symptoms. If a large, local swelling develops at the injection site, the next dose should not be increased because this may be a warning sign of a possible systemic reaction (Vadlamudi & Shaker, 2015).

Nursing Alert

Because the injection of an allergen may induce systemic reactions, such injections are administered only in a setting (e.g., physician's office, clinic) where epinephrine is immediately available.

Therapeutic failure is evident when a patient does not experience a decrease of symptoms within 12 to 24 months, fails to develop increased tolerance to known allergens, and cannot decrease the use of medications to reduce symptoms. Potential causes of treatment failure include misdiagnosis of allergies, inadequate doses of allergen, newly developed allergies, and inadequate environmental controls.

Homeopathic Modalities

Anecdotally, the health benefits of traditional Chinese medicine (TCM) which includes herbal therapies, has been reported for years. Studies are evaluating the impact of herbal medications on food allergy responses, such as FAHF-2 which is a formulation of nine Chinese herbs. Preclinical studies report that FAHF-2 blocked peanut-induced anaphylaxis during and after the development peanut hypersensitivity, with effectiveness sustained for up to 6 months after therapy (Slomski, Lack, & Jones, 2014). A phase II clinical trial is in progress. Additionally, probiotic dietary supplements, typically with *Lactobacillus* and *Bifidobacterium* species, has been used in clinical trials to evaluate the preventive impact on atopic disease and the impact on active disease (Slomski et al., 2014).

CONTACT DERMATITIS

Contact dermatitis, a type IV delayed hypersensitivity reaction, is an acute or chronic skin inflammation that results from direct skin contact with chemicals or allergens.

Types

There are four basic types: allergic, irritant, phototoxic, and photoallergic (Table 38-3). Eighty percent of cases are caused by excessive exposure to or additive effects of irritants (e.g., soaps, detergents, plants, organic solvents). Skin sensitivity may develop after brief or prolonged periods of exposure, and the clinical picture may appear hours or weeks after the sensitized skin has been exposed.

Clinical Manifestations and Assessment

Symptoms include itching, burning, erythema, skin lesions (vesicles), and edema, followed by weeping, crusting, and, finally, drying and peeling of the skin. In severe responses, hemorrhagic bullae may develop. Repeated reactions may be accompanied by thickening of the skin and pigment changes. Secondary invasion by bacteria may develop in skin that is abraded by rubbing or scratching. Usually, there are no systemic symptoms unless the eruption is widespread.

The location of the skin eruption and the history of the exposure aid in determining the condition (see Table 38-3). However, in cases of obscure irritants or an unobservant patient, the diagnosis can be extremely difficult, often involving many trial-and-error procedures before the cause is determined. Patch tests on the skin with suspected offending agents may clarify the diagnosis (American Academy of Dermatology, n.d.). Management is discussed in Table 38-3.

ATOPIC DERMATITIS

Atopic dermatitis is a type I immediate hypersensitivity disorder characterized by inflammation and hyperreactivity of the skin, often causing pruritus. Although most commonly seen in children, the prevalence among adults has increased in the past 5 years. Recent studies confirm atopic dermatitis will persist through adulthood in up to 50% of individuals (Mortz et al., 2015). Other terms used to describe this skin disorder include *atopic eczema, atopic dermatitis/eczema,* and *atopic dermatitis/eczema syndrome* (AEDS).

Clinical Manifestations and Assessment

Most patients with atopic dermatitis have significant elevations of serum IgE and peripheral eosinophilia. Pruritus and hyperirritability of the skin (most commonly seen in flexural folds) are the most consistent features of atopic dermatitis and are related to large amounts of histamine in the skin (Fig. 38-3). Excessive dryness of the skin with resultant itching is related to changes in lipid content, sebaceous gland activity, and sweating. In response to stroking of the skin, immediate redness appears on the skin and is followed in 15 to 30 seconds by pallor, which persists for 1 to 3 minutes. Years of chronically irritated skin resulting in excessive itching can cause lichenification, or a leathery hardened appearance to the affected area. Lesions develop secondary to the trauma of scratching and appear in areas of increased sweating and hypervascularity. Atopic dermatitis is chronic, with remissions and exacerbations, reoccurrences often occurring with allergy flare-ups (Mortz, Andersen, Dellgren, Barington, & Bindslev-Jensen, 2015).

It is important to note that atopic dermatitis is often the first step in a process that leads to asthma and allergic rhinitis, otherwise known as the "allergic/atopic triad." It is the result of interactions among susceptibility genes, the environment, defective function of the skin barrier, and immunologic responses. Factors associated with more severe disease states or increased rates of exacerbations include familial history of atopic dermatitis, being the oldest or only child, having a severe case of dermatitis at a very early age, respiratory disease, early onset, and very high serum IgE levels (Seidman et al., 2015).

TABLE 38-3 Types, Testing, and Treatment of Contact Dermatitis

Type	Etiology	Clinical Presentation	Diagnostic Testing	Treatment
Allergic	Results from contact of skin and allergenic substance. Has a sensitization period of 10–14 days.	Vasodilation and perivascular infiltrates on the dermis Intracellular edema Usually seen on dorsal aspects of hand	Patch testing (contraindicated in acute, widespread dermatitis)	Avoidance of offending material Burow solution (aluminum acetate in water) is a drying agent for weeping skin lesions or cool water compress Systemic corticosteroids (prednisone) for 7–10 days Topical corticosteroids for mild cases Oral antihistamines to relieve pruritus
Irritant	Results from contact with a substance that chemically or physically damages the skin on a nonimmunologic basis. Occurs after first exposure to irritant or repeated exposures to milder irritants over an extended time.	Dryness lasting days to months Vesiculation, fissures, cracks Most common on hands and lower arms	Clinical picture Appropriate negative patch tests	Identification and removal of source of irritation Application of hydrophilic cream or petrolatum to soothe and protect Topical corticosteroids and compresses for weeping lesions Antibiotics for infection, and oral antihistamines for pruritus
Phototoxic	Resembles the irritant type but requires sun and a chemical in combination to damage the epidermis.	Similar to irritant dermatitis	Photopatch test	Same as for allergic and irritant dermatitis
Photoallergic	Resembles allergic dermatitis but requires light exposure in addition to allergen contact to produce immunologic reactivity.	Similar to allergic dermatitis	Photopatch test	Same as for allergic and irritant dermatitis

Medical Management

Treatment of patients with atopic dermatitis must be individualized. Guidelines for treatment include decreasing itching and scratching by wearing cotton fabrics; washing with a mild detergent; humidifying dry heat in winter; maintaining room temperature at 20°C to 22.2°C (68°F to 72°F); using antihistamines, such as diphenhydramine (Benadryl); and avoiding animals, dust, sprays, and perfumes. Keeping the skin moisturized with daily baths to hydrate the skin and the use of topical skin emollients is encouraged and remains the main treatment for atopic dermatitis (Ferri, 2016). Topical corticosteroids are used to prevent inflammation, and any infection is treated with antibiotics to eliminate *Staphylococcus aureus* when indicated. Use of immunosuppressive agents, such as cyclosporine (Neoral, Sandimmune), tacrolimus (Prograf, Protopic), and pimecrolimus (Elidel), may be effective in inhibiting T cells and mast cells involved in atopic dermatitis (Moskowitz, 2014).

Nursing Management

Patients who experience atopic dermatitis and their families require assistance and support from the nurse to cope with the disorder. Often the symptoms are disturbing to the patient and disruptive to the family. The appearance of the skin may affect the patient's self-esteem and his or her willingness to interact with others. Instructions and counseling about strategies to incorporate preventive measures and treatments into the lifestyle of the family may be helpful. Instructions include counseling the patient and family on various triggers of atopic dermatitis (e.g., winter months, heat or exercise, emotional stress, hormonal fluxes in women, skin irritants [perfumes], and microorganisms [bacteria, fungi, viruses, and yeast]) that may lead to an exacerbation. The patient and family need to be aware of signs of secondary infection and of the need to seek treatment if infection occurs. The nurse also teaches the patient and family about the side effects of medications used in treatment.

FIGURE 38-3 Atopic dermatitis. (Courtesy of Anatomical Chart Company.)

DERMATITIS MEDICAMENTOSA (DRUG REACTIONS)

Dermatitis medicamentosa, a type I hypersensitivity disorder, is the term applied to skin rashes associated with certain medications. Although people react differently to each medication, certain medications tend to induce eruptions of similar types. Rashes are among the most common adverse reactions to medications and occur in approximately 2% to 3% of hospitalized patients.

Clinical Manifestations and Assessment

In general, drug reactions appear suddenly, have a particularly vivid color, manifest with characteristics that are more intense than the somewhat similar eruptions of infectious origin, and, with the exception of bromide and the iodide rashes, disappear rapidly after the medication is withdrawn. Rashes may be accompanied by systemic or generalized symptoms, such as bronchospasm, urticaria, and significant angioedema.

Medical and Nursing Management

Upon discovery of a medication allergy, the causative agent must be discontinued immediately and treatment initiated for any symptoms the patient is experiencing. Once stable, the patient is warned that he or she has a hypersensitivity to a particular medication and is advised not to take it again. Patients should carry information identifying the hypersensitivity, and subsequent reaction experienced, with them at all times.

Skin eruptions related to medication therapy suggest more serious hypersensitivities. Frequent assessment and prompt reporting of the appearance of any eruptions are important so that early treatment can be initiated. Some cutaneous drug reactions may be associated with a clinical complex that involves other organs. These are known as *complex drug reactions*.

URTICARIA AND ANGIONEUROTIC EDEMA

Urticaria (hives) is a type I hypersensitive allergic reaction of the skin characterized by the sudden appearance of pinkish, edematous elevations that vary in size and shape, itch, and cause local discomfort (Fig. 38-4). They may involve any part of the body, including the mucous membranes (especially those of the mouth), the larynx (occasionally with serious respiratory complications), and the GI tract.

Each hive remains for a few minutes to several hours before disappearing. For hours or days, clusters of these lesions may come, go, and return episodically. If this sequence continues for longer than 6 weeks, the condition is called chronic urticaria. Chronic urticaria requires an extensive workup, ruling out numerous autoimmune diseases (e.g., lupus, rheumatoid arthritis, thyroid disease, etc.).

FIGURE 38-4 Hives.

Angioneurotic edema involves the deeper layers of the skin, resulting in more diffuse swelling, rather than the discrete lesions characteristic of hives. On occasion, this reaction covers the entire back. The skin over the reaction may appear normal but often has a reddish hue. The skin does not pit on pressure, as ordinary edema does. The regions most often involved are the lips, eyelids, cheeks, hands, feet, genitalia, and tongue; the mucous membranes of the larynx, the bronchi, and the GI canal also may be affected, particularly in the hereditary type (see discussion in the following section). Swellings may appear suddenly, in a few seconds or minutes, or slowly, in 1 or 2 hours. In the latter case, often their appearance is preceded by itching or burning sensations. Seldom does more than a single swelling appear at one time, although one may develop while another is disappearing. Infrequently, swelling recurs in the same region. Individual lesions usually last 24 to 36 hours. On rare occasions, swelling may recur with remarkable regularity at intervals of 3 to 4 weeks.

FOOD ALLERGY

Pathophysiology

IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in about 2% of the adult population; it is thought to occur in people who have a genetic predisposition combined with exposure to allergens early in life through the GI or respiratory tract or nasal mucosa. Researchers also have identified a second type of food allergy, a non–IgE-mediated food allergy syndrome in which T cells play a major role (Ferri, 2016).

Almost any food can cause allergic symptoms, some even resulting in anaphylaxis. The most common offenders are seafood (lobster, shrimp, crab, clams, fish), legumes (peanuts, peas, beans, licorice), seeds (sesame, cottonseed, caraway, mustard, flaxseed, sunflower seeds), tree nuts, berries, egg white, buckwheat, milk, and chocolate. Peanut and tree nut (e.g., cashew, walnut) allergies are responsible for severe food allergy reactions in children and may result in anaphylactic death. The most common cause of anaphylactic death reported in adults is due to stings from insects, whereas in children, anaphylaxis to food may be more common (Chang, 2010; Schwartz, 2016).

Clinical Manifestations and Assessment

The clinical symptoms are classic allergic symptoms (urticaria, dermatitis, wheezing, cough, laryngeal edema, angioedema) and GI symptoms (itching; swelling of lips, tongue, and palate; abdominal pain; nausea; cramps; vomiting; and diarrhea).

A careful diagnostic workup is required in any patient with a suspected food hypersensitivity. Included are a detailed allergy history, a physical examination, and pertinent diagnostic tests. Skin testing is used to identify the source of symptoms and is useful in identifying specific foods as causative agents.

Medical Management

Therapy for food hypersensitivity includes elimination of the food responsible for the hypersensitivity. Pharmacologic therapy is necessary for patients who cannot avoid exposure to offending foods and for patients with multiple food sensitivities not responsive to avoidance measures. Medication therapy involves the use of H_1-blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium. An essential aspect of management is teaching patients and family members to recognize symptoms associated with an anaphylactic reaction, when and how to administer life-saving medication (epinephrine), and when to call for emergency help. Many food allergies disappear with time, particularly in children. About one third of proven allergies disappear in 1 to 2 years if the patient carefully avoids the offending food. However, allergies to peanuts, shellfish, fish, and tree nuts have been reported to persist throughout adulthood in 20% of people. Researchers are hopeful that within the next 10 years more studies will have been performed and oral immunotherapy (OIT) will become an effective treatment option for those with certain food allergies (Slomski, 2012; Slomski et al., 2014).

Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about strategies to prevent its recurrence. The patient is instructed about the importance of carefully assessing foods prepared by others for obvious as well as hidden sources of food allergens and of avoiding locations and facilities where those allergens are likely to be present. This includes careful reading of food labels and monitoring the preparation of food by others to be sure that exposure to even minute amounts of allergenic foods is avoided. One of the dangers of food allergens is that they may be hidden in other foods and not apparent to people who are susceptible to the allergen. For example, often peanuts and peanut butter are used in salad dressings and Asian, African, and Mexican cooking and may result in severe allergic reactions, including anaphylaxis. Previous contamination of equipment with allergens (e.g., peanuts) during preparation of another food product (e.g., chocolate cake) is enough to produce anaphylaxis in people with severe allergy.

The patient and family must be knowledgeable about early signs and symptoms of allergic reactions and must be proficient in emergency administration of epinephrine if a reaction occurs. The nurse also advises the patient to wear a medical alert bracelet or to carry identification and emergency equipment at all times. Patients' food allergies should be noted on their medical records because there may be risk of allergic reactions not only to food but also to some medications containing similar substances.

SERUM SICKNESS

Pathophysiology

Serum sickness is an immune-complex type III hypersensitivity. If these type III complexes are deposited in tissues or vascular endothelium, there is an increase in vascular permeability and tissue injury, resulting in a vasculitis (inflammation of blood vessels). Traditionally serum sickness has resulted from the administration of therapeutic antisera of animal sources for the treatment or prevention of infectious diseases, such as tetanus, pneumonia, rabies, diphtheria, and botulism, as well as the bites of venomous snakes and black widow spiders. With the advent of human antitetanus serum and antibiotics, classic serum sickness is much less common now. However, various medications (primarily penicillin) may cause a serum-sickness–like reaction similar to that caused by foreign sera.

Clinical Manifestations and Assessment

Symptoms are caused by a reaction and immunologic attack on the serum or medication. Antibodies appear to be of the IgE and IgM classes. Early manifestations, beginning 6 to 10 days after administration of the medication, include an inflammatory reaction at the site of injection of the medication, followed by regional and generalized lymphadenopathy and fever. Symptoms may appear as late as 3 weeks afterward. There is usually a skin rash, which may be urticarial or purpuric. Joints are frequently tender and swollen. Vasculitis may occur in any organ but is observed most commonly in the kidney, resulting in proteinuria and, occasionally, casts in the urine. There may be mild to severe cardiac involvement. Peripheral neuritis may cause temporary paralysis of the upper extremities or may be widespread, causing Guillain–Barré syndrome (Nowak-Wegrzyn & Sicherer, 2016).

Medical and Nursing Management

The primary goal in serum sickness therapy is to treat the clinical syndrome symptomatically. This hypersensitivity reaction lasts for several days to a few weeks if untreated, but the patient responds promptly and completely if treated with antihistamines and corticosteroids (Bope & Kellerman, 2016). Aggressive therapy, including ventilator support, may be necessary if peripheral neuritis and Guillain–Barré syndrome occur. If symptoms are severe enough to warrant ventilator support or if hemodynamic instability ensues, the patient is to be admitted to an intensive care unit. See Chapter 46 for nursing management of Guillain–Barré syndrome.

LATEX ALLERGY

Latex allergy, the allergic reaction to natural rubber proteins, has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. Over the past 80 years, the numbers of individuals affected with this allergy has dropped drastically due to the processing of nonlatex materials and nonpowdered latex gloves used in health care settings. Despite numbers and studies confirming this, the severity of illness associated with a latex allergy remains a nursing priority.

Risk Factors

Populations at risk include health care workers, patients with atopic allergies or multiple surgeries, people working in factories that manufacture latex products, and females, as well as patients with spina bifida or spinal cord injuries and congenital abnormalities of the genitourinary tract. Because more food handlers, hairdressers, auto mechanics, and police officers are now wearing latex gloves, they also may be at risk for latex allergy. Latex is the second most common cause of anaphylactic reactions during the intraoperative period (due to repeated latex exposure), preceded only by muscle relaxants (Butterworth, Mackey, & Wasnick, 2013).

Food that has been handled by people wearing latex gloves may stimulate an allergic response in the consumer. Cross-reactions have been reported in people who are allergic to certain food products, such as kiwis, bananas, pineapples, mangos, passion fruit, avocados, and chestnuts (American Academy of Allergy, Asthma & Immunology, n.d.).

TABLE 38-4 Selected Products Containing Natural Rubber Latex and Latex-Free Alternatives

Products Containing Latex	Examples of Latex-Safe Alternatives[a]
Hospital Environment	
Ace bandage (brown)	Ace bandage, white, all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strip (3M), Duoderm, Mepilex
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette; or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Dermaprene, Neoprene, polymer, or vinyl gloves
IV catheters	Jelko, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing.
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper
Penrose drains	Jackson-Pratt, Zimmer Hemovac drains
Prepackaged enema kits	Theravac, Fleet Ready-to-use
Pulse oximeters	Nonin oximeters
Resuscitation bags	Laerdal, Puritan Bennett, *certain* Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Syringes—single use (Monoject, B & D)	Terumo syringes, Abbott PCA Abboject
Suction tubing	PVC (Davol, Laerdal)
Tapes	Dermicel, Micropore
Thermometer probes	Diatec probe covers
Tourniquets	X-Tourn straps (Avcor)
Thera-Band	New Thera-band Exercisers, plastic tubing
Home Environment	
Balloons	Mylar balloons
Diapers, incontinence pads	Huggies, Always, *some* Attends
Condoms, diaphragms	Polyurethane products, Durex/Avanti and Reality products (female condom)
Feminine hygiene pad	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

[a]Confirmation is essential to verify that all items are latex-free before using, especially if risk of latex allergy is present.

TABLE 38-5 Types of Reactions to Latex

Type of Reaction	Cause	Signs/Symptoms	Treatment
Irritant contact dermatitis	Damage to skin because of irritation and loss of epidermoid skin layer; not an allergic reaction. Can be caused by excessive use of soaps and cleansers, multiple hand-washings, inadequate hand drying, mechanical irritation (e.g., sweating, rubbing inside powdered gloves), exposure to chemicals added during the manufacturing of gloves, and alkaline pH of powdered gloves. Reaction may occur with first exposure, is usually benign, and is not life-threatening.	Acute: redness, edema, burning, discomfort, itching Chronic: dry, thickened, cracked skin	Referral for diagnostic testing Avoidance of exposure to irritant Thorough washing and drying of hands Use of powder-free gloves with more frequent changes of gloves Changing glove types Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based skin agents with latex products because they cause breakdown of the latex product
Allergic contact dermatitis	Delayed hypersensitivity (type IV) reaction. Usually affects only area in contact with latex; reaction is usually to chemical additives used in the manufacturing process rather than to latex itself. Cause of reaction is T cell–mediated sensitization to additives of latex. Reaction is not life-threatening and is far more common than a type I reaction. Slow onset; occurs 18–24 hours after exposure. Resolves within 3–4 days after exposure. More severe reactions may occur with subsequent exposures.	Pruritus, erythema, swelling, crusty thickened skin, blisters, other skin lesions	Referral for diagnosis (patch tests) and treatment Thorough washing and drying of hands Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based products unless they are latex-compatible Avoidance of identified causative agent because continued exposure to latex products in the presence of breaks in skin may contribute to latex protein sensitization
Latex allergy	Type I IgE-mediated immediate hypersensitivity to plant proteins in natural rubber latex. In sensitized people, anti-latex IgE antibody stimulates mast cell proliferation and basophil histamine release. Exposure can be through contact with the skin, mucous membranes, or internal tissues, or through inhalation of traces of powder from latex gloves. Severe reactions usually occur shortly after parenteral or mucous membrane exposure. People with any type I reaction to latex are at high risk of anaphylaxis.	Local: swelling, redness, edema, itching Mild systemic: rhinitis, flushing, conjunctivitis Severe systemic: urticaria, laryngeal edema, bronchospasm, asthma, severe vasodilation angioedema, including anaphylaxis, cardiovascular collapse, and death All above reactions can occur within minutes after exposure.	Immediate treatment of reaction with epinephrine, fluids, vasopressors, and corticosteroids, and airway and ventilator support, with close monitoring for recurrence for next 12–14 hours Prompt referral for diagnostic evaluation Treatment and diagnostic evaluation in latex-free environment Strict avoidance of allergy testing and management Assessment of all patients for symptoms of latex allergy Teaching of patients and family members about the disorder and about the importance of preventing future reactions by avoiding latex Encouraging wearing of a medical alert bracelet that identifies latex allergy for emergency situations Warning labels can be attached to car windows to alert police and paramedics about the driver's or passenger's latex allergy in case of a motor vehicle crash. Carrying an EpiPen at all times and being prepared and able to use it

Pathophysiology

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, or aerosol. Allergic reactions are more likely with exposure via the mucous membrane or from the parenteral route but also can occur with cutaneous contact or inhalation. The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or settle on the skin, mucous membranes, or clothing. Mucosal exposure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from IV lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of medical and household items containing latex and a list of alternative products are found in Table 38-4.

Clinical Manifestations and Assessment

Several different types of reactions to latex are possible: irritant contact dermatitis, allergic dermatitis, and latex allergy. Table 38-5 lists the causes, symptoms, and management of each.

The diagnosis of latex allergy is based on the history and diagnostic test results. Sensitization is detected by skin testing, RAST, or enzyme-linked immunosorbent assay (ELISA). Skin tests should be performed only by clinicians who have expertise in their administration and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent.

Medical Management

See Table 38-5 for medical management.

Nursing Management

The nurse can assume a pivotal role in the management of latex allergies in both patients and staff. All patients should be asked about latex allergy, although special attention should be given to those at particularly high risk (e.g., patients with spina bifida, patients who have undergone multiple surgical procedures). Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short-term procedure units, and emergency departments need to pay particular attention to latex allergy.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the person to latex. Patients with latex allergy are advised to notify their health care providers and to wear a medical information bracelet. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. Also, they must become knowledgeable about signs and symptoms of latex allergy as well as emergency treatment and self-injection of epinephrine in case of allergic reaction.

Nursing Alert

Chronic exposure to latex and a history of skin atopy increases the risk of sensitization for health care providers. If a patient is exposed to latex through frequent medical procedures utilizing latex products (e.g., repeated urinary catheterization), they, too, should be considered at increased risk for developing a latex allergy.

Nurses can be instrumental in establishing and participating in multidisciplinary committees to address latex allergy and to promote a latex-free environment. Latex allergy protocols and education of staff about latex allergy and precautions are important strategies to ensure assessment and prompt treatment of affected people.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 17-year-old girl has developed symptoms of asthma thought to be an allergic response to allergens in her environment. Develop an evidence-based plan for avoidance strategies for her while she is living at home and for her move next year to a college dormitory. Describe the strength of the evidence and criteria used to assess its strength. What instructional strategies and outcome measures will you use to educate her about avoidance strategies and to assess the effectiveness of their use?

2. A 72-year-old man is admitted for emergency surgery to treat a strangulated hernia. He reports that he has severe allergies but is unable to be specific about the nature of his allergies or the allergic reactions that he has experienced in the past. He reports that he has had to use emergency epinephrine on several occasions in the past because of severe

allergic reactions. What precautions are needed preoperatively, intraoperatively, and postoperatively for this patient to prevent the occurrence of severe allergic reactions? What interventions and nursing management would be indicated if he developed a severe allergic reaction?

NCLEX-Style Review Questions

1. During a clinical post-conference, the nursing instructor is discussing factors related to the risk of anaphylaxis. Select all statements that properly describe allergic and anaphylactic reactions.
   a. The severity depends on the degree of allergy.
   b. The severity of previous reactions determines the severity of subsequent reactions.
   c. The severity depends on the dose of the allergen.
   d. The severity of previous reactions does not determine the severity of subsequent reactions.

2. Which reaction would be consistent with a mild reaction to an allergen?
   a. Bronchospasm
   b. Warmth
   c. Cough
   d. Tearing of the eyes

3. When reviewing the chart of a patient diagnosed with allergic rhinitis, the nurse understands that this allergic disorder is caused by which type of hypersensitivity reaction?
   a. Type I
   b. Type II
   c. Type III
   d. Type IV

4. A patient is being seen in the dermatology clinic for urticaria. The nurse would expect which medication to be prescribed for the patient?
   a. Pseudoephedrine (Sudafed)
   b. Diphenhydramine (Benadryl)
   c. Dexamethasone (Decadron)
   d. Cromolyn sodium (NasalCrom)

5. What is the most common risk in developing a latex allergy?
   a. Occasional latex condom use
   b. IV line insertions
   c. Use of hemodialysis equipment
   d. Repeated donning of latex gloves

CHAPTER 39

Nursing Management: Patients with Rheumatic Disorders

Linda Alessie Podolak

Learning Objectives

After reading this chapter, you will be able to:

1. Explain the pathophysiology of rheumatic diseases or disorders.
2. Describe the assessment and diagnostic findings seen in patients with a suspected diagnosis of rheumatic disease or disorder.
3. Describe the systemic effects of a connective tissue disease.
4. Discuss the pharmacologic, medical, and nursing management associated with rheumatic disorders.
5. Apply the nursing process as a framework for the care of the patient with a rheumatic disorder.
6. Identify appropriate nursing interventions based on nursing diagnoses that commonly occur with rheumatic disorders.

Rheumatic disorders affect the joints, bones, muscles, and connective tissues. These conditions can be minor illnesses, or they can be life-threatening. Systemic effects caused by rheumatic disorders or diseases result in obvious limitations in mobility and activities of daily living (ADL) as well as more subtle manifestations, such as pain, fatigue, insomnia, and disturbed body image. Organ failure and death may be an end result for some rheumatic disorders. The rheumatic condition may be the patient's primary health problem or a secondary diagnosis. Thorough understanding of rheumatic conditions and their effects on a patient's function and well-being is key to developing an interprofessional plan of care.

OVERVIEW

Commonly called arthritis (inflammation of a joint) and thought of as one condition, the rheumatic diseases are actually more than 100 different types of disorders that primarily affect joints, bones, skeletal muscles, and connective tissues that collectively affect more than 46 million Americans (National Institute of Arthritis and Musculoskeletal and Skin Diseases [NIAMS], 2014a). Some disorders are more likely to occur at a particular time of life or to affect one gender more than the other (see Box 39-1 for Gerontologic Considerations). The symptom that most commonly causes a person to seek medical attention is pain. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue. The onset of these conditions may be acute or insidious, with a course possibly marked by periods of remission (a period when disease symptoms are reduced or absent) and exacerbation (a period when symptoms occur or increase).

Assessment includes a complete health history followed by a complete physical examination combined with a functional assessment. Inspection of the patient's general appearance occurs during initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. Also the symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are noted and recorded. The functional assessment is a combination of history (what the patient reports that he or she can and cannot do) and examination (observation of activities is made: the patient demonstrates what he or she can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness); for example, with shoulder or elbow involvement, the person may bend over to reach a fork, rather than raising the fork to the mouth.

The history and physical assessment data are supplemented by supportive or confirming diagnostic test findings. Common serum laboratory tests used for patients with rheumatic disorders are described in Table 39-1. Radiologic investigations facilitate early diagnosis, guide treatment, and, ultimately, impact prognosis. Scans, computed tomography (CT), and magnetic resonance imaging (MRI) are not the most cost-effective methods for detection of early disease and are not performed routinely at the time of diagnosis. In some instances, many tests are used to monitor the course of the disease. For example, contrast radiography and MRI play a role in diagnosing advancing systems affected in scleroderma; the erythrocyte sedimentation rate (ESR) reflects inflammatory activity and, indirectly, the progression or remission of disease. Ultimately, the health care provider determines which tests are necessary based on the symptoms, stage of disease, cost, and likely benefit of the test.

Box 39-1 Gerontologic Considerations

Although people of all ages may be affected, rheumatic disease is commonly thought of

by the patient, family, and society as a whole as an inevitable consequence of aging. Many older people expect and accept the immobility and self-care problems related to the rheumatic disorders and do not seek help, thinking that nothing can be done. Careful diagnosis and appropriate treatment is crucial and can improve the quality of life for older people. An adequate support system for the elderly is also a critical factor in the ability to follow an interdisciplinary plan of care that includes exercise, nutrition, general health maintenance, pharmacotherapy, and nonpharmacologic management. However, the rheumatic disorders do have some special implications for the older adult.

Age alone causes changes in serologic studies (e.g., ESR, ANA), making interpretation of laboratory values more difficult. Decreased vision and altered balance, often present in elderly people, may be problematic if rheumatic disease in the lower extremities affects locomotion. Also, the combination of decreased hearing and visual acuity, memory loss, and depression contributes to failure to follow the treatment regimen in elderly patients.

Pharmacologic treatment of rheumatic disease in older patients is more difficult. Aging brings many physical and metabolic changes that may increase the elderly patient's sensitivity to both the therapeutic and toxic effects of some drugs, making overtreatment or inappropriate treatment possible. If therapeutic medications have an effect on the senses (hearing, cognition), this effect is intensified in the elderly. The cumulative effect of these medications is accentuated because of the physiologic changes of aging. For example, decreased kidney function in the elderly alters the metabolism of certain medications, such as NSAIDs. In addition, elderly patients are more prone to side effects associated with the use of multiple-drug therapy for various disorders (Lehne, 2013; Miller, 2015).

Nursing Alert

The ESR is a measure of the rate of sedimentation of red blood cells (RBCs) in an anticoagulated whole blood sample over a specified period of time; it is commonly referred to as a "sed" rate. Often increased "sed" rates are associated with inflammatory states. Normally, the distance an RBC falls in 1 hour is less than 15 mm/hr for men and slightly higher in women. The speed with which the RBC moves is related to the clumping of RBCs. The more clumping, the heavier and higher the speed that an RBC falls. Inflammatory states produce proteins that encourage this clumping, thus high ESR levels are associated with inflammation. The ESR does not diagnose a problem, but it is used to monitor status of a disease and response to therapy (Van Leeuwen & Bladh, 2015).

Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relief of systemic effects. The chronic nature of most of these disorders mandates that the patient understand the disease, have the information necessary to make good self-management decisions, be referred to appropriate community agencies (such as the Arthritis Foundation) for support, and be presented with a therapeutic program that is compatible with his or her lifestyle. The goals and strategies of management of basic

rheumatic diseases are outlined in Table 39-2. The trend in management is toward a more aggressive pharmacologic approach earlier in the disease presentation.

Pharmacologic management of rheumatic disorders is used to manage symptoms, control pain and inflammation, and—in some diseases, such as rheumatoid arthritis (RA)—modify the disease course. However, disease typically advances steadily and, as a result, pharmacologic therapy is chronic; thus, success requires motivation and cooperation by the patient. Selection of medication is based on the patient's needs, the stage of disease, and the risk of side effects (Durham, Fowler, Donato, Smith, & Jensen, 2015).

Antiarthritic drugs fall into three major groups: nonsteroidal anti-inflammatory drugs (NSAIDs) including salicylates (e.g., aspirin), disease-modifying antirheumatic drugs (DMARDs), and glucocorticoids (adrenal corticosteroids). These groups differ with reference to time course of effects, toxicity, and ability to slow disease progression. Table 39-3 reviews the medications commonly used in rheumatic disorders, particularly RA.

Nonpharmacologic treatment measures include the use of heat or cold, weight reduction, joint rest and avoidance of joint overuse, orthotic devices (e.g., splints, braces) to support inflamed joints, and an exercise regimen. Occupational and physical therapy can help the patient adopt self-management strategies. Other nonpharmacologic modalities, such as massage, yoga, pulsed electromagnetic fields, transcutaneous electrical nerve stimulation (TENS), and music therapy, have been used in the treatment of arthritis (Berman, Lewith, Manheimer, Bishop, & D'Adamo, 2015; Field, Diego, Delgado, Garcia, & Funk, 2013; Sharma, 2014). In addition, iontophoresis can be used to deliver medication through the skin using direct electrical current. A combination of methods may be required because different methods often work better at different times.

TABLE 39-1 Common Serum Laboratory Tests for Rheumatic Diseases

Test	Normal Value	Implications
Serology		
Erythrocyte Sedimentation Rate (ESR)		
Measures the rate at which red blood cells (RBCs) settle out of unclotted blood in 1 hour	Westergren method *Men,* 0–15 mm/hr, over 50 years of age: 0–20 mm/hr *Women,* 0–20 mm/hr, over 50 years of age: 0–30 mm/hr	Usually increase is seen in inflammatory connective tissue diseases (e.g., RA, SLE, scleroderma), gout, can be seen in elderly An increase indicates rising inflammation; the higher the ESR, the greater the inflammatory activity
Uric Acid		
Measures level of uric acid in serum	*Men,* 3.4–7 mg/dL (202–416 µmol/L) *Women,* 2.4–6 mg/dL (143–357 µmol/L) *Biologic Crystallization Point,* at least 6.8 mg/dL (408 µmol/L)	Increase is seen with gout, where there is an overproduction of uric acids that occurs when there is excessive cell breakdown and catabolism of nucleonic acids
Serum Immunology		
Antinuclear Antibody (ANA)		
Measures antibodies that react with a variety of nuclear antigens Usually the first step, if antibodies are present, further testing determines specific circulating antibodies to extractable nuclear antigens (anti-dsDNA, anti-RNP, anti Ro-SSA).	Screen: negative by ELISA and IFA methods If positive by IFA, specimen is titered. Titer: less than 1:160 Low titers are present in elderly and some healthy adults	Positive test is associated with systemic rheumatic disease, such as mixed connective tissue disease, SLE, RA, scleroderma, CREST syndrome, can be seen in elderly The higher the titer, the greater the inflammation Some negative ANA findings have been found to have positive anti-Ro (SSA)
Anticentromere Antibody Test		
A specific autoantibody, detected by using Hep-2 cells in various stages of cell division, centromere region of the cell chromosomes will stain if positive	Screen: negative by ELISA and IFA methods If positive by IFA, specimen is titered.	Positive test is associated with the CREST syndrome in scleroderma Present in 90% of those with CREST
Anticyclic Citrullinated Peptide (Anti-CCP)		
Disease-specific autoantibody, highly specific diagnostic and prognostic markers for RA Detects patients with early RA at baseline (after 3–6 months of symptoms) Second generation test: CCP2 assay, even higher sensitivity	Negative	Positive in RA Predictive of erosive disease Sensitivity of anti-CCP comparable to rheumatoid factor (RF) but has higher specificity (90–95%) Differentiates other entities that can resemble RA and, at times, be RF positive
Anti–double-stranded DNA (Anti-dsDNA)		
Specific autoantibody to extractable nuclear antigens; differentiates native (i.e., double-stranded) DNA antibodies from other nonnative antibodies; 95% specific for SLE, making it a valuable disease marker	Negative: less than 25 IU by ELISA	DNA-anti-dsDNA immune complexes play a role in SLE pathogenesis, found in 70% of SLE patients Positive: 31–200 IU; strongly positive: over 200 IU Anti-dsDNA concentrations may decrease with successful therapy, may increase with exacerbation of SLE
Autoantibodies, Others		
Specific autoantibodies to extractable nuclear antigens (*anti-RNA, anti-Sm, anti-scl-70*); may reflect disease-specific immune mechanisms but are not pathogenetic by themselves	Negative: less than 20 U/mL by ELISA	Positive: greater than 26 U/mL *Anti-RNA:* mixed connective tissue disease (MCTD), 35–40% of SLE patients *Anti-Sm* (Smith): SLE, MCTD *Anti-scl-70:* Scleroderma

Complement Levels—C3, C4		
Complement component levels: done if a reduction/consumption of complement component concentration is suspected C3 constitutes 70% of the total protein in the complement system (antigen–antibody complexes)	C3: 75–175 mg/dL (or 0.75–1.75 g/L) C4: 14–40 mg/dL (or 140–400 mg/L)	Decrease may be seen in active SLE, immune complex disease (i.e., RA) Decrease indicates autoimmune activity
C-Reactive Protein Test (CRP)		
Measures the presence of abnormal glycoprotein in response to inflammatory cytokines	Less than 1 mg/dL (less than 10 mg/L)	A positive reading indicates active inflammation Often is positive for RA and SLE More sensitive than ESR test
Immunoglobulin Electrophoresis		
Measures the values of immunoglobulins	IgG: 700–1,500 mg/dL (7.0–15.0 g/L) IgM: 60–300 mg/dL (600–3,000 mg/L)	Increased levels of IgG occurs in RA, autoimmune disorders (i.e., SLE) Increased levels of IgM occurs in RA, SLE
Rheumatoid Factor (RF)		
Measures RFs, antibodies directed against the Fe fragment of IgG Determines the presence of abnormal antibodies seen in connective tissue disease	0–20 U/mL Negative titer	Positive titer greater than 1:80 Present in 80% of those with RA; positive RF also may suggest SLE, MCTD Low titers can be seen in OA The higher the titer (number at right of colon), the greater the inflammation

Common choices of complementary and alternative medicine (CAM) used by patients with rheumatologic disorders include dietary supplements, herbal therapies, mind/body and spiritual practices, manual/manipulative therapies, biostimulation, vagus nerve stimulation, and topical ointments (Cheung, Geisler, & Sunneberg, 2014; Koopman, Schuurman, Vervoordeldonk, & Tak, 2014; Lu, Hart, Lutgendorf, & Perkhounkova, 2013; Shengelia, Parker, Ballin, George, & Reid, 2013). It is essential that health care providers remain informed on appropriate indications for use, risks, and limitations of such therapies or practices.

Nurses need to understand the classification of rheumatic diseases. One basic system is to classify disease as either monoarticular (affecting a single joint) or polyarticular (affecting multiple joints) and then to further classify it as either inflammatory (e.g., RA) or degenerative, noninflammatory (e.g., osteoarthritis [OA]). This chapter groups the conditions into those affecting the joints, bones, and muscles and then those affecting the connective tissues.

TABLE 39-2 Goals and Strategies for Rheumatic Diseases

Major Goals	Management Strategy
Suppress inflammation and the autoimmune response	Optimize pharmacologic therapy (anti-inflammatory and disease-modifying agents)
Control pain	Protect joints; ease pain with splints/orthoses, thermal modalities, relaxation techniques
Maintain or improve joint mobility	Implement exercise programs for joint motion and muscle strengthening and overall health
Maintain or improve functional status	Make use of adaptive devices and techniques
Increase patient's knowledge of disease process	Provide and reinforce patient teaching
Promote self-management by patient compliance with the therapeutic regimen	Promote social support and encouragement of change-based interventions compatible with therapeutic regimen and lifestyle

TABLE 39-3 Medications Used in Rheumatic Diseases

Medication	Action, Use, and Indication	Nursing Considerations
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)		
Salicylates		
Acetylated Aspirin *Nonacetylated* Choline salicylate (Arthropan, Trilisate), Salsalate (Disalcid), Sodium salicylate	*Action:* anti-inflammatory, analgesic, antipyretic Acetylated salicylates are platelet aggregation inhibitors Anti-inflammatory doses will produce blood salicylate levels of 20–30 mg/dL	Administer with meals to prevent gastric irritation Assess for tinnitus, gastric intolerance, gastrointestinal (GI) bleeding, and purpuric tendencies Monitor for possible confusion in the elderly
Nonsalicylates		
First-Generation Diclofenac (Voltaren), diflunisal (Dolobid), etodolac (Lodine), flurbiprofen (Ansaid), ibuprofen (Motrin), indomethacin (Indocin), ketoprofen (Orudis, Oruvail), meclofenamate (Meclomen), meloxicam (Mobic), nabumetone (Relafen), naproxen (Naprosyn), oxaprozin (DayPro), piroxicam (Feldene), sulindac (Clinoril), tolmetin sodium (Tolectin)	*Action:* anti-inflammatory, analgesic, antipyretic, inhibition of platelet aggregation, inhibition of prostaglandin synthesis Anti-inflammatory effect occurs 2–4 weeks after initiation NSAIDs are alternative to salicylates for first-line therapy in several rheumatic diseases All NSAIDs are useful for short-term treatment of acute gout attack	Administer NSAIDs with food Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects Avoid salicylates; use acetaminophen for additional analgesia Need to be used regularly for maximal effect Watch for possible confusion in the elderly
Second-Generation: COX-2 Inhibitors Celecoxib (Celebrex)	*Action*: Selective prostaglandin inhibition, inhibit only cyclooxygenase (COX)-2 enzymes, which are produced during inflammation, and spare COX-1 enzymes, which can be protective to the stomach	Monitoring the same as for other NSAIDs Increased risk of cardiovascular events, including myocardial infarction and stroke Appropriate for the elderly and patients who are at high risk for gastric ulcers
Related Agent Acetaminophen (Tylenol)	*Action*: Inhibits the synthesis of prostaglandins; antipyretic, analgesic, no anti-inflammatory properties	Chronic excessive use of more than 4 g/day may lead to hepatotoxicity or renal or cardiac damage Concurrent use of NSAIDs increases the risk of adverse renal effects
Disease-Modifying Antirheumatic Drugs (DMARDs)		
Nonbiologic DMARDs—Traditional Drugs		
Immunosuppressives Methotrexate (Rheumatrex)	*Action:* Immune suppression, inhibits folic acid reductase, leading to inhibition of DNA synthesis and other cellular effects Acts faster than other DMARDs Methotrexate is gold standard for RA treatment; also useful in SLE	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections Monitor CBC, liver enzymes, creatinine every 2–4 weeks Caution with NSAID use Should be on folic acid Advise patient of contraceptive measures because of teratogenicity
Antimalarials Hydroxychloroquine (Plaquenil), chloroquine (Aralen)	*Action:* Anti-inflammatory, inhibits lysosomal enzymes Slow-acting, onset may take 2–4 months Useful in RA and SLE	Administer concurrently with NSAIDs Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair Retinopathy may occur; emphasize (every 6–12 months) ophthalmologic examinations

Sulfonamides sulfasalazine (Azulfidine)	*Action:* Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis Useful in RA, seronegative spondyloarthropathies	Administer concurrently with NSAIDs Do not use in patients with allergy to sulfa medications or salicylates Emphasize adequate fluid intake Assess for GI upset, skin rash, headache, liver abnormalities, anemia
Pyrimidine Synthesis Inhibitor Leflunomide (Arava)	*Action:* Has antiproliferative and anti-inflammatory effects, powerful immunosuppressant Used in moderate to severe RA May be used alone or in combination with other DMARDs (except methotrexate) About as effective as methotrexate but more adverse effects	Long half-life; requires loading dose followed by daily administration Assess for diarrhea, respiratory infection, alopecia, skin rash, mouth sores, nausea Monitor liver function tests Risk for serious infections Contraindicated in patients who are pregnant and breastfeeding Administered orally
Nonbiologic DMARDs—Minor Drugs		
Cyclosporine (Neoral)	*Action:* Immune suppression by inhibiting T lymphocytes Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs Assess for toxic effects: bleeding gums, fluid retention, hair growth, tremors Monitor blood pressure and creatinine every 2 weeks until stable
Gold-Containing Compounds Aurothioglucose (Solganol), gold sodium thiomalate (Myochrysine), auranofin (Ridaura)	*Action:* Inhibits T- and B-cell activity, suppresses synovitis during active stage of rheumatoid disease Slow-acting, onset may take 3–6 months IM preparations are given weekly for about 6 months and then every 2–4 weeks	Administer concurrently with NSAIDs Assess for pruritus, stomatitis, diarrhea, dermatitis, proteinuria, hematuria, bone marrow suppression (decreased WBCs and/or platelets), profound hypotension Monitor CBC and urinalysis with every other injection
Penicillamine (Cuprimine, Depen)	*Action:* Anti-inflammatory, inhibits T-cell function, impairs antigen presentation Slow-acting, onset may take 2–3 months Useful in RA and systemic sclerosis	Administer concurrently with NSAIDs Assess for GI irritation, decreased taste, skin rash or itching, bone marrow suppression, proteinuria with CBC, and urinalysis every 2–4 weeks
Minor Immunosuppressants Azathioprine (Imuran), cyclophosphamide (Cytoxan)	*Action:* Immune suppression, affects DNA synthesis and other cellular effects Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections Monitor CBC, liver enzymes, creatinine every 2–4 weeks Advise patient of contraceptive measures because of teratogenicity
Biologic DMARDs—Immunomodulators		
Tumor Necrosis Factor (TNF) Inhibitors Adalimumab (Humira), etanercept (Enbrel), infliximab (Remicade), golimumab (Simponi), certolizumab pegol (Cimzia)	*Action:* Biologic response modifier that binds to TNF, a cytokine involved in inflammatory and immune responses Used in moderate to severe RA unresponsive to methotrexate Can be used alone or with methotrexate or other DMARDs Humira is administered every 1–2 weeks, and Enbrel is administered twice a week Simponi is the first treatment that is administered once a month	Patient should be tested for tuberculosis before beginning this medication Teach patient subcutaneous self-injection of adalimumab (Humira) or etanercept (Enbrel) Infliximab (Remicade) is administered by IV over 2 hours or more Medication must be refrigerated Monitor for injection site reactions Educate patient about increased risk for serious infection and to withhold medication if fever occurs Contraindicated in CHF class III/IV, and may pose a risk for new onset of heart failure

T-Cell Activation Inhibitors Abatacept (Orencia)	*Action:* selectively modulates T-cell activation, altering immune response (costimulatory blocker) A cost-effective alternative treatment of moderate to severe RA when conventional DMARDs and TNF inhibitors are inadequate	Contains maltose, may falsely elevate blood glucose High risk for infections Do not give live vaccines
B-Cell Depleting Agents Rituximab (Rituxan)	*Action:* monoclonal antibody directed at the CD20 antigen expressed on mature B and pre-B cells B-cell depletion therapy: a course of two IV infusions, 2 weeks apart with a repeat treatment interval of 6–12 months	Usually patient is premedicated with acetaminophen and diphenhydramine to decrease fever, chills as associated with infusion Caution in patients with cardiac and pulmonary diseases
Interleukin (IL)-1 Receptor Antagonist Anakinra (Kineret)	*Action:* Human IL-1 receptor antagonist; blocks IL-1 receptors, decreasing inflammatory and immunologic responses Used in moderate to severe RA unresponsive to methotrexate Can be used alone or with methotrexate or DMARDs but not with TNF inhibitors	Administered daily by subcutaneous injection Teach patient subcutaneous self-injection to be administered daily Medication must be refrigerated at 36–46°F (2–8°C) and warmed to room temperature for 30 minutes prior to injection Monitor for injection site reactions Educate patient about increased risk for infection and to withhold medication if fever occurs
Interleukin (IL)-6 Receptor Antagonist Tocilizumab (Actemra)	*Action*: Human IL-6 receptor antagonist; blocks IL-6 receptors, decreasing inflammatory and immunologic responses Used in moderate to severe RA unresponsive to a TNF inhibitor Can be used alone or with methotrexate or DMARDs but not with TNF inhibitors	Administered as IV therapy or subcutaneous injection; should be refrigerated at 36 –46°F (2–8°C) and warmed to room temperature for 30 minutes prior to injection Risk for serious infections and other serious adverse effects, e.g., liver injury, GI perforation, neutropenia, and thrombocytopenia Can reduce blood levels of other drugs, e.g., oral contraceptives, warfarin, proton pump inhibitors
New Class of DMARDs—Small Molecule Kinase Inhibitors		
Janus Kinase (JAK) Inhibitor Tofacitinib citrate (Xeljanz)	*Action*: JAK inhibitor works deep inside the cell (intracellular) to disrupt activities occurring in signaling pathways that play a role in the inflammation associated with RA Used in moderate to severe RA unresponsive to methotrexate	First oral agent taken p.o. twice a day. Xeljanz should not be given if lymphocyte count, neutrophil count, or red blood cell count is too low or liver tests are too high. Cholesterol levels should be monitored 4–8 weeks after start and as needed after that. High risk for infections Do not give live vaccines
Glucocorticoids		
Adrenal Corticosteroids Prednisone (Deltasone) hydrocortisone sodium succinate (Solu-Cortef) methylprednisolone sodium succinate (Solu-Medrol) methylprednisolone acetate (Depo-Medrol), intra-articular injection	*Action:* Anti-inflammatory Used for shortest duration and at lowest dose possible to minimize adverse effects Useful for unremitting RA, SLE Fast-acting; onset in days Intra-articular injections useful for joints unresponsive to NSAIDs	Assess for toxicity: cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis Joints most amenable to injections include ankles, knees, hips, shoulders, and hands Repeated injections can cause joint damage

CBC, complete blood count; CNS, central nervous system; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; WBCs, white blood cells.

BOX 39-2 Focus on Pathophysiology

Rheumatic Disorders

Each synovial joint has a given range of motion, and the synovial fluid within a joint has three primary functions: lubrication, nutrient distribution, and shock absorption.

Inflammation is manifested in the joints as synovitis. Rheumatic disorders always involve damage to the articular cartilages. Because articular cartilages involve some degree of inflammation and degeneration, the rheumatic disorders can be classified as either inflammatory (e.g., RA) or degenerative, noninflammatory (e.g., OA).

In the inflammatory rheumatic disorder classification, the primary process starts with inflammation due to an altered immune function. The inflammatory reaction includes swelling, pain, and loss of function (see Chapter 36 for the inflammatory and immunologic processes). Degeneration then occurs as a secondary process, spreading to the articular surfaces. The cause of degeneration of the articular cartilage is poorly understood but believed to be metabolically active and, therefore, is more accurately called *degradation.*

On the other hand, in the degenerative (noninflammatory) rheumatic disorder classification, inflammation occurs as a secondary process. The resultant secondary synovitis is usually milder, is more likely to be seen in advanced disease, and represents a reactive process. The synovitis is thought to result mainly from degeneration due to mechanical irritation of two bone surfaces. As the articular cartilage becomes damaged, the matrix (noncellular component of tissue) begins to break down; the exposed cartilage changes from a slick, smooth gliding surface to a rough fibrous network of collagen fibers. Later this network may be converted to bone, locking the articulating elements into position. Fixation of a joint, called ankylosis, eliminates the friction but at the drastic cost of immobility.

CONDITIONS AFFECTING THE JOINTS, BONES, AND MUSCLES

Despite the diversity of rheumatic disorders, the joint is the area most commonly affected and involves some degree of inflammation and damage to the articular cartilages, which may occur simultaneously. Understanding normal anatomy and physiology of articulations, or joints, is the key to understanding the pathophysiology of the rheumatic disorders (Box 39-2).

Osteoarthritis

Osteoarthritis, also known as degenerative joint disease, is a chronic, noninflammatory (even though inflammation may be present), progressive disorder that causes cartilage deterioration in synovial joints and vertebrae. It particularly affects the weight-bearing joints, knees and hips, and joints of the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the fingers (Shelton, 2013). OA is the most common and most frequently disabling of the joint disorders; it is overdiagnosed and trivialized and frequently over- or undertreated. The functional impact of OA on quality of life, especially for elderly patients, is often ignored.

OA has been classified as both primary (idiopathic), with no prior event or disease related to the OA, and secondary, resulting from previous joint injury or inflammatory disease. The distinction between primary and secondary OA is not always clear, but often the clinical presentation and symptoms are similar.

Risk Factors

Risk factors for OA are summarized in Box 39-3. Age is the risk factor most strongly correlated with OA, while obesity is now well recognized as an important contributing factor (Di Cesare, Haudenschild, Samuels, & Abramson, 2013; Felson & Zhang, 2015).

BOX 39-3 Risk Factors for Osteoarthritis (OA)

- Aging
- Obesity (mechanical loading from a higher body mass index is associated with an increased risk of knee OA; the link between OA and adipose-derived leptin is now recognized as a metabolically active contributor to inflammatory cascades)
- Genetic predisposition
- Joint location (joint-specific, age-related articular cartilage changes, varying joint responsiveness to cytokines)
- Malalignment of joints (can lead to rapid development of OA; congenital and developmental disorders, e.g., poorly reduced intra-articular fractures, developmental dysplasia of the hip)
- Trauma (also can lead to rapid development of OA; overuse or abuse of joints, as occurs in high-impact sports; previous joint damage; excessive loading or forces, such as that seen in pneumatic drill operators, or frequent squatting position, such as catchers in baseball, where up to 10 times body weight may be transmitted to the knee.)
- Gender (differences in incidence after 50 years of age may be the result of postmenopausal estrogen deficiency; articular chondrocytes possess functional estrogen receptors)

Adapted from Di Cesare, P. E., Haudenschild, D. R., Samuels, J., & Abramson, S. B. (2013). Pathogenesis of osteoarthritis. In G. S. Firestein, R. C. Budd, S. E. Gabriel, I. B. McInnes, & J. R. O'Dell. (Eds.), *Kelley's textbook of rheumatology* (9th ed.). Philadelphia, PA: Saunders Elsevier.

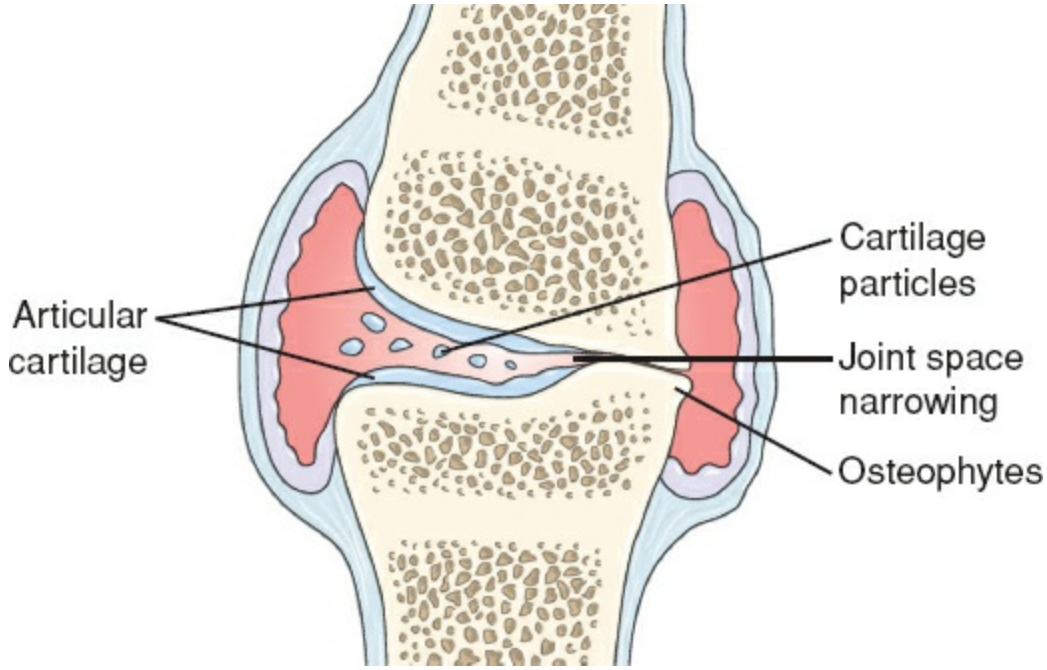

FIGURE 39-1 Osteoarthritic degenerative joint changes: hypertrophy of bone margins resulting in characteristic osteophytes (bone spurs) and narrowing of joint space.

OA generally affects adults 40 years of age and above (American College of Rheumatology [ACR], 2015a; Harris & Crawford, 2015). Prevalence of arthritis in the United States for adults 25 years of age and older having clinical OA of some joint was estimated at nearly 27 million (Nelson & Jordan, 2015). Because of the aging of Western populations and because of the increased prevalence of obesity, a major risk factor, the occurrence of OA is on the rise. In the United States, OA prevalence will increase by 66% to 100% by 2020 (Felson, 2015). Radiologic OA is more prevalent than symptomatic OA. According to the ACR, 70% of people over 70 years of age have x-ray evidence of OA; however, only half ever develop symptoms. OA of the hand, hip, and knee become more frequent with age, and more women are affected than men after 50 years of age (Centers for Disease Control and Prevention [CDC], 2015b).

Pathophysiology

OA may be thought of as the end result of many factors that, when combined, predispose the patient to the disease. In OA, changes in articular cartilage occur first; eventually, changes to secondary soft tissue may occur. OA is characterized by erosion of the articular cartilage combined with hypertrophy of bone at the joint margins, resulting in formation of new bone known as osteophytes or bone spurs (Fig. 39-1) and subchondral (the bony plate that supports the articular cartilage) sclerosis. In addition, OA is characterized by a range of biochemical and morphologic alterations of the synovial membrane and joint capsule. In general, a combination of cartilage degradation, bone stiffening, and reactive inflammation of the synovium occurs (Aigner, Schmitz, & Salter, 2015). Understanding of OA has been expanded greatly beyond what previously was thought of as simply "wear and tear" related to aging.

Clinical Manifestations and Assessment

The general clinical manifestations of OA are pain, stiffness, and functional disability (Altman, 2015; Harris & Crawford, 2015). Pain in one or more joints typically is worsened by activities and is alleviated by rest. Although osteoarthritic pain is unusual during the night or at rest, there are exceptions, including in patients with mild OA using joints for several hours, in patients with advanced OA with destructive arthropathy, and in patients with an acute inflammatory flare-up of OA. Stiffness may be defined as a sensation of a gelling or tightening of the involved joint that usually occurs after inactivity, such as in the morning or when rising after sitting for a prolonged period. Morning stiffness usually resolves after less than 10 minutes (no more than 30 minutes' duration), in contrast to prolonged stiffness seen in inflammatory disorders. Functional impairment is reflected in limited range of motion (ROM) and patient report of limited ability to perform day-to-day activities.

The diagnosis of OA is complicated by many contributing factors. The ACR has established clinical classification criteria for OA of specific joints to promote consistency in the diagnosis of OA. Typically OA is diagnosed by an overall clinical impression based on the patient's age and history, location of joint abnormalities, and radiographic findings. Limited passive movement can be the first and only physical sign of symptomatic OA. During joint examination, crepitus, a continuous grating sensation, may be felt or heard as the joint goes through ROM. Physical assessment of the musculoskeletal system reveals joint enlargement, resulting from joint effusion or bony swelling or both. This is most easily detected in the patient's knees by the evidence of patellar tap or by the elicitation of a fluid thrill (wave test). Joint deformities reflect advanced disease with joint destruction, which then contributes to misalignment, joint instability (causing a sensation in the knees of "giving way" or "locking"), and limb shortening. Fingers also can be misaligned in the presence of Heberden (enlargements of DIP joints) or Bouchard nodes (enlargements of PIP joints) (Fig. 39-2).

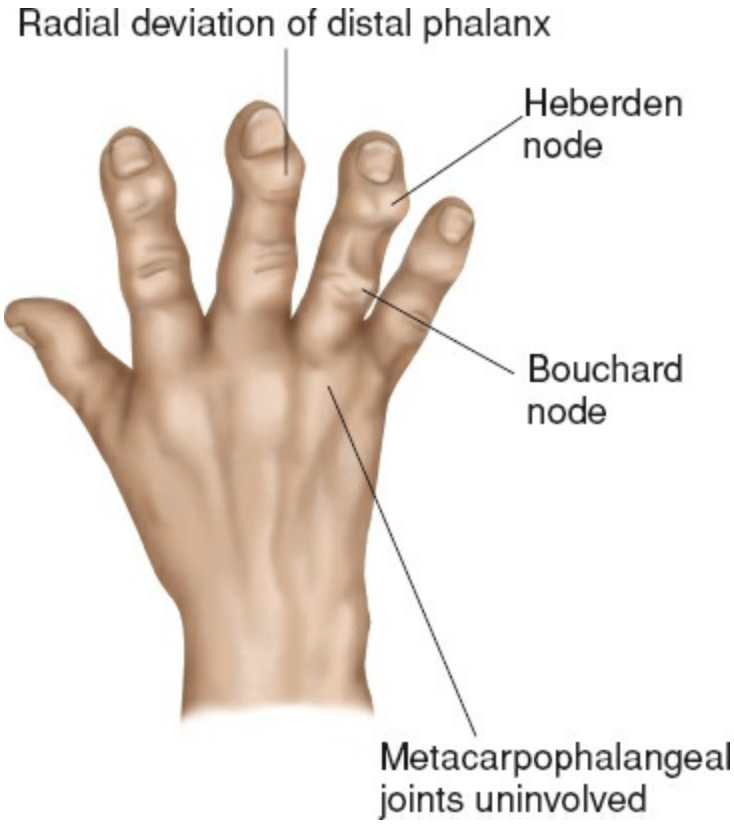

FIGURE 39-2 Heberden and Bouchard nodes. (From Bickley, L. S. (2009). *Bates' guide to physical examination and history taking* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Radiographic assessment has long been considered the gold standard to diagnose OA and to establish severity of joint damage; to monitor disease activity, progression, and response to therapy; and to search for complications of the disorder or the treatment. Standard x-rays of affected joints show osteophytes, the most characteristic feature of OA, and, in more advanced disease, joint space narrowing and sclerosis. One method of classifying the severity of OA (with or without symptoms) is on a plain radiograph using the Kellgren–Lawrence (KL) grading scale. This overall joint scoring system, used extensively in research for more than five decades, grades OA in five levels from 0 (no osteophytes or joint space narrowing) to 4 (severe joint space narrowing with subchondral sclerosis); generally a grade of 2 is considered diagnostic of OA (Nelson & Jordan, 2015). MRI can be used to assess the quantity and function of cartilage, synovium, and bone; however, it is not yet recommended for routine use. Arthroscopy is a more appropriate gold standard in the evaluation of OA, allowing direct visualization of cartilage surface integrity. Routine laboratory testing is rarely required and is primarily used to rule out other conditions, such as metabolic or inflammatory arthropathies. A positive C-reactive protein (CRP) and rheumatoid factors (RFs) can be found in low-grade inflammation in OA. Synovial fluid analysis can be done to differentiate OA from RA. According to the World Health Organization (WHO), biomarkers are an important aspect for clinical diagnosis and treatment for arthritis in general and OA research in particular for drug development. Therefore, molecular biomarkers are currently being explored for clinical utility, such as urinary C-telopeptide fragments of type II collagen (u-CTXII). However, no single marker is yet adequate for predicting or monitoring OA (Altman, 2015; DeGroot, Zuurmond, & Tak, 2013; Nelson & Jordan, 2013).

Medical and Nursing Management

No treatment halts the degenerative process of OA; as a result, management focuses on:

- Educating patients about OA,
- Reducing pain and inflammation,
- Optimizing and maintaining physical function, and
- Attempting to prevent or slow the progression of structural damage (Altman & Hochberg, 2015).

Nonpharmacologic treatment measures mentioned earlier in the chapter are the core for OA management and should be maintained throughout the patient's course of the disease. Interventions mainly center around rest and joint protection, heat application with some use of cold, and weight reduction and exercise. The ACR recommends that the use of TENS and traditional Chinese acupuncture be reserved for patients who are candidates for total joint reconstructive surgery but are either unwilling to undergo the surgery or have medical contraindications to these procedures. CAM therapies for symptom management have become an increasingly popular avenue of treatment, particularly movement therapies such as T'ai chi and yoga (Yan et al., 2013). Regarding nutritional supplements (e.g., glucosamine often in combination with chondroitin), more research is needed because study findings on glucosamine are inconsistent as to the effectiveness of pain management in OA.

Pharmacologic therapy is used in conjunction with nonpharmacologic measures. It is important to obtain a complete blood count, chemistry panel including glucose and creatinine, and liver function tests before initiation of pharmacologic therapy for OA due to an increased risk for adverse events. In OA, the initial analgesic therapy is acetaminophen with doses recommended by the U.S. Food and Drug Administration (FDA) up to 1,000 mg three times daily (Felson, 2015). The safety profile of acetaminophen has been revisited, in particular when considering a daily dose of 4,000 mg. Study results suggest that high doses (over 3,000 mg) place patients at risk for upper gastrointestinal (GI) complications and hepatic toxicity and has been associated with a prolonged prothrombin time (PT) in patients undergoing Coumadin anticoagulation (Altman & Hochberg, 2015). To promote excretion of the drug, adequate water intake of at least 2,000 mL/day is encouraged.

Nursing Alert
Nurses need to educate patients who are taking acetaminophen to avoid the concomitant use of alcohol and over-the-counter (OTC) products that contain acetaminophen, such as cold preparations and use of combination opioid analgesics such as Tylenol #3 (acetaminophen and codeine). Use of either of these substances simultaneously with acetaminophen can lead to the possibility of hepatic toxicity (Lozada, 2013; Shelton, 2013).

For the patient who either fails to obtain adequate pain management with acetaminophen or has moderate to severe pain, an NSAID may provide greater relief. If the

patient is at risk for or experiences GI complications with an NSAID, supplemental treatment with a protective agent, such as misoprostol (Cytotec), may be indicated. As an alternative to traditional NSAIDs, treatment with the cyclooxygenase (COX)-2 inhibitors celecoxib (Celebrex) or etoricoxib (Arcoxia) may be considered in selected patients. The use of COX-2 inhibitors will be discussed later, in the management of RA.

Other medications that may be considered are the opioids and topical analgesics, such as capsaicin (Capsin, Zostrix) and methyl salicylate. Another therapeutic approach is the intra-articular injection of hyaluronic acid, referred to as *viscosupplementation*. Viscosupplementation is used in patients with OA and is thought to act as a short-term lubricant and provide a biomechanical benefit as well as an analgesic effect by buffering synovial nerve endings directly; it also may have some anti-inflammatory effects, and it may stimulate synovial lining cells to produce hyaluronic acid.

For persistent, moderate to severe OA and erosive RA, reconstructive surgery and corticosteroids are used often. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures and the threat of loss of independence is eminent. Surgical procedures include synovectomy (excision of the synovial membrane), arthrodesis (surgical fusion of the joint), tenorrhaphy (suturing of a tendon), and osteotomy (to alter the distribution of weight within the joint). The procedure used most commonly is arthroplasty, a surgical repair and replacement of the joint. Surgery is not performed during disease flare ups.

Tidal irrigation (lavage) and joint debridement of the knee involve the introduction of a large volume of saline into the joint through cannulas and then removal of debris with this fluid. In some cases, this procedure provides pain relief for up to 6 months.

Gout

Gout, one of the most common of the inflammatory arthritides, is a metabolic disorder marked by the deposition of monosodium urate crystals within joints and other tissues. Gout is a heterogeneous group of conditions related to a genetic defect of purine metabolism that results in hyperuricemia (excessive uric acid, a purine end product). The prevalence of gout is reported to be less than 1% to 15.3%, and it appears to be on the rise. It occurs more commonly in males than in females (3–4:1), and the incidence of gout among black men is almost twice that among white men. The general incidence increases with age, body mass index, and increasing levels of serum uric acid (urate) (Burns & Wortmann, 2013; CDC, 2015d; Choi, 2015). While hyperuricemia may indicate an increased risk of gout, the association between hyperuricemia and gout is unclear. Typically, the higher the uric acid level and longer the length of the elevation, the more likely that gout will occur and tophi (deposits of uric acid) will form. On the other hand, some patients with hyperuricemia do not develop gout, and other patients with repeated gout attacks have normal or low levels of serum uric acid (laboratory population–based norm for men is rounded to 8 mg/dL and women is 7 mg/dL) (Van Leeuwen & Bladh, 2015). Therefore, the exact level of uric acid that is considered pathologic is controversial.

Primary gout is characterized by hyperuricemia caused by an overproduction of uric acid or a decreased urate excretion in the kidney. Often primary gout is caused by an inherited disorder in purine metabolism, with a 50% incidence (Keenan, Nowatzky, & Pillinger, 2013; McLean & Dalbeth, 2015). Secondary gout is related to a wide number of diseases or drugs that decrease the kidney's ability to excrete uric acid, increase the production of uric acid, or a combination of both. Conditions associated with secondary gout include diabetic ketoacidosis, severe dieting or starvation, and metabolic syndrome. Disorders, such as multiple myeloma and leukemia, result in increased production of uric acid because of a greater cell turnover and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (e.g., diuretics such as thiazides and furosemide), low-dose salicylates, or ethanol, can contribute to uric acid underexcretion. An excessive intake of foods that are high in purines (shellfish, organ meats) may result in symptoms of gout in susceptible persons.

Pathophysiology

Hyperuricemia denotes an elevated level of uric acid (urate) in the blood, and, in recent years, it has been recognized that the reference ranges are quite wide. The laboratory reference ranges of hyperuricemia often are reported based on population norms, and values vary depending on the population being evaluated. To define individuals with hyperuricemia, current evidence-based reviews recommend that it is more clinically relevant to use the biologic value of 6.8 mg/dL or 408 μmol/L, a level of serum uric acid above the saturation point for crystal formation (Burns & Wortmann, 2013; Edwards, 2015). Asymptomatic hyperuricemia is a laboratory finding, not a disease, but can lead to gout pathogenesis. Attacks of gout appear to be related to sudden increases or decreases of serum uric acid levels. When the uric acid precipitates and then deposits within a joint as urate crystals, an inflammatory response occurs, and an attack of gout begins. With repeated attacks, accumulations of sodium urate crystals, called tophi, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear (lower temperature areas). Renal urate lithiasis (kidney stones), with chronic renal disease secondary to urate deposition, may develop.

Clinical Manifestations and Assessment

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), tophi (crystalline deposits accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four phases (or stages) of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical or interval gout, and chronic tophaceous gout (acute and intercritical gout together are sometimes noted as one phase). Phase 1, asymptomatic hyperuricemia, is when the serum urate level is high, but gout manifested by arthritis or nephrolithiasis has not yet occurred. People can remain asymptomatic throughout their lifetimes. The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout (phase 2).

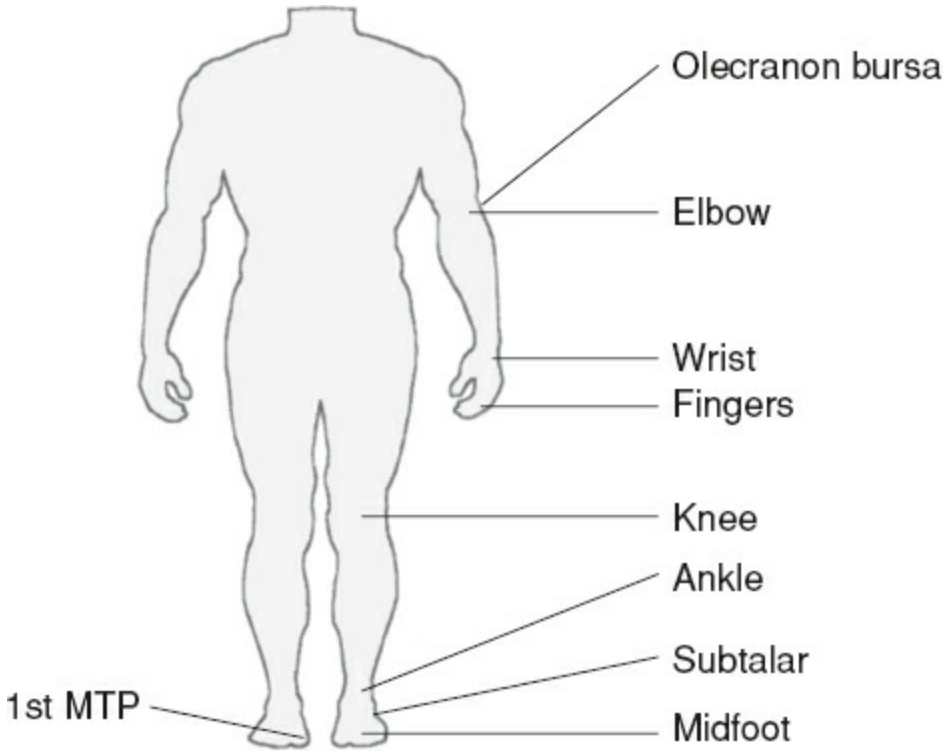

FIGURE 39-3 Gout: common sites of involvement. MTP, (metatarsophalangeal) or gout of the knee. (From Stoller, J. K., Nielsen, C., Buccola, J., & Brateanu, A. (2014). *The Cleveland clinic foundation intensive review of internal medicine*. (6th ed.). Philadelphia, PA: Wolters Kluwer Health.)

Acute arthritis is the most common early clinical manifestation of gouty arthritis. The first attack usually occurs between 40 and 60 years of age in men and after 60 years of age in women (Burns & Wortmann, 2013). The patient experiences excruciating pain and inflammation in one or more small joints. The metatarsophalangeal (MTP) joint of the big toe is the joint affected most commonly (up to 90% of patients) and is referred to as podagra (Bardin & Desideri, 2013; Edwards, 2015; Roddy, Mallen, & Doherty, 2013). The tarsal area, ankle, or knee also may be affected. Less commonly, the wrists, fingers, and

elbows may be affected. Trauma, alcohol ingestion, dieting, medications, surgical stress, or illness may trigger the acute attack (Fig. 39-3). The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days even without treatment. The attack is followed by a symptom-free period (the intercritical stage or phase 3) until the next attack, which may not come for months or years. However, with time, attacks tend to occur more frequently, to involve more joints, last longer, and lead to long-term sequelae (phase 4).

In general, tophi are associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid also are associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, subchondral bone, infrapatellar and Achilles tendons, and subcutaneous tissue on the extensor surface of the forearms and overlying joints. Also they have been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclerae. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause kidney stones and kidney damage.

A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint (ACR, 2015c; Burbage, 2014; Schumacher & Chen, 2015). Uric acid crystals are seen within the polymorphonuclear leukocytes in the fluid. Although the gold standard for diagnosis is correct identification of crystals, clinical impressions are most frequently used.

Medical Management

Treatment of gout is managed in two major phases: management of acute gouty inflammation and long-term management to prevent flare ups and to control hyperuricemia. According to recent ACR guidelines, an acute gout attack should be treated pharmacologically within 24 hours of the onset of symptoms. First-line oral drugs are usually NSAIDs or colchicine. NSAIDs with short half-life are most effective (e.g., indomethacin, naproxen, ibuprofen, and diclofenac). Other agents prescribed to relieve an acute attack of gout are corticosteroids (oral or parenteral) or adrenocorticotropic hormones (ACTH) because of their anti-inflammatory properties and their ability to be used for short periods of time so generally long-term complications can be avoided (Bolzetta, Veronese, Manzato, & Sergi, 2013; Schumacher & Chen, 2015; Stamp & Chapman, 2013; Terkeltaub, 2015).

Drug Alert!
Selection of NSAIDs, colchicine, or corticosteroids is influenced by the patient's comorbid conditions (e.g., renal, cardiac, hepatic, or GI disease). Aging itself is an important risk factor. For instance, age-related decline in kidney function and the use of diuretics in the elderly are common risk factors for NSAID-induced renal injury.

Low-dose colchicine has been used for prophylaxis after resolution of attacks, but it does not prevent accumulation of tophi and urate in joints. Usually management of hyperuricemia, tophi, joint destruction, and kidney disorders is initiated after the acute inflammatory process has subsided. Allopurinol (Zyloprim), a xanthine oxidase inhibitor, is considered the drug of choice for preventing the precipitation of an attack and tophi formation and for promoting the regression of existing tophi. Febuxostat (Uloric) is a nonpurine xanthine oxidase inhibitor that mimics the action of allopurinol and is an effective alternative for patients who experience severe reactions to allopurinol. Uricosuric agents, such as probenecid (Benemid), correct hyperuricemia and stimulate renal urate excretion. Sulfinpyrazone (Anturane) is very similar to probenecid, but it is more potent. Severe blood dyscrasias may occur with use so generally it is reserved for patients with symptoms resistant to other agents. Drugs that metabolize uric acid, such as rasburicase and pegloticase, are called *uricolytic agents*; these new uricases are reserved for refractory tophaceous gout (Bolzetta et al., 2013; Burns & Wortmann, 2013; Harrold, 2013; Mikuls, 2013).

TABLE 39-4 Medications Used to Treat Gout

Medication	Actions and Use	Nursing Implications
Colchicine	Lowers the deposition of uric acid and interferes with leukocyte infiltration, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	*Acute management:* Administer when attack begins; dosage increased until pain is relieved or diarrhea develops *Chronic management:* Causes gastrointestinal upset in most patients
Probenecid (Benemid), sulfinpyrazone (Anturane)	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Be alert for nausea and rash Risk of uric acid deposition in kidney; patient should ingest large volumes of fluids
Allopurinol (Zyloprim), febuxostat (Uloric)	Inhibits xanthine oxidase; interrupts the breakdown of purines before uric acid is formed; inhibits xanthine oxidase because it blocks uric acid formation	Monitor for side effects, including bone marrow depression, vomiting, and abdominal pain
Pegloticase (Krystexxa)	Recombinant form of uric acid oxidase; Pegloticase is an enzyme that converts uric acid to allantoin, a water-soluble compound that is readily excreted by the kidney	Monitor for infusion reactions, such as urticaria, dyspnea, chest discomfort, erythema, and pruritus

When reduction of the serum urate level is indicated, uricosuric agents are the medications of choice. The recommended target goal of therapy is a serum uric acid level of less than 6 mg/dL, a level below the saturation point of 6.8 mg/dL at which urate crystals precipitate from solution (Burns & Wortmann, 2013; Harrold, 2013). Current practice trends have shown that reducing and maintaining the serum uric acid levels result in crystal dissolution from joints, a reduction in gout attacks (flares), and the prevention or reduction in tophaceous deposits. If the patient has, or is at risk for, renal insufficiency or renal calculi (kidney stones), allopurinol is also effective at a lowered adjusted dose. New therapies for acute gout targeting interleukin-1 β blockage are currently under investigation and show promise for successful gout treatment. Ilaris (canakinumab) was approved by the FDA in 2011 and has shown to extend the time to the next attack and reduce the frequency of subsequent attacks. Although not FDA approved, anakinra (Kineret) may be prescribed by health care providers for very severe attacks of gout (ACR, 2015c; Bardin & Desideri, 2013; Stamp & Chapman, 2013). Corticosteroids may be used in patients who have no response to other therapy. If the patient experiences several acute episodes or there is evidence of tophi formation, prophylactic treatment is considered. Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function. Table 39-4 lists the common medications used in treating gout.

Nursing Management

Pain management is the primary concern during the acute phase of an attack. The joint should be rested and elevated, and application of ice, not heat, may help with reducing discomfort. Keeping the bedclothes away from the affected joint using a "bed cage" if available can be of benefit. The management of the intercritical and chronic phases of gout involves teaching self-care measures to decrease the risk of attacks (e.g., avoidance of aspirin [because doses below 2 to 3 g/day impair renal excretion of uric acid retention and higher doses are associated with high renal excretion of uric acids], trauma, stress, alcohol, smoking) and to avoid long-term complications (e.g., importance of medication compliance). During the intercritical period, the patient feels well and may abandon preventive behaviors, which may result in an acute attack. Health care providers recommend that patients restrict consumption of foods high in purines, especially organ meats and shellfish; others believe that limiting protein foods such as red meats, lamb and pork or avoiding trigger foods are sufficient. Patients should be taught to limit alcohol intake, avoid fad starvation diets, and avoid sugary drinks and food that are high in fructose such as fructose corn syrup, sweetened soda, and processed foods. As fructose breaks down in the body, purines are released. The breakdown of purines produces uric acid, the substance that forms painful crystals in the joints and causes gout. Your uric acid levels rise within minutes after you drink high fructose drinks. It is important that patients drink plenty of fluids, at least 2,000 mL daily, to avoid dehydration and lessen renal involvement and the development of urinary stones (ACR, 2015c; Burbage, 2014; Edwards, 2015). Maintenance of normal body weight should be encouraged. Dietary vitamin C supplementation has been shown to reduce the risk of gout. Also, dietary restriction of sodium, fat, and cholesterol can lead to a reduction in gout symptoms and decrease effects associated with coexisting metabolic syndrome. Although research is limited, first acute gout attacks may commonly precede the diagnosis of metabolic abnormalities and associated diseases. Gout studies have shown to be associated with poorer physical health-related quality of life (HRQOL). Both gout-specific features (attack frequency and intensity, intercritical pain and number of joints involved) and comorbid disease were associated with poor HRQOL in all domains. Therefore success of lifelong treatment is dependent on the patient's commitment to treatment. Nurses need to explain lifestyle changes and drug management to the patient as they play a vital role in increasing treatment adherence and, therefore, considerable improvements in patient-centered outcomes (Bardin & Desideri, 2013; CDC, 2015d; Chandratre et al., 2013; Roddy et al., 2013).

Fibromyalgia

Fibromyalgia (FM) is a chronic syndrome characterized by widespread nonarticular musculoskeletal pain or multiple tender points lasting more than 3 months and other general physical symptoms, such as fatigue (NIAMS, 2014b). The pain in FM is not due to tissue damage or inflammation, thus making it fundamentally different from other rheumatic disorders and many other pain conditions. According to the 1990 ACR criteria, which specify 11 or more tender points, FM affects women more frequently than men (10:1 ratio). However, according to alternative ACR criteria for FM, women are only 1.5 times more likely than men to experience chronic widespread pain (CWP) (Clauw, 2015). The newer criteria established in 2010 do not require performing a tender point count, and they are recommended for clinical diagnosis versus the 1990 criteria intended for research. A hallmark of FM is that individuals display diffuse hyperalgesia (increased pain to normally painful stimuli) and/or allodynia (pain to normally nonpainful stimuli). This suggests that these individuals have a fundamental problem with central dysfunction (pain processing mechanisms) that results in central pain sensitization. These findings of centralization of pain have been corroborated by advanced neuroimaging techniques and appear to be due, in part, to imbalances in levels of neurotransmitters that affect pain and sensory transmission (Clauw, 2015; Wolfe & Rasker, 2013). The overall prevalence rate remains at 2% to 5% worldwide (ACR, 2015b; Crofford, 2015).

Clinical Manifestations and Assessment

The core features of CWP and tenderness are almost invariably accompanied by a wide range of symptoms, the most common of which are sleep disturbances, fatigue, morning stiffness, muscle weakness, paresthesias, cognitive dysfunction ("fibro fog"), chronic headaches, mood disturbances, and irritable bowel syndrome (CDC, 2015c; Clauw, 2015; Wolfe & Rasker, 2013). CWP is pain that is typically both above and below the waist on both sides of the body and involves the axial skeleton (neck, back, or chest). The patient complains of a widespread burning pain and often is unable to discriminate if pain occurs in the muscles, joints, or soft tissues. Physical examination typically reveals point tenderness at 11 or more of 18 identified sites characteristically described in ACR 1990 criteria (Fig. 39-4).

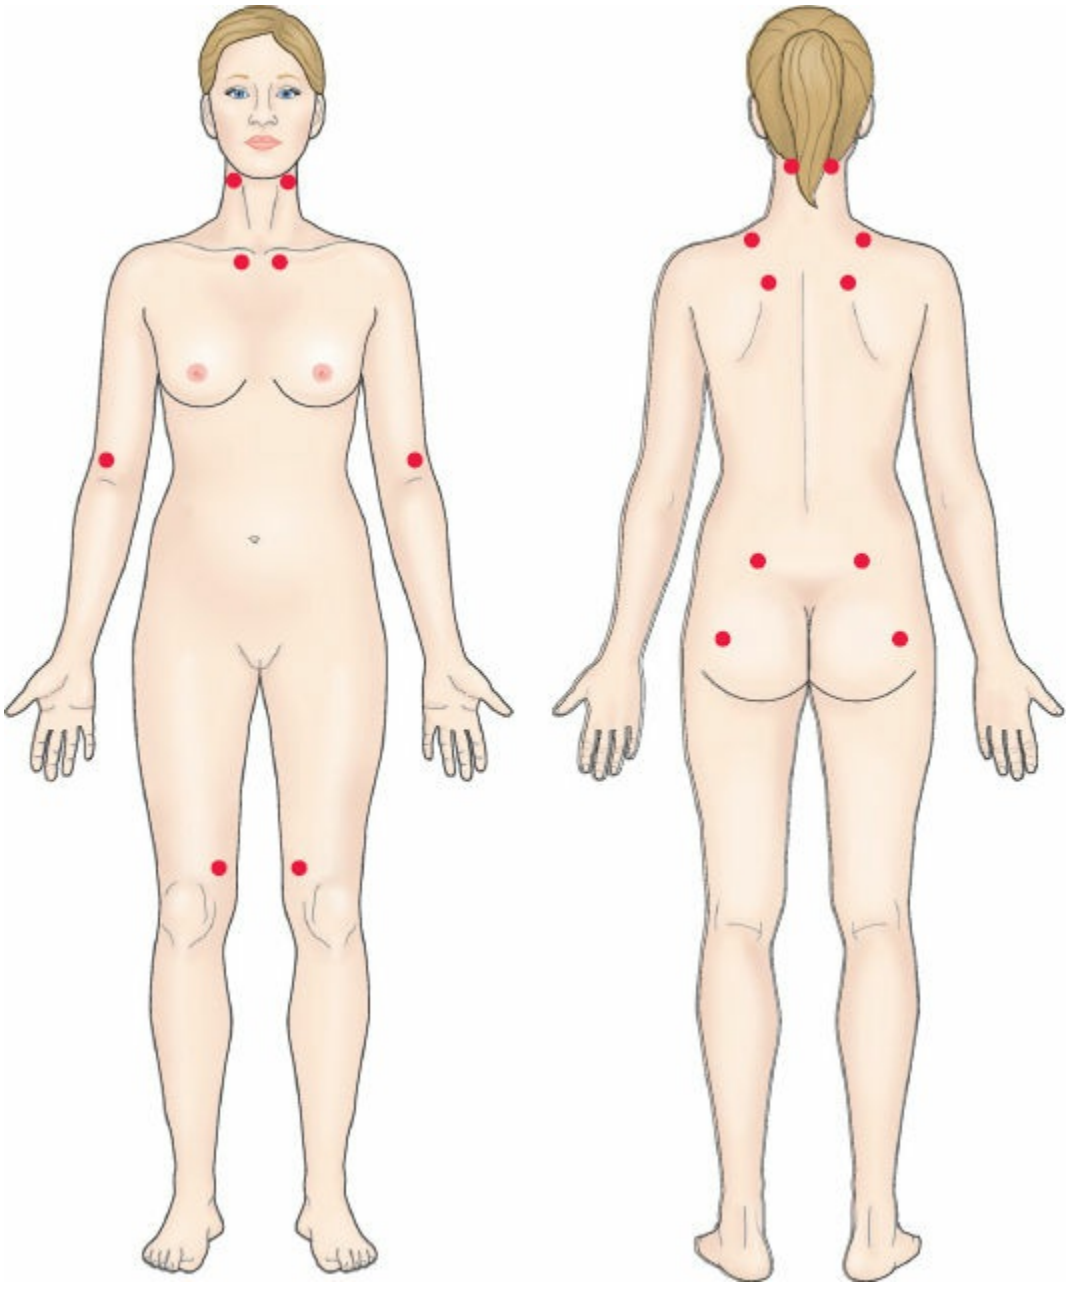

FIGURE 39-4 Fibromyalgia tender points.

Medical Management

It is recommended to use symptom-based pharmacology therapy together with nonpharmacologic therapies. Paying attention to the specific symptoms reported by the patient is important. Patient education, exercise, and cognitive therapy, along with medication, are frequently used.

The pharmacotherapy of FM is mechanism-based; many have been tested to a greater or lesser extent. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tramadol is the only opiate shown to provide some relief. Many drugs have been used off-label to treat FM. Pregabalin (Lyrica), an analgesic, anxiolytic, and anticonvulsant ($\alpha_{2\text{-}\delta}$ receptor ligand agent) is the first to receive FDA approval for FM use. Psychotropic agents have been used to reduce pain centrally, even in the absence of depression: serotonin noradrenaline reuptake inhibitors or SNRIs (duloxetine, milnacipran), least selective serotonin reuptake inhibitors or SSRIs (fluoxetine, paroxetine), dopaminergic agents (pramipexole), and antidepressants, particularly tricyclics (Clauw, 2015; Polston & Wallace, 2013). The two SNRIs, duloxetine (Cymbalta) and milnacipran (Savella), were shown to be effective and are approved by the FDA for symptom relief in FM. Also tricyclic antidepressants in low doses can be used to improve or restore normal sleep patterns. Other drugs acting on the central nervous system also have been used or are under investigation (e.g., gabapentin, cannabinoids). Individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in affected patients. Investigators, Martinez-Amat et al. (2014), found an association of weekly practice of guided physical activity with reduction of falls and symptoms of FM. Nonpharmacologic therapies (e.g., massage, spa treatment, hydrotherapy, acupuncture), including neurostimulation therapies such as peripheral nerve stimulation (PNS), occipital nerve stimulation (ONS), etc. (Dailey et al., 2013), can be extremely helpful and often are underused in clinical practice.

Nursing Management

Typically, patients with FM have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to undertake a holistic assessment to identify the influence of any factors on the pain experienced and management strategies. The assessment should include:

1. Beliefs and thoughts about the cause of the condition— talking about how the pain started can lead to shared insight and provide direction for management strategies,
2. Level of functional activity—FM has been associated with lower levels of health-related quality of life and more work productivity loss (CDC, 2015c),
3. Mood status—the nurse should help the patient identify existing psychological stressors that are having an adverse effect on the pain experienced,
4. Sleep patterns—if pain is interfering with the quality of sleep, the patient will often awaken unrefreshed and experience difficulties with cognitive functioning, including concentration, sentence formation, and memory recall, and
5. Patient's role—the nurse should assess if the patient is experiencing emotional or physical difficulties in the workplace or the family setting (Davis, Moder, & Hunder, 2013; Ryan, 2013).

Nurses need to pay special attention to supporting these patients and providing encouragement as they begin their program of therapy. The goal of FM treatment is to improve the physical and mental health of patients and their quality of life. Interventions or strategies should be developed to promote better functioning. Greater education, lower-intensity fatigue, and using aerobic or strength training exercises were predictors of physical functioning (Kaleth, Saha, Jensen, Slaven, & Ang, 2013; Vural et al., 2014). Nurses need to work with the patient to increase independence, avoiding complications of deconditioning, work disability, and the inability to fulfill social roles. FM has been found to be associated with impaired balance and falls (Rutledge, Martinez, Traska, & Rose, 2013). Stretching, aerobic exercise, and strength training should be in every patient's exercise plan.

Nursing Alert

Nurses should focus on patient safety. Nurses caring for people with FM should assess for potential risk factors of falling and offer plans for individualized fall-prevention strategies. One of the Joint Commission (JC) 2015 National Patient Safety Goals aims at reducing falls. The JC recommends a patient evaluation include fall history, review of medications and alcohol consumption, gait and balance screening; assessment of walking aids, assistive technologies, and protective devices; and environmental assessments.

Motivational interviewing (MI) is a client-centered approach that nurses can use to promote behavioral changes (see the Nursing Process section later in the chapter). Meta-analysis of studies using MI when delivered in brief consultations showed efficacy in medical settings for a wide range of behavioral issues, such as exercise, self-management of

pain, and medication adherence (Ferguson, Ibrahim, Thomas, & Weinman, 2015; Lundahl et al., 2013). Another meta-analysis supports MI in increasing physical activity in people with chronic health conditions, one of the ten conditions being FM (O'Halloran et al., 2014). Other management approaches include patient support groups and the use of meditation, prayer, and other spiritual practices. Careful listening to patients' descriptions of their concerns and symptoms is essential to help patients make the changes that are necessary to improve their quality of life (Clauw, 2015; Hardcastle et al., 2015; Ryan, 2014b).

DIFFUSE CONNECTIVE TISSUE DISEASES

Rheumatic disorders with diffuse inflammation and degeneration in the connective tissues are referred to as *connective tissue diseases*. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although the diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities in which the immune system loses its ability to tell the difference between foreign invaders and the body's normal cells. The common connective tissue diseases, RA, systemic lupus erythematosus (SLE), and scleroderma, are presented in detail.

Rheumatoid Arthritis

RA is the most common inflammatory arthritic disorder and serves as a prototype for the study of many inflammatory and immune-mediated diseases. RA affects 0.5% to 1% of the general population worldwide, with a female-to-male ratio of between 2:1 and 3:1 using 1987 ACR criteria for the classification of RA (CDC, 2015a; Firestein, 2013; Liao & Karlson, 2015). The most recent 2010 RA criteria identify people with early RA; however, there are no current estimates. Globally, out of 291 conditions studied, RA was ranked as the 42nd highest contributor to global disability (Cross et al., 2014).

Pathophysiology

A variety of predetermined genes (e.g., human leukocyte antigens [HLA]), random events, and environmental (e.g., pathogens, smoking) factors contribute to RA susceptibility and pathogenesis. In RA, numerous cell types are involved, including macrophages, T cells, B cells, fibroblasts, chondrocytes, and dendritic cells. The autoimmune reaction primarily occurs in the synovial tissue. Adaptive and innate immune responses in the synovium have been implicated in the pathogenesis of RA. RF antibodies develop in the synovium against the Immunoglobulin G (IgG) to form immune complexes. The activation of the complement system and release of lysosomal enzymes from leukocytes lead to inflammation. It is unknown why the body produces an antibody (RF) against its own antibody (IgG) and, in consequence, transforms IgG to an antigen or foreign protein that must be destroyed. Phagocytosis produces enzymes (proinflammatory cytokines such as interleukin [IL]-1, interleukin-6 [IL-6], and tumor necrosis factor [TNF]) within the joint. These cytokines are the primary factors that drive the inflammatory response in RA. The enzymes (especially cytokines) break down collagen, causing edema, proliferation of the synovial membrane, and, ultimately, formation of pannus (Fig. 39-5). Pannus, formation of vascular granulation tissue, is a characteristic of RA that differentiates it from other forms of inflammatory arthritis. Pannus has a destructive effect on the adjacent cartilage and bone. If response is not suppressed, the disease progresses and the consequences are loss of articular surfaces and joint motion. Muscle fibers also undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

Clinical Manifestations and Assessment

Clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Physical signs of RA are associated with the pathophysiology of the disease. The manifestations of RA can be categorized as early or late disease and as articular (joint) or extra-articular. Joint pain, swelling, warmth, erythema (redness), and lack of function are classic symptoms. Palpation of the joints reveals spongy or boggy tissue. Often, fluid can be aspirated from the inflamed joint. The hallmark of RA is synovial proliferation and tenderness in multiple joints, particularly in the small joints of the hands, wrists, and feet. As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints are affected. In addition to joint pain and swelling, a cardinal sign of inflammatory arthritis that can appear even before pain is morning stiffness, lasting for more than an hour (Brasington, 2015; Shah & Clair, 2015; Sweeney, Harris, & Firestein, 2013).

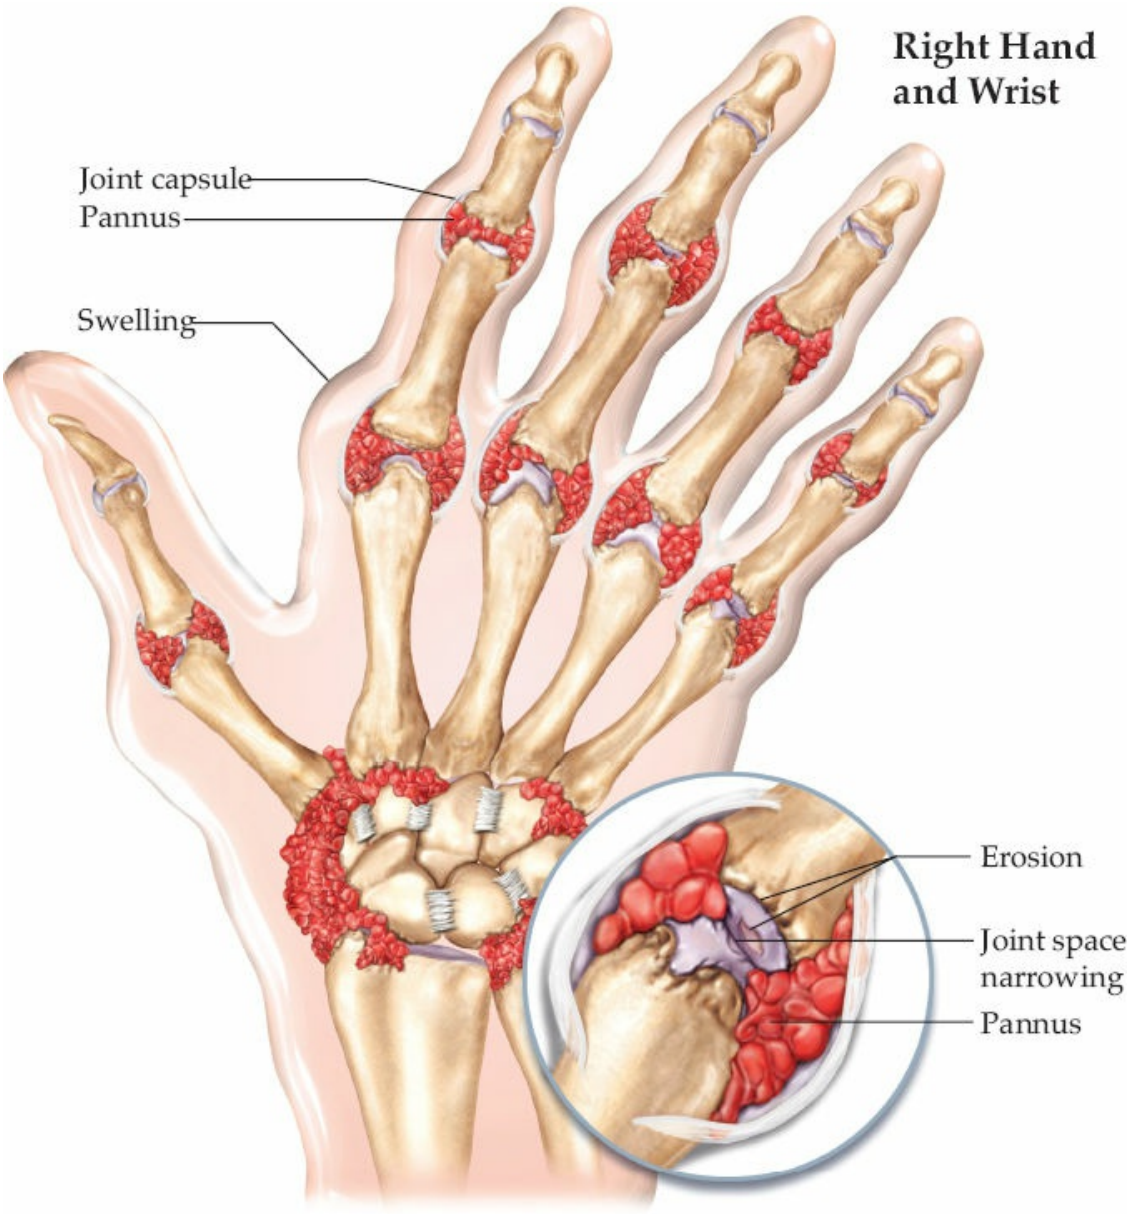

FIGURE 39-5 Joints affected by rheumatoid arthritis.

FIGURE 39-6 Deformity to the hands caused by rheumatoid arthritis.

Deformities of the hands and feet are common in RA (Fig. 39-6). Often the PIP and metacarpophalangeal (MCP) joints of the hands are involved initially. The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when one bone slips over another and eliminates the joint space.

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, anemia, lymph node enlargement, and Raynaud phenomenon (cold- and stress-induced vasospasm causing episodes of digital blanching or cyanosis). Extra-articular disease manifestations occur in about 40% of patients at some time in the course of the disease (Turesson & Matteson, 2015). Rheumatoid nodules may be noted in patients with more advanced RA in about 20% of patients (Brasington, 2015). These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences, most often on extensor surfaces or pressure points, such as the elbow, are varied in size, and can disappear spontaneously. Nodules occur only in people positive for RF. The nodules often are associated with rapidly progressive and destructive disease. Other extra-articular features include arteritis (inflammation of the walls of arteries), neuropathy, scleritis (inflammation of the sclera), pericarditis, splenomegaly, and Sjögren syndrome (dry eyes and dry mucous membranes).

A clinical examination of all synovial joints should be undertaken for evidence of tenderness, swelling, and range of movement. Evidence for synovitis should be seen by a rheumatologist, ideally within 6 weeks after the onset of symptoms to facilitate early diagnosis and clinical management and to achieve optimal outcomes for patients (Beaton, Boers, & Tugwell, 2013; Holers & Deane, 2015; Palmer & El Miedany, 2013; Palmer & El Miedany, 2014; Shah & St. Clair, 2015; Villeneuve, 2013). Presence of deformities, such as hyperextension of PIP joints (swan neck), flexion of PIP joints (Boutonniere), and ulnar deviation, in which fingers point toward the ulna, may be noted on examination. The patient is also assessed for extra-articular changes, such as weight loss, sensory changes,

lymph node enlargement, and fatigue.

Nursing Alert

Patients commonly have the inability to "wring out a wash cloth," need to hold a cup with both hands, and may complain of the sensation of having a "stone in my shoe."

The 2010 RA classification criteria, developed collaboratively by the ACR and the European League Against Rheumatism (EULAR) replaced the 1987 gold standard for disease classification. In addition to active synovitis in at least one joint that cannot be better explained by another diagnosis, additional criteria added include positivity for antibodies to citrullinated proteins (ACPAs or anti-CCP) and abnormal levels of the inflammatory markers, such as the ESR and CRP levels. RF is present in up to 70% to 80% of patients with RA, but its presence alone is not diagnostic of RA. Anticyclic citrullinated peptide (anti-CCP) is a marker that has similar sensitivity but potentially greater specificity to RF (Durham, Fowler, Donato, Smith, & Jensen, 2015; Liao & Karlson, 2015). Some laboratories are currently doing a second generation of the test, called the CCP2 assay. The RBC count and complement C3 and C4 levels are decreased. Complements may be decreased as they are "used up" in some antigen-antibody reactions. Results of antinuclear antibody (ANA), the screening test for autoantibodies (antibodies that form against self), also may be positive. Arthrocentesis shows abnormal synovial fluid that is cloudy, milky, or dark yellow and contains numerous inflammatory components, such as leukocytes and complement. The enzyme MMP-3 is increased in the synovial fluid of the patient with RA, and it may be a marker of progressive joint damage. Synovial biopsy can detect inflammatory cells associated with RA. Radiologic studies are not specifically diagnostic in the early stages of RA; however, they do show characteristic bony erosions and narrowed joint spaces occurring later in the disease and help in monitoring the progression of disease and effectiveness of treatment.

Medical and Nursing Management

Drugs remain the cornerstone of RA treatment. Joint inflammation is the main driver of joint damage and is the most important cause of functional disability in the early stages of disease; thus changes in the therapeutic landscape in RA are seen. Today, treatment is more aggressive. The treatment paradigm changed to adopt a "patient-centered" and "treat-to-target" approach aiming at disease remission. Current guidelines recommend starting a course of DMARDs early, within 3 months of RA diagnosis to delay joint degeneration (O'Dell, 2013). NSAIDs provide fast relief of symptoms but do not prevent joint damage nor slow disease progression. Because the effects of DMARDs take weeks or months to develop, whereas the effects of NSAIDs are immediate, an NSAID is given until the DMARD has had time to act.

The use of traditional NSAIDs (salicylates and nonsalicylates) inhibits the production of prostaglandins and provides anti-inflammatory effects as well as analgesia. Effectiveness, side effects, cost, and dosing schedules are considered in the selection of an NSAID. The incidence of adverse reactions (e.g., gastric irritation, kidney damage, changes in liver function) to the NSAIDs increases with age and long-term use. A second-generation NSAID, the COX-2 inhibitor, has been shown to inhibit inflammatory processes, but it does not inhibit the protective prostaglandin synthesis in the GI tract. Therefore, patients who are at increased risk for GI complications, especially GI bleeding, have been managed effectively with COX-2 inhibitors.

Drug Alert!
COX-2 inhibitors must be used with caution because of the associated risk of cardiovascular disease.

The DMARDs can be classified into nonbiologic and biologic DMARDs. The nonbiologic agent, methotrexate (Rheumatrex, Trexall), is one of the first-choice DMARDs and has become the drug of choice due to its potency and time of action (faster than all other DMARDs). Therapeutic effects or improvement may develop in 3 to 6 weeks, compared to other DMARDs, which can take 3 to 4 months to work (Lehne, 2013). A black-box warning exists for unexpected, severe, and sometimes fatal myelosuppression, aplastic anemia, and GI toxicity reported with methotrexate (usually high dose) in combination with some NSAIDs. Additionally, methotrexate is teratogenic (capable of causing birth defects); therefore, a pregnancy test should be performed if a decision is made to begin treatment in a woman of childbearing age.

Nursing Alert
Nurses should alert patients that taking extra doses of methotrexate is dangerous. The drug is administered weekly or twice a week. Nurses need to encourage feedback to ensure that the patient understands the weekly dosing schedule and that the medication should not be used "as needed" for symptom control.

Institute for Safe Medication Practices (ISMP); www.ismp.org

Another preferred nonbiologic DMARD, hydroxychloroquine (Plaquenil), a drug with antimalarial actions, can be initiated early and used with mild symptoms, but as a rule it is used in combination with methotrexate. By itself, hydroxychloroquine does not slow disease progression; however, early use can improve long-term outcomes.

Leflunomide (Arava), a nonbiologic small-molecule DMARD, is a relatively new and powerful immunosuppressant used for patients with RA. Compared with methotrexate, leflunomide is about equally as effective but more dangerous because of the incidence of liver failure; it is reserved for second-line use. Other minor nonbiologic DMARDs, cyclosporine, gold salts, penicillamine, and azathioprine, have been available for many years. These have been used frequently in the past, but their use today is limited. The drugs are generally reserved for patients with severe, progressive RA disease who have failed to respond to safer DMARDs.

Biologic agents (also referred as *immunomodulators*) are expensive, whereas the nonbiologic small-molecule DMARDs cost much less and are easier to manufacture.

Biologic drugs can be categorized based on their mechanism of action and target specific components of the inflammatory process. They can be used to treat patients with moderate to severe disease who have not responded to DMARDs or in combination therapy with an established DMARD, such as methotrexate. Some biologic agents or modifiers interfere with the action of TNF: etanercept (Enbrel), infliximab (Remicade), and adalimumab (Humira). Most recently, golimumab (Simponi) and certolizumab pegol (Cimzia) have been approved for use in RA. The immunosuppressant actions of TNF inhibitors can increase the patient's risk of serious infections, including bacterial sepsis, invasive fungal infection, and tuberculosis. As a result, prior to initiation of TNF inhibitors, patients should be tested for tuberculosis. A different biologic agent, anakinra (Kineret), interferes with IL-1, which modulates immune and inflammatory responses, and thus has efficacy with rheumatic disorders. Like the TNF inhibitors, anakinra poses a risk of serious infections; therefore, anakinra should not be used in combination with TNF inhibitors.

Nursing Alert

Do not give live vaccines to patients on a biologic agent. Nurses need to monitor for signs of infection (e.g., fever, cough, flu-like symptoms, open sores on body). Also nurses should monitor for heart failure in patients on etanercept (Enbrel) or infliximab (Remicade).

The emerging agents show that a new era in treatment has begun, newly targeting B lymphocyte cells, T-cell activation, and IL-6. These constitute new principles for interference with the disease process (Athanasakis, Petrakis, & Kyriopoulos, 2013; Weinblatt et al., 2013). Tofacitinib (Xeljanz), also a type of DMARD, is the first oral medication in a new class of treatments called Janus kinase (JAK) inhibitors and is FDA approved for moderate to severe RA in which methotrexate did not work well. As most biologics fight inflammation from outside the cell, the JAK inhibitor works deep inside the cell to disrupt activities occurring in signaling pathways. These JAK pathways are believed to be involved in the production of cytokines and in the inflammation of RA (Meier & McInnes, 2014; Vollenhoven, 2015).

The third major group of antiarthritic drugs is the glucocorticoids (adrenal corticosteroids). These are powerful anti-inflammatory drugs used in RA especially during

exacerbations ("flare ups") of the disease or when needing a "bridging" medication while waiting for the slower DMARDs (e.g., methotrexate) to begin taking effect. Oral glucocorticoids, such as prednisone and prednisolone, are indicated for patients with generalized symptoms. Long-term therapy can cause serious toxicity (e.g., osteoporosis, gastric ulceration, adrenal suppression, diabetes) so glucocorticoids should be limited to patients with RA who have failed to respond adequately to all other treatment options. Intra-articular injections, commonly used in severe RA, may be employed if only one or two joints are affected. Antibiotics, the tetracycline derivatives minocycline (Minocin) and doxycycline (Vibramycin), are given to improve symptoms (morning stiffness, joint pain and tenderness), and enhance ADL in patients with RA. These antibiotics have found to decrease the action of enzymes on cartilage degradation. Usage is seen in patients who have not responded to DMARDs.

The *Prosorba Column*, a blood filtration device used in apheresis, has been approved by the FDA for use in treating patients with more severe and longstanding RA who have had no response to or are intolerant of DMARDs. The device, a protein A immunoadsorption column, is used in 12 weekly 2-hour apheresis treatments to bind IgG (i.e., circulating immune complex). As the patient's blood passes through the column, RF is removed.

Drug Alert!
If the patient is on an angiotensin-converting enzyme (ACE) inhibitor, it should be discontinued prior to treatment using Prosorba Column, as the risk of serious hypotension exists with this treatment.

Through all stages of RA, depression and sleep deprivation may require the short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), paroxetine (Paxil), or sertraline (Zoloft), to reestablish an adequate sleep pattern and to manage chronic pain. Furthermore, adults with RA are at high risk of falls and fall-related injuries. Strategies to prevent falls should be implemented (Stanmore et al., 2013a, 2013b).

Systemic Lupus Erythematosus

SLE is a chronic inflammatory multisystem autoimmune disease with variable presentations, courses, and prognoses characterized by remissions and exacerbations. National incidence data are difficult to obtain because onset is difficult to determine. The existing estimates of SLE range widely from 1.8 to 7.6 cases per 100,000 in the United States (CDC, 2015e). Occurrence peaks up to 10 to 12 times more frequently in women than in men (predominantly during a woman's childbearing years), and African Americans and Hispanics are affected more frequently than are Caucasians (ACR, 2015d; Lim & Drenkard, 2015; Simard & Costenbader, 2015).

Pathophysiology

SLE is a result of disturbed immune regulation that causes an exaggerated production of autoantibodies and antigens. The immune abnormalities that characterize SLE occur in five phases: susceptibility (genes and environmental factors), abnormal innate and adaptive immune responses, autoantibodies immune complexes, inflammation, and damage. Interactions of predisposing factors (genes, female gender, and environment) result in abnormal immune responses, specifically in B cells and T cells. These responses produce pathogenic autoantibodies and immune complexes that activate complement, form in tissue, and cause inflammation. Inflammation stimulates antigens, which, in turn, stimulate additional antibodies. The cycle repeats and, over time, leads to irreversible organ damage. Some individuals do not progress through all phases (Crow, 2013).

Drug Alert!
Certain medications, such as hydralazine (Apresoline), procainamide (Pronestyl), isoniazid (INH), chlorpromazine (Thorazine), and some antiseizure medications, can trigger an exaggerated immune response and cause a chemical- or drug-induced SLE.

Clinical Manifestations and Assessment

The onset of SLE may be insidious or acute. For this reason, SLE may remain undiagnosed for many years. The most common presenting manifestations are constitutional symptoms (fever, fatigue, and/or weight loss), cutaneous manifestations, and articular manifestations (arthritis and/or arthralgia). Each of these manifestations appears to be present in at least 50% of patients with lupus at the time of diagnosis (Dall'Era & Wofsy, 2013). SLE is an autoimmune systemic disease that can affect any body system. Clinical manifestations can resemble RA and may be mistaken for it, especially early in the course of the disease. Unlike RA, the arthritis is nonerosive and not seen on x-ray.

Several different types of skin manifestations are prevalent in 80% to 90% of patients with SLE. Photosensitivity rashes are most common; however, the most characteristic skin manifestation is an acute cutaneous lesion consisting of a butterfly-shaped rash across the bridge of the nose and cheeks (Dall'Era & Wofsy, 2013; Dvorkina & Ginzler, 2015) (Fig. 39-7). This malar rash manifests as an erythematous, flat or raised lesion, pruritic (itchy) or painful, and can be transient and heal without scarring. In some cases of discoid lupus erythematosus (DLE), only skin involvement occurs. Discoid (coinlike) lesions are scarring and ring-shaped that may result in erythematous, scaling plaques, and alopecia (hair loss). In some patients with SLE, the initial skin involvement is the precursor to more systemic involvement. The lesions often worsen during exacerbations (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet B light.

FIGURE 39-7 The characteristic butterfly rash of systemic lupus erythematosus.

Nursing Alert
The nurse should teach patients to avoid sunlight or ultraviolet (UV) exposure and to protect themselves with clothing and sunscreen with at least a sun protection factor (SPF) of 30.

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease (60% prevalence). The varied and frequent neuropsychiatric presentations of SLE are now widely recognized. In general, these are demonstrated by subtle changes in behavior patterns or cognitive ability. Headaches, psychiatric disorders (mood disorder, depression, and psychosis), cognitive dysfunction, and seizures are common (Dvorkina & Ginzler, 2015; Hahn, 2015).

Pericarditis and pleuritis are the most common cardiopulmonary disorders (refer to Chapters 10 and 16). Women who have SLE are also at risk for early atherosclerosis. About 50% of patients with SLE have kidney disease, such as glomerulonephritis. Serum creatinine levels and urinalysis are used in screening for kidney involvement. Early

detection allows for prompt treatment so that kidney damage can be prevented. Kidney involvement may lead to hypertension, which also requires careful monitoring and management.

Diagnosis of SLE is based on a complete history, physical examination, and diagnostic tests. SLE has an extreme range of clinical manifestations without classic presentation. Diagnosis is made difficult by the variable manifestations of the disease and relies on the overall clinical picture with the correlation of diagnostic laboratory and imaging studies, possibly including skin biopsy.

The presence of at least four of the criteria established by the ACR is required to make the diagnosis of SLE. Cutaneous manifestations comprise 4 of the 11 diagnostic ACR criteria (malar rash, discoid rash, photosensitivity, and oral ulcers). When performing an assessment, it is critical to inspect skin for erythematous rashes. The nurse asks the patient about the existence of photosensitivity, fatigue, oral ulcers, or pain in joints. Additionally, systemic involvement may encompass several organ systems; therefore, the nurse must review laboratory values or findings that might suggest that the effects of inflammation are targeting organs (e.g., ESR, complete blood count—anemia or thrombocytopenia, creatinine, hematuria).

No single laboratory test confirms SLE. Laboratory features include both hematologic abnormalities (e.g., hemolytic anemia, leukopenia, thrombocytopenia) and immunologic findings indicative of autoimmunity. Most patients with SLE (more than 98%) demonstrate elevated serum levels of ANA, which is another ACR criterion for SLE diagnosis. A small percent of patients will test negative for ANA but will have antibodies to the nuclear antigen anti-Ro (SSA) (Hahn, 2015). Other diagnostic immunologic tests that support SLE diagnosis in the presence of clinical manifestations are CRP, anti–double-stranded DNA (anti-ds DNA), anti-RNA, anti-La (SSB), anti-Sm (Smith) or antiphospholipid antibodies, and high-titer IgG antibodies. The double-stranded DNA test, C3, and C4 indicate whether there is a genetic component that is common in patients with SLE (Dall'Era & Wofsy, 2013).

Medical and Nursing Management

SLE can be life-threatening; however, advances in its treatment have led to improved survival and reduced morbidity. Treatment of SLE includes management of acute and chronic disease. The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disabilities, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

The mainstay of SLE treatment is based on pain management and nonspecific immunosuppression. Therapy includes NSAIDs, DMARDs (including antimalarials) alone or in combination with glucocorticoids, and, in severe SLE cases, immunosuppressive agents (azathioprine, mycophenolate mofetil, methotrexate). Hydroxychloroquine has a central role for long-term treatment. In 2011, the biologic, belimumab (Benlysta) for treatment of mild to moderate SLE became the first FDA-approved drug (ACR, 2015d; Lim & Drenkard, 2015).

Corticosteroids are the single most important medication available for SLE. These drugs are used topically for cutaneous manifestations in low oral doses for minor disease activity and in high doses for major disease activity. IV administration of corticosteroids is an alternative to traditional high-dose oral use (Bertsias, Fanouriakis, & Boumpas, 2013). Important risk factors associated with the use of corticosteroids are osteoporosis and fractures. Corticosteroid toxicity is a major problem, and tapering of the dosage is a primary concern. Treatment of moderate to severe SLE consists of a period of intensive immunosuppressive therapy (induction therapy) followed by a longer period of less intensive maintenance therapy. The main objective of the induction therapy is to stop injury, recover function, and induce remission by managing immunologic activity. The combination of high-dose glucocorticoids with pulses of intravenous cyclophosphamide (CYC), a cyctoxic agent, remains the standard of care for severe SLE with major organ involvement. B-cell–depleting therapies, such as the monoclonal antibodies rituximab (Rituxan) and epratuzumab (humanized anti-CD22 antibody), are the newest form of treatment for SLE and are reserved for patients who have serious forms of SLE that have not responded to conservative therapies.

Nurses also need to be sensitive to the psychological reactions of the patient with SLE. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and unpredictable course of SLE necessitate expert assessment skills and nursing care.

Scleroderma

Scleroderma ("hard skin") is a relatively rare disease that is poorly understood; the cause is unknown. Potential triggers include exposure to certain environmental and occupational agents (e.g., silica dust, heavy metals, polyvinyl chloride) and drugs (e.g., bleomycin, cocaine, fenfluramine appetite suppressants), infection, and human cytomegalovirus (CMV) and other viruses (Varga & Lafyatis, 2015). Scleroderma is classified into localized and systemic (systemic sclerosis), with subclassifications within each one. Incidence estimates range from 9 to 19 people per million per year (Varga, 2015). Similar to other connective tissue diseases, scleroderma is more frequent in women than men (4.6:1).

Pathophysiology

Like other diffuse connective tissue diseases, scleroderma has a variable course, featuring remissions and exacerbations. Systemic scleroderma (SSc) is a progressive, chronic, devastating, and debilitating disease with a prognosis not as optimistic as that of SLE. Pathogenesis integrates three cardinal features: vascular injury and damage, activation of innate and adaptive arms of the immune system autoimmunity, and generalized interstitial and vascular fibrosis.

Scleroderma commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues. Initially, the inflammatory response causes edema formation, with a resulting skin appearance that is taut, smooth, and shiny. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, synovium, skeletal muscles, and internal organ(s) of the heart, lungs, GI tract, and kidneys (Varga, 2013; Varga, 2015).

Clinical Manifestations and Assessment

Scleroderma starts insidiously with Raynaud phenomenon and swelling in the hands. The hallmark of scleroderma is when the skin and the subcutaneous tissues become increasingly hard and rigid and cannot be pinched up from the underlying structures (fibrosis). Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid.

The changes within the body, although not visible directly, are vastly more important than the visible changes. The left ventricle of the heart is involved, resulting in heart failure. The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of hardening (sclerosing) of the intestinal mucosa. Progressive kidney failure may occur.

The patient may manifest a subset of limited cutaneous SSc symptoms referred to as the CREST syndrome (Box 39-4).

BOX 39-4 Focused Assessment

Cutaneous Symptoms of Scleroderma

Be alert for the CREST symptoms:

- Calcinosis (calcium deposits in the tissues)
- Raynaud phenomenon (spasm of blood vessels in response to cold or stress)
- Esophageal dysfunction (acid reflux and decrease in mobility of esophagus)
- Sclerodactyly (thickening and tightening of skin on fingers and hands)
- Telangiectasia (capillary dilation that forms vascular red marks on surface of skin)

Assessment focuses on the hallmark sclerotic changes (thickening) in the skin, contractures in the fingers, and color changes or ulcerations in the fingertips due to poor circulation (Boin & Wigley, 2013; Hoogen et al., 2013). Assessment of systemic involvement requires a systems review with special attention to GI, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed along with the impact the disease has had (or will have) on body image.

There is no one conclusive test to diagnose scleroderma, and testing depends on the possibility or extent of organ involvement. A skin biopsy is performed to identify cellular changes specific to scleroderma. Pulmonary studies show ventilation–perfusion abnormalities. Echocardiography evaluates left ventricular function and pulmonary arterial pressure and identifies pericardial effusion (often present with cardiac involvement). Esophageal studies demonstrate reflux esophagitis (early discriminator) and dysmotility in most patients with scleroderma. Autoantibody testing, particularly ANA, is the most useful laboratory test, with a positive result common in more than 95% of patients with scleroderma and antisclerodermal antibody (anti-scl) 70 (Bolster & Silver, 2015; Fett,

2013; Mayes & Assassi, 2015; Varga, 2015). In the presence of CREST syndrome, 90% have a positive anticentromere antibody test. Other autoantibodies demonstrate an association between scleroderma and a specific clinical pattern, such as anti-topoisomerase I antibodies and lung fibrosis or anti-RNA polymerase I/III and scleroderma renal crisis.

Medical and Nursing Management

Management of scleroderma depends on the patient's clinical manifestations and is based on disease comorbidities (Fett, 2013). In scleroderma, treatment includes management of both acute and chronic disease. Acute conditions require interventions directed at controlling increased disease activity or exacerbations that can involve any organ system. Management of the more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy. Because this is a life-altering disease that has no cure, all patients should receive counseling, during which realistic individual goals may be determined. As in the other rheumatic disorders, support measures include strategies to decrease pain, limit disability, maintain moderate exercise, and prevent joint contractures. No specific medication regimen has proved effective in modifying the disease process in scleroderma, but, along with antiarthritic drugs, various medications are used to treat organ system involvement. Calcium-channel blockers may provide improvement in symptoms of Raynaud phenomenon. ACE inhibitors appear to have improved survival of renal scleroderma crisis, and now there are many therapeutic agents approved for use in pulmonary hypertension (Steen, 2015; Topal & Dhurat, 2013).

In addition to the common problems of rheumatic disorders, nurses need to identify other patient difficulties or needs related to scleroderma and plan accordingly. For instance, patients with scleroderma have problems associated with impaired skin integrity and imbalanced nutrition that is less than what the body requires. The patient with advanced disease also may have impaired gas exchange, decreased cardiac output, impaired swallowing, and constipation. There has been increased attention on psychosocial issues in SSc, but currently there have been no evidence-based interventions (Malcarne, Fox, Mills, & Gholizadeh, 2013).

Providing meticulous skin care and preventing the effects of Raynaud phenomenon are major nursing challenges. Nurses teach patients to avoid the cold and to protect fingers with mittens. In addition, warm socks and properly fitting shoes are helpful in preventing foot ulcers. Careful, frequent inspection for early ulcers is important, and smoking cessation is critical.

NURSING PROCESS

The Patient with a Rheumatic Disorder

ASSESSMENT

The health history and physical and psychological assessments focus on current and past symptoms, such as fatigue, weakness, pain, stiffness, fever, or anorexia and the effects of these symptoms on the patient's lifestyle and self-image. Also the patient's social support systems are assessed as well as his or her ability to participate in daily activities, comply with the treatment regimen, and manage self-care (Box 39-5). Additional areas assessed include the patient's understanding, motivation, knowledge, coping abilities, past experiences, preconceptions, and fears. The impact of the rheumatic disorder on the patient must be assessed to understand the patient's problems so that a plan of care specific to his or her issues can be developed. The nurse assesses the impact of the condition by asking, "Are there things that you cannot do now that you could do a year ago?" "What is it about your condition that you find most frustrating?" "What do you most enjoy doing?" "What things do you find difficult that you would like to be able to do?" and "How do you manage to get around the tasks that are difficult?" (Woolf, 2015). The nurse's assessment and patient response to these questions may lead to identifying issues and concerns that can be addressed by nursing interventions, and, through collaboration with other interprofessional members, expected patient outcomes can be achieved (Crossland, Field, Ainsworth, Edwards, & Cherry, 2014; Iversen, 2013; Iversen & Sharby, 2015; Kjeken, Dagfinrud, Heiberg, & Kvien, 2015).

DIAGNOSIS

Nursing diagnoses for patients with rheumatic disorders may include, but are not limited to:

- Acute and chronic pain related to inflammation and/or progression of joint deterioration, tissue damage, fatigue, lowered tolerance level, or ineffective pain/comfort measures
- Fatigue related to inflammatory process and increased disease activity, pain, inadequate sleep/rest, impaired physical and psychosocial functioning (including emotional stress/depression), and inadequate nutrition
- Insomnia related to pain, anxiety/stress, depression, and medications
- Impaired physical mobility related to musculoskeletal impairment, decreased ROM, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices
- Self-care deficits (specify) related to limitations secondary to progression of disease, pain, fatigue, contractures, or loss of motion
- Ineffective health self-management (formerly ineffective therapeutic regimen management) related to complexity of chronic health problem and medication compliance, decisional conflicts, economic difficulties, and deficient knowledge regarding disease management
- Disturbed body image related to physical (e.g., joint abnormalities) and psychological (e.g., depression) changes, loss of body function, and dependency imposed by chronic illness

- Ineffective coping related to actual or perceived lifestyle or role changes, chronicity of disease, poor prognosis, and sense of powerlessness
- Risk for injury related to adverse effects of medications, high risk of falls, and potential complications

BOX 39-5 Nursing Research

Bridging the Gap to Evidence-Based Practice

What is the Evidence of the Effects of a Self-Care Program in People with Rheumatic Diseases?

Arvidsson, S., Bergman, S., Arvidsson, B., Fridlund, B., & Tingström, P. (2013). Effects of a self-care promoting problem-based learning programme in people with rheumatic diseases: A randomized controlled study. *Journal of Advanced Nursing*, *69*(7), 1500–1514.

Purpose

Empowerment is a concept often used in health care. The World Health Organization (WHO) describes empowerment in health promotion work as a process where individuals receive more control over decisions and actions that affect their own life and health. Therefore, the goal of patient education for individuals with RA is that they must participate actively in their own care and have knowledge and skills to manage their self-care in the best way. The purpose of this study was to evaluate the effects of a self-care promoting problem-based learning program for people with rheumatic diseases in terms of health-related quality of life (HRQL), empowerment, and self-care ability.

Design

A randomized controlled design was selected with test at baseline, 1 week, and 6 months postintervention after completing a 1-year program. The participants were assigned randomly to either the experimental group (n = 54) or the control group (n = 148). The inclusion criteria were that the participants had one or more diagnoses of rheumatic diseases for more than a year, had musculoskeletal pain, and had sleep disturbances and/or fatigue during the last 3 months. The participants in the experimental group were divided consecutively into seven tutorial groups of seven or eight participants and one tutor. Each tutorial group met for 1½ hours, 10 times in a 1-year period. Starting points in the curriculum were: self-awareness and self-confidence, relationship to others, stress and relaxation, physical activity and rest, medicines and herbal remedies, tobacco and alcohol, and food and drink. The program ran alongside the standard care the participants received at a rheumatology unit.

Findings

The participants in the experimental group had a statistically significant difference demonstrating stronger empowerment after participation in the self-care promoting problem-based learning program compared with the control group, at the 6-month postintervention meeting. Approximately two thirds of the participants in the

experimental group stated that they had implemented lifestyle changes due to the program.

Nursing Implications

The results of this study showed that the self-care promoting problem-based learning program enabled people with rheumatic diseases to improve their empowerment compared with the control group. It is important to continue to develop problem-based learning in patient education to find the very best way to use this pedagogical method in the care of patients affected by rheumatologic disorders.

PLANNING

The major goals for the patient may include relief of pain and discomfort, relief of fatigue, promotion of nutrition and restorative sleep, increased mobility and exercise, maintenance of self-care, motivation and adherence to therapeutic regimen, improved body image, effective coping, absence of complications, and promotion of home care.

NURSING INTERVENTIONS

Pain management and optimal functional ability, including the promotion of a healthy, positive life course adaptation, are major goals of nursing intervention. Patient teaching is an essential nursing intervention in the care of the patient with a rheumatic disorder. Education is the key to successfully enabling the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly. Patient teaching focuses on the disorder itself, the possible changes related to the disorder, and the therapeutic regimen prescribed to treat it. Additional teaching is centered on the potential side effects of medications, strategies to maintain independence and function, and patient safety.

RELIEVING PAIN AND DISCOMFORT

Pain has quite different effects on different patients. The response to pain and the degree to which it disrupts the patient's life give a more meaningful indication of severity. Does the pain affect their sleep? How has pain affected their mood? What specific functions or activities does it limit? Understanding the problems it causes can guide how best to manage the patient's pain.

The nurse teaches patients to differentiate between joint pain and stiffness. Medications are used on a short-term basis to relieve acute pain. Because the pain may be persistent, nonopioid analgesics, such as acetaminophen, are often used. After administering medications, the nurse needs to reassess pain levels and response to treatment. With persistent pain, assessment findings should be compared with baseline measurements; evaluations of additional measures include exploring coping skills and strategies that have worked in the past.

The nurse teaches the patient about self-administration of pharmacologic agents and

the need for safety in doing so. The patient needs to understand the importance of taking medications, such as NSAIDs and DMARDs, exactly as prescribed to achieve maximum benefits. These benefits include relief of pain and anti-inflammatory action as the disease is brought under control. Because disease control and pain relief are delayed, the patient may mistakenly believe the medication is ineffective or may think of the medication as merely "pain pills," taking them only sporadically and failing to achieve control over the disease activity. Alternatively, the patient may not understand the need to continue the medication for its anti-inflammatory actions once pain control has been achieved.

Also heat applications are helpful in relieving pain, stiffness, and muscle spasm. Superficial heat may be applied in the form of warm tub baths or showers and warm, moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied. However, in some patients, heat actually may increase pain, muscle spasm, and synovial fluid volume. If the inflammatory process is acute, cold applications in the form of moist packs or an ice bag may be tried. Both heat and cold are analgesic to nerve pain receptors and can relax muscle spasms (Iversen, 2013; Kjeken et al., 2015). The nurse teaches safe use of heat and cold application, in 15- to 20-minute intervals, usually three to four times a day. The nurse checks the temperature of warm soaks and covers cold packs with a towel, particularly for patients with impaired sensation. Further study of the effectiveness of these modalities is needed.

The nurse encourages measures to protect affected joints. There is no clear indication that the use of orthotic devices, such as braces, splints, collars, and shoe modifications, provides pain relief. However, there is preliminary evidence to support the use of extra-depth shoes, with or without semi-rigid insoles, to relieve pain on walking and weight bearing (Kjeken et al., 2015). Patients should be taught to avoid stooping, bending, or overreaching and to rest 5 to 10 minutes when trying to complete a task. The nurse educates the patient regarding other strategies for decreasing pain, such as relaxation techniques, imagery, meditation, and distraction.

DECREASING FATIGUE

Fatigue is a common problem for patients with rheumatic disorders (Matcham, Ali, Hotopf, & Chalder, 2015; Rongen-van Dartel et al., 2014). Fatigue related to rheumatic disorders can be both acute (brief and relieved by rest or sleep) and chronic. Chronic fatigue, related to the disease process, is persistent, cumulative, and not eliminated by rest, but it is influenced by biologic, psychological, social, and personal factors. The nurse discusses related causes of fatigue with patients. Disease-related factors that may influence the amount and severity of fatigue include persistent pain, sleep disturbance, impaired physical activity, and disease duration. Pain increases fatigue because additional physical and emotional energy is required to deal with it. Pain also may cause the patient to expend more energy to do tasks in a way that causes less pain. A plan of nursing care for a patient with a rheumatic disorder is available online at

http://thepoint.lww.com/Honan2e.

PROMOTING NUTRITION

Dietary intake of high-quality food has declined for most Western cultures. Americans are eating an increased amount of processed animal products and foods (high in trans fatty acids and omega-6 free fatty acids), food additives, preservatives, and high–glycemic-index foods (Berman, Lewith, Manheimer, Bishop, & D'Adamo, 2015; Stamp & Cleland, 2013). These factors directly or indirectly stimulate inflammation by increasing levels of arachidonic acid, a key component of many inflammatory mediators. Evidence has suggested incorporating an anti-inflammatory diet to improve serologic and symptomatic markers of inflammation. Fish oil supplements, and omega-3 or omega-6 fatty acids, can be added to the diet.

An anti-inflammatory diet is a predominantly plant-based diet, avoiding excess and high-glycemic-load calories. There is a strong emphasis on avoidance of foods that may potentially exacerbate the inflammatory response (e.g., trans fats, refined sugars, high saturated fats, alcohol, and caffeine in excess). The majority of the diet should be derived from four areas: whole-grain products, fresh fruits and vegetables, legumes, and seeds and nuts. These sources provide several anti-inflammatory components, such as fiber, isoflavones (e.g., soybeans and soy products), carotenoids, and omega-3 free fatty acids (e.g., flaxseed). Patients can be told to keep a journal to assist in monitoring ongoing diet and symptom changes and not to expect immediate results, allowing at least 12 weeks before reevaluating for any benefits. Consultation with a dietitian is highly recommended for understanding the overall diet and suggestions for meal planning.

Nursing Alert
Some medications (i.e., oral corticosteroids) used in the treatment of rheumatic diseases stimulate the appetite and, when combined with decreased activity, may lead to weight gain. Therefore, patients may need to be counseled about eating a healthy, calorie-restricted diet.

PROMOTING RESTORATIVE SLEEP

Restful sleep is important in helping the patient to cope with pain, minimize physical fatigue, and deal with the changes necessitated by a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Also stiffness, depression, and medications may compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep. The nurse encourages patients to take a warm bath or shower before bedtime to relax muscles; showering first thing in the morning may be beneficial to reduce morning stiffness.

Teaching sleep hygiene strategies may be helpful in promoting restorative sleep. These strategies include establishing a set time to sleep and wake up, creating a quiet sleep environment with a comfortable room temperature, avoiding factors that interfere with

sleep (e.g., use of alcohol and caffeine), maintaining proper positioning of joints, using relaxation exercises, and getting out of bed and engaging in another activity (e.g., reading) if unable to fall asleep within 20 to 30 minutes (Taylor, Lillis, Lynn, & LeMone, 2015).

INCREASING MOBILITY

Maintaining some degree of joint mobilization and load on the joints is essential to the preservation of articular cartilage integrity. If the patient is overweight, a weight reduction program is a critical element in relieving stress on painful joints. Proper body positioning is essential to minimize stress on inflamed joints and prevent deformities that limit mobility. All joints should be supported in a position of optimal function. When in bed, the patient should lie flat on a firm mattress, with feet positioned against a footboard and with only one pillow under the head because of the risk of dorsal kyphosis. A pillow should not be placed under the knees, because this promotes flexion contracture. It is best for the patient to lie prone several times daily to prevent hip flexion contracture.

Care must be taken so that splinting for comfort does not restrict mobility later. Regularly removing the splint and exercising the joint through an ROM should be done to prevent joint "freezing." Splint modification may be needed when changes occur in joint structure.

In addition, assistive devices may be necessary for mobility. They should be fitted properly, and the patient should be instructed in their correct and safe use. A cane, long enough to allow for only a slight bend of the elbow, should be held in the hand opposite the affected side. Forearm-trough style crutches (platform crutches) may be needed to protect the upper extremities if the disease also involves the hands and wrists. This is especially important for the patient undergoing rehabilitation after reconstructive surgery on a joint in the lower extremity. Assistive devices can mean the difference between dependence and independence in mobility. However, keep in mind also that use of assistive devices may alter the patient's body image, which can become a barrier to adherence to the treatment regimen.

ENCOURAGING EXERCISE

The ACR has identified exercise as a fundamental part in the management of rheumatic disorders. Active and active/self-assisted ROM exercises are encouraged because they prevent joint stiffness and increase mobility (Farrokhi, Baker, & Fitzgerald, 2015). Active/self-assisted exercises involve the use of overhead pulleys or wand exercises (shoulder exercises using a wand, stick, or cane). Measures to reinforce proper body posture and increase mobility include walking erect and using chairs with straight backs. When seated, the patient should rest the feet flat on the floor and the shoulders and hips against the back of the chair.

A formal program with occupational and physical therapy should be prescribed to educate the patient about principles of joint protection, pacing activities, work simplification, ROM, and muscle-strengthening exercises. An individualized exercise program is crucial to movement. Exercises appropriate in promoting mobility in patients

with rheumatic disorders are summarized in Table 39-5. Appropriate programs of moderate pressure massage therapy and exercise, including T'ai chi, have been shown to decrease pain, improve function, and improve quality of life (Ekelman et al., 2014; Field et al., 2013; Field, Diego, Gonzalez, & Funk, 2014; Iversen, 2013; Sun et al., 2014). The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as RA or SLE, activity levels may vary from day to day and even within a single day.

FACILITATING SELF-CARE

Self-care includes practices that patients undertake to promote their own health and well-being despite having a chronic illness. Self-care practices must be taught and reinforced so the patient does not develop self-care deficits. The nurse needs to keep in mind that a patient's deformity does not necessarily equate with the severity of limitations or disability. For example, swollen (edematous) hands may be more limiting than deformed hands.

The nurse should assist the patient in identifying any self-care deficit and those factors that interfere with the ability to perform self-care activities. The nurse in a hospital or extended care facility can help preserve the patient's independence by making available adaptive equipment for eating, toileting, bathing, and dressing. In the home, the nurse can encourage use of these devices. Also, the nurse should reemphasize the importance of relief for pain, stiffness, and fatigue and its impact on increasing the patient's ability to perform self-care.

PROMOTING MOTIVATION AND ENHANCING HEALTH MANAGEMENT

Motivating patients to make behavioral changes is an important nursing intervention. MI, proved effective in treating addictions, has been adapted for managing chronic illnesses. MI is a skillful clinical style for eliciting from patients their own good motivations for making behavior changes in the interest of their health through exploring and resolving ambivalence (Huffman, 2014; Knittle et al., 2014; Westra & Aviram, 2013). MI is an evidence-based counseling approach that can be used by nurses to help patients adhere to health regimens and can be applied in very brief, 10- to 15-minute patient encounters (Droppa & Lee, 2014; Lundahl et al., 2013; Moral et al., 2015). A key to understanding MI is knowing the phenomenon of ambivalence (Miller & Rollnick, 2013). Patients may feel ambivalent about change. Conflicting motivations are normal and common, to simultaneously want and not want. "I want to exercise, but it hurts," "I mean to take my medicine, but I keep forgetting." Nurses need to recognize the telltale sign of ambivalence is the "but" in the middle of their narrative. The nurse's task is to elicit "change talk" rather than resistance from the patient. Resistance is the patient's way of trying to resolve the discomfort created by ambivalence. Resistance is best handled by restating, using a "but" statement. For example, "You say you want to exercise, but it hurts. What things can you do to help ease the pain with activity?" The nurse refrains from persuading and

confronting but guides the patient toward an acceptable resolution that triggers change. Patient motivation and readiness to change are dynamic states that can be greatly influenced by interactions between nurse and patient. By guiding the patient on what he or she sees as obstacles (the "buts"), nurses can play a vital role in motivating the patient toward change (Box 39-6).

TABLE 39-5 Exercises to Promote Mobility

Type of Exercise	Purpose	Recommended Performance	Precautions
Range of motion	Maintain flexibility and joint motion	Active or active/self-assisted at least daily	Reduce number of repetitions when inflammation is present
Isometric exercise	Improve muscle tone, static endurance, and strength; prepare for dynamic and weight-bearing exercises	Perform at 70% of maximal voluntary contraction daily	Monitor blood pressure; isometric exercises may increase blood pressure and decrease blood flow to muscles
Dynamic exercise	Maintain or increase dynamic strength and endurance; increase muscle power; enhance synovial blood flow; promote strength of bone and cartilage	Start with repetitions against gravity and add progressive resistance; perform 2–3 days per week	May increase biomechanical stress on joints that are unstable or misaligned
Aerobic exercise	Improve cardiovascular fitness and endurance	Perform 3–5 days per week for a maximum of 20–30 minutes of moderate-intensity exercise	Progress slowly as activity tolerance and fitness improve
Aquatic exercise	Water supports or resists movement; warm water may provide muscle relaxation and ease of movement	Provides buoyant medium for performance of dynamic or aerobic exercise	Recommended water temperature (92–94°F); deep water to minimize joint compression; nonslip footwear for safety; receive appropriate instruction in a program designed for people with arthritis

Adapted from Iversen, M. D. (2013). Introduction to physical medicine, physical therapy, and rehabilitation. In G. S. Firestein, R. C. Budd, S. E. Gabriel, I. B. McInnes, & J. R. O'Dell (Eds.), *Kelley's textbook of rheumatology* (9th ed.). Philadelphia, PA: Saunders Elsevier.

As part of standard nursing practice, patient education is the cornerstone to effective health management. Nurses should use therapeutic skills, such as reflective listening and asking open questions, prior to informing (The Advisory Board Company & Nursing Executive Center, 2015). Ask the patient what he or she already knows about the topic before preceding—use the "ask–provide–ask–formula."

Educational topics should include information about the nature and treatment of the disease, pain management strategies, correct posture and body mechanics, correct use of assistive devices, principles of joint protection, energy conservation and pacing techniques, balanced nutrition, weight and stress management, and an individualized exercise program. In the spirit of motivation and enhancement, it is crucial to form a partnership (collaboration) between nurse and patient; the nurse needs to listen and elicit information from the patient, understand the patient's own perspectives (evocation), and recognize that the patient can and does make choices about the course of his or her life (autonomy). In the end, the patient should express confidence in his ability to make treatment decisions and to carry out a health regimen.

IMPROVING BODY IMAGE AND COPING

All aspects of the patient's life, including work role, social life, sexual function, financial status, and perception of self may be altered because of the impact and unpredictability of the course of a rheumatoid disorder. Body image changes can lead to social isolation and depression. Hence, the nurse and the family need to understand and be sensitive to the patient's emotional reactions to the disease and provide support and assistance when appropriate.

BOX 39-6 Four Guiding Principles of Motivational Interviewing (Acronym RULE)

R: Reflect Resistance

When the nurse suggests change and the patient is resisting and arguing against it, the nurse should "roll with the patient's resistance" (i.e., the nurse acknowledges that resistance to change is expected). The patient is the primary source of arguments and solutions. The nurse should reflect resistance nonjudgmentally.

U: Understand

The nurse expresses empathy and communicates acceptance of the patient's experience, including the patient's ambivalence about change. Be interested in the patient's own concerns, values, and motivations.

L: Listen

By listening to what patients say, the nurse can tell how likely they are to change. Listen for verbs in patient narrative indicating change talk, statements in relation to desire, ability, reasons, need, commitment, and taking action.

E: Empower

Nurses assist patients to explore how they can make a difference in their own health, emphasizing the patient's ability to choose and carry out a plan for change. Outcomes are best when patients take an active role in their own health care.

Adapted from Letourneau, K., & Goodman, J. H. (2014). A patient-centered approach for addressing physical activity in older adults: Motivational interviewing. *Journal of Gerontological Nursing, 40*(11), 26–32; Miller, W. R., & Rollnick, S. (2013). *Motivational interviewing: Helping people change.* (3rd ed.). New York: The Guilford Press.

The nurse should encourage the patient and family to verbalize feelings, perceptions, and fears related to the disease. Additionally, the nurse facilitates communication and aids the patient and family in identifying areas in which they have some control over disease symptoms and treatment. By taking action and involving others, the patient develops or draws on coping skills and possibly community support. The role of the nurse aims at addressing these psychological challenges to optimize the physical and psychological status of each patient (Roberts, 2013; Ryan, 2014a). The nurse also assists the patient to identify

past coping mechanisms, as well as use of effective coping strategies, which is a key to positive outcomes.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Medications used for treating rheumatic disorders have the potential for serious and adverse effects. Therefore, an important aspect of care is avoiding medication-induced complications. The provider bases the prescribed medication regimen on clinical findings and medical history and then monitors for side effects with periodic clinical assessments and laboratory testing. The nurse plays a major role in working with the primary care provider and pharmacist to help the patient recognize and deal with medication side effects. If side effects occur, the medication may need to be stopped or the dose reduced. The patient may experience an increase in symptoms while the complication is being resolved or a new medication is being initiated. In such cases, the nurse's counseling regarding symptom management may relieve potential anxiety and distress.

PROMOTING HOME CARE

Depending on the severity of the disorder and the patient's resources and supports, referral for home care may or may not be warranted. The patient who is elderly or frail, has a rheumatic disorder that limits function significantly, and lives alone may need a referral for home care. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations given the increased risk of cardiovascular disease. The patient and family should be informed about support services such as Meals on Wheels and local chapters of the Arthritis Foundation.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Adherence to the treatment program can be monitored more easily in the home setting, where physical and social barriers to adherence are more readily identified. For example, a patient with diabetes who requires insulin may be unable to fill the syringe accurately or be unable to administer the insulin because of impaired joint mobility. Often appropriate adaptive equipment needed for increased independence is identified more readily when the nurse sees how the patient functions in the home. Any barriers to adherence are identified, and appropriate referrals are made. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase.

Furthermore, with each home visit the nurse assesses the patient's physical and psychological status, adequacy of symptom management, and adherence to the management plan. Previous teaching is reinforced, with emphasis on potential side effects of medications and changes in physical status that indicate disease progression and the need to contact the health care provider for reevaluation. Because of the increased risk of involvement of multiple organ systems, the importance of follow-up appointments is emphasized to the patient and family.

EVALUATION

Expected patient outcomes may include the following:

1. Experiences relief of pain or improved comfort level:
   a. Identifies factors that cause or increase pain
   b. Identifies realistic goals for pain relief
   c. Uses pain management strategies safely and effectively
   d. Reports decreased pain and increased comfort level
2. Experiences reduction in level of fatigue:
   a. Identifies factors that contribute to fatigue
   b. Verbalizes the relationship of fatigue to disease activity
   c. Schedules periodic rest periods, and identifies and uses other measures to prevent or modify fatigue
   d. Reports decreased level of fatigue
   e. Practices energy conservation strategies
   f. Discusses the relationship of the inflammatory process to fatigue and nutrition
3. Improves sleep patterns:
   a. Reports fewer nighttime awakenings
   b. Adheres to sleep-inducing routine
   c. Reports feeling rested on awakening
4. Increases or maintains level of mobility:
   a. Identifies factors that impede mobility
   b. Demonstrates normal or acceptable body alignment and posture
   c. Uses assistive devices appropriately and safely
   d. Participates in activities and exercises that promote or maintain mobility
5. Maintains self-care activities:
   a. Participates in self-care activities within capabilities
   b. Uses adaptive equipment and alternative methods to increase participation in self-care activities
   c. Maintains self-care at highest possible level
6. Enhances motivation and health self-management:
   a. Self-initiates goal-directed behavior
   b. Expresses belief in ability to perform activities
   c. Develops contract for health management with mutually agreeable goals for treatment
   d. Performs self-care and health-related activities consistent with ability
   e. Balances treatment, exercise, work, leisure, rest, and nutrition
7. Experiences improved body image and coping:
   a. Verbalizes concerns about the impact of rheumatic disease on appearance and function
   b. Sets and achieves meaningful goals
   c. States acceptance of self-worth
   d. Adapts to body image changes caused by disease

e. Identifies and uses effective coping strategies

8. Experiences absence of complications:
   a. Takes medications as prescribed
   b. States potential side effects of medications and names reportable side effects
   c. Verbalizes understanding of rationale for monitoring
   d. Complies with recommendations for monitoring
   e. Identifies strategies to reduce risks of side effects and potential risks for falling

CHAPTER REVIEW

Critical Thinking Exercises

1. A 79-year-old woman with a 10-year history of OA of the right knee complains of pain every day and difficulty walking. Currently, she uses a walker to ambulate but needs to stop and rest every so often because of the pain. What treatment options are available? Develop an evidence-based plan of care for her.

2. A 20-year-old woman complains of alopecia, skin rash, joint pain, weight loss, and fatigue. Her family states that she does not "seem like herself" lately. A diagnosis of SLE is made. What can you explain to her about her diagnosis and her treatment options?

3. You are caring for a patient with a rheumatic disorder. NSAIDs, corticosteroids, and a biologic response modifier have been prescribed. How do the actions, uses, and indications of these medications differ? What instructions and recommendations would you give to the patient to ensure their safe administration?

NCLEX-Style Review Questions

1. When assessing a patient, the nurse knows that which clinical manifestations are shared by rheumatoid arthritis and OA?
   a. Joint space narrowing and a decreased C4 level
   b. Symmetrical knee involvement and joint effusions
   c. Tophi, joint enlargement, and severe pain
   d. Joint swelling, stiffness, and pain

2. The nursing diagnosis identified for a patient with OA is acute pain. Which action by the patient warrants intervention by the visiting nurse?
   a. Acetaminophen (Tylenol) taken PO in doses no more than 3,000 mg/day
   b. Capsaicin (Capsin) applied topically as needed 3 to 4 times a day
   c. Cold application to localized area for 30 minutes 4 to 5 times a day
   d. Paraffin dips providing concentrated heat applied to the wrist before bedtime

3. The nurse has finished the receiving shift report at 7:30 AM. Which patient should the nurse assess first?

a. The patient with scleroderma who had an episode of dyspnea during the night shift
b. The patient diagnosed with OA who complains of morning joint stiffness
c. The patient who needs to receive a scheduled 8 AM IV adrenal corticosteroid
d. The patient suspected of an acute gout attack who is scheduled for an arthrocentesis

4. A patient with SLE is admitted to the hospital for evaluation and management of acute joint inflammation. Which information obtained in the admission laboratory testing results is of most concern to the nurse?
a. Elevated blood urea nitrogen (BUN)
b. Increased C-reactive protein
c. Positive ANA
d. Positive RF

5. Which statement indicates the patient requires further teaching regarding the nutritional management of gout?
a. "I need to limit my alcohol intake."
b. "I need to avoid fad starvation diets."
c. "I need to follow a high-protein diet."
d. "I need to eliminate fructose drinks."

Problems Related to Musculoskeletal Function

A 26-year-old man is being seen in the orthopedic clinic for complaints of low back pain. He is employed as a construction worker. He complains of pain radiating down his left leg. He states that his back pain started after he lifted a steel beam at work.

- Discuss evaluative data that would be important to gather on this patient.

- Describe diagnostic procedures that would lead to a definitive diagnosis.
- Discuss medical and nursing management for this patient.

CHAPTER 40

Nursing Assessment: Musculoskeletal Function

Geriann B. Gallagher

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the basic structure and function of the musculoskeletal system.
2. Discuss the relationship of the health history to the assessment of musculoskeletal health.
3. Describe the significance of physical assessment findings to the diagnosis of musculoskeletal dysfunction.
4. Specify the diagnostic tests used for assessment of musculoskeletal function.

The musculoskeletal system includes the bones, joints, muscles, tendons, ligaments, and bursae of the body. The functions of these components are highly integrated; therefore, disease in or injury to one component adversely affects the others. For instance, an infection in a joint (septic arthritis) causes degeneration of the articular surfaces of the bones within the joint and local muscle atrophy.

Diseases and injuries that involve the musculoskeletal system are commonly implicated in disability and death. In 2006, patients at least 65 years of age had over 2.1 million visits to the emergency department (ED) for injurious falls, which accounts for 10.5% of all ED visits among the elderly. In addition, 29.6% of these visits required hospital admission (Ferri, 2016). Hip fracture is a serious consequence of falls in the elderly; approximately 73% to 90% of hip fractures occur from a fall (Agency for Healthcare Research and Quality [AHRQ], 2015). Fractures increase the risk of mortality and significantly increase the cost of patient care. Musculoskeletal diseases and injuries can significantly affect overall productivity, independence, and quality of life (QOL) in people of all ages. Nurses in all practice areas encounter patients with disruption in musculoskeletal function.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The health and proper functioning of the musculoskeletal system is interdependent with that of the other body systems. The musculoskeletal system has important functions, including providing protection for vital organs (e.g., brain, heart, liver, kidneys, lungs, spleen) and providing a sturdy framework to support body structures. It also makes mobility possible. Joints hold the bones together and allow the body to move. The muscles attached to the skeleton contract, moving the bones and producing heat that helps maintain body temperature. Movement facilitates the return of deoxygenated blood to the right side of the heart by massaging the venous vasculature. In addition, the musculoskeletal system serves as a reservoir for immature blood cells and essential minerals, including calcium, phosphorus, magnesium, and fluoride. More than 98% of total body calcium is present in the bones. Additionally, the red bone marrow located within bone cavities produces red blood cells (RBCs), white blood cells (WBCs), and platelets through a process referred to as hematopoiesis.

Structure and Function of the Skeletal System

The shape and construction of a specific bone are determined by its function and the forces exerted on it.

Bone Types and Tissue

Bones are constructed of two types of bone tissue: cancellous (trabecular) or cortical (compact). Cancellous bone, or spongy bone, is found in the interior of bones and forms a lattice-like pattern. Red or yellow bone marrow fills the lattice network. Cortical, or compact, bone forms the outer shell of a bone. It has a densely packed, calcified intercellular matrix, making the cortical bone more rigid than cancellous bone (Grossman & Porth, 2014). Varying amounts of both cancellous and cortical bone are found throughout the body in differing proportions depending on the function of the bone.

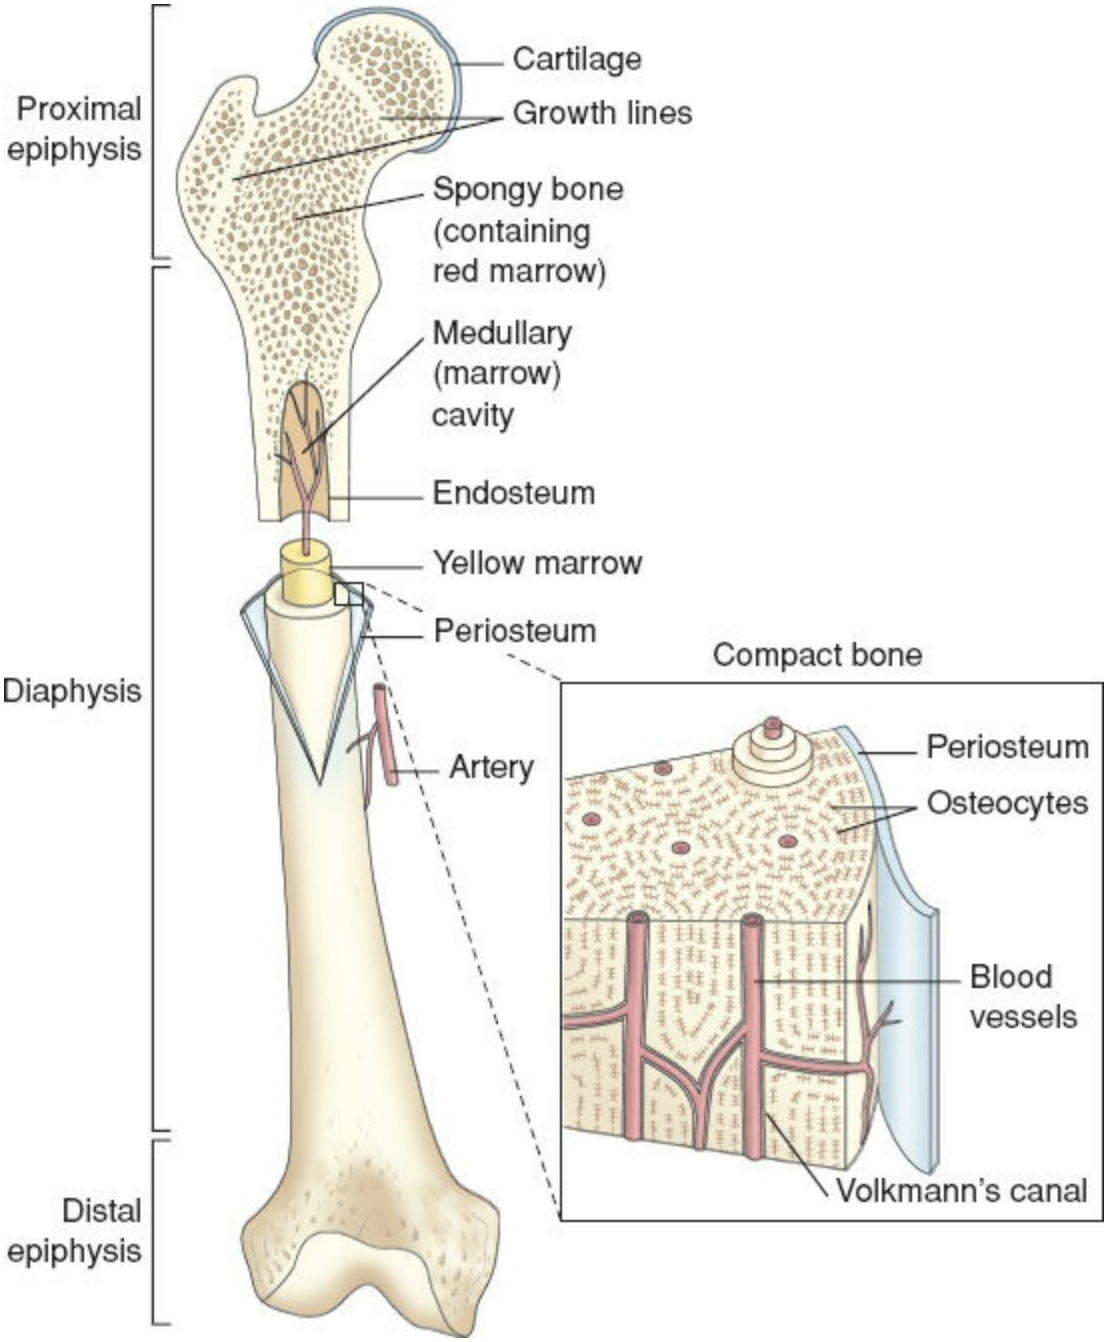

FIGURE 40-1 Structure of a long bone; composition of compact bone.

There are 206 bones in the human body, divided into four categories:

- Long bones (e.g., femur)
- Short bones (e.g., metacarpals)
- Flat bones (e.g., sternum)
- Irregular bones (e.g., vertebrae)

Long bones are shaped like rods or shafts with rounded ends (Fig. 40-1). The shaft, known as the diaphysis, is primarily cortical bone. The ends of the long bones, called epiphyses, are primarily cancellous bone. The epiphyseal plate separates the epiphyses from the diaphysis and is the center for longitudinal growth in children, thus it can be a critical

indicator of potential growth problems if fractured in children. It is calcified in adults. The ends of long bones are covered at the joints by articular cartilage, which is tough, elastic, avascular tissue. Long bones are designed for weight bearing and movement. Short bones consist of cancellous bone covered by a layer of compact bone. Flat bones are important sites of hematopoiesis and frequently provide protection for vital organs. They are made of cancellous bone layered between compact bone. Irregular bones have unique shapes related to their function. An example of irregular shaped bones is the vertebrae.

Bone is composed of three basic cell types—osteoblasts, osteocytes, and osteoclasts. Osteoblasts function in bone formation by secreting bone matrix. The term *blast* refers to immature or precursor cell, thus it is foundational for bone formation (Grossman & Porth, 2014). The matrix consists of collagen and ground substances (glycoproteins and proteoglycans) that provide a framework in which inorganic mineral salts are deposited. These minerals are composed primarily of calcium and phosphorus. Osteocytes are mature bone cells involved in bone maintenance. Osteoclasts are multinuclear cells involved in dissolving and resorbing bone. The microscopic functioning unit of mature cortical bone is the osteon (Haversian system). The center of the osteon, the Haversian canal, contains blood vessels and nerve supply for the osteon. Around the canal are circles of mineralized bone matrix called lamellae. The lamellae follow along the shaft of the long bone to nourish the osteon. Covering the bone is a dense, fibrous membrane known as the periosteum. This membranous structure nourishes bone and facilitates its growth. The periosteum contains nerves, blood vessels, and lymphatics. It also provides for the attachment of tendons, which connect muscles to bones, and ligaments, which connect bones to bones. The endosteum is a thin, vascular membrane that covers the marrow cavity of long bones and the spaces in cancellous bone.

Bone marrow is a vascular tissue located in the medullary (shaft) cavity of long bones and in flat bones. Red bone marrow, located mainly in the sternum, ilium, vertebrae, and ribs in adults, is responsible for producing RBCs, WBCs, and platelets. In adults, the long bone is filled with fatty, yellow marrow.

Bone tissue is well vascularized. Cancellous bone receives a rich blood supply through metaphyseal and epiphyseal vessels. Periosteal vessels carry blood to compact bone through minute openings called *Volkmann canals.* In addition, nutrient arteries penetrate the periosteum and enter the medullary cavity through foramina (small openings). Nutrient arteries supply blood to the marrow and bone. The venous system may accompany arteries or may exit independently.

Bone Formation

Osteogenesis (bone formation) begins long before birth. Ossification is the process by which the bone matrix (collagen fibers and ground substance) is formed and hard mineral crystals composed of calcium and phosphorus (e.g., hydroxyapatite) are bound to the collagen fibers. The mineral components of the bone give it its characteristic strength, whereas the proteinaceous collagen gives bone its resilience.

Bone Maintenance

Bone is a dynamic tissue in a constant state of turnover. During childhood, bones grow and form by a process called *modeling.* By early adulthood (i.e., early 20s), remodeling is the

primary process that occurs. Remodeling maintains bone structure and function through simultaneous resorption (removal/destruction of tissue) and osteogenesis (bone formation). The balance between bone resorption and formation is influenced by physical activity; dietary intake of certain nutrients, especially calcium; and several hormones, including calcitriol (i.e., active vitamin D), parathyroid hormone (PTH), calcitonin, thyroid hormone, cortisol, growth hormone, and the sex hormones estrogen and testosterone. Physical activity, particularly weight-bearing activity, stimulates bone formation and remodeling. Bones subjected to continued weight bearing tend to be thick and strong. Conversely, people who are unable to engage in regular weight-bearing activities, such as those on prolonged bed rest or those with disabilities, have increased bone resorption from calcium loss, and their bones become osteopenic and weak. These weakened bones may fracture easily.

Nursing Alert

It is important to note that after 30 to 45 years of age, the resorption of bone exceeds bone formation. This imbalance is exaggerated in women after menopause, which increases the risk of osteoporosis-related fractures (Kasper et al., 2015).

Good dietary habits are integral to bone health. In particular, absorption of daily calcium, approximately 1,200 mg for adults and 1,500 mg for postmenopausal women, is essential to maintaining adult bone mass. This may be achieved through ingesting calcium-rich foods on a daily basis (e.g., through drinking 16 to 24 oz of milk daily) (Box 40-1).

Several hormones are vital in ensuring that calcium is absorbed properly and available for bone mineralization and matrix formation. Biologically active vitamin D (calcitriol) functions to increase the amount of calcium in the blood by promoting absorption of calcium from the gastrointestinal tract. It also facilitates mineralization of osteoid tissue. A deficiency of vitamin D results in bone mineralization deficit, deformity, and fracture.

PTH and calcitonin are the major hormonal regulators of calcium homeostasis. PTH is one of the important regulators of the concentration of calcium and phosphate in the blood. PTH promotes movement of calcium and phosphorus from the bone into the extracellular fluid. In response to low calcium levels in the blood, levels of PTH increase, promoting the mobilization of calcium from the bone, conservation of calcium by the kidney, enhanced intestinal absorption of calcium, and reduction of phosphate levels. Conversely, calcitonin, which is secreted by the thyroid gland, lowers blood calcium levels. Calcitonin is excreted in response to elevated blood calcium levels. It inhibits bone resorption (the breakdown of bone), reduces the renal resorption of calcium and phosphate, and increases the deposit of calcium in bone (Grossman & Porth, 2014).

BOX 40-1

Nutrition Alert

Bone Health

Calcium is important for bone health. Sources of calcium include:

- Milk, yogurt, and cheese
- Rhubarb, cooked collard greens, Chinese cabbage, kale, and broccoli
- Sardines, oysters, clams, canned salmon with bones
- Tofu
- Calcium-fortified fruit juices, fruit drinks, and cereals

Both thyroid hormone and cortisol have multiple systemic effects with specific effects on bones. Excessive production of thyroid hormone in adults (e.g., Graves disease) can result in increased bone resorption over new bone formation, leading to net bone loss. Increased levels of cortisol have these same effects. Patients receiving long-term synthetic cortisol or corticosteroids (i.e., prednisone) are at increased risk for steroid-induced osteopenia and fractures.

Growth hormone has direct and indirect effects on skeletal growth and remodeling. It indirectly stimulates the liver and, to a lesser degree, the bones to produce insulin-like growth factor-1 (IGF-I), which accelerates bone modeling in children and adolescents. Growth hormone also directly stimulates skeletal growth in children and adolescents. It is believed that the low levels of both growth hormone and IGF-I that occur with aging may be partly responsible for decreased bone formation and resultant osteopenia.

The sex hormones testosterone and estrogen have important effects on bone remodeling. Estrogen stimulates osteoblasts and inhibits osteoclasts; therefore, bone formation is enhanced and resorption is inhibited. Low levels of estrogen or increased levels of corticosteroids cause disruption in normal osteoclast and osteoblast homeostasis. Testosterone has both direct and indirect effects on bone growth and formation. It directly causes skeletal growth in adolescence and has continued effects on skeletal muscle growth throughout the lifespan. Increased muscle mass results in greater weight-bearing stress on bones, resulting in increased bone formation. In addition, testosterone converts to estrogen in adipose tissue, providing an additional source of bone-preserving estrogen for aging men.

Blood supply to the bone also affects bone formation. With diminished blood supply or hyperemia (congestion), osteogenesis and bone density decrease. Bone necrosis occurs when the bone is deprived of blood.

Bone Healing

When a bone is fractured, the bone regenerates itself.

Although the exact process of fracture healing is open to controversy, stages of bone healing are identified below (Grossman & Porth, 2014).

1. *Hematoma formation:* The body responds to a fracture by bleeding into the injured tissue and forming a fracture hematoma. The fragmented ends of the fracture become devitalized because of the interrupted blood supply. This hematoma facilitates the formation of fibrin, which will become the framework upon which new bone will grow. The injured area is invaded by macrophages (large phagocytic WBCs), which débride the area. Inflammatory cells that migrate to the injured area release growth factors that stimulate osteoclast and osteoblast activity. Inflammation, swelling, and pain are present.

The inflammatory stage lasts several days and resolves with a decrease in pain and swelling.

2. *Inflammatory phase:* New capillaries infiltrate the hematoma, and fibroblasts (cells that produce collagen, the major protein of bone) from the periosteum, endosteum, and bone marrow produce a bridge between the fractured bones. This bridge made of tissue not yet ossified—termed a soft tissue callus—establishes a connection between the bone fragment and will, in time, become bone. Under the influence of signaling molecules, cell proliferation and differentiation occur.
3. *Reparative phase:* Chondrocytes (cartilage cells) in the cartilage callus form matrix vesicles, which regulate calcification of the cartilage. Enzymes within these matrix vesicles prepare the cartilage for calcium release and deposit. The calcified cartilage, referred to as *bony callus*, is invaded by blood vessels and becomes resorbed by chondroblasts and osteoclasts. It is replaced by woven bone similar to that of the growth plate.
4. *Remodeling:* Minerals continue to be deposited until the bone is firmly reunited. With major adult long bone fractures, ossification (the making of bone) takes 3 to 4 months. The final stage of fracture repair consists of remodeling the new bone into its former structural arrangement. Remodeling may take months to years, depending on the extent of bone modification needed, the function of the bone, and the functional stresses on the bone. Cancellous bone heals and remodels more rapidly than does compact cortical bone.

Serial x-rays are used to monitor the progress of bone healing. The rate of fracture healing is influenced by the type of bone fractured, the adequacy of blood supply, the surface contact of the fragments, and the age and general health of the person. Adequate immobilization is essential until there is x-ray evidence of bone formation with ossification.

When fractures are treated with open rigid compression plate fixation techniques, the bony fragments can be placed in direct contact. Primary bone healing occurs through cortical bone (Haversian) remodeling. Little or no cartilaginous callus develops. Immature bone develops from the endosteum. There is an intensive regeneration of new osteons, which develop in the fracture line by a process similar to normal bone maintenance. Fracture strength is obtained when the new osteons have become established.

Structure and Function of the Articular System

The junction of two or more bones is called a joint (articulation). There are three basic kinds of joints: synarthrosis, amphiarthrosis, and diarthrosis joints. Synarthrosis joints are immovable (e.g., the skull sutures). Amphiarthrosis joints (e.g., the vertebral joints and the symphysis pubis) allow limited motion; the bones of amphiarthrosis joints are joined by fibrous cartilage. Diarthrosis joints are freely movable joints.

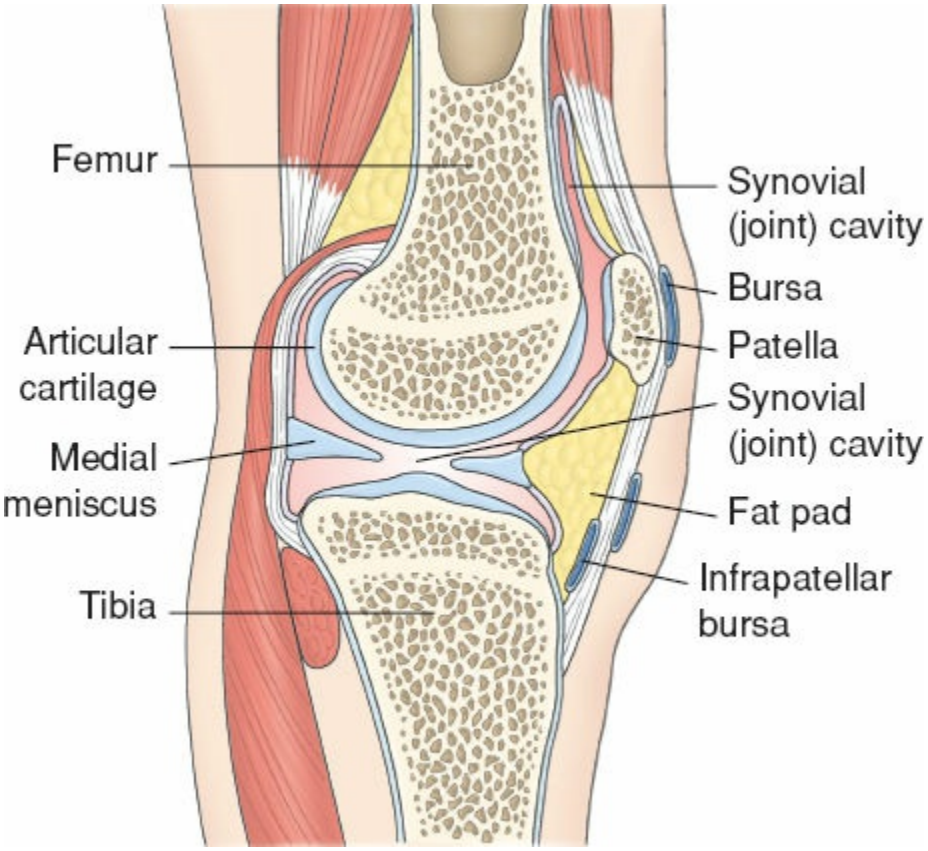

FIGURE 40-2 Hinge joint of the knee.

There are several types of diarthrosis joints:

- *Ball-and-socket* joints (e.g., the hip and the shoulder) permit full freedom of movement.
- *Hinge* joints permit bending in one direction only (e.g., the elbow and the knee) (Fig. 40-2).
- *Saddle* joints allow movement in two planes at right angles to each other. The joint at the base of the thumb is a saddle joint.
- *Pivot* joints are characterized by the articulation between the radius and the ulna. They permit rotation for such activities as turning a doorknob.
- *Gliding* joints allow for limited movement in all directions and are represented by the joints of the carpal bones in the wrist.

The ends of the articulating bones of a typical movable joint are covered with smooth

hyaline cartilage. A tough, fibrous sheath called the joint capsule surrounds the articulating bones. The capsule is lined with a membrane, the synovium, which secretes the lubricating and shock-absorbing synovial fluid into the joint capsule. Therefore, the bone surfaces are not in direct contact. In some synovial joints (e.g., the knee), fibrocartilage disks (e.g., medial meniscus) are located between the articular cartilage surfaces. These disks provide shock absorption.

Ligaments (fibrous connective tissue bands) bind the articulating bones together. Ligaments and muscle tendons, which pass over the joint, provide joint stability. In some joints, intracapsular ligaments (e.g., the cruciate ligaments of the knee) are found within the capsule and add stability to the joint.

A bursa is a thin-walled sac lined with synovial fluid that facilitates the movement of tendons and muscles over bony prominences. Bursae are found at the elbow, shoulder, knee, and some other joints.

Structure and Function of the Skeletal Muscle System

Tendons (cords of fibrous connective tissue) or aponeuroses (broad, flat sheets of connective tissue) attach muscles to bones, connective tissue, other muscles, soft tissue, or skin. The muscles of the body are composed of parallel groups of muscle cells (fasciculi) encased in fibrous tissue called fascia (or epimysium). The more fasciculi contained in a muscle, the more precise the movements. Muscles vary in shape and size according to the activities for which they are responsible. Skeletal (striated) muscles are involved in body movement, posture, and heat-production functions. Muscles contract to bring the two points of attachment closer together, resulting in movement.

Muscle Tone

The contraction of muscle fibers can result in either isotonic or isometric contraction of the muscle. In isometric contraction, the length of the muscles remains constant but the force generated by the muscles is increased; an example of this is pushing against an immovable wall. Isotonic contraction, on the other hand, is characterized by shortening of the muscle with no increase in tension within the muscle; an example of this is flexing the forearm. In normal activities, many muscle movements are a combination of isometric and isotonic contraction.

Relaxed muscles demonstrate a state of readiness to respond to contraction stimuli. This state of readiness, known as muscle tone (tonus), is produced by the maintenance of some of the muscle fibers in a contracted state. Muscle spindles, which are sense organs in the muscles, monitor muscle tone. Muscle tone is minimal during sleep and is increased when the person is anxious. A muscle that is limp and without tone is described as flaccid; a muscle with greater-than-normal tone is described as spastic. In conditions characterized by destruction of lower motor neurons (e.g., polio), denervated muscle becomes atonic (soft and flabby) and atrophies.

Muscle Actionsy

Muscles accomplish movement by contraction. Through the coordination of muscle groups, the body is able to perform a wide variety of movements (Fig. 40-3). The prime mover is the muscle that causes a particular motion. The muscles assisting the prime mover are known as *synergists.* The muscles causing movement opposite to that of the prime mover are known as *antagonists.* An antagonist must relax to allow the prime mover to contract, producing motion. For example, when contraction of the biceps causes flexion of the elbow joint, the biceps are the prime movers, and the triceps are the antagonists. A person with muscle paralysis (a loss of movement, possibly from nerve damage) may be able to retrain functioning muscles within the synergistic group to produce the needed movement. Muscles of the synergistic group then become the prime movers.

Exercise, Disuse, and Repair

Muscles need to be exercised to maintain function and strength. When a muscle repeatedly develops maximum or close to maximum tension over a long time, as in regular exercise with weights, the cross-sectional area of the muscle increases. This enlargement, known as hypertrophy, results from an increase in the size of individual muscle fibers without an increase in their number. Hypertrophy persists only if the exercise is continued. The opposite phenomenon occurs with disuse of muscle over a long period of time. Age and disuse cause loss of muscular function as fibrotic tissue replaces the contractile muscle tissue. The decrease in the size of a muscle is called atrophy. Bed rest and immobility cause loss of muscle mass and strength. When immobility is the result of a treatment modality (e.g., casting, traction), the patient can decrease the effects of immobility by performing isometric exercise of the muscles of the immobilized part.

Gerontologic Considerations

Multiple changes in the musculoskeletal system occur with aging (Table 40-1). Bone mass usually peaks between 18 and 25 years of age (National Osteoporosis Foundation, 2016), after which there is a universal gradual loss of bone. There is also a decrease in muscle mass and strength and an actual loss in the size and number of muscle fibers due to myofibril atrophy with fibrous tissue replacement. Numerous metabolic changes, including menopausal withdrawal of estrogen and decreased activity, contribute to osteoporosis. As a result, women lose more bone mass than men and are at higher risk for fractures. In the elderly, the articular cartilage degenerates in weight-bearing areas and heals less readily. Ultimately, ligaments become weak, and this contributes to the development of osteoarthritis (degenerative joint disease). Decrease in muscle mass, pain, and decrease in range of motion (ROM) can cause functional impairment in the elderly. Decreased activity, diminished neuron stimulation, and nutritional deficiencies also contribute to loss of muscle strength. In addition, remote musculoskeletal problems for which the patient has compensated may become new problems with age-related changes. For example, people who have had polio and who have been able to function normally by using synergistic muscle groups may discover increasing incapacity because of a reduced compensatory ability. However, many of the effects of aging can be slowed if the body is kept healthy and active through positive lifestyle behaviors.

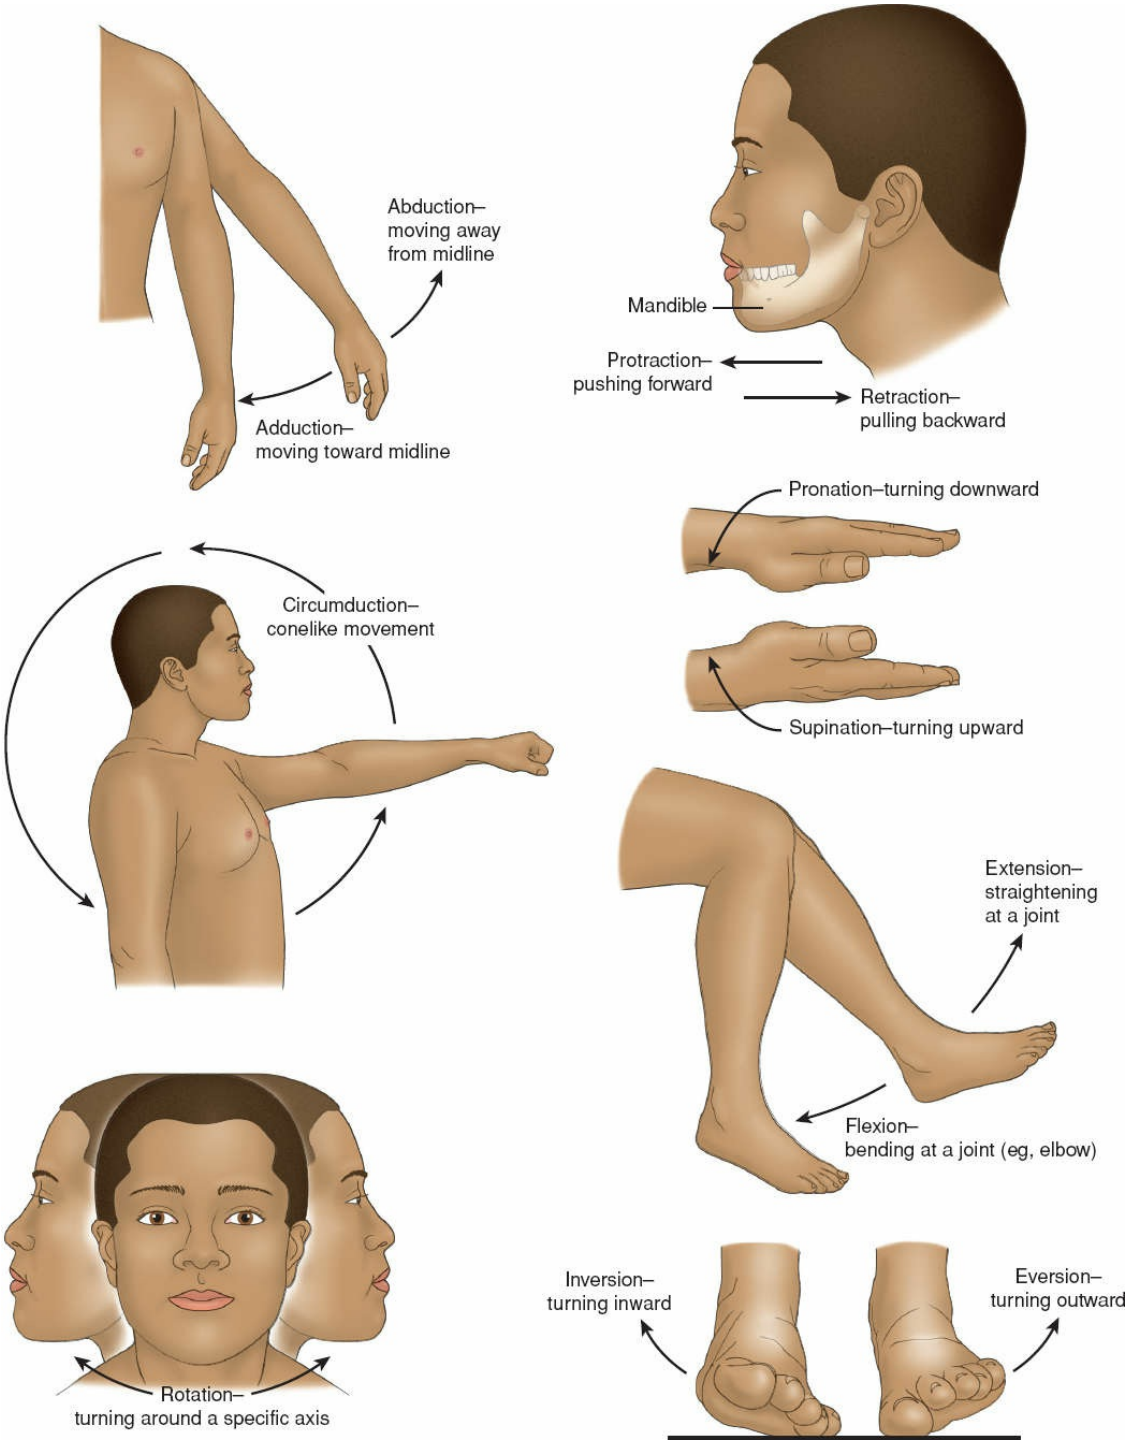

FIGURE 40-3 Body movements produced by muscle contraction.

TABLE 40-1 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes of the Musculoskeletal System

Musculoskeletal System	Structural Changes	Functional Changes	History and Physical Findings
Bones	Gradual, progressive loss of bone mass after 30 years of age Vertebrae collapse; Decreased osteoblastic activity (reduced production of new bone)	Bones fragile and prone to fracture: vertebrae, hip, wrist	Loss of height Posture changes Kyphosis Loss of flexibility Flexion of hips and knees Back pain Osteoporosis Fracture
Muscles	Increase in collagen and resultant fibrosis Muscles diminish in size (atrophy); wasting Tendons less elastic	Loss of strength and flexibility Weakness Fatigue Stumbling Falls	Loss of strength Diminished agility Decreased endurance Prolonged response time (diminished reaction time) Diminished tone Wide based gait History of falls
Joints	Cartilage shows progressive deterioration Thinning of intervertebral discs	Stiffness, reduced flexibility, and pain interfere with activities of daily living	Diminished range of motion Stiffness Loss of height
Ligaments	Lax ligaments (less than normal strength; weakness)	Postural joint abnormality Weakness	Joint pain on motion; resolves with rest Crepitus Joint swelling/enlargement Osteoarthritis (degenerative joint disease)

ASSESSMENT

The nursing assessment of the patient with musculoskeletal dysfunction includes an evaluation of the effects of the musculoskeletal problem on the patient. The nurse is concerned with assisting patients who have musculoskeletal problems to maintain their general health, accomplish their activities of daily living, and manage their treatment programs. The nurse encourages optimal nutrition and teaches the patient strategies to minimize problems related to mobility. Through an individualized plan of nursing care, the nurse helps the patient achieve maximum health.

Health History

Common Complaints

Common musculoskeletal complaints include pain or tenderness and altered sensations.

Pain

Most patients with diseases and traumatic conditions or disorders of the muscles, bones, and joints experience pain. Bone pain is characteristically described as a dull, deep ache that is "boring" in nature, whereas muscular pain is described as soreness or aching and is referred to as "muscle cramps." Fracture pain is sharp and piercing and is relieved by immobilization. Sharp pain also may result from bone infection, with muscle spasm or pressure on a sensory nerve.

Pain that increases with activity may indicate joint sprain or muscle strain, whereas steadily increasing pain points to the progression of an infectious process (osteomyelitis), degenerative changes, a malignant tumor, or neurovascular complications. Radiating pain occurs in conditions in which pressure is exerted on a nerve root. Pain is variable, and its assessment and nursing management must be individualized. It is important that the patient's pain and discomfort be managed successfully. Not only is pain exhausting, but, if prolonged, it can force the patient to become increasingly preoccupied and dependent (see Chapter 7). The nurse notes body positioning and the influence of appliances, such as casts, traction, and surgical pins, when considering the patient's pain.

Altered Sensations

Frequently sensory disturbances are associated with musculoskeletal problems. The patient may describe paresthesias, which are burning, tingling sensations or numbness. Box 40-2 provides assessment questions related to altered sensation. These sensations may be caused by pressure on nerves or by circulatory impairment. Soft tissue swelling or direct trauma can impair function.

Past, Family, and Social History

When taking the history, the nurse assesses for past history pertinent to the musculoskeletal system (e.g., broken bones or any history of musculoskeletal diseases, such as rheumatoid arthritis). The nurse notes any history of family members who have had limitations that prevented them from performing functional activities. The nurse also assesses the patient's activity level. For example, does the patient do weight-bearing exercises on a regular basis? Is the patient involved in high-risk activities and sports that may put him or her at risk for injury? This may evolve into an opportunity for safety education, such as wearing a helmet when bicycle riding.

BOX 40-2 Assessing Altered Sensation

Questions that the nurse should ask regarding altered sensations include the following:

- Is the patient experiencing any abnormal sensations or numbness?

- If the abnormal sensation or feeling of numbness involves an extremity, how does this feeling compare to sensation in the unaffected extremity?
- When did the condition begin? Is it getting worse?
- Does the patient also have pain? (If the patient has pain, then the assessment for pain should include questions related to sensation, numbness, onset, duration, location, characteristics, aggravating factors, alleviating factors, etc. Refer to Chapter 7 for aspects of pain assessment.)
- If the affected part is an extremity, the nurse compares the overall appearance in relation to the unaffected extremity, noting size, shape, and symmetry.
- Can the patient move the affected part?
- What is the color of the part distal to the affected area? Is it pale? Dusky? Mottled? Cyanotic?
- Does rapid capillary refill occur? (The nurse can gently squeeze a nail until it blanches, and then release the pressure. The amount of time for the color under the nail to return to normal is noted. Color normally returns within 2 seconds. The return of color is evidence of capillary refill.)
- Is a pulse palpable distal to the affected area? If the affected area is an extremity, how does the pulse compare to that felt in the unaffected extremity?
- Is edema present? If so, is it pitting?
- Is any constrictive device or clothing causing nerve or vascular compression?

Physical Assessment

An examination of the musculoskeletal system ranges from a basic assessment of functional capabilities to sophisticated physical examination maneuvers that facilitate diagnosis of specific bone, muscle, and joint disorders. The extent of assessment depends on the patient's physical complaints, health history, and physical clues that warrant further exploration. The nursing assessment is primarily a functional evaluation, focusing on the patient's ability to perform activities of daily living.

Techniques of inspection and palpation are used to evaluate the patient's posture, gait, bone integrity, joint function, and muscle strength and size. In addition, assessing the skin and neurovascular status is an important part of a complete musculoskeletal assessment. When specific symptoms or physical findings of musculoskeletal dysfunction are apparent, the nurse carefully documents the examination findings and shares the information with the provider, who may decide that a more extensive examination and a diagnostic workup are necessary.

Special precautions must be taken when assessing a patient with a musculoskeletal injury (Box 40-3).

Posture

The normal curvature of the spine is convex through the thoracic portion and concave through the cervical and lumbar portions. Common deformities of the spine include kyphosis, an increased forward curvature of the thoracic spine; lordosis, an exaggerated curvature of the lumbar spine; and scoliosis, a lateral curving deviation of the spine (Fig. 40-4). Frequently kyphosis is seen in elderly patients with osteoporosis and in some patients with neuromuscular diseases. Scoliosis may be congenital, idiopathic (without an identifiable cause), or the result of damage to the paraspinal muscles, as in polio. Frequently lordosis is seen during pregnancy as the woman adjusts her posture in response to changes in her center of gravity.

Gait

Gait is assessed by having the patient walk away from the examiner for a short distance. The nurse observes the patient's gait for smoothness and rhythm. Any unsteadiness or irregular movements are considered abnormal. Limited joint motion may affect gait. In addition, a variety of neurologic conditions are associated with abnormal gaits, such as a spastic hemiparesis gait (stroke), steppage gait (lower motor neuron disease), and shuffling gait (Parkinson disease).

BOX 40-3 The Patient with Musculoskeletal Injury

Special precautions must be taken when assessing a patient who has sustained trauma. If there is injury to an extremity, it is important to assess for soft tissue trauma, deformity, and neurovascular status. If the patient might have a cervical spine injury and is wearing

a cervical collar, the collar must not be removed until the absence of spinal cord injury is confirmed by appropriate imaging studies. When the collar is removed, the cervical spine area is assessed gently for swelling, tenderness, deformity, and skin integrity. With pelvic trauma, injuries may occur to abdominal organs. The patient is assessed for abdominal pain, tenderness, hematomas, distention, and the presence or absence of femoral pulses. If blood is present at the urinary meatus, the nurse should suspect bladder and urethral injury, and the patient should not be catheterized. Instead, such findings should be reported immediately to the emergency department physician or the surgeon.

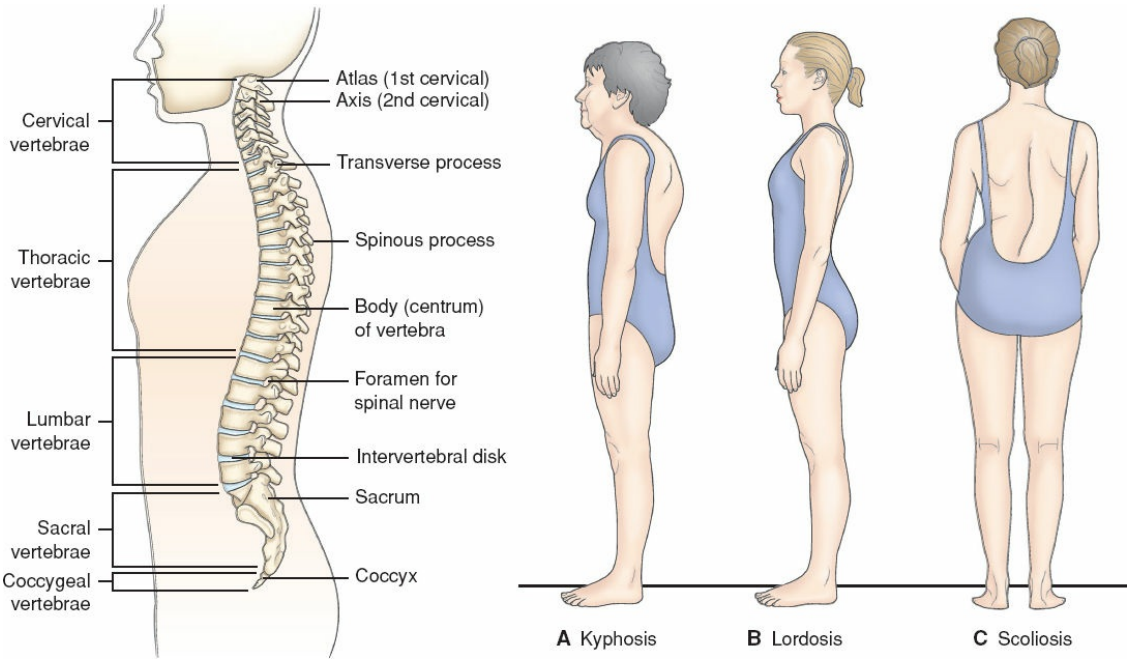

FIGURE 40-4 A normal spine and three abnormalities. A. Kyphosis: an increased convexity or roundness of the spine's thoracic curve. B. Lordosis: swayback; exaggeration of the curve of the lumbar spine. C. Scoliosis: a lateral curvature of the spine.

Bone Integrity

The bony skeleton is assessed for deformities, alignment, and symmetry. During the examination, body parts are compared from side to side. Shortened extremities, amputations, and body parts that are not in anatomic alignment are noted. Fracture findings may include abnormal angulation of long bones, motion at points other than joints, and crepitus (a grating sound) at the point of abnormal motion. Movement of fracture fragments must be minimized to avoid additional injury.

Joint Function

The articular system is evaluated by noting ROM, deformity, stability, and nodular formation. The tissues surrounding joints are examined for nodule formation, color changes, skin integrity, temperature, and injury. ROM is evaluated both actively (the joint is moved by the muscles surrounding the joint without assistance from the nurse) and

passively (the joint is moved by the examiner). The nurse needs to be familiar with the normal ROM of major joints. Limited ROM may be the result of skeletal deformity, joint pathology, or contracture (shortening of surrounding joint structures) of the surrounding muscles, tendons, and joint capsule. With contractures, there is a loss of full movement resulting from a fixed resistance caused either by tonic spasm of muscle (reversible) or by fibrosis of joint structures (permanent). In elderly patients, limitations of ROM associated with osteoarthritis may reduce their ability to perform activities of daily living.

If joint motion is compromised or the joint is painful, the joint is examined for effusion (excessive fluid within the capsule), swelling, and increased temperature that may reflect active inflammation. An effusion is suspected if the joint is swollen and the normal bony landmarks are obscured. The most common site for joint effusion is the knee. If inflammation or fluid is suspected in a joint, consultation with a provider is indicated.

Joint deformity may be caused by contracture, dislocation (complete separation of joint surfaces), subluxation (partial separation of articular surfaces), or disruption of structures surrounding the joint. Weakness or disruption of joint-supporting structures may result in a weak joint that requires an external supporting appliance (e.g., brace).

Palpation of the joint while it is moved passively provides information about the integrity of the joint. Normally, the joint moves smoothly. A snap or crack may indicate that a ligament is slipping over a bony prominence. Slightly roughened surfaces, as in arthritic conditions, result in crepitus (grating, crackling sound, or sensation) as the irregular joint surfaces move across one another.

FIGURE 40-5 A patient with rheumatoid arthritis with involvement of the metacarpophalangeal joints. Note the severe ulnar drift of the fingers. (From Koopman, W. J., & Moreland, L. W. (2005). *Arthritis and allied conditions: A textbook of rheumatology* (15th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Nodule formation is associated with rheumatoid arthritis (Fig. 40-5), gout, and

osteoarthritis. While the subcutaneous nodules of rheumatoid arthritis are soft and occur within and along tendons, the nodules of gout are hard and lie within and immediately adjacent to the joint capsule itself. Osteoarthritic nodules are hard and painless and represent bony overgrowth that has resulted from destruction of the cartilaginous surface of bone within the joint capsule. They are seen frequently in older adults (refer to Chapter 39 for additional details).

Muscle Strength and Size

The muscular system is assessed by noting muscular strength and coordination, the size of individual muscles, and the patient's ability to change position. Weakness of a group of muscles might indicate a variety of conditions. By palpating the muscle while passively moving the relaxed extremity, the nurse can determine the muscle tone. The nurse assesses muscle strength by having the patient perform certain maneuvers with and without added resistance (Table 40-2). For example, when the biceps are tested, the patient is asked to extend the arm fully and then to flex it against resistance applied by the nurse. A simple handshake may provide an indication of grasp strength.

TABLE 40-2 Muscle Strength

Grade	Strength	Physical Findings
0	None	No contraction
1	Trace	Palpable contraction only
2	Poor	Moves joint without gravity
3	Fair	Moves joint against gravity
4	Good	Moves against gravity and resistance
5	Normal	Normal strength

From Staheli, L. T. (2016). *Fundamentals of pediatric orthopedics* (5 ed.). Staheli, Inc.

The nurse may elicit muscle clonus (rhythmic contractions of a muscle) in the ankle or wrist by sudden, forceful, sustained dorsiflexion of the foot or extension of the wrist. Fasciculation (involuntary twitching of muscle fiber groups) may be observed (Fig. 40-6).

The nurse measures the girth of an extremity to monitor increased size due to exercise, edema, or bleeding into the muscle. Girth may decrease due to muscle atrophy. The unaffected extremity is measured and used as the reference standard for the affected extremity. Measurements are taken at the maximum circumference of the extremity. It is important that the measurements be taken at the same location on the extremity, and with the extremity in the same position, with the muscle at rest. Distance from a specific

anatomic landmark (e.g., 10 cm below the tibial tuberosity for measurement of the calf muscle) should be indicated in the patient's record so that subsequent measurements can be made at the same point. For ease of serial assessment, the nurse may indicate the point of measurement by marking the skin. Unilateral calf swelling that is more than 3 cm larger than the opposite limb is a clinical variable associated with deep vein thrombosis (DVT) (Kasper et al., 2015).

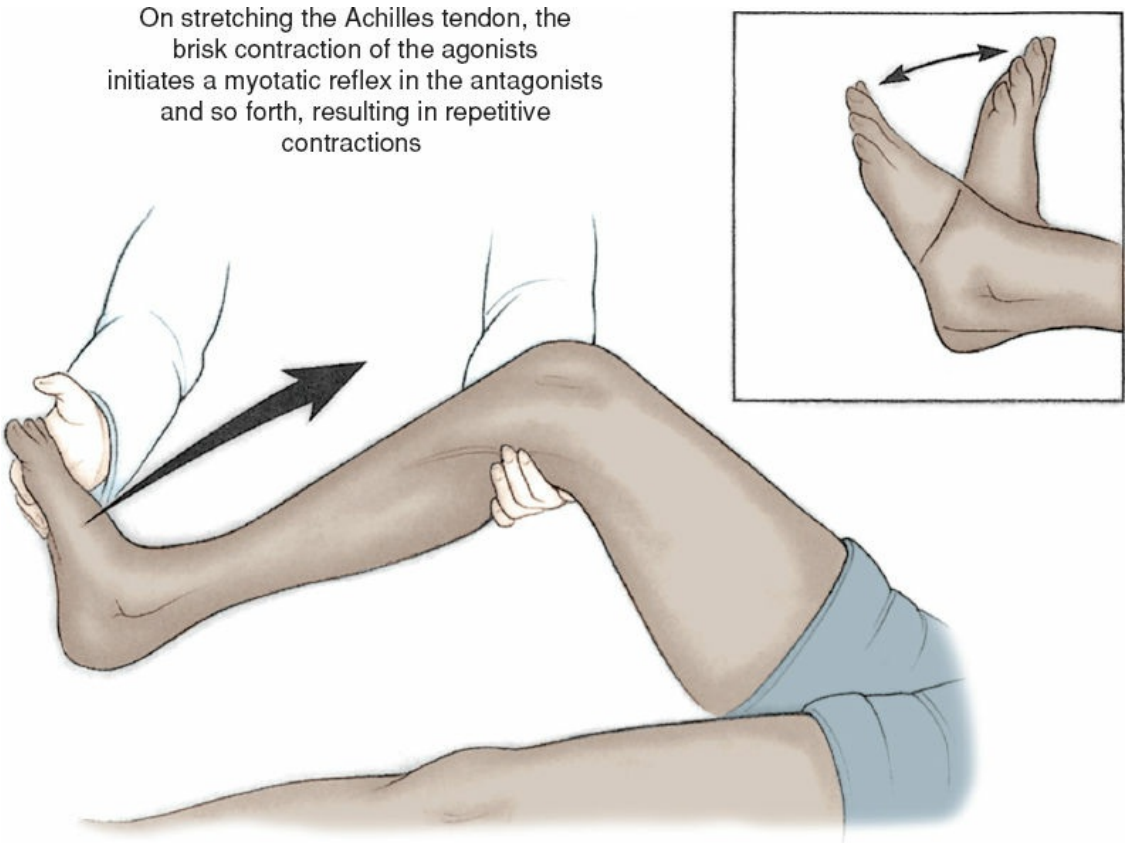

FIGURE 40-6 Clonus. (From Young, P. A., Young, P. H., & Tolbert, D. L. (2015). *Basic clinical neuroscience* (3rd ed.). Philadelphia, PA: Wolters Kluwer.)

Skin

In addition to assessing the musculoskeletal system, the nurse inspects the skin for edema, temperature, and color. Palpation of the skin can reveal whether any areas are warmer, suggesting increased perfusion or inflammation, whereas cooler skin suggests decreased perfusion or the presence of edema. Cuts, bruises, skin color, and evidence of decreased circulation or inflammation can influence nursing management of musculoskeletal conditions.

Neurovascular Status

It is important for the nurse to perform frequent neurovascular assessments of patients with musculoskeletal disorders (especially of those with fractures) because of the risk for tissue and nerve damage. Table 40-3 summarizes peripheral vascular assessment. One complication that the nurse needs to be alert for when assessing the patient is *compartment syndrome*, which is described in detail later in this unit. This major neurovascular problem

is caused by pressure within a muscle compartment that increases to such an extent that microcirculation diminishes, leading to nerve and muscle anoxia and necrosis. Function can be lost permanently if the anoxic situation continues for longer than 6 hours. Assessment of neurovascular status is frequently referred to as assessment of CSM (circulation, sensation, and movement). Symptoms of neurovascular dysfunction are discussed in Box 40-4.

Diagnostic Evaluation

During the period of assessment, the patient requires support and nursing care, including physical and psychological preparation for examinations and tests. Patient education before the tests (what is to be done; why it is being done; what the patient can expect to experience, including tactile, visual, and auditory sensations; and what patient participation is expected) reduces anxiety and enables the patient to be an active participant in care. The resulting medical diagnosis and prescribed treatment regimen affect the nursing management of the patient.

TABLE 40-3 Assessing for Peripheral Nerve Function

Assessment of peripheral nerve function has two key elements: evaluation of sensation and evaluation of motion. The nurse may perform one or all of the following during a musculoskeletal assessment.

Nerve	Test of Sensation	Test of Movement
Peroneal nerve	Stimulate the skin midway between the great and second toe. 	Ask the patient to dorsiflex the foot and extend the toes. 
Tibial nerve	Stimulate the medial and lateral surface of the sole. 	Ask the patient to plantar flex toes and foot. 
Radial nerve	Stimulate the skin midway between the thumb and second finger. 	Ask the patient to stretch out the thumb, then the wrist, and then the fingers at the metacarpal joints. 
Ulnar nerve	Stimulate the distal fat pad of the small finger. 	Ask the patient to abduct all fingers. 
Median nerve	Stimulate the top or distal surface of the index finger. 	Ask the patient to touch the thumb to the little finger. Also observe whether the patient can flex the wrist. 

BOX 40-4 Indicators of Peripheral Neurovascular Dysfunction

Circulation

- *Color:* Pale, cyanotic, or mottled
- *Temperature:* Cool
- *Capillary refill:* More than 2 seconds

Motion

- Weakness
- Paralysis

Sensation

- Paresthesia
- Unrelenting pain
- Pain on passive stretch
- Absence of feeling

Imaging Procedures

X-Ray Studies

X-ray studies are important in evaluating patients with musculoskeletal disorders. Bone x-rays determine bone density, texture, erosion, and changes in bone relationships. X-ray study of the cortex of the bone reveals any widening, narrowing, or signs of irregularity. Joint x-rays reveal fluid, irregularity, spur formation, narrowing, and changes in the joint structure. Multiple views are needed for full assessment of the structure being examined. Serial x-rays may be indicated to determine if healing of a fractured bone is progressing normally or to determine if a bone affected by disease is stable, deteriorating, or responding to prescribed therapy. After being positioned for the study, the patient must remain still while the x-rays are taken.

Computed Tomography

A computed tomography (CT) scan shows in detail a specific plane of involved bone and can reveal tumors of the soft tissue or injuries to the ligaments or tendons. It is used to identify the location and extent of fractures in areas that are difficult to evaluate (e.g., acetabulum). CT studies, which may be performed with or without the use of contrast agents, can last up to 1 hour. The patient must remain still during the procedure.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive imaging technique that uses magnetic fields, radiowaves, and computers to demonstrate abnormalities (i.e., tumors or narrowing of tissue pathways through bone) of soft tissues, such as muscle, tendon, cartilage, nerve,

and fat. Because an electromagnet is used, patients with any metal implants, clips, or pacemakers are not candidates for MRI.

Nursing Alert

Jewelry, hair clips, hearing aids, credit cards with magnetic strips, and other metal-containing objects must be removed from the patient before the MRI is performed; otherwise they can become dangerous projectile objects or cause burns. Credit cards with magnetic strips may be erased, and nonremovable cochlear devices can become inoperable. Also, transdermal patches that have a thin layer of aluminized backing must be removed before MRI because they can cause burns. The provider should be notified before the patches are removed.

To enhance visualization of anatomic structures, IV contrast agent may be used. During the MRI, the patient needs to lie still for 30 to 60 minutes and hears a rhythmic knocking sound. Patients who experience claustrophobia may be unable to tolerate the confinement of closed MRI equipment without sedation. Open MRI systems are available, but they use lower-intensity magnetic fields that reduce the quality of the imaging; thus, repeated imaging may be required. Advantages of open MRI include increased patient comfort, reduced problems with claustrophobic reactions, and reduced noise.

Arthrography

Arthrography is useful in identifying acute or chronic tears of the joint capsule or supporting ligaments of the knee, shoulder, ankle, hip, or wrist. A radiopaque contrast agent is injected into the joint cavity to outline soft tissue structures and the contour of the joint. The joint is put through its ROM to distribute the contrast agent, and then an MRI is obtained. If a tear is present, the contrast agent leaks out of the joint and is evident on the MRI image.

After an arthrogram, a compression elastic bandage is applied as prescribed and usually the joint is rested for 12 hours. The nurse provides additional comfort measures (mild analgesia, ice) as appropriate. The nurse explains to the patient that it is normal to experience clicking or crackling in the joint for a day or two after the procedure, until the contrast agent or air is absorbed.

Nursing Alert

If contrast agents will be used for CT scan, MRI, or arthrography, the nurse carefully assesses the patient for possible allergy. This includes previous experience with contrast studies and past reactions. In addition, the nurse is aware that risk factors for adverse reactions include a history of asthma, allergies, diabetes, renal insufficiency, and cardiac disease. Finally, the nurse assesses risk of pregnancy before decisions are made regarding the use of contrast materials.

Bone Densitometry

Bone densitometry is used to estimate bone mineral density (BMD). This can be performed through the use of x-rays or ultrasound. Most commonly, dual-energy x-ray absorptiometry

(DEXA) is done. This determines BMD at the wrist, hip, or spine to estimate the extent of osteoporosis and to monitor a patient's response to treatment for osteoporosis. In particular, hip BMD is recommended as an osteoporosis screening for all Caucasian women older than 65 years of age and for other people at increased risk for osteoporosis-related fractures (Grossman & Porth, 2014). See Chapter 41 for a further discussion of osteoporosis risks.

Concept Mastery Alert

BMD is used in diagnosing osteoporosis. Bone scans are used to detect metastatic and primary bone tumors, osteomyelitis, certain fractures, and aseptic necrosis, but not osteoporosis.

Bone Scan

A bone scan is performed to detect metastatic and primary bone tumors, osteomyelitis, certain fractures, and aseptic necrosis. A bone-seeking radioisotope is injected IV. The scan is performed 1 to 3 hours after the injection. At this point, distribution and concentration of the isotope in the bone are measured. The degree of nuclide uptake is related to the metabolism of the bone. An increased uptake of isotope is seen in primary skeletal disease (osteosarcoma), metastatic bone disease, inflammatory skeletal disease (osteomyelitis), and certain types of fractures.

Before the patient undergoes an imaging study, the nurse assesses for conditions that may require special consideration during the study or that may be contraindications to the study (e.g., pregnancy; claustrophobia; inability to tolerate required positioning due to age, debility, or disability; metal implants). If contrast agents will be used for CT scan, MRI, bone scan, or arthrography, the nurse carefully assesses the patient for possible allergy (see previous Nursing Alert).

Arthroscopy

Arthroscopy is a procedure that allows direct visualization of a joint to diagnose joint disorders. Treatment of tears, defects, and disease processes may be performed through the arthroscope. The procedure is performed in the operating room under sterile conditions; injection of a local anesthetic into the joint or general anesthesia is used. A large-bore needle is inserted, and the joint is distended with saline. The arthroscope is introduced, allowing for visualization of the joint structures, synovium, and articular surfaces. After the procedure, the puncture wound is closed with adhesive strips or sutures and covered with a sterile dressing. Complications are rare but may include infection, hemarthrosis (bleeding into the joint cavity), neurovascular compromise, thrombophlebitis, stiffness, effusion, adhesions, and delayed wound healing.

The joint is wrapped with a compression dressing to control swelling. In addition, ice may be applied to control edema and discomfort. Frequently, the joint is kept extended and elevated to reduce swelling. It is important to monitor neurovascular status. The nurse administers prescribed analgesics to control discomfort. The nurse explains when the patient can resume activity and what weight-bearing limits to follow, as prescribed by the orthopedic surgeon. The nurse also explains to the patient and family the symptoms (e.g.,

swelling, numbness, cool skin) to observe for in order to determine whether complications are occurring and the importance of notifying the surgeon of these observations. The nurse's verbal instructions are reinforced with written instructions before discharge. Finally, the nurse explains the surgeon's prescription for analgesic medication.

Other Studies

Arthrocentesis

Arthrocentesis (joint aspiration) is carried out to obtain synovial fluid for purposes of examination or to relieve pain due to effusion. Examination of synovial fluid is helpful in the diagnosis of septic arthritis and other inflammatory arthropathies (any joint disease) and reveals the presence of hemarthrosis (bleeding into the joint space), which suggests trauma or a bleeding disorder. Normally, synovial fluid is clear, pale, straw-colored, and scanty in volume. Using aseptic technique, the provider inserts a needle into the joint and aspirates fluid. Anti-inflammatory medications, such as cortisone, may be injected into the joint. A sterile dressing is applied after aspiration. There is a small risk of infection after this procedure.

Electromyography

Electromyography (EMG) provides information about the electrical potential of the muscles and the nerves leading to them. Needle electrodes are inserted into selected muscles, and responses to electrical stimuli are recorded on an oscilloscope. The test is performed to evaluate the electrical potential generated by muscle cells when they are activated. The results can be analyzed to detect medical abnormalities, such as muscle weakness, pain, and disability. The procedure helps to determine any abnormality of function and to differentiate muscle and nerve problems.

Biopsy

Biopsy may be performed to determine the structure and composition of bone marrow, bone, muscle, or synovium to help diagnose specific diseases. The nurse prepares the patient by providing teaching about the procedure and assuring the patient that analgesic agents will be provided. The nurse monitors the biopsy site for edema, bleeding, and infection (fever, erythema, swelling, drainage, and tenderness at site) and asks the patient about their perception of pain. Ice is applied as prescribed to control bleeding and edema. In addition, analgesics are administered as prescribed for comfort.

TABLE 40-4 Blood Chemistry Studies Related to Musculoskeletal Conditions

Blood Chemistry	Musculoskeletal Conditions
Altered serum calcium levels	Osteomalacia, parathyroid dysfunction, Paget disease, metastatic bone tumors, or prolonged immobilization
Serum phosphorus inversely related to calcium levels	Diminished in osteomalacia associated with malabsorption syndrome
Acid phosphatase	Elevated in Paget disease and metastatic cancer
Alkaline phosphatase	Elevated during early fracture healing and in diseases with increased osteoblastic activity (e.g., metastatic bone tumors)
Creatine kinase and aspartate	Elevated with muscle damage
Elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)	Inflammation, infection, autoimmune disorders, neoplasia, pregnancy, renal insufficiency, advanced age, and hyperlipidemia
Elevated uric acid	Gout, nephrolithiasis
Serum myoglobin	Elevated with muscle trauma
Serum osteocalcin (bone GLA protein)	Indicated rate of bone turnover
Calcitonin levels	Bone metabolism
Parathormone	Bone metabolism
Vitamin D levels	Bone metabolism
Urine calcium levels	Increased with bone destruction (e.g., parathyroid dysfunction, metastatic bone tumors, multiple myeloma)

Laboratory Studies

Examination of the patient's blood and urine can provide information about a primary musculoskeletal problem (e.g., Paget disease), a developing complication (e.g., infection), the baseline for instituting therapy (e.g., anticoagulant therapy), or the response to therapy. The complete blood count includes the hemoglobin level (which is frequently lower after bleeding associated with trauma and surgery) and the WBC count (which is elevated with any inflammatory condition, including acute infections, trauma, acute hemorrhage, and tissue necrosis). Before surgery, coagulation studies are performed to detect bleeding tendencies (because bone is very vascular tissue).

Blood chemistry studies provide data about a wide variety of musculoskeletal conditions; see Table 40-4.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 62-year-old Caucasian woman presents to the family practice clinic where you are the nurse manager for her annual wellness examination. She asks you if she should have "a type of bone scan" because her younger sister recently had a hip fracture. What recommendations might be made for appropriate testing in this patient?

2. You are teaching a class at a senior center on age-associated changes in the musculoskeletal system. What age-related changes do you anticipate finding in this population?

NCLEX-Style Review Questions

1. A 78-year-old woman is complaining of neck and upper back pain. The nurse's assessment reveals an abnormal convex curvature of the cervical and thoracic area. What is the terminology for this finding?
   a. Kyphosis
   b. Lordosis
   c. Kyphoscoliosis
   d. Scoliosis

2. A 12-year-old girl complained to the school nurse about back pain. The nurse's assessment revealed a deviation of the vertebrae to the right, with a raised shoulder and hip. What is the terminology for this finding?
   a. Kyphosis
   b. Lordosis
   c. Osteoporosis
   d. Scoliosis

3. A cast was applied to a patient's fractured leg 4 hours ago. Which finding is associated with neurovascular compromise?
   a. Capillary refill of 5 seconds
   b. Ability to move the toes without limitation
   c. Full sensation
   d. Toes warm to touch

4. What food would the nurse recommend for bone health?
   a. Herbal tea
   b. Yogurt
   c. Liver
   d. Eggs

5. An MRI has been ordered for a patient with low back pain. What should be included in the teaching plan for this patient?
   a. The patient will need to lie still for 3 to 4 hours.
   b. A rhythmic rocking sound will be heard during the procedure.
   c. There is no risk of claustrophobia.
   d. It is an invasive technique.

CHAPTER 41

Nursing Management: Patients with Musculoskeletal Disorders

Geriann B. Gallagher

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the rehabilitation and health education needs of the patient with low back pain.
2. Describe common conditions and nursing care of the upper and lower extremities
3. Explain the pathophysiology, pathogenesis, prevention, and management of osteoporosis.
4. Describe management of the patient with Paget disease.
5. Use the nursing process as a framework for care of the patient with osteomyelitis.
6. Describe medical and nursing management as well as potential complications to be encountered in the patient with a bone tumor.

Musculoskeletal disorders carry a heavy economic and health burden. The financial cost of musculoskeletal disorders in the United States was 7.4% of the nation's gross domestic product when analyzing available data from 2004 to 2006 (McPhail, Schippers, & Marshall, 2014). Adding to this burden is the personal, functional, and psychological limitations imposed on the patient. Musculoskeletal disorders are increased in patients with insufficient physical activity. Negative outcomes associated with a sedentary lifestyle include heart disease, diabetes, and depression. Increasing physical activity, which can vary according to the patient's functional level, can improve cardiovascular and respiratory status, reduce the severity of existing health problems, and reduce the impact of physical decline and falls. Nurses must be aware of the clinical manifestations and management of these disorders.

ACUTE LOW BACK PAIN

Low back pain, one of the most common reasons for a visit to a provider, is primarily caused by one of many musculoskeletal problems, including acute lumbosacral strain, unstable lumbosacral ligaments and weak muscles, osteoarthritis of the spine, spinal stenosis, intervertebral disk problems, and unequal leg length.

Older patients may experience back pain associated with osteoporotic vertebral fractures or bone metastasis. Other causes include kidney disorders, pelvic problems, retroperitoneal tumors, and abdominal aortic aneurysms.

In addition, obesity, stress, and, occasionally, depression may contribute to low back pain. Back pain due to musculoskeletal disorders usually is aggravated by activity, whereas pain due to other conditions is not.

Pathophysiology

The spinal column can be considered an elastic rod constructed of rigid units (vertebrae) and flexible units (intervertebral disks) held together by complex facet joints, multiple ligaments, and paravertebral muscles. Its unique construction allows for flexibility while providing maximum protection for the spinal cord. The abdominal and thoracic muscles help to stabilize the spine and are important in lifting activities, working together to minimize stress on the spinal units. Disuse weakens these supporting muscular structures. Obesity, postural problems, structural problems, and overstretching of the spinal supports may result in back pain.

The intervertebral disks change in character as a person ages. A young person's disks are mainly fibrocartilage with a gelatinous matrix. As a person ages, the fibrocartilage becomes dense and irregularly shaped. Disk degeneration is a common cause of back pain. The lower lumbar disks, L4 to L5 and L5 to S1, are subject to the greatest mechanical stress and the greatest degenerative changes. Disk protrusion (herniated nucleus pulposus) or facet joint changes can cause pressure on nerve roots as they leave the spinal canal, which results in pain that radiates along the nerve.

Clinical Manifestations and Assessment

The initial evaluation of acute low back pain (lasting less than 3 months) includes a focused history and physical examination, including general observation of the patient, back examination, and neurologic testing (reflexes, sensory impairment, straight-leg raising, muscle strength, and assessment of muscle atrophy). Signs and symptoms relate to the corresponding dermatome (see Fig. 43-13) or myotome (the group of muscles served by motor neurons of a spinal cord segment). Pressure on the nerve roots or spinal cord will cause symptoms, such as abnormal or painful sensations (paresthesias or dysesthesias), loss of sensation, weakness, and autonomic dysfunction (most commonly bladder or bowel incontinence) (Barbano, 2016). Pain may be felt directly along the spine itself or may be referred (e.g., aortic aneurysm may present with back pain), or the patient may report pain radiating down the leg, which is known as radiculopathy or sciatica (pain from irritation of the sciatic nerve, classically felt from the low back to behind the thigh and radiating down below the knee). The presence of this symptom suggests nerve root involvement. The patient's gait, spinal mobility, reflexes, leg length, leg motor strength, and sensory perception may be affected. Careful examination of both sides will cue the nurse into subtle differences. Physical examination may disclose paravertebral muscle spasm (greatly increased muscle tone of the back postural muscles) with a loss of the normal lumbar curve and possible spinal deformity. The findings suggest either nonspecific back symptoms or potentially serious problems, such as sciatica, spine fracture, cancer, infection, or a rapidly progressing neurologic deficit. If the initial examination does not suggest a serious condition, no additional testing is performed during the first 4 weeks of symptoms.

The diagnostic procedures described in Box 41-1 may be indicated for the patient with potentially serious or prolonged low back pain. The nurse prepares the patient for these studies, provides the necessary support during the testing period, and monitors the patient for any adverse responses to the procedures.

BOX 41-1 Diagnostic Procedures for Low Back Pain

X-ray of the spine: May demonstrate a fracture, dislocation, infection, osteoarthritis, or scoliosis

Bone scan and blood studies: May disclose infections, tumors, and abnormalities in bone marrow

Computed tomography (CT): Useful in identifying underlying problems, such as obscure soft tissue lesions adjacent to the vertebral column and problems of vertebral disks

Magnetic resonance imaging (MRI): Permits visualization of the nature and location of spinal pathology

Electromyogram (EMG) and nerve conduction studies: Used to evaluate disorders of the spinal nerve root (radiculopathies)

Medical and Nursing Management

Management focuses on relief of pain and discomfort, activity modification, use of back-conserving techniques of body mechanics, improved self-esteem, and weight reduction. Most back pain is self-limited and resolves within 4 weeks with analgesics, rest, stress reduction, and relaxation.

Relieving Pain

To relieve pain, the nurse encourages the patient to reduce stress on the back muscles and to change position frequently. The patient is taught to control and modify the perceived pain through behavioral therapies that reduce muscular and psychological tension. Diaphragmatic breathing and relaxation help reduce muscle tension contributing to low back pain. Diverting the patient's attention from the pain to another activity (e.g., reading, conversation, watching television) may be helpful in some instances. Guided imagery, in which the relaxed patient learns to focus on a pleasant event, may be used along with other pain-relief strategies.

If medication is prescribed, the nurse assesses the patient's response to each medication. As the acute pain subsides, medication dosages are reduced as prescribed. Usually nonprescription analgesics are effective in achieving pain relief. At times, a patient may require the addition of muscle relaxants or opioids. Often heat or cold therapy is used and frequently provides temporary relief of symptoms; further study of the effectiveness of heat or cold modalities is needed (Moss et al., 2014). In the absence of symptoms of disease (radiculopathy of the roots of spinal nerves), spinal manipulation performed by a chiropractor or an osteopath may be helpful. Acupuncture, massage, biofeedback, and yoga are other modalities the patient may find to be therapeutic. There is no convincing researched evidence that these modalities are beneficial; however, there is anecdotal evidence that many patients benefit from alternative modalities. Each patient's plan of care should be individualized, and then the nurse evaluates and notes the patient's response to various pain management modalities.

Improving Physical Mobility

Physical mobility is monitored through continuing assessments. The nurse assesses how the patient moves and stands. As the back pain subsides, self-care activities are resumed with minimal strain on the injured structures. Position changes should be made slowly and carried out with assistance as required. The patient should avoid twisting and jarring motions. The nurse encourages the patient to alternate lying, sitting, and walking activities frequently and advises the patient to avoid sitting, standing, or walking for long periods. The patient may find that sitting in a chair with arm rests to support some of the body weight and a soft support at the small of the back provides comfort.

With severe pain, the nurse instructs the patient to limit activities for 1 to 2 days (Barbano, 2016). Extended periods of inactivity are not effective and result in deconditioning. An international campaign (the Victorian WorkCover Authority in Australia), called "Back Pain: Don't take it lying down," is an example of stressing the importance of continued mobility in patients with back pain. Lumbar flexion is increased

by elevating the head and thorax 30 degrees using pillows or a foam wedge as well as another pillow to allow the patient to flex the knees slightly. Alternatively, the patient can assume a lateral position with knees and hips flexed (curled position) with a pillow between the knees and legs and a pillow supporting the head. A prone position should be avoided because it accentuates lordosis (inward curvature of the spine). The nurse instructs the patient to get out of bed by rolling to one side and placing the legs down while pushing the torso up, keeping the back straight.

As the patient achieves comfort, activities are resumed gradually, and an exercise program is initiated. Initially, low-stress aerobic exercises, such as short walks or swimming, are suggested. After 2 weeks, conditioning exercises for the abdominal and trunk muscles are started. The physical therapist designs an exercise program for the individual patient to reduce lordosis, increase flexibility, and reduce strain on the back. Exercise begins gradually and increases as the patient recovers.

The nurse encourages the patient to adhere to the prescribed exercise program. Erratic exercising is ineffective. Some patients may find it difficult to adhere to a program of prescribed exercises for a long period. These patients are encouraged to improve their posture, use good body mechanics on a regular basis, and engage in regular exercise activities (e.g., walking, swimming) to maintain a healthy back. Activities should not cause excessive lumbar strain, twisting, or discomfort; for example, activities such as horseback riding, basketball, and weight-lifting should be avoided. If there is no improvement within 1 month, additional assessments for physiologic abnormalities are performed. Management is based on findings.

Using Proper Body Mechanics

Good body mechanics and posture are essential to avoid recurrence of back pain. The patient must be taught how to stand, sit, lie, and lift properly. Providing the patient with a list of suggestions helps in making these long-term changes (Box 41-2). If the patient wears high heels, the nurse encourages changing to low heels with good arch support. The patient who is required to stand for long periods should shift weight frequently and should rest one foot on a low stool, which decreases lumbar lordosis. Patients who stand in place for a long period of time (e.g., cashiers) should stand on a foot cushion made of foam or rubber. The proper posture can be verified by looking in a mirror to see whether the chest is up, the abdomen is tucked in, and the shoulders are down and relaxed (Fig. 41-1). The patient should avoid locking the knees when standing and bending forward for long periods.

BOX 41-2 Health Promotion

Activities to Promote a Healthy Back

Standing

Advise the patient to adhere to the following guidelines:

- Avoid prolonged standing and walking.
- When standing for any length of time, rest one foot on a small stool or box to relieve lumbar lordosis.
- Avoid forward flexion work positions.

- Avoid high heels.

Sitting

Discuss the following strategies with the patient:

- Avoid sitting for prolonged periods.
- Sit in a straight-back chair with back well supported and arm rests to support some of the body weight; use a footstool to position knees higher than hips if necessary.
- Eradicate the hollow of the back by sitting with the buttocks "tucked under."
- Maintain back support; use a soft support at the small of the back.
- Avoid knee and hip extension. When driving a car, have the seat pushed forward as far as possible for comfort.
- Guard against extension strains—reaching, pushing, or sitting with legs straight out.
- Alternate periods of sitting with walking.

Lying

Encourage the patient to do the following:

- Rest at intervals; fatigue contributes to spasm of the back muscles.
- Place a firm bed board under the mattress.
- Avoid sleeping in a prone position.
- When lying on the side, place a pillow under the head and one between the legs, with the legs flexed at the hips and knees.
- When supine, use a pillow under the knees to decrease lordosis.

Lifting

Emphasize the importance of the following strategies:

- When lifting, keep the back straight and hold the load as close to the body as possible.
- Lift with the large leg muscles, not the back muscles.
- Use trunk muscles to stabilize the spine.
- Squat while keeping the back straight when it is necessary to pick up something off the floor.
- Avoid twisting the trunk of the body, lifting above waist level, and reaching up for any length of time.

Exercising

Daily exercise is important in the prevention of back problems.

- Walk daily, and gradually increase the distance and pace of walking.
- Perform prescribed back exercises twice daily, increasing exercise gradually.
- Avoid jumping and jarring activities.

When the patient is sitting, the knees and hips should be flexed, and the knees should be level with the hips or higher to minimize lordosis. The feet should be flat on the floor. The back needs to be supported, so the patient should avoid sitting on stools or chairs that do

not provide firm back support.

The nurse instructs the patient in the safe and correct way to lift objects—using the strong quadriceps muscles of the thighs, with minimal use of weak back muscles. With feet placed hip-width apart to provide a wide base of support, the patient should bend the knees, tighten the abdominal muscles, and lift the object close to the body with a smooth motion, avoiding twisting and jarring motions (Fig. 41-2). It takes about 6 months for a person to readjust postural habits. Practicing these protective and defensive postures, positions, and body mechanics results in natural strengthening of the back and diminishes the chance that back pain will recur.

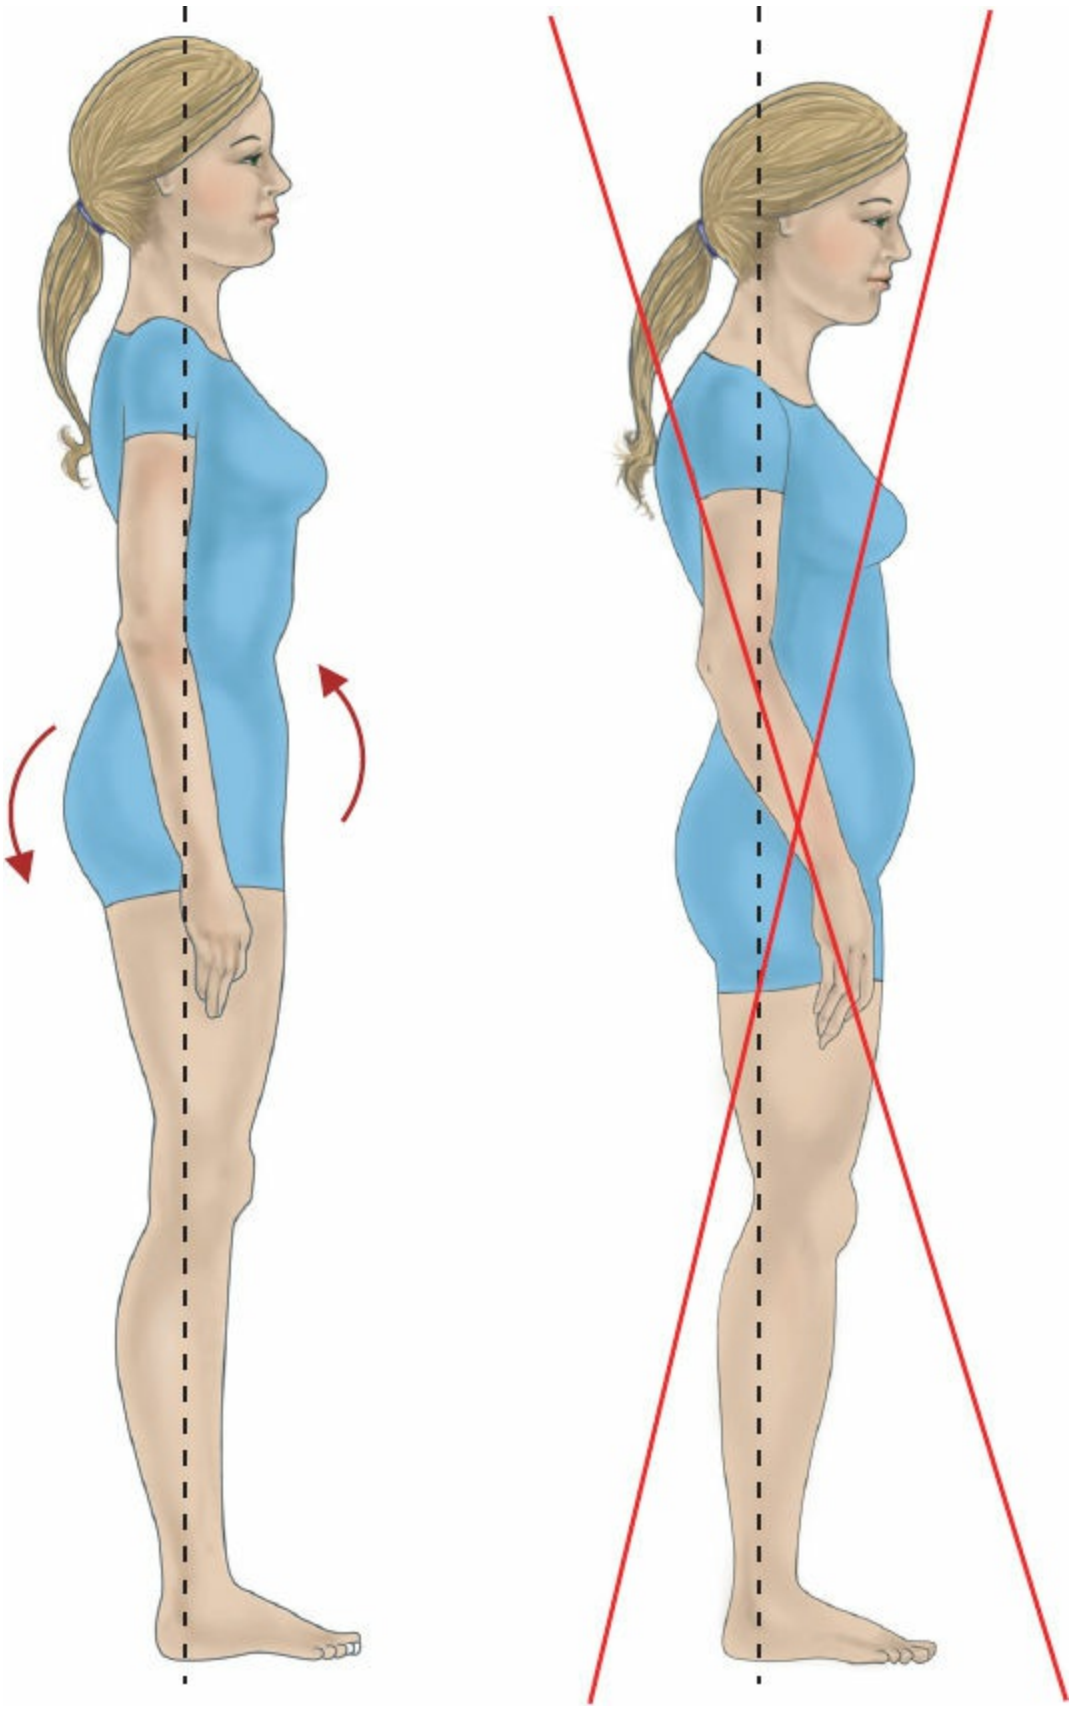

FIGURE 41-1 Proper and improper standing postures. (*Left*) Abdominal muscles contracted, giving a feeling of upward pull, and gluteal muscles contracted, giving a downward pull. (*Right*) Slouch position, showing abdominal muscles relaxed and body out of proper alignment.

FIGURE 41-2 Proper and improper lifting techniques. (*Left*) Correct position for lifting. This person is using the long and strong muscles of the arms and legs and holding the object so that the line of gravity falls within the base of support. (*Right*) Incorrect position for lifting because pull is exerted on the back muscles and leaning causes the line of gravity to fall outside the base.

Nursing Alert

Nurses, by virtue of their daily work, are a group at high risk for acute back injuries (e.g., transferring patients, repositioning patients in bed, lifting a patient in bed, making an occupied bed). The national problem with obesity (64% of US population is classified as overweight, and 30% classified as obese [McGinley & Bunke, 2008]), only compounds this risk. Use of "lift teams" or lift devices should be available to nursing staff as accompanied by ergonomic instruction on body mechanics principles as described above. Currently, 11 states have enacted "safe patient handling" laws or launched regulations that require health care facilities to provide proper equipment, education, and policies that promote worker health and safety (American Nurses' Association, 2016; Association of Safe Patient Handling Professionals [ASPHP], 2015). The nurse would do well to practice and use the postures described above.

Modifying Nutrition for Weight Reduction

Obesity contributes to back strain by stressing the relatively weak muscles of the back and abdomen. Exercises are less effective and more difficult to perform when the patient is overweight. Weight reduction through diet modification may prevent recurrence of back pain. Weight reduction is based on a sound nutritional plan that includes a change in eating habits to maintain desirable weight. Monitoring weight reduction, noting achievement, and providing encouragement and positive reinforcement facilitate adherence. Frequently, back problems resolve as optimal weight is achieved.

COMMON UPPER EXTREMITY PROBLEMS

The structures in the upper extremities are frequently the sites of painful syndromes. The structures affected most frequently are the shoulder, wrist, and hand.

Bursitis and Tendinitis

Bursitis and tendinitis are inflammatory conditions that commonly occur in the shoulder. Bursae are fluid-filled sacs that prevent friction between joint structures during joint activity. When inflamed, they are painful. Tendonitis is inflammation of a tendon. Tendons, which connect muscles to bone, are enclosed in sheaths. At points of friction, the sheath is double layered. The space between the two sheaths is filled with fluid similar to synovial fluid. Overuse of the tendon can result in inflammation and degeneration of the tendon (Grossman & Porth, 2014). Conservative treatment includes rest of the extremity, intermittent ice, heat, ultrasound to the joint, and nonsteroidal anti-inflammatory drugs (NSAIDs) to control the inflammation and pain. Corticosteroid injections may be considered. Stretching and strengthening exercises should be initiated after the acute phase. Further imaging or arthroscopic intervention may be considered if pain and weakness persist.

Impingement Syndrome

Impingement syndrome, or rotator cuff tendinitis, is caused by repeated overhead activity of the shoulder. When the arm is raised overhead, there is decreased space between the humeral head and acromion. The patient may feel a dull achy pain, limited movement, and muscle spasm. Complaints, such as difficulty in dressing oneself and night pain because of difficulty in positioning the shoulders, may be noted. The process may progress to rotator cuff disease (see Chapter 42). Conservative treatment includes rest; application of heat, cold, and ultrasound; NSAIDs; joint injections; and physical therapy (Box 41-3 discusses patient education). Arthroscopic débridement (a minimally invasive surgical procedure that permits evacuation of joint debris) is used for persistent pain. Gentle joint motion is begun after surgery.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is an entrapment neuropathy that occurs when the median nerve at the wrist is compressed by a thickened flexor tendon sheath, skeletal encroachment, edema, or a soft tissue mass. The syndrome is commonly caused by repetitive hand and wrist movements, but it also may be associated with arthritis, hypothyroidism, or pregnancy. Patients who perform repetitive movements or those whose hands are exposed repeatedly to cold temperatures, vibrations, or extreme direct pressure are at a greater risk for developing carpal tunnel syndrome. The patient experiences pain, numbness, paresthesia, and, possibly, weakness along the median nerve (thumb, index, and middle fingers). Phalen test or Tinel sign may be used to help identify carpal tunnel syndrome (Fig. 41-3). Night pain is common.

BOX 41-3 Patient Education

Measures to Promote Shoulder Healing of Impingement Syndrome

- Rest the joint in a position that minimizes stress on the joint structures, to prevent further damage and the development of adhesions.
- Support the affected arm on pillows while sleeping to keep from turning onto the shoulder.
- For the first 24–48 hours of the acute phase, apply cold to reduce swelling and discomfort; then, according to the treatment plan, apply heat intermittently to promote circulation and healing.
- Gradually resume motion and use of the joint. Assistance with dressing and other ADLs may be needed.
- Avoid working and lifting above shoulder level or pushing an object against a "locked" shoulder.
- Perform the prescribed daily ROM and strengthening exercises.

Treatment of carpal tunnel syndrome is based on the cause of the condition. Symptoms may be relieved by wrist splints to prevent hyperextension and prolonged flexion of the wrist, avoidance of repetitive flexion of the wrist (e.g., making ergonomic changes at work to reduce wrist strain), use of NSAIDs, and carpal canal cortisone injections. Specific yoga postures, relaxation, and acupuncture may be nontraditional alternatives to relieve carpal tunnel symptoms. In pregnancy, symptoms usually resolve spontaneously weeks after delivery (Ferri, 2016a).

If conservative treatment fails, surgical management options are traditional open nerve release or endoscopic laser surgery. Both of these procedures are performed under local anesthesia and involve making small incisions into the affected wrist and cutting the carpal ligament so that the carpal tunnel is widened. Smaller incisions are made with the endoscopic laser procedure, and there is less scar formation and a shorter recovery time than with the open method. Following either of these procedures, the patient wears a hand splint

and limits hand use during healing. The patient may need assistance with personal care and activities of daily living (ADLs). Full recovery of motor and sensory function may take several weeks or months after either type of nerve release surgery.

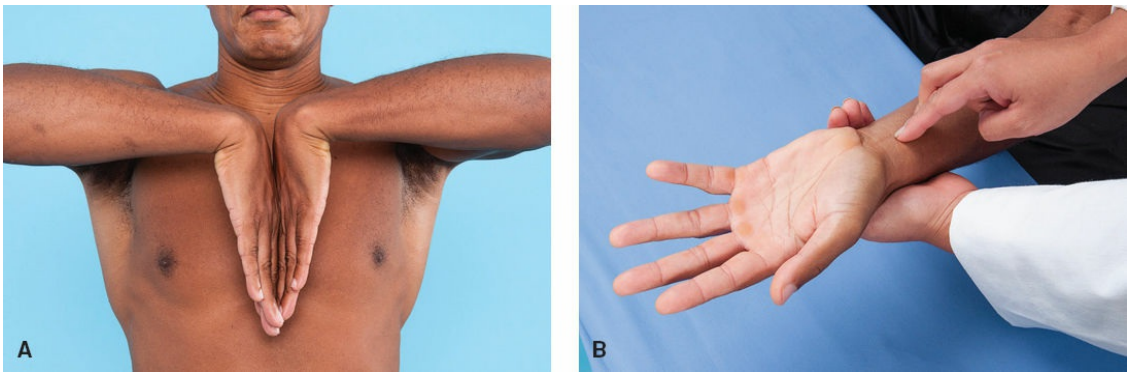

FIGURE 41-3 There are two ways to assess for carpal tunnel syndrome: Phalen test and Tinel sign. A. To perform Phalen test, have the patient hold the position shown for 60 seconds. B. To elicit Tinel sign in a patient, percuss lightly over the median nerve, located on the inner aspect of the wrist. If the patient reports tingling, numbness, and pain, the test for Phalen and Tinel sign is considered positive. (From Weber, J. W., & Kelley, J. (2014). *Health assessment in nursing* (5th ed.). Philadelphia, PA: Wolters Kluwer Health, Lippincott Williams & Wilkins.)

Ganglion

A ganglion, a collection of gelatinous material near the tendon sheaths and joints, appears as a round, firm, compressible, cystic swelling, usually on the dorsum of the wrist (60% to 70%). They may be caused by injury or repetitive activity. The ganglion may or may not be locally tender. The pain may be described as aching and can be aggravated by extreme flexion or extension. Ganglion cysts may occur in any age group, but they are found most commonly in people between 20 and 40 years of age. The incidence is greater in females than in males (Meena & Gupta, 2014). Asymptomatic ganglions are monitored, since approximately 50% will resolve without treatment. Other treatments may include aspiration, corticosteroid injection, or surgical excision. After treatment, a compression dressing and immobilization splint are used.

Dupuytren Disease

Dupuytren disease results in a slowly progressive contracture of the palmar fascia, called Dupuytren contracture, which causes flexion of the fourth and fifth fingers and, frequently, the middle finger (Fig. 41-4). This renders the fingers more or less useless. It is caused by an inherited autosomal dominant trait and occurs most frequently in men who are older than 50 years of age and who are of northern European descent. While strongly inheritable, it is also associated with drug therapy for epilepsy, diabetes, HIV infection, and alcoholism (Nunn & Schreuder, 2014). It starts as a nodule of the palmar fascia. The nodule may not change, or it may progress so that the fibrous thickening extends to involve the skin in the distal palm and produces a contracture of the fingers. The patient may experience dull aching discomfort, morning numbness, cramping, and stiffness in the affected fingers. The patient often seeks care because contracture of the fingers alters the function of the hand. This condition starts in one hand, but eventually both hands can be affected. Initially, finger-stretching exercises may prevent contractures. With contracture development, patients are referred to a hand specialist. Nonsurgical options of treatment include percutaneous needle fasciotomy (fascia is cut to relieve tension or pressure) and injection of collagenase into the palmer cord. The collagenase breaks down the fibrous thickening, and the patient returns to the surgeon for manipulation of the finger, resulting in increased function. Surgical options include palmar and digital fasciectomies. Finger and hand exercises are begun as prescribed on postoperative day 1 or 2.

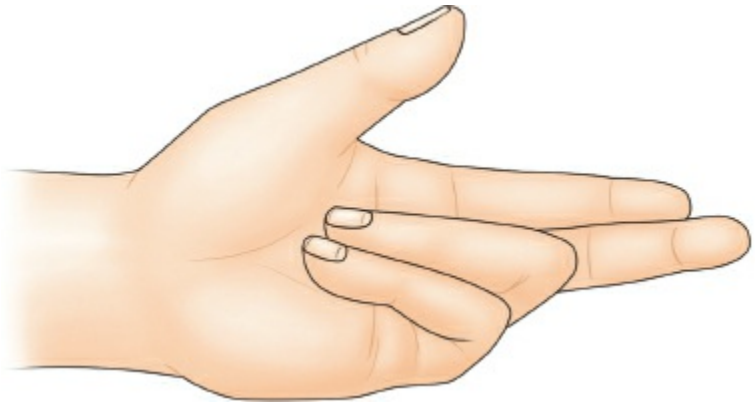

FIGURE 41-4 Dupuytren contracture, a flexion deformity caused by an inherited trait, is a slowly progressive contracture of the palmar fascia, which severely impairs the function of the fourth, fifth, and, sometimes, the middle finger.

Box 41-4 discusses nursing interventions for patients undergoing surgery for upper extremity problems.

COMMON FOOT PROBLEMS

Disorders of the foot are commonly caused by poorly fitting shoes, which distort normal anatomy while inducing deformity and pain.

BOX 41-4 Nursing Interventions for Patient Undergoing Surgery to Treat Upper and Lower Extremity Conditions

Promoting Tissue Perfusion

Neurovascular assessment of the exposed digits every 1–2 hours for the first 24 hours after surgery is essential to monitor the function of the nerves and the perfusion of the tissues. The nurse compares the affected extremity with the unaffected one and the postoperative status with the documented preoperative status. Perfusion is assessed by temperature, color, capillary refill, and grading of peripheral pulses. The nurse asks the patient to describe the sensations in the affected extremity and to demonstrate mobility of the involved area. With tendon repairs and nerve, vascular, or skin grafts, motor function is tested as necessary. Dressings provide support but are not constrictive. If the patient is discharged within several hours after the surgery, the nurse teaches the patient and family how to assess for edema and neurovascular status (circulation, sensation, motion). Compromised neurovascular function can increase the patient's pain.

Relieving Pain

Pain experienced by patients who undergo hand and foot surgery is related to inflammation and edema. Formation of a hematoma may contribute to the discomfort. To control the edema, the extremity should be elevated on several pillows when the patient is sitting or lying. When higher elevation is prescribed for an upper extremity, an elevating sling may be attached to an IV pole or to an overhead frame. If the patient is ambulatory, the affected arm is elevated in a conventional sling with the hand at heart level.

Ice packs applied intermittently to the surgical area during the first 24–48 hours may be prescribed to control edema and provide some pain relief. Dependent positioning of an extremity is uncomfortable, but simply elevating the extremity often relieves the discomfort. Oral analgesics may be used to control the pain. The nurse instructs the patient and family about appropriate use of these medications.

Activity

During the first few days after surgery, the patient may need assistance with ADLs, particularly following surgery of an upper extremity when one hand is bandaged and independent self-care is impaired. The patient may need to arrange for assistance with feeding, bathing and hygiene, dressing, grooming, and toileting. Within a few days, the patient develops skills in one-handed ADLs and is usually able to function with

minimal assistance and use of assistive devices. The nurse encourages use of the involved hand, unless contraindicated, within the limits of discomfort. As rehabilitation progresses, the patient resumes use of the injured hand. Physical or occupational therapy–directed exercises may be prescribed. The nurse emphasizes adherence to the therapeutic regimen.

After lower extremity surgery, the patient will have a bulky dressing on the foot, protected by a light cast or a special protective boot. Limits for weight-bearing on the foot will be prescribed by the surgeon. Some patients are allowed to walk on the heel and progress to weight-bearing as tolerated; other patients are restricted to non–weight-bearing activities. Assistive devices (e.g., crutches, walker) may be needed. The choice of the devices depends on the patient's general condition and balance and on the weight-bearing prescription. Safe use of the assistive devices must be ensured through adequate patient education and practice before discharge. Strategies to move around the house safely while using assistive devices are discussed with the patient. As healing progresses, the patient gradually resumes ambulation within prescribed limits. The nurse emphasizes adherence to the therapeutic regimen.

Preventing Infection

Any surgery carries a risk of infection. In addition, percutaneous pins may be used to hold bones in position, and these pins serve as potential sites for infection. Care must be taken to protect the surgical wound from dirt and moisture. When bathing, the patient can secure a plastic bag over the dressing to prevent it from getting wet. Patient instructions concerning aseptic wound care and pin care may be necessary. Refer to Chapter 42 for pin care.

The nurse teaches the patient to monitor for temperature changes and infection. Drainage on the dressing, a foul odor, or increased pain and swelling could indicate infection. The nurse instructs the patient to report any of these findings to the provider promptly. If prophylactic antibiotics are prescribed, the nurse provides instruction about their correct use.

Promoting Home and Community-Based Care

The nurse plans patient teaching for home care, focusing on neurovascular status, pain management, mobility, and wound care.

The nurse instructs the patient to report the following signs and symptoms, which indicate impaired circulation:

- Change in sensation
- Inability to move toes or fingers
- Digits or extremity cool to touch
- Color changes

The nurse also provides instructions for wound care, including:

- Keep the dressing or cast clean and dry.

- Report signs of wound infection (e.g., pain, drainage, fever) immediately.
- Follow the prescribed antibiotic regimen.
- Keep your appointment with the surgeon for the initial dressing change.

Several systemic diseases affect the feet. Patients with diabetes are prone to develop corns and peripheral neuropathies with diminished sensation, leading to ulcers at pressure points of the foot. Patients with peripheral vascular disease and arteriosclerosis can develop ulcers as a result of ischemia. Complaints of burning and itching feet can be seen, resulting in scratching and skin breakdown. Foot deformities may occur with rheumatoid arthritis. Dermatologic problems commonly affect the feet in the form of fungal infections and plantar warts.

The discomforts of foot strain are treated with rest, elevation, physiotherapy, and orthotic devices. The patient must inspect the foot and skin under pads and orthotic devices daily for pressure and skin breakdown. If a "window" is cut into shoes to relieve pressure over a bony deformity, the skin must be monitored daily for breakdown from pressure exerted at the window area. Active foot exercises promote circulation and help strengthen the feet. Walking in properly fitting shoes is considered the ideal exercise.

Plantar Fasciitis

Plantar fasciitis is an inflammation of the foot-supporting fascia. Often, patients experience severe heel pain with the first steps in the morning. The pain is localized to the anterior medial aspect of the heel and diminishes with gentle stretching of the foot and Achilles tendon. Management includes stretching exercises, wearing shoes with support, orthotic devices (e.g., heel cups, arch supports), weight loss for obese patients, and NSAIDs. In approximately 80% of patients, symptoms of plantar fasciitis will resolve in 12 months (Kasper et al., 2015). Unresolved plantar fasciitis may progress to fascial tears at the heel and eventual development of heel spurs.

Hallux Valgus

Hallux valgus (commonly called a bunion) is a deformity in which the great toe deviates laterally (Fig. 41-5A). Associated with this is a marked prominence of the medial aspect of the first metatarsophalangeal joint. There is also osseous enlargement (exostosis) of the medial side of the first metatarsal head, over which a bursa may form (secondary to pressure and inflammation). Acute bursitis symptoms include a reddened area, edema, and tenderness.

Factors contributing to bunion formation may include heredity, ill-fitting shoes, a loss of arch height, and gradual lengthening and widening of the foot associated with aging. Frequently osteoarthritis is associated with hallux valgus. Treatment depends on the patient's age, the degree of deformity, and the severity of symptoms. If a bunion deformity is uncomplicated, wearing a shoe that conforms to the shape of the foot or that is molded to the foot to prevent pressure on the protruding portions may be the only treatment needed. Corticosteroid injections control acute inflammation. Surgical removal of the bunion (exostosis) and osteotomies to realign the toe may be required to improve function and appearance. Complications related to bunionectomy include limited range of motion (ROM), paresthesias, tendon injury, and recurrence of deformity.

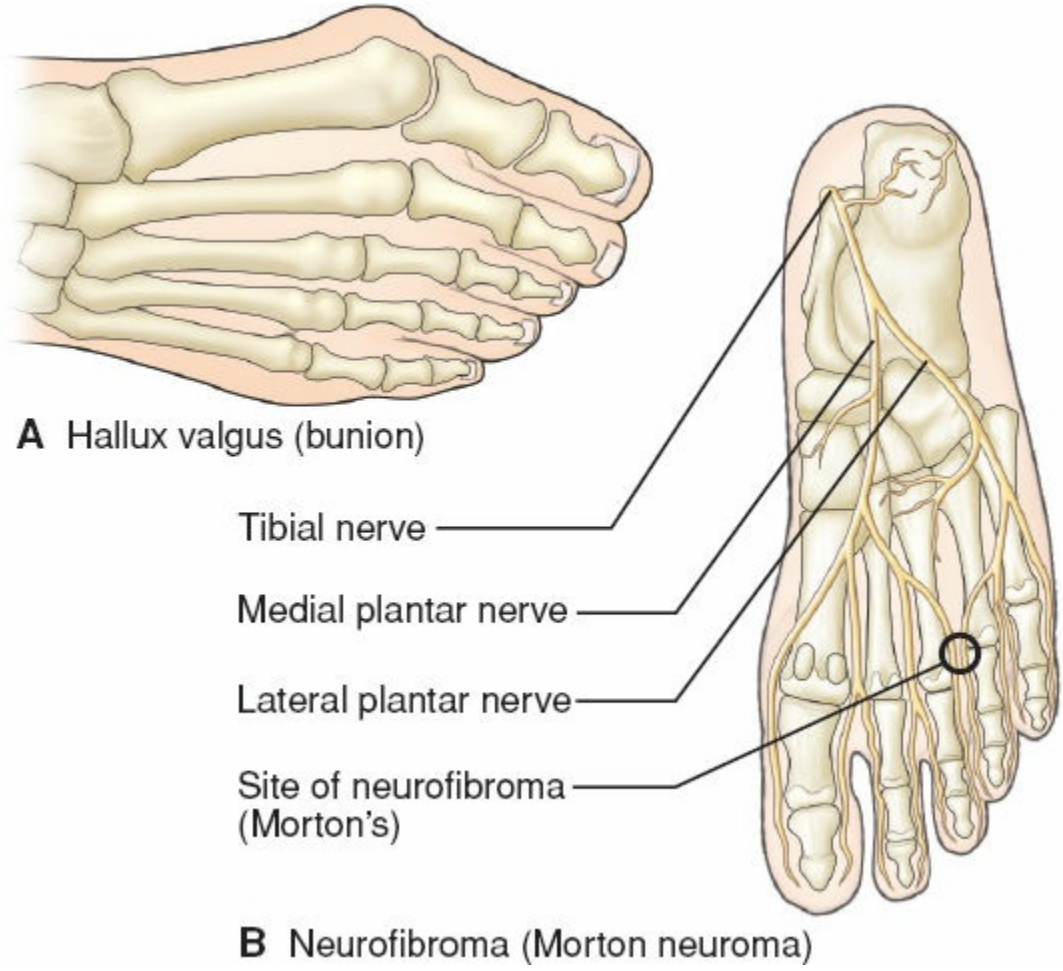

FIGURE 41-5 Common foot deformities.

Postoperatively, the patient may have intense throbbing pain at the operative site, requiring liberal doses of analgesic medication. The foot is elevated to the level of the heart to decrease edema and pain. The neurovascular status of the toes is assessed by noting temperature, color, sensation, movement, and capillary refill of the affected toes. The duration of immobility and initiation of ambulation depend on the procedure used. Toe flexion and extension exercises are initiated to facilitate walking. Shoes that fit the shape and size of the foot are recommended.

Morton Neuroma

Morton neuroma (plantar digital neuroma, neurofibroma) is a thickening of the tissues around the third (lateral) branch of the median plantar nerve (see Fig. 41-5B). The third digital nerve, which is located in the third intermetatarsal (web) space, is most commonly involved. Microscopically, digital artery changes cause an ischemia of the nerve.

The result is a throbbing, burning pain in the foot that is usually relieved when the patient rests. Conservative treatment consists of inserting innersoles and metatarsal pads designed to spread the metatarsal heads and balance the foot posture. Local injections of hydrocortisone and a local anesthetic may provide relief. If these fail, surgical excision of the neuroma is necessary. Pain relief and loss of sensation are immediate and permanent.

See Box 41-4 for interventions for patients undergoing surgery for foot problems.

METABOLIC BONE DISORDERS

Osteoporosis

Osteoporosis is a costly disorder, not only in terms of health care dollars but also in terms of human suffering, pain, disability, and death. It is estimated that 10 million Americans had osteoporosis in 2010, and without efforts, by 2030, that number will likely increase to over 13 million (National Osteoporosis Foundation [NOF], 2016). This includes approximately one in two women and two in five men. It is believed to be the underlying cause of 2 million fractures a year (NOF, 2016). Characteristics of osteoporosis include a reduction of bone density and a change in bone structure. The bones become progressively porous, brittle, and fragile; they fracture easily under stresses that would not break normal bone. Osteoporosis frequently results in compression fractures (Fig. 41-6) of the thoracic and lumbar spine, fractures of the neck and intertrochanteric region of the femur, and Colles fractures of the wrist (refer to Chapter 42). These fractures may be the first clinical manifestation of osteoporosis. Fracture risk increases with increasing age and is greatest in Caucasian women.

Pathophysiology

It is thought that 60% to 80% of a person's peak bone mass is genetically determined. Bone mineral density (BMD) in adults is determined by the magnitude of bone acquisition during adolescence and young adulthood coupled with the rate of bone loss that ensues thereafter. By the early to late 20s, peak bone mass is achieved in most people, but differences are seen in timing by skeletal site (e.g., 18 to 20 years of age for proximal femur, 25 to 30 years of age for spine). Typically, peak bone mass is achieved by the third decade, but after this age, rates of bone loss (0.3% to 0.5% per year from the third through fifth decades of life) are seen; the rate of bone resorption (the lysis or breakdown of bone) is greater than the rate of bone formation, resulting in a reduced total bone mass. As individuals age, mismatches in bone remodeling, due to reduced formation, increased resorption, or a combination of both, result in greater rates of bone loss (Weber, 2016).

Nursing Alert

Nurses are aware that bone density issues in later years are correlated to bone acquisition in younger years. It is important that nurses stress the need for bone health for children and young adults. Early identification of at-risk teenagers and young adults, increased calcium intake, participation in regular weight-bearing exercise, and modification of lifestyle (e.g., reduced use of caffeine, cigarettes, carbonated soft drinks, and alcohol) are interventions that decrease the risk of osteoporosis, fractures, and associated disability later in life.

FIGURE 41-6 Progressive osteoporotic bone loss and compression fractures. (From Rubin, E., Gorstein, F., Schwarting, R., et al. (2004). *Pathology* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

The withdrawal of estrogens at menopause or with oophorectomy causes an accelerated bone resorption that continues during the postmenopausal years. Women develop osteoporosis more frequently and more extensively than men because of lower peak bone mass and the effect of estrogen loss during menopause. Calcium metabolism is illustrated in Figure 41-7.

Secondary osteoporosis is associated with many disease states, nutritional deficiencies, and medications. Coexisting medical conditions, such as gastric bypass, malabsorption syndromes, lactose intolerance, malnutrition, alcohol abuse, kidney failure, liver failure, Cushing syndrome, hyperthyroidism, and hyperparathyroidism, contribute to bone loss and the development of osteoporosis. Medications, including corticosteroids, antiseizure medications, heparin, tetracycline, aluminum-containing antacids, and thyroid supplements, affect the body's use and metabolism of calcium. The degree of osteoporosis is related to the duration of medication therapy. When the therapy is discontinued or the metabolic problem is corrected, the progression of osteoporosis is halted, but restoration of lost bone mass usually does not occur. Specific disease states (e.g., celiac disease,

hypogonadism) and medications (e.g., corticosteroids, antiseizure medications) that place patients at risk need to be identified and therapies instituted to reverse the development of osteoporosis.

Risk Factors

Small-framed, nonobese Caucasian women are at greatest risk for osteoporosis. Also, Asian women of slight build are at risk for low peak bone mineral density (BMD). African-American women, who have a greater bone mass than Caucasian women, are less susceptible to osteoporosis. Men have a greater peak bone mass and do not experience sudden estrogen reduction. As a result, osteoporosis occurs in men at a lower rate and at an older age (about one decade later) (Weber, 2016). It is believed that testosterone and estrogen are important in achieving and maintaining bone mass in men.

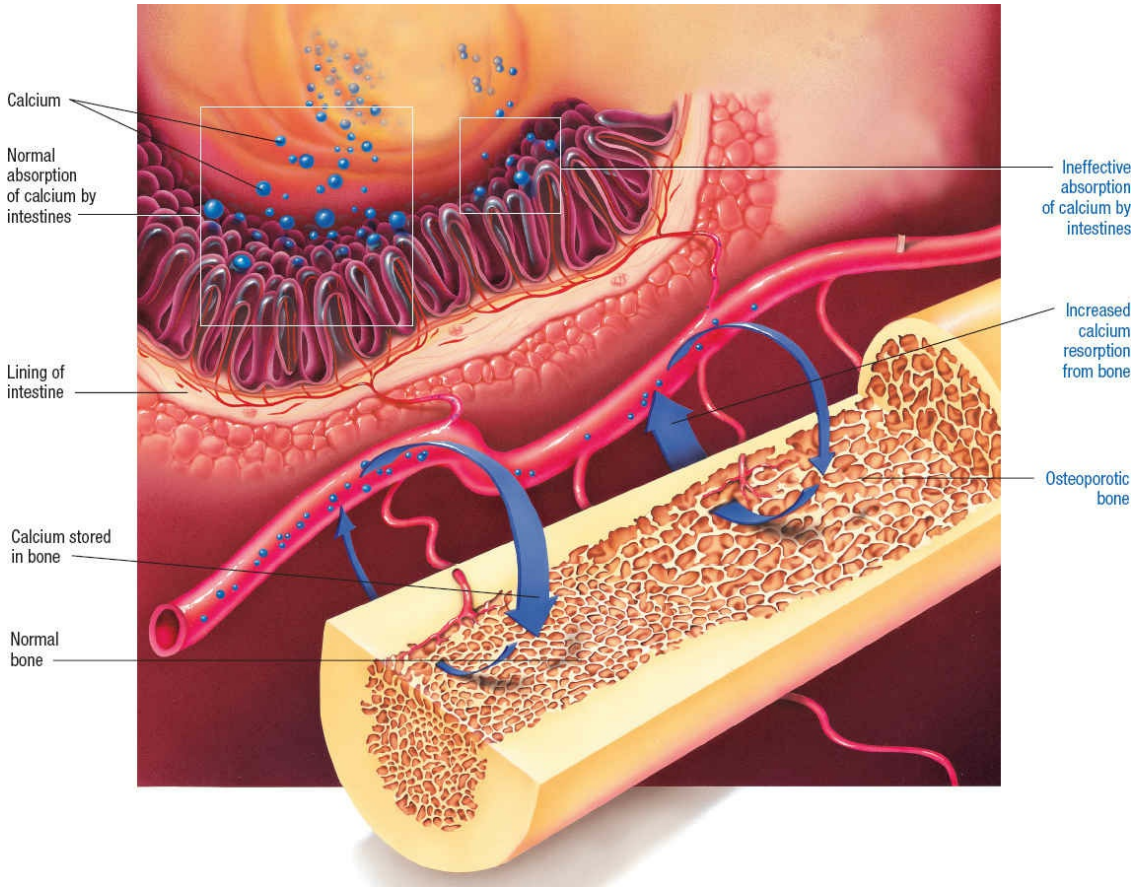

FIGURE 41-7 Calcium metabolism in osteoporosis. Normally, blood absorbs calcium from the digestive system and deposits it into bone. In osteoporosis, blood levels of calcium are reduced. To maintain blood calcium levels, reabsorption of calcium from the bones is increased.

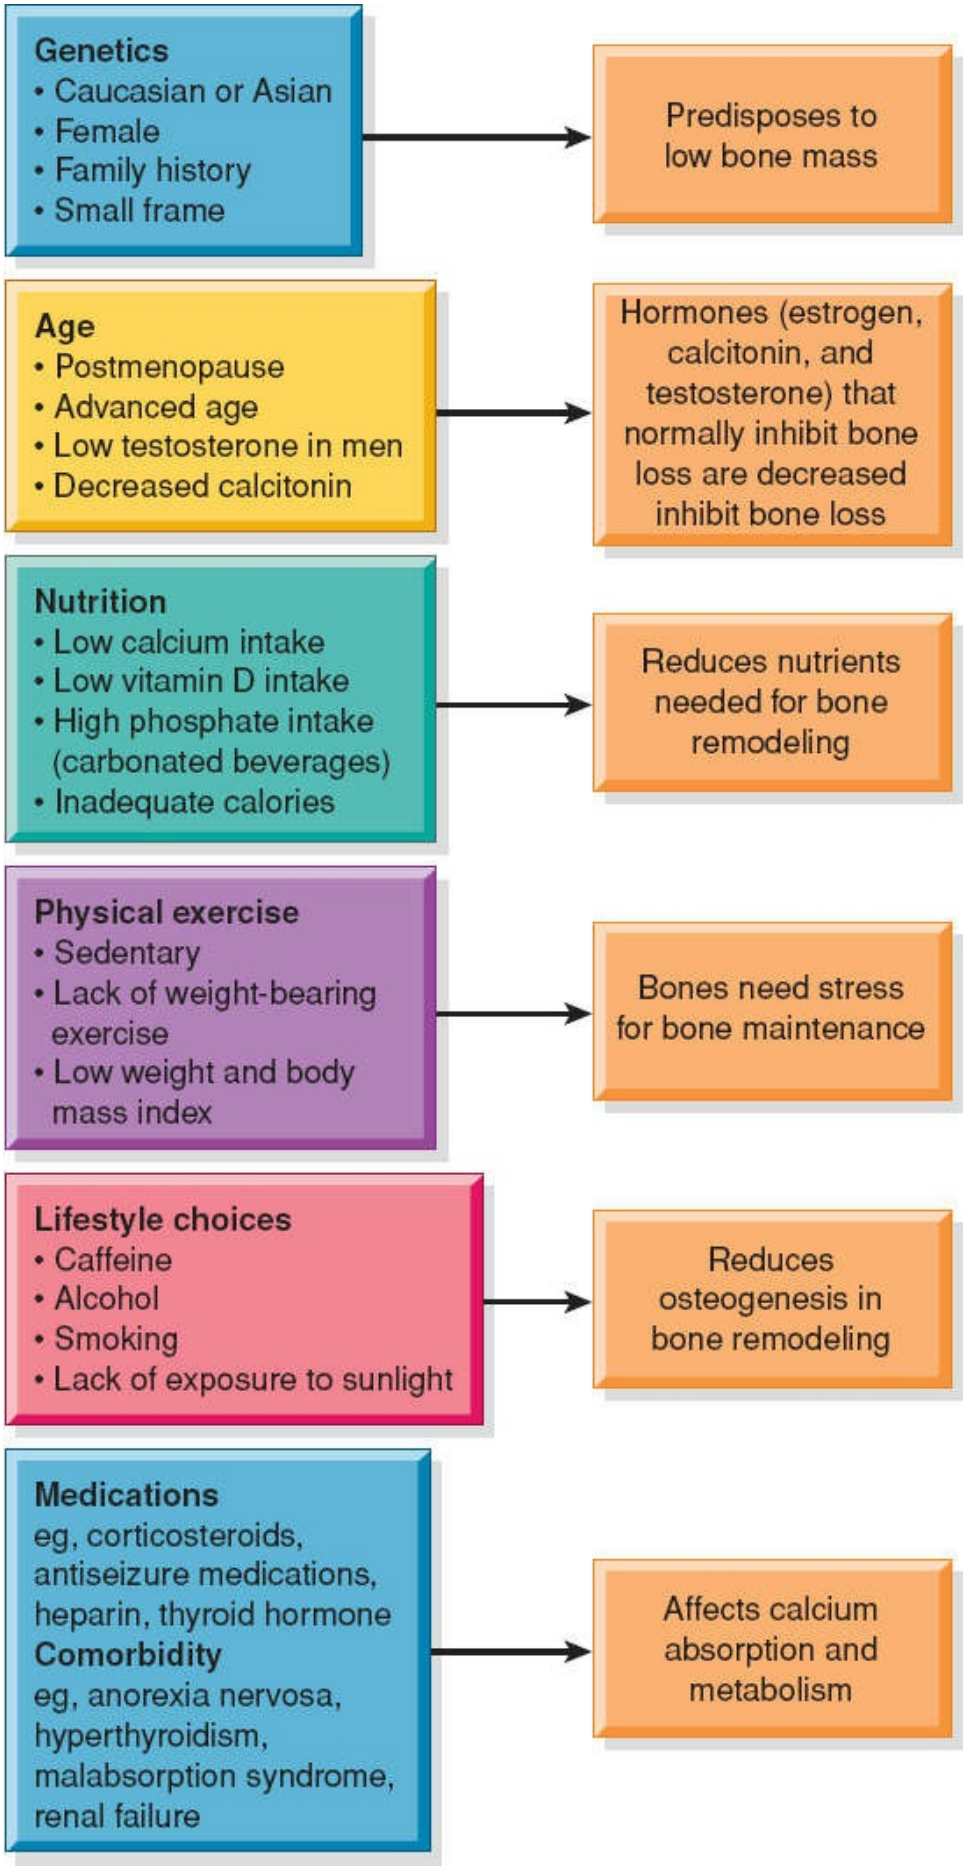
Nutritional factors contribute to the development of osteoporosis. A diet that includes adequate calories and nutrients needed to maintain bone, calcium, and vitamin D must be consumed. Vitamin D is necessary for calcium absorption and for normal bone mineralization. Dietary calcium and vitamin D must be adequate to maintain bone remodeling and body functions. While there is some controversy, it is felt that vitamin D deficiency is more prevalent than previously thought (Kasper et al., 2015) as more than 75% of individuals in the United States are either vitamin D deficient or insufficient (Weber, 2016).

Bone formation is enhanced by the stress of weight and muscle activity. Resistance and

impact exercises are most beneficial in developing and maintaining bone mass. Immobility contributes to the development of osteoporosis. Risk factors for osteoporosis are summarized in Figure 41-8.

Gerontologic Considerations

The prevalence of osteoporosis increases with age; although this disorder is not gender specific, there is an increased incidence in women. By the time a woman reaches 80 years of age, the amount of trabecular and cortical bone lost is approximately 40% from the premenopausal peak BMD (International Osteoporosis Foundation; Szulc & Bouxsein, 2016). Furthermore, elderly people absorb dietary calcium less efficiently and excrete it more readily through their kidneys; therefore, postmenopausal women and the elderly need to consume liberal amounts of calcium. With the aging of the population, the incidence of fractures (more than 2 million osteoporotic fractures per year), pain, and disability associated with osteoporosis is increasing. Most residents of long-term care facilities have a low BMD and are at risk for bone fracture. In addition, restricted sun exposure and a reduced capacity to generate previtamin D in the skin with aging is a consideration.



Genetics
• Caucasian or Asian
• Female
• Family history
• Small frame
Predisposes to low bone mass
Age
• Postmenopause
• Advanced age
• Low testosterone in men
• Decreased calcitonin
Hormones (estrogen, calcitonin, and testosterone) that normally inhibit bone loss are decreased inhibit bone loss
Nutrition
• Low calcium intake
• Low vitamin D intake
• High phosphate intake (carbonated beverages)
• Inadequate calories
Reduces nutrients needed for bone remodeling
Physical exercise
• Sedentary
• Lack of weight-bearing exercise
• Low weight and body mass index
Bones need stress for bone maintenance
Lifestyle choices
• Caffeine
• Alcohol
• Smoking
• Lack of exposure to sunlight
Reduces osteogenesis in bone remodeling
Medications
eg, corticosteroids, antiseizure medications, heparin, thyroid hormone
Comorbidity
eg, anorexia nervosa, hyperthyroidism, malabsorption syndrome, renal failure
Affects calcium absorption and metabolism

FIGURE 41-8 Risk factors for osteoporosis and the effects of these factors on bone.

Nursing Alert

Nurses are aware that corticosteroids are the most frequent cause of medication-related osteoporosis. Often patients with arthritis are prescribed long-term steroids. The combination of the medication and the disease process itself places patients at increased risk for fractures.

Clinical Manifestations and Assessment

Osteoporosis may be undetectable on routine x-rays until there has been 25% to 40% demineralization, resulting in radiolucency of the bones. Frequently, postmenopausal women lose height from vertebral collapse. The gradual collapse of a vertebra may be asymptomatic (1/3 in height loss per year per decade over 50 years of age); it is observed as progressive kyphosis or "dowager's hump" (Fig. 41-9). Multiple compression fractures of the vertebrae result in skeletal deformity. The postural changes result in relaxation of the abdominal muscles and a protruding abdomen. Also the deformity may produce pulmonary insufficiency. Many patients complain of fatigue.

Osteoporosis is diagnosed by dual-energy x-ray absorptiometry (DEXA), which provides information about BMD at the spine and hip. The DEXA scan data are analyzed and reported as T scores (the number of standard deviations [SDs] above or below the average BMD value for a healthy adult at 30 years of age). A normal BMD is less than 1 SD below the young adult mean value. According to Cosman et al. (2014), BMD is known to correlate with bone strength and is considered an important tool in predicting future fracture risk. It is critical to rule out other conditions associated with low BMD. There is also a fracture risk algorithm (FRAX) developed by the World Health Organization (WHO) to evaluate specific risk factors to assess the 10-year absolute fracture risk for all osteoporotic fractures. The WHO defines osteoporosis as being present when the T score is at least 2.5 SD below the young adult mean value on BMD scan (National Osteoporosis Foundation, 2015). Low bone mass (osteopenia) is diagnosed when the BMD T score is between 1 and 2.5 SD below the young adult mean value. Fracture risk increases progressively as the SD of the T score falls below the mean value.

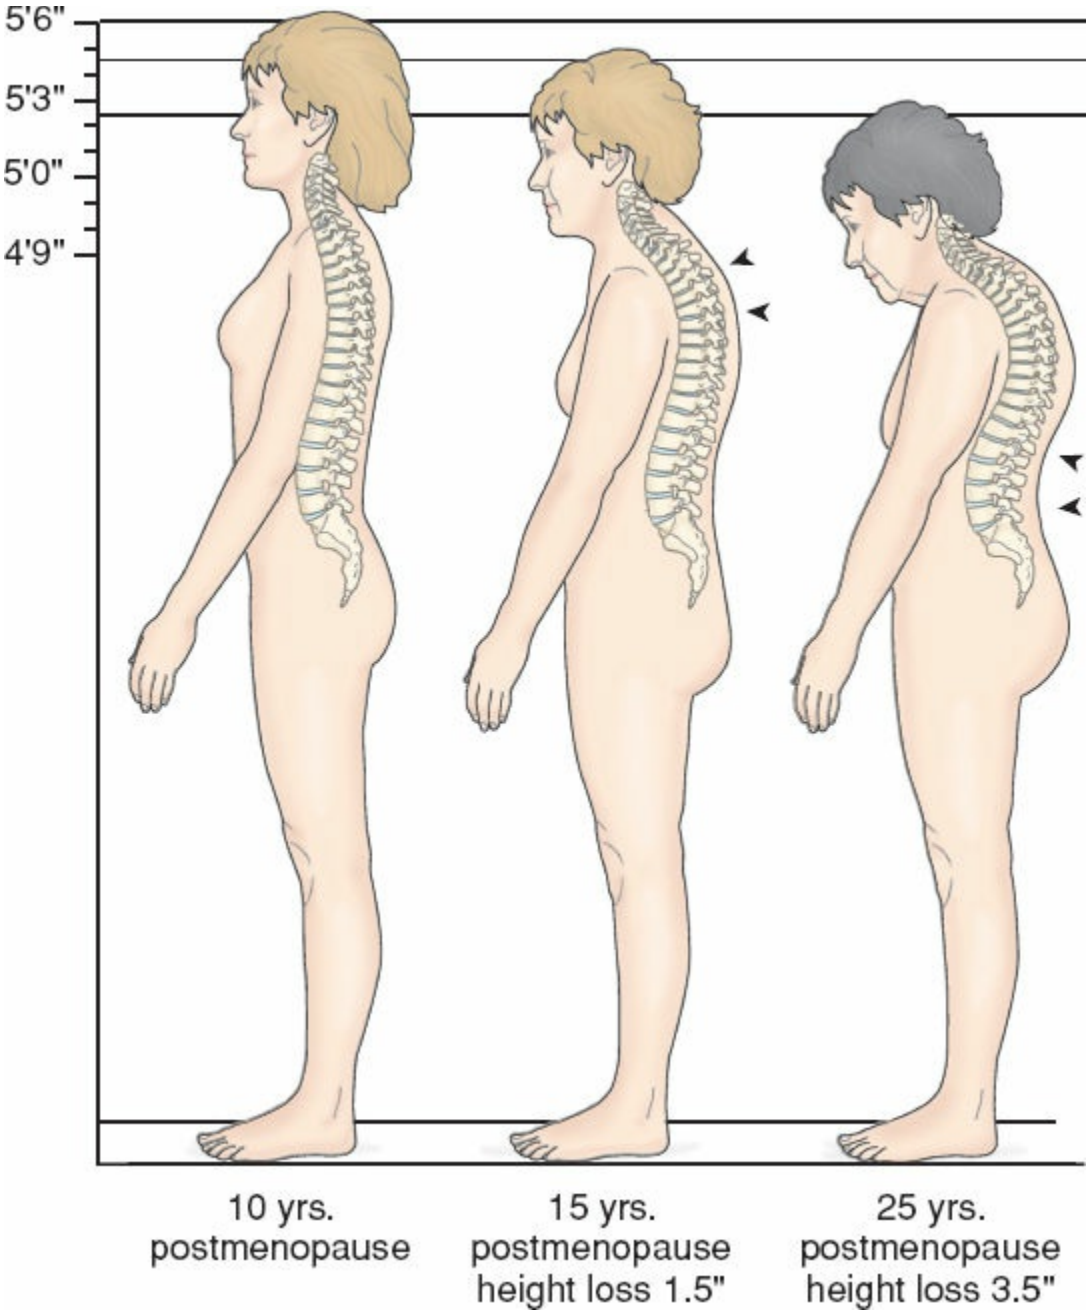


FIGURE 41-9 Typical loss of height associated with osteoporosis and aging.

Quantitative ultrasound studies of the heel and DEXA of the forearm, hip, or spine are used to screen for osteoporosis and to predict the risk of hip and nonvertebral fracture. Current evidence-based guidelines recommend the use of BMD (spine and hip) as the first-line screening test for osteoporosis (Ferri, 2016b; The International Society for Densitometry, 2013) for all postmenopausal women and men over 50 years of age.

BMD studies are useful in identifying low bone mass and osteoporotic bone and in assessing response to therapy. Bone loss and osteoporosis can be reduced through early screening (using both assessment of risk factors and BMD scans), promotion of adequate dietary intake of calcium and vitamin D, encouragement of lifestyle changes, and early institution of preventive medications, resulting in a reduced incidence of fracture.

Other possible medical diagnoses that contribute to bone loss (e.g., multiple myeloma,

osteomalacia, hyperparathyroidism, malignancy, celiac disease, hypogonadism in men) can be excluded through the use of x-ray studies or laboratory studies, such as serum calcium, serum phosphate, vitamin D 25OH, bone-specific alkaline phosphatase, urine calcium excretion, testosterone and estrogen studies, hematocrit, and erythrocyte sedimentation rate (ESR).

Medical and Nursing Management

All people should continue to obtain sufficient calcium, vitamin D (Box 41-5), sunshine, and weight-bearing exercise to slow the progression of osteoporosis.

Pharmacologic Therapy

Medications commonly prescribed to treat osteoporosis are classified based on their mechanism of action: anticatabolic (i.e., antiresorptive) and anabolic (i.e., bone building). Anticatabolic medications, or antiresorptives, inhibit osteoclast activity, resulting in reductions in skeletal turnover and bone loss. Bisphosphonates, such as ibandronate, alendronate, and risedronate, reduce spine and hip fractures associated with osteoporosis through inhibition of osteoclast activity, reducing bone resorption and turnover. Adequate calcium and vitamin D intake is needed for maximum effect. Side effects of bisphosphonates include gastrointestinal (GI) symptoms (e.g., dyspepsia, nausea, flatulence, diarrhea, constipation), and some patients may develop esophageal ulcers, esophagitis, gastric ulcers, or osteonecrosis of the jaw related to bisphosphonate use. Patients must take these medications on an empty stomach with a full glass of water upon arising in the morning, and they must sit upright for 30 to 60 minutes after the administration. Other bisphosphonates are administered intravenously.

BOX 41-5

Nutrition Alert

Calcium and Vitamin D

A diet rich in calcium and vitamin D throughout life, with an increased calcium intake during adolescence, young adulthood, and the middle years, protects against skeletal demineralization. Such a diet includes three glasses of skim or whole vitamin D–enriched milk (a cup of milk or calcium-fortified orange juice contains about 300 mg of calcium) or other foods high in calcium (e.g., cheese and other dairy products, steamed broccoli, canned salmon with bones) daily. The recommended adequate intake (RAI) level of calcium for the age range of puberty through young adulthood (9–18 years of age) is 1,300 mg/day. The goal of this daily level of calcium is to maximize peak bone mass. The RAI level for adults 19–50 years of age is 1,000 mg/day, and the RAI level for adults 51 years of age and older is 1,200 mg/day.

NOF (2015) recommends an intake of 800–1,000 international units (IU) of vitamin D per day for adults 49 years of age and older. Inadequate intake of calcium or vitamin D over a period of years results in decreased bone mass and the development of osteoporosis.

To ensure adequate calcium intake, a calcium supplement with vitamin D may be prescribed and taken with meals or with a beverage high in vitamin C to promote

absorption. The recommended daily dose should be split and not taken as a single dose. Common side effects of calcium supplements are abdominal distention and constipation. Because GI symptoms and abdominal distention are frequent side effects of calcium supplements, the nurse instructs the patient to take the calcium supplements with meals. Also, it is important to teach the patient to drink adequate fluids to reduce the risk of renal calculi.

At natural or surgical menopause, hormone therapy with estrogen and progesterone had been the mainstay of therapy to slow bone loss and reduce the occurrence of fractures. Estrogen replacement decreases bone resorption and increases bone mass, reducing the incidence of osteoporotic fractures. However, studies have demonstrated greater risks, including strokes, venous thromboemboli, and breast cancer, than the benefits of osteoporosis preventive treatment could justify. Although hormone therapy is approved to conserve bone mass and prevent osteoporosis-related fractures, the lowest effective dose for the shortest amount of time is recommended (Cosman et al., 2014).

Selective estrogen receptor modulators (SERMs), such as Raloxifene, reduce the risk of osteoporosis by preserving BMD without estrogenic effects on the uterus. They are indicated for both prevention and treatment of osteoporosis. Raloxifene is the only SERM approved for the treatment of osteoporosis in postmenopausal women as it does not increase the risk of breast or uterine cancer, but it does come with an increased risk of thromboembolism. Duavee®, which is an oral tablet, is a combination of conjugated estrogen and bazedoxifene (another SERM) that is indicated for the prevention of osteoporosis in postmenopausal women. Similarly to raloxifene, bazedoxifene is an estrogen antagonist in the breast and endometrium. The same precautions as with other estrogen products are considered for this drug (e.g., strokes, venous thromboemboli).

Denosumab is approved for the treatment of postmenopausal women with osteoporosis and men who are at high risk for fractures. It is a fully human monoclonal antibody to RANKL, which is a critical determinant of osteoclast activity. Recall osteoclasts dissolve and resorb bone, thus decreasing BMD. Therefore, a RANK-ligand inhibitor is considered a potent inhibitor of osteoclast formation. Denosumab has been shown to increase BMD at the spine, hip, and forearm (Kasper et al., 2015).

Calcitonin directly inhibits osteoclasts, thereby reducing bone loss and may increase osteoblast activity; it also helps to regulate calcium via bone, renal, and GI effects. Calcitonin is administered by nasal spray or by subcutaneous or intramuscular injection. Nasal calcitonin is administered daily, alternating the nares to prevent nasal mucosal dryness. Side effects include nasal irritation, flushing, GI disturbances, and urinary frequency; however, the nasal spray method of delivery has moderate effectiveness. There has been some data to suggest an increase in malignancies, but according to the Food and Drug Administration (FDA, 2015), "*there is no conclusive evidence of a causal relationship between the use of these products and cancer.*"

The anticatabolic drugs described previously are effective at slowing bone loss and reducing fracture risk. Another class of medications are anabolic or "bone-building" drugs such as Teriparatide (Forteo), a recombinant human parathyroid hormone. Teriparatide is a medication administered subcutaneously that is given once daily for the treatment of osteoporosis in postmenopausal women and men at risk for fracture. Teriparatide

stimulates osteoblasts to build bone matrix and facilitates overall calcium absorption. Teriparatide can reduce the risk of vertebral fractures by about 65% and nonvertebral fragility fractures by about 53% in patients with osteoporosis after an average of 18 months of treatment (Cosman et al., 2014).

Preventing Injury

Physical activity is essential to strengthen muscles, improve balance, prevent disuse atrophy, and slow progressive bone demineralization. Regular weight-bearing exercise promotes bone formation. It is recommended that patients perform 20 to 30 minutes of aerobic exercise (e.g., walking), 3 days or more a week. Weight training stimulates an increase in BMD. In addition, exercise improves balance, reducing the incidence of falls and fractures. Isometric exercises can strengthen trunk muscles. The nurse encourages walking, good body mechanics, and good posture. Daily weight-bearing activity, preferably outdoors in the sunshine to enhance the body's ability to produce vitamin D, is encouraged. Sudden bending, jarring, and strenuous lifting are avoided.

Fracture Management

Fractures of the hip are managed surgically by joint replacement or by closed or open reduction with internal fixation (e.g., hip pinning). Surgery, early ambulation, intensive physical therapy, and adequate nutrition result in decreased morbidity and improved outcomes. In addition, patients need to be evaluated for osteoporosis and treated, if indicated. Refer to Chapter 42 for details on nursing management of patients with a fracture.

One of the most common fractures associated with osteoporosis is vertebral compression fracture. It can affect approximately 25% of postmenopausal women and 200 million individuals worldwide (Zhang et al., 2015). Compression fractures can lead to significant deformity and pain, causing disability and decreased quality of life. Typically osteoporotic compression fractures of the vertebra are managed conservatively with analgesics, external braces, and physical therapy. However, patients with ongoing severe pain may choose vertebral body augmentation, such as kyphoplasty or percutaneous vertebroplasty. Percutaneous vertebroplasty/kyphoplasty includes injection of polymethylmethacrylate bone cement into the fractured vertebra, followed by inflation of a pressurized balloon to restore the shape of the affected vertebra. This procedure can provide rapid relief of acute pain and improve quality of life (QOL). Patients who have not responded to first-line approaches to the treatment of vertebral compression fracture can be considered for the procedure. It is contraindicated in the presence of infection, old fractures, uncorrected coagulopathies, and allergic sensitivity to any of the required components.

Box 41-6 discusses fall prevention. Box 41-7 discusses the impact of nurse practitioners on osteoporosis management.

Paget Disease

Paget disease (osteitis deformans) is a disorder of localized rapid bone turnover, most commonly affecting the skull, femur, tibia, pelvic bones, humerus, scapula, and vertebrae. The disease occurs in about 3% of the population older than 50 years of age and up to 10% in those over 90 years of age (Ferri, 2016c). The incidence is slightly greater in men than in women and increases with aging. A family history has been noted, with siblings often developing the disease. The cause of Paget disease is not known.

BOX 41-6 Gerontologic Considerations

Fall Prevention

Elderly people fall frequently as a result of environmental hazards, neuromuscular disorders, diminished senses, cardiovascular responses, and responses to medications. The patient and family need to be included in planning for care and preventive management regimens. For example, the home environment should be assessed for safety and elimination of potential hazards (e.g., scatter rugs, cluttered rooms and stairwells, toys on the floor, pets underfoot). Then a safe environment can be created (e.g., well-lighted staircases with secure hand rails, grab bars in the bathroom, properly fitting footwear).

Pathophysiology

In Paget disease, there is a primary proliferation of osteoclasts, which produces bone resorption. This is followed by a compensatory increase in osteoblastic activity that replaces the bone. As this chaotic bone turnover continues, a classic mosaic (disorganized) pattern of bone develops. Because the diseased bone is of poor quality, highly vascularized, and structurally weak, pathologic fractures occur. Structural bowing of the legs causes malalignment of the joints of the hip, knee, and ankle, which contributes to the development of arthritis and back and joint pain.

Clinical Manifestations and Assessment

Paget disease is insidious; most patients never experience symptoms but have skeletal deformity. A few patients have symptomatic deformity, and up to 40% of patients who come to medical attention present with bone pain (Ferri, 2016c). The condition is identified most frequently on x-ray studies performed during a routine physical examination or during a workup for another problem. Sclerotic changes, skeletal deformities (e.g., bowing of the femur and tibia, enlargement of the skull, deformity of pelvic bones), and cortical thickening of the long bones occur.

In most patients, skeletal deformity involves the skull or long bones. The skull may thicken, and the patient may report that a hat no longer fits. In some cases, the cranium, but not the face, is enlarged. This gives the patient's face a small, triangular appearance. Most patients with skull involvement have impaired hearing from cranial nerve compression and dysfunction. Other cranial nerves also may be compressed.

The femurs and tibiae tend to bow, producing a waddling gait. The spine is bent forward and is rigid; the chin rests on the chest. The thorax is compressed and immobile on respiration. The trunk is flexed on the legs to maintain balance, and the arms are bent outward and forward and appear long in relation to the shortened trunk. Nerve entrapment may be seen.

Pain, tenderness, and warmth over the bones may be noted. The pain is mild to moderate, deep, and aching; it increases with weight-bearing if the lower extremities are involved. Pain and discomfort may precede skeletal deformities of Paget disease by years and often are wrongly attributed by the patient to old age or arthritis.

BOX 41-7 Nursing Research

Bridging the Gap to Evidence-Based Practice

Choi, S.D., & Brings, K., (2016). Work-related musculoskeletal risks associated with nurses and nursing assistants handling overweight and obese patients: A literature review. Work, *53*, 439–448.

Purpose

Nurses and nursing assistants are susceptible to work-related musculoskeletal disorders and injuries (WMSDs) due to the increase in overweight and obese patients they are handling on a daily basis. This study aimed to review work-related musculoskeletal hazards and risks associated with handling overweight and obese patients as well as summarize the recommended interventions to mitigate musculoskeletal concerns among nurses and nursing assistants.

Design

Approximately 350 publications were screened initially and 22 refereed articles were used for this study on the bases of inclusion/exclusion relevance and strength of evidence on handling overweight or obese patients.

Findings

Evidence suggested that the work-related musculoskeletal risks among nurses and nursing assistants included sprains/strains; low back pain; and injuries to the wrist, knee, and shoulders. The findings indicated that the risks of WMSD increased when nurses and nursing assistants were moving or lifting patients manually, especially when the patients were overweight or obese. The recommended solutions included the use of lifting/transfer equipment and devices, ergonomic assessments and controls, no-lift policies, and training and education.

Nursing Implications

Nurses should assess their institutional policies on safe lifting, availability of equipment, and available educational programs. To alleviate the risk of musculoskeletal disorders and injuries among nurses and nursing assistants handling overweight or obese patients, additional research and development into what safe patient handling interventions suit this growing population needs to be addressed.

The temperature of the skin overlying the affected bone increases because of increased bone vascularity. Patients with large, highly vascular lesions may develop high-output cardiac failure because of the increased vascular bed and metabolic demands.

Increased osteoblastic activity is reflected by elevated serum ALP concentration or elevated bone-specific alkaline phosphatase (conditions that affect bone growth or cause increased activity of bone cells affect serum ALP) and excretion of urinary N telopeptide. Higher values suggest more active disease. Patients with Paget disease have normal levels of blood calcium.

Concept Mastery Alert

Elevated serum alkaline phosphatase (SAP) levels, but a normal serum calcium level, are indicative of Paget disease.

X-rays confirm the diagnosis of Paget disease. Local areas of demineralization and bone overgrowth produce characteristic mosaic patterns and irregularities. Bone scans demonstrate the extent of the disease. Bone scintigraphy is the most sensitive test to detail the extent and site of pagetic lesions. Bone biopsy may aid in the differential diagnosis.

Medical and Nursing Management

Several medications reduce bone turnover, reverse the course of the disease, relieve pain, and improve mobility. Pain usually responds to NSAIDs. Gait problems from bowing of the legs are managed with walking aids, shoe lifts, and physical therapy. Weight is controlled to reduce stress on weakened bones and malaligned joints. Diets adequate in calcium (up to 1,200 mg per day) and vitamin D (400 to 800 IU) are important as is periodic monitoring to prevent hypocalcemia and secondary hyperparathyroidism during therapy (Kasper et al., 2015).

Medications, such as bisphosphonates and calcitonin, are used to treat Paget disease. They help to suppress further pain and spread of the disease. Bisphosphonates work well for Paget disease; the preferred option is a one-time infusion of Zoledronate, which has been associated with remission for up to 6 years (Singer et al., 2014). Bisphosphonates produce rapid reduction in bone turnover and relief of pain. They also reduce bone-specific alkaline phosphatase and urinary N telopeptide (a measure of bone turnover) levels. Food inhibits absorption of these medications; therefore, patients ingest the medications on an empty stomach. Calcitonin, a polypeptide hormone, slows bone resorption by decreasing the number and availability of osteoclasts. Calcitonin therapy facilitates remodeling of abnormal bone into normal lamellar bone, relieves bone pain, and helps alleviate neurologic and biochemical signs and symptoms. Calcitonin is administered subcutaneously or by nasal inhalation. Side effects include flushing of the face and nausea. The effect of calcitonin therapy is evident in 3 to 6 months through reduction of bone loss and pain.

Fractures, arthritis, and hearing loss are complications of Paget disease. Fractures are managed according to location. Healing occurs if fracture reduction, immobilization, and stability are adequate. Severe degenerative arthritis may require total joint replacement. Loss of hearing is managed with hearing aids and communication techniques used with people who are hearing-impaired (e.g., speech reading, body language).

Gerontologic Considerations 

Because Paget disease tends to affect elderly people, careful assessment of a patient's pain and discomfort is necessary. Patient teaching helps the patient understand the treatment regimen, the need for a diet with adequate calcium and vitamin D, and how to compensate for altered musculoskeletal functioning. The home environment is assessed for safety to prevent falls and to reduce the risk of fracture. Strategies for coping with a chronic health problem and its effect on QOL need to be developed.

MUSCULOSKELETAL INFECTIONS

Osteomyelitis

Osteomyelitis is an infection of the bone; it can be acute or chronic and is usually bacterial in nature. The bone becomes infected in one of three ways:

- Extension of soft tissue infection (e.g., infected pressure or vascular ulcer, incisional infection)
- Direct bone contamination from bone surgery, open fracture, or traumatic injury (e.g., gunshot wound)
- Hematogenous (blood-borne) spread from other sites of infection (e.g., infected tonsils, boils, infected teeth, upper respiratory infections). Osteomyelitis resulting from hematogenous spread typically occurs in a bone in an area of trauma or lowered resistance, possibly from subclinical (nonapparent) trauma. Examples include immunocompromised patients, blood-borne seeding from a distant infection such as a urinary tract infection, pneumonia, and cellulitis.

Patients who are at high risk for osteomyelitis include those who are poorly nourished, elderly, or obese. Other patients at risk include those with impaired immune systems, those who are IV drug users, those with chronic illnesses (e.g., diabetes, rheumatoid arthritis, neuropathy, and arterial insufficiency), and those receiving long-term corticosteroid therapy or immunosuppressive agents.

Postoperative surgical wound infections occur within 30 days after surgery. They are classified as incisional (superficial, located above the deep fascia layer) or deep (involving tissue beneath the deep fascia). If an implant has been used, deep postoperative infections may occur within a year. Deep sepsis after arthroplasty (surgical procedure that replaces damaged joints) may be classified as follows:

- *Stage 1, acute fulminating:* Occurring during the first 3 months after orthopedic surgery; frequently associated with hematoma, drainage, or superficial infection
- *Stage 2, delayed onset:* Occurring between 4 and 24 months after surgery
- *Stage 3, late onset:* Occurring 2 or more years after surgery, usually as a result of hematogenous spread

Bone infections are more difficult to eradicate than are soft tissue infections because the infected bone is mostly avascular (without blood vessels) and not accessible to the body's natural immune response. Also, there is decreased penetration by antibiotics.

Pathophysiology

Between 70% and 80% of bone infections are caused by *Staphylococcus aureus.* Other pathogenic organisms that frequently are found in osteomyelitis include MRSA: methicillin-resistant *S. aureus, Pseudomonas aeruginosa, Escherichia coli, Neisseria gonorrhoeae, Haemophilus influenzae, Fungi,* and *Salmonella* (Grossman & Porth, 2014). There is increasing incidence of infections that are penicillin resistant, nosocomial, gram negative, and anaerobic.

The initial response to infection is inflammation, increased vascularity, and edema. After 2 or 3 days, thrombosis of the blood vessels occurs in the area, resulting in ischemia with bone necrosis. The infection extends into the medullary cavity and under the periosteum and may spread into adjacent soft tissues and joints. Unless the infective process is treated promptly, a bone abscess forms. The resulting abscess cavity contains dead bone tissue (the sequestrum), which does not easily liquefy and drain. Therefore, the cavity cannot collapse and heal as it does with abscesses in soft tissue. New bone growth (the involucrum) forms and surrounds the sequestrum (Fig. 41-10). Although healing appears to take place, a chronically infected sequestrum remains and produces recurring abscesses throughout the patient's life. This is referred to as chronic osteomyelitis.

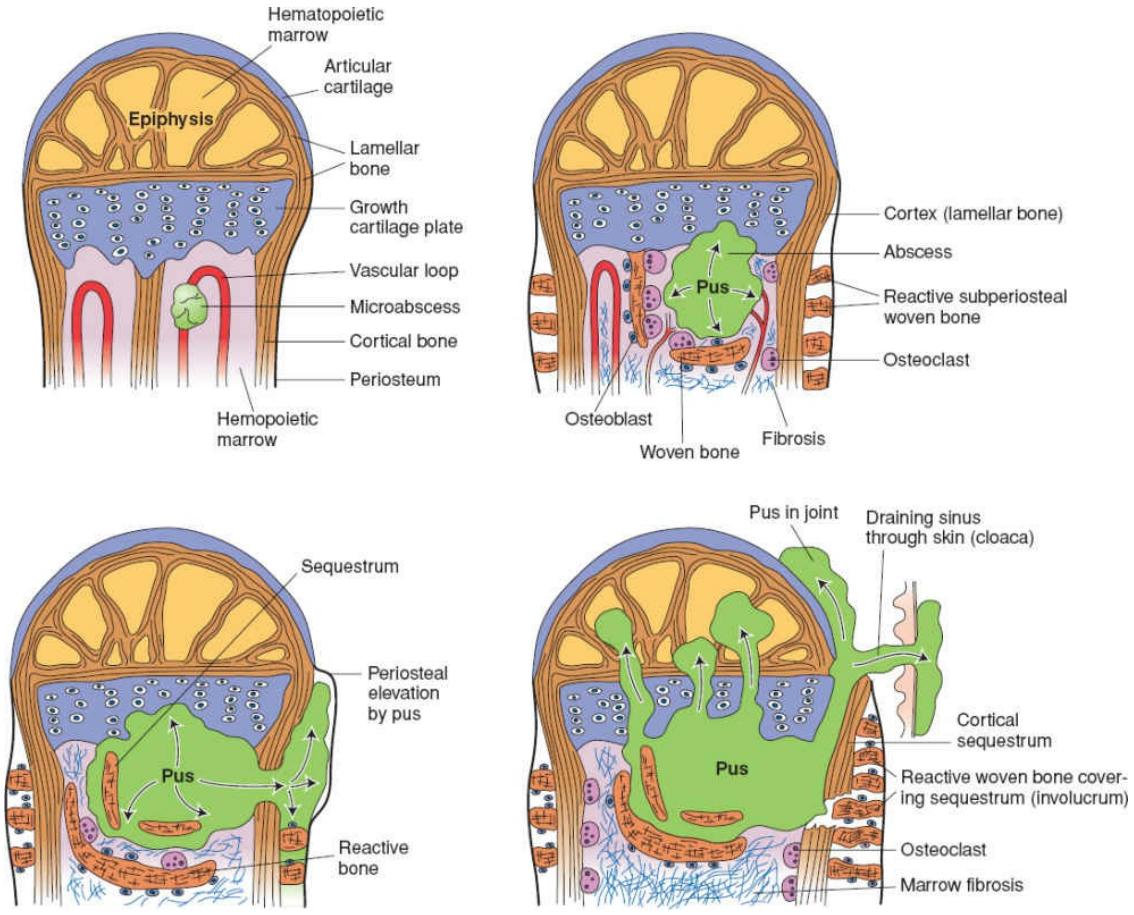

FIGURE 41-10 Stages of osteomyelitis.

Clinical Manifestations and Assessment

The hallmark of osteomyelitis is localized pain over the infected bones. When the infection is blood-borne, the onset is usually sudden, occurring often with the clinical and laboratory manifestations of sepsis (e.g., chills, high fever, rapid pulse, and general malaise). The systemic symptoms, such as fever, may overshadow the local signs at first. As the infection extends through the cortex of the bone, it involves the periosteum and the soft tissues. The infected area becomes painful, swollen, and extremely tender. The patient may describe a constant, pulsating pain that intensifies with movement as a result of the pressure of the collecting pus. When osteomyelitis occurs from spread of adjacent infection or from direct contamination, there may be symptoms of sepsis. The area is swollen, warm, painful, and tender to touch.

In acute osteomyelitis, early x-ray findings demonstrate soft tissue swelling. In about 2 weeks, areas of irregular decalcification, bone necrosis, periosteal elevation, and new bone formation are evident. Radioisotope bone scans, particularly the isotope-labeled white blood cell (WBC) scan, and magnetic resonance imaging (MRI) help with early definitive diagnosis. Blood studies reveal leukocytosis (elevated WBCs) and an elevated ESR and C-reactive protein in hematogenous and acute osteomyelitis, but those counts may be normal in chronic contiguous osteomyelitis. Wound and blood culture studies are performed to identify the offending organisms so appropriate antibiotic therapy can be instituted.

With chronic osteomyelitis, large, irregular cavities, raised periosteum, sequestra, or dense bone formations are seen on x-ray. Bone scans may be performed to identify areas of infection. Usually the ESR and the WBC count are normal. Anemia, associated with chronic infection, may be evident. The abscess is cultured to determine the infective organism and appropriate antibiotic therapy. While both acute and chronic osteomyelitis are associated with infections of the bone, they are differentiated by the presence of dead bone in the latter.

Prevention

Prevention of osteomyelitis is the goal. Elective orthopedic surgery should be postponed if the patient has a current infection (e.g., urinary tract infection, sore throat) or a recent history of infection. During orthopedic surgery, careful attention is paid to the surgical environment and to techniques to decrease direct bone contamination. Prophylactic antibiotics, administered to achieve adequate tissue levels at the time of surgery and for 24 hours after surgery, are helpful. Urinary catheters and drains are removed as soon as possible to decrease the incidence of hematogenous spread of infection.

Treatment of focal infections diminishes hematogenous spread. Aseptic postoperative wound care reduces the incidence of superficial infections and osteomyelitis. Prompt management of soft tissue infections reduces extension of infection to the bone. When patients who have had joint replacement surgery undergo dental procedures or other invasive procedures (e.g., cystoscopy), prophylactic antibiotics are recommended frequently. In order to decrease the incidence of osteomyelitis of the foot in patients with diabetes, therapy should be aimed at controlling the blood sugar, decreasing the incidence of peripheral vascular disease.

Medical Management

The initial goal of therapy is to control and halt the infective process. Antibiotic therapy depends on the results of blood and wound cultures. Frequently, the infection is caused by more than one pathogen. General supportive measures (e.g., hydration, a balanced diet, correction of anemia) should be instituted. If necessary, the area affected with osteomyelitis is immobilized to decrease discomfort and to prevent pathologic fracture of the weakened bone.

Pharmacologic Therapy

As soon as the culture specimens are obtained, IV antibiotic therapy begins. The aim is to control the infection before the blood supply to the area diminishes as a result of thrombosis. Around-the-clock dosing is necessary to achieve a sustained high therapeutic blood level of the antibiotic. After results of the culture and sensitivity studies are known, an antibiotic to which the causative organism is sensitive is prescribed. IV antibiotic therapy usually continues for 6 weeks for acute osteomyelitis; chronic osteomyelitis may require a longer course of medication (Ferri, 2016d). After the infection appears to be controlled, the antibiotic may be administered orally for up to 3 months. To enhance absorption of the orally administered medication, antibiotics should not be administered with food.

Surgical Management

If the infection is chronic, surgical débridement may be indicated. The infected bone is surgically exposed, the purulent and necrotic material is removed, and the area is irrigated with sterile saline solution. Antibiotic-impregnated beads may be placed in the wound for direct application of antibiotics for 2 to 4 weeks. IV antibiotic therapy is continued.

In chronic osteomyelitis, antibiotics are adjunctive therapy to surgical débridement. A

sequestrectomy (removal of enough involucrum to enable the surgeon to remove the sequestrum) is performed. In many cases, sufficient bone is removed to convert a deep cavity into a shallow saucer (saucerization). All dead, infected bone and cartilage (to the extent possible) must be removed before permanent healing can occur, followed by culture-directed IV antibiotic therapy.

The wound is either closed tightly to obliterate the dead space or packed and closed later by granulation or possibly by grafting. The débrided cavity may be packed with cancellous bone graft to stimulate healing. With a large defect, the cavity may be filled with a vascularized bone transfer or muscle flap (in which a muscle is moved from an adjacent area with blood supply intact). These microsurgery techniques enhance the blood supply. The improved blood supply facilitates bone healing and eradication of the infection. These surgical procedures may be staged over time to ensure healing. A wound-assisted vacuum device may help with closure of the wound. Because surgical débridement weakens the bone, internal fixation or external supportive devices may be needed to stabilize or support the bone to prevent pathologic fracture.

NURSING PROCESS

The Patient with Osteomyelitis

ASSESSMENT

The patient reports an acute onset of signs and symptoms (e.g., localized pain, edema, erythema, abrupt fever with acute osteomyelitis, and persistent low-grade temperature with chronic osteomyelitis); also the patient may describe recurrent drainage of an infected sinus tract with associated pain, edema, and low-grade fever. The nurse assesses the patient for risk factors (e.g., older age, diabetes, long-term corticosteroid therapy, PVD) and for a history of previous injury, infection, or orthopedic surgery. The patient avoids pressure on the area and guards movement. In acute hematogenous osteomyelitis, the patient exhibits generalized weakness due to the systemic reaction to the infection.

Physical examination reveals an inflamed, markedly edematous, warm area that is tender. Purulent drainage may be noted. The patient has an elevated temperature with acute osteomyelitis; whereas with chronic osteomyelitis, the temperature elevation may be low grade, occurring in the afternoon or evening.

Nursing Alert

The nurse recognizes there is a normal in oral temperature in 99% of the population with ranges from 36.0°C (96.8°F) to 37.7°C (99.86°F) with a circadian variation of 1°C or more between the morning nadir and the evening

peak (Leggett, 2016).

NURSING DIAGNOSES

Appropriate nursing diagnoses may include:

- Acute pain related to inflammation and edema
- Impaired physical mobility related to pain, use of immobilization devices, and weight-bearing limitations
- Risk for extension of infection: bone abscess formation
- Deficient knowledge related to the treatment regimen

PLANNING

The patient's goals may include relief of pain, improved physical mobility within therapeutic limitations, control and eradication of infection, and knowledge of the treatment regimen.

NURSING INTERVENTIONS

RELIEVING PAIN

The affected part may be immobilized with a splint to decrease pain and muscle spasm. The nurse monitors the neurovascular status of the affected extremity. Frequently the wounds are very painful, and the extremity must be handled with great care and gentleness. Elevation reduces swelling and associated discomfort. Pain is controlled with prescribed analgesics and other pain-reducing techniques.

IMPROVING PHYSICAL MOBILITY

Treatment regimens may consist of activity restriction. The bone is weakened by the infective process and must be protected by immobilization devices and by avoidance of stress on the bone. The patient must understand the rationale for the activity restrictions. The nurse encourages full participation in ADLs within the physical limitations to promote general well-being.

CONTROLLING THE INFECTIOUS PROCESS

The nurse monitors the patient's response to antibiotic therapy and observes the IV access site for evidence of phlebitis, infection, or infiltration. With long-term, intensive antibiotic therapy, the nurse monitors the patient for signs of superinfection (e.g., oral or vaginal candidiasis, loose or foul-smelling stools).

If surgery is necessary, the nurse takes measures to ensure adequate circulation to the affected area (wound suction to prevent fluid accumulation, elevation of the area to promote venous drainage, avoidance of pressure on the grafted area), to maintain needed immobility, and to ensure the patient's adherence to weight-bearing restrictions. The nurse changes dressings using aseptic technique to promote healing and to prevent cross-

contamination.

The nurse continues to monitor the general health and nutrition of the patient. A diet high in protein and vitamin C promotes a positive nitrogen balance and healing. The nurse encourages adequate hydration as well.

TEACHING PATIENTS SELF-CARE

The patient and family are taught about the importance of strictly adhering to the therapeutic regimen of antibiotics and preventing falls or other injuries that could result in bone fracture. They need to learn to maintain and manage the IV access and IV administration equipment in the home. Teaching includes medication name, dosage, frequency, administration rate, safe storage and handling, adverse reactions, and necessary laboratory monitoring. In addition, aseptic dressing and warm compress techniques are taught.

The nurse carefully monitors the patient for the development of additional sites that are painful or for sudden increases in body temperature. The nurse instructs the patient and family to observe for and report elevated temperature, drainage, odor, signs of increased inflammation, adverse reactions, and signs of superinfection.

If warranted, the nurse completes a home assessment to determine the patient's and family's abilities regarding continuation of the therapeutic regimen. If the patient's support system is questionable, or if the patient lives alone, a home care nurse may be needed to assist with IV administration of the antibiotics. The nurse monitors the patient for response to the treatment, signs and symptoms of superinfections, and adverse drug reactions. The nurse stresses the importance of follow-up health care appointments and recommends age-appropriate health screening.

EVALUATION

Expected patient outcomes may include:

1. Experiences pain relief:
   a. Reports decreased pain
   b. Experiences no tenderness at site of previous infection
   c. Experiences no discomfort with movement
2. Increases physical mobility:
   a. Participates in self-care activities
   b. Maintains full function of unimpaired extremities
   c. Demonstrates safe use of immobilizing and assistive devices
   d. Modifies environment to promote safety and to avoid falls
3. Shows absence of infection:
   a. Takes antibiotic as prescribed
   b. Reports normal temperature
   c. Exhibits no edema

d. Reports absence of drainage
e. Laboratory results indicate normal WBC count and ESR.
f. Wound cultures are negative.

4. Adheres to therapeutic plan:
   a. Takes medications as prescribed
   b. Protects weakened bones
   c. Demonstrates proper wound care
   d. Reports signs and symptoms of complications promptly
   e. Consumes a diet high in protein and vitamin C
   f. Keeps follow-up health care appointments
   g. Reports increased strength
   h. Reports no elevation of temperature or recurrence of pain, edema, or other symptoms at the site

Septic (Infectious) Arthritis

Septic arthritis refers to infection of a joint by a microorganism. It is an important medical emergency with high morbidity and mortality; inappropriate or delayed treatment can lead to joint damage and a mortality rate of about 10% (Bohler, Dragana, Puchner, Windhager, & Holinka, 2016).

Pathophysiology

Joints can become infected through spread of infection from other parts of the body (hematogenous spread) or directly through trauma or surgical instrumentation. Previous trauma to joints, joint replacement, coexisting arthritis, diabetes mellitus, rheumatoid arthritis, osteoarthritis, alcoholism, cutaneous ulcers, and diminished host resistance contribute to the development of an infected joint. IV drug abusers or those who have intravenous catheters in place to treat other medical conditions are at particular risk for unusual bacterial infection. Patients taking glucocorticosteroids, other immunosuppressive agents, and biologic response modifiers to manage autoimmune diseases, such as rheumatoid arthritis and inflammatory bowel disease, are also at risk. *S. aureus* causes most adult joint infections, followed by *Streptococci*, accounting for 90% of cases of septic arthritis (Matteson & Osmon, 2016). Prompt recognition and treatment of an infected joint are important because accumulating purulent material results in chondrolysis (destruction of hyaline cartilage), which can cause destruction of the surface of the bones.

Clinical Manifestations and Assessment

The patient with acute septic arthritis usually presents with a warm, painful, swollen joint with decreased ROM. The knee is involved in more than 50% of cases (Matteson & Osmon, 2016). Systemic chills, fever, and leukocytosis are present. Elderly patients and patients taking corticosteroids or immunosuppressive medications may not exhibit typical clinical manifestations of infection, and may not have a marked febrile response. Therefore, they require ongoing assessment to detect infection as early as possible in the infectious process. An assessment for the source and cause of infection is performed. Blood cultures, ESR, C-reactive protein, and complete blood count are evaluated. Diagnostic studies include aspiration, examination, and culture of the synovial fluid. Evaluation of the synovial fluid can be critical when choosing the appropriate antibiotic and treatment plan for the patient. Computed tomography (CT) and MRI may reveal inflammation and damage to the joint and may be helpful in assessing osteomyelitis. Radioisotope scanning may be useful in localizing the infectious process.

Medical and Nursing Management

Prompt treatment is essential and may save a joint prosthesis for patients who have one. Broad-spectrum IV antibiotics are started promptly and then changed to organism-specific antibiotics after culture results are available. The IV antibiotics are continued until symptoms disappear. The synovial fluid is monitored for sterility and decrease in WBCs.

In addition to prescribing antibiotics, the provider may aspirate the joint with a needle to remove excessive joint fluid, exudate, and debris. This promotes comfort and decreases joint destruction caused by the action of proteolytic enzymes in the purulent fluid. Occasionally, arthrotomy (incision into a joint) or arthroscopy is used to drain the joint and remove dead tissue.

The inflamed joint is supported and immobilized in a functional position by a splint that increases the patient's comfort. Analgesics may be prescribed to relieve pain. The patient's nutrition and fluid status is monitored. Progressive ROM exercises are prescribed after the infection subsides.

If septic joints are treated promptly, recovery of normal function is expected. The patient is assessed periodically for recurrence. If the articular cartilage was damaged during the inflammatory reaction, joint fibrosis and diminished function may result.

The nurse describes the septic arthritis process to the patient and teaches the patient how to relieve pain using pharmacologic and nonpharmacologic interventions. The nurse also explains the importance of supporting the affected joint, adhering to the prescribed antibiotic regimen, and observing weight-bearing and activity restrictions. In addition, the nurse demonstrates and encourages the patient to practice safe use of ambulatory aids and assistive devices.

The nurse teaches the patient strategies to promote healing through aseptic dressing changes and proper wound care. Then the patient is encouraged to perform ROM exercises after the infection subsides.

BONE TUMORS

Neoplasms of the musculoskeletal system are of various types, including osteogenic, chondrogenic, fibrogenic, muscle (rhabdomyogenic), and marrow (reticulum) cell tumors as well as nerve, vascular, and fatty cell tumors. They may be primary tumors or metastatic tumors from primary cancers elsewhere in the body (e.g., breast, lung, prostate, kidney). Metastatic bone tumors are more common than primary bone tumors.

Benign Bone Tumors

Benign tumors of the bone and soft tissue are more common than malignant primary bone tumors. Benign bone tumors generally are slow growing, well circumscribed, and encapsulated; present few symptoms; and are not a cause of death.

Benign primary neoplasms of the musculoskeletal system include osteochondroma, enchondroma, bone cyst (e.g., aneurysmal bone cyst), osteoid osteoma, rhabdomyoma, and fibroma. Some benign tumors, such as giant cell tumors, have the potential to become malignant.

Osteochondroma is the most common benign bone tumor. It usually occurs as a large projection of bone at the end of the long bones (at the knee or shoulder). It develops during growth and then becomes a static bony mass. In fewer than 1% of patients, the cartilage cap of the osteochondroma may undergo malignant transformation after trauma, and a chondrosarcoma or osteosarcoma may develop.

Enchondroma is a common tumor of the hyaline cartilage that develops in the hand, femur, tibia, or humerus. Usually, the only symptom is a mild ache. Pathologic fractures may occur.

Bone cysts are lesions that expand within the bone. Aneurysmal (widening) bone cysts are seen in young adults, who present with a painful, palpable mass of the long bones, vertebrae, or flat bone. Unicameral (single cavity) bone cysts occur in children and cause mild discomfort and possible pathologic fractures of the upper humerus and femur, which may heal spontaneously.

Osteoid osteoma is a painful tumor that occurs in children and young adults. The neoplastic tissue is surrounded by reactive bone formation that can be identified by x-ray.

Giant cell tumors (osteoclastomas) are benign for long periods but may invade local tissue and cause destruction. They occur in young adults and are soft and hemorrhagic. Eventually, giant cell tumors may undergo malignant transformation and metastasize.

Malignant Bone Tumors

Primary malignant musculoskeletal tumors are relatively rare and arise from connective and supportive tissue cells (sarcomas) or bone marrow elements (multiple myeloma; see Chapter 20). Malignant primary musculoskeletal tumors include osteosarcoma, chondrosarcoma, and Ewing sarcoma. Soft tissue sarcomas include liposarcoma, fibrosarcoma of soft tissue, and rhabdomyosarcoma, which arise in fat cells, fibrous connective tissue, or soft tissue, respectively. Bone tumor metastasis to the lungs is common.

Osteogenic sarcoma (osteosarcoma) is the primary malignant bone tumor that is most common and most often fatal. Prognosis depends on whether the tumor has metastasized to the lungs at the time the patient seeks health care. Osteogenic sarcoma appears most frequently in males between 10 and 25 years of age (in bones that grow rapidly), in older people with Paget disease, and as a result of radiation exposure. Clinical manifestations include pain, edema, limited motion, and weight loss (which is considered an ominous finding). The bony mass may be palpable, tender, and fixed, with an increase in skin temperature over the mass and venous distention. The primary lesion may involve any bone, but the most common sites are the distal femur, the proximal tibia, and the proximal humerus.

Malignant tumors of the hyaline cartilage are called chondrosarcomas. These tumors are the second most common primary malignant bone tumor. They are large, bulky, slow-growing tumors that affect adults. The usual tumor sites include the pelvis, femur, humerus, spine, scapula, and tibia. Metastasis to the lungs occurs in fewer than half of patients. When these tumors are well differentiated, large bloc excision or amputation of the affected extremity results in increased survival rates. These tumors may recur. Refer to a pediatric text for details of the Ewing family of tumors.

Metastatic Bone Disease

Metastatic bone disease (secondary bone tumor) is more common than any primary bone tumor. Tumors arising from tissues elsewhere in the body may invade the bone and produce localized bone destruction (lytic lesions) or bone overgrowth (blastic lesions). The most common primary sites of tumors that metastasize to bone are the kidney, prostate, lung, breast, ovary, and thyroid. Metastatic tumors most frequently attack the skull, spine, pelvis, femur, and humerus, and they often involve more than one bone (polyostotic).

Pathophysiology

A tumor in the bone causes the normal bone tissue to react by osteolytic response (bone destruction) or osteoblastic response (bone formation). Primary tumors cause bone destruction, which weakens the bone, resulting in bone fractures. Adjacent normal bone responds to the tumor by altering its normal pattern of remodeling. The bone's surface changes and the contours enlarge in the tumor area.

Malignant bone tumors invade and destroy adjacent bone tissue. Benign bone tumors, in contrast, have a symmetric, controlled growth pattern and place pressure on adjacent bone tissue. Malignant invading bone tumors weaken the structure of the bone until it can no longer withstand the stress of ordinary use; pathologic fracture commonly results.

Clinical Manifestations and Assessment

Patients with primary malignant and benign bone tumors present with pain, swelling, and, occasionally, pathologic fracture of the involved bone (Doroshow, 2016). Patients with metastatic bone tumor may have a wide range of associated clinical manifestations. They may be symptom free or have pain (mild and occasional to constant and severe), varying degrees of disability, and, at times, obvious bone growth. Weight loss, malaise, and fever may be present. The tumor may be diagnosed only after pathologic fracture has occurred.

With spinal metastasis, spinal cord compression may occur. It can progress rapidly or slowly. Neurologic deficits (e.g., progressive pain, weakness, gait abnormality, paresthesia, paraplegia, urinary retention, loss of bowel or bladder control) must be identified early and treated with decompressive laminectomy to prevent permanent spinal cord injury.

The differential diagnosis is based on the history, physical examination, and diagnostic studies, including CT, bone scans, myelography, arteriography, MRI, biopsy, and biochemical assays of the blood and urine. Frequently serum ALP levels are elevated with osteogenic sarcoma. With metastatic carcinoma of the prostate, serum acid phosphatase levels are elevated. Hypercalcemia is present with bone metastases from breast, lung, or kidney cancer. Symptoms of hypercalcemia include muscle weakness, fatigue, anorexia, nausea, vomiting, polyuria, cardiac arrhythmias, seizures, and coma. Hypercalcemia must be identified and treated promptly. A surgical biopsy is performed for histologic identification. Extreme care is taken during the biopsy to prevent seeding and resultant recurrence after excision of the tumor.

Chest x-rays are performed to determine the presence of lung metastasis. Surgical staging of musculoskeletal tumors is based on tumor grade and site (intracompartmental or extracompartmental) as well as on metastasis. Staging is used for planning treatment.

During the diagnostic period, the nurse explains the diagnostic tests and provides psychological and emotional support to the patient and family. The nurse assesses coping behaviors and encourages use of support systems.

Medical Management

Primary Bone Tumors

The goal of treatment of a primary bone tumor is to destroy or remove the tumor. This may be accomplished by surgical excision (ranging from local excision to amputation and disarticulation), radiation therapy if the tumor is radiosensitive, and chemotherapy (preoperative [neoadjuvant], intraoperative, postoperative, and adjunctive for possible micrometastases). Preoperative imaging studies determine the extent of tumor penetration and impact on adjacent structures. Survival and QOL are important considerations in procedures that attempt to save the involved extremity.

Typically patients are managed with initial neoadjuvant (given before surgery) chemotherapy, delayed resection of the primary tumor, and then further postoperative chemotherapy (Doroshow, 2016). The SAP level, which often is elevated in patients with osteosarcoma, can be used to monitor disease status. Limb-sparing (salvage) procedures are used to remove the tumor and adjacent tissue. A customized prosthesis, total joint arthroplasty, or bone tissue from the patient (autograft) or from a cadaver donor (allograft) replaces the resected tissue. Soft tissue and blood vessels may need grafting because of the extent of the excision. Complications may include infection, loosening or dislocation of the prosthesis, allograft nonunion, fracture, devitalization of the skin and soft tissues, joint fibrosis, and recurrence of the tumor. Function and rehabilitation after limb salvage depend on positive encouragement and reducing the risk of complications.

Surgical removal of the tumor may require amputation of the affected extremity with the amputation extending well above the tumor to achieve local control of the primary lesion (refer to Chapter 42). Because of the danger of metastasis with malignant bone tumors, combined chemotherapy is started before and continued after surgery in an effort to eradicate micrometastatic lesions. The goal of combined chemotherapy is greater therapeutic effect at a lower toxicity rate with reduced resistance to the medications. There is an improved long-term survival rate when a localized osteosarcoma is removed and chemotherapy is initiated. Soft tissue sarcomas are treated with radiation, limb-sparing excision, and adjuvant chemotherapy.

Secondary Bone Tumors

The treatment of metastatic bone cancer is palliative. The therapeutic goal is to relieve the patient's pain and discomfort while promoting QOL.

If metastatic disease weakens the bone, structural support and stabilization are needed to prevent pathologic fracture. At times, large bones with metastatic lesions are strengthened by prophylactic internal fixation. Internal fixation of pathologic fractures, arthroplasty, or methylmethacrylate (bone cement) reconstruction minimizes associated disability and pain. Patients with metastatic disease are at higher risk than other patients for postoperative pulmonary congestion, hypoxemia, deep vein thrombosis, and hemorrhage.

Hypercalcemia results from breakdown of bone. It needs to be recognized promptly. Treatment includes hydration with IV administration of normal saline solution; diuresis; mobilization; and medications such as bisphosphonates, pamidronate, and calcitonin (refer to Chapter 6 for further details on hypercalcemia). Because inactivity leads to loss of bone

mass and increased calcium in the blood, the nurse assists the patient to increase activity and ambulation.

Frequently hematopoiesis is disrupted by tumor invasion of the bone marrow or by treatment (chemotherapy or radiation). Blood component therapy restores hematologic factors. Pain can result from multiple factors, including the osseous metastasis, surgery, chemotherapy or radiation side effects, and arthritis. Pain must be assessed accurately and managed with adequate and appropriate opioid, nonopioid, and nonpharmaceutical interventions. In the absence of fracture, external beam radiation may be used for painful metastatic sites. Systemic chemotherapy or endocrine therapy also may be considered for palliation. Patients with multiple bony metastases may achieve pain control with systemically administered “bone-seeking” isotopes (e.g., strontium-89).

Nursing Management

The nursing care of a patient who has undergone excision of a bone tumor is similar in many respects to that of other patients who have had skeletal surgery. Vital signs are monitored; blood loss is assessed; and observations are made to assess for the development of complications, such as deep vein thrombosis, pulmonary emboli, infection, contracture, and disuse atrophy. The affected part is elevated to reduce edema, and the neurovascular status of the extremity is assessed.

Providing Patient Education

Patient and family teaching about the disease process and diagnostic and management regimens is essential. Explanation of diagnostic tests, treatments (e.g., wound care), and expected results (e.g., decreased ROM, numbness, change of body contours) helps the patient deal with the procedures and changes. Cooperation and adherence to the therapeutic regimen are enhanced through understanding. The nurse can most effectively reinforce and clarify information given by the provider by being present during these discussions.

Relieving Pain

Accurate pain assessment is the foundation for pain management. Pharmacologic and nonpharmacologic pain management techniques are used to relieve pain and increase the patient's comfort level. The nurse works with the patient in designing the most effective pain management regimen, thereby increasing the patient's control over the pain. Prescribed IV or epidural analgesics are used during the early postoperative period. Later, oral or transdermal opioid or nonopioid analgesics are indicated to alleviate pain. In addition to external radiation, systemic radioisotopes may be used to control pain. See Chapter 7 for further discussion of pain management.

Preventing Pathologic Fracture

Bone tumors weaken the bone to a point at which normal activities or even position changes can result in fracture. During nursing care, the affected extremities must be supported and handled gently. External supports (e.g., splints) may be used for additional protection. At times, the patient may elect to have surgery (e.g., open reduction with internal fixation, joint replacement) in an attempt to prevent pathologic fracture. Prescribed weight-bearing restrictions must be followed. The nurse and physical therapist teach the patient how to use assistive devices safely and how to strengthen unaffected extremities.

Promoting Coping Skills

The nurse encourages the patient and family to verbalize their fears, concerns, and feelings. They need to be supported as they deal with the impact of the malignant bone tumor. Feelings of shock, despair, and grief are expected. Referral to a psychiatric advanced practice nurse, psychologist, counselor, or spiritual advisor may be indicated for specific

psychological help and emotional support.

Promoting Self-Care

Independence versus dependence is an issue for the patient who has a malignancy. Lifestyle is changed dramatically, at least temporarily. It is important to support the family in working through the adjustments that must be made. The nurse assists the patient in dealing with changes in body image due to surgery and possible amputation. It is helpful to provide realistic reassurance about the future and resumption of role-related activities and to encourage self-care and socialization. The patient participates in planning daily activities. The nurse encourages the patient to be as independent as possible. Involvement of the patient and family throughout treatment encourages confidence, restoration of self-concept, and a sense of being in control of one's life.

Monitoring and Managing Potential Complications

Delayed Wound Healing

Wound healing may be delayed because of tissue trauma from surgery, previous radiation therapy, inadequate nutrition, or infection. The nurse assesses the patient's nutritional status by monitoring weight, percentage of weight loss, and evaluating the serum albumin or prealbumin level. An unintentional weight loss of 10% of usual body weight in 3 months is a risk factor for malnutrition.

Nursing Alert

The nurse monitors and reports laboratory markers related to nutritional status. Serum prealbumin has a shorter half-life (2 days) than albumin (21 days) and is not influenced by fluid balance, making it an excellent marker for malnutrition. A normal prealbumin level is 19 to 38 mg/dL with values of 0 to 5, 5 to 10, and 10 to 15 mg/dL reflecting a severe, moderate, and mild protein depletion, respectively (Fischbach & Dunning, 2014). Interventions that promote homeostasis and wound healing should be initiated as soon as possible. In addition, the nurse considers that the patient's requirements for calories, protein, vitamins, and minerals will be expected to increase in times of stress.

The nurse minimizes pressure on the wound site to promote circulation to the tissues. Repositioning the patient at frequent intervals reduces the incidence of skin breakdown and pressure ulcers. Special therapeutic beds may be needed to prevent skin breakdown and to promote wound healing after extensive surgical reconstruction and skin grafting.

Inadequate Nutrition

Because loss of appetite, nausea, and vomiting are frequent side effects of chemotherapy and radiation therapy, it is necessary to provide adequate nutrition for healing and health promotion. Antiemetics, relaxation techniques, and acupuncture reduce the adverse GI effects of chemotherapy. Stomatitis is controlled with anesthetic or antifungal mouthwash (see Chapter 6). Adequate hydration is essential. Nutritional supplements and enteral or parenteral nutrition may be prescribed to achieve adequate nutrition.

Osteomyelitis and Wound Infections

Prophylactic antibiotics and strict aseptic dressing techniques are used to diminish the occurrence of osteomyelitis and wound infections. During healing, other infections (e.g., upper respiratory infections) need to be prevented so that hematogenous spread does not result in osteomyelitis. If the patient is receiving chemotherapy, it is important to monitor the WBC count and to instruct the patient to avoid contact with people who have colds or other infections.

Hypercalcemia

Hypercalcemia is a dangerous complication of bone cancer. The symptoms must be recognized and treatment initiated promptly. Symptoms include muscular weakness, incoordination, anorexia, nausea and vomiting, constipation, electrocardiographic changes (e.g., shortened QT interval and ST segment, bradycardia, heart blocks), and altered mental states (e.g., confusion, lethargy, psychotic behavior). See Chapter 6, Table 6-6 for a discussion of hypercalcemia and its management.

CHAPTER REVIEW

Critical Thinking Exercises

1. At the general medical clinic where you are a nurse, a 64-year-old woman presents with acute onset of low back pain. You discover that she has a history of long-term alcohol use and has smoked one pack of cigarettes daily for the past 45 years. What musculoskeletal conditions is she at risk of developing? What specific questions would you ask her to determine the status of her bone health? Discuss the strength of the evidence that supports any risk factor reduction strategies you consider implementing.

2. You are a home care nurse who is about to visit a 26-year-old patient with osteomyelitis that occurred after a fracture to the left tibia and fibula sustained in a motorcycle crash. What is the strength of the evidence that identifies factors that affect bone healing? Discuss the significance of these factors in determining your health-teaching strategies for this patient.

3. You are caring for an elderly patient who has advanced cancer. During the afternoon, she complains of muscle weakness, extreme fatigue, anorexia, and nausea. Her urinary output is also elevated. What laboratory value would you assess? What nursing interventions would you implement in light of her new symptoms? What might be the pathophysiology behind these new symptoms?

NCLEX-Style Review Questions

1. A 25-year-old woman experienced an open fracture of the right fibula with major soft tissue damage of her lower leg in a motor vehicle accident. Surgical reduction and fixation of the fibula were performed with débridement of nonviable tissue and drain placement in the damaged soft tissue. Which complication is this patient at risk for?

a. Osteoporosis
b. Osteomyelitis
c. Fat emboli
d. Compartment syndrome

2. Which assessment finding may indicate to the nurse an acute peripheral neurovascular dysfunction for the patient recovering from surgery of the foot?
a. Pale skin, atrophy of the limb, with capillary refill of 2 seconds
b. Absence of feeling, capillary refill of 4 to 5 seconds, and cool skin
c. Atrophy of limb, increased motion, and thickened toe nails
d. Pale skin, weakness in motion, and loss of toe hairs

3. Which assessment finding would the nurse expect to find in a patient diagnosed with acute osteomyelitis?
a. Leukopenia and localized bone pain
b. Leukocytosis and elevated sedimentation (SED) rate
c. Leukopenia and elevated fever
d. Petechiae over the chest and abnormal arterial blood gas (ABG) results

4. A client is diagnosed with osteoporosis. Which statements should the nurse include when teaching the client about the disease? *Select all that apply*.
a. Osteoporosis is common in females after menopause.
b. Osteoporosis is a degenerative disease characterized by an increase in bone density.
c. Osteoporosis can increase the risk for fractures.
d. The recommended daily calcium dose should be taken as a single dose, and the patient should be instructed not to lie down for 30 minutes.
e. Weight-bearing exercise should be avoided.
f. The patient's T score is at least 2.5 SD below the young adult mean value on the BMD scan.

5. What places the patient at risk for impaired wound healing after surgery for a primary bone cancer? *Select all that apply*.
a. Radiation therapy
b. Prealbumin level is 28 mg/dL
c. Weight loss of 18% over the previous 3 months
d. Anorexia
e. Satisfactory vitamin C levels

CHAPTER 42

Nursing Management: Patients with Musculoskeletal Trauma

Linda Honan

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate between contusions, strains, sprains, and dislocations.
2. Specify the clinical manifestations of a fracture and the emergency management of the patient with a fracture.
3. Describe the principles and methods of fracture reduction, fracture immobilization, and management of open fractures.
4. Describe the prevention and management of complications of fractures.
5. Discuss nursing management of the patient with a cast.
6. Discuss nursing management of the patient undergoing joint replacement or amputation.

Injury to any part of the musculoskeletal system necessitates evaluation of the damaged area, along with assessment of the structures and organs that underlie the fracture. For example, if a bone is broken, the adjacent muscles cannot function, blood vessels and nerves may be injured with resultant neurovascular complications, and the organs that lie beneath the fracture may have damage secondary to the trauma.

Treatment of injury to the musculoskeletal system involves providing support to the injured part until healing is complete. Frequently, management includes the use of internal and/or external devices, such as bandages, splints, casts, skin or skeletal traction, artificial joint replacement, pins, or a combination of these. Pharmacologic treatment often includes anti-inflammatory agents, muscle relaxants, and analgesics. They may help diminish edema and relax muscles at risk for spasm that can cause further injury to inflamed muscles or to fractured bones. Pain relief is an important factor to facilitate healing.

Patient education is essential for optimal outcomes. Nursing care is planned to maximize the effectiveness of treatment modalities, prevent potential complications associated with interventions, and observe for the development of untoward signs and symptoms as soon as possible. After the immediate and painful effects of the injury have passed, treatment efforts are focused on preventing fibrosis and atrophy or degeneration of the injured muscles and joint structures, respectively.

COMMON MUSCULOSKELETAL INJURIES

Contusions, Strains, and Sprains

Pathophysiology

A contusion is an injury to soft tissue produced by blunt force, such as a blow, kick, or fall, that results in bleeding into soft tissues (ecchymosis, or bruising). A *hematoma* (collection of blood within tissues) develops when the bleeding is sufficient to form an appreciable solid swelling. A muscle strain, or a "pulled muscle," is an injury to a musculotendinous unit caused by overuse, overstretching, or excessive stress. It can occur anywhere within the muscle, but it commonly occurs at the distal muscle-tendon junction (Nelson, 2014). Recall, a tendon connects muscle to bone, whereas a ligament connects bone to bone. A sprain is an injury to the ligaments and supporting muscle fibers that surround a joint often caused by a trauma, wrenching, or twisting motion. The injury can range from a mild stretching of the ligament to a complete tear. While a history and physical examination are important, diagnostic studies of the affected extremity may be ordered to determine diagnosis.

Risk Factors

The main risk factor for contusions, strains, or sprains is participation in sports and physical fitness activities. Strains and sprains occur after intense activity or are associated with overuse repetitive injuries or trauma, whereas contusions can occur in any soft tissue that suffers blunt trauma. Ankles, knees, and wrists are vulnerable to sprains, while strains frequently occur in the neck, lower back, and hamstring muscle (back of the thigh). Previous injuries are a risk factor for reinjury.

Clinical Manifestations and Assessment

An important question for nurses to ask when assessing for musculoskeletal injury is, "What were you doing at the time of the injury?" For example, many ankle sprains occur because of inversion injury (turning ankle in while walking), while muscle strains occur because of a "pulled muscle" while exercising. The nurse assesses the threes "S's," size, shape, and symmetry, of the involved area in comparison to the opposite region. It is important to note presence of edema (swelling), ecchymosis (bruising), tenderness, abnormal joint motion, and pain. Contusions, strains, and sprains can present with similar symptoms of pain, edema, and discoloration from the broken blood vessels. The patient may guard or protect the affected area, and he or she may have difficulty moving the affected area; increased warmth may be noted at the injury site.

With contusions, the nurse notes ecchymosis and edema of the injured area. The patient may complain initially of dull pain at the site that increases as edema develops and subsequent stiffness of the area, usually by the next day. Most contusions resolve in 1 to 2 weeks.

Muscle strains are graded along a continuum based on symptoms and loss of function. A first-degree strain reflects tearing of few muscle fibers and is accompanied by minor edema, tenderness (usually noticed after the activity is over), and mild muscle spasm, without a noticeable loss of function. A second-degree strain involves a tearing of more muscle fibers and is manifested by edema, tenderness, muscle spasm, ecchymosis, and a notable loss of load-bearing strength of the involved extremity. A third-degree strain involves complete disruption of at least one musculotendinous unit that involves separation of muscle from muscle, muscle from tendon, or tendon from bone. Patients present with significant pain, muscle spasm, ecchymosis, a large hematoma, edema, and loss of function. An x-ray should be obtained to rule out bone injury because an avulsion fracture (in which a bone fragment is pulled away from the bone by a tendon) may be associated with a third-degree strain.

Like strains, sprains (ligamentous injuries) are graded to reflect the degree of injury. A mild sprain, termed first-degree sprain (a tear of only a few fibers), may cause minor edema, tenderness, and mild muscle spasm, without a noticeable loss of function. Patients are able to bear weight with minimal pain. A second-degree sprain is an incomplete tear of the ligament (bone-to-bone); as blood vessels rupture, ecchymosis and edema are expected and movement of the joint becomes painful. The degree of disability and pain increases during the first 2 to 3 hours after the injury because of the associated swelling and bleeding. There is restricted motion of the affected limb, and weight bearing is painful. A third-degree sprain involves complete ligament tear with resultant complaints of significant pain, muscle spasm, ecchymosis, edema, and loss of function. Patients are unable to bear weight on the affected limb. Tenderness at the distal tibia (inner ankle) or fibula (outer ankle) is associated with an inversion or eversion injury and may indicate a fracture.

BOX 42-1 RICE

The acronym RICE—*R*est, *I*ce, *C*ompression, *E*levation—is helpful for remembering treatment interventions for musculoskeletal injuries.

Rest prevents additional injury and promotes healing. Intermittent application of moist or dry cold packs for 20–30 minutes during the first 24–48 hours after injury produces vasoconstriction, which decreases bleeding, edema, and discomfort. Ensure care to avoid skin and tissue damage from excessive cold. An elastic compression bandage controls bleeding, reduces edema, and provides support for the injured tissues. Elevation controls the swelling.

Medical and Nursing Management

Treatment of contusions, strains, and sprains consists of resting and elevating the affected part, applying cold, and using a compression bandage (Box 42-1). Immobilization of the affected extremity until definite diagnosis is determined may be appropriate. It is important to monitor the neurovascular status of the injured extremity; this is termed CSM: Circulation, by way of pulses, color, temperature, and capillary refill; Sensation, by noting awareness of light touch; and Movement, by range of motion (ROM) of the m ost distal digits. The nurse compares the injured limb to the uninjured limb.

After the acute inflammatory stage (e.g., 24 to 48 hours after injury), intermittent heat application (for 15 to 30 minutes, four times a day) relieves muscle spasm and promotes vasodilation, absorption, and repair. Depending on the severity of injury, progressive passive and active exercises may begin in 2 to 5 days. Severe sprains and strains may require 1 to 3 weeks of immobilization before exercises are initiated. Excessive exercise early in the course of treatment delays recovery. Strains and sprains take weeks or months to heal because ligaments and tendons are relatively avascular. Splinting may be used to prevent reinjury.

JOINT DISLOCATIONS

Pathophysiology

With dislocation of a joint, the articular surfaces of the bones forming the joint are no longer in anatomic alignment. The bones are literally "out of joint." Dislocations may be congenital, or present at birth; spontaneous or pathologic; or traumatic, resulting from injury in which the joint is disrupted by force. A subluxation is a partial dislocation of the articulating surfaces. Traumatic dislocations are orthopedic emergencies because the associated joint structures, blood supply, and nerves are distorted and severely stressed.

Nursing Alert
If the dislocation is not treated promptly, avascular necrosis (AVN), tissue death due to anoxia and diminished blood supply, and nerve palsy may occur. Tenderness at the site, limited ROM, the affected limb being shortened, pain, and asymmetry of limbs is observed. The limb is immobilized and the provider notified.

Clinical Manifestations and Assessment

Signs and symptoms of a traumatic dislocation include acute pain, change in contour of the joint, change in the length of the extremity (shortening of the affected limb), loss of normal mobility, and change in the axis of the dislocated bones. X-rays confirm the diagnosis and reveal any associated fracture.

Medical and Nursing Management

The affected joint needs to be immobilized while the patient is transported to the hospital. The dislocation is reduced promptly (i.e., displaced parts are brought into normal position) to preserve joint function. Analgesia, muscle relaxants, and, possibly, anesthesia are used to facilitate closed reduction (e.g., noninvasive or nonsurgical reduction). The joint is immobilized by bandages, splints, casts, or traction and is maintained in a stable position. Neurovascular status is monitored (temperature, capillary refill, pulses, color, mobility, sensation). After reduction, if the joint is stable, then gentle, progressive, active, and passive movement is begun to preserve ROM and restore strength. The joint is supported between exercise sessions.

SPECIFIC MUSCULOSKELETAL INJURIES

Common specific musculoskeletal injuries include rotator cuff tears, epicondylitis, and injury to the ligaments of the knee. Table 42-1 summarizes key findings and treatment for these common injuries.

FRACTURES

A fracture is a break in the continuity of bone caused by direct blows, crushing forces, sudden twisting motions, and extreme muscle contractions. When the bone is broken, adjacent structures also are affected, resulting in soft tissue edema and hemorrhage into the muscles and joints, with potential joint dislocations, ruptured tendons, severed nerves, and damaged blood vessels. Because body organs may be injured by the force that caused the fracture or by fracture fragments, it is important for nurses to have knowledge of the organs that lie beneath the fracture. For example, the nurse is alert for liver injuries with fractures to right ribs 6 through 12 and splenic injuries with fractures to left ribs 9 through 11. In addition to the magnitude of the force on the bone, the nurse needs to consider the strength of the bone, which is related directly to its density. Thus a lower force may create a fracture because of bone weakness (e.g., osteoporosis or bone cysts).

Types of Fractures

Fractures are defined according to the bone involved (e.g., humerus, femur, tibia) and can be categorized in several ways, including the direction of the fracture. A *complete fracture* involves a break across the entire cross-section of the bone and frequently is displaced (removed from its normal position). An *incomplete fracture* (e.g., greenstick fracture) involves a break through only part of the cross-section of the bone. An *oblique fracture* runs across the bone at a diagonal angle of 45 to 60 degrees. A *comminuted* fracture is one that produces several bone fragments, while an *impacted* fracture is one whose ends are driven into each other. A *closed fracture* (simple fracture) is one that does not cause a break in the skin. An *open fracture* (compound or complex fracture) is one in which the wound to the skin or mucous membrane extends to the fractured bone. Some fractures have specific names, for example, a fracture of the distal radius (wrist) is termed a *Colles fracture. Stress fractures* occur with repeated bone trauma from athletic activities, most frequently involving the tibia and metatarsals. *Compression fractures* are caused by compression of vertebrae and are associated frequently with osteoporosis. Figure 42-1 depicts types of fractures.

Nursing Alert
On x-rays, long bone fractures will be categorized as proximal (closest to or toward the center of the body), middle, or distal (the portion of the bone that is farthest away). The term intra-articular fracture extends into the joint space, whereas fractures not involving the joint are termed extra-articular. In children, fractures are described in relation to the growth plate (physis); thus, if a fracture is seen between the joint and the growth plate, it will be termed an epiphyseal fracture. A diaphysis fracture refers to the shaft of the bone and metaphysis is between the epiphysis and the diaphysis.

TABLE 42-1 Specific Musculoskeletal Injuries

Injury	Description	Key Assessment Findings	Treatment
Rotator cuff tears	Tear results from an acute injury or from chronic joint stresses; it occurs when there is damage to one or more of the four muscles and their tendons in the shoulder.	• Acromioclavicular joint pain; in many cases, the patient with a rotator cuff tear experiences night pain and cannot sleep on the involved side. • Limited ROM; the patient cannot perform over-the-head activities or activities as simple as putting on a coat. • Muscle weakness	• Rest and modalities such as hot packs, ultrasound, or cold applications, with specific ROM exercises as soon as tolerated. • Nonsteroidal anti-inflammatory drugs (NSAIDs) but most frequent treatment is steroid injection into the shoulder joint or • Arthroscopic débridement (removal of devitalized tissue) • Arthroscopic or open acromioplasty with tendon repair
Epicondylitis (tennis elbow)	Chronic, painful condition that is caused by excessive, repetitive extension and flexion and/or pronation and supination activities of the forearm. These excessive, repetitious activities result in inflammation (**tendinitis**) and minor tears in the tendons at the origin of the muscles on the medial or lateral epicondyles.	• Pain that usually radiates down the extensor (dorsal) surface of the forearm and generally is relieved with rest and avoidance of the aggravating activity • Weakened grasp	• Application of ice for pain after the activity • NSAIDs for pain • In some instances, immobilization of the arm in a molded splint or cast is necessary. • Local injection of a corticosteroid generally is reserved for patients with severe pain who do not respond to NSAIDs and immobilization because of its degenerative effects on tendons. • After pain subsides, rehabilitation exercises that stretch and strengthen the area (including gentle and gradual increased stretching of the tendons) • Tennis elbow counterforce strap that limits extension of the elbow (may be prescribed when activity is resumed) • Occasionally, surgery to release strictures or to débride the joint

Knee injury	Injury to the anterior cruciate ligament (ACL) or the posterior cruciate ligament (PCL), which stabilize forward and backward motion of the femur and tibia, occurs when the foot is firmly planted and the knee is hyperextended and the person twists the torso and femur. Injury to the lateral or medial collateral ligaments of the knee, which provide stability lateral and medial to the knee, occurs when the foot is firmly planted and the knee is struck either medially or laterally.	• Acute onset of pain
		• Point tenderness (e.g., tenderness at the site of injury)
		• Joint instability and inability to walk without assistance
		• Hemarthrosis (bleeding into the joint) may develop, contributing to the pain.
			• Treatment will depend on the severity of the injury, but may include:
			  • RICE
			  • Evaluation of the joint for fracture
			  • Aspiration of joint fluid to relieve pressure
			  • Limited weight bearing
			  • Use of protective elastic bandaging or brace
			  • Surgery; the operation is typically performed as ambulatory arthroscopic surgery, in which the surgeon uses an **arthroscope** to visualize and repair the damage.

Clinical Manifestations and Assessment

The diagnosis of a fracture is based on the patient's symptoms, the physical signs, and the x-ray findings. Usually, the patient reports having sustained an injury to the area. The clinical manifestations of a fracture include pain, loss of function, deformity, shortening, crepitus (described shortly), swelling, and discoloration. These clinical manifestations do not all need to be present in every fracture.

Pain

The pain is immediate, continuous, and increases in severity until the bone fragments are immobilized. The muscle spasms that accompany a fracture begin shortly after the injury and result in increasing pain intensity and further bony fragmentation or malalignment.

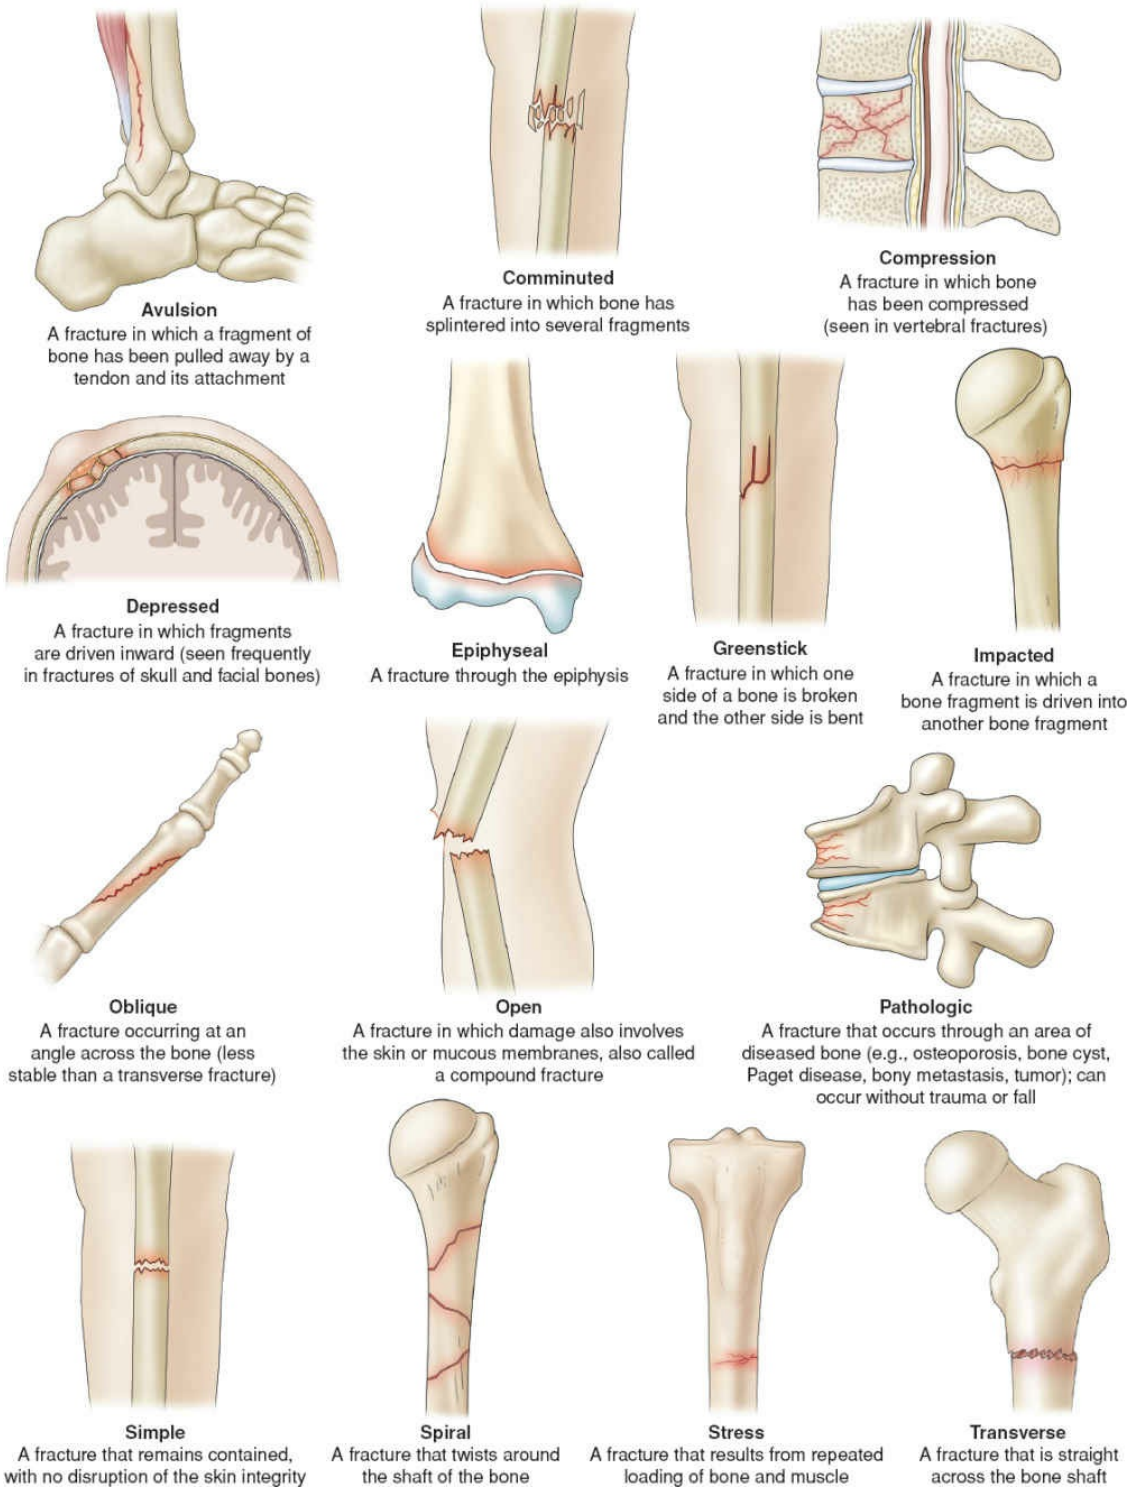

FIGURE 42-1 Specific types of fractures.

Loss of Function

After a fracture, the extremity cannot function properly because normal function of the muscles depends on the integrity of the bones to which they are attached. Pain contributes to the loss of function. In addition, abnormal movement (false motion) may be present.

Deformity

Displacement, angulation, or rotation of the fragments in a fracture or soft tissue swelling causes a visible or palpable deformity. Movement may be noted at the fracture site, whereas under normal circumstances, movement of bones occurs only at joint.

Shortening

In fractures of long bones, there is actual shortening of the extremity because of the contraction of the muscles that are attached distal (furthest away) and proximal (nearest) to the site of the fracture. The fragments often overlap by as much as 2.5 to 5 cm (1 to 2 in).

Crepitus

Palpation of the extremity reveals a grating sensation, called crepitus, caused by the rubbing of the bone fragments against each other.

Swelling and Discoloration

Localized edema and ecchymosis occur as a result of trauma and bleeding into the tissues.

Fracture Blisters

Fracture blisters are tense blisters or bullae (large blister) associated with high-energy injuries commonly occurring in the ankle, elbow, foot, and/or knee. These sites have less anchoring of epidermal–dermal junction and little subcutaneous fat cushioning than do other areas in the limbs. Nurses should be alert to the potential for compartment syndrome (discussed on page 24) since fracture blisters represent underlying increased pressure. Prompt surgical intervention may reduce the incidence of fracture blister formation (within 4 hours after the acute injury). However, the presence of a fracture blister requires an alteration of the surgical approach or a delay in surgery because of potential increase in infection and skin breakdown (Geiderman & Katz, 2014). If possible, fracture blisters should not be disrupted because of risk of infection with skin flora. An ointment, such as silver sulfadiazine, may be applied to the blister to promote re-epithelialization and to prevent infection (Howe, 2016).

Managing Fractures

Immediately after injury, whenever a fracture is suspected, it is important to immobilize the body part before the patient is moved. If an injured patient must be moved before extremity splints can be applied, support the limb distal and proximal to the fracture site to prevent rotation as well as angular motion. It is important to recognize that movement of fracture fragments can cause additional pain, soft tissue damage, and neurovascular damage. Splinting a fracture can include bandaging the legs together, with the unaffected extremity serving as a splint for the injured one. In an upper extremity injury, the arm can be bandaged to the chest, a forearm placed in a sling, or a finger can be taped to the adjacent digit. Taping, splinting, or bandaging too tightly may cause impaired distal perfusion and thus is avoided. Immobilization is applied to the joints above and below the fracture. Neurovascular status distal to the injury is assessed before and after splinting to determine the adequacy of peripheral tissue perfusion and nerve function. An assessment of the

patient also includes observing for the five warning "P's" associated with acute disruption of arterial flow: pain, poikilothermia (cold limb), pallor (paleness), paresthesia (can range from numbness, "pins and needles," burning, itching, and/or tingling), and pulselessness (weak pulses or delayed capillary refill; normal is less than 2 seconds).

If cervical and thoracolumbar spinal injuries are suspected, immobilization of the spine via cervical collar or spinal backboard as well as the avoidance of movement is essential. If moving is necessary, log rolling with the appropriate number of staff is used. Refer to Chapter 45 for further details of spinal fractures.

With an open fracture, the wound is covered with a sterile dressing to prevent contamination of deeper tissues. No attempt is made to reduce the fracture, even if one of the bone fragments is protruding through the wound. The patient is transferred to the hospital for treatment. Tetanus prophylaxis will be administered in the emergency room (ER) if the last known booster was over 5 years ago.

An immediate priority is maintaining hemodynamic stability. Hypovolemic shock, resulting from hemorrhage (both visible and nonvisible blood loss) and from loss of intravascular volume into the interstitial space, may occur in fractures of the extremities, thorax, pelvis, or spine. Because the bone is very vascular, large quantities of blood may be lost as a result of trauma, especially in fractures of the femur and pelvis. A closed fracture of the femur can have an estimated blood loss (EBL) of 1,000 to 1,500 mL, while a closed fracture of the tibia can be 500 to 1,000 mL. A closed humerus fracture can result in the loss of 250 mL, EBL for fracture to the radius and ulna can be 150 to 250 mL, while a pelvic fracture can cause the loss of 3 to 4 L of blood (Geiderman & Katz, 2014). An open fracture results in greater EBL, and increased risk of infection. The nurse is aware that bleeding is a common problem with fractures. The elderly may be at increased risk if vasoconstriction is insufficient to maintain blood pressure. When an acute loss of 15% to 20% of blood volume occurs, a state of inadequate blood volume exists. This has a direct impact on perfusion; as the perfusion decreases, cardiac output falls, and multiple organ failure can occur. Box 42-2 provides focused assessment guidelines for hypovolemic shock. Treatment of shock consists of stabilizing the fracture to prevent further hemorrhage, restoring blood volume and circulation, relieving the patient's pain, providing adequate splinting, and protecting the patient from further injury and other complications.

BOX 42-2 Focused Assessment

Hypovolemic Shock

Be alert for the following signs and symptoms:

- Thirst
- Anxiety, restlessness, altered sensorium
- Elevated heart rate
- Weak pulse (thready)
- Decreased blood pressure
- Cool, clammy skin
- Decreased urine output

- Decreased pulse pressure (difference between the systolic and diastolic pressure)
- Decreased blood pressure; mean arterial pressure (MAP) below 65 mm Hg
- Rapid, shallow respirations
- Delayed capillary refill

Surgical Management

Many patients with unstable fractures undergo surgery to correct the condition. Frequent surgical procedures include open reduction with internal fixation (ORIF) and closed reduction with internal fixation (the fracture is reduced prior to making a surgical incision for "internal fixation" of the fracture) for fractures; amputation for severe extremity conditions (e.g., massive trauma); bone graft for joint stabilization, defect filling, or stimulation of bone healing; and tendon transfer for improving motion.

Ongoing Management

Nursing goals include improving function by restoring motion and stability, and relieving pain and disability. The principles of fracture treatment include reduction, immobilization, and regaining of normal function and strength through rehabilitation.

Reduction

Reduction of a fracture ("setting" the bone) refers to restoration of the fracture fragments to anatomic alignment and rotation. Either closed reduction or open reduction may be used to reduce a fracture. Before fracture reduction and immobilization, the nurse prepares the patient for the procedure, assures permission for the procedure is obtained, and administers an analgesic as prescribed. The nurse gently handles the injured extremity to avoid additional damage.

Closed Reduction. In most instances, closed reduction is accomplished through manipulation and manual traction. The extremity is held in the desired position while the provider applies a cast, splint, or other device. Reduction under anesthesia with percutaneous pinning may be used. The immobilizing device maintains the reduction and stabilizes the extremity for bone healing. X-rays are obtained to verify that the bone fragments are aligned correctly.

Traction (skin or skeletal) may be used to effect fracture reduction and immobilization. Traction is discussed later in the chapter.

Open Reduction. With an open fracture, surgical intervention is needed to align the bone fragments. Internal fixation devices (metallic pins, wires, screws, plates, nails, or rods) are used to hold the bone fragments in position until bone healing occurs (Fig. 42-2). Internal fixation devices ensure firm approximation and fixation of the bony fragments. They are not designed to support the body's weight, and they can bend, loosen, or break if stressed. The estimated strength of the bone, the stability of the fracture, reduction and fixation, and the amount of bone healing are important considerations in determining weight-bearing

limits. Although the incision may appear healed, the underlying bone requires more time to repair and regain normal strength. Some orthopedic procedures require weight-bearing restrictions. The orthopedic surgeon will prescribe the weight-bearing limits and the use of protective devices (orthoses), if necessary, after surgery.

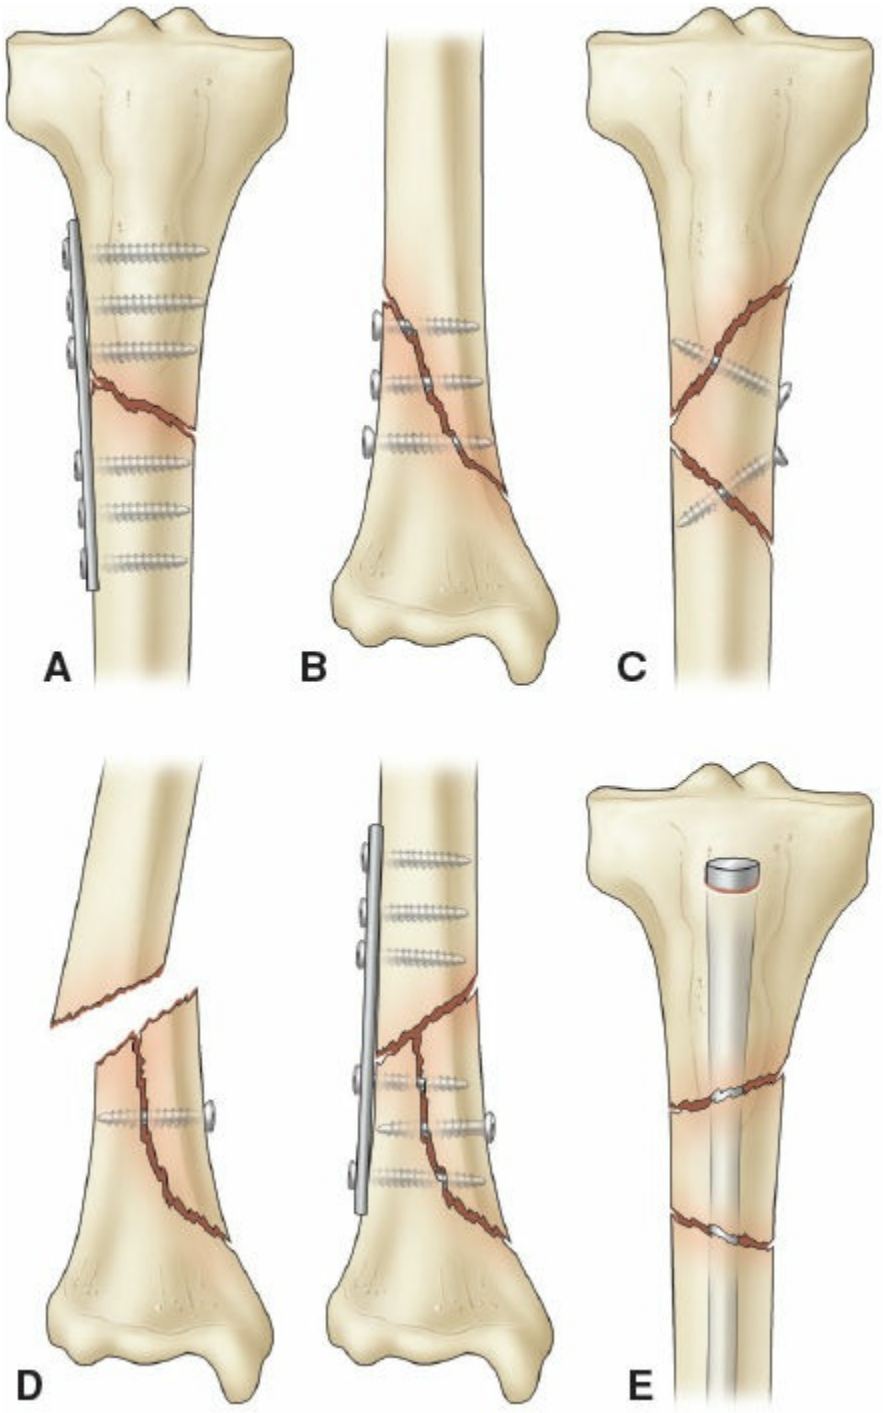

FIGURE 42-2 Techniques of internal fixation. A. Plate and six screws for a transverse or short oblique fracture. B. Screws for a long oblique or spiral fracture. C. Screws for a long butterfly fragment. D. Plate and six screws for a short butterfly fragment. E. Medullary nail for a segmental fracture.

Management of an Open Fracture

For patients with open fractures, prompt, thorough wound irrigation and débridement are necessary to remove foreign bodies, obvious debris, and bacteria. Often this is performed in the operating room. Once the wound is cleaned, the fracture is carefully reduced and stabilized by internal and/or external fixation. All open fractures are considered contaminated and carry risks for osteomyelitis (bone infection), tetanus, and gas gangrene. For this reason, systemic antibiotics are generally ordered and administered within 6 hours after open trauma to reduce the risk of soft tissue infection or osteomyelitis (Sebastin, Chung, & Ono, 2015). The nurse is mindful that fixation of fractures carries a risk of infection. The objectives of management are to prevent infection of the wound, soft tissue, and bone, and to promote healing of soft tissue and bone. Options include sterile dressing changes to allow drainage of wound and edema from heavily contaminated injuries; the use of wound vacuum–assisted closure (VAC) device; or re-exploration of the wound with débridement as necessary to remove infected and devitalized (dead) tissue and increase vascularity in the region. After it has been determined that infection is not present, the wound is closed by grafting of autogenous (patient's own tissue) skin, or a flap, or healing by secondary intention (a full-thickness wound heals from the base upward, by laying down new tissue). The nurse instructs the patient or family to monitor temperature at regular intervals and report signs of infection to their provider (Box 42-3). Infections must be treated promptly. In 4 to 8 weeks, bone grafting may be necessary to bridge bone defects and to stimulate bone healing.

BOX 42-3 Focused Assessment

Infection with an Open Fracture

Be alert for signs and symptoms of infection:

- Elevated temperature
- Tachycardia
- Tachypnea
- Redness, warmth, tenderness, purulent drainage at wound site
- Leukocytosis (elevated WBCs)

Nursing Alert

Do not rely on fever as a marker for infection in the elderly. Consider change in the level of consciousness as an indication of suspicion.

Immobilization

After the fracture has been reduced, the bone fragments must be immobilized, or held in correct position and alignment, until union occurs. Internal fixation, as described above, or external fixation via bandages, casts, and splints are methods used to immobilize fractures. Casts are discussed later in the chapter.

Unfolding Patient Stories: Marilyn Hughes • Part 1

Marilyn Hughes, a 45-year-old female, was brought to the emergency department by her husband after a fall down icy stairs. She is complaining of severe left lower leg pain. She is wearing long pants and boots. What are priority assessments and interventions that the nurse should implement for a suspected lower leg fracture? (Marilyn Hughes' story continues in Chapter 43.)

Care for Marilyn and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Nursing Management

The major goals for the patient with a fracture include knowledge of the treatment regimen, relief of pain, improved physical mobility, achievement of maximum level of self-care, healing of any trauma-associated lacerations and abrasions, maintenance of adequate neurovascular function, and absence of complications.

Teaching Related to Treatment Regimen

Anticipatory guidance is provided to the patient and significant others by explaining the sights, sounds, and sensations (e.g., heat from the hardening reaction of the plaster) associated with application of the internal or external device chosen to treat the fracture. Specific treatment modalities are discussed later in the chapter. Regardless of the treatment modality chosen for the fracture, patient teaching includes self-care, medication information, monitoring for potential complications, and the need for continuing health care supervision. Fracture healing and restoration of full strength and mobility may take many months.

Relieving Pain

The nurse must carefully evaluate pain associated with musculoskeletal conditions, asking the patient to indicate the exact site, character, and intensity of the pain to help determine its cause. Pain associated with the underlying condition (e.g., fracture) is frequently controlled by immobilization. Pain due to edema that is associated with trauma, surgery, or bleeding into the tissues frequently can be controlled by elevation and, if prescribed, intermittent application of cold packs. Ice bags (one third to one half full) or cold application devices are placed on each side of the cast or fixator, if prescribed, making sure not to indent the cast or put undue pressure on external pins. Analgesics are administered as prescribed.

Also pain may be indicative of complications. Unrelenting pain that is unresponsive to usual treatment measures (narcotics, elevation, cold) is associated with compartment syndrome. Severe pain over a bony prominence may warn of an impending pressure ulcer. Discomfort due to pressure on the skin may be relieved by elevation that controls edema or by positioning that alters pressure. However, the affected limb must be elevated no higher than heart level to ensure adequate arterial perfusion. If the fracture is casted, it may be necessary to modify the cast or to apply a new cast.

Nursing Alert
The nurse must never ignore complaints of pain from the patient in a cast because of the possibility of problems such as impaired tissue perfusion or pressure ulcer formation.

Improving Mobility

Every joint and digit that is not immobilized should be exercised and moved through its ROM to maintain function. The nurse encourages the patient to assist in the repositioning,

if not contraindicated, by use of the trapeze or bed rail. If a patient has a spica cast (a cast that stabilizes the hips and thighs, also known as a body cast), a stabilizing abduction bar may be incorporated into the cast to maintain the legs in an abducted position. This bar should never be used as a turning device. If internal fixation is required to stabilize the fracture, the provider determines weight-bearing activity.

Because deep vein thrombosis (DVT) is a significant risk for the immobilized patient, the nurse encourages the patient to do active flexion–extension foot and ankle exercises and isometric contraction of the calf muscles (calf-pumping exercises) every hour while awake to decrease venous stasis in the unaffected limb. In addition, elastic stockings, intermittent compression devices, such as Venodyne boots, and anticoagulant therapy may be prescribed to help prevent thrombus formation. The nurse encourages the patient to move digits and joints distal to the injury hourly when awake to prevent problems related to inactivity (Murr, 2016).

Maintaining Adequate Neurovascular Function

The immobilized extremity's neurovascular status is assessed at least every hour initially, always comparing the affected extremity to the noninjured one. The nurse assesses for the "five P's," as described previously. Edema is a natural response of the tissue to trauma. If the edema is significant, pressure can rise within the area, compromising circulation as well as nerve and motor function. Early recognition of diminished circulation and nerve function, therefore, is essential to prevent loss of function. The affected extremity is adjusted so that it is no higher than heart level to control edema but not impede arterial perfusion. The surgeon is notified at once if signs of compromised neurovascular status are present. The nurse assesses the sensory and motor function of major nerves in the area of injury. Diminished circulation and nerve function must be treated promptly by release of constricting bandages. Refer to Box 42-4 for assessment of peripheral nerves of the upper extremities.

BOX 42-4 GUIDELINES FOR NURSING CARE

Assessing the Radial, Medial, and Ulnar Nerves

Implementation

NURSING ACTION	RATIONALE
1. To assess the radial nerve, ask the patient to extend the forefinger against resistance. If you suspect radial nerve damage, check the sensation at the web space between the thumb and index finger by asking the patient to describe the sensation to light touch.	1. Inability to extend finger or lack of sensation suggests radial nerve abnormality.
2. To test for median nerve integrity, ask the patient to make the "OK" sign using the thumb and forefinger to make a ring. Check the strength of the "O" by trying to open it with your fingers. Assess sensation on the distal surface of the index finger.	2. Weakness indicates a median nerve abnormality.
3. To assess the ulnar nerve, ask the patient to spread his fingers as widely as possible. Also check sensation to the little finger and the ulnar half of the ring finger by asking the patient to describe the sensation as you touch the area described.	3. Difficulty spreading fingers or lack of sensation suggests ulnar neuropathy.

Normal findings of the fractured limb include minimal edema and discomfort, pink color, warm to touch, capillary refill less than 2 seconds, normal sensations, and ability to move fingers or toes. Numbness, tingling, and burning may be caused by nerve injury from pressure at the fracture site. The nurse instructs the patient to report any changes in sensation or movement immediately so that they can be evaluated promptly.

Maintaining and Restoring Function

It is important to teach exercises to maintain the health of unaffected muscles and to increase the strength of muscles needed for transferring and for using assistive devices (e.g., crutches, walker, special utensils). The nurse and physical therapist teach patients how to use assistive devices safely. Isometric and muscle-setting exercises (discussed later in the chapter) are encouraged to minimize disuse atrophy and to promote circulation. Participation in activities of daily living (ADLs) is encouraged to promote independent functioning and self-esteem. Gradual resumption of activities is promoted within the therapeutic prescription. With internal fixation, the surgeon determines the amount of movement and weight-bearing stress the extremity can withstand and prescribes the level of activity. Plans are made to help patients modify their home environment as needed and to secure personal assistance if necessary.

Monitoring and Managing Potential Complications

Fat Embolism Syndrome

Emboli are clots that travel. In pelvic or long-bone fractures, in trauma patients, or in orthopedic surgeries, the fat globules released when the bone was fractured may occlude the small blood vessels that supply the lungs, brain, kidneys, and other organs.

At the time of fracture, fat globules may diffuse into the vascular compartment because the marrow pressure is greater than the capillary pressure or because catecholamines elevated by the patient's stress reaction mobilize fatty acids and promote the development of fat globules in the bloodstream (Porth, 2015). The onset of symptoms is rapid, usually within 12 to 72 hours of injury (Newbigin et al., 2016). Risk factors for fat embolism syndrome (FES) include trauma, fracture of long bones or pelvic bones, multiple fractures, crush injuries, or orthopedic surgery (intramedullary nail fixation, fixation of multiple fractures). FES occurs most frequently in young adults (typically in those 20 to 30 years of age) and in elderly adults who experience fractures of the proximal femur (hip fracture). Time to surgery has been implicated as a risk factor for FES; a fivefold decrease in the rate of FES was noted if surgery (intramedullary nail fixation) was performed in the first 24 hours of injury (Newbigin et al., 2016).

Presenting features of FES include a triad of pulmonary, central nervous system (CNS), and skin manifestations, which may include a change in behavior and disorientation combined with respiratory compromise (nearly 90% of symptoms are pulmonary) and a petechial rash (Newbigin et al., 2016). The nurse observes for hypoxia, tachypnea, tachycardia, and pyrexia. The respiratory distress response includes dyspnea, crackles, wheezes, and substernal chest pain. The cerebral disturbances (due to hypoxia and the lodging of fat emboli in the brain) manifest by mental status changes varying from headache and mild agitation to confusion, delirium, and coma. The skin manifestations include petechial rash to the axillary, subconjunctival, or chest (upper anterior torso)

region; however, this rash does not appear until 3 to 5 days after the onset of respiratory symptoms and thus is generally not helpful in establishing an early diagnosis (Newbigin et al., 2016).

Occlusion of a large number of small vessels causes the pulmonary pressure to rise. Edema and hemorrhages in the alveoli impair oxygen transport, leading to hypoxia. Arterial blood gas values show the partial pressure of oxygen (PaO_2) to be less than 70 mm Hg, with early respiratory alkalosis (hyperventilation) and later respiratory acidosis (hypoventilation). The chest x-ray reveals a typical "snowstorm" infiltrate; however, this finding is associated with other pathologies, thus a CT of the chest and, in particular, high-resolution CT (HRCT) is the modality of choice to assess for FES (Newbigin et al., 2016). Magnetic resonance imaging (MRI) may be performed to diagnose cerebral fat embolism. Without prompt, definitive treatment, acute pulmonary edema, acute respiratory distress syndrome (ARDS), and heart failure may develop.

With systemic embolization, the patient appears pale. Petechiae, possibly due to a transient thrombocytopenia, are noted in the buccal membranes and conjunctival sacs, on the hard palate, and over the chest and anterior axillary folds. The patient develops a fever greater than 39.5°C (~103°F). Free fat may be found in the urine if emboli are filtered by the renal tubules; however, this is a nonspecific finding in the setting of multitrauma (Newbigin et al., 2016). Acute tubular necrosis and kidney failure may develop.

Immediate immobilization of fractures (including early surgical fixation), minimal fracture manipulation, adequate support for fractured bones during turning and positioning, and maintenance of fluid and electrolyte balance are measures that may reduce the incidence of fat emboli. The nurse monitors high-risk patients (adults between 20 and 30 years of age with long-bone, pelvic, or multiple fractures or crush injuries, and elderly patients with hip fractures, or multiple fixations of fractures) to identify this complication. Prompt initiation of respiratory support is essential to prevent respiratory failure and to correct homeostatic disturbances. Acute pulmonary edema and ARDS are the most common causes of death. Oxygen therapy, mechanical ventilation, and use of positive end-expiratory pressure (PEEP) may be used to maintain arterial oxygenation. Continuous monitoring of oxygen saturation is initiated. Corticosteroids may be administered IV to treat the inflammatory lung reaction and to control cerebral edema in cases of fulminant FES. However, current evidence does not support routine administration in the majority of patients (Newbigin et al., 2016). Vasopressor medications to support cardiovascular function are administered IV to prevent hypotension, shock, and interstitial pulmonary edema. Accurate fluid intake and output records facilitate adequate fluid replacement therapy. In addition, the nurse provides calm reassurance to allay apprehension. FES has a 7% mortality rate; therefore, the nurse must recognize early indications of FES and report them promptly to the provider (Newbigin et al., 2016).

Nursing Alert

Subtle personality changes, restlessness, irritability, or confusion in a patient who has sustained a fracture are indications for immediate reassessment of the patient (vitals, O_2 saturation, physical examination, and laboratory data).

Delayed Union, Malunion, and Nonunion

When prolonged healing for union of the fracture is noted, it is termed delayed union. The fracture eventually does heal. In malunion, there is flawed union of fractured bone, whereas nonunion results from failure of the ends of a fractured bone to unite in normal alignment. Patient complaints of persistent discomfort and abnormal movement or instability at the fracture site indicate potential delayed union, malunion, or nonunion.

Delayed union may be due to inadequate blood supply, inadequate bone-to bone-contact, infection, or incorrect immobilization of the fracture. It may be associated with a fracture that involved a significant loss of bone, a hematoma at the fracture site, or comorbidity (e.g., diabetes mellitus, autoimmune disease). Malunion is associated with inadequate reduction of the fracture, misalignment of the fracture at the time of immobilization, or infection at the fracture site, and it presents as a deformity at the site visually or on x-ray. In nonunion, fibrocartilage or fibrous tissue exists between the bone fragments; no bone salts have been deposited. Nonunion is associated with infection, inadequate circulation, malignancy, and noncompliance with activity restrictions. Cigarette smoking and poor nutrition place the patient at a higher risk of delayed healing, and higher nonunion rates (Brinker & O'Connor, 2015). Nonunion most commonly occurs with open tibia fractures, scaphoid fractures, fractures of the fifth metatarsal or the hamate (carpal bone in the wrist), and, in elderly people, at the neck of the femur because of their tenuous blood supply. Factors contributing to both nonunion and malunion include interposition of tissue between the bone ends, or manipulation that disrupts callus formation, excessive space between bone fragments (bone gap), limited bone contact, bone or soft tissue loss, and impaired blood supply, resulting in AVN. Finally, a false joint (pseudarthrosis) often develops at the site of the fracture.

Nursing Alert

Nurses encourage patients with bone fractures to quit smoking since nicotine inhibits vascular ingrowth and early revascularization of bone and diminishes osteoblast activity. Additionally, poor nutrition is a risk factor for impaired fracture healing. A serum albumin level of at least 3.0 g/dL is preferred (Brinker & O'Connor, 2015).

Nonsteroidal anti-inflammatory drugs (NSAIDs) and older nonselective anti-cyclooxygenase (COX)-2 agents have been implicated in delayed fracture healing, although the magnitude of the effect of these drugs on fracture healing in humans is uncertain, and a causal relationship has not been proven (Solomon, 2015). Cigarette smoking, poor nutrition, excessive alcohol intake, diabetes, and use of steroids place the patient at a higher risk of delayed healing.

Nonunion is treated with internal fixation, bone grafting, electrical bone stimulation (thought to stimulate osteoblasts or bone formation), or a combination of these therapies. Internal fixation stabilizes the bone fragments and ensures bone contact. A bone graft may be an autograft (tissue, frequently from the iliac crest, harvested from the patient for his or her own use) or an allograft (tissue harvested from a donor for a recipient). The bone graft fills the bone gap, provides a lattice structure for invasion by bone cells, and actively promotes bone growth.

After grafting, immobilization and non–weight-bearing exercises are required while the bone graft becomes incorporated and the fracture or defect heals. Depending on the type of bone grafted, healing may take from 6 to 12 months or longer. Bone grafting problems

include wound or graft infection, fracture of the graft, persistent pain, sensory loss, and nonunion (Brinker & O'Connor, 2015).

Venous Thromboemboli

Venous thromboemboli, including DVT and pulmonary emboli (PE), are associated with reduced skeletal muscle contractions and bed rest. Patients with fractures of the lower extremities and pelvis are at high risk for venous thromboemboli. PEs may cause death several days to weeks after injury.

Depending on the size and location of the emboli, symptoms vary. A large PE can cause an increase in pulmonary arterial resistance, which can lead to right heart failure and hypoxemia (DeHart, 2015). Massive emboli can present as shock and loss of consciousness. The most frequent signs are sudden-onset shortness of breath (dyspnea), restlessness, increased respiratory rate, tachycardia, chest pain, cough, and low-grade fever. Pleuritic pain that increases with inspiration is seen with pulmonary infarct. Moderate hypoxemia occurs, without retention of CO_2, and a cough that is productive of blood-tinged sputum may be seen. It is important that a high degree of suspicion is maintained for PE since patients may have mild or nonspecific symptoms. Refer to Chapters 18 and 10 for details on DVT and PE.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a systemic disorder that results in widespread hemorrhage and microthrombosis with ischemia. Its causes are diverse and can include massive tissue trauma. Early manifestations of DIC include unexpected bleeding after surgery as well as bleeding from the mucous membranes, venipuncture sites, and gastrointestinal and urinary tracts. The treatment of DIC is discussed in Chapter 20.

Avascular Necrosis of Bone

AVN or osteonecrosis occurs when the bone loses its blood supply and dies. The cause of AVN is not well understood but may include vascular occlusion, altered lipid metabolism/fat emboli, intravascular coagulation, mechanical stress, and primary cell death (Qasem, 2016). It may occur after a fracture with disruption of the blood supply (especially of the femoral neck). It is also seen with dislocations, bone transplantation, prolonged high-dose corticosteroid therapy, excessive alcohol intake, cigarette smoking, chronic kidney disease, systemic lupus erythematosus, and other diseases. Use of glucocorticoids and excessive alcohol intake are associated with more than 80% of atraumatic cases of AVN (Jones & Mount, 2014). The devitalized bone may collapse or reabsorb. The patient develops pain and experiences limited movement. X-rays reveal loss of mineralized matrix and structural collapse. Treatment generally consists of attempts to revitalize the bone with bone grafts, prosthetic replacement, or arthrodesis (joint fusion).

Reaction to Internal Fixation Devices

Internal fixation devices may be removed after bony union has taken place. However, in most patients, the device is not removed unless it produces symptoms. Common reasons cited for removal include pain, neurologic symptoms, decreased function, or fear of future complications in active individuals (Bessette & Hammert, 2014). Problems may include

mechanical failure (inadequate insertion and stabilization); material failure (faulty or damaged device); corrosion of the device, causing local inflammation; allergic response to the metallic alloy used; and osteoporotic remodeling adjacent to the fixation device, in which stress needed for bone strength is transferred to the device, causing a disuse osteoporosis. If the device is removed, the bone needs to be protected from refracture related to osteoporosis, altered bone structure, and trauma. Bone remodeling reestablishes the bone's structural strength.

Reaction to External Fixation Devices

Because the screws or pins are inserted externally (Fig. 42-3), infection is a complication for which nurses must be vigilant. Rates of pin tract infections range from 0.5% to 30% in the literature when looking at external fixation (regardless of site) (Mitchell et al., 2016). Signs of infection include erythema, purulent drainage, warmth, leukocytosis, fever, and loosening pins (pins should be immobile in the bone). It is important to note that in a recent review of international protocols of pin-site care where practice varied, no one standard was associated with a 0% infection rate. Currently no consensus exists about which protocol should be applied universally (Lethaby, Temple, & Santy-Tomlinson, 2013; Mitchell et al., 2016). The mainstay of prevention and/or reduction of the incidence of pin-site infections is surgical technique during pin insertion and implementation of one of the existing protocols of pin-site care. Thus, pin care is performed according to hospital and provider protocol (Mitchell et al., 2016, p. 91).

FIGURE 42-3 External fixation device. Pins are inserted into bone. The fracture is reduced and aligned and then stabilized by attaching the pins to a rigid portable frame. The device facilitates treatment of soft tissue damaged in complex fractures.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS), formerly called *reflex sympathetic dystrophy* or *RSD*, is a painful sympathetic nervous system problem characterized by constant and intense limb pain associated with vasomotor and neurosensory abnormalities, skin changes, and demineralization of bone (Ferri, 2016a). It occurs in 7% of patients who have limb fractures, limb surgery, or other injuries (burns, stroke) (Bruehl, 2015). When it does occur, it is seen most often in women (60% to 82%); with a mean range of 36 to 46 years of age; whose injury was a fracture (16% to 46%), strain, or sprain (10% to 29%); was acquired postoperatively (3% to 24%); or from a contusion or crush injury (8% to 18%) (Dinakar, 2016). There are two types of CRPS: in *CRPS I* no definable nerve lesion is found, whereas in *CRPS II* definable nerve lesion is seen (Dinakar, 2016).

Clinical manifestations of CRPS include severe burning pain, swelling, hyperesthesia, limited ROM, discoloration, vasomotor skin changes (i.e., fluctuating warm, red, dry and cold, sweaty, cyanotic), and abnormal nail, skin, and hair changes. *Livedo reticularis* is common in CRPS; *Livedo* describes the red, nonblanchable (i.e., does not turn white when pressed) network pattern (reticulated) in the skin. About 60% of patients may report excessive sweating in the affected limbs. Temperature asymmetry between the affected and unaffected sides may exceed 1°C (Dinakar, 2016). The cardinal feature of CRPS is excruciating pain, often described as burning, aching, pricking, or shooting. Also edema of the affected limb frequently is present; initially it may be very mild; however, it may be so severe that a Doppler test is needed to rule out the possibility of a DVT (Dinakar, 2016). This syndrome is frequently chronic, with extension of symptoms to adjacent areas of the body. Disuse muscle atrophy and bone deossification (osteoporosis) occur with persistence of CRPS. Patients may exhibit ineffective individual coping related to the chronic pain. The best treatment is prevention with vitamin C supplementation and early active mobilization, imagery treatment with imagined hand movements and mirror therapy for upper extremity CRPS, and pharmacologic treatment.

Prevention may include elevation of the extremity after injury or surgery and selection of an immobilization device (e.g., external fixator) that allows for the greatest ROM and functional use of the rest of the extremity. Early effective pain relief is the focus of management. Pain may need to be controlled with a variety of agents, including anesthetic nerve blocks, spinal cord stimulation, tricyclic antidepressants, anticonvulsants, NSAIDs, corticosteroids, muscle relaxants, and, for those with severe pain, an opioid. Bisphosphonates also are considered. Physical and occupational therapy (including imagery and mirror therapy), tai chi, and yoga have been recommended (Bruehl, 2015; Jones, Lawson, & Backonja, 2016). With pain relief, the patient can participate in ROM exercises and functional use of the affected area. The nurse needs to help the patient cope with CRPS manifestations and explore multiple ways to control pain (see Chapter 7).

Nursing Alert
Since patients with CRPS feel severe and long-lasting pain to light touch, the nurse avoids using the involved extremity for blood pressure measurements and venipunctures.

Heterotopic Ossification

Heterotopic ossification (myositis ossificans) is the abnormal formation of bone, near bones or in muscle, in response to soft tissue trauma after blunt trauma, fracture, or total joint replacement. It is also commonly seen in patients with traumatic brain injury, spinal cord injury, cerebrovascular accident (CVA), and burns (Harrington, Eliason, & Bockenek, 2015). Heterotopic ossification is both more common and more extensive in patients with severe spasticity, with incidence rates varying from 11% to 75% in patients with severe traumatic brain injury and spinal cord injury (Harrington et al., 2015). The muscle is painful, and normal muscular contraction and movement are limited. Early mobilization may prevent its occurrence. NSAIDs (e.g., ibuprofen [Advil, Motrin]) to decrease inflammation or bone formation and prophylactic low-dose radiation therapy have been shown to help prevent heterotopic ossification after total hip arthroplasty (THA). Usually, the bone lesion resorbs over time, but the abnormal bone eventually may need to be excised if symptoms persist. Exercises to maintain joint ROM are considered the foundation of prevention, and continuous passive motion (CPM) machines are beneficial in increasing ROM after surgical resection.

Fractures of Specific Sites

Injuries to the skeletal structure may vary from a simple linear fracture to a severe crushing injury. The type and location of the fracture and the extent of damage to surrounding structures determine the therapeutic management. Maximum functional recovery is the goal of management.

Clavicle

Fracture of the clavicle (collar bone) is a common injury that results from a fall or a direct blow to the shoulder. These injuries frequently are associated with equestrian sports and cycling, when a rider is thrown forward and lands on the unprotected shoulder. Head or cervical spine injuries may accompany these fractures. They are also seen in the geriatric population after a low-impact fall. When the clavicle is fractured, the patient assumes a protective position, slumping the shoulders and immobilizing the arm to prevent shoulder movements. A deformity of the clavicle may be observed, with obvious local tenderness. The treatment goal is to align the shoulder in its normal position by means of closed reduction and immobilization or, if displaced, an ORIF.

Depending on the site of the clavicular fracture, most minimally displaced or nondisplaced fractures can be treated nonsurgically with a sling or a figure-eight bandage (also called a *clavicular strap* or *broad arm sling*) to pull the shoulders back, reducing and immobilizing the fracture (Fig. 42-4) (Silverstein, Moeller, & Hutchinson, 2016). Each treatment has advantages and disadvantages. When a clavicular strap is used, the axillae are well padded to prevent skin breakdown or a compression injury to the brachial plexus and the axillary artery. In most cases, a simple sling for comfort is adequate over the first few weeks followed by progressive ROM activities (Silverstein et al., 2016). If the clavicle is displaced significantly or if there is significant comminution or excessive shortening (more than 2 cm), referral to an orthopedic surgeon is warranted. When internal fixation is indicated, surgery may be performed with either a plate and screws or an intramedullary device.

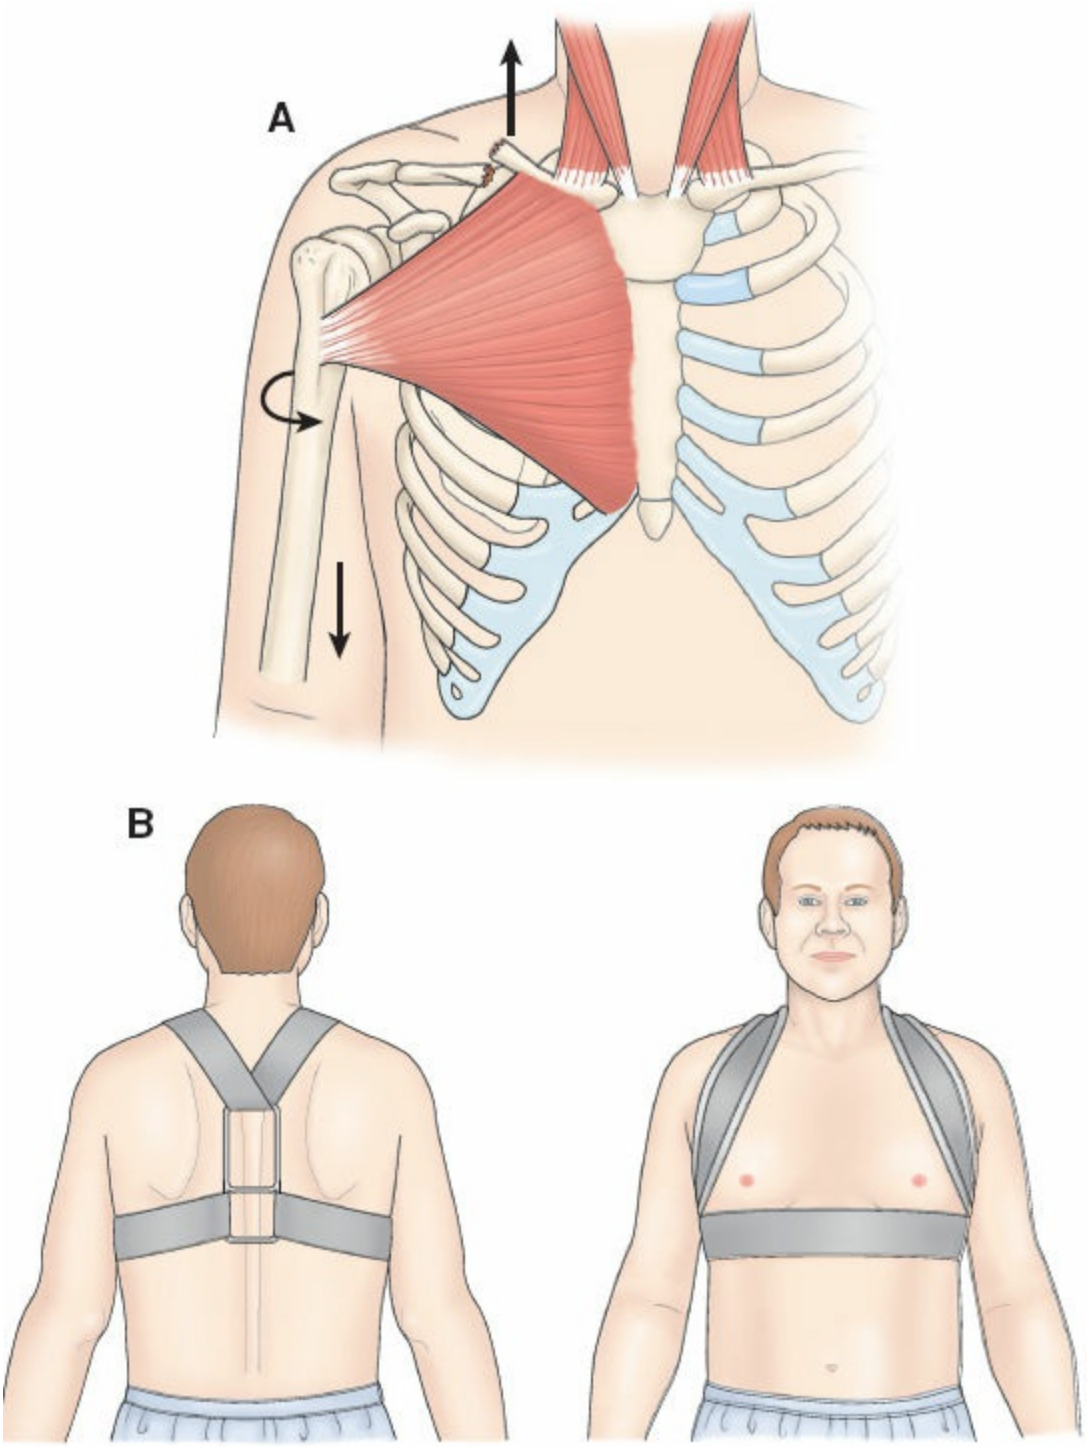

FIGURE 42-4 Fracture of the clavicle. A. Anteroposterior view shows typical displacement in midclavicular fracture. B. Immobilization is accomplished with a clavicular strap.

The nurse monitors the skin integrity and circulation and nerve function of both arms. An arm sling may be used to support the arm and to relieve pain. A sling may cause the elbow to stiffen so the patient is encouraged to perform elbow ROM exercises to maintain normal function and prevent stiffness. The patient may be permitted to use the arm for light activities within the range of comfort.

With a clavicular fracture, the nurse cautions the patient not to elevate the arm above the shoulder level until the ends of the bone have united (about 6 weeks) but encourages

the patient to exercise the elbow, wrist, and fingers as soon as possible. Vigorous activity is limited for 3 months. Complications of clavicular fractures include trauma to the nerves of the brachial plexus, injury to the subclavian vein or artery from a bony fragment, and malunion (faulty union of fractured bone) or nonunion (failure of the ends of a fractured bone to unite in normal alignment). Nonunion occurs more frequently with distal clavicular fractures managed nonsurgically.

Humeral Shaft

Fractures of the shaft of the humerus may injure the nerves and brachial blood vessels in the affected arm; therefore, neurovascular assessment is essential to identify when immediate attention is required. Table 42-2 provides guidelines for neurovascular evaluation. A wrist drop is indicative of radial nerve injury. An inability to oppose the thumb indicates a median nerve lesion, and an inability to spread the fingers indicates an ulnar nerve injury (Acklin & Sommer, 2015). An ORIF of a fracture of the humerus is necessary if the patient has nerve palsy, blood vessel damage, comminuted fracture, or pathologic fracture. There are two distinct populations who are more at-risk for humeral shaft fractures: young adults injured in high-energy motor vehicle accidents, falls from height, or gunshots; and the elderly who falls from a standing height.

If the fracture is uncomplicated, well-padded splints, overwrapped with an elastic bandage, are used to immobilize the upper arm initially and to support the arm in 90 degrees of flexion at the elbow. A sling or collar and cuff support the forearm (Fig. 42-5). The weight of the hanging arm and splints reduces the fracture. Functional bracing is another form of treatment used for these fractures. A contoured thermoplastic sleeve is secured in place with interlocking fabric (Velcro) closures around the upper arm, thus immobilizing the reduced fracture. As swelling decreases, the sleeve is tightened, and uniform pressure and bone stability is maintained. The forearm is supported with a collar and cuff sling. Functional bracing allows active use of muscles, motion in the shoulder and elbow, and good approximation of fracture fragments. After, the first week, pendulum shoulder exercises are performed as prescribed to provide active movement of the shoulder, thereby preventing adhesions of the shoulder joint capsule (Acklin & Sommer, 2015). If an ORIF was required for the humeral fracture, immediate mobilization of the elbow joint and active-assisted shoulder mobilization should be possible (Acklin & Sommer, 2015). Isometric exercises may be prescribed to prevent muscle atrophy. Complications that are seen with humeral shaft fractures include delayed union and nonunion (failure of the ends of a fractured bone to unite).

Elbow

Fractures of the elbow result from motor vehicle crashes, falls on the elbow (in the extended or flexed position), or a direct blow. Radial head fractures are the most common fractures involving the elbow; however, the distal humerus or proximal ulna is also commonly involved. Nondisplaced or minimally displaced fractures can be treated nonoperatively; however, a displaced fracture may require operative treatment. Elbow fractures may result in injury to the median, radial, or ulnar nerves. The patient is evaluated for paresthesia and signs of compromised circulation in the forearm and hand. The most serious complication is *Volkmann contracture* (an acute compartment syndrome [ACS]), which results from

antecubital swelling or damage to the brachial artery (Fig. 42-6). Contracture of the fingers and wrist occurs as the result of obstructed arterial blood flow to the forearm and hand. The patient is unable to extend the fingers, describes abnormal sensation (e.g., unrelenting pain, pain on passive stretch), and exhibits signs of diminished circulation to the hand. Although the incidence of Volkmann contracture is low, its devastating complications are preventable if detected early. This serious complication warrants nursing vigilance to minimize limb loss. The nurse needs to monitor the patient regularly for compromised neurovascular status. Refer back to Box 42-4 for focused assessment guidelines for evaluation of the radial, medial, and ulnar nerve in upper extremity fractures. Severe pain at the elbow and increasing tenseness of the forearm are worrisome signs of increasing intracompartmental pressure. Compartment syndrome is discussed on pages 1232–1234.

TABLE 42-2 Neurovascular Assessment and Expected Findings

Assessment Component	Technique	Normal Findings
Skin color	Evaluate the injured area in relation to the noninjured area.	No change is noted compared to other parts of the body.
Skin temperature	Palpate using the dorsum of the hand as it is more sensitive to temperature.	No change is noted compared to other parts of the body.
Pulses	Assess proximal and distal pulses. Grade as 0, absent; 1+, weaker than normal; 2+, normal; or 3+, full and bounding.	No change is noted compared to other extremity.
Capillary refill	Depress the nail bed and note return of color.	Capillary refill is less than 2 seconds.
Sensation	With his eyes closed, evaluate the patient's ability to feel light touch of the affected extremity (e.g., assess on the first web space of foot [between great toe and second toe] for the peroneal nerve, or base of thumb [radial nerve], or little finger [ulnar nerve]). Assess presence of numbness or tingling.	No sensory deficit is noted.
Mobility	Observe the ROM in joints or digits distal to the injury. Note edema and tenseness of the injured area. Mark and measure circumference if concerned.	Full movement of digits is noted. Minimal edema and ecchymosis are noted. In a nontraumatized limb, a difference of 1 cm at the ankles and 2 cm at mid-calf is expected.

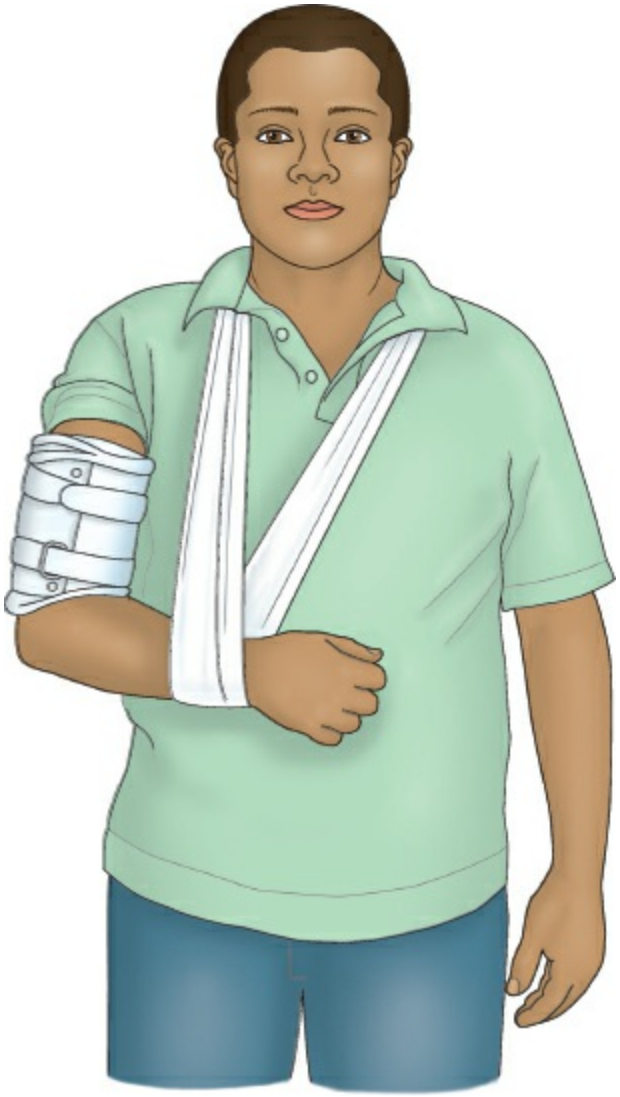

FIGURE 42-5 Humeral brace with collar and cuff sling.

Nursing Alert
Absence of a radial pulse is a critical finding that warrants emergency notification of the provider.

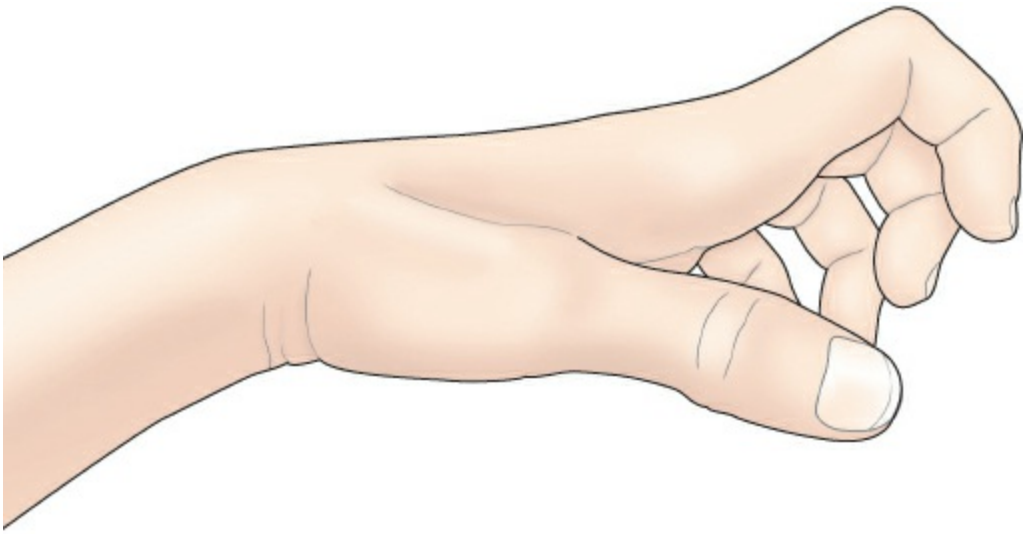

FIGURE 42-6 Volkmann contracture.

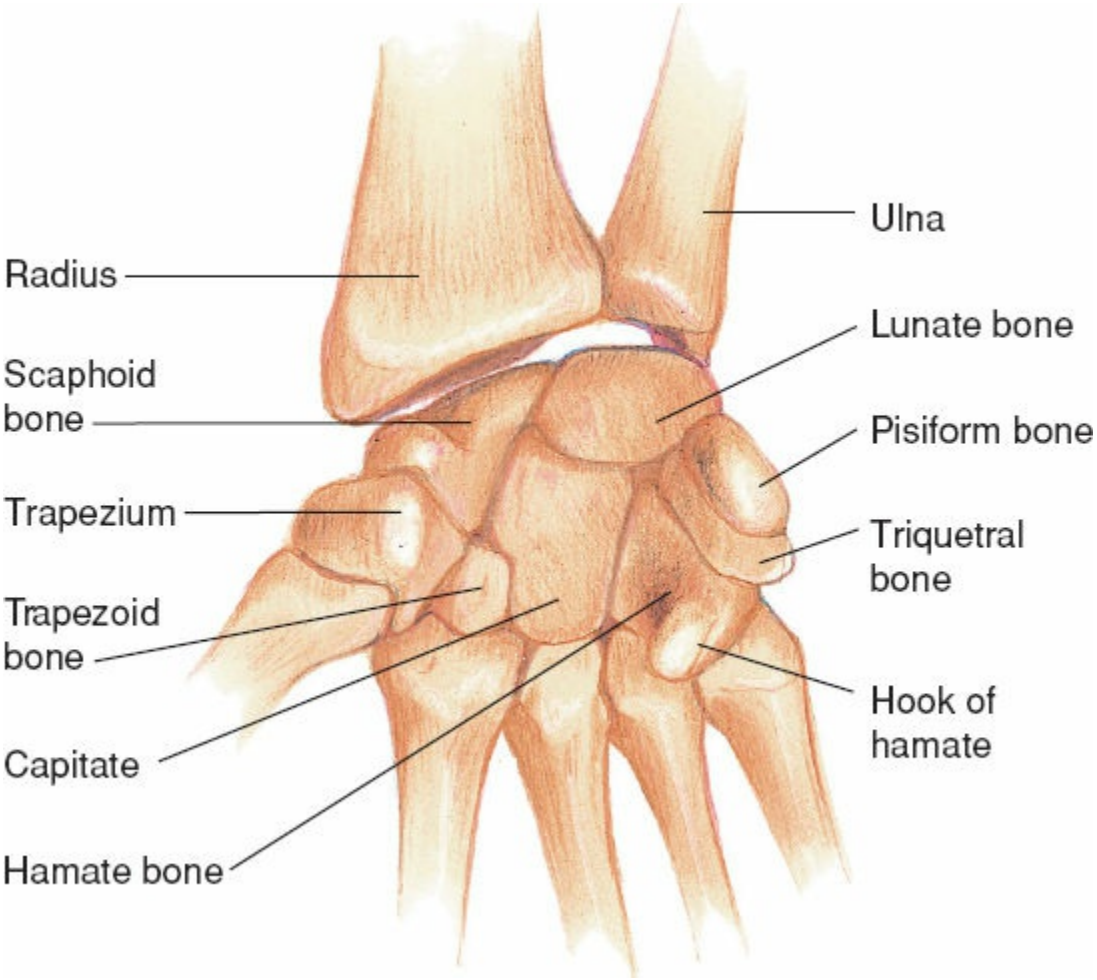

FIGURE 42-7 Palmar view of Carpal bones. (Courtesy of Anatomical Chart Company.)

Hand

Trauma to the hand often requires extensive reconstructive surgery. The objective of treatment is always to regain maximum function of the hand. Scaphoid fractures (bone on

the thumb side of the wrist) are the most common carpal bone fractures, far exceeding all other carpal bone injuries. Fifteen percent of patients with scaphoid displacement exhibit nonunion, and 10% of fractures develop AVN because of disturbances in blood supply (Owens, 2016). Refer to Figure 42-7 for carpel bones details. Patient complaints include radial-sided wrist pain, tenderness in the anatomical snuff box, bruising, and edema (swelling at the base of the thumb). Cast treatment results in healing of the majority of scaphoid fractures. For an undisplaced fracture of the phalanx (finger bone), the finger is splinted for 3 to 4 weeks to relieve pain and to protect the finger from further trauma. Displaced fractures and open fractures may require ORIF, using wires or pins.

Arm

The most frequently broken arm bone is the radius, and the site most commonly affected is the distal radius. Termed a Colles fracture (the broken fragment of the radius tilts upward), the distal radius fracture usually is the result of a fall on an open, dorsiflexed hand. This fracture is frequently seen in elderly women with osteoporotic bones and weak soft tissues that do not dissipate the energy of the fall or in younger people involved in high impact trauma (e.g., falls, sports injuries). The patient presents with a deformed wrist, radial deviation, pain, swelling, weakness, limited finger ROM, and numbness.

Treatment usually consists of closed reduction and immobilization with a short-arm cast if the fracture is nondisplaced or minimally displaced. The extremity may be treated initially in a splint for 5 to 7 days until swelling subsides and then casted in a short-arm cast. For fractures with extensive comminution (bone is broken into a number of pieces) or impaction, ORIF, arthroscopic percutaneous pinning, or external fixation is used to achieve and maintain reduction and to allow for early functional rehabilitation. The wrist and forearm are elevated for 48 hours after reduction to control swelling, and active motion of the fingers and shoulder begins promptly. The nurse monitors for signs of neurovascular compromise comparing findings on the affected limb to the other limb.

Tibia and Fibula

The most common fractures below the knee are tibia and fibula fractures, and these tend to result from a direct blow, falls with the foot in a flexed position, or a violent twisting motion. The patient presents with pain, deformity, obvious hematoma, and considerable edema. Frequently, these fractures are open and involve severe soft tissue damage because there is little subcutaneous tissue in the area.

The peroneal nerve is assessed for damage that may result in foot drop (inability to lift the foot), by checking for sensation of the web between the great and second toes, and for increased sensitivity of the dorsal surfaces of the foot (top). If nerve function is impaired, the patient cannot dorsiflex the great toe and has diminished sensation in the first web space (between first metatarsal and hallux [big toe]). As with all fractures, the patient is observed for signs of neurovascular complications. The development of ACS (see discussion later in this chapter) requires prompt recognition and resolution to prevent permanent functional deficit. Other complications include delayed union, infection, impaired wound edge healing due to limited soft tissue, and loosening of the internal fixation hardware (if ORIF is performed to repair fracture).

Most closed tibial fractures are treated with closed reduction and initial immobilization

in a long-leg walking cast or a patellar tendon–bearing cast. Reduction must be relatively accurate in relation to angulation and rotation. Comminuted fractures may be treated with skeletal traction, internal fixation with intramedullary nails or plates and screws, or external fixation. External support may be used with internal fixation.

Pelvis

Numerous classification systems have been used to describe pelvic fractures in relation to pelvic anatomy, stability, and mechanism of injury. Some fractures of the pelvis do not disrupt the pelvic ring; others do—therefore the severity of pelvic fractures varies.

Stable Pelvic Fractures

Stable fractures of the pelvis (Fig. 42-8) heal rapidly because the pelvic bones are mostly cancellous bone, which has a rich blood supply. The fractures are treated with a few days of bed rest and symptom management until the pain and discomfort are controlled. The patient with a fractured sacrum is at risk for paralytic ileus, and bowel sounds should be monitored.

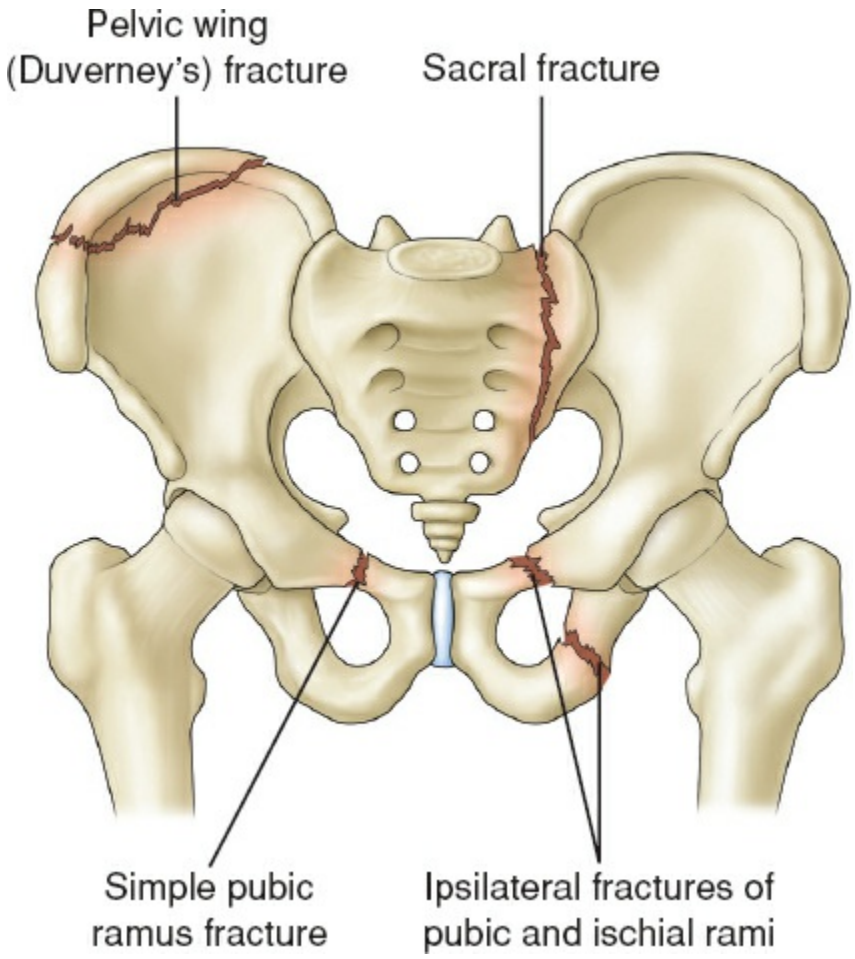

FIGURE 42-8 Stable pelvic fractures.

Unstable Pelvic Fractures

Unstable fractures of the pelvis may result in rotational instability (e.g., the "open book"

type, in which a separation occurs at the symphysis pubis with sacral ligament disruption), vertical instability (e.g., the vertical shear type, with superior–inferior displacement), or a combination of both (Fig. 42-9).

Managing Pelvic Fractures

Falls, motor vehicle crashes, and crush injuries can cause pelvic fractures. Pelvic fractures are serious because at least two thirds of affected patients have significant and multiple injuries. Twenty percent of multitrauma patients sustain pelvic fractures with a mortality rate approaching 15% to 20%, whereas if the pelvic fracture is open, a mortality rate of 25% to 50% is seen (Perkins & Quinnan, 2016). Management of severe, life-threatening pelvic fractures is coordinated with the trauma team. Hemorrhage and thoracic, intra-abdominal, and cranial injuries have priority over treatment of fractures. There is a high mortality rate associated with pelvic fractures related to hemorrhage, pulmonary complications, fat emboli, thromboembolic complications, and infection.

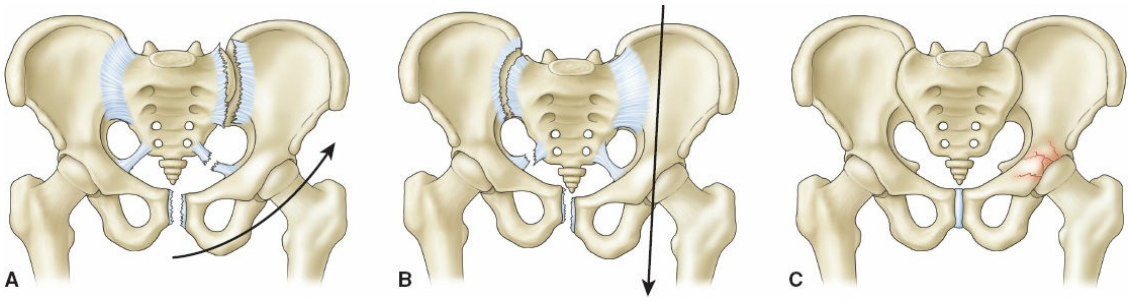

FIGURE 42-9 Unstable pelvic fracture. A. Rotationally unstable fracture. The symphysis pubis is separated and the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments are disrupted. B. Vertically unstable fracture. The hemipelvis is displaced anteriorly and posteriorly through the symphysis pubis, and the sacroiliac joint ligaments is disrupted. C. Undisplaced fracture of the acetabulum.

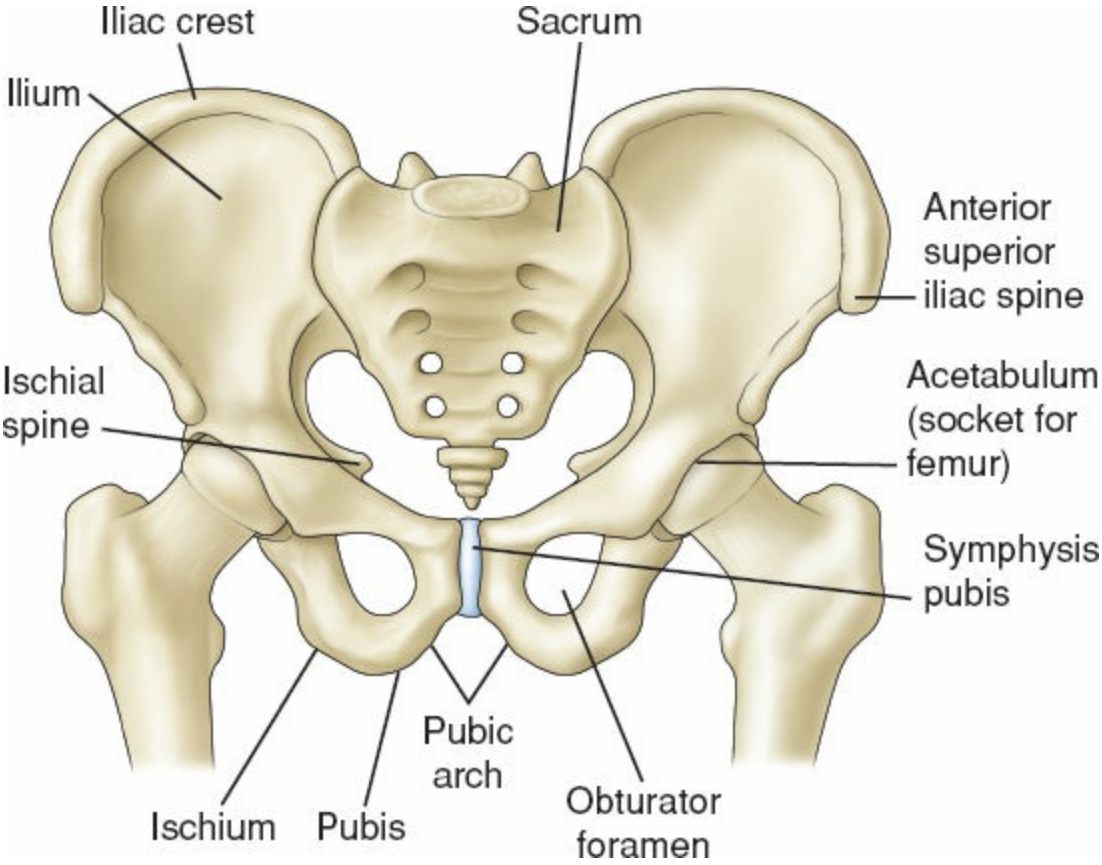

FIGURE 42-10 Pelvic bones.

Signs and symptoms of pelvic fracture include ecchymosis; tenderness over the symphysis pubis, anterior iliac spines, iliac crest, sacrum, or coccyx; local edema; numbness or tingling of the pubis, genitals, and proximal thighs; and inability to bear weight without discomfort. Neurovascular assessment of the lower extremities is performed to detect injury to pelvic blood vessels and nerves. Figure 42-10 details the pelvic bones. The peripheral pulses of both lower extremities are palpated; absence of a pulse may indicate a tear in the iliac artery or one of its branches.

Hemorrhage and shock are two of the most serious consequences that may occur. Bleeding arises from the cancellous surfaces of the fracture fragments, from laceration of veins and arteries by bone fragments, and possibly from a torn iliac artery. Focused assessment with sonography in trauma (FAST) examination can be used to identify intra-abdominal injuries quickly. Diagnostic peritoneal lavage or abdominal CT may be performed to detect intra-abdominal hemorrhage and intrapelvis injuries. Retrograde cystourethrogram can be performed to diagnose genitourinary injuries.

Nursing Alert

The risk of hemorrhagic shock from intrapelvic bleeding or associated abdominal injury is high with pelvic fractures, thus the patient is handled gently to minimize further bleeding and shock. Manual compression of the pelvis should be avoided, and, when log rolling the patient, rotation more than 15 degrees is avoided until the patient is stabilized (Perkins & Quinnan, 2016).

Injuries to the bladder, urethra, rectum, intestines, other abdominal organs, and pelvic vessels and nerves are associated with pelvic fracture. Injuries to the bladder and urethra are seen most commonly (63%) (Perkins & Quinnan, 2016). To assess for urinary tract injury, the patient's urine is examined for blood (hematuria) or blood at the introitus, or if the patient is a male, observed for scrotal hematoma. A urinary drainage catheter should not be inserted until the status of the urethra is known. Ecchymosis of the anterior abdominal wall, flank, or sacral or gluteal region is suggestive of significant internal bleeding. Diffuse and intense abdominal pain, hyperactive or absent bowel sounds, and abdominal rigidity and hyper-resonance (free air) or dullness to percussion (blood) suggest injury to the intestines or abdominal bleeding. Additionally, the nurse is aware that the loss of dullness over the liver (normally percusses a dull sound) indicates the presence of free air and that dullness over regions normally tympanic may indicate the presence of blood or fluid.

Immediate treatment in the emergency department of a patient with an unstable pelvic fracture includes stabilizing the pelvic bones and tamponading or compressing bleeding vessels. A simple method of stabilizing the pelvis is the tying of a sheet circumferentially around the hips at the level of the greater trochanters or the use of a pelvic prefabricated binder (Perkins & Quinnan, 2016). This is often done in the field, and this temporary measure applies pressure, closes the "open-book" pubic symphysis (anteroposterior compression injury to the pelvis), and assists in controlling bleeding.

If major vessels are lacerated, the bleeding may be stopped through emergent embolization using interventional radiology techniques prior to surgery. Patients with pelvic fractures can lose up to 4 to 5 L of blood and therefore are at risk for exsanguination. Mortality rate for patients presenting with hypotension associated with pelvic fractures is approximately 50%. Once the patient is hemodynamically stable, treatment generally involves external fixation or ORIF. These measures promote hemostasis, hemodynamic stability, comfort, and early mobilization. Long-term complications of pelvic fractures include malunion, nonunion, residual gait disturbances, and back pain from ligament injury.

Acetabular Fractures

Acetabular fractures primarily occur in young adults as a result of high-velocity trauma (Thacker, 2014). Drivers and passengers sitting in the right front seat in motor vehicle crashes may forcibly propel their knees into the dashboard, injuring the knee–thigh–hip complex; the force exerted through the head of the femur extends into the acetabulum. The acetabulum (see Fig. 42-10) is particularly vulnerable to fracture with these types of injuries. Treatment depends on the pattern of fracture. Stable, nondisplaced fractures may be managed with traction and protective (toe-touch) weight bearing so that the affected foot is only placed on the floor for balance. Displaced and unstable acetabular fractures are treated with open reduction, joint débridement, and internal fixation or arthroplasty (replacement of all or part of the joint surfaces). Internal fixation permits early non–weight-bearing ambulation and ROM exercise. Complications seen with acetabular fractures include nerve palsy, AVN, heterotopic ossification, and posttraumatic arthritis.

Femoral Shaft

Considerable force is required to break the shaft of the femur in adults since it is the longest

and strongest bone in the body. Most femoral fractures are seen in young adults who have been involved in a motor vehicle crash, who have fallen from a high place, or who have received a gunshot wound. Older women with osteoporosis are also at risk for femur shaft fractures after low to moderate level trauma (Gösling & Giannoudis, 2015). Frequently, these patients have associated multiple injuries and significant soft tissue damage.

The nurse assesses for the presence and location of the pain, edema, bruising, deformity, and instability. The patient presents with an enlarged, deformed, painful thigh and cannot move the hip or the knee. The fracture may be transverse, oblique, spiral, or comminuted. Frequently, the patient develops shock because the loss of up to 1,250 mL of blood into the tissues can be seen with these fractures. An expanding diameter of the thigh may indicate continued bleeding.

The fracture is immobilized so that additional soft tissue damage does not occur. In general, skeletal traction or splinting is used to immobilize fracture fragments until the patient is physiologically stable and ready for ORIF procedures.

Internal fixation usually is carried out within a few days after injury. Intramedullary locking nail devices are used for midshaft (diaphyseal) fractures. Depending on the supracondylar fracture pattern, intramedullary nailing or screw plate fixation may be used. Internal fixation permits early mobilization. A thigh cuff orthosis may be used for external support. To preserve muscle strength, the patient is instructed to perform active exercises of the upper and lower extremities on a regular basis. Active muscle movement enhances healing by increasing blood supply and electrical potentials at the fracture site. Prescribed weight-bearing limits are based on the type of fracture. Physical therapy includes ROM and strengthening exercises, safe use of ambulatory aids, and gait training. Functional ambulation stimulates fracture healing. Healing time is 4 to 6 months.

A common complication after fracture of the femoral shaft is restriction of knee motion. Active and passive knee exercises begin as soon as possible, depending on the management approach and the stability of the fracture and knee ligaments.

Femur

Fracture of the proximal femur is termed a *hip fracture* and is classified as either intracapsular or extracapsular. Intracapsular fractures include femoral head and femoral neck fractures, while extracapsular fractures includes trochanteric, intertrochanteric, and subtrochanteric fractures (Fig. 42-11). Fractures of the neck of the femur may damage the vascular system that supplies blood to the head and the neck of the femur, and the bone may become ischemic. For this reason, AVN is common in patients with femoral neck fractures. The elderly are particularly vulnerable to intertrochanteric fractures and generally have a much worse prognosis than do younger patients. It is important for the nurse to be aware that the mortality rate after hip fracture surgical repair is 2% to 3%, and the mortality rate within 1 year in the elderly patients is 25% to 30%. DVT and subsequent PE are well-known complications of patients undergoing hip surgery, with rates of 1.6% within 30 days after surgery. Without prophylaxis, the rate of objectively confirmed DVT occurring within 7 to 14 days after lower extremity orthopedic surgery is around 40% to 60% (Kakkar & Rushton-Smith, 2013, p. 11). Also, older adults have a five- to eightfold increased risk for all-cause mortality during the first 3 months after hip fracture (Ferri, 2016d).

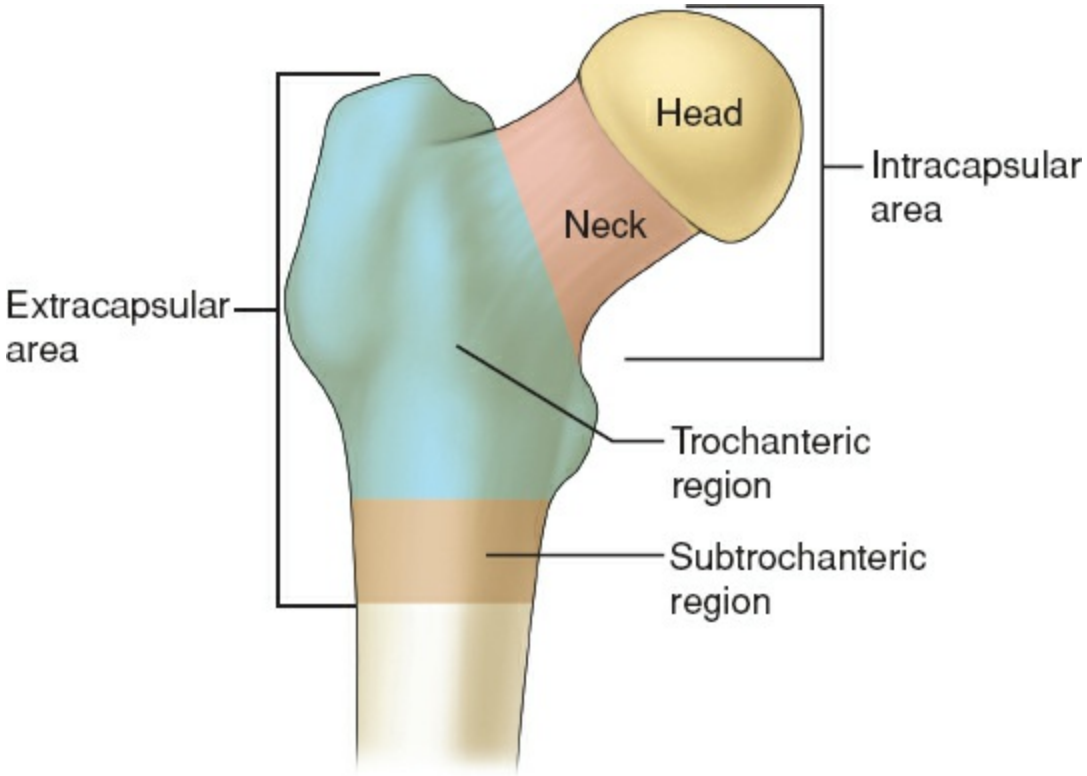

FIGURE 42-11 Regions of the proximal femur.

Clinical Manifestations and Assessment

With displaced fractures of the femoral neck, the leg is shortened, abducted, and externally rotated (Murray, 2014). The patient complains of pain in the hip and groin or knee. Nondisplaced fractures (e.g., stress fractures) will not be shortened or externally rotated, but the patient will complain of pain. With most fractures of the femoral neck, the patient cannot move the leg without a significant increase in pain. Impacted intracapsular femoral neck fractures cause moderate discomfort (even with movement), may allow the patient to bear weight, and may not demonstrate obvious shortening or rotational changes. With extracapsular femoral fractures of the trochanteric or subtrochanteric regions, the extremity is significantly shortened, externally rotated to a greater degree than in intracapsular fractures, exhibits muscle spasm that resists positioning of the extremity in a neutral position, and has an associated large hematoma or area of ecchymosis. The diagnosis of fractured hip is confirmed with an x-ray.

Gerontologic Considerations

Elderly people (particularly women) who have brittle bones from osteoporosis and who tend to fall frequently have a high incidence of hip fracture. Weak quadriceps muscles, general frailty due to age, and comorbidities that produce decreased cerebral arterial perfusion (transient ischemic attacks, anemia, emboli, cardiovascular disease, and medication effects) contribute to the incidence of falls.

Often, a fractured hip is a catastrophic event that has a negative impact on the patient's lifestyle and quality of life. Hip fractures are a frequent contributor to death after 75 years of age. Because of the risk of DVT and PE with hip surgery, regional anesthesia is

recommended since it reduces the risk for proximal DVT following total hip replacement by two- to threefold and also reduces the overall risk for DVT by at least 20% (Mackenzie & Su, 2016, p. 1832). Additionally, many elderly people hospitalized with hip fractures exhibit delirium as a result of the stress of the trauma, unfamiliar surroundings, sleep deprivation, and medications. An incidence rate of 24% of postoperative delirium following hip fracture repair in elderly patients was seen in a recent systematic review (Yang et al., 2016). Preoperative predictors of postoperative delirium include advanced age, living in an institution, heart failure, multiple comorbidities, THA, and morphine usage. Females were less likely to develop delirium after hip surgery (Yang et al., 2016).

Nursing Alert
When a patient presents with a change in the level of consciousness, the nurse recalls the mnemonic DOG: Drugs are reviewed to evaluate whether a medication could be associated with the altered sensorium, Oxygen saturation level is assessed for hypoxemia via pulse oximeter, and a Glucose level is obtained to evaluate for hypoglycemia/hyperglycemia via a finger stick since all are associated with altered LOC.

To prevent complications, the nurse must assess the elderly patient for chronic pre-existing conditions as described above, including polypharmacy. Dehydration and poor nutrition may be present, contributing to hemoconcentration, and this predisposes the patient to the development of venous thromboemboli. Therefore monitoring intake and output in the elderly and assessing for DVT are particularly important.

Muscle weakness and wasting, which may have initially contributed to the fall and fracture, will be further compromised by bed rest and immobility. The nurse encourages the patient to move all joints except the involved hip and knee. Strengthening of the arms and shoulders will facilitate walking with assistive devices. A plan of nursing care for an elderly patient with a fractured hip is available online at http://thepoint.lww.com/Honan2e.

Medical Management

If surgery cannot be performed immediately, the fracture is immobilized so that additional soft tissue damage does not occur. Temporarily, traction can either be applied as skin or skeletal (pins or wires inserted into bones) traction. Each carries risks. Skin traction can put undue pressure on skin for prolonged periods of time, is limited in the amount of weight that can be applied (5 to 7 lb or less), and as a result, has limited use (Gösling & Giannoudis, 2015). Higher weights risk damage to the skin and neurovascular status of the involved extremity.

Skeletal traction is used more frequently to immobilize fracture fragments until the patient is physiologically stable and ready for surgical treatment. However, skeletal traction can increase the risk of infection since sterile pin(s) are drilled or wires are placed into the bone. The weight for skeletal traction is determined by body size and the extent of the injury. With either choice, continued neurovascular monitoring and assessment of the skin is needed.

Additionally, there are several types of traction. *Straight* or *running traction* applies the pulling force in a straight line with the body part resting on the bed. Buck's extension

traction is an example of skin traction that is straight traction. It may be used for patients with fractures of the hip as a temporary measure to reduce muscle spasm, immobilize the extremity, and relieve pain. Another type of traction is *balanced suspension traction* (see Fig. 42-14 on page 1237), in which the affected extremity "floats" or is suspended in the traction apparatus by the balanced weights. The line of traction on the extremity remains fairly constant despite patient movement as long as the pull remains constant.

Nursing Alert
The nurse must never remove weights from skeletal traction unless an emergency situation occurs. Removal of the weights completely defeats their purpose and may result in injury to the patient.

The goal of surgical treatment of hip fractures is to obtain a satisfactory fixation so that the patient can be mobilized quickly and avoid secondary medical complications. Surgical intervention is carried out as soon as possible after injury. Surgical treatment consists of one of the following:

- Open or closed reduction of the fracture and internal fixation; a thigh cuff orthosis may be used for external support
- Replacement of the femoral head with a prosthesis (hemiarthroplasty). This is usually reserved for fractures that cannot be satisfactorily reduced or securely nailed, or to avoid complications of nonunion and AVN of the head of the femur. It is similar to a total hip replacement but only replaces the ball portion of the hip joint, not the socket (which is replaced in total hip replacement [discussed later in the chapter]).
- Closed reduction with percutaneous stabilization for an intracapsular fracture.

Nursing Management

The immediate postoperative care for a patient with a hip fracture is similar to that for other patients undergoing major surgery.

Encouraging Activity. The patient is encouraged to exercise as much as possible by means of the overbed trapeze. This device helps strengthen the arms and shoulders in preparation for protected ambulation (e.g., toe touch, partial weight bearing). A common complication after fracture of the femoral shaft is restriction of knee motion. In general, active and passive knee exercises begin as soon as possible, depending on the management approach and the stability of the fracture and knee ligaments. To preserve muscle strength, the patient is instructed to exercise the noninjured hip and the lower leg, foot, and toes on a regular basis. The surgeon prescribes the degree of weight bearing and the rate at which the patient can progress to full weight bearing. On the day of surgery or first postoperative day, generally, the patient transfers to a chair with assistance and begins assisted ambulation. The amount of weight bearing that can be permitted depends on the stability of the fracture reduction. In general, hip flexion and internal rotation restrictions apply *only* if the patient has had a hemiarthroplasty (replacement of the ball of the hip). Physical therapists work with the patient on ROM and strengthening exercises, safe use of ambulatory aids,

and gait training. Functional ambulation stimulates fracture healing. The patient can anticipate discharge to home or to an extended care facility with the use of an ambulatory aid. Some modifications in the home may be needed, such as installation of elevated toilet seats and grab bars.

Monitoring and Managing Potential Complications. Attention is given to pain management as well as prevention of secondary medical problems, such as hemorrhagic shock, atelectasis, pneumonia, DVT, heart failure, constipation, pressure ulcer development, bladder control problems, and pain. Early mobilization of the patient is important so that independent functioning can be restored. Elderly people with hip fractures are particularly prone to complications that may require more vigorous treatment than the fracture. Frequently, the patient develops shock because the loss of two to three units of blood into the tissues is common with these fractures. Achievement of homeostasis after injury and after surgery is accomplished through careful monitoring of vital signs, wound drainage from dressings and external drains (drains are typically removed 24 to 48 hours after surgery), laboratory results, and physical assessment findings, as well as through collaborative management, including adjustment of therapeutic interventions as indicated. Refer back to Box 42-2 for signs and symptoms of hypovolemic shock.

Neurovascular complications may occur from direct injury to nerves and blood vessels or from increased tissue pressure. Assessment includes checking the neurovascular status of the extremity, especially circulatory perfusion of the lower leg and foot (popliteal, posterior tibial, and pedal pulses; toe capillary refill time; color; temperature; sensation and movement). A Doppler ultrasound device may be needed to assess blood flow. With hip fracture, bleeding into the tissues is expected. Excessive swelling may be observed and may further impair the neurovascular status. Patients may complain of increased pain at the site, and swelling may be noted in the thigh and buttock due to hematoma formation. Ice may be applied to decrease the swelling. The nurse marks the extent of drainage on the dressing by circling the extent and noting initials, date, and time. If excessive, the nurse should notify the provider.

DVT is a common postoperative complication contributing to significant morbidity and mortality in patients undergoing hip fracture surgery. To prevent DVT, the nurse encourages intake of fluids, and ankle and foot exercises. The nurse assesses the patient's legs for signs of DVT, which may include unilateral calf edema, tenderness, warmth, redness, a palpable cord, and Moses sign (pain with calf compression against the tibia) (DeHart, 2015). However, objective evidence is found in fewer than 50% of patients with these classic signs of DVT; therefore, the nurse maintains a high degree of suspicion for this complication (DeHart, 2015). The symptoms are related to inflammatory processes, and, therefore, the nurse also assesses for low-grade fever, malaise, and elevated white blood cell (WBC) count and sedimentation rate (Porth, 2015). The nurse administers the anticoagulant and mechanically based prophylaxis (e.g., elastic compression stockings, sequential compression devices, and prophylactic anticoagulant therapy) as prescribed.

Pulmonary complications, which commonly include atelectasis and pneumonia, are a threat to elderly patients undergoing hip surgery. Deep-breathing exercises, a change of position at least every 2 hours, and the use of an incentive spirometer hourly help prevent

respiratory complications. The nurse assesses breath sounds at least every 4 hours to detect adventitious or diminished sounds. Oxygen saturation should be assessed; supplemental oxygen may be ordered to keep the level above 95%. Pain must be treated with analgesic agents, typically opioids; otherwise, the patient may not be able to readily cough, deep breathe, or engage in prescribed activities. Out-of-bed (OOB) activities will be beneficial for lung function as well as muscle strength.

Heart failure is a frequent cause of mortality in elderly patients with hip fracture. The cumulative effect of trauma, major surgery, and concurrent medical history place the patient at risk for heart failure. The nurse is alert for signs and symptoms associated with left-sided heart failure, including shortness of breath, cough, dyspnea on exertion (DOE), crackles, orthopnea, and paroxysmal nocturnal dyspnea. Right ventricular failure presents with peripheral edema (may be pitting), jugular vein distention, and abdominal distention. Edema will be in dependent areas so the nurse assesses the sacral area as well as extremities. Accurate recording of intake and output (noting decreased urinary output), auscultation of heart (noting presence of S_3) and lung sounds (crackles), and monitoring O_2 saturation and vital signs (noting decreasing blood pressure, tachycardia, and tachypnea) are important nursing responsibilities. The nurse consults with the surgeon if signs and symptoms of excess fluid volume persist or worsen. The nurse expects fluid restriction and administers diuretics as ordered.

Skin breakdown is often seen in elderly patients with hip fracture. Blisters caused by tape are related to the tension of soft tissue edema under the nonelastic tape. An elastic hip spica wrap dressing or elastic tape applied in a vertical fashion may reduce the incidence of tape blisters. In addition, patients with hip fractures tend to remain in one position and may develop pressure ulcers; therefore, the nurse ensures that the patient is changing position at least every 2 hours. Proper skin care, especially on the heels, back, sacrum, and shoulders, as well as turning and frequent repositioning and supporting the legs with pillows and lifting the heels off the mattress all help to relieve pressure. Special mattress may provide protection by distributing pressure evenly.

Reduced GI motility, immobility, and the effects of anesthesia may result in constipation. Accurate assessment of intake and output, assessing bowel sounds, and noting distention of the abdomen are important nursing interventions, as prevention of constipation is the goal. A diet high in fiber and fluids may help stimulate gastric motility and since ambulation improves GI peristalsis, the nurse assists the patient in OOB activities and ambulation as prescribed. If constipation develops, therapeutic measures may include stool softeners, laxatives, suppositories, and enemas. To improve the patient's appetite, the nurse identifies and includes the patient's food preferences, as appropriate, within the prescribed therapeutic diet.

Loss of bladder control (incontinence or retention) may occur. In general, the routine use of an indwelling catheter is avoided because of the high risk for urinary tract infection (UTI). If a catheter is inserted at the time of surgery, it usually is removed on the morning of the first postoperative day. Because urinary retention is common after surgery, the nurse must assess the patient's voiding patterns and amounts, noting bladder distention and voiding of small amounts of urine (less than 100 mL) frequently. To ensure proper urinary tract function, the nurse monitors intake via IV route and/or by mouth if allowed and output. If no pre-existing cardiac disease (e.g., heart failure, coronary artery disease) exists, then liberal intake of fluids is encouraged. The patient is informed to notify the nurse if

complaints of bladder fullness or inability to void are noted. A bladder scan can be performed by the nurse to evaluate postvoid residual, which should be less than 100 mL.

Infection is suspected if the patient complains of persistent, moderate discomfort in the hip, experiences chills or malaise, and has an elevated WBC count and erythrocyte sedimentation rate (ESR). The nurse observes the surgical incision for erythema, warmth, and tenderness and notes color, amount, and consistency of wound drainage. In the elderly, symptoms of infection may be nonspecific (e.g., patients may be afebrile without complaints); an important marker is a decline in the patient's functional status and/or the presence of confusion. The closed-wound drainage system is observed for color and amount of drainage and functioning of the drainage device. International research suggests that preoperative serum albumin is a reliable predictor of an infection at the surgical site in patients admitted for elective total joint arthroplasty (Alfargieny, Bodalal, Bendardaf, El-Fadli, & Langhi, 2015).

Delayed complications of hip fractures include malunion, delayed union or nonunion, AVN of the femoral head (particularly with femoral neck fractures), and fixation device problems (e.g., protrusion of the fixation device through the acetabulum, loosening of hardware) (discussed earlier in this chapter). Healing time is 4 to 6 months.

Promoting Health. Osteoporosis screening of patients who have experienced hip fracture is important for prevention of future fractures (Box 42-5). Specific patient education is needed regarding dietary requirements, lifestyle changes, and weight-bearing exercise to promote bone health. Prevention of falls is also important and may be achieved through exercises to improve muscle tone, flexibility, and balance and through the elimination of environmental hazards such as throw rugs. Other environmental considerations are the use of hand rails on the stairs, nonskid surfaces in the bathroom, grab bars in the shower, raised toilet seats, well-fitting shoes with nonskid soles, and adequate home lighting.

BOX 42-5 Risk Factors for Osteoporosis

- Age
- Female
- Caucasian
- Small bone structure
- Postmenopausal
- Sedentary lifestyle
- Chronic obstructive pulmonary disease
- Smoking
- Steroid use
- Family history
- Calcium deficiency
- Poor nutrition
- Excessive alcohol intake
- Excessive caffeine intake

- Malignancy
- Hyperthyroidism
- Rheumatoid arthritis
- Diabetes mellitus
- Cushing disease
- Gastrectomy
- Inflammatory bowel disease
- Malabsorption
- Multiple myeloma

TREATMENT MODALITIES

Cast

A cast is a rigid external immobilizing device that is applied for a variety of medical surgical disorders including fractures and deformities. Many injuries that were previously treated with casts may now be treated with other immobilization devices (e.g., immobilizers). In general, casts permit mobilization of the patient while restricting movement of a body part. The cast provides adequate stability to the injured area and does not restrict circulation and nerve supply. Additionally, it must be smooth and free of ridges to prevent pressure on underlying tissue.

Casting Materials

Casts may be made of plaster or nonplaster materials. Refer to Box 42-6 for cast application.

Fiberglass

Nonplaster casts are generally referred to as fiberglass casts. These water-activated polyurethane materials are light in weight, strong, water resistant, and durable. They are made of nonabsorbent fabric impregnated with cool water–activated hardeners that bond and reach full rigid strength in minutes. The material does not soften when wet, which allows for hydrotherapy when appropriate. When wet, the casts are dried with a hair dryer on a cool setting; thorough drying is important to prevent skin breakdown.

BOX 42-6 GUIDELINES FOR NURSING CARE

Assisting with Cast Application

Equipment

Tubular stockinette, casting material as specified by the provider (plaster rolls/plaster splints); sink equipped with plaster trap or bucket of water, gloves, padding, sponge or felt padding (if necessary)

Implementation

NURSING ACTIONS	RATIONALE
1. Support extremity or body part to be casted.	1. Minimizes movement; maintains reduction and alignment; increases comfort
2. Position and maintain body part to be casted in the position indicated by the provider during the casting procedure.	2. Facilitates casting; reduces incidence of complications (e.g., malunion, nonunion, contracture)
3. Drape the patient.	3. Avoids undue exposure; protects other body parts from contact with casting materials
4. Wash and dry the body part to be casted.	4. Reduces incidence of skin breakdown
5. Place knitted material (e.g., stockinette) over the body part to be casted. • Apply the material in a smooth and nonconstrictive manner.	5. Protects skin from casting materials Protects the skin from pressure Folds over edges of cast when finishing application; creates smooth, padded edge; protects skin from abrasion
6. Wrap soft, nonwoven roll padding smoothly and evenly around the body part. Use additional padding around bony prominences to protect superficial nerves (e.g., head of fibula, olecranon process).	6. Protects the skin from pressure of the cast Protects the skin at bony prominences Protects superficial nerves
7. Apply plaster or nonplaster casting material evenly on body part. • Choose appropriate width bandage. • Overlap preceding turn by half the width of the bandage. • Use continuous motion, maintaining constant contact with the body part. • Use additional casting material (splints) at joints and at points of anticipated cast stress.	7. Creates a smooth, solid, well-contoured cast Facilitates smooth application Creates a smooth, solid, immobilizing cast Shapes the cast properly for adequate support Strengthens the cast
8. "Finish" cast: • Smooth the edges. • Trim and reshape with a cast knife or cutter.	8. Protects skin from abrasion Allows full range of motion of adjacent joints
9. Remove particles of casting materials from the skin.	9. Prevents particles from loosening and sliding underneath the cast
10. Support the cast during hardening. • Handle hardening casts with the palms of your hands. • Support the cast on a firm, smooth surface. • Do not rest the cast on hard surfaces or on sharp edges. • Avoid pressure on the cast.	10. Casting materials begin to harden in minutes; maximum hardness of nonplaster cast occurs in minutes; maximum hardness of plaster cast occurs with drying (24–72 hours, depending on environment and thickness of cast) Avoids denting of cast and development of pressure areas
11. Promote drying of cast. • Leave cast uncovered and exposed to air. • Turn patient every 2 hours, supporting the major joints. • Fans may be used to increase air-flow and speed drying.	11. Facilitates drying

Plaster

Traditional casts are made of rolls of plaster bandage that are wet in cool water and applied smoothly to the body. A crystallizing reaction occurs, and heat is given off (an exothermic reaction). The heat given off during this reaction can be uncomfortable, and the patient needs to be informed about the sensation of increasing warmth that generally dissipates after 15 minutes. Additionally, the nurse explains that the cast needs to be exposed to air (i.e., uncovered) to allow maximum dissipation of the heat and facilitate drying, which can take 24 to 72 hours. Because the plaster cast remains wet and somewhat soft, the cast needs to remain uncovered until it is completely dry. A wet plaster cast appears dull and gray, sounds dull on percussion, feels damp, and smells musty. A dry plaster cast is white and shiny, resonant to percussion, firm, and odorless.

BOX 42-7 Focus on Pathophysiology

Rhabdomyolysis

A wide variety of etiologies are associated with rhabdomyolysis, including seizures, drug reactions (e.g., statins), extreme exercise, soft tissue infections, burns, malignant

hyperthermia, extended lithotomy position and lateral decubitus positions, use of pneumatic antishock garments or tourniquet ischemia, compartment syndrome, toxins (alcohol, cocaine, heroin, amphetamines, ecstasy, phencyclidine, snakebite), and electrical and crush injuries. With trauma injuries, the nurse is alert for rhabdomyolysis, in which the crushing injury causes the breakdown of skeletal muscle, resulting in the release of muscle cell contents, including myoglobin (a protein released from muscle when injury occurs), creatine phosphokinase (CPK), phosphate, enzymes, and potassium, into the systemic circulation. Myoglobin, which gives skeletal muscle its color, is released from the damaged muscle and filtered by the kidney, resulting in brown or tea-colored urine. Myoglobinuria does not occur in the absence of rhabdomyolysis; therefore, when present, it is the best marker and diagnostic cornerstone of rhabdomyolysis (Ferri, 2016b). Urine dipstick for blood may be positive because of the cross-reaction with myoglobin; however, microscopic examination of urine may reveal no red blood cells. The myoglobin threatens kidney function due to renal tubular obstruction and direct toxic effects, resulting in acute kidney failure (5–30% of patients develop AKF). The CPK typically peaks 2–5 days after the initial insult and, in general, is in excess of five times the normal serum level. Anion gap metabolic acidosis may be present due to the release of organic acids from damaged muscle (Ferri, 2016b). Goals of management are to prevent acute kidney failure by countering the effects of myoglobin with the use of aggressive fluid resuscitation (reduces the accumulation of toxic intracellular contents), bicarbonate administration (urine that is alkalized lessens myoglobin toxicity), and possibly the administration of mannitol (Osmitrol), an osmotic diuretic to "wash out" the myoglobin. In addition, management of hyperkalemia with insulin/dextrose is expected. The nurse assesses urine output hourly, monitors vital signs, maintains strict intake and output, and assesses for fluid volume deficit (secondary to the trauma) versus fluid volume excess (secondary to overhydration). The nurse monitors for disseminated intravascular coagulation (DIC), which can occur in up to 30% of severe cases and is associated with higher mortality rates (Ferri, 2016c).

Nursing Alert

The nurse ensures that all jewelry is removed from the injured limb that is to be casted since edema is expected in fractures.

Nursing Management

Monitoring and Managing Potential Complications

Compartment Syndrome

There are three types of compartment syndromes: ACS, chronic compartment syndrome, and crush compartment syndrome. *ACS* involves a sudden and severe decrease in blood flow to the tissues distal to an area of injury that results in ischemic necrosis if prompt, decisive intervention does not occur. It is a potentially limb-threatening complication that occurs when increased pressure occurs within a limited space (e.g., cast, muscle compartment) that compresses the blood vessels and nerves within the area. The pressure within the confined space becomes so high that there is massive compromise to circulation and nerve transmission in the affected extremity. Permanent damage develops within a few hours if action is not taken.

Chronic compartment syndrome is characterized by pain, aching, and tightness in a muscle or muscle group that has been subjected to inordinate stress or exercise. In this instance, muscle volume increases by as much as 20% within a short time, resulting in stretching of the fascia and inflammation. *Crush compartment syndrome* is caused by massive external compression or crushing of a compartment; for instance, this may occur when a car jack fails and a car falls on a mechanic. This type of massive injury results in systemic effects that include rhabdomyolysis (Box 42-7) that causes acute kidney failure and that may eventually lead to multiple organ dysfunction syndrome (MODS), further discussed in Chapter 54.

A specific type of compartment syndrome in the arm is Volkmann contracture (discussed on page 1223). It is frequently associated with supracondylar fractures of the humerus (refer to Figure 42-6). The following discussion focuses on ACS.

Fascia is tough connective tissue that surrounds muscle groups, organs, nerves, blood vessels, bones, and internal structures. It does not expand readily. Therefore, if a compartment begins to swell, the pressure in the area rises, leading to venous obstruction, compromising circulation and nerve and motor function to the point at which the limb may need to be amputated (Fig. 42-12).

Risk factors for this complication include trauma from accidents, surgery, or crushing injuries, in which massive edema and bleeding is expected. Casts and tight bandages are also associated with this complication as the external devices increase the pressure within the injured area. In addition, it may be caused by any condition that increases the risk of bleeding or edema in a confined space, including patients with soft tissue injury, without fractures, who are on anticoagulants or have bleeding dyscrasias (e.g., prolonged malposition, burns, electrocutions, snake venom, stressful athletic activity, contusions, and infiltrations from intravenous [IV] sites). Long bone fractures (open tibial fractures [6% to 9%]; tibial plateau fracture) and multitrauma patients (24%) are implicated in ACS; however, it can occur in other parts, such as the foot, thigh, gluteal region, and abdomen (Ferri, 2016b; Shuler, Roskosky, & Freedman, 2014; Sise, 2016). Further details on ACS of the abdomen are in Chapter 53.

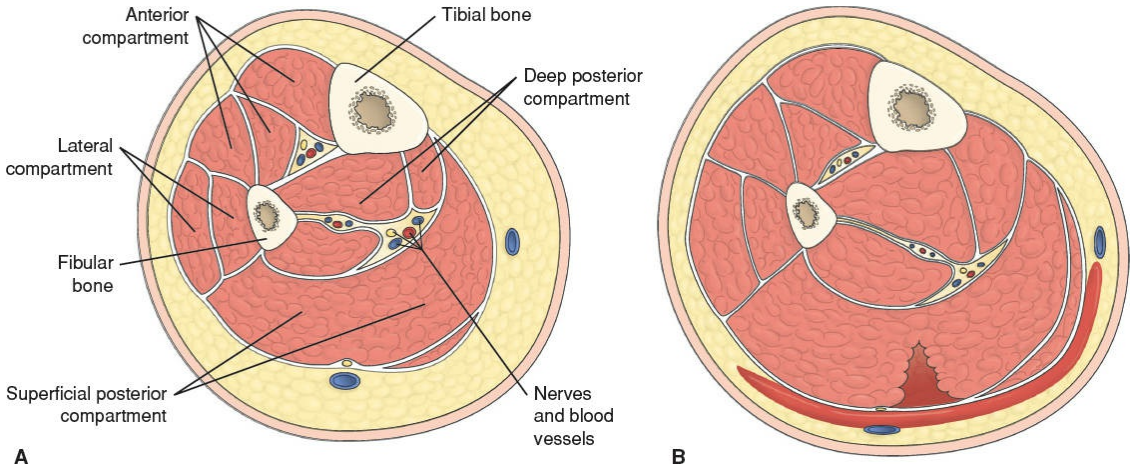

FIGURE 42-12 A. Cross-section of normal lower leg with muscle compartments. B. Cross-section of lower leg with compartment syndrome. Swelling of muscles causes compression of nerves and blood vessels.

It is essential to detect this complication early. The first clinical finding is loss of light touch sensation in the distribution of the nerve in the compartment (e.g., first web space for lower extremity, see Table 42-2); however, this may be difficult to assess because of altered mentation of patients (unresponsive, uncooperative patient [e.g., ETOH (ethylalcohol and alcohol), overdose], or those with peripheral nerve deficits). Clinical manifestations include paleness of limb, cool skin temperature, delayed capillary refill, weak pulsations, paresthesia (tingling/burning sensation in the involved muscle), decreased sensation and mobility, tight and full muscle, and pain (progressive—not relieved by position changes, ice, or analgesia, or pain that is disproportional to the injury). A hallmark sign is pain that occurs or intensifies with passive ROM. Ominous *late* signs are pallor and loss of pulses. If the nurse is concerned about neurovascular impairment, the provider is notified immediately.

Nursing Alert

It is important to note that late signs of compartment syndrome are pulselessness and pallor. The presence of a pulse does not rule out compartment syndrome.

If the complication is secondary to a tight bandage or cast, the nurse anticipates that the bandage would be loosened or removed and the cast bivalved (cut in half longitudinally) to release the constriction. While the surgeon is bivalving the cast, the nurse assists in maintaining limb alignment (Box 42-8). The affected limb must be elevated no higher than heart level to ensure arterial perfusion. Intracompartmental pressure monitoring may be required to diagnose compartment syndrome. A variety of commercial systems is available for the provider to measure intracompartmental pressure. The intracompartmental pressure of a normal muscle compartment at rest is less than 10 mm Hg (Sise, 2016). A high tissue pressure indicates compartment syndrome. Debate exists on the intracompartmental pressure that mandates fasciotomy, but pressures exceeding 25 mm Hg suggest the need to consider a fasciotomy (Sise, 2016). Another reliable method of assessment for ACS is *perfusion pressure* or δP of the limb, which is calculated as

ΔP = diastolic blood pressure – intracompartmental pressure

A perfusion pressure of less than 30 mm Hg is considered a criterion for fasciotomy (Sise, 2016).

BOX 42-8 Procedure for Bivalving a Cast

The following procedure is followed when a cast is bivalved.

1. With a cast cutter, a longitudinal cut is made to divide the cast in half.
2. The under padding is cut with scissors.
3. The cast is spread apart with cast spreaders to relieve pressure and to inspect and treat the skin without interrupting the reduction and alignment of the bone.
4. After the pressure is relieved, the anterior and posterior parts of the cast are secured together with an elastic compression bandage to maintain immobilization.
5. To control swelling and promote circulation, the extremity is elevated (but no higher than heart level) to minimize the effect of gravity on perfusion of the tissues.

If pressure is not relieved by removing the bandage or cast, and circulation is not restored, a fasciotomy may be necessary to relieve the pressure within the muscle compartment. A fasciotomy is a surgical procedure in which the skin and affected compartment's fascia are opened, allowing the pressure to be relieved and circulation restored. Patients who develop this complication unrelated to a cast or dressing undergo this sterile procedure. The fasciotomy area may be surgically repaired, or wound VAC or graft tissue may be used when the swelling subsides. Complications that may occur after fasciotomy include AVN and infection.

The nurse closely monitors the patient's response to conservative and surgical management of compartment syndrome. Limb assessment of circulation, sensation, and mobility continues as ordered, and the nurse promptly reports changes to the provider.

Nursing Alert
If ACS is suspected, the injured extremity should not *be elevated to decrease edema, as this action will increase the intracompartmental pressure and decrease perfusion to the extremity (Sise, 2016). The extremity should be maintained at heart level (Shuler et al., 2014).*

Pressure Ulcers

Pressure ulcers are breakdowns in the skin caused by prolonged pressure on a body part. Casts or bandages can put pressure on soft tissues, causing tissue anoxia and pressure ulcers. Susceptible sites in the lower extremity include the heel, malleoli, dorsum of the foot, head of the fibula, tibial tuberosity, and anterior surface of the patella (Fig. 42-13). Upper extremity sites are located at the medial and or lateral epicondyle of the humerus, olecranon, and the ulnar styloid.

The pathophysiology of and risk factors for pressure ulcers are discussed in Chapter 52. The nurse has a high degree of suspicion that a pressure ulcer is developing under a cast or dressing when the patient reports pain and tightness in a defined casted area. The area is

inspected for drainage on the cast and any emitted odor. In addition, the nurse palpates the bandage or cast noting increasing warmth, which suggests underlying tissue erythema. Even if discomfort does not occur, there may be extensive loss of tissue with skin breakdown and tissue necrosis; therefore, any suspicious findings are reported to the provider.

The cast may be bivalved or an opening (window) cut in the cast in order to assess for pressure ulcer development. A window allows inspection of the affected area and possibly treatment. The portion of the cast is replaced and held in place by an elastic compression dressing or tape. The nurse assesses for "window edema"—that is, swelling of the underlying tissue through the window, which creates pressure areas around the window margins. Patients who have histories of impaired sensation due to neuropathy or neurologic injury are at high risk for ulcer development; thus, removable braces may be used for management of fractures with frequent skin assessments.

Disuse Syndrome

When a muscle is left inactive, it loses its strength and size. Disuse syndrome is the nursing diagnosis defined as muscular deconditioning and atrophy resulting from inactivity or immobilization (Murr, 2016). Depending on the status of the patient and length of time since the initial trauma, strengthening exercises may be ordered. The nurse will teach the patient to tense or contract muscles (isometric muscle contraction) without moving the underlying bone. The internal or external devices stabilize the underlying bone. Isometric activity, such as teaching a patient in an arm cast to "make a fist," helps reduce muscle atrophy and maintain muscle strength. Muscle-setting exercises (e.g., quadriceps-setting and gluteal-setting exercises) are important in maintaining muscles essential for walking (Box 42-9). Isometric exercises should be performed hourly while the patient is awake. Physical therapy can assist in developing an exercise regimen for the patient.

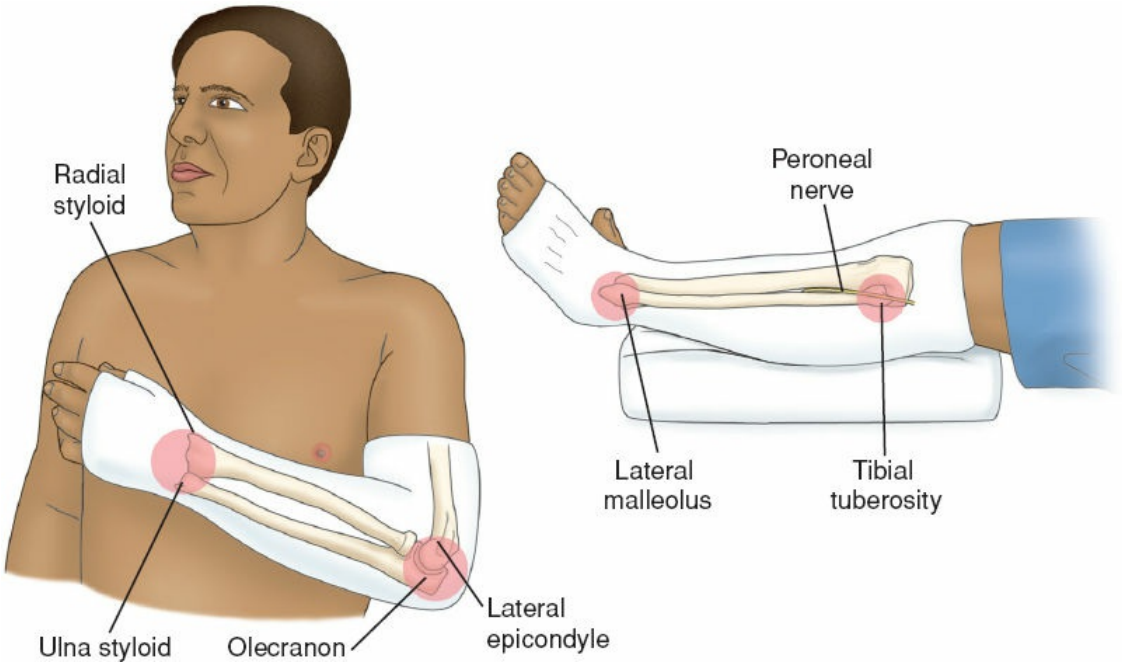

FIGURE 42-13 Pressure areas in common types of casts. *Left,* long-arm cast. *Right,* short-leg cast.

BOX 42-9 Muscle-Setting Exercises

Isometric contractions of the muscle maintain muscle mass and strength and prevent atrophy.

Quadriceps-Setting Exercise

- Position the patient supine with the leg extended.
- Instruct the patient to push his or her knee back onto the mattress by contracting the anterior thigh muscles.
- Encourage the patient to hold the position for 5–10 seconds.
- Let the patient relax.
- Have the patient repeat the exercise 10 times each hour when awake.

Gluteal-Setting Exercise

- Position the patient supine with legs extended, if possible.
- Instruct the patient to contract the muscles of the buttocks.
